and the optimal set was chosen based on the performance measurement of AUC. Please refer to Table S8 in Multimedia Appendix 1 for detailed information on the search space and final adopted parameters. To evaluate the predictive performance of the models, we constructed and compared the traditional Cox proportional hazards model with the LightGBM model. Both models used identical predictor variables to ensure fairness and consistency in the comparison. The Cox model assessed hazard ratios for each variable through multivariate regression analysis, while the LightGBM model leveraged its robust ability to handle nonlinear relationships and variable interactions for risk prediction. Subsequently, the performance of both models was systematically compared using consistent evaluation metrics (such as AUC) to determine their predictive effectiveness within the study dataset. This comparison aims to validate the potential advantages of the LightGBM model in risk prediction and to provide a reference for the application of the traditional Cox model. The Cox proportional hazards model was also used to account for competing risks, which ensured that the risk of death did not bias the estimation of dementia event probabilities. To enhance the model's stability and applicability, a time validation approach was used for data analysis. Additionally, we calibrated the raw predicted probabilities into actual dementia risks (Figures S12-S14 in Multimedia Appendix 1). Finally, to assess the clinical utility of the prediction model, decision curve analysis (DCA) was conducted. First, the model's net benefit was calculated across various threshold probabilities and then compared with the baseline strategies of "treat all" and "treat none." The DCA curves were plotted using the *rmda* package in R (R Foundation for Statistical Computing) to illustrate the model's potential value in clinical decision-making. The ML algorithm was implemented using LightGBM library (version 3.3.2) and scikit-learn library (version 1.0.2) in Python (version 3.9; Python Software Foundation).

We also performed a 5-fold cross-validation to assess the stability of feature importance, randomly dividing the dataset into 5 equal parts. In each iteration, 4 folds were used for training, and 1 fold for validation. The training involved 2 stages: model development and calibration. The 4 training folds were split 3:1, with 3 folds for development and 1 fold for calibration. Validation sets were exclusively for performance evaluation. Results were averaged across folds with corresponding SDs.

Statistical Analysis

In an analysis of the variables of interest, continuous variables were summarized using the median and IQR, while discrete variables were summarized using frequency and percentage. Group comparisons (no dementia vs incident dementia or AD or VD) were conducted using chi-square tests for discrete variables and 2-tailed Student *t* tests for continuous variables. Multivariate analysis was used to calculate odds ratios based on normalized data.

The model's performance was evaluated using 2 accuracy metrics: discrimination and calibration. Discrimination was assessed using the AUC, which ranges from 0.5 for a noninformative model to 1 for a perfectly discriminating model. Calibration measures the agreement between predicted probabilities and observed event proportions. It was evaluated using the Kolmogorov-Smirnov test with 10 subgroups and visually represented in calibration plots. A *P* value greater than .05 signified an adequate goodness of fit.

Furthermore, we reported accuracy, sensitivity, specificity, precision, and the F_1-score, which were determined using the cutoff that maximized the Youden index. Additionally, we used Shapley Additive Explanations (SHAP) plots to visualize the individual contributions of each predictor to the target variable. All data analysis and visualizations were performed using Python (version 3.9) with packages from the scikit-learn library (version 1.0.2) and the SHAP library (version 0.40.0).

Results

Population Characteristics

After quality control, a total of 29,561 participants with ASCVD were included in this study. The median age of the participants was 62.0 (IQR 58.0-66.0) years. Among the participants, 36.63% (10,829/29,561) were women, and 94.12% (27,822/29,561) were White. During a median follow-up time of 10.3 (IQR 7.6-12.4) years, a subset of 1334 participants developed dementia after their baseline visits. Specifically, 617 participants had incidents within 10 years, and 136 had incidents within 5 years. Besides, the prevalence of all-cause dementia was 4.51% (1334/29,561), AD was 1.44% (425/29,561), and VD was 1.81% (536/29,561) in this study. The critical baseline predictors are presented by incident dementia, AD, and VD status in Table 2, and the percentage of missing values for the predictors is shown in Table S3 in Multimedia Appendix 1.

Table 2. The baseline characteristics of UK Biobank participants included in the study by dementia, Alzheimer disease (AD), and vascular dementia (VD) status.

Participants characteristics	Overall (n=29,561)	No dementia (n=28,227)	All incident dementia (n=1334)	All incident AD (n=425)	All incident VD (n=536)
Age (years), median (IQR)	62.0 (58.0-66.0)	62.0 (57.0-66.0)	66.0 (63.0-68.0)	66.0 (64.0-68.0)	66.0 (63.0-68.0)
Sex (female), n (%)	10,829 (36.63)	10,353 (36.68)	476 (35.68)	170 (40.00)	163 (30.41)
Ethnicity (White), n (%)	27,822 (94.12)	26,565 (94.11)	1257 (94.23)	404 (95.06)	504 (94.03)
Education (years), median (IQR)	10.0 (9.0-11.0)	10.0 (9.0-11.0)	10.0 (9.0-11.0)	9.0 (9.0-10.0)	9.0 (9.0-10.0)
Forced vital capacity (L), median (IQR)	3.5 (2.9-4.2)	3.5 (2.9-4.2)	3.2 (2.6-3.9)	3.2 (2.7-4.0)	3.1 (2.6-3.9)
Summed MET[a] minutes per week for all activity (minutes per week), median (IQR)	1662.0 (693.0-3546.0)	1671.0 (698.0-3546.0)	1398.0 (510.0-3288.0)	1653.0 (660.0-3546.0)	1308.0 (408.8-2942.6)
Pairs matching time (seconds), median (IQR)	411.0 (325.0-534.0)	408.0 (324.0-529.0)	487.5 (368.0-678.8)	487.0 (372.0-673.5)	496.0 (370.5-701.0)
Mean sphered cell volume (fL), median (IQR)	82.4 (79.2-85.9)	82.4 (79.2-85.8)	83.1 (79.5-86.7)	82.5 (79.6-86.1)	83.2 (79.2-87.3)
Glucose (mmol/L), median (IQR)	5.0 (4.7-5.5)	5.0 (4.7-5.5)	5.1 (4.7-5.9)	5.1 (4.7-5.6)	5.2 (4.7-6.2)

[a]MET: metabolic equivalent.

[b]FEV1: forced expiratory volume in 1 second.

[c]CAD: coronary artery disease.

[d]CeVD: cerebrovascular disease.

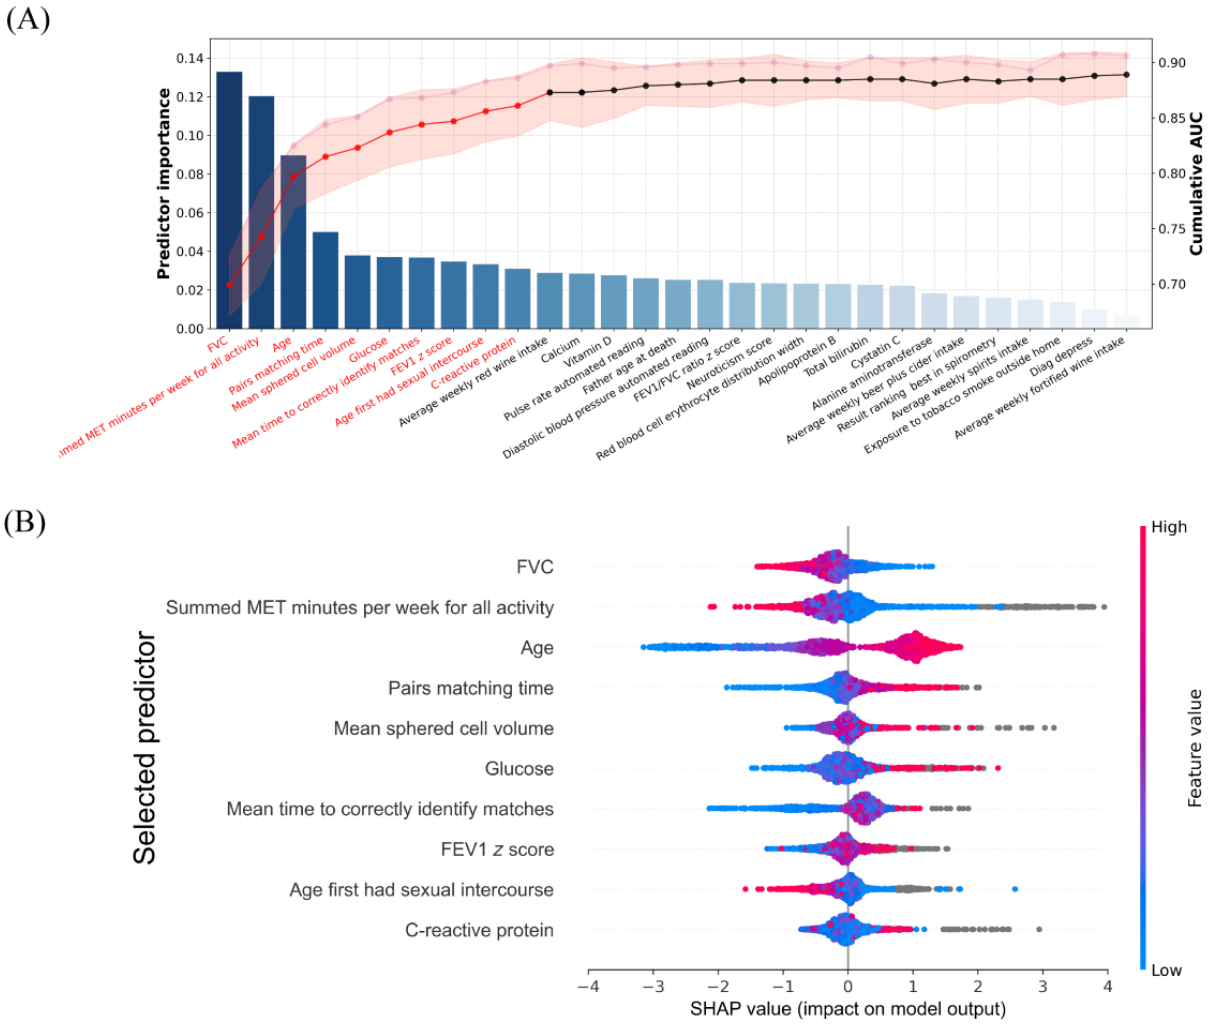
[e]PAD: peripheral artery disease.

[f]AAA: abdominal aortic aneurysm.

Data-Driven Predictors Selection

Among the 316 candidate variables, we initially selected the top 50 variables based on the LightGBM classifier and performed the hierarchical clustering to eliminate the multicollinearity [21]. As shown in the bar chart of Figure 2A, a total of 29 variables were sorted according to their importance in the prediction task. The SFS strategy was used to strike a balance between model performance (AUC on the right axis) and the number of variables selected, as depicted in the line chart. The line chart showed that the model's performance experienced a sharp increase when incorporating the first few variables and eventually reached a plateau with the inclusion of additional variables. Ultimately, the top 10 variables were chosen as the final predictors for ML model development. Their summary statistics are displayed in Table 2.

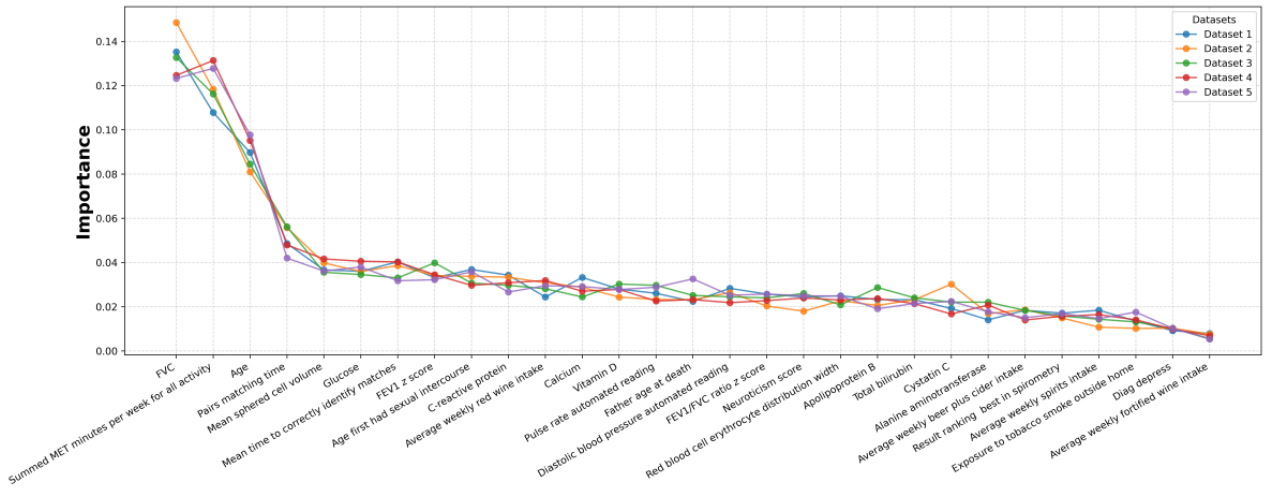
Figure 2. Predictive variable selection and interpretation on all incident dementia. (A) Sequential forward selection from a preselected predictor pool. A bar chart ranked predictor importance by their contribution to classification, while a line chart depicted cumulative AUCs with each iterative predictor inclusion. The top 10 predictors, marked red, were selected for machine learning model construction. (B) SHAP-based visualization of salient predictors. Horizontal bar widths correspond to predictor impact on model predictions, with wider ranges indicating greater influence. Predictor intensity was color-coded, graduating from blue (low) to red (high), as per the color bar on the right. The x-axis orientation signified the probability of either dementia (right) or health (left). AUC: area under the receiver operating characteristic curve; FEV1: forced expiratory volume in 1 second; FVC: forced vital capacity; MET: metabolic equivalent; SHAP: Shapley Additive Explanations.



Model Interpretation of Selected Predictors

To interpret the influence of each selected predictor, we used SHAP values and visualized them in Figure 2B. The predictors were interpreted based on value magnitude (coded by gradient colors) and tendency on the horizontal axis (indicting the likelihood of developing dementia). Take the predictor forced vital capacity (FVC) as an example. Patients with ASCVD with lower FVC values (colored blue) were more likely to develop dementia (right side) compared to those with higher FVC values (colored red). Similarly, for the remaining predictors, patients with ASCVD who spend less time engaging in activities, being older, who take longer time to complete pair matching tasks, and who have higher mean sphered cell volume (MSCV), forced expiratory volume in 1 second *z* score, C-reactive protein, and glucose levels tend to have an increased risk of developing dementia. Interestingly, we found that patients who engaged in sexual intercourse at an earlier age were more likely to develop dementia. Moreover, a 5-fold cross-validation stability analysis of feature importance was conducted. The results indicated that most features exhibited high stability across different data subsets. Figure 3 shows the distribution of key feature importance across all folds.

Figure 3. Stability analysis of feature importance across different data subsets in the model of all incident dementia. The stability of feature importance in the model of all incident dementia was assessed across different data subsets, providing insights into the robustness of identified predictors. Each line represented the variability of feature importance in a specific subset, illustrating how consistent the predictive factors are across varying conditions. FEV1: forced expiratory volume in 1 second; FVC: forced vital capacity; MET: metabolic equivalent.



Model Performance Across Different Populations and Algorithms

Compared with other ML algorithms, it can be seen in Table 3 that LightGBM demonstrated superior performance across various metrics. We used the AUC metric to evaluate the discrimination performance of the UK Biobank ASCVD risk prediction model. As depicted in Table 4, the model achieved a mean AUC of 0.866 (SD 0.027) for all incident dementia cases. Furthermore, the model demonstrated promising results for the prediction of 10-year and 5-year incident dementia, with mean AUCs of 0.876 (SD 0.024) and 0.903 (SD 0.076), respectively. The model for all incident dementia exhibited a mean accuracy of 0.883 (SD 0.01), mean sensitivity of 0.637 (SD 0.084), mean specificity of 0.914 (SD 0.012), mean precision of 0.479 (SD 0.031), and mean F_1-score of 0.546 (SD 0.043). Apart from the 5-year AD and VD predictions, the model also displayed valuable discrimination abilities for different AD and VD population groups. Specifically, the mean AUCs for all and 10-year incident AD were 0.836 (SD 0.043) and 0.828 (SD 0.112), respectively, while the mean AUCs for all and 10-year incident VD achieved 0.870 (SD 0.029) and 0.881 (SD 0.031), respectively. For specific metrics of all, 10-year, and 5-year dementia, AD, and VD predictions, please refer to Table 4 and Figures S3-S11 and S15 in Multimedia Appendix 1. We also compared the performance of the traditional Cox proportional hazards model and the LightGBM-based model in risk prediction. The AUC of all incident dementia, AD, and VD for the Cox model were 0.67, 0.67, and 0.71, respectively (Figure S1 in Multimedia Appendix 1). After competing risk analysis with death, the prediction power of the Cox model did not show a significant difference in predicting AD and VD (Tables S5-S7 and Figure S2 in Multimedia Appendix 1).

[c]AD: Alzheimer disease.

[d]VD: vascular dementia.

DCA demonstrated that our prediction model exhibited a higher net benefit within the threshold probability range of 0.04 to 0.97 across different time periods, significantly outperforming both the “treat all” and “treat none” baseline strategies (Figure 4). The Kolmogorov-Smirnov test was conducted to assess the calibration of the model. A *P* value greater than .05 indicates sufficient goodness of fit. Satisfactory calibrations for the development of all population groups, including 5-year or 10-year or all incident dementia, AD, and VD, were observed (Table 5 and Figures S12-S14 in Multimedia Appendix 1).

[d]VD: vascular dementia.

A Temporal Validation of the Constructed Model

To assess the stability and generalizability of our dementia prediction model, we used a time validation approach using data from the UK Biobank. The model was trained and validated on samples recruited between 2006 and 2009 and tested on the 2010 cohort. In the training and validation set, the model achieved a mean AUC of 0.866 (SD 0.027) in predicting all incident dementia, indicating strong discriminatory ability. When applied to the test set from 2010, the model maintained robust performance with an AUC of 0.819, suggesting good generalization to future data. Other performance metrics in the test set: accuracy was 0.851, sensitivity was 0.691, specificity was 0.866, precision was 0.315, and the F_1-score was 0.433 (Table 6).

Table 6. Model performance metrics for the prediction on the test data divided by time period[a].

	Accuracy	Sensitivity	Specificity	Precision	F_1-score	AUC[b]
All incident dementia	0.851	0.691	0.866	0.315	0.433	0.819
All incident AD[c]	0.921	0.500	0.933	0.182	0.267	0.718
All incident VD[d]	0.916	0.619	0.926	0.218	0.322	0.838
10-Year incident dementia	0.925	0.576	0.943	0.350	0.435	0.824
10-Year incident AD	0.916	0.517	0.922	0.093	0.157	0.804
10-Year incident VD	0.946	0.590	0.953	0.207	0.307	0.834
5-Year incident dementia	0.984	0.480	0.991	0.4	0.436	0.882
5-Year incident AD	0.181	1	0.181	0.001	0.002	0.605
5-Year incident VD	0.002	1	0	0.002	0.004	0.595

[a]Cutoffs were established by maximizing the Youden index (YI=sensitivity+specificity–1).

[b]AUC: area under the receiver operating characteristic curve.

[d]VD: vascular dementia.

Discussion

Principal Findings and Comparisons With Prior Work

In this study, we developed a predictive model using the LightGBM algorithm and leveraging big data from the UK Biobank to assess the risk of dementia in patients with ASCVD. To the best of our knowledge, this is the first model that uses big data to predict the risk of dementia specifically in patients with ASCVD. Our model incorporates 10 clinical predictive factors, selected based on their importance, to accurately estimate the risk of dementia. Notably, our model demonstrates particularly strong performance in predicting all-cause dementia and VD, with AUC values exceeding 0.85. Furthermore, the model effectively calibrates the predicted probabilities and aligns well with the observed event ratios, indicating its reliability and accuracy in estimating the risk of dementia in patients with ASCVD.

The ASCVD has long been recognized as one of the most significant risk factors for dementia, especially VD [22]. Although previous studies have primarily concentrated on the influence of atherosclerotic CeVDs on dementia, emerging research suggests that systemic atherosclerotic diseases beyond CeVDs also significantly contribute to the development of dementia [23]. To the best of our knowledge, no prior studies have used big data to predict the risk of dementia in patients with ASCVD. Unlike models based on variables obtained from intricate neuroimaging and neuropsychological tests, the predictors in this model are more accessible and can be applied in various clinical settings and medical institutions.

Recent studies have indicated the importance of vascular risk factors in the development of dementia, which should be taken into consideration by clinical practitioners. During the establishment of a dementia risk model in the population with ASCVD, we identified several key and distinctive risk factors that differ from other longitudinal studies. Age was identified as one of the most significant influencing factors in this study. Other factors include low exercise time, high fasting blood glucose, and reaction time including pair matching time and mean time to correctly identify matches. These risk factors have been shown to have a close relationship with the overall health of the vascular system and are critical in the development of ASCVD events [24,25]. Besides, high plasma levels of C-reactive protein at baseline were associated with a high risk of all incident dementia in this study, which is corresponded with the result of the latest research [26]. Furthermore, we found that MSCV should be considered as a new and significant factor in assessing the risk of dementia in patients with ASCVD. MSCV is primarily a parameter in hematology used to assess changes in the volume of spherocytes. Currently, there is no evidence to suggest a direct relationship between MSCV and dementia. However, overall blood health can indirectly affect cognitive function, especially in the presence of chronic anemia or other systemic diseases [27]. If an abnormal MSCV is observed in clinical practice or research, it is important to consider the patient's overall health status comprehensively, including but not limited to neurological function, to fully evaluate the patient's dementia risk. Recent studies have also gradually found that lung function may play a role in the onset of dementia by influencing brain structure [28]. Our model indicated FVC and forced expiratory volume in 1 second *z* score as protective factors in decreasing dementia risk. Finally, age first had sexual intercourse, also known as age at first intercourse (AFS), was first identified as one of the significant risk factors for dementia in populations with ASCVD, which is interesting and worth attention. Compared to other biological traits, reproductive behaviors, especially sexual factors, have long been neglected when it comes to the study of CVDs and neurological disorders. Recent studies show that the earlier the age of first sexual intercourse, the higher the likelihood of developing hypertension and CVDs [29,30]. The specific processes driving this relationship are not yet fully understood, but they may include a mix of environmental and genetic influences. For instance, early sexual activities are often accompanied by adverse environmental factors, including lower educational attainment, increased smoking and alcohol consumption, and the use of illicit drugs [31], which are all closely associated with CVDs. Recent studies have identified a causal relationship between AFS and CVDs at the genetic level [30,32]. Although AFS has no direct impact on dementia, it might be induced from our study that AFS is indirectly related to dementia through intriguing CVDs especially in patients with ASCVD.

In our study, we performed a stability analysis of feature importance using 5-fold cross-validation to ensure the robustness of the identified predictors. The analysis revealed that several key features consistently ranked highly across all folds, indicating their strong and reliable association with the outcome. Specifically, FVC, summed metabolic equivalent minutes per week, age, and pair matching time maintained relatively high importance scores in every subset, underscoring their role as robust predictors. Although these 4 variables exhibited significant variation compared to other variables, the impact of this variation is minimal relative to their importance.

We acknowledge that the Cox proportional hazards model, as a mature and interpretable method, holds a significant position in survival analysis. However, our study results show that the LightGBM-based ML model significantly outperforms the Cox model in predictive performance metrics such as AUC, demonstrating its advantages in handling nonlinear relationships and complex interactions between variables. LightGBM effectively captures patterns in high-dimensional data, thereby enhancing the accuracy of risk prediction. Although ML models face certain challenges in terms of computational resources and interpretability, their substantial improvement in predictive performance illustrates their added value in practical applications. Future research could explore combining traditional Cox models with ML methods to balance predictive performance and model interpretability, thereby meeting diverse clinical application needs. Besides, our study indicated that mortality had a minimal impact on the primary outcomes, and the overall conclusions of the study remained largely unchanged. This suggested that the prediction power of our model remained robust even after accounting for competing risks.

The time validation results demonstrate that our dementia prediction model maintains robust performance across different

temporal cohorts. Specifically, in the population of all incident dementia, the AUC remained consistently high, with a slight decrease from 0.866 in the training set to 0.819 in the test set. Similarly, other performance metrics such as accuracy, precision, recall, and F_1-score showed only minor declines over time. This stability suggests that the model effectively captures underlying patterns associated with dementia risk that are persistent across the studied time periods. The consistency of performance metrics across the training and test sets indicates that the model's predictive capabilities are not significantly affected by temporal shifts in the data. The stable performance of the model over different time periods enhances its long-term applicability in clinical and public health settings. A model that maintains its predictive accuracy over time is invaluable for ongoing and future dementia screening programs, enabling early identification of at-risk individuals with confidence in its sustained reliability. However, it is also essential to acknowledge the significant performance decline observed in the test set when predicting the risk of 5-year AD and VD, which may be attributed to the low prevalence in patients with ASCVD during a relative short period. To ensure continued efficacy, periodic retraining and validation of the model with new data may be necessary. This approach would allow the model to adapt to any emerging trends or shifts in risk factors that may influence dementia incidence over time.

In clinical practice, the LightGBM model can be applied during the initial diagnosis or follow-up stages to early identify individuals with high dementia risk among patients with ASCVD, thus promoting timely intervention and treatment. For instance, using this predictive model during a patient's initial visit can assist physicians in swiftly identifying patients at high risk and arranging further diagnostic tests or interventions. Moreover, integrating the model's predictions into electronic health record systems can generate alerts and recommend further evaluations, thereby enhancing diagnostic accuracy and personalized treatment plans. To effectively communicate the predicted risk, doctors should use easily understandable language to explain the model results and their implications to the patient while also providing clear next steps and support resources to alleviate patient anxiety. Consider a hypothetical example: a 55-year-old male patient with hypertension and high cholesterol who recently experienced a heart attack. After using the LightGBM model for assessment, the results indicate a high dementia risk. Based on this, the doctor decides to schedule detailed cognitive function tests and recommends a comprehensive plan that includes cognitive training, a healthy diet, and regular exercise. Through these interventions, the patient can better manage his cardiovascular health while taking steps to reduce the likelihood of developing dementia.

However, the application of such predictive models raises potential ethical issues. First, there may be prediction bias due to training data, leading to unequal care, so continuous monitoring and validation are needed to ensure fairness. Second, doctors need to carefully communicate the model's predictions to avoid causing unnecessary anxiety for patients. Additionally, patient data use should require clear consent and ensure privacy protection. Finally, caution against overreliance on model predictions is necessary, with doctors maintaining primary responsibility for care decisions.

Limitations

Several limitations should be considered when interpreting the results. First, our study focused on a specific population of patients with ASCVD. Due to the relatively small sample size, we observed a lower AUC value when predicting the 5-year incidence rates of dementia, especially for AD and VD incidence over a 5-year period. This issue can be addressed by further expanding the sample size. Additionally, this study primarily used samples of European descent, which may restrict the generalizability of our findings to other populations. Genetic, environmental, and lifestyle differences across diverse ethnic groups could influence the model's performance and predictive accuracy. The limited diversity of the sample may affect the model's applicability to non-European populations. To ensure broader relevance and robustness, future research should include diverse ethnic backgrounds to validate and potentially refine the model for varied demographic groups. While the time validation results are promising, the model currently relies on static features collected at baseline. Integrating longitudinal data and time-varying covariates could potentially improve predictive performance and adaptability over extended periods. Despite incorporating death as a primary competing risk, there might still be other unrecognized or unadjusted competing factors, such as other chronic diseases or lifestyle changes, that could influence the results to some extent. The application of competing risk models relied on the correct specification of models and assumptions; any biases in model setup might affect the accuracy of the analysis. Therefore, future research should further explore additional potential competing risk factors and use more sophisticated statistical methods to comprehensively assess the prediction power. Regarding the ML algorithms chosen for our study, the use of LightGBM may lead to data overfitting because it generates deep decision trees. To mitigate overfitting, a maximum depth limit should be imposed during the use of LightGBM. Furthermore, it is important to acknowledge that LightGBM is a bias-based algorithm and can be sensitive to noise in data processing, which may potentially affect the final data analysis results. Additionally, it should be noted that the predictive variables identified in this study were derived from data-driven analytical models, which may induce some bias compared to actual clinical diagnostic and treatment experiences. While advanced predictive models and results have been obtained, their applicability to clinical practice remains uncertain. Therefore, future research should focus on validating the analysis results using other independent cohorts with larger sample sizes and extending the study methodology to populations from different countries, regions, and ethnicities. The integration of clinical practice experiences will contribute to the development of more universally applicable and practical models.

Conclusions

This study has identified several practical and novel predictors for dementia screening in patients with ASCVD. It is worthy of testing and evaluating the applicability of these factors in clinical practice. Future studies should focus on investigating

whether intervening in these factors can help prevent the incidence of dementia in patients with ASCVD. By exploring these possibilities, we can potentially improve the management and outcomes of patients with ASCVD and reduce the burden of dementia in this population.

Acknowledgments

This study was funded by grants from the Natural Science Foundation of Shanghai (23JS1400500 and 22ZR1420500), the Shanghai ShenKang Hospital Development Center (SHDC2020CR1038B), and 234 discipline peak climbing program of Shanghai Changhai Hospital (2019YXK013). The funding sources were not involved in the study's design and execution; data collection, management, analysis, and interpretation; manuscript drafting, review, or approval; nor the decision to submit the manuscript for publication. This study was conducted by the use of the UK Biobank Resource (application 97366). The authors appreciate all the participants and researchers from the UK Biobank.

Data Availability

All data used during this study are available from the UK Biobank Resource. As the datasets are the property of UK Biobank, they are not available for direct request. Researchers interested in the data can apply for access through the UK Biobank Access Management System.

Authors' Contributions

XS, XB, and BD designed the project and were responsible for the integrity of data and accuracy of analysis. HM, SL, and YL played a major role in the model's development and validation as well as statistical analysis. ZG, BD, XJ, and XG contributed to the discussion of results and drafted the manuscript. All authors contributed to the paper and took responsibility for submitting it for publication.

Conflicts of Interest

None declared.

Abstract

Background: Precise assessment of brain aging is crucial for early detection of neurodegenerative disorders and aiding clinical practice. Existing magnetic resonance imaging (MRI)–based methods excel in this task, but they still have room for improvement in capturing local morphological variations across brain regions and preserving the inherent neurobiological topological structures.

Objective: To develop and validate a deep learning framework incorporating both connectivity and complexity for accurate brain aging estimation, facilitating early identification of neurodegenerative diseases.

Methods: We used 5889 T1-weighted MRI scans from the Alzheimer's Disease Neuroimaging Initiative dataset. We proposed a novel brain vision graph neural network (BVGN), incorporating neurobiologically informed feature extraction modules and global association mechanisms to provide a sensitive deep learning–based imaging biomarker. Model performance was evaluated using mean absolute error (MAE) against benchmark models, while generalization capability was further validated on an external UK Biobank dataset. We calculated the brain age gap across distinct cognitive states and conducted multiple logistic regressions to compare its discriminative capacity against conventional cognitive-related variables in distinguishing cognitively normal (CN) and mild cognitive impairment (MCI) states. Longitudinal track, Cox regression, and Kaplan-Meier plots were used to investigate the longitudinal performance of the brain age gap.

Results: The BVGN model achieved an MAE of 2.39 years, surpassing current state-of-the-art approaches while obtaining an interpretable saliency map and graph theory supported by medical evidence. Furthermore, its performance was validated on the UK Biobank cohort (N=34,352) with an MAE of 2.49 years. The brain age gap derived from BVGN exhibited significant difference across cognitive states (CN vs MCI vs Alzheimer disease; $P<.001$), and demonstrated the highest discriminative capacity between CN and MCI than general cognitive assessments, brain volume features, and apolipoprotein E4 carriage (area under the receiver operating characteristic curve [AUC] of 0.885 vs AUC ranging from 0.646 to 0.815). Brain age gap exhibited clinical feasibility

combined with Functional Activities Questionnaire, with improved discriminative capacity in models achieving lower MAEs (AUC of 0.945 vs 0.923 and 0.911; AUC of 0.935 vs 0.900 and 0.881). An increasing brain age gap identified by BVGN may indicate underlying pathological changes in the CN to MCI progression, with each unit increase linked to a 55% (hazard ratio=1.55, 95% CI 1.13-2.13; *P*=.006) higher risk of cognitive decline in individuals who are CN and a 29% (hazard ratio=1.29, 95% CI 1.09-1.51; *P*=.002) increase in individuals with MCI.

Conclusions: BVGN offers a precise framework for brain aging assessment, demonstrates strong generalization on an external large-scale dataset, and proposes novel interpretability strategies to elucidate multiregional cooperative aging patterns. The brain age gap derived from BVGN is validated as a sensitive biomarker for early identification of MCI and predicting cognitive decline, offering substantial potential for clinical applications.

Introduction

Background

As human life expectancy steadily rises, the global population aged ≥60 years is projected to nearly double by 2050, reaching an estimated 2.1 billion [1]. This demographic shift presents substantial burdens to society, including rising health care costs and caregiving demands [2]. In the area of aging, dementia accounts for 11.2% of disability years, surpassing that caused by strokes (9.5%), musculoskeletal disorders (8.9%), cardiovascular diseases (5%), and all types of cancer (2.4%) [3]. Scientific investigations have illuminated the association between an aging brain and neurodegenerative conditions, such as Alzheimer disease (AD), by revealing the molecular and cellular mechanisms, particularly mitochondrial impairment [4,5]. There is an urgent demand for accurate assessment of brain aging to enable early detection of age-related neurodegenerative diseases, with neuroimaging-based brain age estimation methods gaining popularity in recent years [6].

Given its exceptional soft tissue contrast, noninvasive nature, and multimodal capabilities, magnetic resonance imaging (MRI) is the preferred method for timely visualizing brain structure and subtle lesions [7,8]. Brain age gap estimation [9], a quantified MRI-based score, has been considered a reliable brain age scale [10,11], with numerous studies associating a positive brain age gap with brain abnormalities and mortality [12,13]. The typical approach in this field involves constructing a standardized model using structural MRI data from healthy individuals. This model is then used to evaluate neuroanatomical deviations from the norm in new participants, providing insight into underlying brain abnormalities [14]. Recent publications have demonstrated the efficacy of traditional methods for brain age gap estimation, such as support vector regression and relevance vector regression, with mean absolute errors (MAEs) ranging from 2.6 years to 7.7 years [15] and 3.7 years to 4.7 years [16], respectively. However, these approaches often rely on supervised learning, with inherent limitations related to manual labeling and model performance influenced by dataset bias [14].

In recent years, the emergence and widespread adoption of deep learning (DL) techniques, which require no manual annotation and excel in handling high-dimensional data [17], have propelled model precision to unprecedented heights, achieving MAEs of <3 years [18-20]. For instance, BrainAgeNeXt [21] achieved an MAE of 2.78 years. Convolutional neural networks (CNNs) are lauded for their adeptness in automatic feature extraction from MRI images but are limited by the gradient explosion or vanishing issue in deeper layers. Residual neural networks (ResNets) have made significant strides by introducing skip connections to mitigate these training challenges, albeit at the cost of increased computational complexity. Transformer-based models represent a paradigm shift with their self-attention mechanisms adept at capturing long-range dependencies, but they demand substantial data for optimal training. Ensemble DL approaches have garnered attention for their ability to synthesize the predictions of multiple models, thereby enhancing the robustness and accuracy of brain age estimation. This prediction strategy, while beneficial for improving generalization, incurs the surcharge of increased training complexity. However, most DL-based approaches regard brain MRI as a cube constructed of voxels and then transfer models that perform well in natural images or videos directly to this task. This approach neglects the unique biological characteristics of the brain, which distinguish it from natural images [22], particularly in morphology [23]. Moreover, the human connectome exhibits intricate higher-order connectivity, encompassing spatial, functional, and sex-specific distinctions [24] among different brain voxel regions. Common CNN architectures designed for natural images lack the capacity to modify their topologies [25]. Currently, there is a notable absence of a DL framework that simultaneously considers both brain morphology and voxel regions connectivity for assessing brain aging. In addition, there is insufficient evidence to compare and quantify the clinical application value of the brain age gap and the relationship between narrowing MAEs with improving clinical application performance.

This Study

Here we proposed a novel graph-based DL framework, a brain vision graph neural network (BVGN), which uses deformable kernels to extract brain morphological features and incorporated a graph neural network (GNN) to characterize voxel regions connectivity. We pioneered the adaptation of vision GNN [26], a backbone widely researched in natural image processing, to the domain of brain aging by extending its framework to 3D MRI. The BVGN leveraged an individual's standard

T1-weighted MRI as input and generated the corresponding neuroimaging biomarker-brain age gap to evaluate brain aging. Subsequently, we constructed multiple logistics regression models, each incorporating different types of input variables, to classify data samples labeled as cognitively normal (CN) and with mild cognitive impairment (MCI). We aimed to compare and validate the effects of brain age gap against conventional variables, including demographic factors, brain volume features, apolipoprotein E4 (APOE4) carriage, and general cognitive scales, in distinguishing CN and MCI states. In addition, we assessed the combined utility of the brain age gap with the Functional Activities Questionnaire (FAQ) cognitive assessment and the impact of lower MAEs. Cox proportional hazards regressions were performed separately using data from participants classified as CN and those with MCI at baseline to evaluate the potential of brain age gap as a risk biomarker for cognitive decline over a 2-year follow-up period.

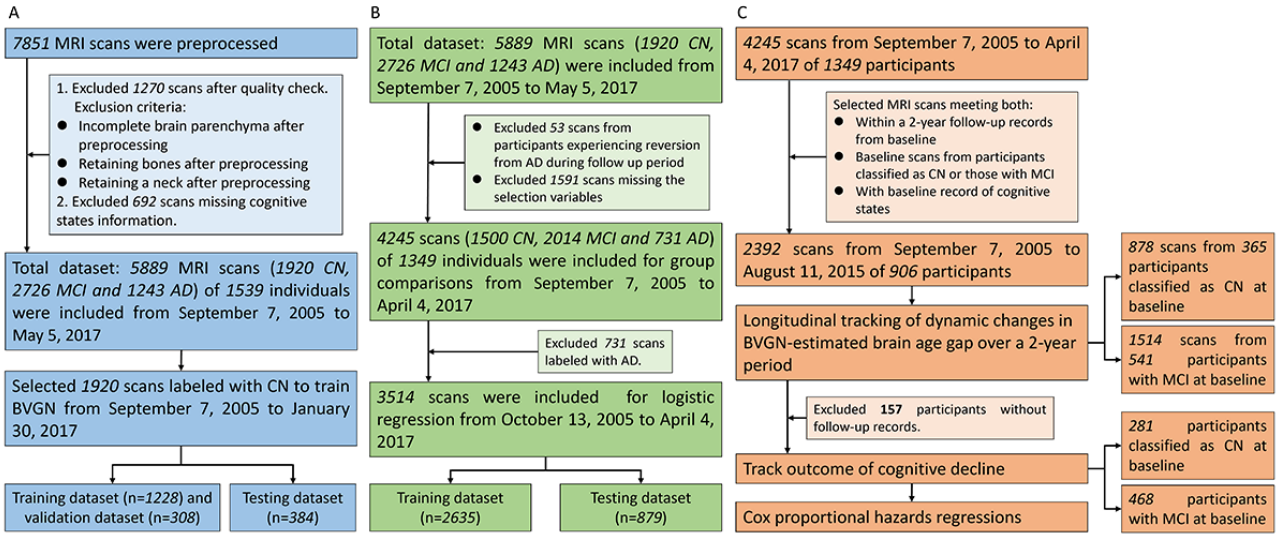
Methods

Dataset, Study Design, and Inclusion Criteria

Data used in the preparation of this paper were obtained from the database of Alzheimer's Disease Neuroimaging Initiative (ADNI) studies [27-29]. The ADNI was launched in 2003 as a public-private partnership, led by principal investigator Michael W Weiner, MD. The primary goal of ADNI has been to test whether serial MRI, positron emission tomography, other biological markers, and clinical and neuropsychological assessment can be combined to measure the progression of MCI and early AD.

This study gathered 7851 T1-weighted MRI scans from ADNI-1, ADNI-2, and ADNI-GO (Grand Opportunities) studies. The research design comprised 2 sequential phases: development and validation of the BVGN model for accurate brain age estimation, and clinical effect validation of the BVGN-estimated brain age gap metric by integrated cross-sectional and longitudinal analysis. For BVGN model development, we specifically chose 5889 scans from 1539 individuals that contained cognitive states labels and met both the ADNI MRI scanner protocols [30,31] and our strict training criteria (ie, presenting complete structural information after preprocessing). Data regarding the patient's cognitive states were retrieved from the ADNI web portal [32]. Only 1920 MRI scans of participants classified as CN were used for training the BVGN model (Figure 1A). To ensure comprehensive model development and evaluation, we divided the dataset consisting of participants classified as CN into training set with validation set and test set in a ratio of 8:2. The training set and validation set were used for model training and hyperparameter setting, while the test set was used to validate the performance of the model. A subset of the UK Biobank (UKB) dataset [33] was used for external validation to evaluate model generalizability. We curated 34,352 MRI scans, partitioned into training set (n=21,985, 64%), validation set (n=5497, 16%), and test set (n=6870, 20%).

Figure 1. Flow diagram to show study design and inclusion criteria. (A) Brain vision graph neural network (BVGN) training and testing part; (B) cross-sectional validation part; (C) longitudinal validation part. AD: Alzheimer disease; CN: cognitively normal; MCI: mild cognitive impairment; MRI: magnetic resonance imaging.



Given the progressive nature of dementia caused by neurodegenerative disorders, we excluded scans from participants who experienced reversion from AD during the follow-up period (Figure 1B). Following feature selection, 4245 MRI scans from 1349 participants were retained for cross-sectional analysis. All scans were used for intergroup comparisons, while only those from participants classified as CN and those with MCI were used for logistic regression analysis aiming at binary classification between CN and MCI. To validate the performance of logistic regression models, the dataset was split into training and test sets at an 8:2 ratio.

We combined various MRI scans from the same individual for longitudinal analysis (Figure 1C). Specifically, we used a dual-component longitudinal design to investigate the trajectories of BVGN-estimated brain age gap across cognitive progression groups and quantify cognitive decline risks through Cox proportional hazard models. For the brain age gap trajectory analysis, cognitive progression categories (CN-CN, CN-MCI or CN-AD, MCI-CN or MCI-MCI, and MCI-AD) were stratified

based on recorded cognitive states from baseline to a 2-year follow-up. The inclusion criteria required participants to be classified as either CN or having MCI at the baseline, yielding 1514 scans from 541 participants with MCI and 878 scans from 365 participants classified as CN.

To evaluate time-dependent cognitive decline, we conducted Cox proportional hazards regression stratified by baseline groups. We excluded 157 participants without follow-up data and performed separate analyses for the baseline CN group (tracking MCI conversion) and MCI group (tracking AD conversion). The final analysis included 749 participants, comprising 281 (37.5%) individuals classified as CN and 468 (62.5%) individuals with MCI, with the time-to-event defined as the interval between baseline MRI and first observed cognitive transition.

Quality Control and Data Preprocessing

For the ADNI dataset, each series within every examination was subjected to a rigorous quality control process at the Mayo Clinic. This involved 2 distinct levels of scrutiny—compliance with protocol-specific parameters and an assessment of the series-specific quality, such as the participant's movement and the extent of anatomical coverage. The quality of the scans was evaluated by trained analysts who assigned a subjective grade—scores of 1 to 3 were considered satisfactory, while a score of 4 indicated a failure, rendering the scans unusable. While the UKB dataset was only used to test the model's generalizability, all data also underwent standardized quality control procedures [34].

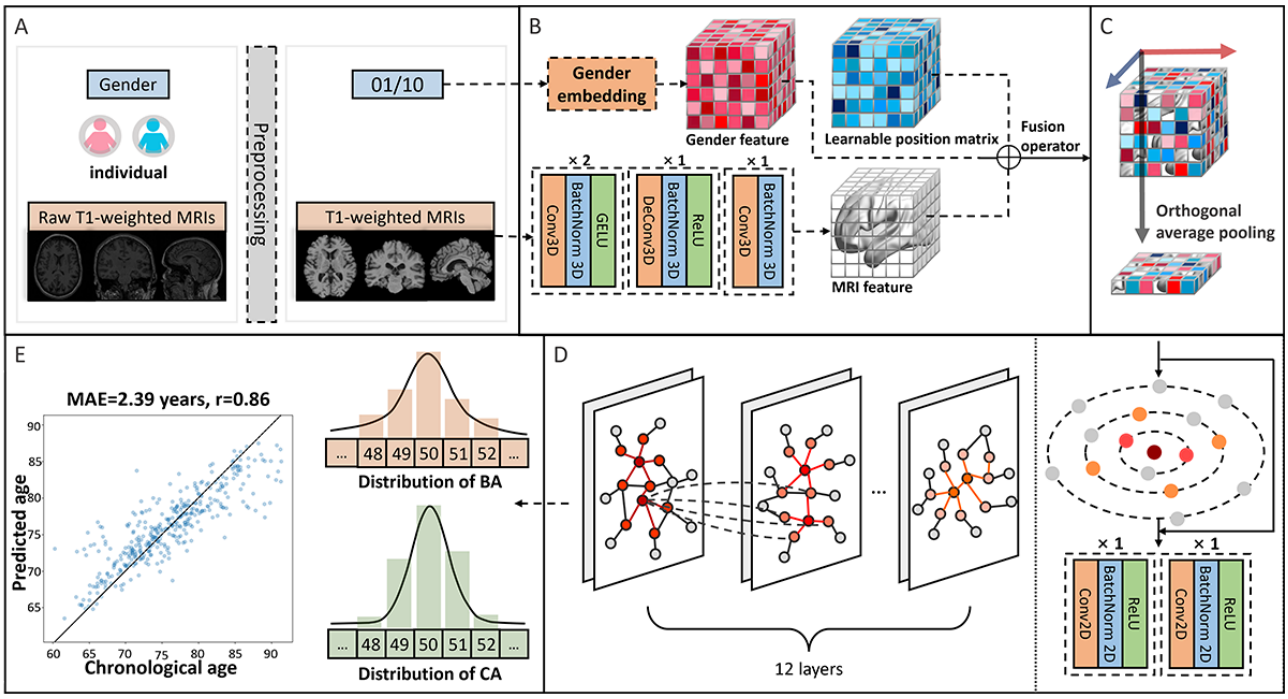
The acquisition protocols of different datasets required data preprocessing to ensure compatibility. The entire MRI preprocessing pipeline could be divided into 4 steps. First, the raw MRI data in neuroimaging informatics technology initiative format underwent minimum-maximum normalization. Second, nonbrain tissue, such as the skull and neck, was removed. In the third step, each MRI was registered from its native space to the standard Montreal Neurological Institute 152 1-mm^3 template [35] chosen for registration in our study. Finally, central cropping was performed on the complete MRI volume, resulting in a final output size of 160×196×160 mm^3. In addition, further preprocessing steps were conducted to exclude MRIs with incomplete brain structures, ensuring dataset quality. The preprocessing pipeline was implemented using SimpleITK [36] and FMRIB software library [37].

During the logistic and Cox regression modeling phase, *z* score normalization was applied to numerical variables, while categorical variables were transformed using one-hot encoding.

BVGN Model Development

Owing to the need for a large number of high-quality handcrafted features in traditional methods [14] and because inductive bias to brain structures is not effectively transferable from natural images when applying classical DL architectures, there are limitations in extracting features from irregular objects, such as cortical sulcus and gyrus, as well as parenchyma using grid-like convolution kernels that perform weighted summation of pixel values at the centroid and its neighbors [25,38,39]. Furthermore, CNN architectures lack the ability to modify topological relationships between voxel regions [22]. To address these issues, we proposed an end-to-end framework called BVGN (Figure 2), which used standardized MRIs to estimate brain aging of individuals. To be more specific, BVGN makes it easier to extract irregularly shaped structures in brain MRI by superimposing deformable convolution kernels. A graph CNN was used to model the relationship between different regions.

Figure 2. Overview of the brain vision graph neural network model. (A) A preprocessing pipeline was implemented, which involved converting gender into 1-hot encoding and transforming raw magnetic resonance imaging (MRI) data into brain tissue located in a standard space. (B) Discretization layer, the voxel space of brain is divided by the discretization layer, which uses a combination of multiple convolution modules and deformable convolution modules. Subsequently, positional features and gender features are integrated into cubes. (C) Orthogonal average pooling module (coronal axis, sagittal axis, transverse axis, the 3D feature cube is transformed into a 2D feature map). (D) Stacked graph neural network modules. (E) During training, the image on the right illustrates that the supervised signal of back-propagation is computed by evaluating the Kullback-Leibler divergence between estimated brain age and chronological age; whereas the image on the left depicts the model's performance. BA: brain age; CA: chronological age.



The BVGN framework consists of 3 components: discretization layer, stacked GNN layer, and aging distribution prediction header. Specifically, standardized MRIs were discretized into multiple cubes using nonoverlapping multiple deformable convolutional modules [38], where each cube's feature vectors contained all information within the receptive field range of deformable convolutional modules. In addition, an individual's sex and position information for each cube was incorporated into the feature map by passing through a projection module, modal-type embedding [40] and initializing a learnable parameter matrix [41]. An orthogonal average pooling module was implemented to project the 3D volumetric feature tensor along 3 mutually perpendicular anatomical axes (coronal, sagittal, and transverse). This dimensionality reduction operation transforms the 3D spatial representation into a 2D feature map while preserving critical spatial information across orthogonal planes. Detailed explanations of Figure 2 are provided in Multimedia Appendix 1.

The feature map was subsequently transformed into a graph using Euclidean distance and nearest neighbors as the basis, which was then input into a stacked GNN [26,42]. Importantly, the dynamic construction of the graph during forward processing relied on assessing similarity between feature maps at different depths. Ultimately, aging probability distributions [43,44] were obtained in the prediction header by integrating the feature map through bottlenecked convolutional kernels [45], based on predefined age ranges. Inspired by vision GNN [26], we implemented 2 distinct neural network architectures—the pyramid-shaped BVGN and the isotropic BVGN. The isotropic BVGN was used for interpretability analyses, while the pyramid-shaped BVGN was used to enhance overall performance. Both architectures were initiated with an identical discretization module featuring the same number of nodes. However, as the network deepened, the isotropic BVGN maintained a constant node count, ensuring uniform information flow akin to the transformer model's approach. In contrast, the pyramid-shaped BVGN underwent a process of node consolidation, progressively reducing the number of nodes to form a pyramidal structure, echoing the hierarchical feature extraction of CNNs in computer vision.

BVGN Model Training

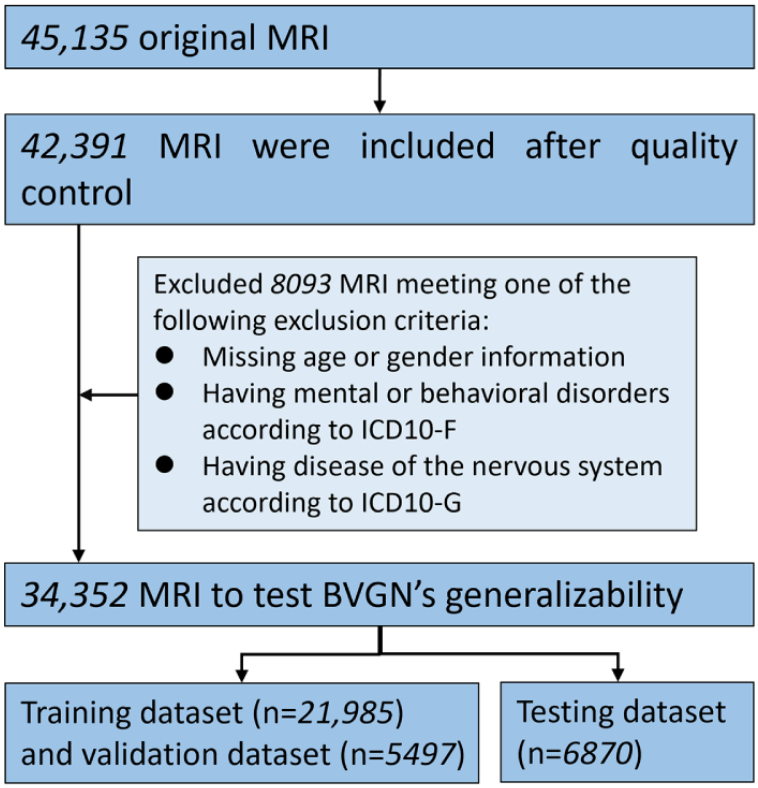
The BVGN model was trained using multiple graphics processing units to ensure efficient computation. For optimization purposes, we implemented the stochastic gradient descent optimizer with an initial learning rate of 0.01, aiming to minimize the Kullback-Leibler divergence between the predicted age distribution and label age distribution. To prevent overfitting, an L2 weight decay coefficient value of 0.001 was applied during training sessions lasting up to 160 epochs. Furthermore, a batch size of 32 was adopted for improved performance, while progressively decreasing the learning rate by multiplying it with a factor of 0.7 after every consecutive span of 30 epochs.

BVGN Model Performance and Generalizability Evaluation

To objectively assess the performance of our framework, we used MAE and Pearson correlation as validation metrics to evaluate the efficacy of BVGN as a prediction model. Furthermore, we simultaneously trained and tested the simple

fully convolutional network (SFCN) and ResNet models on the same dataset, ensuring a fair comparison. To validate the model's generalizability, we retrained it using the UKB dataset, which is large scale and not restricted to disease-specific populations. The detailed inclusion process and demographic characteristics of the included UKB dataset are presented in Figure 3 and Table S1 in Multimedia Appendix 1.

Figure 3. Flow diagram to show inclusion criteria for brain vision graph neural network's (BVGN's) generalizability. ICD: International Classification of Diseases; MRI: magnetic resonance imaging.



BVGN Model Interpretation

In contrast to models exclusively relying on CNNs, BVGN incorporates graph convolutional kernels to modify the relationships among local regions. This enables BVGN to offer interpretability not only through saliency maps but also by considering pertinent properties of the graph structure. More specifically, we first visualized a gradience-based saliency map [45] for participants classified as CN and those with MCI and AD. Subsequently, certified radiologists used the automated anatomical labelling atlas to ascertain the specific brain regions to which the saliency map corresponded. Furthermore, we conceptualized the brain as a graph-based complex system and characterized the interregional cooperative aging patterns by analyzing the connectivity of critical nodes across different hierarchical levels through data-driven visualization techniques.

Cross-Sectional Analysis: Intergroup Comparisons and Logistic Regression

During cross-sectional analysis, each MRI scan was treated as an individual sample, and all statistical analysis was conducted accordingly. Numerical variables in demographics and selection features were presented as mean (SD), while categorical variables were presented as counts (n) and percentages (%). Statistical comparisons between training and testing sets were performed with 2-tailed significance. Specifically, the Student *t* tests and a 1-way ANOVA were used for numerical variables, and chi-square tests were used for categorical variables. A $P<.05$ was considered statistically significant.

For intergroup comparisons, we first characterized the distribution of the brain age gap using the median and IQRs across CN, MCI, and AD classifications. Subsequently, we used the Kruskal-Wallis test followed by 1-tailed Dunn test to evaluate potential significant differences in the brain age gap among these groups, with a significance level set at $P<.05$. Potential confounding effects were addressed through a multiple linear regression model incorporating age and gender as covariates.

We used multiple logistic regression models aiming at binary classification between CN and MCI samples. Our objective was to validate the diagnostic ability of the brain age gap compared to other conventional variables and to assess the potential clinical value of achieving lower MAEs in brain age gap estimation. Inspired by previous studies, we considered the brain age gap along with other relevant cognitive variables, including demographic characteristics, general cognitive assessments, brain volume features, and APOE4 carriage. Given the simplicity and high discriminative and predictive power of FAQ as reported by previous studies, we specifically investigated the impact of combining the brain age gap with FAQ to determine if their integration improves diagnostic classification.

Model performance was evaluated using metrics, including accuracy, precision, recall, F_1-score, the receiver operating characteristic curves, and the area under the receiver operating characteristic curves (AUCs).

We initially established a benchmark model incorporating only demographic variables. Subsequently, brain age gap, various cognitive assessment scores, brain volume characteristics, and APOE4 carriage were added to the benchmark model to construct various logistic regression models. A comprehensive model integrating all the abovementioned variables was then developed, and their coefficients were compared. These analyses aimed to provide a holistic view in comparing the brain age gap with conventionally recognized cognition-related variables. Furthermore, we included both the FAQ and the brain age gap in the benchmark model to explore their combined utility. We also investigated the potential clinical value of lower MAEs by including diverse brain age gaps estimated from models with different precision, both in conjunction with the benchmark and comprehensive models, and compared their performances.

Longitudinal Analysis: Brain Age Gap Trajectories and Risk Quantification

We conducted a longitudinal analysis to investigate changes in brain age gap across follow-up scans of the same participants and assess the risk of brain age gap for cognitive decline. We used BVGN, SFCN, and ResNet models to estimate brain age gap across the total 2392 scans and depicted how the estimated brain age gap changed over follow-up time in different progression groups.

After excluding participants without follow-up records, we performed Cox regression using the baseline brain age gap for both the CN and MCI groups. This allowed us to evaluate the association between brain age gap and cognitive decline, as well as to quantify its hazard ratio (HR). We initially estimated the HR of brain age gap using a univariate Cox proportional hazards model, followed by adjustment for demographic features to control for potential confounding bias. Subsequently, a multivariable Cox proportional hazards model that included all selected variables was used to assess the HR of the brain age gap from a holistic view. In addition, we plotted Kaplan-Meier survival curves stratified by the upper and lower 50% levels of brain age gap in both CN and MCI groups to visualize the performance of the brain age gap in predicting cognitive decline.

Ethical Considerations

Data used in the preparation of this paper were obtained from the ADNI database. Consequently, the investigators within the ADNI contributed to the design and implementation of ADNI and provided data but did not participate in analysis or writing of this report. A complete listing of ADNI investigators can be found [46] on the internet.

Data collection and sharing for this project were funded by the ADNI (National Institutes of Health grant U01 AG024904) and DOD ADNI (Department of Defense grant W81XWH-12-2-0012).

The data used in the preparation of this paper were obtained from the UKB database. UKB has generic ethical approval from the North West Multi-centre Research Ethics Committee as a Research Tissue Bank (91486), and therefore researchers do not require separate ethical clearance to use the resource.

Results

Demographics and Selection Variable Characteristics

During the BVGN development process, the sample sizes for training, validating, and testing sets were 1228, 308, and 384, respectively. As shown in Table S2 in Multimedia Appendix 1, the mean ages for the training with validating sets and testing sets were 75.65 (SD 6.31) and 75.89 (SD 6.60) years, respectively. The percentages of male individuals in the training and validating set and testing set were 47.1% (724/1536) and 43.5% (167/384), respectively. No significant difference (P=.51) was observed.

Table 1 details the basic information of the dataset for intergroup comparison, which included 4245 MRI scans from 1349 participants. The discrepancy in participant count (1585 in Table 1) reflects instances where participants exhibited multiple cognitive manifestations during the follow-up period, leading to some being counted multiple times across groups. Specifically, the dataset comprised 1500 MRI scans from 499 participants classified as CN, 2014 scans from 709 participants with MCI, and 731 scans from 377 participants experiencing AD. The mean age was 75.39 years for participants classified as CN, 72.96 years for participants with MCI, and 74.76 years for participants with AD. The percentage of male participants was 46.1% (691/1500) for those classified as CN, 55.2% (1112/2014) for those with MCI, and 49.3% (360/731) for those with AD. Significant differences were observed between the CN, MCI, and AD groups for both age and gender characteristics.

Table 1. Demographic characteristics for the dataset of group comparisons.

	CN[a]	MCI[b]	AD[c]	*P* value
MRI[d] scans, n	1500	2014	731	—[e]
Participants[f], n	499	709	377	—
Age (y), mean (SD)	75.39 (6.06)	72.96 (7.45)	74.76 (7.53)	<.001
Gender, n (%)				<.001
Male	691 (46.1)	1112 (55.2)	360 (49.3)	
Female	809 (53.9)	902 (44.8)	371 (50.7)	

[a]CN: cognitively normal.

[b]MCI: mild cognitive impairment.

[c]AD: Alzheimer disease.

[d]MRI: magnetic resonance imaging.

[e]Not applicable.

[f]The total number of participants (n=1585) in Table 1 included instances where some participants had multiple cognitive manifestations during follow-up, leading to duplicates between groups. This total differed from the 1349 unique participants reported in Figure 1. Statistical analysis was performed by ANOVA test for age and chi-square test for gender. Two-tailed significance was used, with $P<.05$ indicating the presence of significance.

For the logistic regression modeling process, 3514 scans were included, with 2635 (74.99%) in the training set and 879 (25.01%) in the testing set. The characteristics of all variables used in the logistic regression are presented in Table 2. No significant differences were observed between training and testing sets for all the selected variables.

Table 2. Characteristics of selected variables in the training and testing datasets for logistic regression.

Variables	Total dataset (n=3514)	Training dataset (n=2635)	Testing dataset (n=879)	*P* value

Performance and Generalizability of BVGN

We have simultaneously trained various strong baseline models alongside our proposed model using the same training set and explored their performance on the same test set. The results are shown in Table 3.

Table 3. Performance of benchmark models and the brain vision graph neural network (BVGN) model.

Models	Performance	
	MAE[a] (y)	Pearson correlation coefficient (*r*)
3D ResNet15[b]	3.03	0.76
SFCN[c]	2.41	0.87
Isotropic BVGN	3.08	0.79
Pyramid BVGN	2.39	0.86
Pyramid BVGN (external validation)	2.49	0.92

[a]MAE: mean absolute error.

[b]ResNet15: residual neural network with 15 layers.

[c]SFCN: simple fully convolutional network.

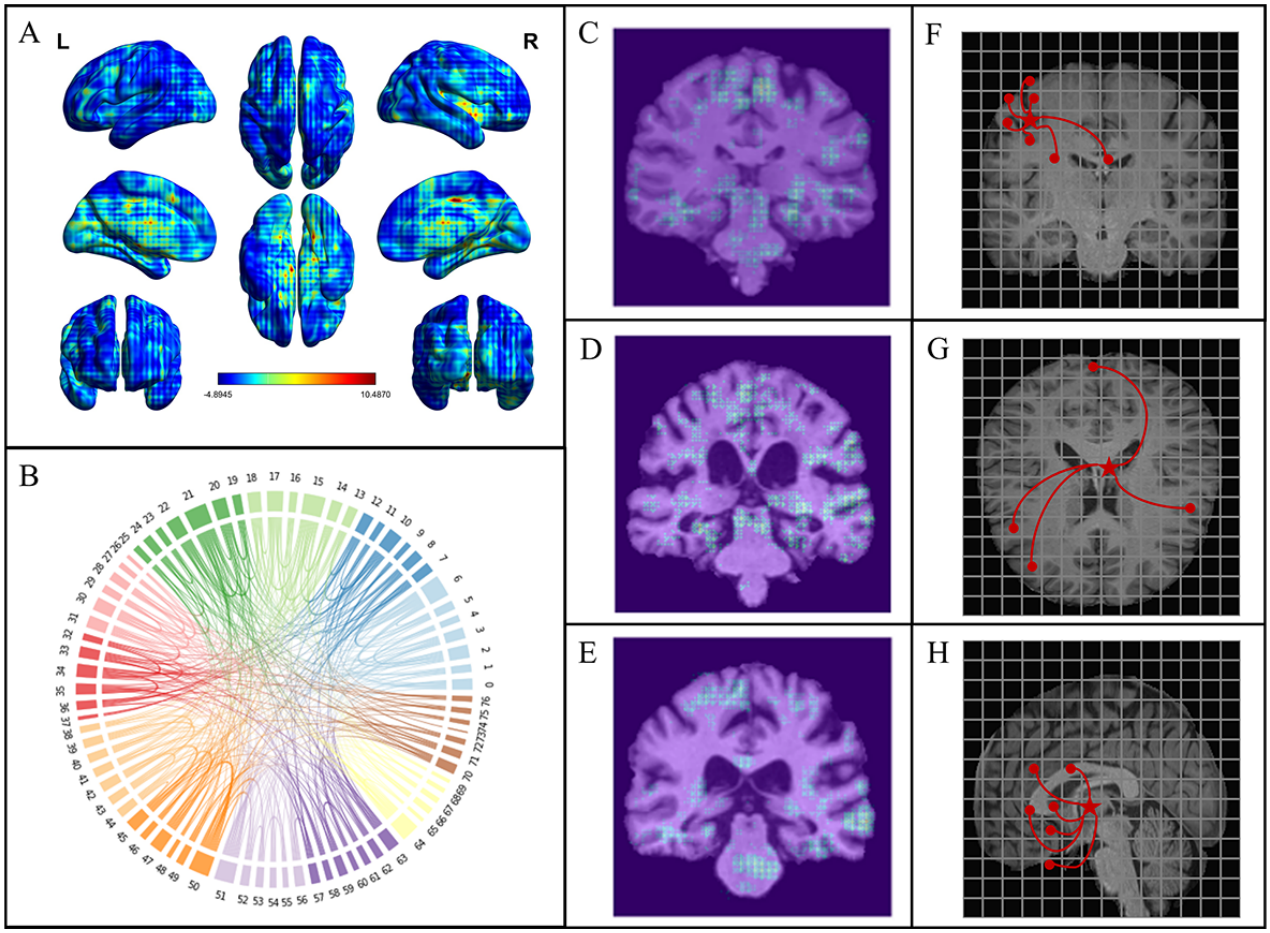
Our isotropic BVGN attained an MAE of 3.08 years, which was slightly worse than the currently optimal model, SFCN, specifically designed for the brain age gap estimation (with an MAE of 2.41 years). After applying deformable convolutions, our pyramid BVGN achieved the best performance among all the tested models with an MAE of 2.39 years and a Pearson correlation coefficient of 0.86 between the predicted and chronological age.

The BVGN model, when retrained on the UKB dataset, exhibited robust performance with an MAE of 2.49 years and a Pearson correlation coefficient of 0.92 (Figure S1 in Multimedia Appendix 1), underscoring its strong generalization capacity.

Interpretability Analysis of BVGN

As shown in Figures 4A and 4B, the saliency map indicated that our model exhibited a moderate focus on various dispersed regions within the cortical layer, while notably emphasizing relatively concentrated parenchymal regions. The regions of concern of the model are different in the population identified as CN (Figure 4C) and those with MCI (Figure 4D) and AD (Figure 4E).

Figure 4. Results for interpretability analysis.



In addition, we described the brain as a complex system by extracting edge and node features from the last layer of an isotropic BVGN backbone. In Figure 4B, the top nodes with the highest degree centrality in the final layer of the isotropic BVGN are depicted, showcasing both these central nodes and their immediate neighboring nodes. This visualization provides insights into the most influential regions within the brain's voxel network as determined by the BVGN's analysis. Specifically, key cortical areas involved the frontal lobe and temporo-parieto-occipital regions, and parenchymal regions included the corpus callosum, cingulate gyrus, and parahippocampal gyrus, covering the striatum, thalamus, and adjacent hippocampus. In Figures 4F-4H, we leveraged a distinctive visualization approach inherent to the vision GNN backbone to illustrate the spatiotemporal dynamics of interregional aging patterns. The red star marks a specific voxel block, and the most relevant regions are delineated through red line connections.

Comparison of Brain Age Gap Among Different Cognitive State Groups

The median of brain age gap was 0.32 (IQR 0.13-1.17) among 1500 CN samples, 4.42 (IQR 2.18-7.73) across 2014 samples with MCI, and 5.20 (IQR 2.53-8.36) in 731 samples with AD (Figure 5A). A statistically significant difference in brain age gap was observed between AD and MCI (P=.008), with MCI demonstrating a significantly higher gap than CN (P<.001), indicating the potential of our model to better distinguish between individuals classified as CN and those with MCI. The results adjusted for age and gender are provided in Table S3 in Multimedia Appendix 1, which were similar to the results mentioned earlier.

Multiple Logistic Regression Models

Brain Age Gap Compared to Other Cognition-Related Variables

Detailed metrics of various logistic regression analyses aiming to compare brain age gap and other cognition-related variables are provided in Table 4, while multiple receiver operating characteristic curves and corresponding AUC scores are illustrated in Figure 5B. Initially, the benchmark model, including only demographic features, yielded an AUC of 0.588. Subsequent incorporation of additional variables, such as FAQ [47], Alzheimer's Disease Assessment Scale-Cognitive Subscale13-item version [48], Rey Auditory Verbal Learning Test [49], Mini-Mental State Examination [50], trail making test part B, time [51], brain volume features, APOE4 carriage, and brain age gap led to improved AUC scores, reaching 0.815, 0.798, 0.777, 0.731, 0.646, 0.672, 0.660, and 0.885, respectively. Notably, the comprehensive model encompassing all variables achieved an AUC of 0.945, with the brain age gap exhibiting the highest coefficient (Figure 6B). These results underscore the robust and superior discriminative ability of the brain age gap in distinguishing between CN and MCI samples.

Table 4. Performance of the logistics regression models in classifying cognitive states: cognitively normal and mild cognitive impairment (brain age gap versus conventional cognitive variables).

Input features	Accuracy	Precision	Recall	F_1-score	AUC[a]
Overall	0.882	0.915	0.875	0.895	0.945
Demographic+BVGN_BAG[b]	0.820	0.890	0.784	0.833	0.885

Combined Performance of Brain Age Gap With FAQ

In the comprehensive logistics regression model of BVGN, FAQ demonstrated the second-largest coefficient following brain age gap (Figure 6B). When comparing the comprehensive models that included all selective variables with another model incorporating demographic variables, brain age gap and FAQ, minimal declines in AUCs were observed—BVGN decreased by 0.011 (from 0.945 to 0.935), SFCN by 0.024 (from 0.923 to 0.900), and ResNet by 0.031 (from 0.911 to 0.881; Table 5; Figure 5C). Notably, BVGN exhibited the smallest AUC reduction when all variables except FAQ were missing, outperforming other frameworks. In addition, with only demographic variables, brain age gap, and FAQ, BVGN could provide a higher AUC (0.935) compared to other frameworks, even when all selective features were incorporated (SFCN: AUC=0.923; ResNet: AUC=0.911). This underscored the combined efficiency of FAQ and brain age gap, as well as the robustness of BVGN in scenarios with missing variables.

Table 5. Performance of logistics regression models: brain age gaps evaluated by models with different precisions (mean absolute errors) and combined utility of brain age gap with Functional Activity Questionnaire (FAQ).

Potential Clinical Value of Lower MAEs in Brain Age Gap Estimation

In assessing the potential clinical utility of models with lower MAEs, our BVGN model consistently outperformed SFCN and ResNet models (Table 5), both in the simplified model comprising only demographic features and brain age gap and in the comprehensive model incorporating all variables. Notably, brain age gap estimated by BVGN demonstrated the highest AUCs (Figure 5C). Specifically, in the simplified model, BVGN achieved AUCs of 0.885, while SFCN and ResNet yielded AUCs of 0.842 and 0.800, respectively. Similarly, in the comprehensive model, BVGN achieved AUCs of 0.945, surpassing SFCN and ResNet with AUCs of 0.923 and 0.911, respectively. These findings were consistent with the ranking of MAEs obtained from these 3 frameworks, indicating that models with lower MAEs might have the potential to enhance the model's discriminatory ability.

Longitudinal Value of BVGN

Brain Age Gap Trajectories in 2 Years

The number of MRI scans for CN-CN, CN-MCI or CN-AD, MCI-CN or MCI-MCI, and MCI-AD were 849, 29, 1261, and 253, respectively.

As illustrated in Figure 6A, we observed consistent ordering of brain age gaps across progression groups in all the frameworks over the 2-year period (MCI-AD>MCI-CN or MCI-MCI>CN-MCI or CN-AD>CN-CN). Moreover, brain age gaps tended to decrease over the 2-year follow-up period in each progression group in both the SFCN and ResNet models, as well as in all groups in the BVGN model except the CN-MCI or CN-AD group. However, in the BVGN model, an interesting increase in the brain age gap was observed in the CN-MCI or CN-AD group.

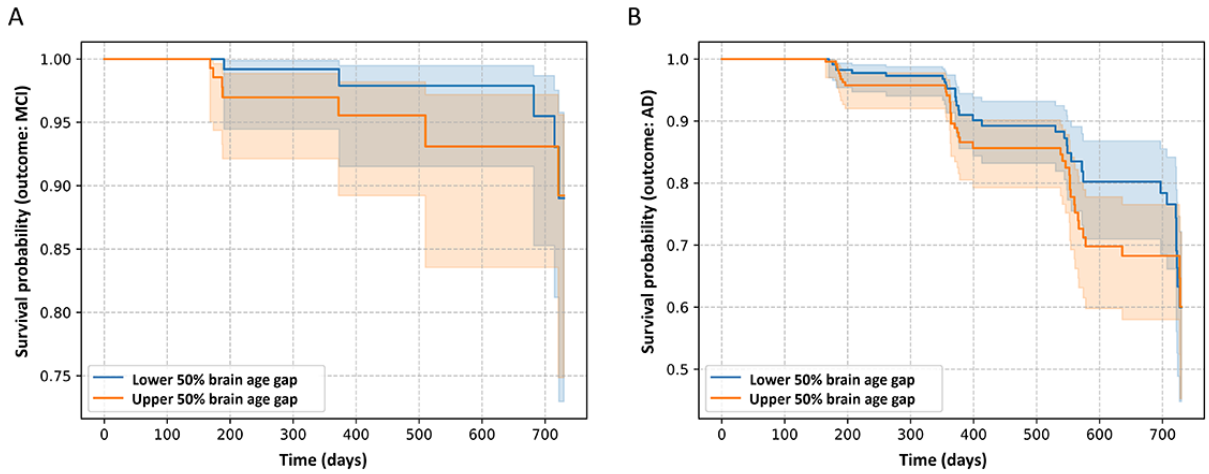
Risk Evaluation by Brain Age Gap

Among the 281 individuals classified as CN at the baseline, 12 (4.3%) declined to MCI, while 269 (95.7%) remained in the CN state. Among the 468 participants with MCI at the baseline, 74 (15.8%) declined to AD while 394 (84.2%) remained in the MCI state or improved to the CN state.

Both univariable Cox regression models and demographic-adjusted as well as fully adjusted multivariable models demonstrated that the brain age gap was a significant risk factor for cognitive decline in both the CN and MCI groups (Table S4 in Multimedia Appendix 1). In the univariable model, the HR for brain age gap was 1.55 (95% CI 1.13-2.13) in the CN group and 1.29 (95% CI 1.09-1.51) in the MCI group. For the CN group, the HR for the brain age gap was 1.47 (95% CI 1.06-2.05) in the demographic-adjusted model and increased to 2.13 (95% CI 1.01-4.47) in the fully adjusted model. In the MCI group, the HR was 1.30 (95% CI 1.10-1.53) for the demographic-adjusted model and 1.24 (95% CI 1.03-1.48) for the fully adjusted model.

The Kaplan-Meier curves indicated that in both CN (Figure 7A) and MCI (Figure 7B) groups, the survival curve for the lower 50% of the brain age gap group was higher than that for the upper 50% group. This finding aligned with the HRs, suggesting that a higher level of brain age gap was associated with an increased risk of cognitive decline.

Figure 7. Visualization of Kaplan-Meier curves stratified by the upper and lower 50% levels of brain age gap in both (A) cognitively normal and (B) mild cognitive impairment (MCI) groups. AD; Alzheimer disease.



Discussion

Principal Findings

In summary, this study proposed a novel framework, BVGN, for brain age estimation. This model not only introduced an innovative modeling approach but also achieved lower MAEs (2.39 years) compared to current state-of-the-art frameworks for brain age gap estimation. It also demonstrated a robust performance on a large-scale external dataset, maintaining strong generalizability (MAE=2.49 years; *r*=0.92; Figure S1 in Multimedia Appendix 1). In addition, BVGN offers an interpretable analysis approach not found in other DL models, which reveals patterns of coaging between brain regions by visualizing the locations of neighboring nodes associated with high-importance nodes. In our study, BVGN provided interpretable attention regions corroborated by medical evidence. Our validation experiments demonstrated its robust performance in MCI diagnosis, its capacity as a risk biomarker for cognitive decline, and its potential to aid in screening and clinical applications.

BVGN integrates deformable convolutional kernels and a dynamic graph for brain age gap estimation. To the best of our knowledge, this work represents the first successful application of vision GNN to T1-weighted MRI data without requiring additional brain segmentation, achieving competitive performance. Unlike 3D CNNs, which process brain images as regular voxel grids and struggle with the inherently irregular morphological characteristics of cerebral regions, often resulting in redundant computations and information loss, BVGN leverages graph-structured representations to preserve complex anatomical features. The integration of deformable convolutional kernels enables the model to focus on specific pathological patterns while suppressing extraneous noise, thereby enhancing local feature modeling [34]. Furthermore, the topological properties of graph structures facilitate multiregional feature aggregation across distant brain regions [38,39], a capability unattainable by grid-based CNNs. To strengthen age prediction accuracy, we transformed age from a discrete numerical variable into a smoothed probability distribution, preserving its continuity and capturing interval similarity [40,41,49,50]. Comparative evaluations demonstrate superior performance of BVGN over existing CNN-based models such as BrainAgeNeXt, achieving an MAE of 2.39 versus 2.78 years, and maintaining robust generalization capabilities (MAE=2.49 years; *r*=0.92) on the UKB dataset after retraining. Structure-functional coupling has garnered increasing attention in neuroscience, with graph-based modeling serving as a critical analytical framework [52]. For instance, structural connectivity derived from diffusion-weighted imaging via white matter fiber tractography and functional connectivity computed from functional MRI are commonly represented as adjacency matrices in graph structures. The framework, being graph-based in design, is inherently more scalable and adaptable to the aforementioned MRI modalities compared to other DL approaches, providing an interface with modal-type embedding for early feature fusion [40]. This capability not only enhances multimodal integration but also helps mitigate the semantic gap across different MRI modalities [53].

We found substantial evidence validating the BVGN's focused brain regions associated with cognitive decline, which provided strong interpretability for our model. The frontal lobes exhibited particularly prominent changes within an annual 0.87% reduction in overall cortical volume [54], while the temporo-parieto-occipital junction was intricately involved in high-level human neurological functions, such as language, memory, calculation, and writing [55]. Shape characteristics in the corpus callosum were demonstrated to have potential for distinguishing cognitive deterioration [56,57], and the cingulate gyrus was implicated in the onset of neurodegenerative and psychiatric disorders [58]. In addition, the parahippocampal gyrus integrates signals from the limbic and neocortex, predicting later memory [59], and the fractional anisotropy alterations in the parahippocampal white matter have been observed across AD stages [60,61].

In recent years, despite the substantial academic focus on the brain age gap, questions have persisted regarding its reliability as a clinical tool compared to cognitive assessments for diagnosing cognitive decline. After multiple experiments that incorporated various kinds of input variables to distinguish CN and MCI, our findings revealed that except for the trail making

test part B, time (AUC=0.646), cognitive assessments exhibited AUCs from 0.731 to 0.815, which surpassed both the AOPE4 carriage (AUC=0.660) and brain volume characteristics (AUC=0.672), and were inferior to brain age gap (AUC=0.885). While cognitive assessments provided affordability, the subjective bias among clinical practitioners might impact diagnosis [62], with limitations in sensitivity observed in certain cases, such as mild levels of impairment [32], subjective deficits, and healthy cognitive aging [63]. According to our findings, our model could offer alternative and more objective evaluations for clinical settings, potentially reducing physicians' workload and enhancing convenience.

The FAQ is a 10-item collateral-report scale with 4-point ordinal responses per item, totaling 0 to 30 points, with higher scores indicating greater functional impairment [64]. This makes it highly accessible in clinical settings and convenient for clinical practitioners. Scientific publications have demonstrated its good internal consistency and high discriminative validity for differentiating between CN and MCI, as well as between MCI and very mild AD [65,66]. Its high predictive validity in detecting individuals at risk of progression from MCI to AD and from CN to MCI has also been reported [47]. In our study, we observed minimal reductions in AUCs when comparing models that incorporated all selective variables and models with only demographic variables, brain age gap, and FAQ. Our selected demographic variables, education years, gender, and marriage status, were deliberately straightforward. This simplicity would enhance the feasibility of our proposed model for clinical applications, especially in cases of uncertain MCI diagnosis. By integrating basic demographics, FAQ responses, and T1-weighted MRI scans, our BVGN model could serve as a reliable assistant tool for clinicians in MCI diagnosis.

In our comprehensive model that integrated brain age gap, cognitive assessments, and other relevant variables, we observed the highest AUC of 0.945 in classification tasks. The integration of variables from diverse perspectives might contribute to improving performance. In addition, we observed brain age gap possessed the highest variable coefficient, with each scalarized unit increase associated with a 10.6 times higher risk of MCI. This further supported the brain age gap's capacity in MCI diagnosis.

Furthermore, our analysis revealed a relationship between model performance, as indicated by lower MAEs, and superior performance in discriminating between CN and MCI. Specifically, BVGN, SFCN, and ResNet achieved MAEs of 2.39, 2.41, and 2.65 years, respectively. Their corresponding AUCs in the simplified and comprehensive logistics models for classifying CN and MCI were 0.885, 0.842, and 0.800 and 0.945, 0.923, and 0.911. This finding underscored the importance of striving for minimal MAE in model development for enhanced predictive accuracy in subsequent cognitive decline tasks.

During longitudinal analysis, we observed an increase in the brain age gap derived from BVGN in CN-MCI or CN-AD progression group within 2 years after baseline. This increase was not observed in either SFCN or ResNet models. This group of participants classified as "CN" might be some individuals at high risk who have already experienced early pathological changes related to dementia yet remain classified as "CN" due to the absence of noticeable cognitive impairments. This finding supported BVGN as a sensitive marker for identifying participants at high risk who, despite being classified as "CN," were likely to progress to MCI in a few years. Existing scientific research suggests that MCI can be reversible to a certain extent, whereas AD, which is associated with significant cognitive degeneration, is challenging to reverse once it has progressed [67-69]. Therefore, early identification of these individuals at high risk for MCI is of great significance for better patient prognosis.

Multiple Cox proportional hazard models and Kaplan-Meier curves revealed a clear association between a higher brain age gap and an increased risk of cognitive decline. Specifically, each 1-unit increase in the brain age gap was associated with a 55% higher risk of cognitive decline in the CN group and a 29% increased risk in the MCI group. This finding underscored the brain age gap derived from BVGN as a sensitive risk biomarker for cognitive decline. Notably, the brain age gap appeared more sensitive in the CN groups. This observation aligned with existing research, which indicated the ability of the brain age gap to detect subtle preclinical or early neurodegenerative changes in populations classified as CN [70,71].

In clinical settings, the BVGN-estimated brain age gap serves as a tool for detecting cognitive decline and assessing the efficacy of innovative therapeutic interventions. For example, in the United States, 2 antiamyloid monoclonal antibodies, lecanemab (brand name Leqembi) and aducanumab (brand name Aduhelm) [72,73], have been approved for the treatment of AD. Despite the potential therapeutic benefits, these interventions are not devoid of inherent risks. Patients require vigilant monitoring for potential side effects, such as amyloid-related imaging abnormalities and infusion reactions, particularly at the onset of treatment. Currently, imaging provides limited insight into a patient's therapeutic response. However, BVGN could theoretically offer a novel approach by capturing changes in brain age pre- and posttreatment with monoclonal antibodies. This could provide an objective measure of a patient's response to the medication, enhancing our ability to assess the efficacy of these treatments.

Limitations and Future Directions

The limitation of BVGN lies in its inability to evaluate the performance and interpretability analysis results on larger datasets. In addition, the use of 3D deformable convolutional kernels in BVGN leads to increased computational costs during the training process when compared to other DL models. Our proposed DL-based brain aging framework is specifically designed for the early screening and prediction of neurodegenerative diseases. Epidemiological and neuroimaging studies indicate that structural alterations linked to neurodegenerative processes begin to manifest or accelerate after the age of 50 years [74]. To better capture brain age deviations closely associated with these pathological conditions, we selected individuals aged >45 years as our study population. This age threshold ensures the inclusion of individuals at the critical transition phase where neurodegeneration-related biomarkers become detectable. However, extending this

framework to the entire life span remains essential to comprehensively understand age-related neurodegenerative processes and identify potential early intervention strategies across all life stages.

Despite its limitations, BVGN remains a valuable tool in the study of brain aging, as it surpasses cognitive assessments, brain volume features, and susceptibility genes in classifying participants as CN and those with MCI, and has been demonstrated to be a risk factor for cognitive decline. This underscores the effectiveness of the brain age gap, estimated through individual MRI using BVGN, as an impactful neuroimaging biomarker. Furthermore, BVGN introduces graph theory analysis as a novel component of interpretability for the first time in brain age gap estimation. In the future, we will leverage the advantages of GNNs in brain analysis, and integrate them with other modalities of medical imaging to further enhance our framework and provide a more robust interpretability analysis based on graph theory. Future work will focus on 3 key directions to enhance the clinical utility and scientific depth of our framework. First, we will explore diverse graph convolutional feature aggregation mechanisms to optimize computational efficiency, enabling broader deployment in real-world clinical environments. Second, we aim to integrate multimodal MRI data by converting different imaging sequences (eg, T1-weighted, T2-weighted, and fluid attenuated inversion recovery) into graph-based representations within the BVGN framework. This multimodal integration will not only enhance the accuracy of brain aging quantification but also enable systematic investigation of cross-modal interactions underlying neurodegenerative processes. Finally, we plan to extend our framework across the entire life span to uncover age-specific aging patterns and their associations with disease progression.

Conclusions

This study proposed a novel DL framework, BVGN, for accurate brain age estimation. Our BVGN model used deformable convolutional kernel to capture brain complex morphology and graph theory to model brain topology, which was applicable to the biological nature of brain MRI. BVGN achieved a superior MAE of 2.39 years in the same testing set compared to other methods, with its attention region aligning with medical evidence of cognitive decline. The robust capacity of BVGN-derived brain age gap was validated through both cross-sectional and longitudinal analysis, which outperformed all conventional tools in aiding the diagnosis of MCI and was sensitive for identifying individuals at high risk for future MCI. The BVGN model can precisely evaluate brain aging and predict cognitive decline, offering substantial potential for improving early identification of neurodegenerative disorders and enhancing clinical applications.

Abstract

Background: Alzheimer disease (AD) is the leading type of dementia, demanding comprehensive understanding and intervention strategies. In the United States, where over 6 million people are impacted, the prevalence of AD and related dementias (AD/ADRD) presents a growing public health challenge. However, individuals living with AD/ADRD and their caregivers frequently express feelings of marginalization, describing interactions characterized by perceptions of patient infantilization and a lack of respect.

Objective: This study aimed to address 2 key research questions (RQs). For RQ1, we investigated the needs and concerns expressed by participants in online social communities focused on AD/ADRD, specifically on 2 platforms–Reddit's r/Alzheimers and ALZConnected. For RQ2, we examined the prevalence and distribution of social support corresponding to these needs and concerns, and the association between these needs and received support.

Methods: We collected 13,429 posts and comments from the r/Alzheimers subreddit spanning July 2014 to November 2023, and 90,113 posts and comments from ALZConnected between December 2020 (the community's earliest post) and November 2023. We conducted topic modeling using latent Dirichlet allocation (LDA), followed by labeling to identify the major topical themes of discussions. We used transfer learning classifiers to identify the occurrences of emotional support (ES) and informational support (IS) in the comments (or responses) in the discussions. We built regression models to examine how various topical themes are associated with the kinds of support received.

Results: Our analysis revealed a diverse range of topics reflecting community members' varying needs and concerns of individuals affected by AD/ADRD. These themes encapsulate the primary discussions within the online communities: memory care, nursing and caregiving, gratitude and acknowledgment, and legal and financial considerations. Our findings indicated a higher prevalence of IS compared to ES. Regression models revealed that ES primarily occurs in posts relating to nursing and caring, and IS primarily occurs in posts concerning medical conditions and diagnosis, legal and financial, and caregiving at home.

Conclusions: This study reveals that online communities dedicated to AD/ADRD support engage in discussions on a wide range of topics, such as memory care, nursing, caregiving, and legal and financial challenges. The findings shed light on the key pain points and concerns faced by individuals managing AD/ADRD in their households, revealing how they leverage online platforms for guidance and support. These insights underscore the need for targeted institutional and social interventions to address the specific needs of AD/ADRD patients, caregivers, and other family members.

Introduction

Alzheimer disease and related dementias (AD/ADRD) consist of neurodegenerative conditions characterized by cognitive impairment, memory loss, and executive function decline [1]. Over 6 million individuals in the United States grapple with the challenges imposed by AD/ADRD [2], signaling a substantial and escalating public health concern, and underscoring the urgent need for comprehensive understanding and intervention. However, despite the existence of available resources, the long-term services and support for people with AD/ADRD exhibit inconsistencies within the existing health care system [3,4]. People with AD/ADRD and their caregivers often perceive interactions with others as reflective of patient infantilization and a lack of sensitivity and respect [5]. They frequently encounter added challenges, encompassing mental health issues, social exclusion, and instances of discrimination [6,7]. In fact, if caregivers' concerns are overlooked, it may accelerate cognitive decline in individuals with AD/ADRD [8].

As technology gets more integrated into our lives and society, previous research has also noted the use of technology by AD/ADRD individuals and their caregivers [9]. Research highlights the significance of acknowledging and addressing the technology requirements and acceptance within AD/ADRD care [10]. However, more emphasis is placed on incorporating technology into AD/ADRD care, with the objective of improving the user experience to assist both patients and caregivers in managing daily life and monitoring their health status on a regular basis. A significant concern among AD/ADRD caregivers, however, remains the limited availability of adequate support systems at both institutional and social levels [11,12]. With the ubiquity of the internet, more individuals are turning to online spaces to seek information, discuss challenges, and share personal experiences. In particular, online communities are spaces that enhance a sense of belonging by connecting individuals with similar experiences. These online communities enable individuals to candidly self-disclose their concerns and seek support from others [13-20]. Previous work also noted how these online platforms could play a role in shaping the experiences of those living with progressive AD/ADRD [21-23]. These online support communities are very much in line with the social support behavioral theory (SSBC) that identifies the interactions intended to provide social support toward helping individuals cope with stress, enhance well-being, and foster positive relationships [24]. Nonetheless, social expectations and requirements in these online communities are largely unknown. Such knowledge would not only enhance our understanding of how the needs and concerns of AD/ADRD individuals and caregivers evolve over time but also help inform the design of targeted online interventions to address these needs.

This study aims to explore the needs and concerns of members within online communities on AD/ADRD, as well as the social support they actively provide and seek. To avoid any biases embedded within specific communities, we examined 2 distinct online communities—r/Alzheimers on Reddit and AlzConnected—dedicated discussion forums for AD/ADRD. Our study is guided by the following research questions (RQs): (1) RQ1: What are the needs and concerns people discuss in online AD/ADRD communities? (2) RQ2: What is the prevalence and distribution of social support across various needs and concerns, and how are different types of needs associated with the types of support received?

Methods

Data

We sourced our data from 2 distinct online AD/ADRD communities—r/Alzheimers on Reddit and AlzConnected, which we describe below:

Reddit

Reddit is a widely used semianonymous online platform that houses a network of over 52 million active users and 100 thousand active online communities. These communities are called "subreddits,"—each offering demographic, topical, or interest-specific discussion boards. The semianonymity of Reddit is known to enable candid self-disclosure and seek social support on stigmatized and sensitive topics [13,25,26], including discussions related to AD/ADRD [22,23,27].

We used Reddit's search feature to look up subreddits related to AD/ADRD, and 2 of the largest subreddits returned were r/AlzheimersGroup (over 117 thousand members) and r/Alzheimers (over 13 thousand members). We then conducted sanity checks to understand the content of these subreddits. These investigations revealed that r/AlzheimersGroup was a community centered on humor and sarcasm, where people predominantly pretended to have forgetfulness and shared memes and cartoon references to Garfield [28]. r/AlzheimersGroup also self-describes that "Serious discussion belongs in r/Alzheimers," Therefore, we omitted r/AlzheimersGroup from our ensuing analyses. The r/Alzheimers subreddit consisted of discussions where people shared troubles and provided social support on AD/ADRD. We collected all the posts and comments data from this subreddit—1000 posts and 12,429 comments between July 2014 and November 2023.

AlzConnected

AlzConnected is another freely accessible website (alzconnected.org) consisting of discussion boards dedicated to AD/ADRD patients and their caregivers. Although a more recent online community, it has already grown a significant user base and is supported by the Alzheimer Association (alz.org). Here, community members express AD/ADRD-related concerns and provide and seek support from one another. This community has multiple thematic discussion boards—(1) living with AD/ADRD, further broken down into "I am living with Alzheimer or other dementia and I am living with younger-onset Alzheimer," and (2) Supporting someone living with AD/ADRD, further broken down into, "I am a caregiver (general topics), caring for a spouse or partner, caring for a parent, caring long distance, and supporting those who have lost someone."

We adopted web scraping approaches to collect the entire data from ALZConnected amounting to 10,328 posts and 79,785 comments from the community between December 2020 (earliest post in the community) and November 2023.

Table 1 summarizes our dataset from the 2 online communities.

Table 1. Summary of dataset from online communities catering to discussions on AD/ADRD[a].

Community	Number of posts	Number of comments
r/Alzheimers	1000	12,429
ALZConnected	10,328	79,785

[a]AD/ADRD: Alzheimer disease and related dementias.

Analyzing the Needs and Concerns

Toward answering RQ1, we conducted unsupervised topic modeling followed by human annotation to obtain the needs and concerns expressed by members of AD/ADRD online communities.

Topic Modeling and Thematic Analysis

We started by examining the content of posts and comments in r/Alzheimers and AlzConnected to gain insights into the prevalent needs and concerns discussed within AD/ADRD online communities.

Building a Topic Model

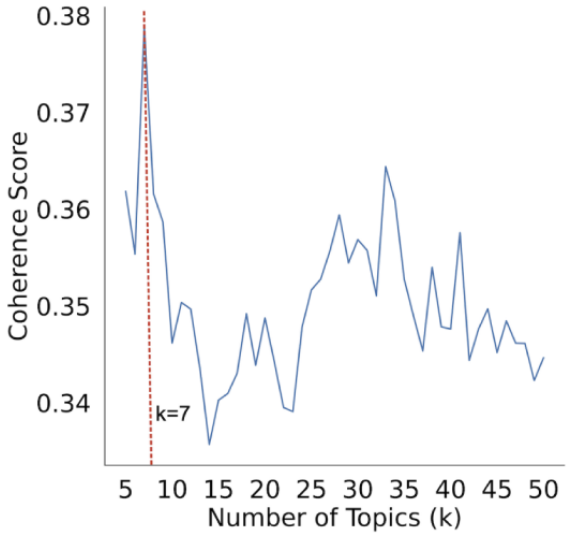
Topic modeling techniques have been adopted to analyze and identify key themes within social media discourse [29-32] including AD/ADRD-related discussions [22,23]. We built topic models on our entire dataset (posts and comments) by using latent Dirichlet allocation (LDA) [33], an unsupervised machine learning algorithm widely used for analyzing corpora. LDA generates latent topic distributions, making it a valuable tool for analyzing large, unlabeled document collections and their clustering into distinct groups based on common themes. LDA has been heavily leveraged in previous work on social media language analysis [29,30]. After tokenization, stop word removal, and adding n-grams (n=2,3), we created bag-of-words representations of the dataset.

Determining the Optimal Number of Topics

Given that LDA does not automatically determine the optimal number of topics, we adopted a semiautomated approach, motivated by previous work [22,30,31]. For this, we first used the coherence score as a metric to assess the model fit, varying the number of topics. The coherence score evaluates the tendency of words within a topic to co-occur and correlates well with topic modeling quality [34]. Then, we hand-selected a few topic models that occurred in the zone of highest coherence scores. Two coauthors manually evaluated the quality of these different topic models in terms of assessing the between-topic heterogeneity and within-topic homogeneity of words to narrow down the best topic model for our ensuing analyses.

We computed the coherence score for our 3 preprocessed corpora, varying the number of topics (k) from 5 to 50 (refer to Figure 1). We found the highest coherence at k=7. Consequently, we manually evaluated the quality of the topic modeling for k=5, k=7, and k=10.

Figure 1. Coherence values over varying number of topics in the LDA (latent Dirichlet allocation) topic model.



Labeling the Topics

The above steps yielded topical clusters, each of which contained clusters of keywords. We adopted a thematic analysis approach to label each topical cluster in a meaningful and interpretable way. The thematic analysis was conducted by 2 authors, familiar with social media analysis and AD/ADRD literature. They adopted an inductive coding approach to first independently code the topics based on the cluster of keywords, referencing sample posts corresponding to each topic. Then,

the authors engaged in collaborative discussions, comparing their codes, and gradually converging on cohesive thematic labels. This meticulous process ensured a nuanced and comprehensive analysis of the data. We found that the topic modeling with k=7 yielded the best results in terms of coherency within topics and boundaries between topics.

Classifying Support and Examining Supportive Expressions

Toward answering RQ2, we analyzed the responses within the online communities to examine the nature and forms of social support provided. This section details our methodology for categorizing these responses into distinct subcategories and contrasts the patterns of support provision within the Alzheimer community against those observed in a broader user demographic.

Classifying Support Expressions

Overview

The role of social support is essential in assisting individuals in managing psychological distress and various life adversities [35]. The emergence of social media platforms and virtual communities has led to the digital transposition of traditional social support mechanisms [13,36]. Specifically, online forums such as Reddit have increasingly mirrored the characteristics of virtual support groups, providing a platform for communal interaction and aid. The SSBC schema [37] offers a structured approach for classifying various types of support. Within this framework, informational support (IS) and emotional support (ES) emerge as 2 pivotal categories. Notably, these forms of support have garnered significant theoretical and empirical interest within social computing, as documented in various studies [20,38-43]. ES encompasses actions that provide encouragement, empathy, or care, whereas IS consists of assistance involving advice, information, or knowledge [37]. These 2 forms of support are particularly dominant in online interactions, as they can be effectively conveyed through text, making them well-suited for digital environments where individuals seek both guidance and emotional reassurance.

We categorized support offered in comments into ES and IS across both Reddit and ALZConnected datasets. To achieve this, we used a transfer learning methodology, a process wherein a machine learning classifier is developed by transferring insights from one labeled dataset to another unlabeled dataset with similar characteristics [44]. Specifically, we used a labeled Reddit dataset, previously expert-annotated with ES and IS labels on 396 comments collected from 55 mental health-related subreddits on Reddit [40]. This served as the seed dataset to train our classifiers. In addition, we manually labeled the ES and IS of 100 comments from AlzConnected and 100 comments from r/Alzheimers datasets and added these to the training datasets of the support classifiers. Our initial classifier was a supervised learning classifier for ES and IS, using n-grams (with n=1,2) as features in alignment with methodologies outlined in previous research [39-41]. We adopted a k-fold cross-validation (k=10) approach for evaluating our models.

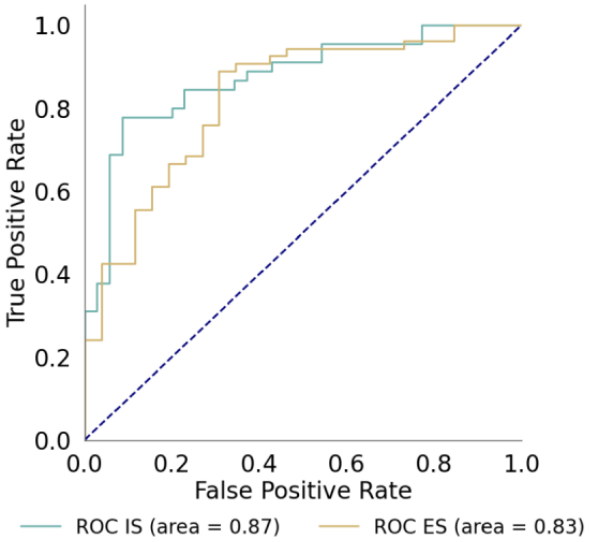
We used a range of classification algorithms, including naive Bayes, logistic regression, support vector machine (SVM), random forest, and neural network. Among these, the Linear SVM model demonstrated the best performance, achieving a mean area under the curve of 0.84 for ES and 0.87 for IS (refer to Table 2). Figure 2 provides the receiver-operating-characteristic area-under-curve plot for the classifiers used in identifying support types. We use the linear SVM model for our ensuing analyses. For the ES classifier, the predominant features include: “good,” “sorry,” “right,” “dont,” “going,” “people,” “get,” “life,” “im,” and “feel.” In contrast, the IS classifier highlighted features such as: “help,” “might,” “thing,” “go,” “think,” “try,” “get,” “see,” “probably,” and “doesnt.”

Table 2. Performance metrics of machine learning models of social support classifiers.

Model	Emotional support			Informational support		
	Precision	Recall	Area under the curve	Precision	Recall	Area under the curve
Naive Bayes	0.70	0.58	0.80	0.67	0.66	0.76
Logistic regression	0.73	0.69	0.76	0.75	0.76	0.81
Support vector machine	0.74	0.74	0.80	0.73	0.73	0.83
Random forest	0.68	0.54	0.75	0.67	0.66	0.75
Neural network	0.71	0.68	0.79	0.70	0.65	0.77
After adding augmented labeled data from AD/ADRD[a] communities						
Logistic regression	0.74	0.72	0.77	0.74	0.76	0.80
Support vector machine	0.75	0.76	0.83	0.77	0.78	0.87

[a]AD/ADRD: Alzheimer disease and related dementias.

Figure 2. Receiver-operating-characteristic area-under-curve plot of the emotional and informational support classifiers. ES: emotional support; IS: informational support.



To validate the applicability and relevance of the model, we applied transfer-based learning to the classifiers within our dataset. We conducted a manual validation on a randomly selected subset of 100 comments. This process involved 2 independent annotators classifying each reply for ES and IS. Discrepancies in annotations were resolved through the intervention of a third adjudicator. Further, we compared these manual annotations with the predictions made by the machine learning classifiers. The comparison resulted in an F_1-score of 0.76 for ES, characterized by a precision of 0.74 and accuracy of 0.76, and an F_1-score of 0.77 for IS, precision of 0.77, and accuracy of 0.77, which is an increase from the initial classifier. Given these results, we consider the classifier's performance satisfactory for further analysis. It is important to note that in our classification, ES and IS are not mutually exclusive categories; a single comment may be either both, or neither forms of support. Table 3 shows some example comments in our dataset with labels of ES and IS.

Table 3. Example comments and support labels with emotional and informational support (each comment may be either both, or neither forms of support).

Example comment	Emotional support	Informational support
Just as a note, when my Uncle passed away, I still remember him as the strong figure versus any thoughts of his Alzheimer. Man, my condolences and it's more of a blessing for him and your family for the rapid decline.	✓	x
Lumbar punctures are great and the data is very solid in the ability to diagnose AD[a]. However, LPs can be lengthy (and therefore expensive) procedures and are generally viewed as invasive by the general population. A blood test such as this would highly impact our ability to screen people more quickly for drug trials :)	x	✓
Sometimes you just have to chuckle. I just received yet another call from my person with dementia telling me they needed someone to fix their phone. The same phone they made a call with. And we live over three hours away.	✓	✓
This feels like a lecture, which is not what I need right now. No reply is necessary.	x	x

[a]AD: Alzheimer disease.

Associating the Relationship Between Topics of Concern and Support Received

To assess the support associated with each topic, we used linear regression models to predict the likelihood of receiving different types of support. We built separate models for ES and IS. Each model was designed to predict the probability of receiving a specific type of support based on the topic being discussed. So, we used the topics in the posts' content as independent variables, and the received support as the dependent variable. Essentially, by examining ordinary least squares regression models, we aimed to understand how different topics are associated with the probability of receiving a type of support. This approach allowed us to quantify the relationship between topics and the support they generate, providing valuable insights into the dynamics of support within the community.

Ethical Considerations

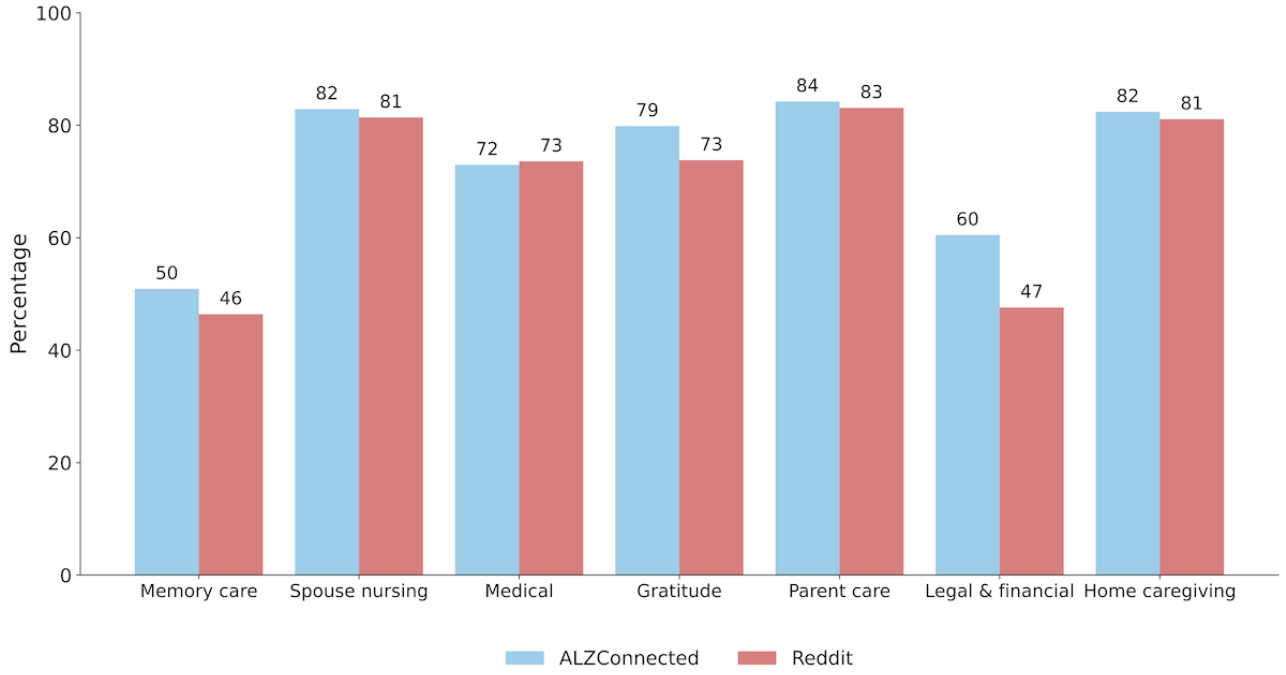
This project used publicly available data from online communities, and did not involve any direct interaction with human subject participants. Therefore, this research did not require ethics board approval. However, we are committed to the ethics of the research and followed practices to secure the privacy of the individuals in our dataset. We recognize the sensitivities of our study in terms of revealing the identities of the individuals, and thus deidentified all collected data. This paper only presents paraphrased quotes to reduce traceability while providing necessary context.

Results

RQ1: Themes of Needs and Concerns in Online Communities

We now describe the findings from our topic modeling followed by thematic analyses. Table 4 shows the 7 topics and relevant thematic analysis derived through LDA topic modeling. These topics serve as the primary themes, summarizing the needs and concerns of members within the AD/ADRD online communities. Figure 3 shows the overall distribution of topical occurrences in the 2 datasets, showing that the topics appear similarly on both platforms.

Figure 3. Distribution of topics as a percentage of posts on r/Alzheimers and ALZConnected.



We describe these topical themes as: First, the topics reveal diversity in community members' needs based on relationships with patients experiencing AD/ADRD. We find that several topics, such as memory care support, nursing for a spouse, caring for patients, and caregiving at home are linked to informal caregivers, such as patients' spouses, children, and close family members, along with professional caregivers providing in-home assistance. This reveals that community members with different roles may encounter various concerns and needs.

We find a substantial amount of content focusing on memory care, particularly about early onset patients with AD/ADRD, with words like "memory care" and "assisted living facility" (Topic 1, 5, and 7). In general, memory loss is a common symptom of AD/ADRD [45]. Memory care is frequently observed as dedicated and free-standing memory care living spaces within assisted living communities or integrated into life care communities [46]. Individuals also discuss how to choose an assisted living home with a memory care unit for patients and issues encountered in memory care units. One individual posted in r/Alzheimers to seek suggestions:

> *Hello everyone, could we discuss the options for finding an assisted living facility with memory care? My wife has Early-onset Alzheimer, and she is 57.*

We also find members who are early-stage patients looking for advice to plan the future and are gaining insight into experience within the memory care unit. An early onset patient posted:

> *Next week, I plan to visit an assisted living home with a memory care unit. My doctor has advised me to begin preparing for my future no matter what I can.*

AD/ADRD leads to a progressive decline in the capacity to perform daily living activities [47]. We found extensive discussions related to nursing and care, with the majority originating from caregivers and patients' family members (Topic 2, 5, and 7). Some content involves sharing AD/ADRD-related books and information. Within these posts, members recommend or summarize useful knowledge in a comprehensive way, and they are enthusiastic about discussing it with others. For instance, one caregiver posted their thoughts on the recommended book, "I recommend giving this book a read. Feel free to share your thoughts with me if you explore it." Also, a significant amount of content revolves around the sharing of experiences and challenges. Some members shared experiences when they felt happy in a largely challenging journey of caregiving for their family members with Alzheimer. For instance, a member wrote;

> *He didn't know who I was, but he got very excited that I helped him make handprint art to take to his 2 daughters and 3 granddaughters. He may not recognize me, but things like this show me the love is still there. Feeling blessed.*

Table 4. Topic themes with representative keywords and example posts.

	Topic keywords	Example post
Topic 1: Memory care and assisted living	care, facility, memory, memory care, wife, home, living, darling, dear darling, dear, darling wife, dear darling wife, assisted, assisted living, nursing, staff, significant, living facility, assisted living facility, and room	*Is there anyone willing to share their experience of placing their loved one into a memory care unit?*
Topic 2: Nursing for spouse	significant, director, director nursing, nursing, just, husband, know, dear, time, like, day, good, dear husband, think, sorry, hope, things, did, going, and got	*If I get COVID, would my wife have to be placed in a nursing home? What actions should I do in such a situation?*
Topic 3: Medical condition and diagnosis	years, alzheimer, disease, husband, ago, alzheimer disease, significant, diagnosed, year, just, stage, diagnosis, early, time, years agodementia, months, know, care, and memory	*What support or resources are available for people in the MCI stage who may be unaware of it? I'm asking because my younger sister has been diagnosed with early-onset Alzheimer.*
Topic 4: Acknowledgment and gratitude	significant, thank, dementia, good, hospice, help, loved, support, meds, know, doctor, thanks, best, sorry, disease, helpful, forum, new, and information	*I'd like to thank those who recommended getting an electronic pet for a loved one with Alzheimer. I bought one for my grandma. She absolutely loves it!*
Topic 5: Caring for parents	mom, just, significant, like, time, help, know, mother, things, home, going, day, really, think, doesn, house, need, feel, dad, and tell	*I am an only daughter and I have taken on the responsibility of caring for my mother who received a diagnosis of Alzheimer and vascular dementia for 2 years.*
Topic 6: Legal and financial matters	attorney, husband, dear husband, care, dear, power, power of attorney, need, law, Medicaid, significant, help, elder law, money, long, state, law attorney, elder law attorney, and pay	*My husband was just diagnosed with younger onset Alzheimer. We are in search of an elder care lawyer in the Naperville or surrounding area to assist us with financial planning.*
Topic 7: Caregiving at home	dementia, dad, person, mom, family, care, make, person dementia, people, like, time, life, significant, need, help, things, think, caregiver, nursing, and home	*I have taken on the role of a "mom" for my mom; she relies on me for all her necessities, and needs, or just for chat. I'm only 20. I wish to live my own life. However, guilt keeps me at home, and I'm concerned that moving out might intensify it. Please tell me what to do.*

Some members place individuals with AD/ADRD in skilled nursing homes, while others serve as caregivers at home, leading to varying sets of issues. Some common concerns in nursing homes are the occurrence of living issues faced by patients residing in facilities, inappropriate interactions among patients, and instances where patients get expelled from the nursing facility and sent back home. We also found an instance where the patient required hearing aids, but the care provided by nursing facilities was not satisfactory. Consequently, a member posted:

> *Regrettably, there are many instances where the thing is either not carried out properly or not done at all. During my visits, I've observed that there are times when she has the hearing aids in, but they are non-functional.*

In-home caregivers share the fatigue and strain arising from family relationships, as well as the distress of balancing their own lives with caregiving responsibilities. One member posted about being the sole caregiver without other siblings' assistance. They wrote, seeking advice:

> *I have a full-time job and my own family. I find myself in need of a break, and I'm hesitant to consider placing her in a nursing home. I'm concerned that the unfamiliar environment might exacerbate her dementia.*

Community members also expressed gratitude, encouragement, and acknowledgment. Members within online AD/ADRD communities can communicate about specific health-related topics, often finding online support a welcoming and comfortable venue for discussing sensitive issues [48]. Part of this involves mutual support and appreciation among community members, often occurring when someone shares their story or receives help and support from other members. Notably, posts and comments of this nature are typically longer and more detailed, prompting many individuals to express gratitude at the end, thanking others for taking the time to read their detailed posts. For instance, a member on r/Alzheimers, after venting about the challenges of being a caregiver, expressed:

> *Thanks for the opportunity to share my thoughts right here. I'll read your many posts before mine and offer my opinions and encouragement.*

Individuals also express gratitude not only directed toward other community members but also between caregivers and patients. Following the death of a loved one, members grieved recalling their shared past, the challenges of life, and caregiving after the diagnosis, such as, "I am thankful that his suffering finally ends. He is with my mom now in heaven." Furthermore, when reminiscing about early shared experiences, members often express gratitude and love for the individuals with AD/ADRD, such as, "Reflecting on the cherished moments we shared brings me joy, and I am grateful for the knowledge he imparted to me."

Finally, we also observed concerns related to legal and financial matters. Many of these concerns come from family members of individuals with AD/ADRD. With the progression of AD/ADRD, patients require increasing levels of care and assistance, leading to legal issues such as establishing guardianship or power of attorney (POA). Besides, financial concerns are a widely discussed topic in the communities, covering aspects such as handling patient's assets, as well as the costs associated with caregiving and treatment. For example, a member posted to seek advice from the community:

> *Her funds is running down. We still hope that we can place her in a nursing facility after her funds are used up by the memory care (MC) facility. I need to know if there is any assistance available to support her continued stay in MC.*

RQ2: Social Support in Online AD/ADRD Communities

Distribution of ES and IS

We first examined how ES and IS are distributed in our datasets. We observe similar trends in the distribution of support in both communities—on average, IS is 6% more prevalent in r/Alzheimers and 10% more prevalent in AlzConnected than ES in respective communities. Figure 4 shows the overall distribution of ES and IS in the 2 datasets.

As previously noted, we obtained the topics on the posts and the support received in the comments to the posts. We break this down into the topics of the posts, and Figure 5 shows the distribution of ES and IS in the comments to the posts of varying topics in the 2 datasets.

Both Figures 4 and 5 also show independent sample *t* tests between the occurrences of ES and IS. For each topical theme, we note statistically significant differences in occurrences of the 2 types of support.

Figure 4. Distribution of ES and IS to posts on r/Alzheimers and ALZConnected.

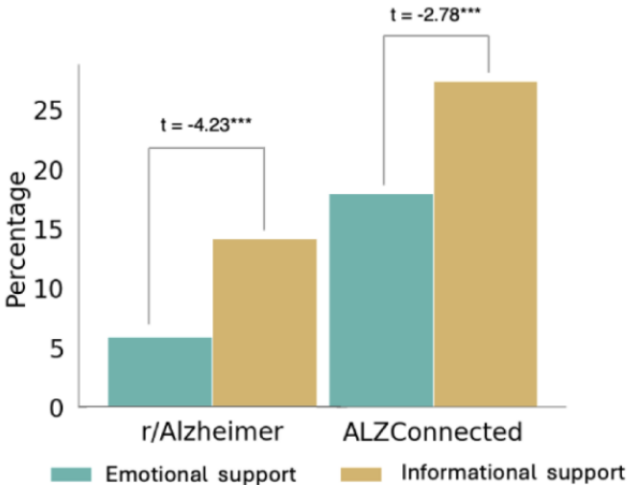


Figure 5. Distribution of emotional and IS in comments to posts with varying topics on (A) r/Alzheimers and (B) ALZConnected.

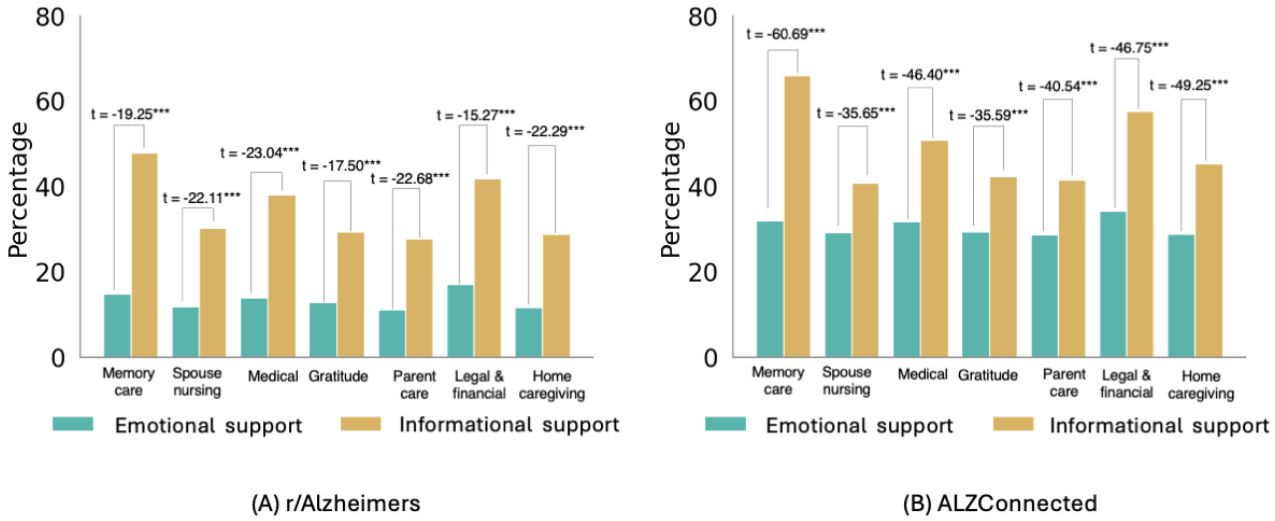

Regression Models for Predicting Support

To further analyze how support was provided corresponding to each topic, we built regression models. For each of our datasets (r/Alzheimers and AlzConnected), we built 2 models, 1 with IS as the dependent variable and another with ES as the dependent variable. Both of the models had all the topic occurrences as independent variables. Essentially, these models examined the likelihood of receiving ES and IS for each topic.

Table 5 shows the coefficients of the independent variables (topics) for ES and IS across the 2 datasets of r/Alzheimers and AlzConnected. All of these models show a significant goodness-of-fit (R^2). These coefficients signal the likelihood of receiving the respective support in the community. We describe our observations below.

Table 5. Coefficients of linear regression models with the topics of posts as independent variables and support (emotional and informational) responses as dependent variables.

Independent variables	Dependent variables, coefficient			
	Emotional support		Informational support	
	r/Alzheimers	ALZConnected	r/Alzheimers	ALZConnected
Intercept	–3.00E-04	3.00E-04	–0.008[a]	0.027[a]
Memory care	0.014	0.012[b]	0.191[a]	0.258[a]
Nursing for spouse	0.016[b]	0.079[a]	0.066[a]	0.013[a]
Medical condition	0.048[a]	0.067[a]	0.182[a]	0.164[a]
Acknowledgment and gratitude	0.041[a]	0.058[a]	0.038[a]	0.034[a]
Caring for parents	0.014[c]	0.089[a]	0.031[a]	0.048[a]
Legal and financial	0.056[a]	0.075[a]	0.088[a]	0.13[a]
Caregiving at home	0.035[a]	0.038[a]	0.055[a]	0.129[a]
R^2	0.777[a]	0.144[a]	0.260[a]	0.294[a]

[a]$P<.001$.
[b]$P<.01$.
[c]$P<.05$.

ES Posts and Topics

For both r/Alzheimers and AlzConnected, we find that topics relating to nursing and caring, such as “Nursing for Spouse,” “Caring for Parents,” and “Caregiving at Home” show high positive coefficients with statistical significance, that is, posts with these topics are likely to receive ES. Further, topics that are seemingly about informational content, such as “Legal and Financial” and “Medical Conditions and Diagnosis” also receive ES.

For instance, an individual self-disclosed their stress about the fact that their mom changed a POA and was in complete denial of her symptoms:

> *I believe my mom just changed her POA and took me completely off. Her husband is covering for her and is in complete denial about her diagnosis. [..] She is clearly paranoid and delusional. I will consult with an elder care attorney soon. Any other advice? She blames me for her driver's license getting taken away. I am the only family member in the state. Neither she nor her husband are capable of overseeing her medical care. [..] I am very stressed about this situation. Thank you for any thoughts.*

IS Posts and Topics

For both r/Alzheimers and AlzConnected, posts relating to "Memory Care Support," "Medical Condition and Diagnosis," "Legal and Financial," and "Caregiving at Home" show high positive coefficients with statistical significance. Interestingly, posts relating to "Nursing for Spouse" and "Caring for Parents," which occurred high for ES, are also likely to receive IS. For instance, an individual who described their situation, also asked, "How are folks keeping their careers while helping to care for a parent?"

Discussion

Principal Results

This study sheds light on the complex needs of individuals dealing with AD/ADRD as patients, caregivers, family members, and loved ones. Our analyses revealed seven primary topical themes—(1) memory care and assisted living, (2) nursing for a spouse, (3) medical condition and diagnosis, (4) acknowledgment and gratitude, (5) caring for parents, (6) legal and financial aspects, and (7) caregiving at home. We found that IS was more prevalently provided than ES across both platforms. In particular, ES was predominantly found in posts related to nursing and caregiving, suggesting that caregivers turn to these communities to cope with the emotional burdens associated with their roles. In addition, IS was more frequently associated with concerns about medical conditions, legal and financial issues, and caregiving at home, indicating a demand for practical advice and resources in managing the complexities of AD/ADRD.

These findings highlight the critical role that online communities play in supplementing the support networks of AD/ADRD caregivers and family members. Many caregivers face challenges in accessing adequate in-person support due to stigma, social isolation, or lack of resources, making online platforms an important alternative for both emotional validation and practical advice—as also noted in the case of other stigmatized mental health [13,38-41,49] and health conditions (such as cancer [17,19,20] and HIV [50]). The predominance of IS suggests that individuals seek concrete advice to manage the daily realities of caregiving, including navigating health care systems, legal documentation, and financial planning. This aligns with previous research indicating that caregivers often experience a steep learning curve when managing AD/ADRD, requiring access to timely and accurate information [51,52]. Furthermore, the need for ES around nursing and caregiving emphasizes the significant emotional and psychological toll on caregivers [53]. These findings underscore the importance of community support in mitigating mental health issues such as feelings of burnout, stress, and isolation—some of the major concerns experienced by AD/ADRD caregivers [54]. We also noted expressions of gratitude and acknowledgment within these communities, which may indicate a sense of belonging and solidarity among the members of online communities, especially among caregivers to help boost their resilience and sustain their caregiving roles over the long term. Therefore, fostering these online communities can be a low-cost and scalable way to address caregiver burnout, which is a critical issue given the growing aging population and the increasing prevalence of AD/ADRD.

Our study also bears important implications for health care practitioners, policy makers, and support organizations. First, online communities provide empirical insights into the plausible gaps in accessible resources for caregivers. For instance, institutional support from governmental policies, health care systems, and AD/ADRD care organizations can leverage online platforms to identify the needs. Further, these platforms can be used to disseminate accurate and specific information tailored to the needs of the caregivers, potentially reducing the burden on healthcare professionals and improving caregiver confidence in managing AD/ADRD-related challenges. In addition, these platforms can be integrated into existing health care support structures and information.

Health care systems and AD care organizations could leverage online platforms to disseminate accurate, easily digestible information tailored to the needs of caregivers, potentially reducing the burden on health care professionals and improving caregiver confidence in managing AD/ADRD-related challenges. In addition, these platforms could be integrated into existing health care support structures, allowing caregivers to receive timely advice from health care professionals, thus improving patient outcomes. From a policy perspective, there is a need to enhance public health initiatives that support caregivers, especially in terms of financial planning and legal guidance, which was one of the major topics of discussion.

Policy makers could consider developing targeted programs that address these specific needs, such as offering workshops on financial planning for families affected by AD/ADRD or increasing access to legal assistance. Moreover, expanding caregiver support programs, including respite care and mental health services, could alleviate the emotional burden as prevalently discussed in the online communities. For technology designers and developers, our study suggests opportunities to enhance digital tools aimed at supporting caregivers. In particular, with the increasing prevalence of using artificial intelligence (AI) in different sectors, platforms can also incorporate AI-driven recommendation systems to provide personalized resources based on each individual's specific question or concern. In addition, integrating mental health support tools, such as access to counseling services or peer support groups within these online communities, could further enhance the mental well-being of caregivers.

Limitations

Our study has limitations which also suggest interesting future research directions. Although adopting computational

approaches enabled our exploration of the depth and breadth of support dynamics across various topics, our findings are not necessarily generalizable to the broader population or other contexts beyond the online communities analyzed. As noted in Figure 3, although both communities follow the trend of having more IS posts than ES, the overall level of engagement across the 2 communities is not the same. In particular, our study is inherently limited by self-selection bias, as we only study individuals who actively chose to post and engage in these online communities. This means that our findings may disproportionately reflect the experiences of individuals who are more active on social media and are motivated and willing to share publicly on these platforms. In addition, this study does not capture the perspectives of passive users who browse forums for information without directly participating, which may exclude a significant portion of the online communities. Furthermore, digital inequity presents another challenge. Not all individuals have equal access to digital platforms, reliable internet, or the necessary skills to engage effectively online. This disparity can exclude voices from socioeconomically disadvantaged or digitally marginalized groups, leading to a biased understanding of support dynamics in online communities.

Accordingly, future research should explore strategies to mitigate these limitations by examining the representativeness of the user base and incorporating voices from underrepresented groups. For example, comparing findings from active participants with those of passive users or supplementing online data with offline sources could provide a more comprehensive view of support mechanisms. In addition, understanding how users of online support communities differ from those who might use AI-driven tools for AD/ADRD management is critical. Exploring the overlap and divergence between these groups will help inform the design of inclusive and effective digital interventions. Finally, the emergence of generative AI and large language models has enabled the development of personalized assistants and chatbots [55,56]. It would be interesting to examine how these AI chatbots respond to people's queries on AD/ADRD and how effective they are compared to online communities.

Comparison With Previous Work

Previous research has highlighted the significant burden imposed by AD/ADRD on patients, caregivers, and health care systems [54,57,58]. These caregivers often face stigma due to societal misconceptions about caregiving, which can result in judgment and disapproval, further intensifying their feelings of isolation and stress [59,60]. The growing demand for caregiving support due to the neurodegenerative progression of AD/ADRD necessitates increased levels of care over time that by 2030, an additional 1.2 million direct care workers will be required in the United States to address the rising needs of this population, pointing to a substantial gap in the current AD/ADRD caregiving infrastructure [2]. Our findings offer empirical evidence on the specific needs and concerns of individuals affected by AD/ADRD as they seek and exchange support within online communities.

Prior research has also underscored the psychosocial burdens faced by AD/ADRD caregivers, including feelings of marginalization and neglect of well-being [60,61]. A total of 69% of caregivers experience moderate to severe levels of caregiving burden, with the severity of the patient's condition significantly impacting their stress levels [62]. Our study expands on this by underlining the specific concerns expressed in online communities and revealing that discussions frequently center on memory care, nursing, caregiving challenges, and legal and financial issues. This suggests that caregivers seek both practical advice as well as ES to manage the complexities of their roles.

A notable contribution of our research is its focus on the role of online platforms as a source of support for AD/ADRD caregivers. Previous studies have acknowledged the use of digital tools among caregivers [63] and highlighted a disconnect between the availability of digital support and the recognition of caregiving efforts within social circles [64]. Our findings on the major concerns and needs—as identified by topic modeling—also align with recent computational and qualitative analyses of Reddit and other online communities for AD/ADRD caregivers, which have identified similar themes, including ES-seeking, decision-making about care facilities, and management of behavioral symptoms [23,27]. Therefore, the integration of individuals with AD/ADRD and caregivers' needs into the development of health and wellbeing technologies is necessary for future design [9,64]. Our study contributes to the recent body of work on the role of technologies in supporting caregivers—Bhat et al [65] emphasized the crucial role of caregiver-focused technological supports, and Kim et al [66] highlighted the need for tailored support strategies caregivers need during different phases of challenging behavioral episodes, and Meyerhoff et al [67] stressed the importance of user-centered digital mental health tools that adapt to individual needs.

The high prevalence of IS identified in our study aligns with existing literature that suggests caregivers often turn to digital platforms to fill gaps in health care services, particularly due to inconsistent coordination of long-term care [4]. The distribution of ES and IS across topics highlights a nuanced understanding of how caregivers use online communities to address specific facets of the caregiving experience. Aligning with how previous work focused on the use of technology for caregiving support [3,4], our study revealed the unique dynamics of social media as a tool for fostering a sense of belonging, solidarity, and social support among AD/ADRD caregivers. These observations align with findings from studies by Rains et al [68] and Naslund et al [69], who noted that individuals often leverage online spaces to combat loneliness and build supportive relationships. Together, our study builds upon the foundation laid by the SSBC, which categorizes support into 5 types—informational, emotional, esteem, tangible, and social network support [24]. Although this study focused specifically on ES and IS, we observed overlaps with other forms of support as well.

Conclusions

This study reveals that online communities centered on AD/ADRD engage in extensive discussions on a diverse array of topics. These topics include memory care strategies, nursing and caregiving practices, as well as legal, financial, and emotional challenges associated with managing the disease. The findings highlight not only the primary concerns and pain points experienced by caregivers and families who manage AD/ADRD in their homes but also the critical role online platforms play in providing them with a sense of community, practical advice, and ES. By analyzing these discussions, the study identifies how individuals affected by AD/ADRD turn to online communities to share personal experiences, seek solutions to caregiving dilemmas, and obtain validation and reassurance from others who are navigating similar challenges. These online interactions can alleviate feelings of isolation, foster a collaborative environment for exchanging best practices, and serve as an essential resource for information and guidance. Our findings underscore the urgent need for targeted institutional and social interventions that address the nuanced and evolving needs of AD/ADRD patients, their caregivers, and their families. These interventions could include enhanced support services, caregiver education programs, and accessible mental health resources that are tailored to the specific challenges highlighted in these online discussions. By recognizing and addressing these needs, stakeholders can improve the quality of life for both patients and caregivers, ultimately contributing to a more supportive and inclusive environment for those affected by AD/ADRD.

Abstract

Background: During the COVID-19 pandemic, telemedicine services represented a widely implemented alternative to in-person doctor and therapist appointments. Consequently, rates of telemedicine use rapidly increased worldwide, also in Germany. Research regarding longitudinal determinants of telemedicine use is needed, particularly from nationally representative German samples, to improve understanding of the use behavior of major target groups such as middle-aged and older adults.

Objective: This study aimed to longitudinally investigate determinants of online health consultation use among middle-aged and older individuals during the COVID-19 pandemic in Germany.

Methods: Nationally representative longitudinal data of German middle-aged and older adults (≥46 years old) were taken from the German Ageing Survey (DEAS). Data from the Compact Survey (conducted between June and July 2020) and wave 7 (conducted between November 2020 and March 2021) of the DEAS were observed (pooled analytic sample N=5456). Having experienced consultations with doctors or therapists on online platforms served as the outcome measure. Associations with socioeconomic, health- and health behavior–related, psychological, and COVID-19–related determinants were tested using random effects logistic regressions.

Results: In our sample, 49% (2673/5456) of participants were female and the mean age of the participants was 67.8 (SD 9.4) years. Past experience with online health consultations was reported by 10.3% (561/5456) of the sample. Online health consultation use was associated with high education (OR 1.43, 95% CI 1.06 - 1.93; *P*=.02), poor self-rated health (OR 0.60, 95% CI 0.49 - 0.75; *P*<.001), and higher frequency of physical activity (reference: low frequency; medium frequency: OR 1.58, 95% CI 1.15 - 2.17; *P*=.005; high frequency: OR 1.73, 95% CI 1.09 - 2.76; *P*=.02). Moreover, greater levels of loneliness (OR 1.43, 95% CI 1.06 - 1.93; *P*=.04) and life satisfaction (OR 1.33, 95% CI 1.02 - 1.73; *P*=.04) as well as perceiving the COVID-19 crisis as a greater personal threat (OR 1.08, 95% CI 1.01 - 1.15; *P*=.02) were associated with having online health consultations during the COVID-19 pandemic.

Conclusions: Online health consultation use does not seem to be exclusively associated with the health of middle-aged and older patients. Study findings emphasize the longitudinal association of education and psychosocial factors as well as health factors with telemedicine use during the COVID-19 pandemic in Germany. This knowledge may help to improve and adapt services to this patient group, which could contribute to higher utilization rates in the future. Future studies are needed to verify these initial findings under postpandemic circumstances and across different countries.

KEYWORDS

telemedicine; digital health; remote consultation; health services for the aged; patient acceptance of health care; COVID-19

Introduction

Worldwide, health care systems are facing multiple challenges in the future related to the delivery of services (eg, access and continuity of care), human resources (eg, staff distribution and sufficiency), as well as leadership and governance (eg, strategic policies) [1]. In particular, the increasing prevalence of noncommunicable diseases, disability, and multimorbidity in connection with population aging calls for new solutions in health care (eg, [2]). According to predictions of the World Health Organization (WHO) [3], the number of global deaths due to noncommunicable diseases may increase from 36 million (2008) up to 52 million in 2030.

Promising methods for the delivery of health care in the future include digital solutions such as telemedicine [4]. The WHO Global Observatory for eHealth [5] defines telemedicine as

follows: (1) its purpose is to provide clinical support, (2) it is intended to overcome geographical barriers, connecting users who are not in the same physical location, (3) it involves the use of various types of information and communication technology, and (4) its goal is to improve health outcomes. Major strengths of telemedicine include improved access to care and information, time and cost savings, as well as convenience and flexibility [6,7]. Multiple studies evaluated the effectiveness and cost-effectiveness of telemedicine services. The services seem to be effective and can produce at least comparable effects to in-person services [8,9]. Moreover, the current literature suggests that telemedicine can be a cost-effective service delivery method [8-11]. In addition, providers as well as patients seem to be highly satisfied with the services [8,9,12].

Despite its benefits, telemedicine implementations were only limited and remained at a low level up until the occurrence of the COVID-19 pandemic [13-15]. To prevent further spreading of the virus and relieve the health care system, major changes in the delivery of health care services had to be made in response to the pandemic [15]. Telemedicine represented a valuable tool to avoid personal contact during health consultations. Consequently, the global telemedicine utilization increased tremendously [13-16]. For example, Koonin et al [17] reported a 154% increase in telehealth visits in the United States in March 2020 compared with March 2019. Also in Germany, which is the focus of our study, the proportion of contract physicians and psychotherapists who offered and billed for telemedicine services increased from 6.1% (2019) to 24.6% (2021) [18]. Particularly among the psychotherapeutic care sector, utilization rates were high in Germany [18]. Since many nonessential in-person medical appointments were canceled or postponed due to the pandemic in Germany [19,20], remote health consultations represented a valuable alternative format to assure the continuity of care in spite of pandemic circumstances. This digital transformation of the German health care system was facilitated by the introduction of laws including the Digital Health Care Act [21] and the Digital Health Application Ordinance [22], which supported the prescription of health care apps, provision of video consultations, and integration of digital provider networks. In the German health care system, health insurance is compulsory with about 90% of the population having statutory and 10% having private health insurance [23]. The implementation of the new laws enabled the coverage of digital health care by statutory insurances, ensuring that telemedicine users incur no additional costs.

Considering population aging, telemedicine is particularly relevant for the older patient groups. Telemedicine was found to be effective in older adults [24-26]. For instance, van den Berg et al [25] reviewed 68 interventional telemedical studies with a controlled design examining older adults and found that none of the included studies reported better outcomes for the control group (eg, randomized or matched control groups that received usual in-person care). Moreover, older adults seem to accept and are satisfied with the services [24,27]. Taking older adults' higher need for health care and probable mobility restrictions into account, older adults can particularly benefit from the remote format. Nevertheless, older patients use telemedicine services less often than younger age groups and report multiple barriers to using the services (eg, [28-32]). For example, Wilson et al [30] identified factors such as physical difficulties (eg, visual or hearing impairments), privacy concerns, lack of experience, training, or support as barriers to the use of eHealth by older adults.

In Germany, older patients also used telemedicine services less frequently than younger patients did during the pandemic [18,33-36]. However, increasing telemedicine use in older age groups can be helpful for the future delivery of health care services in Germany to deal with problems such as physician shortages or increased demand for (long-term) care caused by demographic change [37]. Therefore, it is important to examine factors that are associated with telemedicine use in older adults to increase utilization in Germany. Previous international reviews highlighted older patients' characteristics associated with higher telemedicine use [38-40]. This included younger age, higher education, higher self-efficacy, greater experience or skills in using electronic devices, access to technology and internet, greater social support or influence, higher (health-related) motivation, and greater openness to experience as well as fewer privacy concerns and less severe health impairments.

So far, only limited evidence from Germany regarding the determinants of telemedicine use during the pandemic exists. The previous studies stressed the association of socioeconomic (male or female sex, younger age, high or low education, social status, living in an urban area, and having children under 18 years), psychosocial (loneliness, digital literacy), health (mental or physical health problems), and COVID-19–related factors (higher perceived severity of COVID-19 infection, having had COVID-19 infection, subjective COVID-19–related challenges, COVID-19–related cognitive preoccupation, anxiety, and worries) with telemedicine use [18,34-36,41-43]. Very few studies exclusively looked at middle-aged and older adults in Germany during the pandemic. These studies highlighted the positive association of telemedicine use with education, living with a partner in the same household, mental (ie, anxiety and depression) or physical health problems, loneliness, life satisfaction as well as forgoing medical treatment due to the fear of being infected by the coronavirus [44,45]. A large variety of determinants was observed in the existing studies and more research is needed to further explore and verify the findings.

In addition to the small number of studies that observe determinants of telemedicine use in middle-aged and older adults during the pandemic in Germany, hardly any studies examined the determinants longitudinally. Solely, von der Groeben et al [35] used a quasi-longitudinal design (ie, they observed cross-sectional data from 3 different time points) to detect determinants of patient use and attitude toward using video and telephone conferences in a population-representative sample of adults (18 - 69 y) affected by depression during 3 different pandemic time points in Germany. Since telemedicine use and acceptance varied over the course of the pandemic (eg, [31,35,46]), it may be beneficial to consider more than just one time point when observing telemedicine use behavior during the pandemic. Moreover, the longitudinal approach gives further insight into the directionality of the relationships. Therefore,

our study aimed to longitudinally investigate determinants of online health consultation use in a large representative sample of middle-aged and older individuals during the COVID-19 pandemic in Germany.

Expanding the knowledge regarding determinants of online health consultation use in middle-aged and older adults could help to identify target groups for telemedicine services, as well as groups that would benefit from additional support for using the services. Furthermore, this knowledge may help to adapt telemedicine services to the needs and preferences of middle-aged and older adults. Consequently, important practical and theoretical implications may be derived from our findings, which could foster greater use of telemedicine services among middle-aged and older individuals, ultimately helping to deal with future health care challenges posed by population aging.

Methods

Sample

Nationally representative cross-sectional and longitudinal data were taken from the German Ageing Survey (DEAS [47]). The DEAS focuses on the German middle-aged and older population (starting at 40 y) and aims to describe living conditions and diversity among this population as well as aging and social change processes that are related to this life stage [47]. The first wave of the DEAS was conducted in 1996, followed by further waves in 2002, 2008, 2011, 2014, 2017, 2020/2021. The survey has a cohort-sequential design in which new baseline samples were added in 2002, 2008, and 2014. The baseline samples of the DEAS were disproportionally stratified into age groups, gender, and region [47]. In response to the COVID-19 pandemic, an additional Compact Survey to measure the pandemic impact on middle- and older adults' lives in Germany was implemented in 2020.

For the purpose of our study, data from the Compact Survey [48] and wave 7 [49] of the DEAS were observed. The Compact Survey was conducted from June until July 2020 and consisted of paper-and-pencil questionnaires that were sent to individuals who had taken part in the DEAS at least once in the past. The response rate for the Compact Survey was 57% (4823/8533) [50]. Due to the ongoing pandemic during wave 7, the usual computer-assisted personal interviews were replaced by telephone-administered interviews as well as an additional paper-and-pencil questionnaire. The data collection for wave 7 took place from November 2020 until March 2021 and the response rate was 66% (5402/8207) [51]. Overall, 4103 individuals participated in both surveys [51]. Since the last DEAS baseline sample was added in 2014, participants of the Compact Survey and wave 7 of the DEAS were at least 46 years old.

The DEAS is funded by the German Federal Ministry for Family Affairs, Senior Citizens, Women, and Youth and was conducted and developed by the German Centre of Gerontology. The fieldwork was carried out by the INFAS Institute for Applied Social Sciences.

Ethical Considerations

Written informed consent was obtained from all individuals who participated in the DEAS, and opting out of the survey was possible at all times [47]. DEAS participants received an incentive (eg, €10 in DEAS wave 7; conversion rate US $1=€0.951 in 2022 [51]). Due to data protection guidelines, a data distribution contract needs to be signed prior to using the anonymized DEAS data [47]. The DEAS study complies with the Declaration of Helsinki and did not require further ethical examination since the criteria for the need of ethical approval were not met for this survey (eg, missing information regarding the study or aim of the study, examination of vulnerable groups or patients, high risk or burden for participants due to participation).

Dependent Variable

For the sake of our study, we exclusively included DEAS participants, who indicated having access to the internet (Compact survey: 3858/4676, 83%; wave 7: 3676/4276, 86%). In both DEAS waves, participants were asked "How often do you use the Internet for the following purposes?." Among the listed items was "Consultations with doctors and therapists via an online platform" in the Compact survey and "Providing consultations with doctors or therapists on online platforms" in wave 7 of the DEAS. The response format consisted of a 6-point Likert scale indicating use frequency as "never," "less often or seldom," "1 to 3 times a month," "once a week," "several times a week," or "daily." Since only a small number of participants had multiple consultations with doctors or therapists on online platforms, the outcome was dichotomized for our analysis (0="never"; 1="less often or seldom," "1 to 3 times a month," "once a week," "several times a week," or "daily").

Independent Variables

Based on theoretical considerations and previous research [38-40,44,45], different groups of determinants were considered. This included socioeconomic, health- and health behavior–related, psychological, and COVID-19–related determinants. Regarding socioeconomic characteristics, we examined sex, age, educational level (International Standard Classification of Education 97 [52]: low, medium, or high education), employment status (used, retired, and other or unemployed), household income, migration background (no, yes), area lived in (metropolitan districts, urban districts, [partially] densely populated rural districts, sparsely populated rural districts), residential form of partnership (no partner, partner in the same household, and partner not in the same household), and presence of children (no, yes).

Health-related factors included self-rated health (ranging from 0=very bad to 4=very good) as well as the frequency of physical activity and walks (ranging from 0=never to 5=daily) as measures of health-related behavior. For the sake of our analysis, the values for the frequency of physical activity and walks were divided into tertiles and were included as categorical variables (low, medium, and high frequency).

Psychological determinants that were considered were depressive symptoms, loneliness, attitude toward own aging, and life satisfaction. Depressive symptoms were measured using

a 10-item German short form of the Center for Epidemiologic Studies - Depression scale [53] (CES-D; scores ranging from 0 to 30, higher values indicate more severe depressive symptoms) in the Compact survey. In wave 7 of the DEAS, depressive symptoms were measured using the German version of the 15-item CES-D [54] (scores ranging from 0 to 45, higher values indicate more severe depressive symptoms). The values for both scales were standardized to assure comparability between both surveys in our analysis. Both of these well-established instruments were evaluated in the past and have good psychometric properties [53,55,56]. Cronbach α values for both scales were 0.83 (Compact survey) and 0.84 (wave 7) and McDonald Omega was 0.85 (Compact survey) and 0.86 (wave 7) in our sample. In addition, loneliness was measured with the 6-item De Jong Gierveld Loneliness Scale [57] (scores ranging from 1 to 4, higher values indicate higher levels of loneliness). The scale has favorable psychometric properties [57] (Compact survey: Cronbach α=0.78, McDonald's Omega =0.79; wave 7: Cronbach α=0.80, McDonald Omega =0.81). The self-perception of one's own aging was examined using the German version of the 5-item Attitude Toward Own Aging subscale of the Philadelphia Geriatric Center Morale Scale [58,59] (scores ranging from 1 to 4, higher values indicate a more positive perception of own aging). This widely used scale was evaluated in different age groups in the past (eg, [60]). In our sample, Cronbach α was 0.77 (Compact Survey and wave 7) and McDonald Omega was 0.77 (Compact Survey and wave 7). Life satisfaction was measured with the German version of the Satisfaction with Life Scale [61,62] (scores ranging from 1 to 5, higher values indicate greater life satisfaction). The German version of the scale was evaluated in the past and showed good psychometric properties [63]. For this scale, the Cronbach α was 0.86 (Compact survey) and 0.84 (wave 7) and the McDonald Omega was 0.87 (Compact survey) and 0.86 (wave 7) in our sample.

Finally, we controlled for COVID-19–related determinants, which included perceiving the Corona crisis as a personal threat (scores ranging from 1=not at all a threat for me to 10=extreme threat for me), past infection with the Coronavirus by oneself (no, yes, and unknown), or by people from one's personal environment (no, yes, and unknown) as well as the feeling of being able to influence the infection with the Coronavirus (scores ranging from 1=not at all to 7=entirely).

Statistical Analysis

In the first step, sample characteristics of our pooled analytic sample were computed. The analytic sample consisted of individuals who participated in at least one of the 2 surveys (5456 observations corresponding to 3222 individuals). Second, random effects logistic regressions were calculated to test the associations of the determinants with online health consultation use. The random effects regression model considers the panel structure of the data and allows the inclusion of not only time-varying but also time-constant predictors in our model, under the assumption that unobserved unit-specific heterogeneity is not correlated with the independent variables [64]. When this independence assumption is fulfilled, the random effects model may be more efficient than the fixed effects model as it considers both between and within variation [64]. Our choice was supported by the Hausman test. The null hypothesis of the Hausman test states that both models (fixed and random effects model) are consistent while the random effects model is more efficient [64,65]. Therefore, the random effects model is preferred when the null hypothesis cannot be rejected. Since the Hausman test statistic was nonsignificant for our sample (P=.72), we used random effects models for our analysis. Stata (version 16.0, StataCorp) was used for the statistical analyses and the random effects logistic regression was calculated using the "xtlogit" command with the "re" option. The sample was stratified by sex and age groups (≤64 and ≥65 years) in additional analyses. Statistical significance was defined as an alpha level of P<.05. Missing data were handled using listwise deletion.

Results

Sample Characteristics

The pooled analytic sample characteristics for all included variables are presented in Table 1. In the pooled sample of the Compact survey and wave 7 of the DEAS, 49% (2673/5456) were female and the mean age of the participants was 67.8 (SD 9.4) years. When examining past consultations with doctors or therapists on online platforms, 10.3% (561/5456) reported past experience with online consultations.

Table . Analytic pooled sample characteristics (N=5456).

Characteristics[a]	Values
Consultations with doctors or therapists on online platforms, n (%)	
No	4895 (89.7)
Yes	561 (10.3)
Sex, n (%)	
Male	2783 (51)
Female	2673 (49)
Age (years), mean (SD)	67.8 (9.4)
Educational level, n (%)	
Low (ISCED[b] 0 - 2) or medium (ISCED 3 - 4)	2455 (45)
High (ISCED 5 - 6)	3001 (55.0)
Employment status, n (%)	
Employed	1745 (32.0)
Retired	3475 (63.7)
Other or unemployed	236 (4.3)
Monthly household income (€), mean (SD)[c]	4051.2 (11,806.1)
Migration background, n (%)	
No	5223 (95.7)
Yes	233 (4.3)
Area lived in, n (%)	
Metropolitan districts	1524 (27.9)
Urban districts	2014 (36.9)
(Partially) densely populated rural districts	1135 (20.8)
Sparsely populated rural districts	783 (14.4)
Residential form of partnership, n (%)	
No partner	1069 (19.6)
Partner in the same household	4152 (76.1)
Partner not in the same household	235 (4.3)
Having children, n (%)	
None	602 (11)
One or more	4854 (89)
Self-rated health, mean (SD)[d]	2.6 (0.8)
Frequency of physical activity, n (%)	
Low frequency	1589 (29.1)
Medium frequency	3234 (59.3)
High frequency	633 (11.6)
Frequency of walks, n (%)	
Low frequency	2135 (39.1)
Medium frequency	2147 (39.4)
High frequency	1174 (21.5)
Depressive symptoms, mean (SD)[e]	−0.1 (0.9)
Loneliness, mean (SD)[f]	1.8 (0.5)

Characteristics[a]	Values
Life satisfaction, mean (SD)[g]	3.9 (0.7)
Attitude toward own aging, mean (SD)[h]	3.0 (0.5)
Perceiving the Corona crisis as a personal threat, mean (SD)[i]	4.3 (2.1)
Oneself infected with the Coronavirus, n (%)	
No	5244 (96.1)
Yes	57 (1)
Unknown	155 (2.8)
People from personal environment infected with the Coronavirus, n (%)	
No	4517 (82.8)
Yes	853 (15.6)
Unknown	86 (1.6)
Feeling that one can influence the infection with the Coronavirus, mean (SD)[j]	4.7 (1.4)

[a]Due to differences in measurement tools, values for depressive symptoms had to be standardized. The standardized values should be interpreted as number of SDs by which the original values lay above or below their mean. For example, a value of 1 or -1 indicates that the reported overall score in the CES-D lays one SD above/below the mean CES-D score.

[b]ISCED: International Standard Classification of Education.

[c] Range (0-500,000); the conversion rate of USD to Euro was US $1=€0.846 in 2021 and US $1=€0.951 in 2022.

[d]Range 0-4. Higher values indicate better self-rated health.

[e]Range for standardized values –1.8 to 5.9. Higher values indicate more depressive symptoms.

[f]Range 1-4. Higher values indicate higher loneliness levels.

[g]Range 1-5. Higher values indicate greater life satisfaction.

[h]Range 1-4. Higher values indicate a more positive perception of own aging.

[i]Range 1=not at all a threat for me to 10=extreme threat for me.

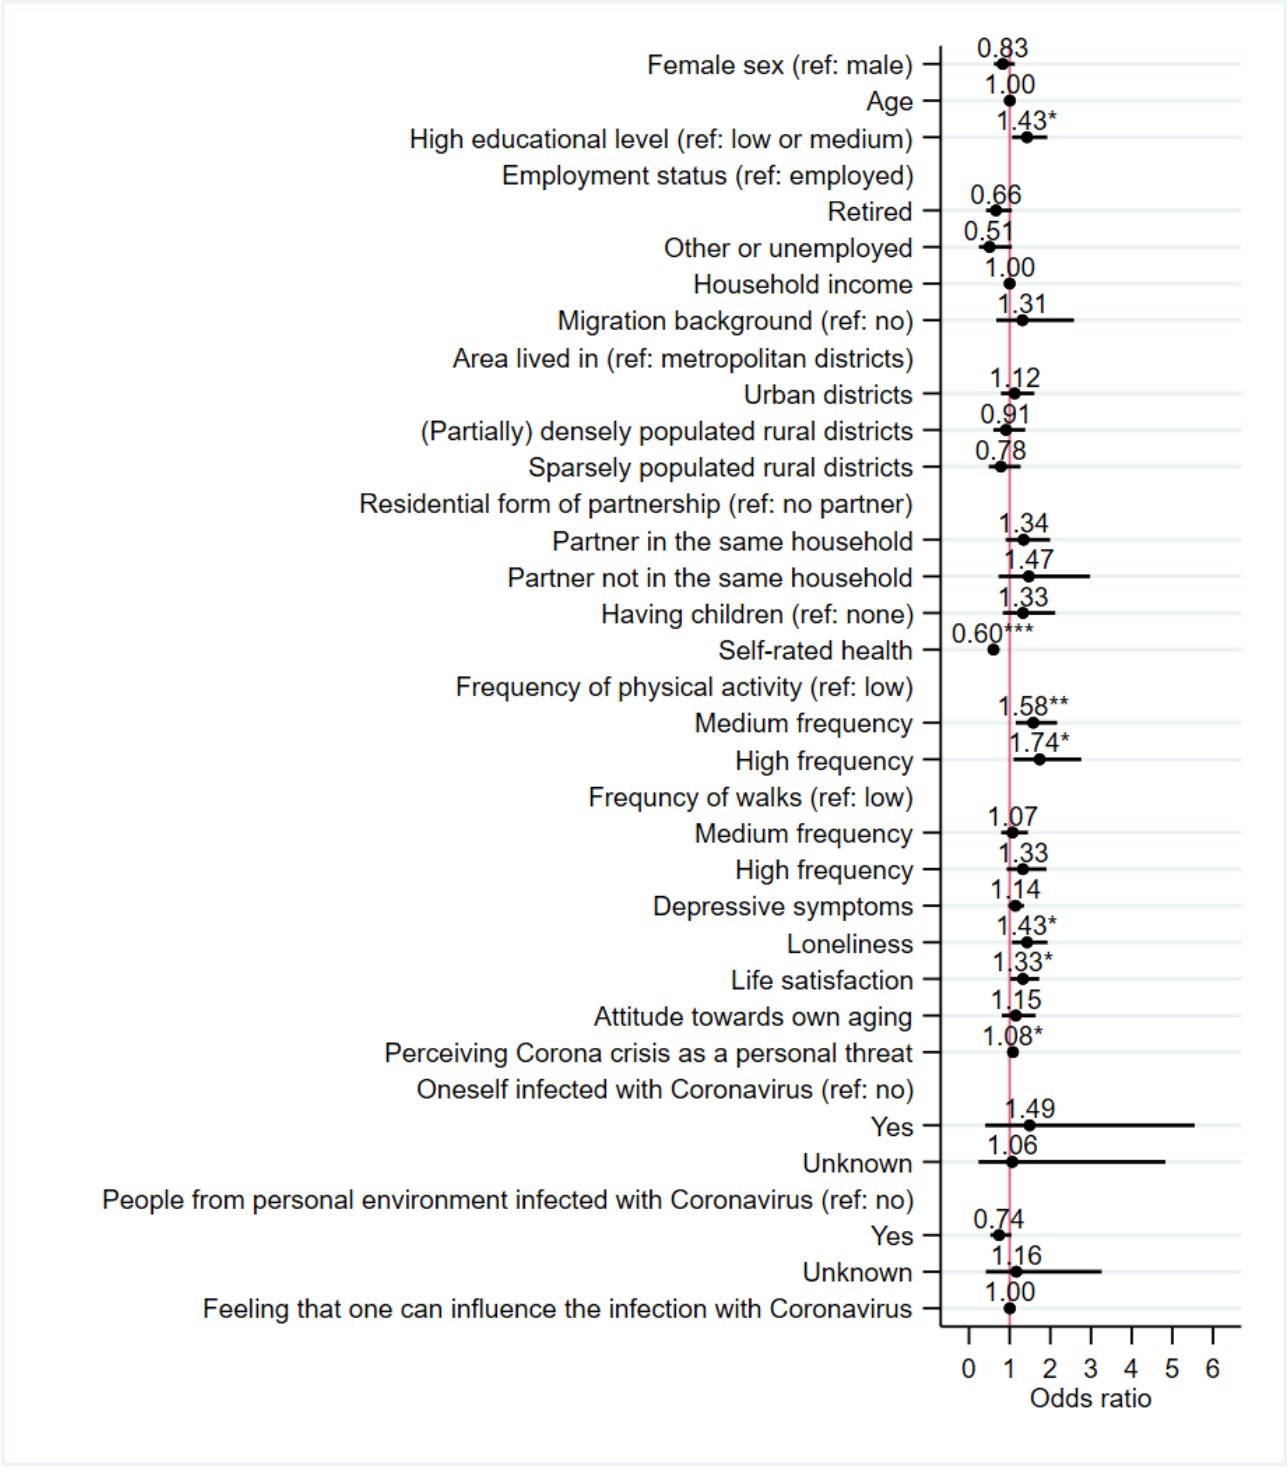
[j]Range 1=not at all to 7=entirely.

Regression Analysis

The results of the random effects logistic regression are presented in Figure 1 (Table S1 in Multimedia Appendix 1). The majority of the determinants were not significantly associated with online health consultation use during the COVID-19 pandemic. Nevertheless, we found a significant longitudinal association of the outcome with high education (OR 1.43, 95% CI 1.06 - 1.93; *P*=.02), poor self-rated health (OR 0.60, 95% CI 0.49 - 0.75; *P*<.001), higher frequency of physical activity (medium frequency: OR 1.58, 95% CI 1.15 - 2.17; *P*=.005; high frequency: OR 1.73, 95% CI 1.09 - 2.76; *P*=.02), higher loneliness (OR 1.43, 95% CI 1.06 - 1.93; *P*=.04), greater life satisfaction (OR 1.33, 95% CI 1.02 - 1.73; *P*=.04), and perceiving the Corona crisis as a greater personal threat (OR 1.08, 95% CI 1.01 - 1.15; *P*=.02).

In additional analyses, we stratified the sample by sex and age group (Tables S2 and S3 in Multimedia Appendix 1 for more details). While online health consultation use in female participants was only associated with poor self-rated health (OR 0.62, 95% CI 0.45 - 0.85; *P*=.004), in male individuals the outcome was associated with poor self-rated health (OR 0.59, 95% CI 0.44 - 0.79; *P*<.001) as well as high education (OR 1.70, 95% CI 1.12 - 2.56; *P*=.01), living with a partner in the same household (OR 2.27, 95% CI 1.13 - 4.59; *P*=.02), living with a partner not in the same household (OR 2.86, 95% CI 1.04 - 7.87; *P*=.04), higher loneliness (OR 1.94, 95% CI 1.25 - 2.99; *P*=.003), higher frequency of physical activity (medium frequency: OR 1.88, 95% CI 1.22 - 2.90; *P*=.004; high frequency: OR 2.17, 95% CI 1.17 - 4.03; *P*=.01) and walks (high frequency: OR 1.99, 95% CI 1.24 - 3.20; *P*=.004). In participants aged ≤64 years, online health consultation use was associated with poor self-rated health (OR 0.59, 95% CI 0.42 - 0.83; *P*=.003) and higher frequency of physical activity (medium frequency: OR 1.91, 95% CI 1.14 - 3.21; *P*=.01). In older participants (≥65 years), poor self-rated health (OR 0.61, 95% CI 0.46 - 0.81; *P*=.001) as well as older age (OR 1.03, 95% CI 1.00 - 1.07; *P*=.05), high education (OR 1.58, 95% CI 1.06 - 2.37; *P*=.026), and higher loneliness (OR 1.52, 95% CI 1.01 - 2.29; *P*=.04) were associated with online health consultation use.

Figure 1. Results of random effects logistic regression for determinants of online health consultation use during the COVID-19 pandemic (N=5456). Odds ratios with 95% CI are reported. Unless stated otherwise, the reference category is always zero or absence of the characteristic. ref: reference category; *** *P*<.001; ** *P*<.01; * *P*<.05.



Discussion

Principal Findings

Nationally representative longitudinal data from Germany were used to observe the longitudinal association of various determinants with the use of online consultations with doctors or therapists during the COVID-19 pandemic in a large sample of middle-aged and older individuals with access to the internet. Random effects logistic regressions revealed associations of education, health, and psychosocial factors with online health consultation use during the pandemic. In additional analyses stratified by sex and age, self-rated health was negatively associated with the outcome in all groups. Additional relationships with age, education, relationship status, and loneliness were only observed among the male and older (≥65 years) subgroups. Considering the limited evidence regarding determinants of telemedicine use (particularly based on longitudinal data), our longitudinal study considerably extend current knowledge on socioeconomic, health- and health

behavior–related, psychological, and COVID-19-related determinants.

Relation to Previous Research

In contrast to findings from other German samples [18,33,35,36,41,42,66], most of the socioeconomic determinants, such as sex or age, were not associated with online health consultation use in our sample. Nevertheless, a study that exclusively observed an older German sample also found no associations with socioeconomic characteristics [45]. This could imply that socioeconomic characteristics are less relevant for telemedicine use in middle-aged and older patients in Germany. However, the individual's educational level was positively associated with the outcome in our analysis. This is in line with findings from other large German [33,34,36,42] and international samples [38,40,67,68] and could suggest that high education is linked to higher digital literacy as well as access to necessary technical equipment for using telemedicine. A systematic review by Estrela et al [69] examined 36 international articles on digital health literacy and highlighted its positive relationship with education. Correspondingly, in a large US sample of old-aged Medicare beneficiaries (≥65 years), Choi et al [70] found associations of younger age and higher income with telemedicine use during the COVID-19 pandemic, which disappeared when controling for technology-enabling factors (eg, information and communication technology device ownership or use experience). Consequently, technology-enabling factors could be particularly considered when trying to enhance telemedicine use among older patients. For instance, implementing supporting material (eg, leaflets or video instructions), technical support (eg, via telephone) or hybrid care combinations in clinical practice may be helpful to strengthen competence and digital health literacy in older patients.

Health and health behavior were associated with online health consultation use in our sample. Individuals who reported a poorer health status were more likely to use online health consultations during the pandemic. Likewise, severe health limitations or poor health were associated with telemedicine use in the German Survey of Health, Ageing and Retirement in Europe (SHARE) sample of middle-aged and older adults [45] and in international samples [68,71]. This association could have been caused by greater health needs in unhealthy individuals or may be connected to precautions due to the COVID-19 pandemic. Likewise, perceiving the Corona crisis as a greater personal threat was associated with online health consultation use. Telemedicine might have presented a treatment option for patients who were scared of becoming infected with the Coronavirus and wanted to avoid personal contact (eg, [72]). Fear of the Coronavirus and pandemic-related challenges were also associated with telemedicine use in other German samples during the pandemic [36,41,42,45]. Other COVID-19–related factors such as the infection of oneself or close others with the virus were not associated with the outcome in our sample. A reason for that could be that only a small proportion of our pooled sample was infected with the virus (1%) or knew someone in their close personal environment who was infected (15.6%). Furthermore, the frequency of physical activity was positively associated with online consultation use. Physical activity is an important determinant of health and was associated with higher utilization of preventive or office-based health services and lower use of inpatient or emergency care among adults in previous international research (eg, [73,74]). Therefore, physically active individuals seem to show greater levels of health awareness, which might have been connected to the higher telemedicine use in this group.

Some psychological factors were associated with the outcome in our sample. Whereas depressive symptoms and the attitude towards one's own aging did not show an association, psychosocial factors including loneliness and life satisfaction had a significant relationship with online health consultation use. In the German SHARE sample, a positive association of depressive symptoms as well as loneliness with telemedicine use in middle-aged and older individuals was observed [45]. The mixed evidence concerning the relationship of depressive symptoms with telemedicine utilization might be explained by the different pandemic periods that were considered in the studies (Summer and Winter 2020 vs Summer 2021). In fact, depressive symptoms [75] and telemedicine acceptance [35] were found to have increased over the course of the pandemic. Regarding loneliness, Robbins et al [76] also observed higher loneliness rates among telemedicine users (telephone contacts), while in-person visits were associated with fewer feelings of loneliness among older adults (≥65 years) residing in the United States during the pandemic. It might be the case that older adults who indicated higher levels of loneliness were more open to using telemedicine services to satisfy their unmet social needs during pandemic times. Telemedicine services may be more accessible for older individuals (eg, no traveling for mobility-restricted individuals needed), which might encourage lonely individuals to take the initiative to foster social interaction through telemedicine appointments. Regarding life satisfaction, König et al [77] recently observed a positive correlation between life satisfaction and digital health literacy in a nationally representative survey of the population in Germany, which could explain the observed relationship between higher life satisfaction and online health consultation use in our sample. In addition, higher life satisfaction was associated with health-promoting behaviors in previous studies [78-80], which could have contributed to higher online health consultation use.

Additional analyses stratified by sex and age further highlighted the relationships with the determinants, especially in male and older participants. While online consultation use in females was only associated with health needs, male individual's use behavior was additionally associated with psychosocial factors (ie, relationship status and loneliness), education, and health behavior (ie, frequency of walks and physical activity). The decision of male patients to use telemedicine services seems to be connected to additional factors and therefore more complex compared with female patients. Male patients may be facing additional barriers to telemedicine utilization. Therefore, future research is needed to explore gender-specific determinants and barriers to the use of telemedicine. Furthermore, particularly among individuals aged 65 years and older, loneliness, education, and age were associated with online health consultation use. Consequently, compared with individuals aged

40 to 64 years, older patients might be especially affected by disparities in education or loneliness.

When considering the international context, multiple reviews mainly based on quantitative cross-sectional, randomized controlled or qualitative studies observed determinants of telemedicine use in older age groups and found positive associations with educational level, health needs, and health-related motivation to use the services [38-40], which is in line with our findings. Moreover, they observed additional relationships (eg, with age, sex, and social support or influence), which we did not find in our analysis. Age or sex were not associated with overall telemedicine use in our sample. The reviews [38-40] mostly included studies from the United States or Europe. Telemedicine regulations differ substantially between Germany and the United States, but also in the European context. Whereas Germany has implemented national telemedicine coverage rules during the pandemic, large state-specific variation in insurance coverage and regulations exist in the United States [71,81], which may have caused additional barriers for older telemedicine users. Nevertheless, our stratified analyses indicated differences in determinants of use in the different sex and age groups. Furthermore, we observed a positive relationship of loneliness with telemedicine use, which is in contrast to the observed negative relationship of social isolation or lack of social support with telemedicine use in international studies [39]. Raja et al [82] reviewed studies of older adults in European countries and found that social support and lack of social support were both associated with using new technologies, including telemedicine. Social support may be crucial when older adults are faced with problems when learning new technologies, which was also observed in US samples [68]. Nevertheless, lack of social support or loneliness might also motivate older adults to try out new technologies to address their social needs, which we observed in our sample. Moreover, the discrepancies might also be explained by differences in regulations or access to telemedicine care (eg, variations in out-of-pocket payments, supply, or complexity of use). For instance, the requirement for additional out-of-pocket payments or high barriers to use may lower the probability of using telemedicine services for the primary purpose of social interaction. Future research concerning differences in psychosocial determinants across different countries is needed.

Strengths and Limitations

The nationally representative, large DEAS sample of middle-aged and older individuals in Germany represents a key strength of our study. Middle-aged and older adults are a major target group for future telemedicine services in Germany, thus it is of particular importance to explore the telemedicine use behavior of this age group. In addition, longitudinal data were exploited, which enabled us to consider two different pandemic stages and account for the exceptional circumstances during that time. Since only few studies observed determinants of online health consultation use in German middle-aged and older adults in the past, our study adds valuable knowledge to the existing literature.

Nevertheless, some limitations should be noted. Telemedicine use was represented by having online consultations with doctors or therapists in our study. We neither examined specific patient groups nor focused on a certain telemedicine format (eg, video conferences or mobile apps). Therefore, we observed a potentially heterogeneous user group. Since telemedicine acceptance during the pandemic was found to vary across medical specialties and telemedicine formats [31], future research that tests for differences in use among patient groups or different telemedicine formats is needed to tailor future services to major user groups. However, our study provides initial insights into telemedicine use in middle and old age. In addition, the DEAS panel holds a slight selection bias. Young, highly educated, healthier, and female individuals were somewhat more likely to participate in the DEAS [83]. However, selection bias in the DEAS sample was found to be small and the distribution of major sociodemographic characteristics closely mirrors the distribution within the overall population of Germany [47]. Moreover, only individuals with access to the internet were included in our study. Therefore, generalization of the results might be slightly limited for some groups of the German middle-aged and older population.

Conclusion

Telemedicine services represent a valuable tool to deal with the increasing demand for health care caused by population aging. Knowledge about telemedicine use and its determinants, particularly in middle-aged and older individuals, is essential to promote widespread implementations in the future. Our study highlights the relationship of education, psychosocial, and health factors with telemedicine use of community-dwelling middle-aged and older individuals in Germany during the COVID-19 pandemic. Therefore, telemedicine use does not only depend on health needs of middle-aged and older patients. The finding that particularly highly educated individuals used online health consultations may point toward social inequality among telemedicine users. Consequently, efforts should be made to enable access to telemedicine for all patient groups and individual support should be provided (eg, for patients with low [digital] health literacy) to remove barriers to telemedicine use. Moreover, special attention should be paid to individuals with low life satisfaction and an unhealthy lifestyle since they seem harder to reach through telemedicine services. Finally, future research is needed to test the relevance of the observed relationships in the postpandemic context and identify potential reasons for use or nonuse of telemedicine services in middle-aged and older adults in Germany (eg, based on qualitative data). Moreover, cross-country comparisons regarding the determinants of telemedicine use remain to be explored.

Abstract

Background: The demand for home medical care services has increased in aging societies. Therefore, allocating health care resources optimally to meet the needs of each community is essential. Geographical accessibility is an important factor affecting access to home medical care services; however, little research has been conducted on regional disparities in geographical accessibility.

Objective: This study aims to analyze the regional disparities in geographical accessibility to home medical care services using the Kokuho database (KDB), a comprehensive medical claims database for a prefecture in Japan.

Methods: This study included 39 municipalities in Nara Prefecture, Japan. Using a geographical information system, accessibility to home medical care services, that is, travel distance and time from hospitals and clinics to hypothetical patients, was analyzed in two scenarios: (1) an ideal scenario, where we assumed that all hospitals or clinics in Nara Prefecture provided those services and (2) an actual scenario, where hospitals or clinics in Nara Prefecture that actually provided home medical care services, identified from KDB data analysis, were used in the analysis. Hypothetical patients were randomly distributed on the geographical information system in accordance with the usage rates of home medical care services and with the distributions of the population aged ≥75 years. The usage rate by municipalities was aggregated from the analysis of KDB data of Nara Prefecture in FY2019.

Results: The median travel distance was longer than 16 km, the reference limit value specified in the Japanese fee table, and the median travel time exceeded 30 min in certain rural municipalities in the southern part of Nara Prefecture, in the actual scenario, whereas the travel distance and time were improved in the ideal scenario. The differences in travel time between the ideal and actual scenarios were the largest in the depopulated municipalities in the southern part, such as Totsukawa (32.6 vs 5.8 min), Kawakami (30.1 vs 11.8 min), Kurotaki (21.3 vs 5.2 min), and Kamikitayama (20.7 vs 3.5 min). The usage rates were also lower in rural municipalities in the southern part.

Conclusions: The results revealed that geographical accessibility was lower in depopulated municipalities in the southern part, and the disparity could be partly solved in the ideal scenario, especially in that area, highlighting the necessity of increasing supply in the southern areas. KDB is a comprehensive database that includes medical claims information for home medical care patients and details of the provision of medical institutions, enabling geographical analysis that reflects actual health care usage.

Introduction

Most limited-income countries have aging societies, including Japan, which is the most aging country in the world with an aging rate (rate of population aged ≥65 y) of 28.1% in 2018, followed by Italy (23.3%), Portugal (21.9%), and Germany (21.7%) [1]. Medical demand is estimated to increase with demographic changes [2]. The Japanese government has been promoting a structure in which home medical care and long-term care services are provided comprehensively to older adults,

ensuring they live their lives in the areas they are used to in an aging society [3]. Therefore, increased promotion of the use of home medical care services is of great societal importance.

The demand for home medical care services has also increased in recent years, with a peak at around 2040 [3]. Each prefecture in Japan is responsible for creating a Regional Medical Plan to ensure that health care services are effectively provided to meet the needs of the local population [4]. The Regional Medical Plan includes a plan to provide home medical care services, and each prefecture must specify the problems faced and measures to resolve them. Prefectures must consider optimal allocations and make the most of their limited resources to meet the needs.

Geographical accessibility is among the factors that could affect the provision of home medical services. The relationship between geographical factors and the usage of medical services has been previously studied [5-7]. For example, Schwarz et al [5] analyzed the relationship between the distance from hospitals to patients and the psychiatric treatments that patients received. Herein, people living in peripheral communities were mainly treated in inpatient settings. In contrast, those living in residential areas were more likely to receive intensive psychiatric home treatment. Similar to their study findings, geographical accessibility is important for home medical care services since health care providers need to travel to patients' homes.

Kuwayama et al [8] conducted a literature review of studies on home care nursing in Japan using a geographical information system (GIS) and discovered a few related studies [9,10]. In those studies, Naruse et al [7] performed a multilevel logistic analysis of the association between the use of home care nursing and the proportion of older adults reachable by facilities providing home-visit nursing services (calculated by buffer analysis using GIS). They found that people living in less reachable municipalities were less likely to use these services. However, few studies have been conducted on the geographical accessibility of home-based medical care services. Moreover, these previous studies were limited to visualizing the current situation.

Extensive databases containing medical claims and national health insurance information, such as the National Database of Health Insurance Claims and Specific Health Checkups of Japan (NDB) and National Health Insurance Database (Kokuho database: KDB), have recently become essential tools for medical and health care policy research. These real-world data sources provide valuable insights into health care usage, treatment patterns, and outcomes. The main advantages of using such databases include the ability to study targeted populations and understand the actual clinical practice comprehensively. Using such databases, a geographical analysis that reflects the actual health care usage and trends will be possible.

Several studies have conducted geographical analysis using a large real-world database. Cheng et al [11] analyzed the prescribing patterns of cardiovascular drugs across townships in Taiwan using a national claim database covering 97.5% of the total population. Kwak et al [12] analyzed the relationship between the incidence of obstetric complications for pregnant women and access time to delivery units in South Korea, using the national claim database.

However, there are few previous studies analyzing geographical accessibility to home medical care services using an extensive database.

Therefore, this study aimed to develop a methodology for analyzing regional disparities in geographical accessibility to home medical care services using the KDB database to help consider achieving the provision of more efficient and equitable service. Given the global trend of aging, the findings of this study in Japan may contribute to improving the efficiency and equity of service delivery and policymaking of home medical care services in other countries facing similar demographic challenges.

Methods

Subjects and Scheme

This study was conducted in the 39 municipalities in Nara Prefecture, Japan, as a model region. Nara Prefecture is located in the center of Japan's main island of Honshu (Figure 1A) and has both urban and rural (mountainous) areas. Nara Prefecture has a population of 1,286,651 (approximately 1/100th of the national total), a land area of 3691 km^2 (approximately 1/100th of the national total) [13,14], and 32% (0.4/1.25) of adults aged ≥65 years (compared to 36.4/125.52, 29% nationally; Table 1). The characteristics of municipalities, such as population and aging rate, are shown in Table 1. Figures 1B and C illustrate the geographical locations of the 5 secondary medical areas and 39 municipalities. Nanwa secondary area, in the southern part, is the most rural area with mountains. Since there seems to be a geographical difference within Nara Prefecture, it would be suitable as a model region for geographical analysis. Secondary medical areas provide general inpatient medical services, whereas municipalities or smaller regional units provide more basic medical services.

Figure 1. The geographical locations of Nara Prefecture in Japan, secondary medical areas in Nara, and municipalities in Nara show the geographical location of (A) Nara Prefecture in Japan and also illustrate the distributions of hospitals or clinics (B) in the actual scenario and (C) in the ideal scenario.

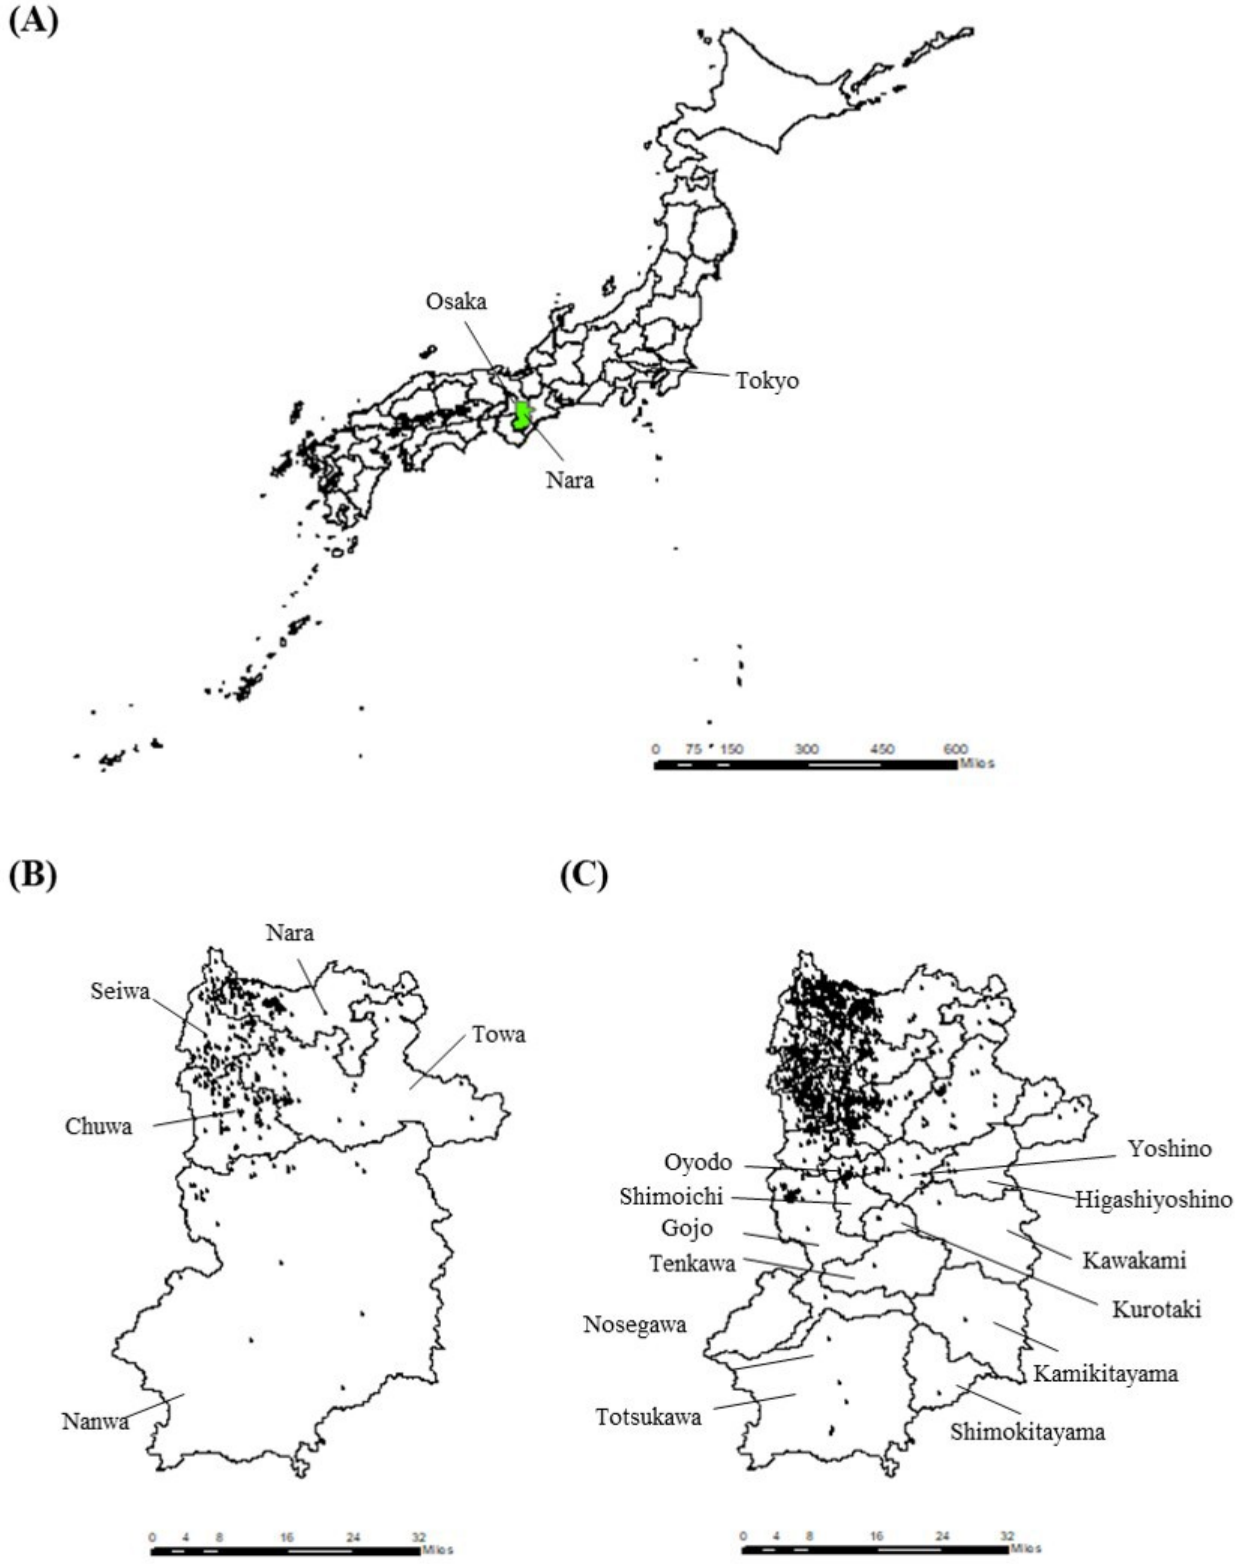

Table . Characteristics of each municipality and the result of usage rate.

Municipality	Population [14]	Aging rate (%) [14]	Land area (km^2) [13]	Population density (/km^2)	Number of claims	Usage rate (%)

For each municipality, geographical accessibility to home medical care services was analyzed using GIS (ArcGIS Desktop version 10.8.1; ESRI Japan Corporation) in the following two scenarios: (1) actual scenario: geographical accessibility to patients from hospitals and clinics in Nara Prefecture that actually provided home medical care services, and (2) ideal scenario: geographical accessibility to patients from all hospitals or clinics in Nara Prefecture was used. The latter simulates geographical accessibility in an ideal scenario in which the number of hospitals or clinics that provide home medical care services would increase. These scenarios were different only in terms of the number of hospitals and clinics used in the analysis, as described hereafter. Hypothetical patients were generated on a GIS by using the methodology described in a subsequent section "Geographical Analysis."

Data

For the actual scenario, hospitals and clinics that provided home medical care services were defined using data from the KDB database of Nara Prefecture (Nara KDB) in FY2019. This is a prefecture-wide database of medical and long-term care insurance claims. To be defined as hospitals and clinics that actually provided home medical care services, hospitals and clinics were required to have at least one claim with home medical care service fees (medical service code: 114001110, 114030310, 114042110, 114042210, 114042810, 114046310, 114027710, and 114027810 in the national fee schedule) for patients aged ≥75 years in Nara KDB in FY2019. Consequently, 346 hospitals and clinics were identified in the actual scenario.

The ideal scenario used all the hospitals and clinics in Nara prefecture, that is, those providing or not providing home medical care services. The geographical data on the 1308 hospitals and clinics were obtained from the Geospatial Information Authority of Japan [15]. Dental clinics were excluded from the study. The distribution of hospitals and clinics in the 2 scenarios is shown in Figure 1.

Population data at each 500 m^2 mesh (ESRI Japan Corporation) were used to distribute the locations of the hypothetical patients.

Geographical Analysis

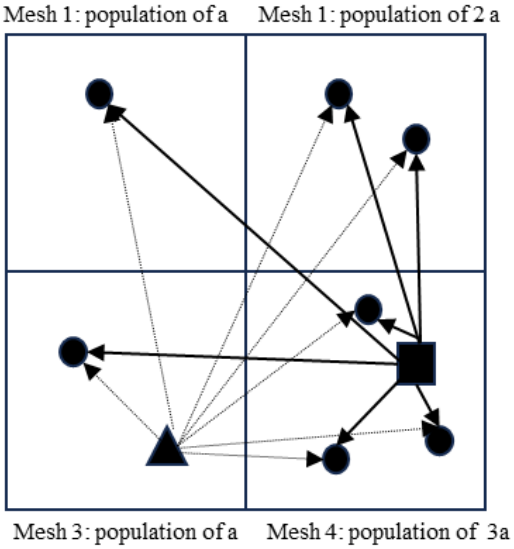
First, hypothetical patients were generated on GIS. The number of patients in each municipality was that of patients aged ≥75 years who used home medical care services in each municipality, identified from the Nara KDB data analysis. The usage of home medical care was defined in the same manner as identifying the hospitals and clinics in the actual scenario. That number of patients was randomly allocated to 500 m^2 meshes on GIS, reflecting the distribution of the population aged ≥75 years based on the national census 2020. In other words, the hypothetical patients were allocated to each mesh in a manner that the number of patients in each mesh is proportional to the mesh population aged ≥75 years using R version 4.1.2 (The R Foundation) [16,17]. This methodology enables the simulation of accessibility, reflecting the actual geographical distribution of potential patients. Thereafter, based on the patient allocations, hypothetical patient points were created on randomly determined points within the allocated meshes on ArcGIS using the "Create Random Points" function.

Subsequently, travel time from the patients to the hospitals or clinics was analyzed using the "Find Closest Facilities" function of ArcGIS for the 2 scenarios, respectively. We assumed that the travel to the patients was from the closest hospital or clinic. However, the closest hospitals or clinics can be located outside the municipality where the patients live.

The median and 25 - 75 percentiles of travel distance and time were aggregated for the patients in each municipality. Moreover, the rates of patients for whom travel distances were over 16 km were calculated since, in the Japanese universal fee table, the travel distance to provide home medical care services needs to be 16 km or less, unless an exceptional reason is present [18].

The usage rate was calculated by dividing the number of patients aged ≥75 years using home medical care services by the total population aged ≥75 years. The entire process of geographical analysis was repeated 10 times to consider the uncertainty of patient locations in each trial. The scheme of geographical analysis is visualized in Figure 2.

Figure 2. Scheme of the geographical analysis illustrating the scheme of the geographical analysis. GIS: geographical information system.



1. The hospitals or clinics defined to provide home medical care services (■) were identified from claims database analysis
2. All hospitals and clinics (both ▲ and ■) were identified from an open source
3. Locations of hypothetical patients were randomly decided in a manner to reflect actual distributions of population over 75 or more and usage rates for each municipality (using R 4.1.2) (eg. in a mesh with "2a" population likely has twice more patients than that with "a" population on average)
4. The hypothetical patients were mapped on GIS
5. Travel distance and time were analyzed using GIS
   - in ideal scenario: both ▲ and ■ were used
   - in actual scenario: only ■ was used (solid arrows)

Ethical Considerations

This study was approved by the ethics committee of the National Institute of Public Health, Japan (NIPH-IBRA number 12324 - 2). The requirement for informed consent was waived because all data were anonymized.

Results

The number of claims and usage rates are presented in Table 1. The distributions of hospitals or clinics used in each scenario were visualized in Figure 1. The travel time and distance results are shown in Figures 3-6 and Multimedia Appendices 1 and 2. In the actual scenario, the median travel time for all the patients in Nara Prefecture was 3.0 (IQR 2.0 - 4.3) minutes, and the travel distance was 0.7 (IQR 0.5 - 1.2) km. In the ideal scenario, the median travel time for all patients was 2.0 (IQR 1.2 - 2.9) minutes, and the travel distance was 0.5 (IQR 0.3 - 0.9) km.

Figure 3. The median travel time in the two scenarios. This figure illustrates the median travel time in (A) the ideal scenario and (B) the actual scenario.

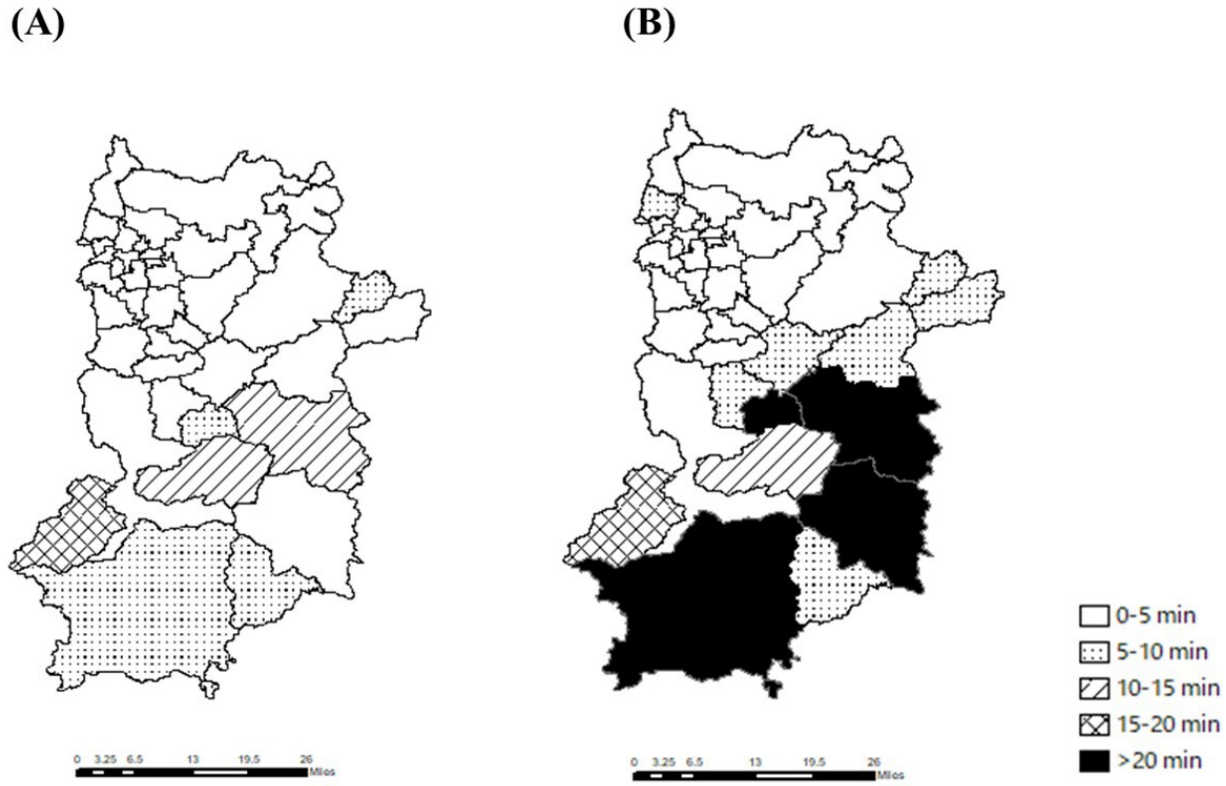


Figure 4. The rates of patients for whom the travel time was longer than 30 minutes. This figure illustrates the rates of patients for whom the travel time was longer than 30 minutes in (A) the ideal scenario and (B) the actual scenario.

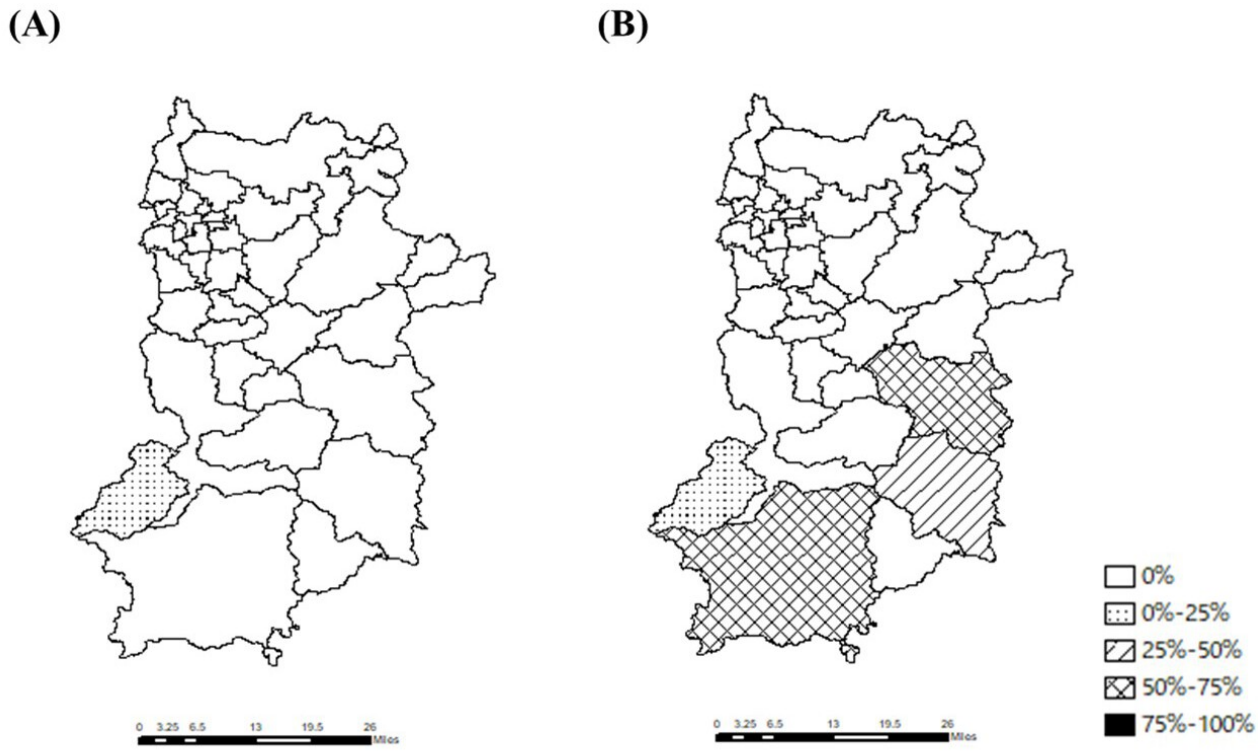

Figure 5. The median travel distance for each municipality in the two scenarios illustrates the median travel distance in (A) the ideal scenario and (B) the actual scenario.

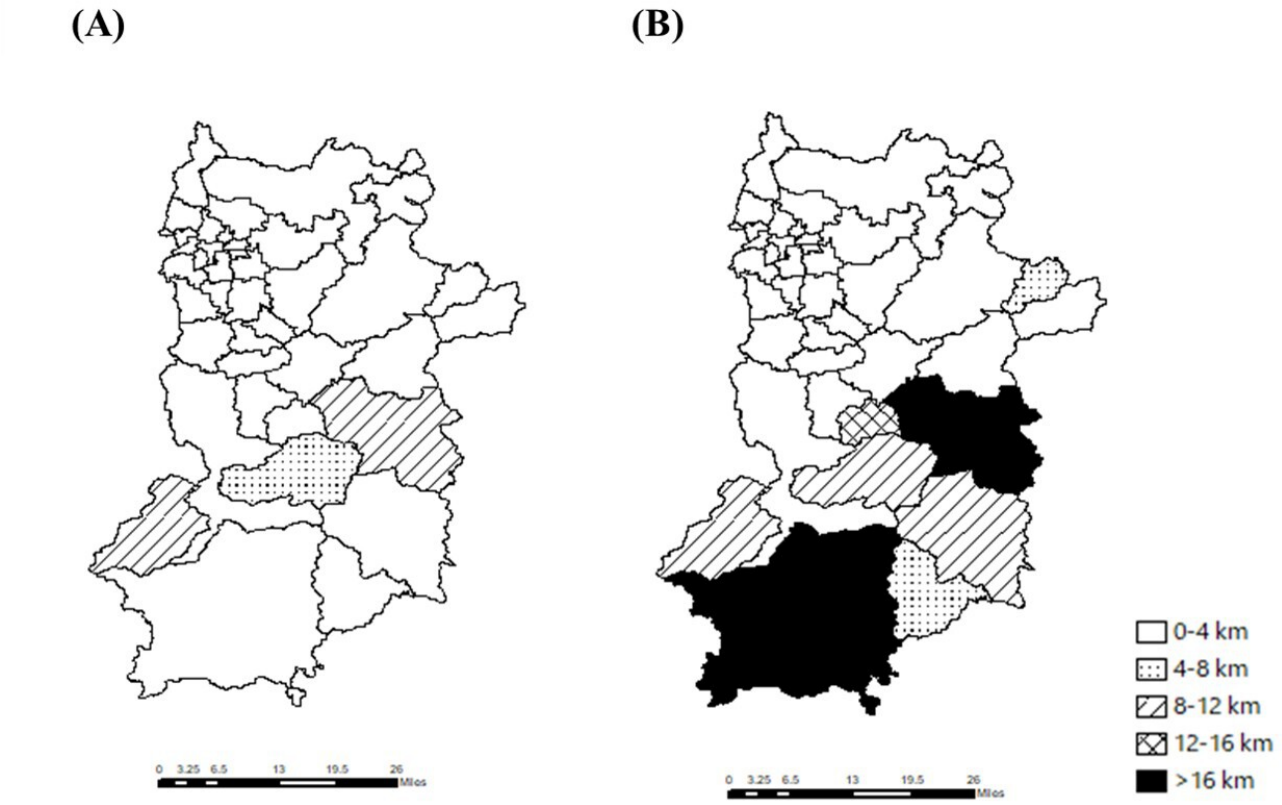

Figure 6. The rates of patients for whom the travel distance was longer than 16 km. This illustrates the rates of patients for whom the travel distance was longer than 16 km in (A) the ideal scenario and (B) the actual scenario.

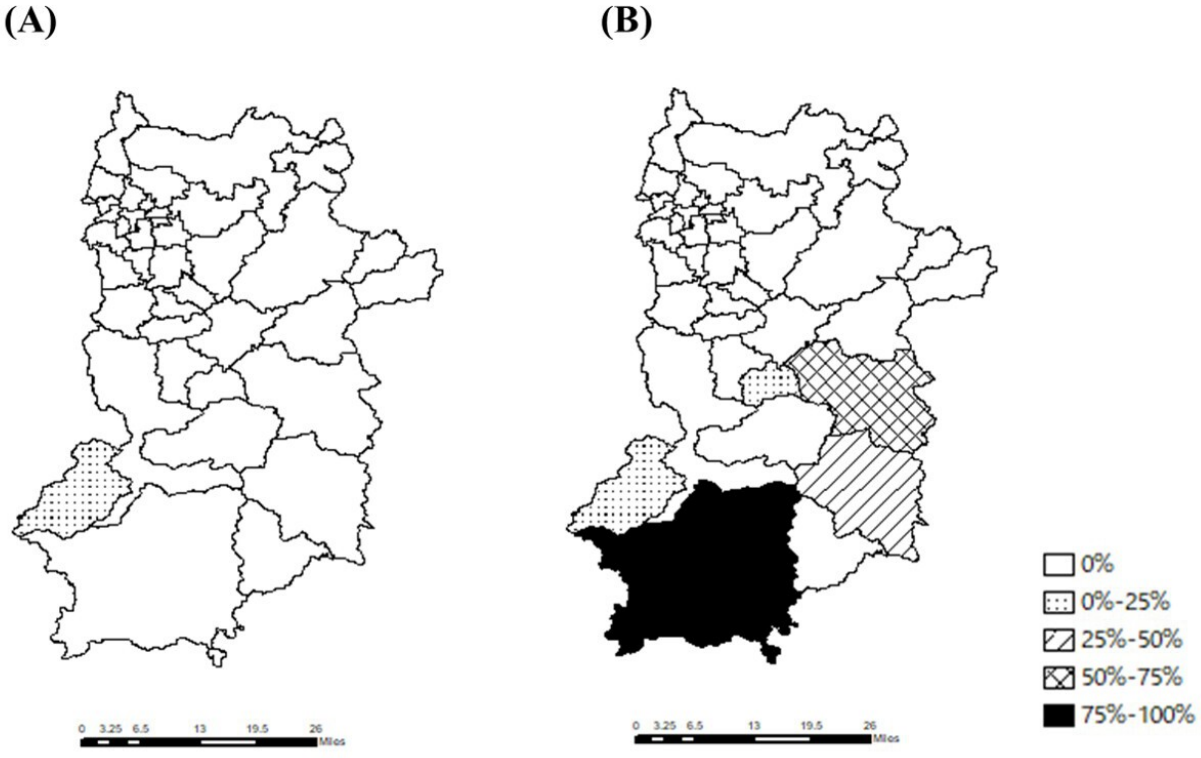

The median travel times for each municipality in the 2 scenarios are shown in Figures 3 and 4. In the ideal scenario, the median travel time was less than 15 minutes, except for Nosegawa (18.1, IQR 2.2 - 25.5 min), while in the actual scenario, the median travel time was longer in the municipalities in the Nanwa area, the southern part (in Totsukawa (32.6, IQR 21.2 - 40.5 min), Kawakami (30.1, IQR 16.5 - 32.4 min), Kurotaki (21.3, IQR 20.2 - 24.1 min), and Kamikitayama (20.7, IQR 19.7 - 26.1 min; Figure 3).

When comparing the 2 scenarios, the differences in travel time between the scenarios were the largest in Totsukawa (26.8 min), Kawakami (18.3 min), Kamikitayama (17.2 min), and Kurotaki (16.1 min). All of these 4 municipalities are located in a depopulated secondary medical area of Nanwa.

Figure 4 shows the number of patients for whom the travel time was longer than 30 minutes. In the actual scenario, the rates were highest in Totsukawa (58.0%), Kawakami (50.0%), Kamikitayama (30.0%), and Nosegawa (25.0%).

The median travel distances for each municipality in the 2 scenarios are shown in Figure 5. In the ideal scenario, the median travel distances were shorter than 12 km for all municipalities. However, in the actual scenario, the median travel distances were longer than 16 km in Totsukawa (28.4, IQR 16.7 - 32.3 km) and Kawakami (17.2, IQR 10.3 - 19.3 km). Kurotaki, Nosegawa, and Kamikitayama showed similar findings (13.9, IQR 12.6 - 14.4; 11.5, IQR 1.3 - 16.1; and 10.8, IQR 10.3 - 16.4 km, respectively). The differences in travel distance between the scenarios were the largest in Totuskawa (24.5 km), Kurotaki (11.8 km), Kamikitayama (9.3 km), and Kawakami (8.6 km).

Figure 6 shows the number of patients whose travel distance was >16 km. In the actual scenario, the rates were 77.6% for Totsukawa, 56.2% for Kawakami, 30.0% for Kamikitayama, 25% for Nosegawa, 20% for Kurotaki, and 0% for the other municipalities. In the ideal scenario, the rate was zero, except in Nosegawa (25.4%).

The usage rates by municipalities are shown in Table 1. This table shows the usage rates of home medical care services in each municipality. As can be seen, the usage rates tended to be lower in the municipalities in the Nanwa area (colored black), except for Nosegawa, which had the highest rate.

Discussion

Principal Findings

In this study, an accessibility analysis of home medical care services in Nara Prefecture was conducted as a model region, using the KDB data to investigate the equitable distribution of home medical care services. Using the KDB, we accurately identified medical institutions that provide home medical care, estimated the usage rates of home medical care services for each municipality, and demonstrated the feasibility of analyzing geographical accessibility to home medical care services that reflect actual health care usage and clinical trends.

The findings of this study revealed that in certain municipalities within the Nanwa area, a rural secondary medical area with a declining population, the travel distance to a health care patient's home exceeded 16 km, and the travel time exceeded 30 minutes in some cases. These results highlight disparities among municipalities in terms of geographic accessibility to home medical care services. Its supply in the Nanwa area needs to be increased from the perspective of geographic accessibility.

In addition, the usage rates of these services were lower in rural municipalities in the Nanwa area. To promote the use of home medical care services, improving accessibility in these municipalities is necessary. Geographical accessibility—that is, the distance from service providers to patients—could affect service usage. Naruse et al [7] reported that travel distance can affect the usage of home nursing care services. Although geographical accessibility would also likely affect the usage of home medical care services, the extent of the effect has not been clear since this study did not quantify the effect by controlling other factors, such as socioeconomic status, care quality, and regional characteristics. Further studies with additional information beyond medical claim data are required to clarify this point.

In recent years, the government has promoted the use of home medical care to meet the increasing medical demands within each area, enabling local people to live their lives in areas they have always lived in [3]. Our results showed that a disparity occurred in geographical accessibility to home medical care based on the current practice in the actual scenario; however, in the ideal scenario, no municipality was observed in which the travel distance to any patient was longer than 16 km, except for Nosegawa. Geographical accessibility is much better in this scenario. For example, the average travel time was less than 15 minutes, except for Nosegawa. These results indicate that the disparity in terms of geographical accessibility would have been mostly resolved if all hospitals and clinics had provided these services. Furthermore, our results indicated that the potential benefit would be the largest in the Nanwa area, the most depopulated area. Therefore, if the number of hospitals or clinics providing these services is increased by a policy (eg, through dispatching health care professionals or funding), this will be effective in ensuring sufficient geographical accessibility for patients in the Nanwa area (specifically, Kawakami, Totsukawa, Kurotaki, and Kamikitayama). That is especially necessary in Kawakami and Kurotaki, since no hospitals or clinics were providing services, and the usage rates were low in these municipalities. However, it is neither feasible nor efficient for all hospitals and clinics to provide services because of limited resources. Further analysis using GIS could clarify how residents' geographical accessibility will change when a specific hospital or clinic starts to provide home medical care services.

Notably, while the travel distance was longer in Nosegawa than in the other municipalities in both scenarios, the usage rate was the highest. The high usage rate could have been achieved by factors other than geographical accessibility. Further study, including factors other than geographical accessibility, is required to clarify the reason.

Our study is among the few that have analyzed geographical accessibility to home medical care services using GIS and KDB. The Nara KDB used in this study is an integrated database of

medical and long-term care insurance claim information covering all residents aged 75 years and older, which matches the primary population of home medical care patients. This methodology enabled us to conduct a geographical analysis that reflected actual health care usage. Furthermore, our results are important when considering the optimal allocation of medical resources related to home medical care services and equal accessibility to these services. Japan is the most aging country in the world [1]. Home medical care services will be more important in other countries, and ensuring accessibility to these services will be of greater importance in the future. Geographical analyses using nationwide health care claims databases have been conducted in other countries for health care fields, such as drug prescription and pregnancy outcomes [11,12]. Likewise, our methodology can be applied to other countries for home medical care services, as those services will be more important as the aging of the population progresses.

Limitations

The KDB is a comprehensive database that includes medical claims information for home medical care patients and details the provision of medical institutions, enabling a geographical analysis that reflects actual health care usage. However, this study had some limitations. First, it did not consider the capacity of each hospital or clinic because it focused on geographical accessibility. Further studies are required to consider its capacity to be more informative for optimal resource allocation. Second, a hospital or clinic was regarded as providing home medical care services if at least one claim regarding services from a hospital or clinic was identified. Some hospitals and clinics included in the actual scenario might not routinely provide home medical care services. Third, the disparity in geographical accessibility within each municipality is beyond the scope of this study. Such disparities may exist particularly in municipalities with lower geographical accessibility. Fourth, the KDB was used to analyze home medical care patients aged ≥75 years; therefore, home health care patients aged <75 years were not included. In the future, using the NDB or KDB and applying the developed methods, the analysis could be expanded to include pediatric home medical care patients and those under the age of 75 years. Finally, this study only used KDB data from FY 2019 to conduct geographical analysis while excluding the impact of the COVID-19 pandemic. The usage of home medical care has been increasing over the years, and the usage patterns could also change over the years. By applying the methodology established in this study, a nationwide analysis using the most recent data, free from the influence of the COVID-19 pandemic, can provide valuable insights into the future of home medical care.

Conclusions

This study conducted a geographical accessibility analysis of home medical care services using Nara Prefecture as a model region with GIS and KDB. The results revealed that geographical accessibility was lower in depopulated municipalities in the southern part, such as Totsukawa, Kawakami, Kamikitayama, and Nosegawa, which have lower accessibility than urban areas. However, the results also showed that the disparity could be partly solved in the ideal scenario. The differences in travel time between the scenarios were especially larger in the depopulated areas in the southern part, such as Totsukawa (32.6 vs 5.8 min), Kawakami (30.1 vs 11.8 min), Kurotaki (21.3 vs 5.2 min), and Kamikitayama (20.7 vs 3.5 min). These results highlight the necessity of increasing supply in the southern areas.

Abstract

Background: Older adults (65 years and older) often present to the emergency department (ED) with an unclear need for hospitalization, leading to potentially harmful and costly care. This underscores the importance of measuring the trade-off between admission and discharge for these patients in terms of patient outcomes.

Objective: This study aimed to measure the relationship between disposition decisions and 3-day, 9-day, and 30-day revisits, readmission, and mortality, using causal inference methods that adjust for potential measured and unmeasured confounding.

Methods: A longitudinal observational study (n=3591) was conducted using electronic health records from a large tertiary teaching hospital with an ED between January 1, 2014 and September 27, 2018. The sample consisted of older adult patients with 1 of 6 presentations with significant variability in admission: falls, weakness, syncope, urinary tract infection, pneumonia, and cellulitis. The exposure under consideration was the ED disposition decision (admission to the hospital or discharge). Nine outcome variables were considered: ED revisits, hospital readmission, and mortality within 3, 9, and 30 days of being discharged from either the hospital for admitted patients or the ED for discharged patients.

Results: Admission was estimated to significantly decrease the risk of an ED revisit after discharge (30-day window: −6.4%, 95% CI −7.8 to −5.0), while significantly increasing the risk of hospital readmission (30-day window: 5.8%, 95% CI 5.0 to 6.5) and mortality (30-day window: 1.0%, 95% CI 0.4 to 1.6). Admission was found to be especially adverse for patients with weakness and pneumonia, and relatively less adverse for older adult patients with falls and syncope.

Conclusions: Admission may not be the safe option for older adults with gray area presentations, and while revisits and readmissions are commonly used to evaluate the quality of care in the ED, their divergence suggests that caution should be used when interpreting either in isolation.

Introduction

Care for acute illnesses has shifted from outpatient offices to emergency departments (EDs), leading to an increase in ED use that has outpaced population growth [1]. EDs diagnose and treat acute illnesses [2]. Therefore, emergency providers diagnose patients, initiate treatment, and predict the disease trajectory to decide whether to admit the patient to an inpatient unit or discharge the patient home [3,4]. Any change to admission decisions can impact outcomes and costs since two-thirds of ED health care costs in the United States come from visits that end in admission [5,6].

Whether to admit or discharge a patient is a weighty decision. This point is best exemplified with older adults (≥65 years of age). Discharging an older adult carries a high risk of adverse health outcomes, especially when compared with younger

patients [7-12]. Hence, increasing interest has been placed on identifying patients at risk for adverse outcomes after ED discharge [7,11,13,14] or on developing strategies for following up on discharged patients [15]. Admitting a patient who can be discharged carries its own risks. Older adults are vulnerable to deconditioning and hospital acquired infection, as well as developing delirium and accelerated cognitive decline [16-19]. These issues underscore the importance of measuring the trade-off between admitting and discharging a patient.

Admission decisions are usually based on well-defined clinical factors and practice guidelines, but often, patients fall into a gray area in which the need for hospital admission is unclear based on objective information or even local standards of care. A large group of such gray-area patients is those presenting with syndromic diagnoses such as falls [20] or weakness [21], or patients presenting with more definite diagnoses that are associated with wide variability in admission decision, such as syncope [22], chest pain [5,23,24], urinary tract infection (UTI) [25], pneumonia [26], and cellulitis [27]. Moreover, other factors influence disposition decisions including triage [28], crowding [29], patient home environment [30], diagnostic testing [31], patient ethnicity [32], and hospital capacity [32]. Consequently, admission rates vary widely for these patients between providers and between hospitals, leading to potentially harmful practice variation [33]. Reducing this variation may avoid harmful admissions while safeguarding patient safety, but in order to do so evidence must be used to guide decision-making.

In this study, we focused on older adults in the ED with gray-area diagnoses as follows: diagnoses associated with clinical ambiguity or high rates of potentially preventable hospitalizations and variability in admissions [16,17]. The goal of this work was to identify how the decision to admit drives subsequent revisit, readmission, and mortality among older adult patients with diagnoses that are syndromic (falls and weakness) or lacking a clear standard of practice (syncope, UTI, pneumonia, or cellulitis). This question was difficult to answer since patients with different disposition decisions differ in their clinical severity, complexity, and needs. Without adjusting for these differences, unfair conclusions can be drawn if patients with different disposition decisions are directly compared. We thus used a causal inference methodology for observational data to measure the relationship between disposition decisions and outcomes for these older adult patients [34,35].

Methods

Data

ED visits were analyzed using electronic health records (EHRs) from a large Midwestern academic health system. The dataset used was from a common EHR system, and the analyzed population consisted of encounters with a specific large ED between January 1, 2014 and September 27, 2018. ED visits were included for older adult patients (65 years of age or older) with presentations for falls (n=1581), weakness (n=564), syncope (n=468), UTI (n=456), pneumonia (n=299), and cellulitis (n=223). For all 6 presentations, inclusion and exclusion criteria were specified to capture patients who, based on objective criteria present in the EHR occupied a “gray area” with regards to criteria for admission. In general, the strategy was to include patients who met diagnostic criteria for each presentation but did not have further abnormalities indicating a clear indication for admission present within discrete fields of the EHR. General inclusion criteria were an acuity level (emergency severity index; ESI) of 2 or 3, excluding visits assigned the most and least severe ESI levels; and treated and either admitted to the hospital or discharged to their residence, excluding patients who eloped, left against medical advice, or were transferred to another facility. General exclusion criteria were a missing disposition decision, a visit in the last 45 days of the sample period (as these patients had inadequate follow-up for outcomes), indicators of acute coronary syndromes (troponin levels >0.10 ng/mL), severe vital sign abnormalities at any point during the ED visit (systolic blood pressure <80 mmHg, respiration rate >30 BPM, pulse oximetry <88%, or heart rate >120 BPM), or a specific diagnosis that unambiguously required admission (ie, stroke, myocardial infarction, or femur fractures). In addition, patients presenting to the ED with a combination of cellulitis and a higher temperature than 100.3 F were eliminated from the analysis since these encounters had a high admission probability.

Variables

Seven variables represented baseline characteristics as follows: age, sex, insurance, history of diabetes, history of congestive heart failure, history of hypertension, and Centers for Medicare and Medicaid Services Hierarchical Condition Category (HCC) score [36]. HCC scores predict health care costs and outcomes by assigning risk weights to comorbidities based on ICD codes; higher scores indicate a greater predicted risk and resource use. These baseline characteristics were selected because they are available prior to the ED visit and can capture key clinical variations that could influence a patient’s ED visit and outcomes.

Five variables represented initial observations serving as a proxy for underlying latent health state at the start of the admission process: acuity, temperature, blood pressure, respiratory rate, and heart rate. Acuity was measured using the ESI level, a 5-level triage system where lower ESI levels (eg, 1 or 2) indicate higher acuity, meaning the patient requires more urgent care and significant resources. These proxy variables were included because they are available before the admission process begins and can be considered indirect (or “noisy”) measurements of the patient’s latent health state.

Two variables represented the admission process: treatment time (duration between when a patient is placed in an ED room after triage for treatment and when their admission decision is made) and admission decision. Patients discharged to a Skilled Nursing Facility or Inpatient Rehabilitation Facility were treated as a discharge.

Three primary outcome variables were considered: ED revisits, hospital readmission, and mortality within 30 days of being discharged from either the hospital for admitted patients or the ED for discharged patients. Binary variables for revisits indicated whether an individual returned to the study ED (based on EHR data) within 30 days of discharge. Similarly, binary variables for readmission and mortality indicated whether an individual was readmitted or died within 30 days of discharge,

respectively. Alternative windows (3 d and 9 d instead of 30 d) were also considered as secondary outcomes, since a short window is likely to capture only subsequent events related to the original ED visit, whereas a long window is likely to capture all subsequent events related to the original ED visit. To optimize this trade-off, a 9-day window has previously been recommended [37].

Missing continuous and categorical variables were imputed with the median and most frequent category, respectively. Continuous variables were standardized and these transformed variables were then used for estimation.

Analysis

Admission decisions were evaluated using 3 types of analyses: unadjusted, adjusted, and subgroup. Each type of analysis was repeated for each of the 3 primary outcomes, and for the overall sample and each presentation group. Unadjusted analyses involved estimating the observed (ie, unadjusted) difference in risk of an outcome between admitted patients and discharged patients. Wald 95% CIs were recovered.

Adjusted analyses, constituting our primary analyses, involved estimating these same risk differences (RDs) but adjusted for the unmeasured or latent health state in addition to measured variables (ie, baseline characteristics and proxy variables). These estimates were recovered by implementing a latent-variable approach for evaluating admission decisions (see Cochran et al [34] for details and applied in Alvarez Avendaño et al [35] to chest pain patients). Briefly, this approach involves modeling both the measured variables and a latent "health state" variable, and then fitting this model to data using expectation maximization, from which an estimate of the average treatment effect (ie, average difference in potential outcomes were we to admit vs discharge a patient) and Wald CIs can be recovered. The latent health state is included to account for potential unmeasured confounding between the admission decision and each outcome. More specifically, it accounts for confounding by indication, whereby admission decisions are based on factors not captured in the data. The inclusion of proxy variables, such as acuity and vitals, is crucial as they provide indirect measures of the latent health state, thereby strengthening the model's ability to mitigate confounding by indication.

The model comprised several regression components: logistic regression to model the latent health state as a function of baseline characteristics; logistic and linear regression to model the proxy variables (eg, acuity and vitals) as a function of latent health and baseline factors; threshold regression to model the admission process (decision and timing) as a function of latent health, baseline characteristics, and proxy variables; and linear regression to model each outcome based on latent health. Once model parameters are estimated, we calculate average treatment effects by comparing outcomes for each visit under hypothetical admission and discharge scenarios while holding all other variables at their original value. We then calculate the difference between these hypothetical outcomes and average this difference across all visits to obtain the overall treatment effect. For subgroup analyses, we recover subgroup-specific average treatment effects by averaging these hypothetical outcomes across only those visits with certain baseline characteristics (eg, female patients).

To check the sensitivity of our conclusions to various factors, several additional analyses were conducted. First, we checked sensitivity to 2 key assumptions for the latent-variable approach, which is that potential outcomes are independent of admission decisions with similar latent health needs and baseline characteristics and that events related to different ED visits are independent. Second, we analyzed the secondary outcomes, which use alternative time windows (3 days and 9 days instead of 30 days). Third, we estimated the same RDs as the main analyses, but only adjusted for the measured variables as opposed to both the measured variables and the latent health state. These estimates were recovered using the causal inference methods known as inverse probability weighting (IPW) and g-estimation.

Due to space considerations, sensitivity analyses are detailed in Multimedia Appendix 1. Importantly, estimates from checking violations to our 2 key assumptions were generally consistent in terms of direction and magnitude with the adjusted estimates reported in the main text, and estimates from IPW and g-estimation were similarly consistent with unadjusted estimates, with a few exceptions detailed in Multimedia Appendix 1. In addition, cellulitis had a small sample size (n=223) relative to other diagnostic groups, leading to imprecise estimates. Therefore, results for cellulitis are presented in Multimedia Appendix 1. Finally, subgroup analyses for individual diagnoses and technical details of all our adjusted analyses can also be found in Multimedia Appendix 1.

Significance was considered at an α level of 0.05. Hypothesis tests were 2-tailed Wald tests. Multiple comparisons were not adjusted for, and as such, nominal CIs and *P* values are reported.

Ethical Considerations

This study was reviewed by the UW Minimal Risk Research Institutional Review Board (ID 2024-0106-CP001) and was deemed to meet the federal criteria for exemption.

Results

Baseline Characteristics

Sample characteristics are summarized in Table 1. Patients were predominantly female (2102/3591, 58.5%) with Medicare insurance (1460/1589, 91.9%) and had an average age of 79 years. Patients were diagnosed with falls (1581/3591, 44%), weakness (564/3591, 16%), syncope (468/3591, 13%), UTI (456/3591, 13%), pneumonia (299/3591, 8%), and cellulitis (223/3591, 6%).

[a]UTI: urinary tract infection.

[b]HCC: hierarchical condition category.

Revisits

Table 2 summarizes the unadjusted RD between admission and discharge for 30-day revisits across all presentations and for individual presentations. Across all presentations, admission carried a significantly lower unadjusted risk than a discharge of 30-day revisits (RD=−5.2%, 95% CI −6.3 to −4.1). Individual presentations yielded unadjusted estimates that generally agreed with that of the entire sample, with 1 exception. For syncope

patients, admission carried a greater unadjusted risk than a discharge of 30-day revisits (RD=2.5%, 95% CI 0.0 to 5.0).

Table . Unadjusted and adjusted estimates (95% CI) of risk differences (RD) for 30-day revisits, comparing admission to discharge (reference). Adjusted estimates account for latent health state and measured variables.

	Unadjusted RD (95% CI)	Adjusted RD (95% CI)
All	−5.2 (−6.3 to −4.1)	−6.4 (−7.8 to −5.1)
Falls	−4.5 (−6.5 to −2.5)	−33.2 (−35.5 to −30.8)
Weakness	−8.8 (−11.6 to −6.0)	4.4 (−2.8 to 11.6)
Syncope	2.5 (0 to 5)	−38.6 (−43.2 to −34.1)
UTI[a]	−10.8 (−14.1 to −7.5)	−56.7 (−61.3 to −52.2)
Pneumonia	−3.0 (−7.6 to 1.7)	23.4 (18.7 to 28.1)

[a]UTI: urinary tract infection.

Table 2 also summarizes the estimated RDs, adjusted for latent health state and measured patient variables, between admission and discharge for 30-day revisits. Across all presentations, admission carried a significantly lower adjusted risk than a discharge of 30-day revisits (RD=−6.4%, 95% CI −7.8 to −5.0). Individual presentations yielded adjusted estimates that generally agreed with that of the entire sample, with the following exceptions. For patients with weakness, admission carried a numerically greater adjusted risk than a discharge of 30-day revisits (RD=4.4%, 95% CI −2.8 to 11.6). For patients with pneumonia, admission carried a significantly greater adjusted risk than a discharge of 30-day revisits (RD=23.4%, 95% CI 18.7 to 28.1).

Readmission

Table 3 summarizes the unadjusted RD between admission and discharge for 30-day readmissions across all diagnoses and for individual diagnoses. Across all diagnoses, admission carried a significantly greater unadjusted risk than a discharge of 30-day readmission (RD =14.8%, 95% CI 14.1 to 15.4). Individual diagnoses yielded unadjusted estimates that agreed in terms of direction, significance, and magnitude (within 3%) with that of the entire sample.

Table . Unadjusted and adjusted estimates (95% CI) of risk differences (RDs), in percentage points, for 30-day readmissions, comparing admission to discharge (reference). Adjusted estimates account for latent health state and measured variables.

	Unadjusted RD (95% CI)	Adjusted RD (95% CI)
All	14.8 (14.1 to 15.4)	5.8 (5.0 to 6.5)
Falls	15.0 (14.1 to 15.9)	3.2 (2.3 to 4.0)
Weakness	14.3 (12.6 to 16.0)	61.6 (57.7 to 65.5)
Syncope	12.8 (11.1 to 14.6)	4.9 (3.0 to 6.9)
UTI[a]	17.9 (15.6 to 20.2)	9.4 (6.8 to 12.1)
Pneumonia	12.9 (8.7 to 17.2)	25.8 (20.9 to 30.6)

[a]UTI: urinary tract infection.

Table 3 also summarizes estimated RDs, adjusted for latent health state and measured patient variables, between admission and discharge for 30-day readmissions. Across all diagnoses, admission carried a significantly greater adjusted risk than a discharge of 30-day readmission (RD=5.8%, 95% CI 5.0 to 6.5). Individual diagnoses yielded adjusted estimates in the same direction as that of the entire sample, but the magnitude was notably larger in a few cases. For patients with weakness, admission carried a greater adjusted risk than a discharge 30-day readmission (RD=61.6%, 95% CI 57.7 to 65.5). For patients with pneumonia, admission carried a significantly greater adjusted risk than a discharge of 30-day readmission (RD=25.8%, 95% CI [20.9, 30.6]).

Mortality

Table 4 summarizes the unadjusted RD between admission and discharge for 30-day mortality across all diagnoses and for individual diagnoses. Across all diagnoses, admission carried a significantly greater unadjusted risk than a discharge of 30-day mortality (RD=3.8%, 95% CI 3.3 to 4.3). Individual diagnoses yielded unadjusted estimates that agreed in terms of direction, significance, and magnitude (within 3%) with those of the entire sample.

Table . Unadjusted and adjusted estimates (95% CI) of risk differences (RDs), in percentage points, for 30-day mortality, comparing admission to discharge (reference). Adjusted estimates account for latent health state and measured patient variables.

	Unadjusted RD (95% CI)	Adjusted RD (95% CI)
All	3.8 (3.3 to 4.3)	1.0 (0.4 to 1.6)
Falls	2.8 (1.9 to 3.7)	−0.9 (−1.8 to 0.0)
Weakness	6.9 (5.3 to 8.5)	58.1 (54.1 to 62.0)
Syncope	2.4 (1.6 to 3.3)	−21.9 (−53.6 to 9.7)
UTI[a]	1.9 (0.7 to 3.1)	1.1 (−0.3 to 2.5)
Pneumonia	5.3 (1.4 to 9.2)	7.7 (4.4 to 11.0)

[a]UTI: urinary tract infection.

Table 4 also summarizes estimated RDs, adjusted for latent health state and measured patient variables, between admission and discharge for 30-day mortality. Across all diagnoses, admission carried a significantly greater adjusted risk than a discharge of 30-day mortality (RD=1.0%, 95% CI 0.4 to 1.6). Individual diagnoses yielded adjusted estimates differing from that of the entire sample in several meaningful ways.

Reporting from high to low, admission for patients with weakness carried a significantly greater adjusted risk than a discharge of 30-day mortality (RD=58.1%, 95% CI 54.1 to 62.0). For patients with pneumonia, admission also carried a significantly adjusted risk than a discharge of 30-day mortality (RD=7.7%, 95% CI 4.4 to 11.0). For patients with UTI, admission carried a numerically greater adjusted risk than a discharge of 30-day mortality (RD=1.1%, 95% CI −0.3 to 2.5). For patients with syncope, admission carried a numerically lower adjusted risk of 30-day mortality (RD=−21.9%, 95% CI −53.6 to 9.7). For patients with falls, admission carried a lower adjusted risk than a discharge of 30-day mortality (RD=−0.9%, 95% CI −1.8 to 0.0).

Subgroup Analyses

Table 5 summarizes subgroup-specific estimates of RDs, adjusted for latent health state and measured patient variables, between admission and discharge for 30-day outcomes. All subgroup estimates had the same direction as that of the entire sample: negative for 30-day revisits and positive for 30-day readmission and mortality. For all 30-day outcomes, 5 subgroups had numerically greater adjusted estimates than that of the entire sample. These subgroups (in decreasing order of prominence) were individuals with congenital heart disease, individuals with diabetes, individuals with HCC scores greater than the mean score of 1.65, individuals greater than the mean age of 79.2 years, and individuals with hypertension. Of note, all these subgroups tend to have worse baseline health than their counterpart. The subgroup with the numerically lowest adjusted estimate for all 30-day outcomes was individuals with insurance other than Medicare.

Table . Subgroup-specific adjusted estimates (95% CI) of risk differences, in percentage points, for 30-day outcomes, comparing admission to discharge (reference). Adjusted estimates account for latent health state and measured patient variables.

Variable and subgroup	Revisit	Readmission	Mortality
Age (years)			
65 - 79.2	−7.2 (−8.7 to −5.6)	5.4 (4.7 to 6.2)	0.9 (0.2 to 1.5)
>79.2	−5.6 (−7.0 to −4.1)	6.1 (5.3 to 7.0)	1.2 (0.6 to 1.9)
Sex			
Male	−6.5 (−8.0 to −4.9)	5.8 (5.0 to 6.6)	1.0 (0.4 to 1.7)
Female	−6.4 (−7.9 to −5.0)	5.8 (5.0 to 6.6)	1.0 (0.4 to 1.7)
Insurance			
Medicare	−6.2 (−7.6 to −4.9)	5.8 (5.1 to 6.6)	1.1 (0.5 to 1.7)
Other	−8.5 (−10.8 to −6.3)	4.9 (3.9 to 5.9)	0.6 (−0.2 to 1.3)
Diabetes			
No	−6.8 (−8.2 to −5.4)	5.6 (4.9 to 6.4)	0.9 (0.3 to 1.6)
Yes	−5.0 (−6.7 to −3.2)	6.4 (5.4 to 7.4)	1.4 (0.7 to 2.1)
Congenital heart failure			
No	−7.0 (−8.4 to −5.6)	5.5 (4.8 to 6.2)	0.9 (0.3 to 1.5)
Yes	−1.8 (−3.9 to 0.3)	7.8 (6.6 to 9.0)	2.1 (1.3 to 2.9)
Hypertension			
No	−6.9 (−8.4 to −5.4)	5.6 (4.8 to 6.3)	0.9 (0.3 to 1.5)
Yes	−6.1 (−7.5 to −4.6)	5.9 (5.1 to 6.7)	1.1 (0.5 to 1.7)
Hierarchical condition category			
≤1.65	−7.4 (−8.8 to −6.0)	5.3 (4.6 to 6.1)	0.8 (0.2 to 1.4)
>1.65	−4.7 (−6.2 to −3.2)	6.5 (5.6 to 7.4)	1.4 (0.8 to 2.1)

Discussion

Principal Findings

Our goal was to investigate the impact of admitting older adult patients with 6 common but variably managed ED presentations: falls, weakness, syncope, UTI, pneumonia, and cellulitis. In particular, these conditions show considerable variability in admission practices, and understanding their specific outcomes can help clinicians better determine when admission is beneficial or potentially harmful. Using causal inference methods, we analyzed EHR data to compare outcomes such as ED revisits, hospital readmissions, and mortality, measuring these outcomes at 3, 9, and 30 days after discharge. By focusing on this “gray area” where no standard practice exists, we wanted to provide insights that support more consistent and evidence-based admission decisions for these presentations.

Our primary finding is that admission was associated with a significant decrease in the risk of an ED revisit, but with a significant increase in the risk of hospital readmission and mortality. The association with an increased readmission risk was consistent for all individual diagnoses, for all time frames, and for all estimation approaches (unadjusted, IPW, g-estimation, and latent variable as the primary analysis). The associations with a decreased revisit risk and with an increased mortality risk were generally consistent for individual diagnoses, all time frames, and all approaches, with a few exceptions discussed below. These results would suggest that while admission may help prevent immediate returns to the ED, it could lead to worse long-term outcomes for certain patients. This balance of risks highlights the importance of carefully weighing the short-term benefits of admission against the potential for readmission and mortality, especially in older adults with these conditions.

In our primary analysis, admission was associated with an increased revisit risk for patients with weakness and pneumonia, along with a notably higher readmission and mortality risk for these conditions compared with others. This suggests that patients with weakness or pneumonia may be especially vulnerable to poor outcomes from admission. In contrast, admission was associated with a numerically lower 30-day mortality risk for patients with falls or syncope, indicating that these individuals may benefit more from being admitted. These findings can help guide clinicians in prioritizing which patients may require closer monitoring, alternative care options, or potential admission.

Our subgroup analysis identified patient factors that may influence outcomes from hospital admission. Overall, admission appears less favorable for older individuals (>79 years) and those with comorbidities (ie, congenital heart disease, diabetes, high HCC scores, or hypertension). Important factors for

admission, however, may vary by specific presentation, as shown in our subgroup analysis in Multimedia Appendix 1. Despite these differences, we found consistent trends across subgroups, suggesting that standardized admission recommendations could potentially be based on the type of presentation alone, rather than on patient-specific factors like age, sex, insurance, or comorbidity.

For comparison, another study examined the impact of admitting older adult patients presenting to the ED with chest pain, another presentation with variable admission practices, and found that admission had a lower readmission risk but an increased mortality risk [35]. This study similarly estimated an increased mortality risk, yet it also found an increase in readmission risk for almost all presentations. The association of admission with both increased and decreased risks for revisits, readmission, and mortality, underscores why standardized care pathways are lacking for these presentations [21]. While our results suggest that, in general, discharge may be associated with lower readmission and mortality risks, discharging an older adult can still carry significant risks. These findings support the need for safe alternatives to hospitalization, such as outpatient care coordination or at-home ambulatory providers [38]. Such alternatives have been shown to effectively reduce hospital readmission rates on older adult patients discharged from the ED [39,40].

Limitations

A primary limitation of this study is the potential for unmeasured confounding, especially confounding by indication, where treatment decisions are influenced by clinical indicators not fully captured in the EHR. This limitation is significant because it directly impacts our ability to interpret the findings causally. Although we used multiple methods, including a latent variable approach to account for unobserved health status [34], no method can fully guarantee that all confounding is addressed. Consequently, our findings remain subject to potential bias if residual confounding exists. This is particularly relevant for interpreting the effect of admission on outcomes, as patients who are “sicker” based on unmeasured factors are more likely to be admitted, and these same factors could drive poor outcomes. While the latent variable approach yielded estimates generally more favorable to admission—suggesting some adjustment for underlying severity—and results were consistent across different time frames and presentations, caution is warranted in interpreting these effects as causal. This limitation highlights the need for further research to strengthen the causal inference of admission effects on outcomes.

In addition, this was a retrospective, observational study conducted using EHR data from an academic ED in the US Midwest, thereby limiting the generalizability of our findings. Moreover, the resulting patient population for specific presentations after applying our filters was relatively small, leading to nonsignificant estimates. Replicating this analysis in different EDs with larger samples is needed.

Conclusions

This study is one of the few to quantify the risks and benefits associated with admission decisions for ED presentations associated with unclear need for hospitalization. Existing studies have mainly focused on identifying factors that influence hospital admission of noncritically ill patients, often through physician surveys [41] or identifying risk patterns [33,42,43]. This study is intended to quantify the trade-offs of admission at a population level rather than directly influencing bedside decisions. Our findings indicate that admission is not always the “safe” choice, underscoring the need for further research to establish specific criteria that can better guide admission decisions for older adults in the ED.

Abstract

Background: Researchers in Nova Scotia and Ontario, Canada, implemented a passive remote monitoring (PRM) model of home care unique to their health system contexts. Each PRM model integrated tailored PRM devices (eg, motion sensors, cameras, and door alarms) into home care patients' residences with the aim of linking patients, family and friend caregivers, and health care providers to support older adults' aging in place.

Objective: The purpose of this study was to examine the use of PRM technologies in the home to support older adults' safe aging in place and avoidance or delay of higher levels of care.

Methods: This multiprovincial pragmatic randomized controlled trial examined how PRM technologies support older adults to safely remain in their home and avoid or delay admission to higher levels of care. Pairs of home care patients and their family and friend caregivers were recruited in Ontario and Nova Scotia. Participant pairs were randomly assigned to one of two conditions: (1) standard home care (ie, control) or (2) standard home care plus study-provided PRM (ie, intervention). Participants provided their provincial health insurance numbers to link with provincial health administrative databases and identify if patients were admitted to higher levels of care after 1 year. Cox proportional hazards models were used to evaluate the primary outcome in each province.

Results: In total, 313 patient-caregiver pairs were recruited: 174 pairs in Ontario (intervention: n=60; control: n=114) and 139 pairs in Nova Scotia (intervention: n=45; control: n=94). Results indicate PRM was associated with a nonsignificant 30% reduction in risk of patients being admitted to higher levels of care in Ontario (hazard ratio 0.7, 95% CI 0.3-1.4) and no reduction in risk in Nova Scotia (hazard ratio 1.1, 95% CI 0.3-3.7). Adjusting for patient sex had no impact on model estimates for either province.

Conclusions: Limitations related, in part, to the impact of the COVID-19 pandemic may have contributed to the effectiveness of the intervention. While our study did not yield statistically significant results (P=.30 and P=.90) regarding the effectiveness of the PRM model in prolonging home stays, the observed trends suggest that technology-assisted aging in place may be a valuable

goal for older adults. Further study is required to understand if longer follow-up time allows more effects of PRM on patients' avoidance of higher levels of care to be detected.

KEYWORDS

remote monitoring technology; home care; health service use; aging in place

Introduction

Creative and effective ways to meet the health care needs of an aging population, often related to the high prevalence of chronic disease, are complicated by a strained health care work force, competing economic priorities, and evolving health information. Yet, these challenges create opportunities to reimagine how health care systems can provide Canadians with the right care, at the right time, in the right place. Although older adults may experience significant chronic disease that may challenge their ability to live independently, most older adults want to remain at home [1,2]. This sentiment was underscored by the findings of a recent survey where 85% of Canadian adults and 96% of Canadians aged ≥65 years reported that they would do everything they can to avoid institutionalization in a long-term care (LTC) setting [2,3]. Home care services that are appropriately managed and integrated into the health care system support older adults to successfully age at home, can improve the health and well-being of older adults and their families, and reduce costs of care in hospitals and LTC facilities [2,4]. However, in Canada, beyond the challenges previously noted, the provision of publicly funded home care services is limited and home care providers are increasingly unable to meet existing demands for home care service needs [2,4-6]. In fact, approximately 75% of home care support for older Canadians is provided *supposedly for free* by an unpaid family and friend caregiver [2,7], creating enhanced personal risk of physical health problems, stress, burnout, and depression [2,8].

A noted challenge of caring for older adults at home is providing suitable home care services and ensuring that older adults can safely follow established treatment plans. Common adverse events among older adults at home (eg, medication administration errors and falls) have been associated with increased use of health services, disability, and death [9,10]. Furthermore, many older adults have complex health needs, and the home care service gaps for older adults with complex care needs are further magnified by limited health human resources, access to partial home care services, a lack of direct support for or involvement of caregivers, and a lack of innovative strategies to expand home care [2,5]. These challenges highlight the urgency to develop more effective and respectful home care options for older adults.

A plausible intervention to address these home care challenges is the implementation of active and passive remote monitoring (PRM) technologies to support older adults to remain in their homes [11]. Active monitoring applications require individual participation, such as pushing a button on a wearable device (eg, pendant or bracelet), while passive monitoring technologies, such as motion sensors, do not require any action by the individual for the system to work. Remote monitoring is useful for tracking the behaviors of older adults with cognitive decline (eg, forgetting to take medications) and intervening quickly in the case of adverse events, such as falls. It also increases individuals' confidence in their ability to care for themselves and live independently at home [11,12]. These technologies can also benefit older adults living at home and their caregivers by increasing communication and collaboration among people in their circle of care and by enabling big data analytics that can contribute to improving health care delivery practices [11,12]. While there is emerging evidence around the value of monitoring technologies to support older adults at home, there is limited insight into the outcomes of PRM, the preferences of older adults and their caregivers, and the costs and benefits associated with the wide variety of remote monitoring technologies available.

The purpose of this study was to examine the use of PRM technologies in the home to support older adults with complex care needs to safely remain in their home and avoid or delay admission to higher levels of care, such as long-term hospitalization and LTC. We evaluated a technology-enabled remote monitoring model of home care conceptually informed by the principles of person-centered care, family as a client, supported self-management, and stakeholder collaboration, to address gaps in home care for older adults. Supportive self-management speaks to the extended health care responsibilities taken up by older adults and their caregivers that create care work. Supportive self-management within home care would include both clinical (eg, medication administration, symptom monitoring, and care coordination) and nonclinical (eg, homemaking, meal preparation, supportive housing, daily check-ins, transportation, and a 24/7 helpline) funded services [13,14]. In this model of care, family was conceptualized as the patient or client receiving home care services *and* their caregiver. Typically, caregivers play an integral role as part of the care team to support older adults in the home; health care assessments remain largely focused on the needs of the older adult with relatively marginal inquiry into caregiver health and well-being [13,14]. The primary focus of this study was to investigate the impact of the PRM model of home care on older adult home care recipients with a secondary focus on assessing the impact of PRM on caregivers' health and well-being. Reported here are our findings as to whether PRM along with usual home care supported older adults with complex care needs to safely remain in their home longer and delay or avoid admission to higher levels of care (ie, hospitalization and LTC)

when compared with older adults receiving usual home care alone.

Methods

Overview

This study was informed by the findings of previous pilot studies conducted in the Canadian provinces of Alberta, British Columbia, New Brunswick, and Nova Scotia [15,16]. The primary outcome of this study was to support older adults with complex care needs to safely remain in their home and avoid or delay admission to higher levels of care, such as long-term hospitalization and LTC. This outcome was operationalized among complex care older adult home care recipients as the occurrence of and time to the following events: terminal admission to the hospital awaiting admission to LTC and direct admission to LTC. The secondary outcomes were an assessment of health service use and mortality rates of home care recipients within 1 year of trial enrollment. A complete description of the study's methodology is reported elsewhere [17] and is summarized in the subsequent sections.

Study Design

This study was an unblinded pragmatic randomized controlled trial (PRCT) [18,19] with 2 parallel arms in two Canadian provincial sites: (1) Central, Western, and Northern Zones in Nova Scotia and (2) the South West Region in Ontario. PRCTs are well-suited to supporting decision-making around complex interventions tested in the *real world* in comparison to usual forms of care [20,21]. As PRCTs are meant to capture real-world situations and the experiences of individuals, broad inclusion criteria developed in collaboration with regional health care partners were purposely selected for this study (see Textbox 1 for the full criteria). For this study, participants were recruited in home care client-caregiver dyads because the PRM requires that older adults have a family caregiver who is willing to receive system notifications. This PRCT is registered with the ISRCTN (registration 79884651).

Textbox 1. Participant eligibility.

Participant group and inclusion criteria (eligible if all criteria are met)

- Home care clients
- Adult who is aged ≥65 years
- Requires home care and is at risk for higher levels of care as determined by the home care provider who makes these decisions
- Has a caregiver who is willing and able to receive the remote monitoring sensor notifications using a cell phone or a regular phone (ie, landline)
- Able to read and write in English or French
- Has the decisional capacity to consent or have a substitute decision-maker to consent for participation
- Caregivers
- Adult who is aged ≥18 years
- Is a caregiver to an adult who is aged ≥65 years that requires home care services and is assessed by home care service providers to be at risk for higher levels of care
- Can be a spouse, partner, child, sibling, other family relation, or friend who helps care for the patient at home
- Willing and able to receive the remote monitoring sensor notifications using a cell phone or a regular phone (ie, landline)
- Able to read and write in either English or French
- Has the decisional capacity to consent for participation

Recruitment

The participant sample size was determined using information from one health region regarding the time to higher levels of care for older adults who previously required complex home care. The sample size calculation was based on the following criteria: total institutionalization proportion among controls being 0.41, and the proportion for the experimental participants being 0.27 (a 34% reduction compared with controls); a 10% attrition rate due to dropout or loss to follow-up; a power of 80%; and a statistical significance level of α=.05. This resulted in a total target sample size of 160 home care clients (and paired caregivers) for the intervention group and 320 home care clients (and paired caregivers) in the control group for a total study sample size of 480 home care clients and 480 caregivers across the Ontario and Nova Scotia study sites. The required sample was estimated based on a prospective test of independence (continuity-corrected chi-square statistic test) between the experimental and control groups using 2 controls per intervention case to increase the study's power due to the cost of the intervention [22].

Participant recruitment occurred from April 2017 through January 2020 and was supported by the respective provincial regional authorities. Assessors and care coordinators employed at the health service provider that assesses and facilitates home care services in each region identified potential study participants (ie, clients) based on the study inclusion criteria (Textbox 1). The home care clients may have been on the assessors and care coordinators' case load for up to 6 months before being contacted about the study. Care coordinators provided information about the study to potential study participants and their family and friend caregivers and requested permission to provide their names and contact information to

the study research coordinator. Research staff contacted potential participants who agreed to have their contact information disclosed to arrange an appointment (in person or by telephone) to provide more information about the study. If both the home care client and family and friend caregiver met the eligibility criteria and verbally agreed to participate, the research staff scheduled an in-home meeting with the pair to obtain written consent and complete the baseline data collection forms (detailed in the *Data Collection* section).

Randomization

With participants' consent, baseline data were collected before random allocation into control or intervention groups. A block randomization process was used after every 3 pairs of participants were recruited [23] to randomly assign pairs in a 2:1 ratio to usual home care (ie, control group) or to usual home care plus study-provided PRM (ie, intervention group). This process was carried out independently in each province by members of the research team. Allocation bias was addressed through allocation concealment, and neither the home care case coordinator nor the researchers knew which group the participant would be assigned before baseline data collection. Following randomization research staff contacted each participant pair to inform them of their study arm. For intervention participants, research staff also forwarded their contact information to the technology provider to schedule an installation date.

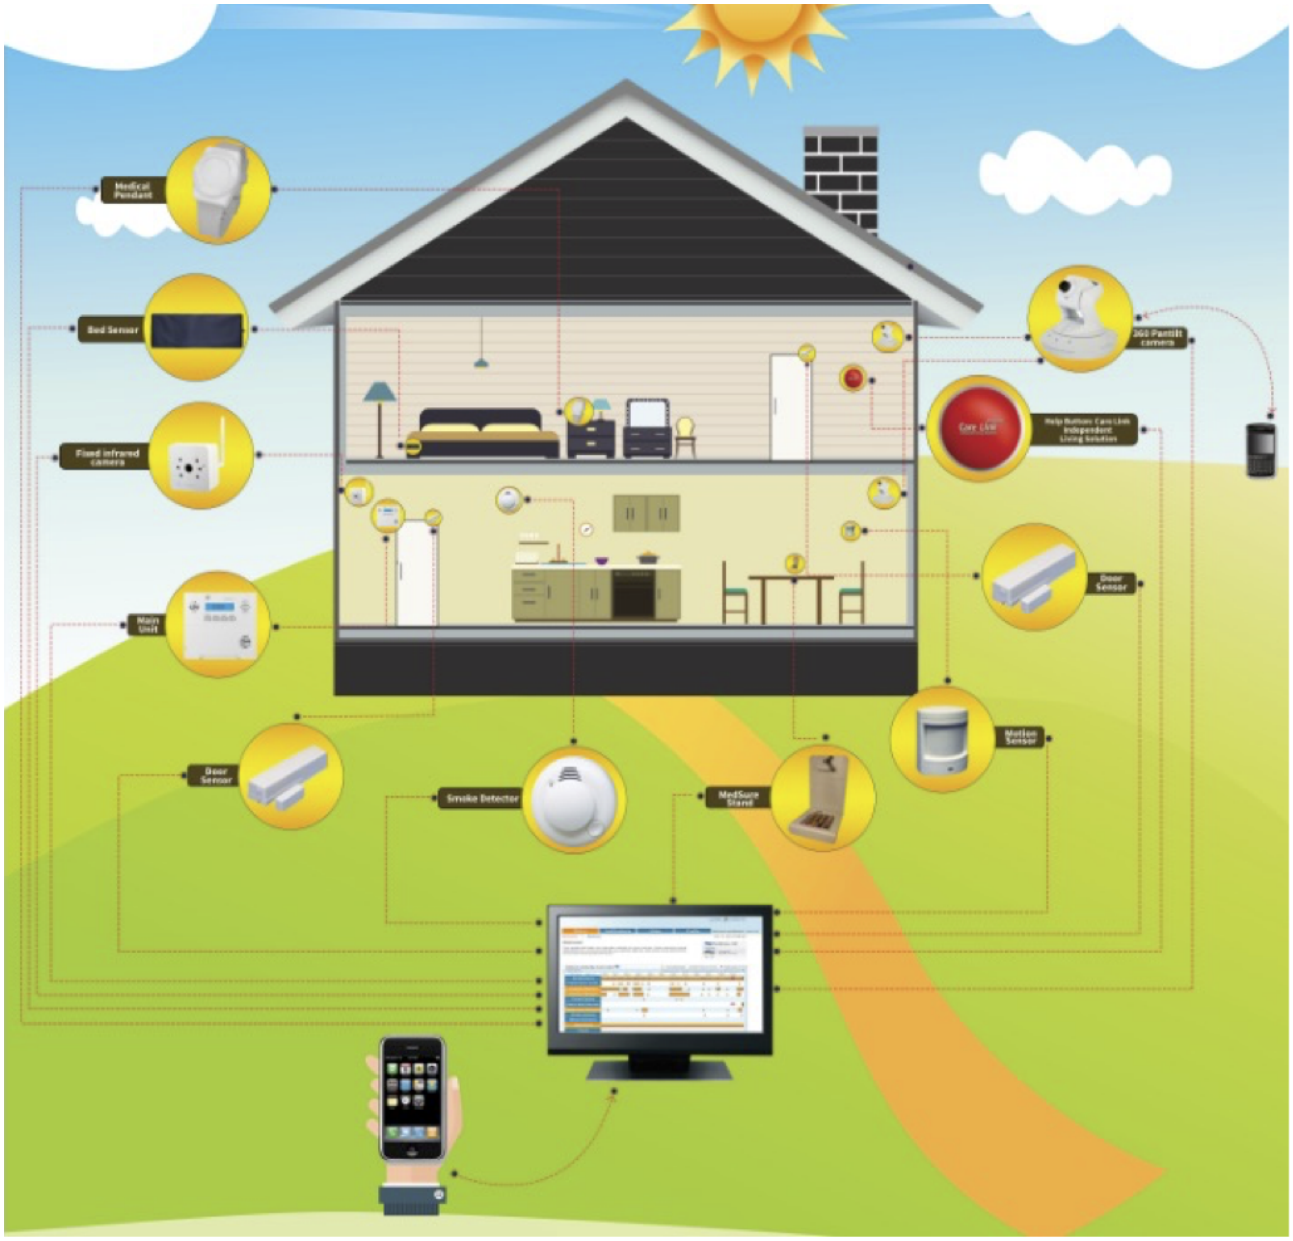
Control Group

Participants received their usual publicly funded home care services provided by their provincial or regional health care authority; some participants also purchased privately funded home care services to supplement the publicly funded services received. These services included home visits by assistive personnel for activities of daily living, nursing care, and other supports deemed necessary by the home care case coordinator or case manager. Home care assessments were conducted as usual by the regional authority case coordinator or case manager. Once the assessment was completed and care services were decided, services were provided by a contracted home care agency.

Intervention Group

Participants received their usual home care services (described earlier) and PRM systems provided and funded by the study technology partner. Once enrolled in the study, the technology partner visited the clients and their caregiver. Participants received written and verbal overviews of the PRM options. Each PRM system installed was tailored to meet the needs and preferences of both the home care client and their caregiver. PRM system options included a combination of long-life battery–powered sensors including motion sensors; Wi-Fi–enabled cameras; fall alert pendants or bracelets; contact sensors for internal or external doors, cupboards, and refrigerators; pressure mats that could be placed at the base of a toilet, under a mattress, or on a chair; and a medication sensor system. Each PRM system had a main panel that was connected to a phone jack installed in the home care client's residence. The main panel received the signals from each sensor and sent them to a secured server to be transmitted back to the authorized recipient (eg, a caregiver) via a cellular signal or broadband module (Global System for Mobile Communications radio). The PRM systems only required internet access to transmit Wi-Fi-camera data. See Figure 1 for an example of how a PRM system used in this study could be set up.

Figure 1. Example of a passive remote monitoring system setup.



The role of the caregiver was key to the successful implementation of the PRM intervention. In addition to an array of sensors, the technology partner, in consultation with the home care client and caregiver, configured each PRM system to provide home care clients and their caregivers with a range of alerts for atypical events tailored to their situation. Examples of alerts include reminders for clients to take their medication; the ability for caregivers to monitor medication use; home care client movement patterns within the home or when leaving the home; fall emergencies; abnormal eating patterns; and abnormal length of time in bed, on a chair, or in a toilet. Notifications of atypical events were sent to the caregiver via email, SMS text message, or phone call. Notably, notifications of home care clients' atypical behaviors were not directly transmitted to a health care provider; rather, health care providers were notified at the discretion of the caregiver and in collaboration with the home care client, as appropriate. Possible caregiver actions based on notifications could include a telephone call to check on the client's safety, deploying assistive home care supports, checking the video (if cameras are present), taking the client to seek medical attention, or emergency action such as calling an ambulance. The technology partner provided education (written and verbal) to the home care clients and caregivers about PRM sensors and the types of alerts; the technology provider technician communicated any changes to the sensor system within the home with the research staff.

The intervention was provided to participants for 12 months during the study. After this time, the home care client was transitioned to usual care if they did not wish to retain their PRM system at a reduced cost.

Data Collection

Data Collection Window

Data collection aligned with the rolling recruitment of participants (see the *Recruitment* section) and lasted from April 2017 to February 2021. Paper format surveys comprised of standardized and researcher-developed tools were used to collect

data from participant pairs three times over the course of a 12-month period: (1) at the point of recruitment when consent was obtained (ie, baseline), (2) 6 months following recruitment, and (3) 12 months following recruitment. Data were collected in person at the home care client's home at baseline and by telephone or in person at the client's home for the 6-month and 12-month follow-ups. Home care clients and caregivers were interviewed separately where possible.

Survey

Both home care clients and caregivers completed a survey consisting of validated questionnaires and researcher-developed questions to provide demographic information (eg, date of birth, education, sex, marital status, and household income); provincial health insurance numbers (used for data linkage to provincial administrative health databases); feelings of home care clients' safety in their home; appraisals of home care quality; and satisfaction with and impact of PRM on both client and caregiver well-being (asked to the intervention group only). Additional researcher-developed items were asked of caregivers to understand their life satisfaction, self-rated mental health, and daily stress.

Home care clients completed standardized tools to assess their quality of life [24], Hospital Admission Risk Profile score, cognitive capacity (Mini-Mental State Exam) [25], and independent activities of daily living [26]. Caregivers also responded to standardized tools to assess their caregiving context, experiences, and information needs [27,28]; caregiver burden [29]; the home care client's abilities to complete independent activities of daily living (a part of the Hospital Admission Risk Profile) [26]; positive aspects of caregiving [30]; presenteeism at work [31]; and the financial impact of caregiving [32].

Impact of the COVID-19 Pandemic on Data Collection

The onset of the COVID-19 pandemic response in March 2020 occurred during the data collection period. Research staff adhered to all public health guidelines for risk mitigation and collected data entirely by phone during this period. Changes to health care service delivery models and stay-at-home orders in Ontario and Nova Scotia altered how these participants (1) could access and use health care services and (2) interacted with their participant partner (ie, the other half of the client-caregiver dyad). Participants' adherence to public health stay-at-home orders resulted in behaviors (eg, hesitancy to engage with acute and LTC services) that completely conflicted with and was contrary to our research outcome creating significant bias within the proportion of participants' data collected after March 2020. In consultation with epidemiologists and statisticians, a decision was made to control for the effects of the pandemic response, and participant pairs were only included for analysis if all study activities were completed before March 2020.

Administrative Data Linkage

Overview

Participants were enrolled between April 11, 2017, and January 15, 2020, in Ontario and between November 29, 2017, and December 16, 2019, in Nova Scotia. To determine the impact of the intervention on the primary study outcomes, the data collected by the research team (herein referred to as the PRCT database) was linked to health administrative databases held at the Institute for Clinical Evaluative Sciences (ICES; Ontario) and Health Data Nova Scotia (HDNS; Nova Scotia).

ICES is an independent, nonprofit research institute funded by an annual grant from the Ontario Ministry of Health and the Ministry of Long-Term Care. As a prescribed entity under Ontario's privacy legislation, ICES is authorized to collect and use health care data for the purposes of health system analysis, evaluation, and decision support. Secure access to these data is governed by policies and procedures that are approved by the Information and Privacy Commissioner of Ontario.

HDNS is a similar institution to ICES. It is a data repository based in the Faculty of Medicine, Department of Community Health and Epidemiology at Dalhousie University, that is focused on supporting data-driven research for researchers in Nova Scotia. HDNS facilitates research and innovation in Nova Scotia by providing access to linkable administrative health data and analysis for research and health service assessment purposes in a secure, controlled environment, while respecting the privacy and confidentiality of Nova Scotians.

Data Sources

We used the PRCT database to identify patient and caregiver participants, including measures of risk that the patient had to alternate levels of care and hospital admission and measures of burden on caregivers. Health administrative databases in both Ontario and Nova Scotia were used to determine other baseline characteristics and outcomes and identify participant data, as follows:

1. Demographic and geographic information as recorded in administrative data
2. Preexisting comorbidities (using validated algorithms)
3. Previous emergency department visits
4. Previous surgeries
5. Previous outpatient, primary care, and specialist visits and follow-up LTC claims
6. Previous prescription use and follow-up LTC
7. Previous home care services
8. Previous and follow-up hospital admissions
9. International classification of diseases diagnosis codes—version 10 and Ontario health insurance plan diagnosis codes.

In Ontario, datasets were linked using unique encoded identifiers and analyzed at ICES. In Nova Scotia, the databases were matched whenever possible. When databases could not be matched, HDNS used alternate databases with similar data to approximate what was done in Ontario. For a complete listing of all databases used, see Table 1.

Table 1. Databases used by the Institute for Clinical Evaluative Sciences (ICES) and Health Data Nova Scotia (HDNS) to support analysis.

Characteristics	ICES databases (Ontario)	HDNS databases (Nova Scotia)

Primary Outcome

The primary outcome of interest was to support older adults with complex care needs to safely remain in their home and avoid or delay admission to higher levels of care, such as long-term hospitalization and LTC. The primary outcome was defined as time to a client's inability to return home given the need for LTC or hospital admission under an alternative level of care designation within 1 year of enrollment in the trial. This was ultimately determined by the most responsible provider. The secondary outcome of health service use and mortality was assessed to confirm similar mortality rates within 1 year of enrollment in the trial. Clients were followed up to 1 year until February 28, 2020, to control for the impact of the COVID-19 pandemic. Participants enrolled before February 28, 2019, were included to ensure 1 year of follow-up before the COVID-19 pandemic.

Data Analysis

Baseline characteristics were summarized using descriptive statistics: continuous variables as means and SDs and categorical variables as proportions. Baseline characteristics between the control and intervention participants were examined to verify successful randomization using standardized differences that when greater than 0.1, indicates a potentially meaningful difference [33]. In accordance with ICES and HDNS privacy policies, cell sizes less than or equal to 5 were not reported.

A Cox proportional hazards model was used to evaluate our primary outcome of unable to return home, censoring on mortality and 1 year after enrollment, and our secondary outcome of mortality, only censoring on 1 year after enrollment. Hazard ratios (HRs) with 95% CI were reported. Proportional hazards were assessed using interaction with time terms, and no violations were observed.

Subgroup analyses compared health care use 1 year before and after enrollment for home care clients to determine what effect the intervention had on participants' use of the health care system. For the subgroup analysis, a paired analysis was conducted using the McNemar test for proportions and the Wilcoxon signed rank test for means to compare differences in health care use 1 year before and after enrollment in both patients (Ontario: n=108; Nova Scotia: n=105) and caregivers (Ontario: n=104; Nova Scotia: n=101). All analyses were conducted using SAS (version 9.4; SAS Institute). A statistical significance was defined as a 2-tailed α value less than .05.

Ethical Considerations

This study was approved by the Research Ethics Board at Western University (registration IRB 00000940) and at Nova Scotia Health (registration IRB 102203). All participants

provided written informed consent and could withdraw from the study at any time without penalty. All data were deidentified and assigned a study ID number to support data linkages throughout data collection and analyses. Participants received no compensation to complete the study; intervention group participants received the PRM systems at no personal expense.

Results

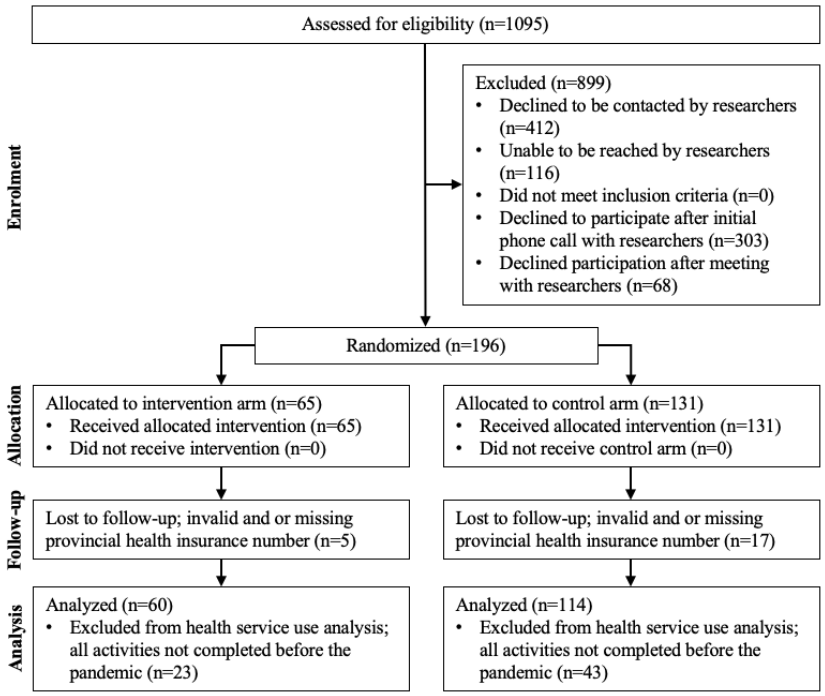
Due to challenges joining administrative patient data—such as data collected as part of this study—across provincial jurisdictions, a single analysis was not possible. The following sections present the results of the separate analyses conducted by ICES in Ontario and HDNS in Nova Scotia to address this study's research question.

Participant Characteristics

Ontario Cohort

The total Ontario cohort comprised 339 participants (home care clients: n=174; caregivers: n=165). In total, 196 home care clients were enrolled in Ontario from April 11, 2017, to January 15, 2020, of which 22 were excluded due to invalid or missing health card numbers, leaving 174 home care clients to be included in analysis. We were able to link 165 caregivers to the home care clients. In Ontario, 116 participants (home care clients: n=60; caregivers: n=56) included in this analysis received the study-provided PRM intervention plus their normal home care and 223 participants (home care clients: n=114; caregivers: n=109) received their normal home care without PRM. Figure 2 provides the randomization and analysis study flow diagram for the Ontario home care client cohort.

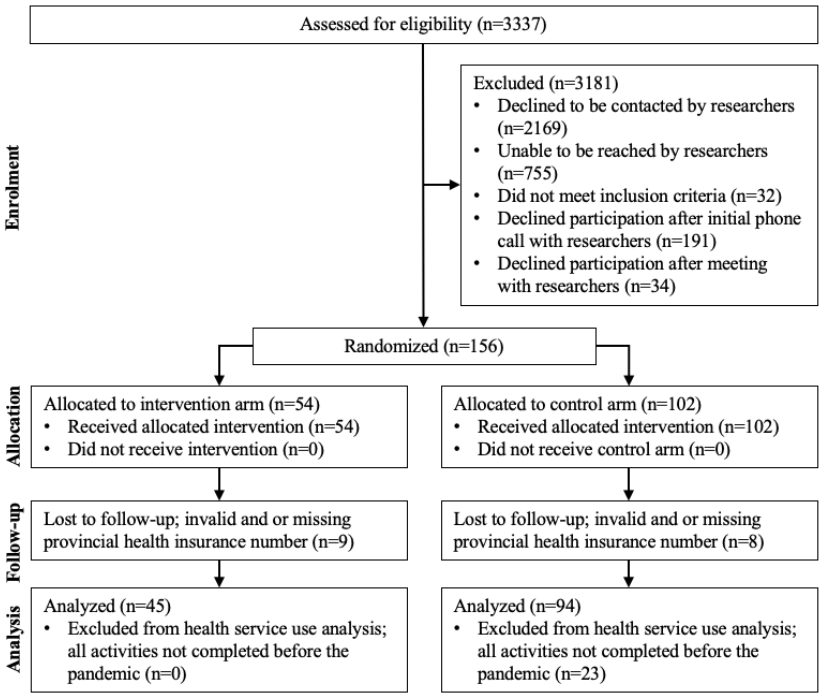
Figure 2. Ontario home care client cohort randomization and analysis flow diagram.



Nova Scotia Cohort

The total Nova Scotia cohort comprised 273 participants (home care clients: n=139; caregivers: n=134). In total, 156 home care clients were enrolled in Nova Scotia from November 29, 2017, to December 16, 2019, of which 17 were excluded due to invalid or missing health card numbers, leaving 139 home care clients to be included in the analysis. We were able to link 134 caregivers to the home care clients. In Nova Scotia, 92 participants (home care clients: n=45; caregivers: n=47) included in this analysis received the study-provided PRM intervention plus their normal home care and 181 participants (home care clients: n=94; caregivers: n=87) received their normal home care without PRM. Figure 3 provides the randomization and analysis study flow diagram for the Nova Scotia home care client cohort.

Figure 3. Nova Scotia home care client cohort randomization and analysis flow diagram.



Home Care Clients

Ontario Home Care Clients

In Ontario, there were no significant differences between home care clients in intervention and control groups at baseline on any of the demographic characteristics evaluated (all $P>.05$). At baseline, Ontario home care clients were on average aged 78 (SD 6.9) years. There was a higher proportion of male participants in the intervention group (40/60, 67%) compared with the control group (57/114, 50%). Most home care clients (125/174, 73%) resided in midsize urban centers. Approximately 20% (35/174) of home care clients resided in the lowest-income neighborhoods (quintile 1), while about 15% (26/174) resided in the highest-income neighborhoods. Most Ontario home care clients (109/174, 63%) lived with their spouse. Nearly all Ontario home care clients (>106/174, >90%) were at medium or high risk of hospitalization. Ontario home care clients had a variety of chronic disease comorbidities, most notably hypertension (144/174, approximately 83%), diabetes (95/174, approximately 55%), and dementia (67/174, approximately 40%). Complete home care client baseline characteristics are presented in Table 2.

Table 2. Ontario and Nova Scotia home care client baseline characteristics.

Nova Scotia Home Care Clients

In Nova Scotia, there were no significant differences between home care clients in intervention and control groups at baseline on any of the demographic characteristics evaluated (all *P*>.05). In Nova Scotia, home care clients were on average 81 (SD 7.5) years of age. At baseline, there was a higher proportion of male participants in the control group (32/94, 34%) compared with the intervention group (12/45, 27%). Most Nova Scotia home care clients (101/139, 75%) resided in midsize urban centers. Approximately 20% (25/139) resided in the lowest-income neighborhoods, while approximately 15% (23/139) resided in the highest-income neighborhoods. The majority of Nova Scotia home care clients (85/139, approximately 60%) lived alone. Nearly all home care clients (>114/139, >90%) were at a medium or high risk of hospitalization. The Nova Scotia home care clients also had a variety of chronic disease comorbidities, most notably hypertension (52/139, approximately 40%), dementia (43/139, approximately 30%), and diabetes (41/139, approximately 30%). Complete home care client baseline characteristics are presented in Table 2.

Family and Friend Caregivers

Ontario Caregivers

In Ontario, there were no significant differences between intervention and control caregivers at baseline for any of the characteristics evaluated (all *P*>.05). Ontario caregivers were on average 67 (SD 12.4) years of age. There was a higher proportion of male participants in the control group (39/109, 36%) compared with the intervention group (13/56, 23%). Most caregivers (116/165, 70%) resided in midsize urban centers. Approximately 20% (32/165) resided in the lowest-income neighborhoods, while about 17.6% (29/165) resided in the highest-income neighborhoods. About 40% (<55/165) of Ontario caregivers attained a postsecondary education. Just over half of the caregivers in both groups (99/165, 60%) were retired, with 10% (12/109) of control and 25% (15/56) of intervention caregivers reporting full-time employment. Approximately 66% (114/165) of caregivers were participating in the study with their spouse or partner, and over 80% (144/165) of caregivers lived with the home care client they supported. Approximately 33% (58/165) indicated they would consider moving the home care client to a LTC facility. Ontario caregivers also had a variety of chronic disease comorbidities, most notably hypertension (control: 56/109, 51%; intervention: 37/56, 66%), diabetes (32/165, 20%), and chronic obstructive pulmonary disease (29/165, 18%). Ontario caregivers provided an average of 109 to 119 hours of care or support each week. Scores on the Zarit Burden Interview suggest that caregivers in both groups were similarly burdened by caregiving responsibilities and that such levels of caregiver burden approached high levels of burden. Complete caregiver baseline characteristics are presented in Table 3.

Table 3. Ontario and Nova Scotia family and friend caregiver baseline characteristics.

[f]COPD: Chronic Obstructive Pulmonary Disease.

[g]CHF: congestive heart failure.

[h]AMI: acute myocardial infarction.

Nova Scotia Caregivers

In Nova Scotia, there were no significant differences between intervention and control caregivers at baseline for any of the characteristics evaluated (all *P*>.05). On average, caregivers were aged 63 (SD 11.6) years. Approximately 35% (46/134) of Nova Scotia caregivers were male. Most caregivers (99/134, 75%) resided in midsize urban centers. Approximately 15% (21/134) of Nova Scotia caregivers resided in the lowest-income neighborhoods, while about 20% (30/134) resided in the highest-income neighborhoods. Postsecondary school was the highest level of education for 48% (42/87) of control caregivers and 32% (15/47) of intervention caregivers. Less than 30% (36/134) of Nova Scotia caregivers were employed full time; approximately 50% (48/87) of control caregivers and 30% (14/47) of intervention caregivers were retired. Approximately 35% (48/134) were participating with their spouse or partner, while approximately 45% (59/134) were participating with their parent. Approximately 66% (99/134) of Nova Scotia caregivers lived with the home care client they supported. Approximately 25% (36/134) of caregivers indicated they would consider moving the home care client to an LTC facility. Nova Scotia caregivers also had a variety of chronic disease comorbidities, most notably hypertension (control: 34/87, 39%; intervention: 13/47, 28%) and diabetes (control: 22/87, 25%; intervention: 7/47, 15%). Nova Scotia caregivers provided an average of approximately 81 hours of care or support each week. Scores on the Zarit Burden Interview suggests that caregivers in both groups were similarly burdened by caregiving responsibilities and that such levels of caregiver burden constituted high levels of burden. Complete caregiver baseline characteristics are presented in Table 3.

Home Care Clients' Admission to Higher Levels of Care

For the primary outcome in Ontario, there was a median follow-up time of 365 days, and the intervention group had an event rate of 5.5 per 10,000 person-days compared with the event rate of 8.0 per 10,000 person-days for the control group (Table 4). The intervention group was associated with a nonsignificant 30% reduction in risk of being unable to return home (HR 0.7, 95% CI 0.3-1.4). For the secondary outcome in

Ontario, home care client mortality, there was a median follow-up time of 365 days, and the intervention group had an event rate of 2.9 per 10,000 person-days vs the control group that had an event rate of 2.5 per 10,000 person-days (Table 4). Both groups had similar risk of mortality (HR 1.2, 95% CI 0.4-3.2).

Table 4. Unadjusted hazard ratio of primary and secondary outcomes and 95% CIs.

	Ontario			Nova Scotia

[a]Not applicable.

For the primary outcome in Nova Scotia, there was a median follow-up of 365 days, and the intervention group had an event rate of 3.2 per 10,000 person-days compared with the event rate of 2.9 per 10,000 person-days for the control group (Table 4). The intervention group was associated with a nonsignificant 10% increase in risk of being unable to return home (HR 1.1, 95% CI 0.3-3.7). For the secondary outcome in Nova Scotia, home care client mortality, there was a median follow-up time of 365 days, and the intervention group had an event rate of 6.2 per 10,000 person-days versus the control group that had an event rate of 5.8 per 10,000 person-days (Table 4). Both groups had similar risk of mortality (HR 1.1, 95% CI 0.5-2.5).

Health Care Use

Ontario Home Care Clients

There was no significant difference in health care use at the 1-year poststudy enrollment for Ontario control home care clients for all services included in the analysis (all $P>.05$). For Ontario intervention home care clients, significantly fewer participants used emergency departments ($P=.01$) at the 1-year poststudy enrollment (24/37, 65%) compared with prestudy enrollment (31/37, 84%). In addition, on average, Ontario intervention home care clients made significantly fewer visits to outpatient services (enrollment: mean 42.2, SD 31.0; after enrollment: mean 32.9, SD 26.0; $P=.04$) and specialist services (enrollment: mean 20.7, SD 25.3; after enrollment: mean 14.6 SD 18.4; $P=.02$). There were no differences in hospital admissions, primary care visits, or prescriptions at the 1-year poststudy enrollment for Ontario intervention home care clients. Complete health care use outcomes for both groups of Ontario home care clients are presented in Table 5.

Table 5. Ontario home care client health care use at the prestudy and 1-year poststudy enrollment.

Nova Scotia Home Care Clients

On average, Nova Scotia home care clients in the control group made significantly fewer visits to primary care at the 1-year poststudy enrollment (enrollment: mean 9.2, SD 5.7; after enrollment: mean 7.8, SD 5.7; *P*=.004). There was no significant difference in health care use at the 1-year poststudy enrollment for Nova Scotia control home care clients for all other services included for the analysis (all *P*>.05). At the 1-year poststudy enrollment, Nova Scotia intervention home care clients averaged significantly more hospitalization visits (enrollment: mean 0.3, SD 0.5; after enrollment: mean 0.6, SD 0.9; *P*=.04) and emergency department visits (enrollment: mean 0.9, SD 1.3; after enrollment: mean 1.5, SD 1.8; *P*=.02) and significantly fewer outpatient services (enrollment: mean 16.6, SD 13.2); after enrollment: mean 13.1, SD 11.4; *P*=.005) and primary care visits (enrollment: 8.5, SD 6.8; after enrollment: mean 6.7, SD 5.5; *P*=.02). There were no differences in prescriptions at the 1-year poststudy enrollment for Nova Scotia intervention home care clients (all *P*>.05). Complete health care use outcomes for both groups of Nova Scotia home care clients are presented in Table 6.

Table 6. Nova Scotia home care client health care use at the prestudy and 1-year poststudy enrollment.

Health care use	Control			Intervention		
	Before enrollment (n=71)	After enrollment (=71)	*P* value	Before enrollment (n=34)	After enrollment (n=34)	*P* value
Hospital admissions						
Values, n (%)	19 (26.8)	27 (38)	.10	9 (26.5)	15 (44.1)	.08

Discussion

Primary Outcome of PRM Within Home Care

While our study did not yield statistically significant results regarding the effectiveness of the PRM model in prolonging home stays, the observed trends suggest that technology-assisted aging in place may be a valuable goal for older adults. Despite the underpowered design of our study, the use of the PRM model of care was associated with meaningful, albeit nonstatistically significant, differences between control and intervention groups on the primary outcome (ie, home care clients' ability to stay at home) in Ontario and Nova Scotia. Specifically, our findings with the Ontario intervention participants trended toward a greater number of home care clients staying home and staying home longer compared with those without PRM in their home. This is similar to the findings of others who have examined the impact of remote monitoring technologies on patient and caregiver well-being [34,35]. The Canadian Expert Panel on Aging highlights the importance of even insignificant delays to admission to LTC [2]. They report that retaining and appropriately supporting older adults at home—even for a month—positively impacts the overall LTC system incapacity or capacity and growing waitlist for care. Furthermore, Canadian older adults' overwhelmingly prefer to age at home and 11% to 30% of Canadians admitted to LTC could have remained at home and in their communities if adequate home care and community supports were available [36,37].

It is important to highlight several participant characteristics that contextualize the nature of this study's patient-caregiver dyads when considering participants' ability to stay at home. The PRM intervention in this study purposefully targeted a select cohort of older adult home care clients (mean age range 77-81 years), many (125/314, 40%) with limited personal resources (ie, education or income) but all who required significant supportive care to remain in their home environment. Home care clients in Ontario were mostly cared for by a spouse living in the same home residence, whereas in Nova Scotia, most older adults lived alone. All older adult home care clients in this study were dealing with significant comorbidities; the most prevalent were hypertension, diabetes, and dementia. In Ontario, about 2 in 5 home care clients were managing dementia, as were approximately 1 in 3 of those in Nova Scotia. This is significant, as previous research demonstrates that older adults (ie, home care clients in this study), especially those with

dementia, express a greater quality of life and social connections, less loneliness, and fewer depressive symptoms when living at home compared with institutionalized LTC [38-41]. The health status of home care clients in this study was characteristic of older adults at risk for higher levels of care, with dementia being the greatest predictor of LTC home admissions [2].

Secondary Outcomes of PRM Within Home Care

What was notable among Ontario intervention home care clients was a significant reduction in their health service use over the course of the study. We found that compared with those receiving usual care, a smaller proportion of Ontario older adult home care clients in the intervention group used emergency departments after 1 year compared with baseline; no such difference was observed in home care clients in the control arm. In addition, Ontario intervention home care clients experienced a significant decrease in the average number of visits to outpatient and specialist services after 1 year, while there were no changes in average visits to these services for home care clients in the control arm. This is an important finding given the *at-risk* health status of older adult home care recipients in the study. Finch et al [35] reported a reduction in health care costs reflective of fewer hospitalizations and emergency visits among "nursing home–eligible" older adults who were monitored by home-based PRM sensors to track their safety (eg, falls) and activities of daily living (eg, time in bed, toilet use, and opening and closing the refrigerator). Consistent with the findings of this study, Finch et al [35] concluded that PRM systems may contribute to a reduction in older adult health service use and associated reductions in health care costs.

However, this was not the case among home care clients in Nova Scotia who received the intervention. In contrast to their Ontario counterparts, Nova Scotia intervention home care clients averaged significantly greater hospital admissions and emergency department visits but significantly fewer outpatient and primary care visits. Discussion with Nova Scotia project partners (health care decision makers) provided some insight into the unanticipated health service use trends of Nova Scotia home care clients in our study. Consistent with our findings, Nova Scotia health system partners reported an observed trend of increased health system use among the Nova Scotia older adult population. The provincial health care decision makers conveyed that emergency services and hospitalization may be a work-around strategy people use to expedite access to LTC services ("skip the line") and circumvent existing policies governing LTC access. Current policies elevate the LTC priority status of hospitalized at-risk older adults who are on the LTC waitlist and given priority consideration for LTC placement (personal communication, June 2024). Home surveillance of older adults' behaviors, activities, and habits through PRM technologies by caregivers may also have contributed to increased health service use. Caregivers' surveillance of older adults' activities in their home may have illuminated older adults' need for greater care. In addition, PRM may generate greater insight into older adults' care needs that may influence (ie, increase) their health service use. This is consistent with pilot study findings of PRM home care services conducted in Nova Scotia (Report of CareLink Evaluation: The Nova Scotia experience, unpublished data, 2015).

Our findings of increased hospital health service use patterns may also be consequential to the 12% to 17% shortfall of primary care service provision within Nova Scotia [42]. With underresourced primary health care services, it may be that Nova Scotians, including complex care older adults needing health care services, would be inclined to access tertiary care services in the absence of primary care services. The Canadian Expert Panel on Aging cautioned that the lack of adequate home care and community-based health care services creates the conditions for premature institutionalization of older adults into LTC. Concernedly, current estimates suggest that up to 1 in 3 Canadians admitted to an LTC home could have remained home with adequate home care services [2]. Avoiding or delaying institutionalized care eases the health system burden particularly in LTC health settings that are perpetually underresourced and ill-equipped to manage the current and pending need for older adult care [43]. An estimated 52,000 Canadian adults are on waiting lists for a placement into an LTC home, while more than 430,000 are estimated to have unmet home care needs, with about 167,000 of them being aged ≥65 years [6,43].

Qualitative research evaluating active remote monitoring and PRM technologies has supported the use of PRM technology as a way to keep at-risk older adults in their home or extend their time at home before requiring institutionalized care [44]. The study, conducted in Nova Scotia, engaged expert key informants including provincial health care policy makers, home care providers, and remote monitoring technology experts to provide their insight into the use of home-based remote monitoring technologies. Key informant participants supported the use of active and PRM technologies as a way to keep complex care older adults at home or extend their time at home. The mitigated risk of adverse events, greater responsiveness to health emergencies (eg, falls), enhanced independence among older adults, and enhanced oversight and greater safety were reported with home monitoring compared with the oversight of care within LTC facilities [44].

Limitations and Strengths

This study was limited by a restricted sample size included in the primary outcomes analysis. Our study was profoundly affected by the COVID-19 pandemic response; public health measures to mitigate the spread of COVID-19 changed the nature of home care and expectations of family and friend caregivers in the middle of this study's sampling frame. This impacted the nature of the family caregiving relationships and the nature of support that caregivers were able to provide. The pandemic response also impacted what was considered normal standard of care for home care services due to resources being redirected to other sectors within the publicly funded health care systems in Ontario and Nova Scotia. Despite this, we did observe promising trends in the data related to PRM as a potentially supportive home care strategy among a cohort of older adults with significant and complex care needs. In addition, we acknowledge the unique opportunity to collect data via PRM systems (ie, information from the sensor notifications) regarding older adults' behaviors within the home setting and the ability to leverage PRM data into large datasets to be analyzed and used to better understand the home care needs of complex care older adults.

Perhaps a strength and limitation of the PRM model of home care for health care systems is the reliance on unpaid caregivers to receive and act on PRM system notifications and not the health care system. Alternatively, the PRM model of home care enhances unpaid caregivers' responsibility and accountability to the care of their family member.

There was also limited representation of marginalized communities within our study, which limits our understanding of the impact of PRM home care models among culturally diverse populations. Finally, the fact that most caregivers were spouses to the patient participants limited this study's understanding of how PRM technologies may impact caregivers in the sandwich generation (ie, those individuals caring for older adult parents and children dependents).

Future Research

There are several opportunities for future research. An economic analysis of the PRM model of care will provide greater insight regarding the implementation of the model of care among health system decision makers. Additional research is needed to fully explore concerns related to home care client, caregiver, and home care provider privacy. Research is needed into the contributions of the PRM model of home care intervention to resolve the challenges of limited health human resources within home care while balancing the health care (physical, emotional, and financial) services given to family caregivers. We also propose an opportunity for data science research in analyzing the aggregated data on older adults' behaviors to leverage historical tracking of data to support trend analysis and the development of best practices within the home care setting and, importantly, to generate a plan of home care services targeted to the unique needs of complex care older adults. A consideration of this PRM model of care against available DIY or off-the-shelf sensor systems requires investigation. The use of off-the-shelf systems has implications for enhanced digital skills with caregivers and older adults that is not required to the same extent with the PRM model of care in this study. Investigation into older adults' and caregiver digital health literacy skills will further inform uptake and use of the PRM model of home care. Research into system data visualization—dashboard components for older adult clients and caregivers—would also support informed decision-making and provide insight into user-friendly dashboards. Longitudinal studies with populations with different chronic diseases (eg, cancer and dementia) is also needed to determine PRM model impact.

Conclusions

The combination of growing waitlists for LTC, limited home care resources, and older adults' preference to remain in their home as long as possible creates the care context for PRM technologies. These technologies hold promise to support complex care older adults to safely remain in their home and avoid or delay admission to higher levels of care. Home is preferred by most older adults even if their health conditions challenge their ability to live independently; almost all Canadians aged ≥65 years reported their intention to take extraordinary measures to avoid institutionalization in an LTC setting. The PRM model of care in this study relied on unpaid caregivers, not the health care system, to receive and act on PRM notifications. While not statistically significant, the findings of this study demonstrate a trend in favor of PRM to support patients' aging in place and positive changes in health service use among older adult home care recipients. To appreciate the provincial differences reported in this study, the PRM model of care, as with any health care system intervention, must be considered within the larger health, social, and political context. Further study is required to understand if longer follow-up time allows more effects of PRM on patients' avoidance of higher levels of care to be detected.

Acknowledgments

This study was supported by the Institute for Clinical Evaluative Sciences, which is funded by an annual grant from the Ontario Ministry of Health and the Ministry of Long-Term Care. Portions of the data used in this report were made available by Health Data Nova Scotia of Dalhousie University. Abstract

Background: Smart health wearables offer significant benefits for older adults, enabling seamless health monitoring and personalized suggestions based on real-time data. Promoting adoption and sustained use among older adults is essential to empower autonomous health management, leading to better health outcomes, improved quality of life, and reduced strain on health care systems.

Objective: This study investigates how autonomy-related contextual factors, including artificial intelligence (AI) anxiety, perceived privacy risks, and health consciousness, are related to older adults' psychological needs of competence, autonomy, and relatedness (RQ1). We then examined whether the fulfillment of these needs positively predicts older adults' intentions to adopt these devices (H1), and how they mediate the relationship between these factors and older adults' intentions to use smart health wearables (RQ2). Additionally, it compares experienced and nonexperienced older adult users regarding the influence of these psychological needs on use intentions (RQ3).

Methods: A web-based survey was conducted with individuals aged 60 years and above in Singapore, using a Qualtrics survey panel. A total of 306 participants (177 male; mean age of 65.47 years, age range 60 - 85 years) completed the survey. A structural equation model was used to analyze associations among AI anxiety, perceived privacy risks, and health consciousness, and the mediating factors of competence, autonomy, and relatedness, as well as their relationship to smart health wearable use intention.

Results: Health consciousness positively influenced all intrinsic motivation factors—competence, autonomy, and relatedness—while perceived privacy risks negatively affected all three. AI anxiety was negatively associated with competence only. Both privacy risk perceptions and health consciousness were indirectly linked to older adults' intentions to use smart health wearables through competence and relatedness. No significant differences were found in motivational structures between older adults with prior experience and those without.

Conclusions: This study contributes to the application of self-determination theory in promoting the use of smart technology for health management among older adults. The results highlight the critical role of intrinsic motivation—particularly competence—in older adults' adoption of smart health wearables. While privacy concerns diminish motivation, health consciousness fosters it. The study results offer valuable implications for designing technologies that align with older adults' motivations, potentially benefiting aging populations in other technologically advanced societies. Developers should focus on intuitive design, transparent privacy practices, and social features to encourage adoption, empowering older adults to use smart wearables for proactive health management.

smart health wearables; self-determination theory; AI anxiety; perceived privacy risk; health consciousness

Introduction

Background

Smart health wearables are devices powered by artificial intelligence (AI) designed to be worn on the body, enhancing health management. This technology holds significant promise for the older population, offering a nonintrusive way to continuously monitor health information and provide valuable assistance [1,2]. The use of smart health wearables has been verified in clinical intervention research and proven to assist in self-health management and prevention of chronic diseases,

such as diabetes, hypertension, and dementia [3]. With technological advancements today, some of these technologies have already been integrated into personal devices, such as smartphones and other mobile devices, making it easier for older adults to track their health conveniently [4]. To fully leverage the potential of health wearables, it is essential to promote the adoption and sustained use among older adults, empowering them in autonomous health management. This can lead to better health outcomes, an improved quality of life, and reduced strain on the health care system [5].

The promotion of adoption and sustained use of smart health wearables can be understood through the lens of self-determination theory (SDT) [6,7], which posits that fostering intrinsic motivation, rather than extrinsic, is essential for encouraging prolonged active engagement in a behavior. SDT suggests that fostering an environment which supports an individual's self-determination in engaging in a specific behavior is crucial for satisfying fundamental human needs that drive intrinsic motivation [6]. We examine AI anxiety, privacy risk perceptions, and health consciousness as the critical contextual factors shaping self-determination of using smart health wearables. These 3 contextual factors are closely tied to key smart health wearable aspects. (1) AI anxiety [8] stems from the automated, AI-driven recommendations in smart health wearables, which can make users feel they are losing control over health decisions. (2) Privacy risk perceptions [9] relate to the continuous data collection by smart health wearables; if inadequately protected, users' sense of control over their personal information can be reduced. (3) Health consciousness aligns with smart health wearables' purpose of empowering users to take charge of their health, reinforcing autonomy for proactive self-management [10].

Another key proposition of SDT is that fulfilling the 3 psychological needs of competence, relatedness, and autonomy is essential for intrinsic motivation [6]. When applied to smart health wearables for older adults, the extent to which these devices help older adults feel capable, enable independent choices, and foster a sense of connection with others can shape their intrinsic motivation to engage with the devices and promote sustained usage.

Taken together, this study explores how 3 contextual factors related to self-determination in using smart health wearables—AI anxiety, privacy risk perceptions, and health consciousness—are associated with fulfilling the needs for competence, relatedness, and autonomy, thereby promoting use intentions. Additionally, the study examines whether differences exist between experienced and nonexperienced wearable users in terms of the psychological needs influencing their intentions. Understanding these distinctions provides insight into the motivators for each group at different adoption stages, offering evidence for targeted strategies to sustain user engagement among older adults and thereby promote continuous, effective self-health management [11].

Through this study, we aim to contribute to the literature on self-determination in health promotion through smart technology by identifying key factors that intrinsically motivate older adults to use smart health wearables, which ultimately enhances their long-term well-being. A web-based survey has been conducted in Singapore, one of the world's most connected nations with high information and communication technology penetration and a robust AI ecosystem [12]. Furthermore, Singapore has recently become a "super-aged society," with nearly one-fifth of its population over 65 years old [13]. As such, the insights gained from this research can offer valuable, generalizable implications for designing technologies that align with older adults' motivations, potentially benefiting aging populations in other technologically advanced societies.

Literature Review: Smart Health Wearables for Older Adults' Self-Health Management

Wearables refer to "intelligent computing devices integrated into various accessories, including clothing, fashion accessories, and other everyday items worn by consumers" [14]. Smart health wearables are wearable devices designed to enhance users' health management, offering users a seamless and integrated user experience. Smart health wearables have many benefits, with their main benefit being empowering older adults to take charge of their health [15]. By integrating sensors, (eg, bio, motion, and environmental sensors), internet connection, as well as AI, smart health wearables enable individual users to track and exchange data, and even make smart and personalized decisions for their health management [1]. Some examples of smart health wearables include biosensors, GPS, and radio frequency identification (RFID) technologies that can monitor health conditions by tracking physical information such as blood pressure, oxygen level, and sleep patterns to provide personalized health feedback and medical suggestions. This feedback is valuable for those managing chronic conditions, such as diabetes or cardiovascular diseases [16]. New and improved wearable designs (eg, smartwatches) incorporate advanced algorithms and machine learning to analyze users' data and provide personalized workout programs and nutrition recommendations [17].

The potential of health wearables to improve self-health management is increasingly recognized. However, adoption rates among older adults remain low, largely due to skepticism about the tangible benefits of using wearables [18,19]. Despite a growing body of research exploring enablers and barriers to adopting smart health wearables, the literature remains fragmented [20]. Further studies are needed to understand how these devices are perceived and what motivates older adults to adopt them long-term. For example, recent studies have reported that older adults are more likely to adopt technology if they perceive a clear and immediate benefit from its usage. If the advantages of wearables are not clearly communicated or experienced, older adults may not see them as worth the investment [21]. However, such insights only scratch the surface. More in-depth exploration is necessary to uncover intrinsically motivated factors that can help older adults perceive a clear benefit from adopting wearables. Understanding these factors is crucial to fostering long-term engagement with these wearable devices. This study draws upon SDT and the motivational technology model to identify intrinsic motivators that can encourage older adults to adopt smart health wearable devices for their self-health management.

Three Contextual Factors Related to Autonomous Motivation

Overview

One of the key propositions of SDT is that creating an environment that supports one's self-determination in engaging in a given behavior is essential for fulfilling the key human needs required for fostering intrinsic motivation. In environments that respect and encourage individuals' autonomy, they are more likely to develop a sense of their true selves and achieve self-determination for their actions [6]. In social conditions that pressure people's autonomous behavior, autonomy is deprived. In such situations, the fulfillment of the 3 needs for intrinsic motivation will be hampered. However, the key human needs for intrinsic motivation will be nurtured in autonomy-supportive contexts, where the external environment supports one's self-initiation and choice.

The role of autonomous motivation in encouraging behavior is particularly significant in health-specific contexts. Being in an autonomy-supportive health care climate, for instance, and having autonomous motivation are linked to successful physical activity and dietary management, which, in turn, leads to better health outcomes for patients with type 2 diabetes [22]. Likewise, feelings of autonomous motivation positively impacted the behavioral intentions and usage behaviors of sports apps among students, contrary to feelings of controlled motivation [23]. However, solely using smart health wearables is insufficient to encourage self-health management. A study that sought to promote physical activity among adolescents using health wearables found that, contrary to expectations, feelings of autonomous motivation decreased over an 8-week period because of feelings of peer comparison that created a social environment where participants' autonomy was undermined [24]. This highlights the importance of contextual factors in shaping autonomous motivation to use smart health wearables for health management. Moreover, the technology acceptance model (TAM) [25] and the unified theory of acceptance and use of technology (UTAUT) [26] explain how users accept a given technology. These theories suggest that external factors, such as social influence, should be considered to understand people's attitudes and intentions to use technology.

This study examines the roles of 3 social-contextual factors—AI anxiety, perceived privacy risks, and health consciousness—that are crucial for creating a context that fosters the autonomy of older adults in engaging in self-health management using smart health wearables.

AI Anxiety

There is growing tension between human agency and machine agency in the context of the rise of AI, especially when user experience relies on the algorithms of smart technology [27]. Deci and Ryan [28] defined human agency as motivated behaviors that emanate from one's integrated self. In the context of communication with smart technology, user agency is defined as "the degree to which the self feels like that he or she is a relevant actor" and a feeling that the technology provides "manipulability" for the user to exercise their influence throughout the interaction [29, p. 61]. The feeling of being in control is essential as it bolsters people's intrinsic motivation.

However, as AI techniques advance at an unprecedented speed, people may begin to experience negative psychological tension driven by their natural desire to limit AI agency [27]. AI anxiety describes the psychological status of fear and trepidation when people are concerned that they will lose autonomy and be controlled by AI [8]. It is caused by the constantly evolving technological advancement of AI, along with the challenges and uncertainty that AI brings [30]. For example, Airbnb hosts experienced this algorithm-related AI anxiety as they navigated a complex ecosystem filled with uncertainty and frustration, since the algorithms comprise both "known and unknown factors" [31, p. 9].

While existing research indicates the prevalence of AI anxiety across various populations [32], AI anxiety may be particularly prominent among older adult users. Research shows that age is positively associated with greater anxiety over computers [33]. Although there are ontological differences between traditional computing technologies and AI, AI technologies may generate a wider range of anxieties because of their complexity and perceived autonomy [34]. Furthermore, low levels of technological literacy among older adults may worsen AI anxiety since a key dimension of AI literacy involves the ability to learn AI, which can be particularly challenging for older adults [34,35].

AI anxiety becomes even more pronounced when AI is used to deliver health care services, like in the case of smart health wearables. The decision-making processes of AI models that directly affect the user's well-being may be beyond the understanding of users [36]. Studies have highlighted the fear and frustration expressed by older adults when using smart health wearables to monitor their blood oxygen saturation levels [37], which illustrates how smart health wearables can deepen pre-existing anxieties. Since studies indicate that technological anxiety can negatively affect attitudes and intentions to use technology [3,38,39], we investigate AI anxiety as a significant factor shaping intrinsic motivation for using smart health wearables.

Perceived Privacy Risks

Privacy risks, throughout the various stages of designing, distributing, and using smart health wearables, can cause privacy violations. Technically, (1) most wearable devices are equipped with various sensors (eg, motion, location, and physiological sensors) that continuously collect data, (2) these data are highly personal and thus sensitive, and (3) opportunistic data usage can lead to privacy breaches [40]. Hence, using smart health wearables for health management inevitably triggers people's concerns about smart health wearables' ability to protect privacy. Complicated terms regarding data collection and sharing further exacerbate this concern, with many users unaware of how their data are managed [18,41]. Additionally, incidents involving unauthorized access and cyberattacks compound these concerns [40]. Particularly for older adult users, concerns about privacy and data security are heightened [9].

Moreover, privacy is essential for developing an autonomous self. It is commonly accepted that the human body and health data are "the central mediator of autonomy and individual privacy" [42, p. xvi]. Therefore, individuals' controllability over their information [43] or "selective control of access to the self or to one's group" [44, p. 18] is the core element of privacy. Through such processes of boundary regulation, individuals decide how open they want to be to others. However, smart health wearables need health-related personal information to function (eg, customize exercise plans and make smart recommendations). Hence, there exists this tension between (1) the need to grant controlling power of private information to smart health wearables and (2) people's need for autonomous decision-making about information disclosure. For example, when using smart home applications integrating sensors and other network technologies, older adult users expressed their concern about their controllability over their privacy; however, this sense of tension can be ameliorated if they have "full control of the sensor," meaning they would feel more in control if they have a say about when to activate or deactivate the device [45, p. 4750]. Thus, perceived privacy risks are closely tied to feelings of autonomy, and the control of personal information is key to intrinsic motivation for using health care wearables [46].

Health Consciousness

Health consciousness refers to how individuals care about their health and the level at which they are motivated to engage in preventive health practices such as health information seeking, home-based exercise, and healthy food choices [47]. Specifically, health consciousness reflects people's orientation toward three health-related dimensions: (1) personal health awareness, (2) self-responsibility, and (3) health motivation [48]. Health consciousness has repeatedly been shown to have a positive effect on health-related behaviors like using the internet to search for health information [10], choosing foods based on their health benefits [47], or using dietary and fitness apps [49].

There are several reasons to explain why health consciousness motivates older adults to engage in self-health management. Health-conscious people tend to have a stronger belief in their ability to control their health, which influences their decisions to engage in health-promoting activities [50]. Furthermore, health consciousness can motivate people to be proactive in looking for ways to evaluate their conditions, like taking up information and communication technology to mitigate loneliness [51]. Proactiveness is a distinct characteristic of health consciousness and differs from simply reacting to negative health outcomes. This aligns with research using the health belief model, which suggests that health-related internet use was more strongly proactively motivated by health consciousness, rather than being influenced by perceptions of one's health risk in a reactive manner [10]. Smart health wearables that are designed to enable self-directed health management activities [52] precisely meet the needs of health-conscious individuals. Thus, it would be fruitful to assess health consciousness as a potential factor encouraging the adoption of smart health wearables among older adults.

Three Basic Needs for Self-Determination

We used the SDT [6,7] to examine the factors related to the motivation for adopting smart health wearables among older adults. The core idea of SDT is that intrinsic motivation is necessary for sustaining engagement in a particular behavior. The 3 basic needs—competence, relatedness, and autonomy—are fundamental sources of intrinsic motivation and the natural tendency for self-development.

Competence refers to the ability to achieve personal goals. Autonomy is the freedom to make self-initiated choices, and relatedness reflects feeling connected and cared for by social groups or communities. When individuals perceive that a particular behavior fulfills these 3 basic needs, they tend to find it enjoyable (ie, intrinsically motivating) and will engage in it without relying on external rewards. Hence, from the lens of SDT, this study examines how the 3 psychological needs shape intrinsic motivation and ensures the long-term use of smart health wearables for older adults' self-health management.

As with other interactive technologies, design elements in smart health wearables can influence the sense of competence, autonomy, and relatedness through their intelligent, user-focused features [53]. For example, features such as goal setting and reward badges can enhance users' competence by providing feedback on their achievements and progress. Yet, older adults often struggle with setting up or understanding the data generated by these devices, which can undermine their sense of competence [54]. Additionally, while personalized nudges and recommendations from these devices may sometimes compromise users' sense of autonomy by making decisions based on their data [27], customizable interfaces can empower users to feel more in control. Furthermore, social features—such as communities, friend invitations, and participation in challenges—can enhance a sense of relatedness among users [24,53]. Wu and Lim [21] found that older adults are more likely to use wearables when family members or friends in their close social circle also adopt the devices.

Overall, this study explores 3 social-contextual factors influencing the autonomous use of smart health wearables for health management—AI anxiety, perceived privacy risks, and health consciousness—and their potential associations with the psychological needs related to intrinsic motivation among older adults. Accordingly, we pose the following research question:

RQ1: How are autonomy-related contextual factors regarding smart health wearable use (ie, AI anxiety, perceived privacy risks, and health consciousness) associated with the sense of competence, autonomy, and relatedness among older adults?

In addition, we aim to unpack the relationship between the psychological needs of older adults and their intention to use smart health wearables. Self-determined motivation shaped by the fulfillment of these 3 needs plays a crucial role in people's intention to use technology [55]. For instance, a study found that intentions to use health technology, such as wellness clouds for health tracking, were positively associated with intrinsic motivation, driven by expectations of performance, playfulness, and ease of use [56]. Thus, we hypothesize:

H1: Perceived competence, autonomy, and relatedness in using smart health wearables will be positively associated with older adults' intentions to use these devices.

We expect that the needs of competence, autonomy, and relatedness fulfilled by health wearables use would mediate the relationships between the autonomy-related contextual factors and use intention. This study will explore these indirect associations by proposing the following research question:

RQ2: How do perceived competence, autonomy, and relatedness in using smart health wearables mediate the relationships between the autonomous-related contextual factors (ie, AI anxiety, perceived privacy risks, and health consciousness) and older adults' intentions to use these devices?

Experienced Versus Nonexperienced Users

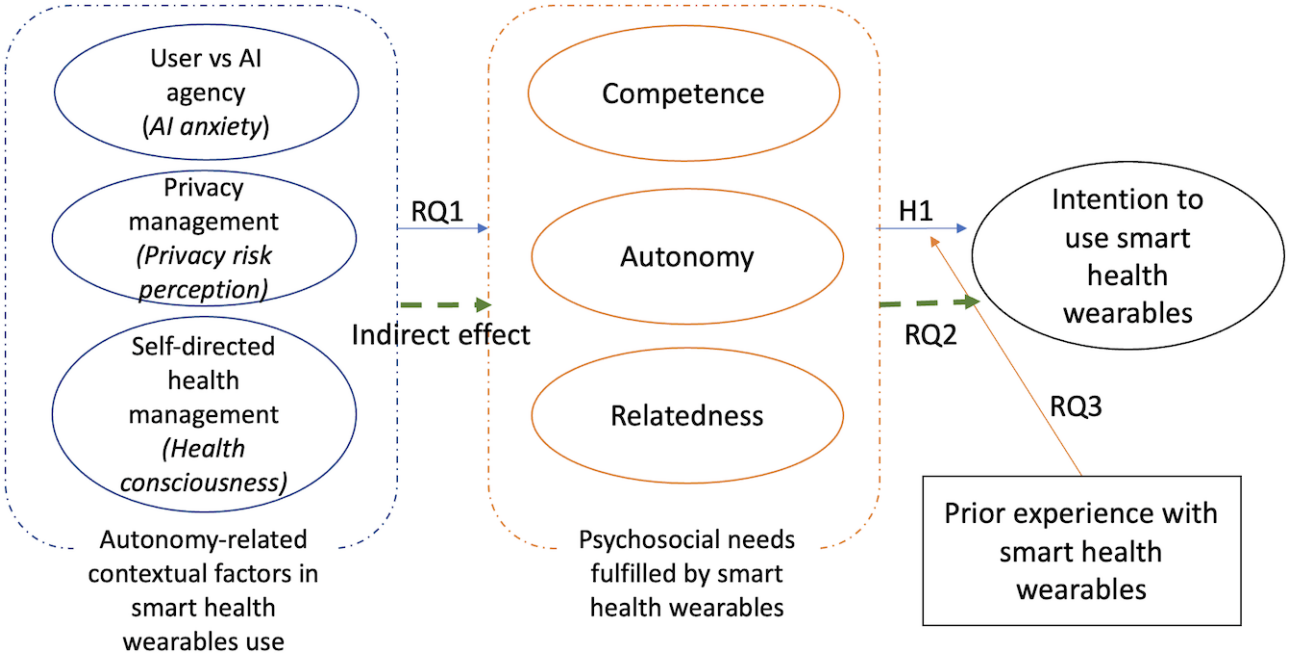
We also examine potential differences in motivation between older adults with and without prior experience using smart health wearables. According to the UTAUT and TAM models, as discussed earlier, users' prior experience with using the technology is also one of the key variables, as prior experience can work as a conditional factor in changing the degree of effect of other antecedent factors on technology acceptance (eg, intention to use and attitudes toward a technology) [26]. Specifically, whether a user has experience using a technology may affect their evaluation of motivations, effort expectancy, social influence, and perceived ease of use, among other factors [26,57]. For example, one study about smart health wearables found that the relation between behavior intention and actual use is stronger for more experienced users, compared with the new users; in addition, the experienced users rated the facilitating conditions (eg, resource and knowledge they received) as less important [58]. Interestingly, among older adults, whether users have prior experience also showed a difference in what types of smart health wearables they choose: compared with experienced users whose choice focuses mostly on smartwatches and wristbands, nonexperienced users' choices were more dispersed, showing a wide variety of preferences such as smart rings and clips among others. This indicates that prior experience might affect users' overall expectations among many technology acceptance indicators [59], supporting the proposition that prior experience may be a conditional factor that differentiates users' motivational structure predicting their technology adoption intentions [60], as experienced users tend to exhibit greater confidence and skill in navigating wearable features [61,62]. Experienced older adults may more readily recognize benefits such as improvements in health metrics or physical activity [16]. Conversely, older adults with limited or no prior experience may have different expectations regarding wearables, often accompanied by uncertainty. While such uncertainty can foster positive expectations about the benefits of devices, it may also provoke feelings of intimidation. Older adults without prior experience may struggle to fully grasp the benefits of smart health wearables early on. Moreover, without clear evidence of the device's impact on their well-being, these older adults might question the use of the technology, resulting in lower intrinsic motivation to adopt such devices [63].

However, the moderating effect of prior experience from existing literature shows inconsistent effects. For example, one study examined whether users' prior experience of using robots predicts their approval of autonomous delivery robots, and the correlation was not significant [60]. In light of these discrepancies, we will examine whether and how these 2 groups—those with and without prior experience—differ in their motivational structures for using smart health wearables in health management. Understanding the motivational differences between those who are experienced versus not experienced users of smart health wearables offers valuable insights into the distinct needs of users in different adoption stages. These insights can guide the development of more user-friendly designs and tailored educational strategies, ultimately encouraging wider adoption among hesitant or inexperienced individuals. Accordingly, we propose the following research question:

RQ3: How are experienced older adult users different from the nonexperienced older adult group regarding the relationship between the 3 psychological needs and use intention?

Figure 1 summarizes the model tested in this study.

Figure 1. Hypothesized model summary. AI: artificial intelligence; H: hypothesis; RQ: research question.



Methods

Data Collection

A web-based survey was conducted with individuals over the age of 60 years in Singapore from March to April 2022. For data collection, we used a survey panel from Qualtrics, one of the major global survey companies, which provides panels across various age groups in different countries. In total, 306 participants (177 male; mean age of 65.47 years, age range 60 - 85 years; ethnicity: 84.6% [259/306] Chinese, 3.3% [10/306] Malay, 6.5% [20/306] Indian, and 5.6% [17/306] others) completed the survey. At the beginning of the study, they were given descriptions and examples of smart health wearables. Then, they were asked if they had used such devices before. Of the 306 participants, 163 (53.3%) responded "yes" indicating their prior experiences with smart health wearables, and fitness trackers were the most common type of wearable used (135/306, 44.1%). Meanwhile, 143 (46.7%) responded "no" to the question asking about their prior experience.

Ethical Considerations

The survey procedure and materials were reviewed and approved by the institutional review board at Nanyang Technological University (IRB-2022-163). Informed consent was obtained before participants began the survey, and they had the option to opt out. All collected data were deidentified. Compensation was provided to participants by the survey company in the form of credit points in accordance with its policy.

Measurement

AI Anxiety

To measure the anxiety caused by uncertainty about how AI works, 3 items were adapted from Meuter et al [64], originally developed for measuring user anxiety about service technology. A 7-point Likert scale was used (1=strongly disagree to 7=strongly agree; eg, "I feel apprehensive about using AI technology").

Perceived Privacy Risk

Perceived privacy risk regarding wearable health technology was measured using 3 items [65], each rated on a 7-point Likert scale (1=strongly disagree to 7=strongly agree; eg, "It would be risky to disclose my personal health information to wearable device vendors").

Health Consciousness

Health consciousness was measured using a 3-item scale, with participants indicating their agreement with each statement on a 7-point Likert scale (1=strongly disagree to 7=strongly agree; eg, "I take responsibility for the state of my health") [66].

Self-Determination Factors

Adapted from Ryan et al [67], 3 factors of self-determination—competence, autonomy, and relatedness—were measured using a 7-point Likert scale (1=strongly disagree to 7=strongly agree). Competence in using wearable health devices was measured using a 3-item scale (eg, "I would feel competent in using a smart wearable health care device"). Autonomy was assessed with a 4-item scale (eg, "I would feel free to decide for myself how to do things on a smart wearable health care device"). Relatedness to other users of wearable health care devices was measured using 3 items (eg, "I would find the relationships with other users of smart wearable health care devices fulfilling").

Future Use Intention

Intention to adopt smart wearable health care technology was measured using a 3-item semantic differential scale. Participants rated their likelihood, probability, and willingness to use smart wearable health care technology in the next 3 months, with responses ranging from 1 to 7 (eg, likelihood: 1=unlikely to 7=likely).

Refer to Table 1 for the measurement items, internal reliability (Cronbach α), and basic statistics for each factor's composite score.

Table . Measurement items, internal reliability, and descriptive statistics.

Measures and items			Cronbach α	Mean (SD)
AI[a] anxiety			0.78	3.95 (1.28)
	I feel apprehensive about using AI technology.			
	I hesitate to use AI technology for fear of making mistakes I cannot correct.			
	I have difficulty understanding AI-related technological matters.			
Perceived privacy risk			0.92	4.40 (1.44)
	It would be risky to disclose my personal health information to wearable device vendors.			
	There would be a high potential for loss associated with disclosing my personal health information to vendors providing wearable devices.			
	There would be too much uncertainty associated with giving my personal health information to vendors providing wearable devices.			
Health consciousness			0.63	5.37 (1.06)
	I am concerned about my health all the time.			
	I notice how I feel physically as I go through the day.			
	I take responsibility for the state of my health.			
Competence			0.95	4.83 (1.31)
	I would feel competent in using a smart wearable health care device.			
	I would feel capable when using a smart wearable health care device.			
	I would feel like I am effective when using a smart wearable health care device.			
Autonomy			0.91	4.70 (1.17)
	I would feel free to decide for myself how to do things on a smart wearable health care device.			
	I would generally feel free to express my ideas and opinions on a smart wearable health care device.			
	I would feel like I can pretty much be myself when I use a smart wearable health care device.			
	I would experience a lot of freedom when I use a smart wearable health care device.			
Relatedness			0.70	4.03 (.97)
	I would find the relationships with other users of smart wearable health care devices fulfilling.			
	I would find the relationships with other users of smart wearable health care devices important.			
	I would not feel close to other smart wearable health care device users (reverse-coded).			
Intention			0.94	4.78 (1.93)
	How likely are you to use smart wearable health care devices in the next 3 months?			
		Unlikely or likely (1 to 7 scale)		
		Not probable or probable (1 to 7 scale)		

Measures and items	Cronbach α	Mean (SD)
Unwilling or willing (1 to 7 scale)		

[a]AI: artificial intelligence.

Measurement Model

The measurement model was tested using comparative fit index (CFI) analysis. Covariances for the first 3 autonomy items and the first 2 competence items were allowed to improve model fit. After this modification, the model showed good fit: χ^2_{185}=365.9, *P*<.001, root mean square error of approximation (RMSEA)=0.057 (90% CI 0.048-0.065), CFI=0.966, Tucker-Lewis index (TLI)=0.957, and standardized root mean square residual (SRMR)=0.048, all within acceptable ranges.

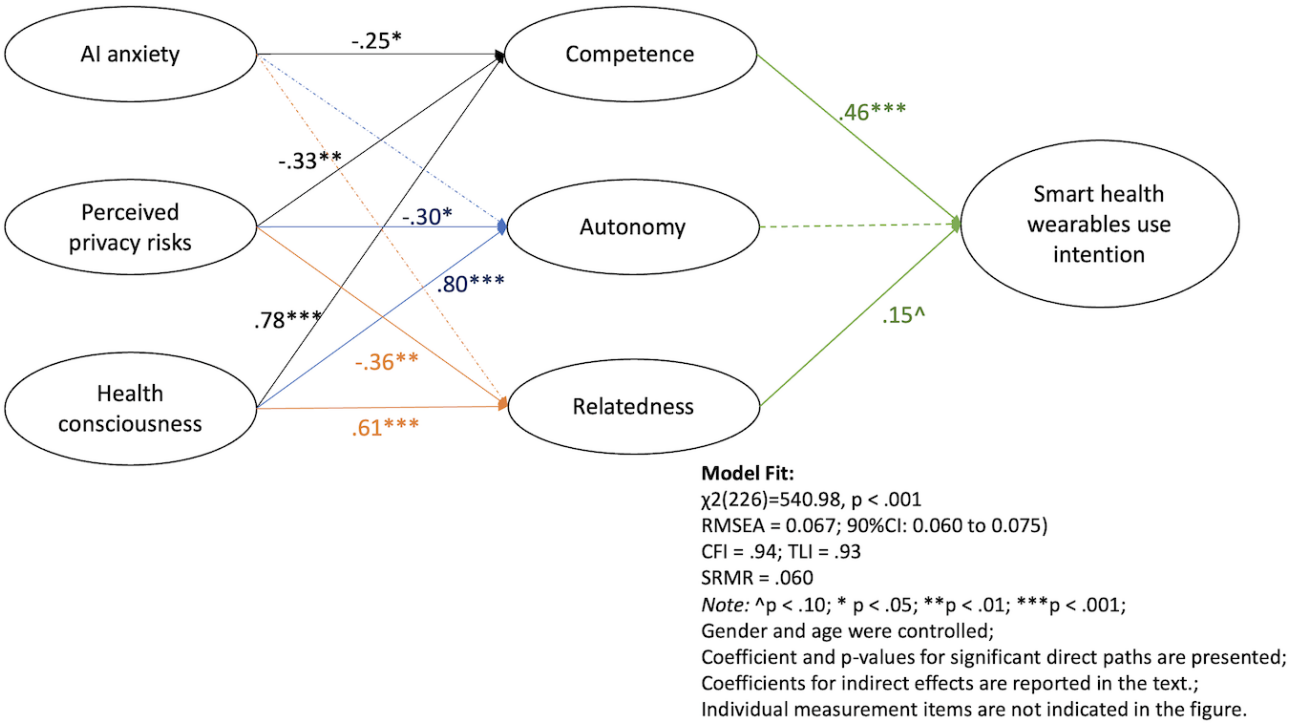
Results

The structural equation model (SEM) results indicate significant associations among AI anxiety, perceived privacy risks, and health consciousness, and the mediating factors of competence, autonomy, and relatedness, which are related to smart health wearable use intention. Model fit indices suggested a good fit: χ^2_{226}=541, *P*<.001; RMSEA=0.067 (90% CI 0.06-0.075); CFI=0.94; TLI=0.93; SRMR=0.06.

For RQ1, AI anxiety was negatively associated only with competence (β=−.25, *P*=.039); perceived privacy risks showed a significant negative association with competence (β=−.33, *P*=.002), autonomy (β=−.3, *P*=.012), and relatedness (β=−.36, *P*=.001). Health consciousness was positively associated with competence (β=.78, *P*<.001), autonomy (β=.8, *P*<.001), and relatedness (β=.61, *P*<.001).

H1 examined the associations between the 3 self-determination model dimensions and the intention to use smart health wearables. Competence was significantly associated with use intention (β=.46, *P*<.001), and relatedness also showed a marginally significant association (β=.15, *P*=.05). Figure 2 summarizes the SEM results.

Figure 2. Structural equation model results for RQ1 and H1. AI: artificial intelligence; CFI: comparative fit index; H: hypothesis; RMSEA: root mean square error of approximation; RQ: research question; SRMR: standardized root mean square residual.



To answer RQ2, we examined the indirect effects of AI anxiety, perceived privacy risks, and health consciousness on use intention through competence, autonomy, and relatedness as mediators, using 5000 bootstrapped samples. The total indirect effect of AI anxiety on use intention was not statistically significant (*B*=−0.31, 95% CI −0.78 to 0.05) although the indirect pathway through competence was significant in a negative direction (*B*=−0.27, 95% CI −0.71 to −0.05). For perceived privacy risks, the total indirect effect was significant in a negative direction (*B*=−0.36, 95% CI −0.59 to −0.14), via competence (*B*=−0.24, 95% CI −0.52 to −0.08) and relatedness (*B*=−0.09, 95% CI −0.23 to −0.004). Lastly, health consciousness showed a significant total indirect effect on use intention in a positive direction (*B*=1.37, 95% CI 1.01-2.08), with a strong positive mediation through competence (*B*=0.97, 95% CI 0.44-1.78) and relatedness (*B*=0.25, 95% CI 0.02-0.58). We found no significant indirect pathways through autonomy for any predictors.

Finally, RQ3 asked if experienced versus not experienced older adult users would have different motivation structures shaping the intention to use smart health wearables. First, measurement

invariance between experienced versus nonexperienced users for the 3 self-determination factors and use intention were tested. The models allowing for free estimation of all parameters across groups showed a good fit to the data: χ^2_{110}=183.8, *P*<.001; RMSEA=0.066, 90% CI 0.049-0.083; CFI=0.979; TLI=0.971; and SRMR=0.045. Additionally, the chi-square difference test comparing the model constraining the factor loadings to be equal across groups, against the unconstrained model, was not significant ($\Delta\chi^2_9$=6.8, *P*=.66), indicating that the factor loadings are invariant across groups. To assess the relationship between the 3 motivation factors and behavioral intention across experienced and nonexperienced user groups, 2 SEMs were estimated: an unconstrained path coefficient model (χ^2_{18}=38.5, *P*=.003, RMSEA=0.086, 90% CI 0.048-0.124, CFI=0.968) and a constrained model (χ^2_{30}=50.5, *P*=.011, RMSEA=0.067, 90% CI 0.032-0.098, CFI=0.968), both showing acceptable model fits. However, the chi-square difference test indicated that the relationships between competence, autonomy, and relatedness, and behavioral intention between the 2 groups do not statistically differ ($\Delta\chi^2_{12}$=12, *P*>.05).

Discussion

Theoretical Implications

Drawing on SDT, this study sheds light on the motivational factors influencing older adults' intention to use smart wearables for health care. By examining external contextual factors that may shape older adults' autonomous use of smart wearables for health management, we provide more nuanced insights into the self-determination model, enhancing the understanding of how to promote self-determined, proactive health management through technology. Moreover, this age-specific insight contributes to a deeper understanding of how SDT can be adapted to different user populations in the smart health wearables context.

Our study examined how external contextual factors influence intrinsic motivation, particularly in the adoption of smart health wearables among older adults (RQ1). The results reveal that perceived privacy risks erode all motivation factors: competence, autonomy, and relatedness. The fear of data breaches or the misuse of personal health information can make older adults feel that they lack control over their personal data, directly undermining their sense of autonomy. Perceived privacy risks also affect competence, as older adults may feel uncertain about their ability to navigate complex privacy settings or how their data are collected and used. This uncertainty creates a barrier to engaging with smart health wearables, as users who feel less competent in managing their personal information may be less likely to adopt such technologies. The negative association between privacy risk perception and relatedness may imply that fears of data misuse or unauthorized access can undermine users' willingness to engage in social features of smart health wearables, such as sharing health information with peers or participating in health communities. We also found a significant association between AI anxiety and competence, among 3 intrinsic motivation factors. AI anxiety is characterized by fear and apprehension about AI's decision-making processes [8]. Older adults, who may already feel less confident in their technological abilities, may find AI's opaque algorithms intimidating, leading them to doubt their capacity to effectively use smart health wearables, consequently reducing their intrinsic motivation to use them.

However, health consciousness strongly supports the fulfillment of all 3 psychological needs among older adult users; health-conscious older adults are more likely to feel competent, autonomous, and socially connected through the use of smart health wearables. This result indicates that the tendency of being proactive in self-health management among health-conscious individuals [47,50] can be largely translated to self-determined smart health wearables adoption. Especially, the significant association between health consciousness and relatedness suggests that older adults who care about their health are more likely to engage with smart health wearables and connect with others through health communities and shared goals, not just for self-health management. These findings suggest that while SDT offers a strong framework for understanding motivation across various domains, it may require adjustments for technology adoption among older adults.

We then examined the associations between the 3 psychological needs that foster intrinsic motivation and the intention to use smart health wearables (H1). The results indicate that, for older adults, feeling capable of using smart health wearables (competence) is a significant driver of wearable use, and experiencing social connection (relatedness) showed a marginally significant association. However, independent decision-making (autonomy) was not a significant factor. This result might be because older adults recognize the benefits of delegating monitoring and decision-making for health management to technology, which provides personalized recommendations for users. This result suggests that older adults may prioritize supported autonomy in using smart health wearables. Studies [29,68] have suggested that users seek to benefit from the autonomous capacity of AI-based technology while maintaining control over it.

It is also worth noting that our result contradicts Jung and Kang [52], who found that only autonomy, among the 3 intrinsic motivation factors, significantly predicted enjoyment in using smart fitness wearables, based on a survey conducted with a general population in the United States. This also indicates a possibility that autonomy might be experienced or expected differently among the older population in Singapore. Future research should explore how older adults balance autonomy and supported autonomy through health technologies and how smart health wearables can foster this balance without diminishing their sense of agency, especially through comparison with young users.

The mediating roles of the 3 psychological needs between contextual factors and the intention to use smart health wearables (RQ2) offer a deeper understanding of the factors influencing self-determination in wearable health technology use. The findings underscore the importance of fostering feelings of competence to encourage smart wearable adoption among older adults. Competence, as a key driver of intrinsic motivation, is particularly crucial for this demographic, who may feel

intimidated or uncertain about using such technology [54]. The strong indirect associations between privacy risk perceptions, health consciousness, and usage intentions through competence suggest that merely addressing privacy concerns and promoting health awareness may be insufficient. Instead, efforts should also focus on clearly communicating privacy safeguards and emphasizing the value of self-directed health management in a way that reinforces older adults' confidence and competence, ultimately helping them integrate wearables into their health routines successfully.

While relatedness played a secondary role, it nonetheless contributes to older adults' intrinsic motivation, aligning with previous research identifying relatedness as an important intrinsic motivator in social media use [69]. Our study indicates that the feelings of being connected to peer users, family, and caregivers remain a significant need for older adult users even when engaging with technology primarily intended for purposes other than social interaction or relationship building.

Finally, the lack of significant differences between experienced and nonexperienced users regarding the associations between motivational factors and use intention (RQ3) suggests that the need for competence and relatedness is important in shaping the intention to adopt smart health wearables, regardless of prior experience with such devices. Previous research found that individuals with prior experience using smart devices (eg, smartphones and smart televisions) perceived them as less complex and were more willing to try new technologies, as compared to those without experience [19]. However, the absence of differences between the 2 groups in our study could be interpreted in 2 ways. First, advancements in user-centered design and AI may have made smart health wearables more intuitive and less cognitively demanding [18], reducing the potential barriers or concerns around competence in using these devices. Alternatively, it is possible that smart health wearables remain complex and intimidating, even for older adults who have had prior experience with similar technology. Future research could use a qualitative approach, such as in-depth interviews with older adult users, to explore the underlying reasons behind this nonsignificant result. In addition, for older adult users, connecting with family and friends was identified as a major gratification in using new media technology [69-71]. Our study demonstrates that, for both experienced and nonexperienced groups, fostering relatedness with others remains an important reason for adopting health wearables among older adults, which often did not hold truth in other populations [24,52].

Practical Implications

Our findings indicate that perceived privacy risks can negatively impact older adults' sense of competence and autonomy when adopting smart health wearables. To address perceived privacy risks, smart health wearables should offer easy-to-use privacy settings that give older adults control over how their data are shared. Transparent communication about data security can enhance users' sense of control and trust, encouraging wider adoption and sustained use.

Competence emerged as the strongest predictor of smart health wearables adoption. Therefore, developers should focus on creating intuitive, easy-to-use devices tailored to older adults, with guides, tutorials, and support resources that enhance users' confidence and ability. Features such as personalized feedback, goal-setting, and progress tracking can further reinforce older adults' sense of accomplishment in managing their health, fostering continued engagement. By helping older adults feel capable and effective, developers can promote long-term use of wearables.

The feeling of social connectedness (relatedness) also plays a significant role in driving smart health wearables adoption. Developers should incorporate social features that allow older adults to connect with family, friends, or health communities—such as shared health data, group challenges, and support groups. These features foster a sense of social support, enhancing motivation. Health care providers and caregivers can encourage older adults to use smart health wearables in social settings, which can strengthen their motivation for ongoing use.

The nonsignificant difference between experienced and nonexperienced users in terms of the motivational structure for smart health wearables use suggests that both groups rely on feeling competent and socially connected when deciding to use smart health wearables. From a practical standpoint, this indicates that interventions aimed at enhancing these motivational factors—such as simplifying the technology to improve competence and fostering social connections—are equally important for both groups. For example, social workers and government organizations can provide training courses for older adults focusing on these aspects. A recent study showed that even short training courses (eg, teaching older adults how to use smartphones for social interaction and medical use) increased the positive effect of older adult users' effort expectancy (how understandable and easy to learn to use the technology) on behavior intention [72]. Therefore, strategies to increase smart health wearables adoption should focus on addressing these core needs universally, rather than differentiating between experienced users and nonexperienced users.

Limitations and Future Research

We acknowledge several limitations in this study. First, our cross-sectional design limits the ability to establish causal relationships between autonomy-related factors and wearables adoption. As a result, the associations observed in this study are correlational. Longitudinal research would be valuable in examining how variables such as AI anxiety, privacy concerns, and health consciousness impact both short- and long-term use of wearables over time, providing a clearer understanding of causality.

Second, this study was conducted via a web-based survey, which inherently requires participants to have a certain level of digital literacy and internet access. Consequently, our sample may not fully represent older adults with limited internet access or low digital literacy. To capture a more inclusive profile of older adult participants, future studies should consider using offline methods, such as paper-based surveys, to ensure a broader representation of older adults with varying digital skills.

Third, while our research primarily focuses on intrinsic motivation among older adult users for adopting smart health wearables, actual behavioral intention (ie, intention to use) is also influenced by external factors, such as the usability designs of the devices. Studies indicate that older adults have specific performance expectations regarding wearable functionality and ease of use [73]. Therefore, future studies should consider both intrinsic and external factors when exploring predictors of older adults' adoption and sustained use of smart health wearables.

Fourth, the high ownership rate of fitness trackers among our participants (135/306, 44.1%) can be attributed to Singapore's National Steps Challenge, initiated in 2015, which provided free fitness trackers to encourage physical activity. This unique context may have influenced our results, highlighting the need for further cross-cultural studies in other countries to gain complementary insights and verify the generalizability of these findings across different cultural and health care contexts.

Finally, according to the National Population and Talent Division, 81.8% of those over 60 years old are ethnic Chinese, 11% are Malay, 8% are Indian, and 1% belong to other ethnicities as of 2024 [74]. While our sample largely reflects the overall ethnic group composition, Chinese (259/306, 84.6%) and other ethnicities (17/306, 5.6%) are slightly overrepresented, and Malay (10/306, 3.3%) and Indian participants (20/306, 6.5%) are slightly underrepresented. Given that cultural and ethnic differences could significantly influence health-related [75] as well as technology and privacy-related factors [76,77], future research should aim for a more representative sample to capture the diverse experiences and preferences of all ethnic groups, ensuring broader applicability of the findings.

Conclusions

Through the lens of SDT, this study advances our understanding of older adults' adoption of smart health wearables. The results highlighted the critical roles of competence, relatedness, and autonomy-supporting contexts in shaping their intrinsic motivation. While perceived privacy risks and AI anxiety negatively impact motivation, health consciousness emerges as a strong enabler of self-determined adoption of health wearables. Our findings emphasize the need for user-friendly designs, robust privacy safeguards, and social features that foster connection and confidence among older adults. By addressing these factors, developers and stakeholders can better support older adults in integrating smart wearables into their proactive health management routines.

Abstract

Background: The Timed Up and Go test (TUG) is recommended as an evidence-based tool for measuring physical capacity. Instrumented TUG (iTUG) approaches expand classical supervised clinical applications offering the potential of self-assessment for older adults.

Objective: This study aimed to evaluate the concurrent validity and test-retest reliability of a smartphone-based TUG self-assessment "up&go app."

Methods: A total of 52 community-dwelling older adults (>67 years old) were recruited. A validated and medically certified system attached with a belt at the lower back was used as a reference system to validate the "up&go app" algorithm. The participants repeated the TUG 5 times wearing, a smartphone with the "up&go app" in their front trouser pocket and an inertial sensor to test the concurrent validity. A subsample of 37 participants repeated the "up&go app" measurement 2 weeks later to examine the test-retest reliability.

Results: The correlation between the "up&go app" and the reference measurement was r=0.99 for the total test duration and r=0.97 for the 5 single repetitions. Agreement between the 5 repetitions was intraclass correlation coefficient (ICC)=0.9 (0.84 - 0.94). Leaving out the first repetition, the agreement was ICC=0.95 (0.92 - 0.97). Test-retest agreement had an ICC=0.79 (0.53 - 0.9).

Conclusions: The duration of 5 repetitions of the TUG test, measured with the pocket-worn "up&go app," was very consistent with the results of a lower-back sensor system, indicating excellent concurrent validity. Participants walked slower in the first round than in the other 4 repetitions within a test run. Test-retest reliability was also excellent. The "up&go app" provides a useful smartphone-based approach to measure 5 repetitions of the TUG. The app could be used by older adults as a self-screening and monitoring tool of physical capacity at home and thereby help to early identify functional limitations and take interventions when necessary.

Introduction

The baby boomer generation embraces smartphone technology [1]. This particular cohort is willing and capable of using mobile health applications especially when they are designed in a user-centered way and increase the likelihood of a self-determined future [2-4]. Good examples are the use of fitness trackers, heart rate monitoring, and glucose monitoring [5].

The World Health Organization (WHO) and United Nations (UN) member states have declared the current decade as the UN "Decade of Healthy Ageing" (2021 - 2030) to improve the lives of older people, their families, and the communities in which they live [6-8]. Early identification of health risks and functional limitations in older adults is crucial to enable timely preventive measures and promote the maintenance of independence [9]. A recent systematic review was conducted to guide WHO recommendations and to establish a "standard" for evidence-based assessment of physical capacity [10]. It recommends the Timed Up and Go Test (TUG), in addition to the 30-Second Chair Rise Test, due to the high quality evidence for its sufficiently valid and reliable measurement of physical capacity in community-dwelling older adults [10,11]. The standard TUG captures the time recorded by a trained test administrator using a stopwatch. The test person rises from a chair, walks 3 meters at their usual pace, turns around, walks back, and sits down again. Longer test durations indicate limitations in physical capacity, particularly in strength and balance [10-12] and predict hospitalization and associated functional decline in older adults [13]. The need for and lack of a digital version of the TUG has been addressed during the meetings of the WHO Locomotor Capacity Working Group. This is even more relevant for persons living remotely or in low and middle-income countries where smartphone technology is often available but health care professionals are often lacking [2].

Wearable technologies offer opportunities to lower the barrier for integrating functional tests like the TUG into the assessment and clinical management of older people [14,15]. Such an instrumented Timed Up and Go Test (iTUG) not only enables standardized and digitized measurement in supervised settings [16-18] but also opens an option for low-cost self-screening and monitoring in people's everyday lives [19,20]. In clinical studies, camera-based systems, inertial sensors or smartphones that are attached to the back (eg, with a belt) are most commonly used to perform the iTUG [21]. For self-assessment purposes, however, an approach using common technologies and a convenient placement on the body would be more feasible, without the need for additional materials or training. Therefore, the "up&go" iTUG was developed as a self-test for older adults. The prototype of the "up&go" app emerged from several EU projects [17-19,22,23] and a cocreation process with older adults [24]. It incorporates an innovative approach: placing a smartphone in the user's front trouser pocket during 5 repetitions of the test. An unsupervised smartphone-based iTUG could fill a gap in the landscape of mobility assessment methods that is still dominated by patient-reported outcome measures and supervised assessments conducted in laboratory or clinical settings [25]. Digital self-assessments could support older adults to take up an active role in risk screening or monitoring, and to early identify changes in their mobility. If necessary, this would allow them to initiate further medical diagnostics, and to take primary or secondary preventive measures in a timely manner. Thus, the motivation for this study is to examine if the "up&go" self-assessment app fulfils the criteria of validity and reliability to be considered trustworthy and to serve as a credible tool for implementation in future iTUG studies and in the self-management of older people.

Hence, this study aims to examine the concurrent validity and test-retest reliability of the "up&go" smartphone-based TUG self-assessment for older adults. The measures considered are the total TUG test duration and the duration of the 5 individual repetitions. This study corresponds to an analytical validation according to the V3 framework [26].

The objectives of this study are to analyze the concurrent validity of the algorithm used in the "up&go app" against a validated and medically certified sensor-based system and to determine the test-retest reliability of the "up&go app" algorithm in the home environment of older adults.

Methods

Participant Recruitment

The findings are reported following the guidelines for reporting reliability and agreement studies [27]. Participant were recruited from the SMART-AGE randomized controlled trial conducted at Heidelberg University, Germany [28]. Participants were included in the SMART-AGE study if they were 67 years or older, lived in the community, had basic knowledge of using PCs or tablets and of the German language. Exclusion criteria were severe medical conditions (ie, heart failure with shortness of breath at rest, cardiac arrhythmia with dizziness, Parkinson disease with use of a walker or wheelchair, cancer with chemotherapy or radiotherapy, chronic lung disease with oxygen therapy, and planned major medical procedure with inpatient hospitalization within the next 3 months), severe visual or hearing impairment, and severe cognitive impairment.

Data for the sample description were extracted from the SMART-AGE initial assessment data: age, sex, BMI, citizenship, living situation, employment, WHO Quality of Life Scale score [29], Satisfaction With Life Scale score [30], fall history, Groll Functional Comorbidity Index [31], Trail Making Test A and B score [32], Six-item Cognitive Impairment Test score [33], Short Falls Efficacy Scale International score [34], 4-Meter Walk Test score [35], 30-second Chair Rise Test score [36], and stopwatch-measured Timed-Up and Go Test score [11].

Ethical Considerations

The SMART-AGE study and the amended protocol for this sub study were approved by Heidelberg University Medical Faculty's Ethical Committee (S-672/2022). All participants provided informed signed consent before participating.

Data Collection and Processing

The data collection was performed during a home visit 3 to 4 months after the SMART-AGE study's baseline assessment. A total of 3 pretrained assessors with a professional background in psychology (AB and EL) or physiotherapy (MJB) conducted the home visits following a standardized manual.

"Up&go App": Smartphone-Based Timed Up and Go Test

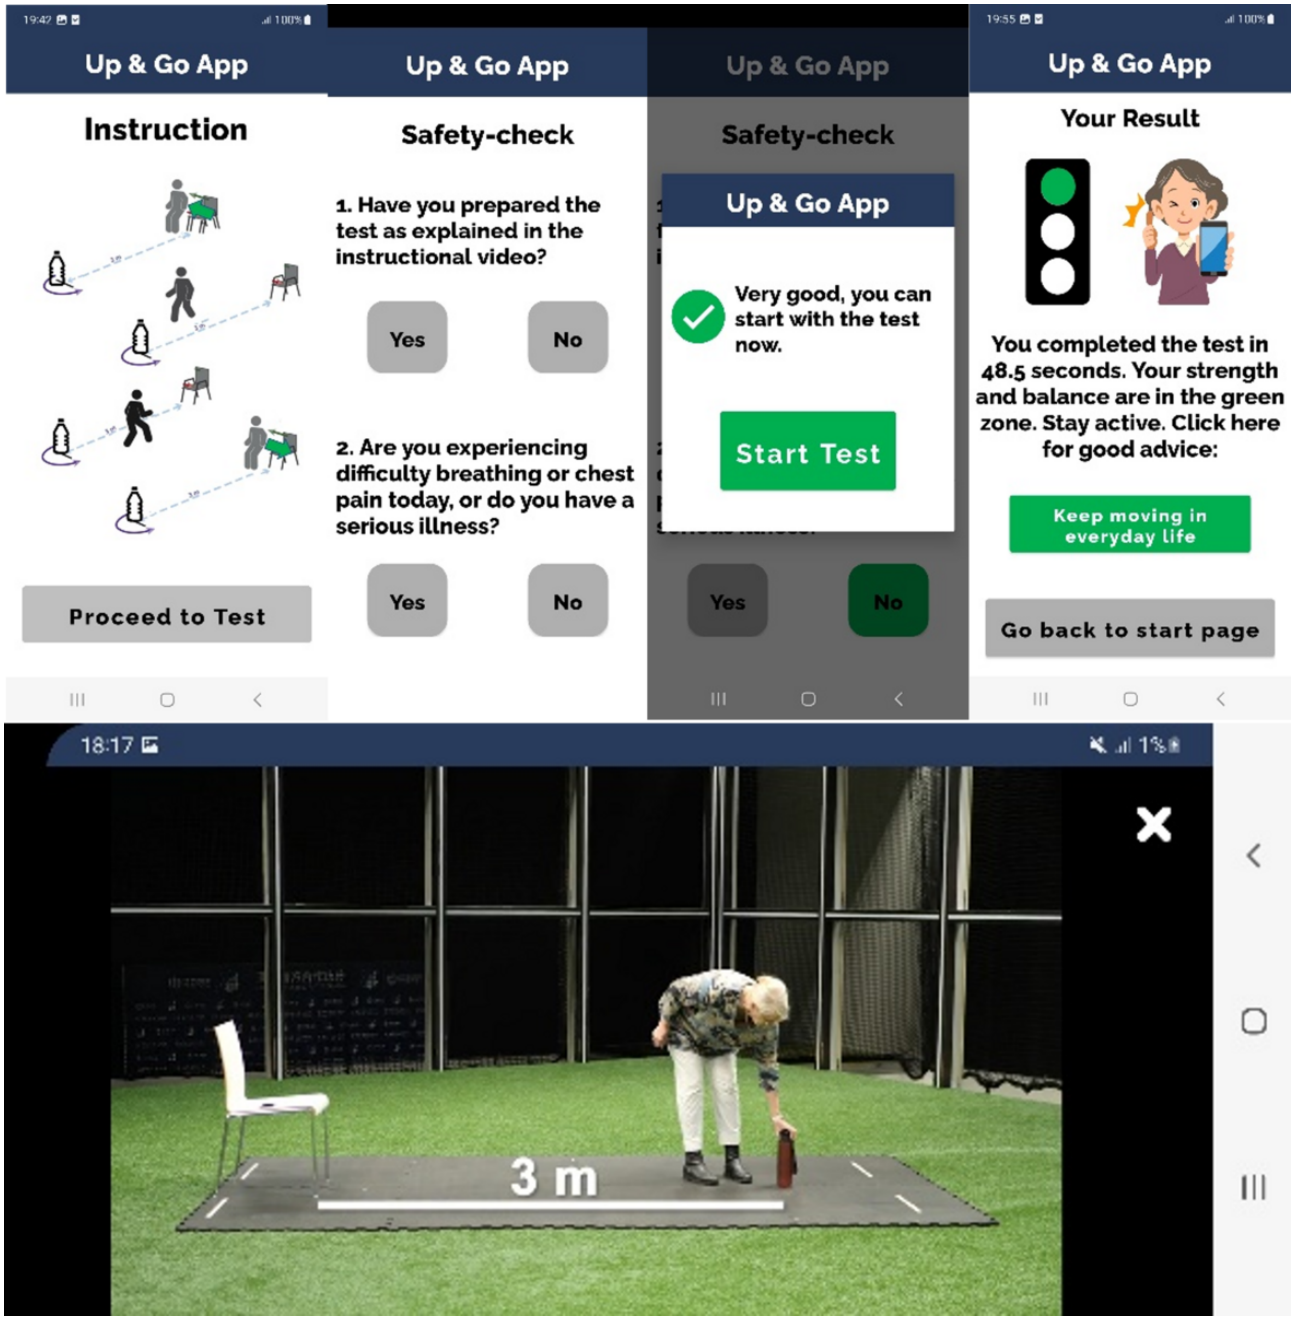
Previous versions of the "up&go app" algorithm have been developed and validated within the 2 European Commission funded projects, Farseeing [17,22] and PreventIT [18,19,23].

The “up&go app” investigated in this study [37] is a further development of the previous versions. It is based on the results of a study examining the usability of the previous Norwegian version of the PreventIT project [19] and a cocreation study with older adults [24].

In order to run the TUG test within the “up&go app,” the user is invited to watch and read the test instructions, prepare the test setting (chair, 3 m distance, marker), answer 2 safety questions, press the “start test” button, place the smartphone in one of the front trouser pockets and sit down to begin with the first round of the test at usual gait speed (Figure 1). The app includes an algorithm processing real-time accelerometer data to detect the body movements to guide the user through 5 consecutive repetitions of the TUG via audio prompts (eg, “Please put the phone in your front trouser pocket and sit down”). After each run there is a pause of about 3 seconds in which the algorithm detects the position change, and the new audio announcement is played (eg, “This was the third run. Please wait for the next start signal”). The embedded sensors in the smartphone collect data during the test.

After the test, the algorithm automatically postprocesses accelerometer data and computes the total time needed to complete 5 repetitions, excluding pauses between runs. The total time is shown on the smartphone screen in seconds together with a traffic light (Figure 1, green=<60 s, yellow 60 - 90 s, red>90 s) and an according recommendation for action (eg, green light: recommendation to stay active, yellow light: recommendation for supervised training, and red light: recommendation to seek medical advice). The color coding thresholds are based on the cut-off value of 12 seconds for 1 repetition, respectively 60 seconds for 5 repetitions, to indicate normal versus below normal mobility in community-dwelling older adults [13,38].

Figure 1. Screenshots from the “up&go app".

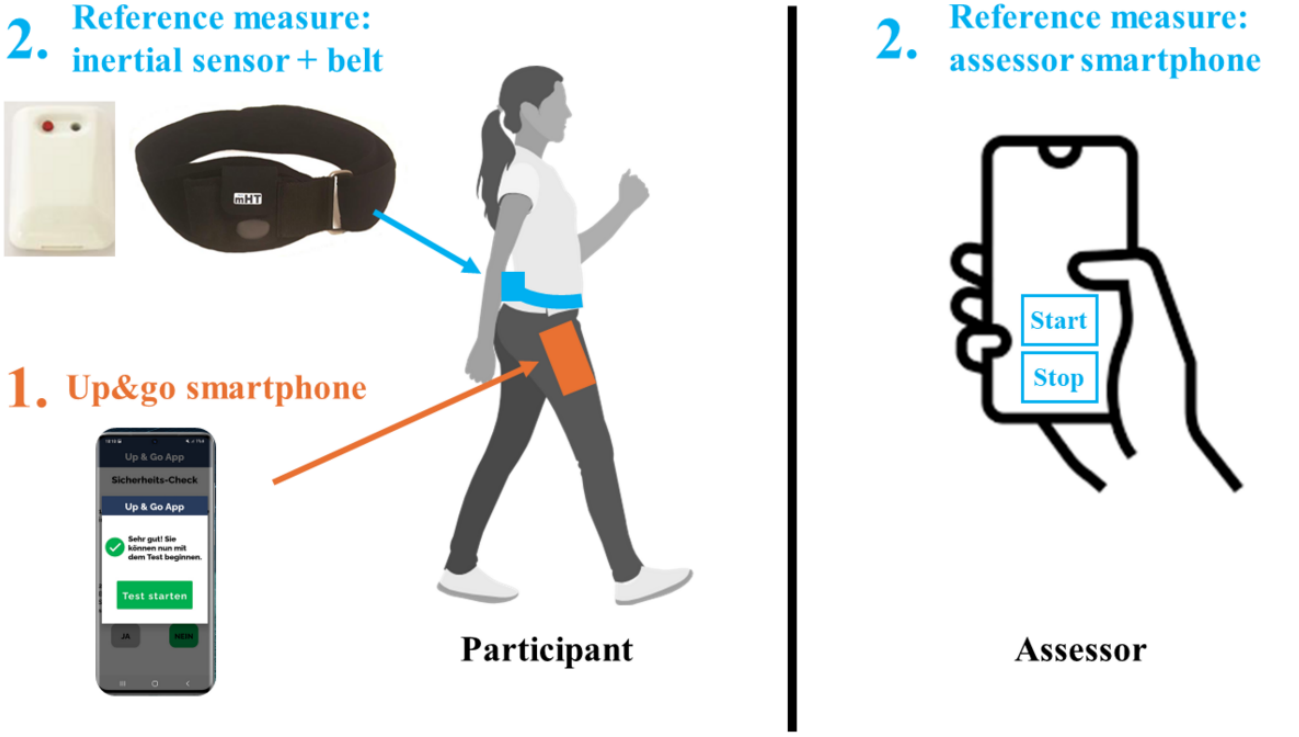


Concurrent Validity

In this study, the “mTUG” system (“mTUG” medical device, mHealth Technologies) was used as a reference measure to validate the “up&go app” algorithm. “mTUG” is a sensor-based system that has been validated in a population of older adults [17] and is certified as a medical device. The system consists of an inertial sensor (mHealth Technologies triaxial accelerometer range±2 g, triaxial gyroscope range±250°/sec, sampling rate: 100 Hz) connected by Bluetooth to an assessor smartphone (Samsung Galaxy S10e, Android 5.0.1) including a customized app (mHealth Technologies) allowing the assessor to manually start and stop the sensor measurement.

The TUG was repeated 5 times with participants wearing the 2 measurement systems simultaneously (Figure 2), smartphone with “up&go app” in their right front trouser pocket and an inertial sensor (mHealth Technologies) attached to an elastic belt worn on the lower back. A previous study with hospitalized hip fracture patients found that the performance of three TUG trials is recommended to achieve performance stability [39]. In this study, 5 repetitions were performed to take into account more variability in the performance of older adults conducting the test at home.

Figure 2. : Simultaneous measurement with (1) the "up&go app" and (2) the reference measure.



Participants were familiar with the TUG procedure as the conventional stopwatch TUG [11] had been performed beforehand as part of the baseline motor assessments within the SMART-AGE study. As the feasibility of the "up&go app" self-assessment was not part of this study, test preparation, viewing of instructional videos by participants were omitted for data collection. The test procedure was explained to the study partner (5 repetitions, usual walking pace, and follow audio instructions). The assessor prepared the TUG test setting, mounted the sensor in the belt on the participant's lower back and started the test on the "mTUG" assessor smartphone. Then, the assessor started the test on the "up&go" smartphone and handed it over to the participant. The participant then placed it in the right front trouser pocket and performed the 5 repetitions of the TUG test, following the audio instructions of the "up&go app."

The "up&go app" does not store any data on the user's smartphone to guarantee data confidentiality. We therefore developed an adapted version for this study, allowing the app to store all raw data collected from the accelerometer and gyroscope embedded in a Samsung Galaxy S21 smartphone (Android 5.0.1, triaxial accelerometer range±8 g, triaxial gyroscope range±1000°/sec, sampling rate 500 Hz) on the smartphone memory. This allowed postprocessing of the raw data and analysis of not only the total test duration, but also the duration of each of the 5 repetitions (rep1, rep2, rep3, rep4, and rep5).

Within the "mTUG" system, raw data was automatically stored on the assessor smartphone's memory and processed by a validated algorithm [17].

Test-Retest Reliability

To investigate the test-retest reliability of the "up&go app" algorithm, we repeated the "up&go" measurement at an additional home visit within 2 weeks after the first measurement, following the same procedure as described above.

Participants were asked to participate in the retest if they lived <20 km from the study center to reduce the burden of assessor time.

Statistical Analysis

The sample size for the validation part of the study was calculated using R (version 2023.09.1, R Foundation for Statistical Computing, package "pwr"). A strong correlation of ≥0.75 was assumed. With a power of 95% and a statistical significance level of α=.05, ≥45 participants are required. The sample size for the test-retest part of the study was calculated using R (version 2023.09.1, package "ICC.sample.size"). An intraclass correlation coefficient (ICC) of ≥0.75 was assumed. With power=95% and α=.05, ≥37 participants were required for 2 measurements (first measurement vs retest). Assuming a 15% dropout rate, 52 participants were recruited for the study. From this sample, we consecutively recruited participants for the retest measurement until a subsample size of at least 37 participants was reached to examine the test-retest reliability of the "up&go app" algorithm. The distribution of the data was checked before analyses (Shapiro-Wilk test). All data fulfilled the normal distribution assumption. For all statistical tests, α=.05 was used as the threshold for statistical significance. Pearson correlation coefficients were calculated to examine the association between the systems ("up&go app" and reference measure) regarding the total duration needed to complete the test as well as the duration of the 5 single repetitions. Correlation coefficients of 0 - 0.19 are interpreted as very weak, 0.2 - 0.39

as weak, 0.4 - 0.59 as moderate, 0.6 - 0.79 as strong, and 0.8 - 1 as very strong [40]. For graphical description of the agreement between the 2 systems ("up&go app" and reference measure), Bland-Altman plots were used [41], including the lower and upper limits of agreement (LLoA and ULoA). From the data collected during the first measurement ("up&go app" and reference measure), ICC 3,1 were calculated to analyze the agreement between the 5 repetitions. Test-retest reliability of the "up&go app" was evaluated using ICC [1,2,42]. An ICC value<0.4 indicates poor reliability, an ICC value between ≥0.4 and <0.75 fair to good reliability and an ICC value ≥0.75 indicates excellent reliability [43]. It was assumed that the association between "up&go app" and the reference measure is very strong (r>0.8) and the agreement between "up&go" and the reference measure is good (Bland-Altman plot). Furthermore, we assumed that the test-retest reliability of the "up&go" test meets excellent levels (ICC≥0.75). Statistical analyses were computed using statistical software R (version 2023.09.1) and MATLAB (version R2022b, MathWorks).

Results

Participant Data

A total of 52 community-dwelling older adults aged between 66 and 88 years (mean 73.6, SD 5.4) were measured, with a similar distribution of men (25/52, 48%) and women (27/52, 52%) and a mean BMI of 27.1 kg/m^2 (SD 4.1). Of those who provided the data, all were retired, almost all were German citizens (49/52, 98%) and one third (16/52, 33%) lived alone. Participants indicated an average of 2.3 (SD 1.7) comorbidities according to the Groll Index. Of these, degenerative disc disease (17/52), visual impairment (13/52), depression (11/52), and osteoarthritis (11/52) were reported most frequently. Cognition was normal (<7 errors on the Six-item Cognitive Impairment Test) and executive functions (Trail Making Test A and B) were in accordance with normative data of this age group [44]. The average duration of the TUG measured with the stopwatch in the SMART-AGE initial assessment was 9.7 (SD 1.7) seconds. None of the study participants used a walking aid during the TUG. Table 1 provides a detailed description of the sample.

Table . Characteristics of the study sample.

Data from the SMART-AGE initial assessment[a]		Values	Available sample
Age (years), mean (SD)		73.6 (5.4)	52
Female sex, n (%)		27 (52)	52
BMI (kg/m^2), mean (SD)		27.1 (4.1)	52
German citizenship, n (%)		49 (98)	50
Living alone, n (%)		16 (33)	49
Retired, n (%)		50 (100)	50
Stopwatch-measured TUG (s), mean (SD)		9.7 (1.7)	52
4-meter walk test, mean (SD)			
	Duration (s)	4.2 (0.9)	52
	Gait speed (m/s)	1.0 (0.2)	52
30-Second chair rise test, mean (SD)			
	Number of repetitions	12.3 (3.3)	52
Short Falls Efficacy Scale International, mean (SD)			
	Score	8.2 (2.2)	49
Groll Functional Comorbidity Index (score), mean (SD)		2.3 (1.7)	48
Fall history ("Yes, I fell in the last 12 months")[b], n (%)		19 (37)	51
Trail making test, mean (SD)			
	Test duration A (s),	45.2 (16.6)	52
	Test duration B (s)	99 (50.3)	52
	Ratio (B/A)	2.3 (1.1)	52
Six-item cognitive impairment test [c] , mean (SD)			
	Score	1.0 (1.5)	52
Satisfaction with life scale, mean (SD)			
	Score	5.0 (1.2)	49
WHO Quality of Life Scale, mean (SD)			
	Physical domain (score)	77.3 (13.1)	49
	Psychological domain (score)	72.4 (10.3)	49
	Social relationships domain (score)	65.3 (13.6)	49
	Environment domain (score)	79.8 (10.1)	49

[a]The initial SMART-AGE assessment took place 3-4 months before the data collection for this study.

[b]Fall history data was obtained one month after the initial SMART-AGE assessment.

[c]Participants with >7 error points were excluded from the SMART-AGE study due to a suspected dementia disorder.

Concurrent Validity

In total, 35 (67.3%) participants completed the test successfully on the first attempt. Due to technical problems (eg, smartphone shifted in trouser pocket), 12 (23.1%) participants had to repeat the test a second time, 4 (7.7%) participants a third time, and 1 (1.9%) participant a fourth time. After an unsuccessful attempt, participants always took a break of at least 5 minutes. As the app only saves data from complete test runs, failed attempts were not included.

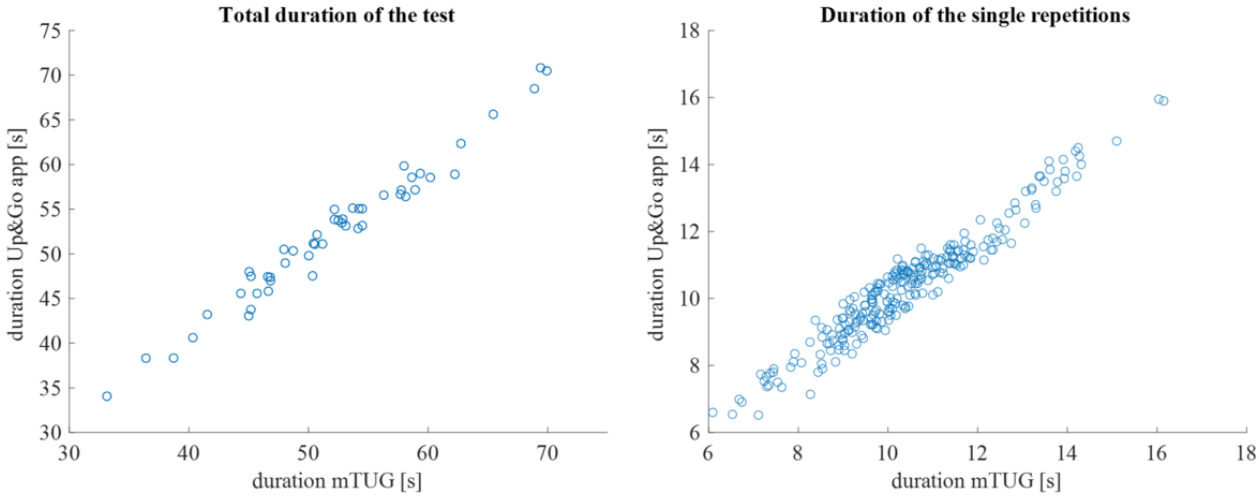
On average, participants needed 52.4 (SD 7.8) seconds to complete 5 repetitions of the TUG, as measured by the "up&go app". Table 2 shows the results for the total duration of the test and the duration of the 5 repetitions as measured by the "up&go app" and the reference measure.

Data from all 52 participants were available for the concurrent validity analysis ("up&go app" vs reference measure). The Pearson correlation coefficient (r) for the total duration was 0.99 (95% CI 0.98 - 0.99) and that for the durations of the 5 single repetitions was 0.97 (95% CI 0.96-.97; Figure 3).

Table . Total test duration and duration of the 5 repetitions measured by the "up&go app" and reference measure.

Duration	"up&go app", mean (SD)	Reference measure, mean (SD)
Total duration of the test (s)	52.38 (7.8)	52.31 (8.11)
First repetition (s)	10.99 (2.1)	11.11 (2.17)
Second repetition (s)	10.33 (1.54)	10.39 (1.61)
Third repetition (s)	10.25 (1.57)	10.34 (1.64)
Fourth repetition (s)	10.21 (1.52)	10.2 (1.52)
Fifth repetition (s)	10.11 (1.46)	10.26 (1.6)

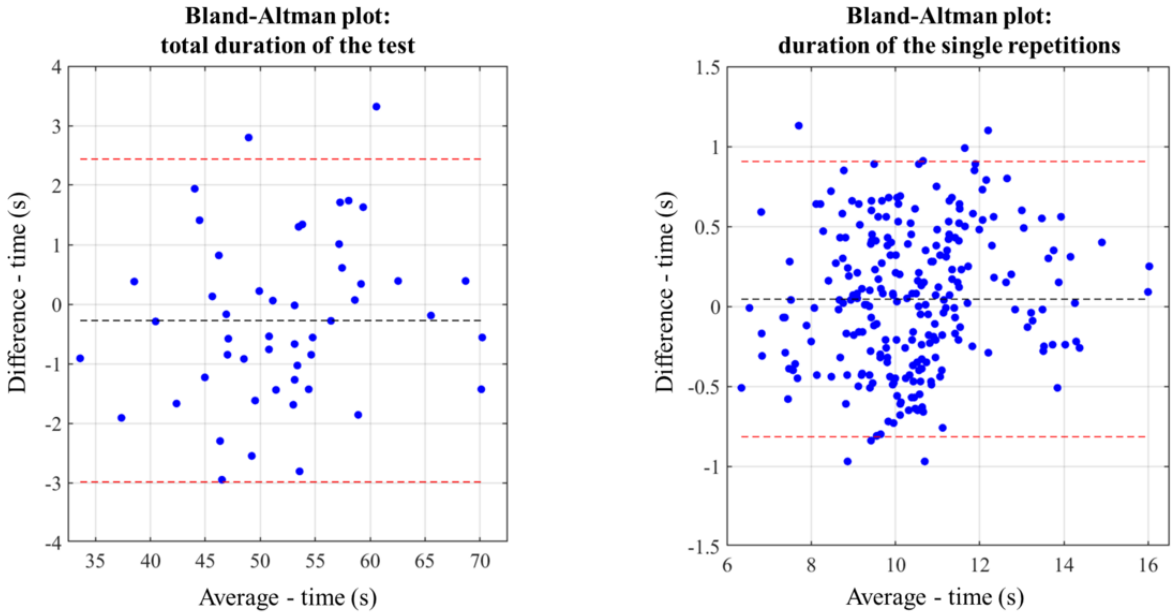
Figure 3. Correlation analysis between "up&go app" and reference measure: total duration and duration of the single repetitions. TUG: Timed Up and Go Test.



The agreement between the total duration measured by the "up&go app" and the reference measure is shown in Figure 4 (Bland-Altman plots). According to Bland-Altman analysis, the mean difference was −0.27 for the total duration of the test and −0.05 for the duration of the single repetitions. The difference in the total duration of the test was between −2.99 seconds (LLoA) and −2.44 seconds (ULoA) and the difference in the duration of a single repetition was within −0.82 seconds (LLoA) and −0.91 seconds (ULoA) with respect to the estimate of the reference measure.

Agreement between all "up&go app" repetitions was ICC(3,1)=0.9 (95% CI 0.84 - 0.94) and ICC(3,1)=0.87 (95% CI 0.80 - 0.93) between all repetitions measured by the reference measure. Leaving out the first repetition, the agreement of repetitions 2 - 5 was ICC(3,1)=0.95 (95% CI 0.92 - 0.97) for the "up&go app" and ICC(3,1)=0.93 (95% CI 0.89 - 0.96) for the reference measure.

Figure 4. Statistical agreement between the "up&go app" and the reference measure—Bland-Altman plot.



Test-Retest Reliability

Of the 52 participants, 37 were measured twice, and 1 participant was excluded due to noncompliance with the retest instruction to walk at habitual gait speed. Retests were performed on average 6 (SD 2.6) days after the first measurement. At the "up&go app" retest measurement, participants needed on average 48.6 (SD 8.5) seconds to complete the 5 repetitions. The ICC between the total duration during the first home visit and during the retest was ICC(2,1)=0.79 (95% CI 0.53 - 0.9).

Discussion

Principal Findings

To enable self-assessment for older people in their own homes, the "up&go app" was developed as a pocket-worn approach with 5 repetitions of the TUG. This study aimed to investigate the concurrent validity and test-retest reliability of the "up&go app," which records and processes data from sensors embedded in a smartphone that is placed in the front pocket of the trousers. The results show excellent agreement between the "up&go" data and the comparator system, a previously validated medically certified lower-back inertial sensor system. Overall, the correlation of the 5 single repetitions was very strong. The results indicate that participants did not seem to walk at the same speed in each of the 5 test rounds, that is, they tended to walk slower during the first round. This trend probably shows a learning or accustoming effect. Similar observations have been made in previous studies [39,45] where participants started rather slowly and more carefully during the first attempt of motor performance tests to follow the instructions precisely and to avoid errors [45]. This first round may therefore be comparable to a "trial run," which is often performed in assessments before the actual measurement. Performing several repetitions of the test provides the opportunity to observe any changes in walking speed during the test and, if necessary, to interpret it clinically regarding physical capacity. For example, in more frail populations, a significant reduction in walking speed during the test could indicate fatigue. Furthermore, this approach might achieve a better approximation toward the "real" usual walking speed compared with measuring only 1 or 2 rounds. Using the app to monitor differences in the total test duration across several measurements would be a clinically relevant use case. But what would be considered a "relevant change"? Minimal important differences (MID) of >2 seconds for 1 TUG repetition were reported in studies observing populations with age-associated disorders and TUG baseline values around 20 seconds [46,47]. In another study observing older adults with hip osteoarthritis and a TUG baseline duration of 7 seconds, a sample that is comparable with this study, the MID is significantly lower with, 0.8 seconds [48]. This suggests that ceiling effects make it more difficult to screen for relevant changes in more robust individuals. The "up&go app," however, should not only aim to screen for subjectively noticeable changes, but also for changes falling below the abovementioned MID thresholds. Looking at the Bland-Altman plots, a clinically relevant change could be assumed if the measured change is outside the limits of agreement. The limits identified in this study were about ±3 seconds (LLoA, ULoA) for the total duration of 5 repetitions and about ±1 second (LLoA, ULoA) for a single round. Especially in relatively fit, prefrail older adults, a 5-repetition approach could be more sensitive to capture small changes and clinically more useful for early identification of declining physical capacity.

The test-retest reliability analysis showed excellent results. Looking at the average total test duration, we observed a shorter total test duration in the retest. On average, retests took place 6 days after the initial measurement, which makes an improved TUG test performance through training effects unlikely. A similar observation was described elsewhere [45]. A learning effect could account for the shorter duration of the retest. Since participants were already familiar with the test from the first measurement, they may have been more confident and faster during the retest. Other iTUG systems measuring at the height of the navel, (ICC=0.97) [49] and the lower back (ICC=0.9 - 0.96) [50] show slightly higher test-retest reliability

values. This is to be expected, as the “up&go app” pocket position, specifically selected for the self-assessment purpose, is located more distant from the center of mass. Another reason could be that individuals wore different clothes with different types of pockets; these pockets may be tight or loose, which aggravates individual differences.

For future monitoring purposes, machine learning could be implemented to enable an in-app plausibility check. This might be a helpful feature to detect implausible changes in test duration (eg, >20% compared with previous test performances very recently).

Limitations

The sample was predominantly White, and participants were relatively fit, as demonstrated by the TUG performance. The average time needed to complete one repetition (9.7, SD 1.7 seconds; Table 1) is below the threshold of 12 seconds to distinguish normal versus below normal mobility [38]. The results are therefore limited in their transferability to more diverse cultural populations with greater mobility restrictions. For pragmatic reasons, we did not include a gold-standard reference measure, that is, optoelectronic measurement, limiting the results of this study accordingly. A segmental analysis of the “up&go app” data (sit-to-stand, walking, turning, and stand-to-sit) was not considered to be useful for self-monitoring. Furthermore, signal noise caused by the pocket-worn approach would be expected, as the smartphone moves back and forth in the trouser pocket in addition to the body movement during the test. Thus, the pocket-worn approach should be considered as a consumer-centered approach and not as a measurement system for segmental or kinematic analysis. For an accurate segmentation of the test, the use of technology that is placed close to the center of mass would be recommended. The instruction to walk at “usual walking speed” leaves room for individual interpretation, hampering standardization. The extent to which the gait speed during the TUG test corresponds to an individual’s actual real-world gait speed was not assessed in this study. It is assumed that performing 5 repetitions and the familiar home setting enabled a greater approximation to the normal walking speed. However, an activity measurement of several days would be required for comparison [51].

Future Perspectives

The smartphone app used in this study could be suitable as a physical capacity screening and monitoring tool incorporating an instrumented approach for the widely used TUG test. It is designed to be used by older adults, but it could also be implemented by health care professionals to measure TUG total time in clinical settings.

As this study was aimed at validating the test algorithm, it is currently not possible to draw conclusions on the feasibility and user experience of older adults when operating the app, setting up and conducting the test independently. The app should therefore be examined and further developed in future cocreation studies with the target group.

The investigated app is designed to screen physical capacity, representing one of several health domains. In the future, it could be used as part of a comprehensive digital self-assessment, which should include other relevant risk factors such as physical activity, cognition, and vision in addition to physical capacity [24,52]. Self-guided early detection of risks in these domains could enable timely, more specific clinical diagnostics and the initiation of appropriate care interventions. Implementing the app as an upstream assessment within a digital training platform would allow adopting the dosage and supporting the selection of target-specific exercises to be tailored to the user’s individual level of physical capacity.

Conclusion

The results show excellent concurrent validity and test-retest reliability of the pocket-worn iTUG approach with 5 repetitions. The “up&go app” could be suitable as a self-screening and self-monitoring of physical capacity for older adults at home. It provides a smartphone-based approach to accurately measure the total duration of TUG. This novel approach offers the potential for older adults to take an active role in their health management and preclinical risk detection.

Acknowledgments

This publication is based on data from the study "Smart Aging in Community Contexts: Testing Intelligent Assistive Systems for Self-regulation and Co-regulation under Real-Life Conditions" (SMART-AGE). The study is funded by the Carl-Zeiss-Foundation. We thank all project members from the SMART-AGE project and the TSG Research Lab for their contribution. In particular, the authors extend thanks to Carlo Tacconi, Jan Spielmann, Jan Mayer, Ronny Bergquist, Sarah Zimmermann, Tobias Eckert, Claudia Hellmund, Franziska Kramer-Gmeiner, Meike Steinhilber, Anna-Lena Schubert and Alica Mertens.

Authors' Contributions

MJB, CB, and KGO conceptualized the study. MJB, AB, EL, and MS took part in data collection. MJB and SM took part in the data analysis. MJB drafted the manuscript, JK, SM, CB, and KGO took part in a preliminary process of reviewing and editing the manuscript. All authors participated in the subsequent editing process, read the entire manuscript, and agreed to the published version.

Conflicts of Interest

SM holds a share of the mHealth Technologies srl company. None of the other authors declared conflicts of interest. The “up&go app” is freely available in the Google Play and Apple App Store, in German speaking countries.

Abstract

Background: Sleep-dependent memory (SDM) is the phenomenon where newly obtained memory traces are consolidated from short-term memory stores to long-term memory, underpinning memory for daily life. Administering SDM tasks presents considerable challenges, particularly for older adults with memory concerns, due to the need for sleep laboratories and research staff being present to administer the task. In response, we have developed a prototype mobile app aimed at automating the data collection process.

Objective: This study investigates the perspectives of older adults, with subjective or objective cognitive impairment, regarding barriers and facilitators to using a new mobile app for at-home assessment of SDM.

Methods: In total, 11 participants aged 50 years and older were recruited from the Healthy Brain Ageing memory clinic, a specialized research memory clinic that focuses on the assessment and early intervention of cognitive decline. Two focus groups were conducted and thematically analyzed using NVivo (version 13; Lumivero).

Results: On average, participants were aged 68.5 (SD 5.1) years, and 4/11 were male. Eight participants had subjective cognitive impairment, and 3 participants had mild cognitive (objective) impairment. Two main themes emerged from the focus groups, shedding light on participants' use of mobile phones and the challenges and facilitators associated with transitioning from traditional laboratory-based assessments to home assessments. These challenges include maintaining accurate data, engaging with humans versus robots, and ensuring accessibility and task compliance. Additionally, potential solutions to these challenges were identified.

Conclusions: Our findings underscore the importance of app flexibility in accommodating diverse user needs and preferences as well as in overcoming barriers. While some individuals required high-level assistance, others expressed the ability to navigate the app independently or with minimal support. In conclusion, older adults provided valuable insights into the app modifications, user needs, and accessibility requirements enabling home-based SDM assessment.

Introduction

There are over 55 million people living with dementia [1]. Dementia is an umbrella term for a diverse number of substantial cognitive impairments that significantly interfere with an individual's daily living. The most common form of dementia is Alzheimer disease, in which memory impairment is a critical early feature [2] that is intricately linked to diminished well-being and quality of life [3]. Some facets of memory can be assessed by standardized neuropsychological tests that examine a person's ability to recall information presented to them after a short delay (eg, 20 - 30 minutes). An aspect of memory that cannot be assessed during a standardized neuropsychological test is sleep-dependent memory (SDM). This is a process by which memories encoded during the day are consolidated and strengthened during sleep [4]. This mechanism greatly influences overall memory capabilities by bolstering long-term memory storage, integration, and retrieval.

To date, most studies have explored SDM in younger adults [5]. Thus, tasks are tailored to suit the cognitive capacities of

younger individuals and often involve memorizing many items. This poses significant challenges for older adults, particularly those with cognitive impairments, leading to a notable research gap in this demographic. Given this gap and the importance of SDM in memory for daily life, our team developed an SDM task [6] tailored explicitly for older adults with cognitive concerns and mild cognitive impairment (MCI). MCI refers to a transitional state between normal aging and dementia, where cognitive impairment is apparent, but daily functioning is largely intact. Our prior work demonstrated that individuals with multiple-domain MCI had significantly more compromised SDM than healthy controls and those with single-domain MCI [6]. In this study, poorer SDM was linked to having greater sleep apnea severity for older adults without MCI. In contrast, for those with MCI, poorer performance was associated with decreased sleep spindle duration and smaller hippocampal subfield size. As various age-related sleep changes occur both naturally [7] and with neurodegenerative diseases [8,9], it is crucial to understand how these alterations impact SDM. Notably, preliminary evidence suggests that SDM may be improved through sleep apnea management [10], transcranial electrical stimulation [11], and acoustic stimulation [12]. These findings underscore the importance of identifying clinical correlates and predictors of poor SDM performance to inform targeted interventions.

Unfortunately, our understanding of SDM is limited to small sample case-control studies, and it is not routinely assessed in clinical evaluations. This may be partly attributable to the type of task used and the setting within which most research has been conducted. In addition to being predominantly in younger healthy samples, studies to date have largely been conducted in sleep laboratories where participants are asked to do memory testing before and after sleep [13]. This requires participants to sleep in an unfamiliar environment, meaning their sleep that night may not reflect their usual sleep [14], and they are often asked to learn significant amounts of information before sleep using tasks that are not feasible or suitable for clinical settings. Another barrier is the high demand for staff to conduct these studies (Naismith, personal communication, 2024). Staff must be present to administer SDM tasks before sleep (often within 3 hours before sleep) and after sleep (often after 1-hour postwaking) and to stay overnight to monitor the participant. Together, the requirement for sleep laboratories and high staff demand result in high costs associated with conducting SDM tasks. These barriers could be addressed by adapting SDM tasks for older clinical samples and delivering the tasks in the home environment.

The adoption of digital health technology in older adults has been increasing [15], including by individuals with subjective concerns about their cognition and those with MCI [16]. However, when considering new app-based approaches, barriers and facilitators that influence adoption and effective use must be identified [17]. A prior systematic review showed that barriers preventing the use of digital technology in older adults (including those with cognitive impairment) can include motor, sensory, cognitive, lack of familiarity, and device-specific challenges, though these factors can be mitigated through design modifications [18]. In contrast, digital health technology adoption can be facilitated by the perceived usefulness of the app, pre-existing knowledge, and ease of use. For SDM tasks, additional considerations are required, given that they are optimally tested under strict timings (ie, before and after sleep) and may require participants' sustained attention and interaction with a mobile app for extended periods (eg, potentially up to an hour).

This study sought to explore the perspectives of older adults with subjective or objective cognitive impairment regarding barriers to and facilitators of an at-home assessment of SDM using a new "chatbot" (mobile app), approach to assessment, named "Sleep Memories." A chatbot is designed to simulate human-like conversation with users through text or voice interactions and, in our scenario, to deliver a memory task and record a participant's responses. Previous work has shown the use of chatbots in various health populations, including chronic pain populations to deliver pain education [19], and monitoring of chemotherapy outcomes in older adults with cancer [20]. The objective was to use co-design methodologies to assess an initial app prototype, which could be incorporated into a revised version suitable for clinical testing. We were specifically interested in potential barriers to and facilitators of use.

Methods

Digitalization of the SDM Task

The SDM task, as described in Lam et al [6], was initially adapted to be suited for an app-based platform (Figure 1). This task is a verbal memory task that comprises 32 word pairs, half of which are semantically related and the other half unrelated. In step 1, participants are presented with all 32 pairs. In step 2, individual words are presented, for which participants are required to identify the corresponding pair word by speech or text. As described in the initial study [6], participants performed this task 4 times in the evening within 3 hours of bedtime to facilitate learning. In the morning, participants completed the recall component (step 2) and a multiple-choice test, comprising an individual word and 4 possible answers (1 correct corresponding pair word and 3 incorrect pair words), approximately 1 hour after waking. This task was digitalized for use in a mobile app, using a chatbot for automatic delivery and data collection. To humanize the chatbot for prototype testing, we named it "Aurora." The Sleep Memories app's development, in-house testing, and evaluation are detailed in Ireland et al [21].

Sleep Memories was designed to collect information about a participant's habitual sleep patterns, through a short survey on opening the app, and deliver the SDM task within 3 hours of the participant's regular sleep time. After the participants respond to the questions about their sleep, the app provides a trial run, enabling participants to become comfortable with its functionalities. In line with Lam et al [6], each word pair is presented to the participants for 10 seconds. For the recall component, the app offers a 10-second window, allowing participants to either type or vocally record their answers, ensuring a user-friendly response period. In the morning, participants are prompted to confirm their bedtime and wake-up

time, which is followed by recall and multiple-choice testing to assess their memory retention.

Qualitative methods were selected for this study, as they are ideally suited to elicit participants' perspectives of Sleep Memories and their experiences with current digital health technologies relative to other methodologies. An interpretative philosophical perspective [22] was selected, as this method allowed us to situate the participants' perspectives within their broader life contexts and allowed for flexibility and adaptability regarding the emergent themes and meanings arising from the data.

Figure 1. Screen captures of the Sleep Memories app. (**A**) Aurora (chatbot) introducing themselves to the participant. (**B**) Aurora asking demographic and habitual sleep pattern questions. (**C**) Aurora giving instructions for the word-pairs task. (**D**) Learning component of the word-pairs task being delivered by the app (**E**) Recall component of the word-pairs task being delivered by the app. (**F**) Multiple-choice testing component of the word-pairs task being delivered by the app.

Participant Recruitment

Participants were recruited via convenience sampling from the Healthy Brain Ageing (HBA) memory clinic. As described previously [23], the HBA clinic is a specialized memory clinic that accepts referrals from general practitioners and medical specialists and provides comprehensive neuropsychological, medical, and mood assessments for older adults aged >50 years with recent subjective cognitive or mood decline. Exclusion criteria are a Mini-Mental State Examination score<20 [24], intellectual disability, insufficient English proficiency for standardized neuropsychological assessment, history of nonaffective psychiatric disorder (eg, schizophrenia), history of stroke, history of head injury (loss of consciousness>30 minutes) or other neurological disorder (eg, epilepsy), or current substance dependence or abuse. Basic demographic (eg, age, sex, and years of education) and clinical data (eg, Mini-Mental State Examination score and MCI status) collected at the HBA clinic are reported here for descriptive purposes. MCI status was categorized into 3 distinct groups: subjective cognitive impairment (absence of objective cognitive impairment), nonamnestic MCI (objective cognitive impairment in nonmemory domains), and amnestic MCI (defined by objective cognitive impairment in memory domain). Participants were invited to participate in the study via email or phone call. Interested participants were provided with a participant information statement identifying the research team, funding, research aims, and risks and explaining confidentiality, consent, and withdrawal. Once informed consent was obtained, participants were invited to attend 1 of 2 digital focus groups via Zoom (Zoom Video Communications).

Data Collection

Before the focus groups, participants were required to complete a digital survey consisting of an Abbreviated version of the previously validated Mobile Device Proficiency Questionnaire (AMDPQ) [25]. In general, the abbreviated version of the questionnaire captured 7 items on basic proficiency in mobile phone use (eg, charging the phone and typing with the keyboard), 8 items on proficiency in communication (eg, sending emails and messaging), 3 items on data and file storage (eg, transferring files from mobile to computer), 8 items on internet use, and 6 items on troubleshooting and software management (eg, updating and deleting apps). Higher scores on each item indicated greater proficiency in each aspect.

A semistructured focus group guide was developed in collaboration with AL (male, program manager), Peta Mills (female, clinical project officer, PhD), SS (female, postdoctoral research associate), and SLN (female, professor and clinical neuropsychologist with extensive experience in focus groups, workgroups, interviews, and working parties for a variety of purposes such as to develop guidelines or models). The focus groups and questions were structured around three core themes (see Multimedia Appendix 1 for the question guidelines used):

1. Current use of mobile phone apps: informed by prior literature [17,18], this theme focuses on participants' current use of mobile phone apps, particularly for health and sleep-related functions. The theme includes use habits, types of health apps used, and experience with speech recognition features on mobile devices. Related questions were designed to assess participants' familiarity with mobile phone technology, health-related apps, as well as their interactions and experiences with speech recognition features.

2. Interest in completing cognitive tasks through a mobile app: informed by previous studies [18,26], this theme was selected to explore participants' willingness and comfort in using a mobile app for memory assessments. This theme includes the potential benefits and challenges of this approach compared to traditional methods. The aim is to understand the acceptability, motivation, practicality, and barriers or facilitators of adopting mobile apps for cognitive assessments.
3. Feedback on the proposed mobile app: this theme seeks to gather participants' perspectives on various aspects of the proposed mobile app, including the clarity of instructions and tasks, visual appeal, potential distractions, and privacy concerns. Participants were also invited to provide suggestions for enhancing the usability and engagement of the mobile app. The questions specifically targeted feedback on the app's features, such as the chatbot and task length or design, and were developed based on internal testing of the mobile app.

A Microsoft PowerPoint presentation (Multimedia Appendix 2) was used to guide participants through the focus group material. The presentation introduced the concept and significance of SDM, highlighting its potential impairment in aging and cognitive decline and its understudied nature due to current limitations in traditional data collection methods (ie, in a sleep laboratory setting). We showed how our mobile app may be a novel solution to these barriers to facilitate home-based assessments. The presentation also illustrated how participants would interact with Aurora, including the delivery of the word-pairs task, in which the process and structure of the SDM assessment involving learning and recall word pairs were explained.

Data were collected via 2 focus groups between October and November 2022. Each focus group was facilitated by separate researchers: SS, a postdoctoral research associate with 10 years of applied research experience and 4 years of qualitative research experience (interviews and focus groups), and Peta Mills, a clinical project officer with 11 years of applied research experience and 18 months of qualitative research experience (focus groups). At the time of the focus groups, both facilitators were not involved in this research project in any capacity and thus provided an impartial perspective. AL and DI (male, software engineer) attended the focus group sessions to answer participants' logistical and technical questions. Focus groups lasted 60 - 90 minutes and were audio-recorded, transcribed, and de-identified.

Ethical Considerations

This study was approved by The University of Sydney Human Ethics Committee (2022/HE000563) and conducted in accordance with the World Medical Association Declaration of Helsinki. Written informed consent was obtained from all participants prior to any study procedures and given the option to opt out of the study at any given time. Participants were given a A$20 (US $12.75) gift voucher as compensation for their time. All data collected were deidentified to ensure participant privacy and confidentiality.

Data Analysis

For clinical and survey data, frequency and descriptive statistics were computed using SPSS Statistics (version 24.0; IBM Corp). Focus group transcripts were analyzed thematically in NVivo (version 13; Lumivero), a qualitative data analysis computer software package, using the techniques described by Braun and Clarke [27]. The thematic analysis approach described by Braun and Clarke [27] is a systematic, iterative, and inductive process comprising 6 phases. Initially, researchers immerse themselves in the data to discern patterns and potential coding schemes. Subsequently, they generate initial codes to categorize salient features systematically. These codes are then organized into potential themes. Themes undergo rigorous validation to ensure coherence and alignment with the dataset. Once themes are finalized, they are defined, and any hierarchical relationships are identified. Finally, thematic insights are woven into a narrative to address relevant research questions.

As we had identified our 3 core themes during the development of the focus group guide, our thematic analysis was focused on a deeper exploration of these themes. Following Braun and Clarke [27] phases, AL and SS became familiar with the data via repeated reading and individually created initial codes for all transcripts by noting evocative phrases, ideas, and perceptions. Codes were then organized into meaningful groups and sorted into subthemes. Where there was disagreement in coding or theme development, the codes or themes were discussed and refined. To ensure the study conformed to best practice guidelines, we used the COREQ (Consolidated Criteria for Reporting Qualitative Research) checklist and met 27 of 32 items [28].

Results

Participants

In total, 19 people from the HBA memory clinic were invited to participate in the focus groups, and 11 of these agreed to participate. Their demographics and clinical information are reported in Table 1. Briefly, the sample on average was aged 68.5 (SD 5.1) years and predominately female (n=7, 64%). The sample also comprised 8 subjective cognitive impairment, 2 nonamnestic MCI, and 1 amnestic MCI. Of these participants, 10 completed the AMDPQ, with 1 participant declined, as they did not have sufficient proficiency to access the digital questionnaire. On average, participants demonstrated relatively high mobile proficiency (see Multimedia Appendix 3 for a full breakdown of participant responses to each individual item).

Table . Participant demographic and clinical information.

	Values
Age (years), mean (SD)	68.5 (5.1)
Sex (male), n (%)	4 (36)
Education (years), mean (SD)	15.1 (2.9)
MMSE[a] score (out of 30), mean (SD)	29.2 (0.9)
Subjective cognitive impairment, n (%)	8 (73)
Nonamnestic mild cognitive impairment, n (%)	2 (18)
Amnestic mild cognitive impairment, n (%)	1 (9)
AMDPQ[b] total score (out of 25), mean (SD)	20.5 (4.6)
AMDPQ—mobile device basic subscale (out of 5), mean (SD)	4.4 (0.6)
AMDPQ—communication subscale (out of 5), mean (SD)	4.0 (1.0)
AMDPQ—data and file storage subscale (out of 5), mean (SD)	3.7 (1.3)
AMDPQ—internet subscale (out of 5), mean (SD)	4.2 (1.1)
AMDPQ—troubleshooting and software management subscale (out of 5), mean (SD)	4.1 (1.1)

[b]AMDPQ: Abbreviated Mobile Device Proficiency Questionnaire.

Thematic Analysis

Overview

The thematic analysis revealed two broad themes relevant to the 3 core focus group themes: (1) context of mobile phone use and (2) shifting from traditional laboratory-based assessments to home assessments. The latter theme should be considered within the framework of the former theme, as shown in Textbox 1. That is, theme 2 considers the challenges and facilitators identified by participants when shifting from laboratory settings to home environments within 2 specific contexts: (1a) participants' existing familiarity and proficiency with mobile phones and apps and (1b) the prevalent stereotypes and preconceived notions concerning aging and technology.

Textbox 1. Breakdown of the overarching themes and subthemes identified in our study by 2 primary domains: "context of mobile phone use" and "shifting from traditional laboratory-based assessments to home assessments."

Context of mobile phone use

- Current phone use
- Aging

Shifting from traditional laboratory-based assessments to home assessments

- Accuracy of data
- Human versus robot
- Accessibility
- Compliance

Context of Mobile Phone Use

Current Phone Use

Participants were asked to share their mobile phone use patterns and specify the types of apps they used. Across participants, mobile phone use varied substantially from the use of basic phone functions, such as phone calls, text messaging, and camera functions, to more complex use involving apps, such as emails, social media, search engines, maps, news, weather, and music. Although minimally used, health and sleep apps were accessed for relaxation and to monitor sleep, heart rate, and physical activity. One participant felt highly proficient in phone use and that the phone was integral to the organization of their day-to-day life: "I would be lost without my mobile phone." Speech-to-text functions were used as needed, particularly when driving and composing text messages, using navigation maps, or playing music. However, it is worth noting that not all participants chose to use this feature.

Aging

Individuals who reported limited phone use perceived their age as a barrier to gaining proficiency with new technologies.

> *I don't think I am alone in this, but it is a real problem when you're a bit older trying to pick up the technology that seems to be intuitive to other people.*

Participants expressed a sense of not keeping pace with technology, which stemmed from their preference for relying on what they were familiar with or their self-perception as old-fashioned. Even when participants successfully used a new technology, they felt the need to use it continuously to avoid losing the knowledge of how to operate it effectively.

> *There is so much learning involved and if you don't use these things more than once in 6 months it's gone.*

Irrespective of the reasons for their limited access to, and use of, technology, a prevailing sentiment among these individuals was a sense of missing out.

> *I have a Samsung phone, one of the latest, and I know there are lots of lovely things for me and I'm not using them. I would use them if they were set up.*

Younger adults were viewed as having an innate familiarity with and competence in using digital tools and, thus, were flagged as potential facilitators of accessing and using technology. Subsequently, participants who did not have a younger adult available to facilitate their use of new technologies felt at a disadvantage. These observations reinforced the prevailing belief that older generations faced a variety of disadvantages with technology.

The insights gathered suggest a spectrum of technology assistance needs among participants. Some individuals may require comprehensive setup support, including step-by-step instructions and human interaction throughout their tech journey, while others might only require minimal assistance. This underscores the importance of adopting 1 of 2 design approaches for apps: either a straightforward and user-friendly design that prioritizes ease of use or, in the case of complex apps, the provision of substantial human support.

These findings carry significant implications for the design of apps intended for home use as opposed to controlled laboratory settings. They serve as a foundation for understanding the crucial factors and context that should inform the app design process when moving apps from the laboratory to the home.

Shifting From Traditional Laboratory-Based Assessments to Home Assessments

Overview

There were several considerations for moving the SDM task from laboratory-based assessments to home assessments raised during focus groups. Participants identified facilitators as well as challenges and proposed potential solutions to overcome these obstacles (Table 2).

Table . Moving sleep-dependent memory from laboratory to home: challenges, solutions, and changes.

Challenge	Potential solution	App updates
Unexpected events during task completion (eg, phone ringing and someone knocking on the door).	Function to pause and recommence task.	The task was not implemented with a pause option because it could impact the results. Instead, Aurora advised participants to find a quiet, distraction-free place at the start of the task. If they could not finish because of unforeseen circumstances, they were offered another chance on a different night.
Difficulty with setting up apps and need help with troubleshooting.	Set up the app for participants and having someone to contact.	Through email, participants can reach a contact person who will provide technical support.
Participants did not want to enter identifying information (eg, names or date of birth).	Using a participant ID rather than identifying information.	We have given the participants an option to enter their participant ID. We now only collect participant initials and not name or date of birth.
Participants flagged that sometimes they ignore push notifications on their phones in the evening.	Option for the phone to ring or a text message.	The app now sends additional notifications to remind the participants to complete the task. Furthermore, the phone now sends short audio notification reminders to participants.

Accuracy of Data

Participants generally regarded the home environment as conducive to achieving higher accuracy levels relative to the laboratory environment, which was described as "ghastly" and distressing. Indeed, because of this perception, participants questioned the reliability of sleep laboratories, primarily because of the unconventional and unfamiliar sleep conditions they imposed. These doubts extended to the execution of the SDM task in the laboratory. Participants posited that conducting the SDM task in the laboratory might cause reduced accuracy compared to conducting the same tasks within the comfort of their homes, where they felt more relaxed as they did not have a researcher watching them and where they could expect a more restful night's sleep. Similarly, there was a recognition that the peculiar sleep laboratory environment might introduce sleep disturbance that may disrupt SDM processes. Therefore, the results of the SDM task completed in a laboratory may not truly reflect an individual's performance. To further illustrate these insights, one participant shared their personal experience with a sleep laboratory:

> *I recently, did a sleep study. It's just not what I consider to be an indicator of anything that's going on. I had a two-and-a-half-hour sleep if that through the whole night strapped into all these other things*

> *as well ... So definitely at home I think you'll get more relaxed, and you get a true picture of what's going on.*

Conversely, having a researcher present and demanding attention could lead to better performance.

> *In the clinic, I was being put on the spot ... "we're not just being casual here, we're doing a trial and I'm seeking your recall results, so you need to pay attention." So being in the clinic I was really on purpose for fear of failure ... At home I'd be far more relaxed and maybe that's a good thing too.*

In the laboratory setting, participants interact with the SDM task by saying their responses aloud. When considering the at-home mobile app version of the SDM task, participants were given a choice between typing their responses into an open text field or vocalizing their answers. Preferences varied, as participants felt that while using verbal responses may be more convenient than typing, the accuracy of verbal responses could be reduced. Nonetheless, being able to choose to use a text or a verbal response resonated positively with participants.

Human Versus Robot

During thematic analysis, some initial disagreements arose among the 2 scorers regarding the classification of human versus robot. AL suggested that the theme "human versus robot" may encompass accessibility as well, while SS suggested creating a separate theme for "accessibility." To resolve this, the team engaged in iterative discussions, referring back to the original transcripts to ensure alignment with participants' narratives. Through this process, a consensus was reached to have "human versus robot" and "accessibility" as 2 separate themes.

The facilitators explained to participants that they would primarily interact with Aurora, a chatbot designed to guide them through the SDM task via written text or verbal instructions. Participants overwhelmingly agreed that any kind of computerized intelligence should be as humanlike and natural as possible, suggesting that a computerized voice might be difficult to engage with.

> *I found it very easy to do it in the lab and the interaction with [researcher name] it was simple to do and it was a softer voice and it is relaxed and it is encouraging. All that subliminal processing of getting the task done.*

Relying solely on a computerized and automated system without human support raised several challenges, and the lack of human interaction was primarily viewed as a drawback. Indeed, participants flagged the importance of human support, both during setup and for ongoing assistance. Participants also identified that the app may struggle to accommodate diverse accents or may lack the mechanism to clarify potential response errors, tasks that were easily accomplished by a human. To assist with these challenges, participants recommended that the app should be capable of detecting potential errors and should offer corrections or alternative suggestions when necessary.

Additionally, participants expressed apprehension around the security of data, given personal information was to be entered directly into the app. There was a hesitation to provide personal information, such as names or dates of birth. Instead, participants proposed using participant IDs only for entry into the app and that other information, such as date of birth, is gathered by the researcher in another way and is linked externally to this ID. However, other participants displayed indifference to this issue, expressing a belief that personal information is already widely accessible: "Everyone knows everything about us anyway."

Accessibility

Participants identified 2 primary barriers that could impact the app's accessibility. These were physical and economic barriers. Several participants expressed concerns regarding age-related vision problems, which can hinder their ability to read or view small text. Participants proposed using larger screens, like tablets, and increasing font sizes might address this barrier. Participant responses from the AMDPQ suggested that certain participants exhibited greater proficiency when using personal computers or tablets than smartphones, indicating the potential value of designing apps with flexibility and accessibility across different platforms.

> *I do I get a bit irritable with the smallest of the screen prefer to do things on the laptop.*

Another physical barrier that was discussed was physical dexterity, which refers to fine motor skills and the ability to move their fingers. Age-related factors, such as tremors and arthritis, may be challenging for older adults to respond to Aurora or complete the SDM task.

> *The dexterity on the fingers may be important on how well someone clicks on the screen ... I might have trouble because I haven't done it on a phone and only do it on a PC.*

One participant raised concerns about whether the app required high bandwidth to use. High bandwidth apps can increase difficulty in accessing and using mobile apps as well as increase costs associated with using the app. Therefore, it is important to optimize apps for low bandwidth.

> *Is your application bandwidth heavy that it's just going to slow things down for those of us who actually don't have a proper wireless connection or a slow data connection and it's just going to make it after a while just unusable nothing.*

Participants noted that the initial setup phase of new technologies (eg, installing and setting up of apps) was either too challenging or time-consuming. Participants recognized that they required assistance or guidance to set up, navigate, and use technology effectively. This support could encompass various aspects, such as learning to use new devices, understanding complex software apps, or troubleshooting technical issues. However, they found that, in general, such support was lacking or insufficient. The consensus among participants strongly supports the idea that offering setup assistance, particularly during the initial stages of technology adoption, would be immensely beneficial. This will help familiarize participants with the mobile app, save time, and alleviate stress for older adults. Any kind of automation was also supported to avoid repeated data entry:

> *I don't need to put that same information in every time that I'm doing this test because this would be 5 - 10 minutes every day just putting in the same information ... when you are actually setting up the app on your phone is when you actually key that data in and then you don't have to do it again*

Compliance

The facilitators explained to the participants that the home-based completion of the chatbot would require dedicating approximately 40 minutes to the learning component, followed by a subsequent delay of 20 - 30 minutes and another 10 minutes to complete the task. While participants expressed comfort with the overall duration of the task, the true challenge was quarantining the time to do this task.

> *I think anything more than 40 minutes it may be burdensome. I do think 40 minutes is the top. The challenge is disruptions and to really quarantine the time and be strong about that.*

Participants proposed a solution, emphasizing the necessity of proactively earmarking dedicated time in advance to ensure the completion of the task. Having a large time window during which participants could complete the task would provide the flexibility needed for accommodating various schedules and preferences of participants.

> *I would quarantine in the time then for the next day and prepare myself because I don't have any other commitments or pressures on my time.*

Alternatively, participants suggested introducing a pause feature to mitigate any potential disruptions caused by unforeseen events, such as incoming phone calls or unexpected visitors. However, it is crucial to acknowledge that the introduction of a pause feature could potentially influence the integrity of the test. While these features may be convenient for the participants, this will introduce confounds to the results. Subsequently, a pause button was not implemented in Aurora.

> *I always find a pause button is important. For example: if I am starting the memory test or memory exercise right now and someone knock the door ... I have the opportunity that I can come back to that when I need to do something.*

Another challenge identified was participants occasionally forgetting to complete the task. The facilitators explained to the participants that there are existing notifications within the app to remind the participants to do the task in the evening and in the morning. It was suggested that increasing the frequency of notifications could be a viable solution. Moreover, participants highlighted a tendency to ignore push notifications, particularly in the evening. To address this, participants proposed implementing alternative reminder methods, such as phone calls or text messages. Participants identified that their interest and motivation to complete the memory task were closely tied to the app's clarity. The consensus was that instructions and information presented in an easily digestible manner would keep participants' engagement. It was evident that it is important to prioritize clear and straightforward instructions that would lead to sustained participant engagement, especially when participants are asked to complete the task on multiple occasions.

> *Okay, if you wanted me to use it repeatedly then it's got to be clear and simple and easy to access if you're talking about once every three months and that's ok I'll come back anytime.*

Participants nearly unanimously highlighted the critical role of feedback on their task performance. They underscored the importance of receiving real-time feedback to gauge their progress and enable a sense of accomplishment and motivation to improve and continue to complete the task for multiple assessments.

> *I don't want money but I do want feedback. I am involved in a lot of medical research I am surprised I don't find out about the results.*

Even participants who did not think that feedback was necessary thought it would be a welcomed supplementary feature, as it would motivate them to continue using the app. Subsequently, Sleep Memories integrated informative feedback to enhance user engagement and promote continued motivation. For others, the motivation was intrinsic (ie, feedback not needed), and people would remain motivated to contribute to science. Participants trusted that scientists knew what they were doing and would follow their guidance because they are experts in the field.

> *... The work that this unit does is so important. Just thanking them for their time and delivering, any material or rewards I find it degrading. I just want to donate my data to be used for the greater good. There is nothing you can give me to make it better.*

Discussion

Principal Findings

This study aimed to investigate the perspectives of older adults both with subjective or objective cognitive impairment regarding barriers and facilitators to using an at-home assessment of SDM through a novel app named Sleep Memories. Through co-design methodologies, we assessed the initial prototype of the mobile app to incorporate user feedback into a revised version suitable for clinical testing.

We found that digitalization and technological advancements can both facilitate and hinder everyday life for older adults. This phenomenon is reflected in the term Janus-faced technology [29]. According to this concept, the successful integration of technology can substantially improve daily activities for older adults. However, barriers to use can evoke feelings of alienation and disconnection from the digital world. Understanding these barriers is essential to minimize these negative feelings and to, instead, develop accessible and user-friendly technology solutions for older adults, particularly those with cognitive impairments.

One of the key findings of our study was the importance of app flexibility in accommodating users' diverse needs and preferences and in challenging barriers. While some individuals reported requiring high-level assistance, others indicated that

they could navigate the app independently with minimal support. A recent systematic review highlighted the critical importance of tailoring technology to meet the specific needs and preferences of older adults with MCI and dementia [30]. Below we examine each of the facilitators and barriers we identified and explore corresponding, flexible solutions in light of existing research.

Comparison to Prior Work

The "first night effect" is a confounding variable in sleep research where participants' sleep is disrupted due to being in an unfamiliar environment. This effect has been studied in prior studies. For instance, one study [31] demonstrated its potential to impact sleep disorder diagnoses. The benefit of home-based testing is that participants can sleep in their usual environment, removing the need for multiple night sleep laboratory testing. Furthermore, the SDM data collected are not confounded by the first night effect and more accurately represent a participant's true abilities than traditional SDM testing.

Within the discussion of voice responses, our findings align with prior work, with concerns from older adults regarding the accuracy of audio (eg, the chatbot's ability to accurately capture verbal responses) and text (eg, spelling mistakes) inputs [32]. In response to these concerns, Sleep Memories has implemented a dual-layered validation process. First, an autocorrect function is used to rectify minor spelling inaccuracies automatically. Second, when the system is uncertain of the response, a request for confirmation by a researcher is made. The implementation and availability of a voice response option increase the accessibility of the mobile app for those who may have age-related declines or disabilities [32].

To increase the accessibility of mobile apps for older adults, it is important to navigate both technological and socioeconomic challenges. Our focus groups highlighted concerns like high bandwidth and data consumption, which could impede the functionality and availability of health apps such as "Sleep Memories" for older adults. Furthermore, older adults may have age-related physical limitations, such as arthritis or hand pain, which may impact their interaction with mobile devices. To address the high bandwidth and data consumption, we allow the app to be used without an internet connection, and data are uploaded when connectivity is available. As previously mentioned, the implementation of voice responses can be a solution to enable those with physical limitations to use the app.

Participants raised concerns about forgetting to complete the task, particularly for those who might overlook setting personal reminders. This aligns with previous research in the context of medication compliance, where it was observed that a single reminder was often insufficient to prompt action, suggesting that a backup notification could serve as a viable solution [33]. A solution in our context that was proposed was to increase the frequency and elevate the distinctiveness of reminder notifications (eg, for Sleep Memories, we implemented a unique auditory notification, specifically a vocal prompt stating "it is now time to complete your memory task").

Similar to a previous study [34], we found that incorporating feedback mechanisms, like scores, within eHealth tools is imperative to foster user engagement and empowerment. These features motivate users by providing immediate, tangible feedback on their performance. However, it is essential for app developers and researchers to communicate the context and limitations of their scores, particularly when there is a lack of established normative data. Without proper context, participants may misinterpret their scores, leading to unnecessary anxiety or concerns.

Our study revealed that conducting tasks within a home setting may introduce various distractions. This was aligned with prior research on the environmental interference of unsupervised home cognitive assessments [26]. To mitigate this challenge, 2 solutions emerged during our focus group discussions. The first involves incentivizing participants' engagement through targeted motivation strategies, such as feedback, to maintain focus despite potential distractions. The second suggests the need for flexibility in task design, allowing participants to pause and resume activities, accommodating the unpredictability of the home environment. However, this approach must be balanced against the risk of compromising data integrity. For instance, in "Sleep Memories," participants can pause and take short breaks between trials without permitting interruptions during the trials themselves to safeguard data continuity and accuracy.

Limitations

Our study comprised older adults who had relatively high mobile proficiency at least in the subdomains that we examined, so our findings may not be generalizable to older adults who have a low mobile proficiency. Another limitation is that our sample had less representation from individuals with MCI (n=3), which limited our ability to detect or uncover differences in responses related to cognitive impairment. Future research is necessary to explore this important area by recruiting a larger cohort of individuals with MCI. Similarly, our participants generally scored highly on the AMDPQ, meaning that they showed decent proficiency in mobile phone use. Whether these findings apply to older adults with low proficiency in mobile phones needs further investigation. Nonetheless, our study is one of the first to examine the potential barriers and facilitators to the use of mobile device apps, in particular to complete memory tasks, in those with cognitive impairment.

Future Directions

In addition to the app modifications mentioned earlier, our findings provide valuable insights to meet the needs and preferences of our older adult users. When deploying Sleep Memories, we will first conduct a needs assessment to assess the ability to use existing and new technology as well as the user's circumstances (eg, Do they have time to complete the task in the app without distraction?) and environment (eg, Do they have access to a technology-savvy person in their network?). Based on this assessment, we will offer users various levels of support such as the ability for a phone call by a researcher or various notification options.

Conclusions

Our study demonstrates that while there are barriers related to accessibility, usability, and data integrity to using health-related phone apps in this population, there are important facilitators

that can be implemented in phone apps to create a flexible and inclusive digital health tool. Furthermore, we have shown evidence on the potential feasibility of the "Sleep Memories" app to enable the collection of SDM data within a user's natural environment.

Acknowledgments

The authors would like to extend their deepest gratitude to all the participants who dedicated their time and shared their experiences with them. The authors also wish to acknowledge Peta Mills for her assistance with their focus groups. Finally, the authors thank their clinical and research team at the Healthy Brain Ageing clinic. This study was supported by the National Health and Medical Research Council (NHMRC) Centre of Research Excellence to Optimise Sleep in Brain Ageing and Neurodegeneration (CogSleep), the Commonwealth Scientific and Industrial Research Organisation, and an NHMRC Fellowship awarded to SLN (GNT1135639) and AD (GNT2008001).

Abstract

Background: Previous research has shown that in-lab motor skill acquisition (supervised by an experimenter) is sensitive to biomarkers of Alzheimer disease (AD). However, remote unsupervised screening of AD risk through a skill-based task via the web has the potential to sample a wider and more diverse pool of individuals at scale.

Objective: The purpose of this study was to examine a web-based motor skill game ("Super G") and its sensitivity to risk factors of AD (eg, age, sex, *APOE* ε4 carrier status, and verbal learning deficits).

Methods: Emails were sent to 662 previous MindCrowd participants who had agreed to be contacted for future research and have their *APOE* ε4 carrier status recorded and those who were at least 45 years of age or older. Participants who chose to participate were redirected to the Super G site where they completed the Super G task using their personal computer remotely and unsupervised. Once completed, different Super G variables were derived. Linear and logistic multivariable regression was used to examine the relationship between available AD risk factors (age, sex, *APOE* ε4 carrier status, and verbal learning) and distinct Super G performance metrics.

Results: Fifty-four participants (~8% response rate) from the MindCrowd web-based cohort (mean age of 62.39 years; 39 females; and 23 *APOE* ε4 carriers) completed 75 trials of Super G. Results show that Super G performance was significantly associated with each of the targeted risk factors. Specifically, slower Super G response time was associated with being an *APOE* ε4 carrier (odds ratio 0.12, 95% CI 0.02-0.44; *P*=.006), greater Super G time in target (TinT) was associated with being male (odds ratio 32.03, 95% CI 3.74-1192,61; *P*=.01), and lower Super G TinT was associated with greater age (β −3.97, 95% CI −6.64 to −1.30; *P*=.005). Furthermore, a sex-by-TinT interaction demonstrated a differential relationship between Super G TinT and verbal learning depending on sex ($\beta_{male:TinT}$ 6.77, 95% CI 0.34-13.19; *P*=.04).

Conclusions: This experiment demonstrated that this web-based game, Super G, has the potential to be a skill-based digital biomarker for screening of AD risk on a large scale with relatively limited resources.

Introduction

Since the number of cases of Alzheimer disease (AD) is expected to double in the next 2 decades [1], there is an urgent need for widespread screening of older adults for their individual AD risk profile, which has implications for clinical care and research. Current options, such as positron emission tomography for measuring tau and beta amyloid pathology, tend to be expensive and invasive and require advanced imaging facilities [2]. Blood-based biomarkers may make screening for AD more affordable and less invasive, but their validity and standardization are still being established at this time [3,4]. Cognitive screening tests can indicate deficits, but these largely rely upon in-person administration from a trained clinician and may have reduced sensitivity in identifying individuals at high risk of AD in the earliest stages [5]. Thus, it is important to

identify measures that are sensitive to AD risk and yet can also be delivered accurately, easily, and directly to patients and prospective participants in clinical trials and research studies.

Digital biomarkers have great potential to meet the need for accessible and remote testing of AD risk. Broadly speaking, digital biomarkers are measurable indicators of health or disease collected from a digital device or through digital means. Some digital biomarkers of AD include finger tapping [5,6], repeated cognitive assessment on a Wi-Fi–enabled device [7], recorded speech [8], and digital clock drawing [9], which have all been shown to be sensitive to cognitive impairment. These measures have also been associated with disease status, differentiating between cognitively intact versus mild cognitive impairment (MCI) and MCI versus dementia to some degree. However, these examples have overall low sensitivity to risk factors of AD, such as age [10], sex [11], apolipoprotein-E (*APOE*) ε4 carrier status [12,13], and brain amyloid [9]. Considering this, another potential digital biomarker of AD could be motor skill. Motor skill acquisition is the within-session improvement in a motor skill as a function of practice [14]. Previous in-lab studies have associated motor skill deficits with *APOE* carrier status, hippocampal atrophy, functional decline, and amyloid deposition among people diagnosed with amnestic MCI [15-18]. This task can also be collected remotely [19,20], which would allow for a wider and more diverse sample of individuals at potential risk for AD and can more easily facilitate longitudinal testing as desired.

This study developed a web-based tool for assessing motor skill performance called Super G [21], which can be reliably played unsupervised on the web [20] regardless of device type and without downloading any app. Specifically, the objective of this study was to examine whether Super G performance was individually related to known risk factors of AD (eg, age, sex, *APOE* ε4 carrier status, and verbal learning). Based on prior motor skill studies in AD, it was hypothesized that Super G performance would be negatively associated with each risk factor.

Methods

Study Design

This was a cross-sectional descriptive study that examined within-session performance characteristics from a web-based motor skill task (Super G) and their association with AD risk factors among adults recruited from the MindCrowd study.

Participants

Participants were recruited in May of 2021 through MindCrowd, a web-based research study launched in 2013 to crowdsource demographic, medical history, lifestyle, and cognitive data to identify risk factors of AD [22,23]. Emails were sent through MindCrowd to a subset of 662 individuals who met our inclusion or exclusion criteria and were older than 45 years, who had previously provided a dried blood spot or saliva sample for *APOE* genotyping (see section “AD Risk Factors and Other Participant Characteristics From MindCrowd” for details) and had provided consent to be contacted for future studies. A hyperlink was included in the email that directed individuals to the Super G game website, on which participants digitally provided consent (approved by the Arizona State University institutional review board study no. 13081). Of the 662 individuals emailed, 54 participants (age: mean 62.39, SD 7.4 years; female: n=39) appropriately registered and completed all 75 trials of the game, equating to an 8.1% response rate. The mean (SD) time between MindCrowd data collection (specifically verbal learning, see section “AD Risk Factors and Other Participant Characteristics From MindCrowd” for details) and Super G data collection was 5.9 (1.4) years.

Super G

The Super G game was developed in Unity 5.3.1 and is hosted on Hostinger. Thus, participants were not required to download an app or program to their device. Super G was developed as a gamified version of a seminal motor skill paradigm [24] and has been validated against the original version [21]. The goal of Super G is to help an astronaut explore as many planets as possible within the game’s solar system. There are 16 planets to visit but only 75 attempts to reach them all. Participants use the left and right arrow keys on their keyboard to move the astronaut onto a planet. However, the game uses a rate control mechanism that may not be immediately apparent to participants [21]. Specifically, pressing the right arrow key applies a constant positive force to move the astronaut toward the planet, while pressing the left arrow key applies an equal negative force away from the planet. Since the virtual environment lacks gravity or drag, any force applied will result in a constant velocity until a negative force is applied to slow it down. Thus, participants must learn to apply negative force at the right time and for the right duration to land the astronaut on each planet.

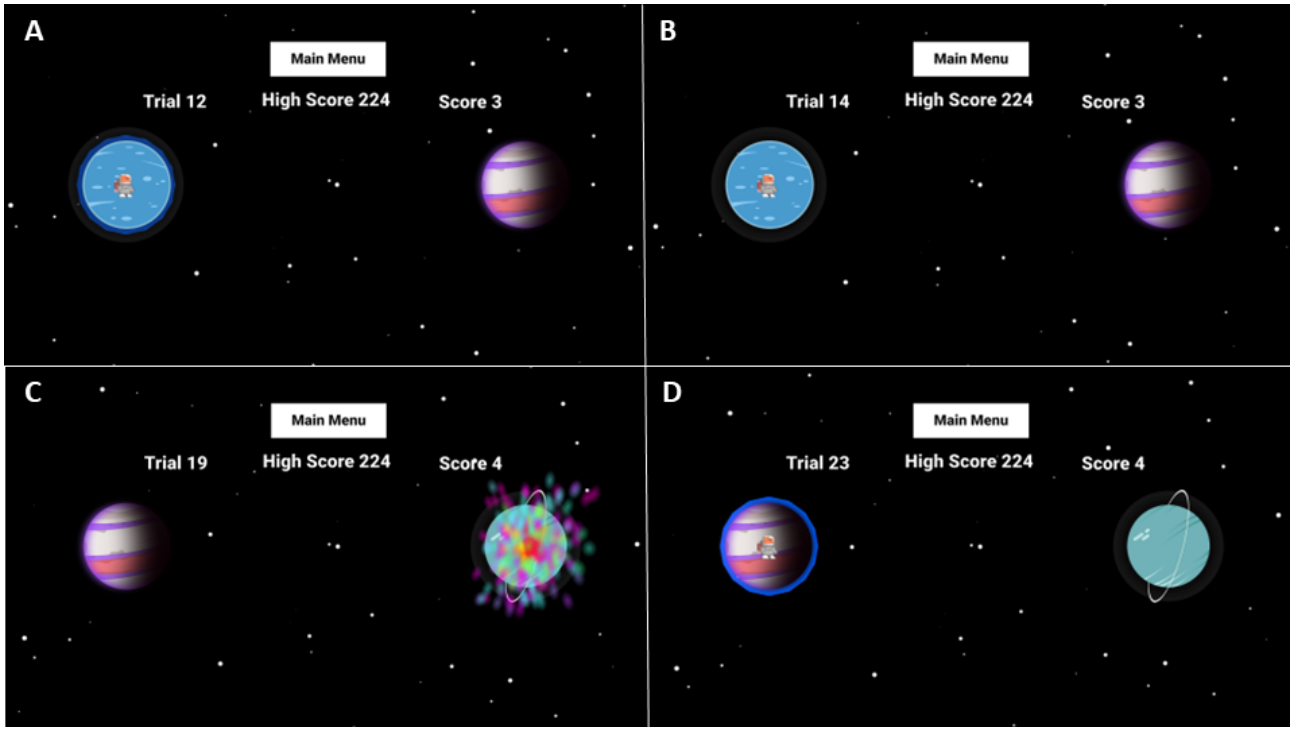
Each trial in Super G begins with the astronaut positioned on the left side of the screen on the initial start planet. The target planet is located on the opposite side of the screen to the right (Figure 1A). The trial lasts 4.5 seconds, but the astronaut cannot leave the start planet until 1.5 seconds have elapsed, as indicated by the disappearance of the blue atmosphere around the start planet (Figure 1B). If the astronaut leaves too early, the trial resets and the astronaut is returned to the initial position on the start planet. Once the blue atmosphere disappears, the participant has 3 seconds to land the astronaut on the target planet. To achieve a successful landing, the astronaut must stay within the boundary of the target planet for 1 continuous second. If successful, a reward tone plays, and fireworks erupt from the target planet (Figure 1C). After a successful landing, Super G repositions at the start position, and the previously landed planet becomes the start planet, with a new target planet appearing in its place (Figure 1D). In the event of a failed landing, the planets for the next trial remain the same, and astronaut reappears at the start position. All 75 trials are completed within a single session for a total session length of approximately 6 minutes.

Cursor position and key press data from each trial of Super G were collected at 100 Hz, along with high scores, time and date of each trial. From these data, four performance variables were calculated. First, scaling ratio (SR) represents the ratio of negative force (duration of left button press) applied to Super G over positive force (duration of right button press), where values equal to 1 indicate equal scaling of forces. Second, time

of reversal (TR) is a measure of how well participants execute the timing of their movements by identifying when the left arrow key press occurs during the trial, where higher values are reversals that occur later in the trial. Successful trials require equal scaling of forces (ie, SR close to or equal to 1) and a reversal timed at the midway point of the trial, although we note that there can be trade-offs between the SR and TR to still allow for some degree of success in the task. Third, total time in the target (TinT) planet is the time that the cursor stayed within the target planet, with higher values representing better performance. Fourth, response time (RT) is a measure of how soon the cursor left the home planet after the disappearance of the start planet's atmosphere, and lower values equate to a faster RT.

Although these performance metrics do strongly correlate with one another, each represents distinct phases of individual motor skill acquisition, as it is possible to have a fast RT with a low TinT if either timing of cursor reversal or scaling of forces is not well executed. Overall, average TinT across all 75 trials is the primary measure of performance since it directly represents the task goal and performance of the task as it relates to execution of SR and TR. Average RT across all 75 trials was considered as a secondary measure of performance because it represents the earlier stage of skill acquisition as participants first need to anticipate when to exit the start planet prior to execution of their acquired movement strategy. Average TinT and RT across the 75 trials are used as the Super G metrics of individual performance due to our prior work [21], which demonstrated that average TinT and RT well describe individual within-session change in performance and delayed retention.

Figure 1. Each panel represents the different phases a participant may experience during Super G play. (A) The astronaut, Super G, spawns on the start planet at the beginning of each trial. There is a blue atmosphere around the planet that signals to the participant that Super G cannot leave yet. (B) Once the blue atmosphere disappears, then Super G can leave the start planet and attempt to land on the target planet. (C) If Super G successfully stays within the target planet boundary for 1 continuous second, then a reward tone plays and fireworks erupt from the planet. (D) Subsequent trials then render the previous target planet as the new start planet and a new target planet is put in place.



AD Risk Factors and Other Participant Characteristics From MindCrowd

Super G data were harmonized with MindCrowd through merging of hashed email addresses linked to MindCrowd data and used as the login for the Super G game. Super G variables were then merged with participant age, sex, level of education, verbal learning (measured via paired associates learning [PAL]) score [25], simple visual reaction time (svRT), and *APOE* genotype data, which were available in MindCrowd. The PAL is a verbal learning task that measures the ability to remember the associations between different word pairs. Specifically, participants are visually presented with 12 word pairs, with each word pair presented separately and at 2-second intervals. Participants were then presented with the first word of each pair and then used their keyboard to type the missing word. This procedure was repeated for 2 additional trials. The maximum score on the PAL is 36 (12 words across 3 trials). The svRT task measured the median reaction time across 6 trials, in which participants had to press any keyboard button as soon as a target stimulus appeared on their screen, with reaction time for each trial recorded in milliseconds. Median svRT was used due to the skewness of the distribution of reaction time in each participant's individual data (skewness svRT median 1.2 vs skewness svRT mean 4.1). The svRT test was used in this study as a control variable only. Participants were classified as *APOE* ε4 carriers or noncarriers. Carriers were defined as individuals who had either 1 or 2 copies of the ε4 allele, and noncarriers were defined as individuals with 0 copies of the ε4 allele. This was based on prior genotyping from biospecimen collection via

self-administered saliva or dried blood spot kits that were mailed to the participants by MindCrowd and then processed by the Translational Genomics Research Institute. Details regarding biospecimen collection and genotyping can be found here [26]. Complete visualization of *APOE* ε4 carrier status with svRT, PAL, and age can be viewed in Figure S1 in Multimedia Appendix 1.

Statistical Analysis

Wilcoxon rank sum tests were used due to a difference in sample sizes between *APOE* ε4 carriers (n=23) and noncarriers (n=31), since uneven sample sizes may lead to inaccurate and disproportionate estimates of variance of each group and violate assumptions of parametric testing. This determined whether there were differences in age, PAL score, svRT, and Super G performance between the 2 groups. Chi-square tests were used to determine whether there was a difference in proportion based on sex, race, education, and ethnicity between carriers and noncarriers. To provide broader context of the verbal learning (PAL) and reaction time (svRT) of this sample, percentile scores were calculated for each participant adjusted for their age, sex, and level of education. This allowed for better contextualization of the relative performance on each measure between carriers and noncarriers relative to the entire MindCrowd cohort (ie, if participants in this study are under- or overperformers compared with what would be expected to a random sample across the entire cohort).

Separate linear and logistic multivariable regression analyses, depending on outcome variable type, were used to test the relationship between Super G performance and the dependent variables, that is, AD risk factors. Specifically, different models were constructed to identify which Super performance metrics are related to specific AD risk factors, while controlling for possible confounding effects of the other AD risk factors and participant characteristics. Multivariable logistic regression was used for the dependent variable of *APOE* ε4 carrier status (where carriers were coded as “true” and noncarriers as “false”), along with the primary and secondary measures of Super G performance (TinT and RT), and control variables of age, sex, PAL score, hour of day Super G played, level of education, and svRT. This approach controlled for the other factors and was repeated with sex as the dependent variable (whereby male was coded as “true” and female as “false”) while switching *APOE* ε4 carrier status to a control variable. Multivariable regression was used when the dependent variable was PAL score, with a primary independent variable of mean Super G performance (TinT, RT, SR, or TR), and control variables of age, sex, *APOE* ε4 carrier status, hour of day Super G played, level of education, and svRT. The same approach was repeated with age as the dependent variable while switching PAL score to a control variable. In addition, to control for the potential delay between initial PAL scores and Super G measurement, PAL-adjusted scores were also generated and analyzed. Individual PAL scores were adjusted based on the amount of time between their PAL and Super G measurement, given previously reported expected decline in PAL based on age reported by Talboom and colleagues [26]. This resulted in an expected 0.2-point decline in PAL for every year between the initial PAL and current Super G measurement. The formulation of each model can be viewed in the following equations:

1. *APOE* ε4 carrier status ~ Super G Performance (TinT or RT) + age +sex + hour played + education +svRT + PAL (Logistic regression)
2. Sex ~ Super G Performance (TinT or RT) + age + hour played + education + svRT + PAL + *APOE* ε4 carrier status (Logistic regression)
3. Age ~ Super G Performance (TinT or RT) + sex + hour played + education + svRT + PAL + *APOE* ε4 carrier status (Linear regression)
4. PAL ~ Super G Performance (TinT or RT) + age + sex + hour played + education + svRT + *APOE* ε4 carrier status (Linear regression)
5. PAL adjusted ~ Super G Performance (TinT or RT) + age + sex + hour played + education + svRT + *APOE* ε4 carrier status (Linear regression)

Participants could play Super G at any time throughout the day, the variable of hour played (measured with a 24-hour clock rather than a 12-hour clock) was transformed using a cosine function to ensure that adjacent hours 0 and 23 were close together. This is visualized in Figure S2 in Multimedia Appendix 1. All numeric variables were standardized (age, svRT, PAL, hour played, and Super G Performance) to be centered at their respective mean and divided by their respective SD. Thus, a 1-unit change in the results of these variables with respect to all reported odds ratios (ORs) and beta coefficients represents a 1 SD change in either the outcome or the performance metric. This allowed for better relative comparison between all independent variables within each model. To detect multicollinearity, the variance inflation factor was calculated, and any variable with a variance inflation factor of >5 was removed. Outliers were identified using Cook’s distance and removed if their distance was >1.

Ethical Considerations

The study protocol was reviewed and approved by the office of Research Integrity and Assurance at Arizona State University (approval number STUDY00013081). To participate, participants needed to provide digital informed consent. All data collected from this experiment were deidentified for privacy and confidentiality. Participants were not compensated for their time in this study.

Results

Participant Characteristics

Overall, there were 23 *APOE* ε4 carriers (20 heterozygotes and 3 homozygotes) and 31 noncarriers. Between-group comparisons (carriers vs noncarriers) using the Wilcoxon rank sum test demonstrated that groups did differ by age (W=471; *P*=.04), with noncarriers being an average of 4.3 years older than carriers (carriers=59.9 years, noncarriers=64.2 years). For all other control variables, there were no observed group differences (Table 1).

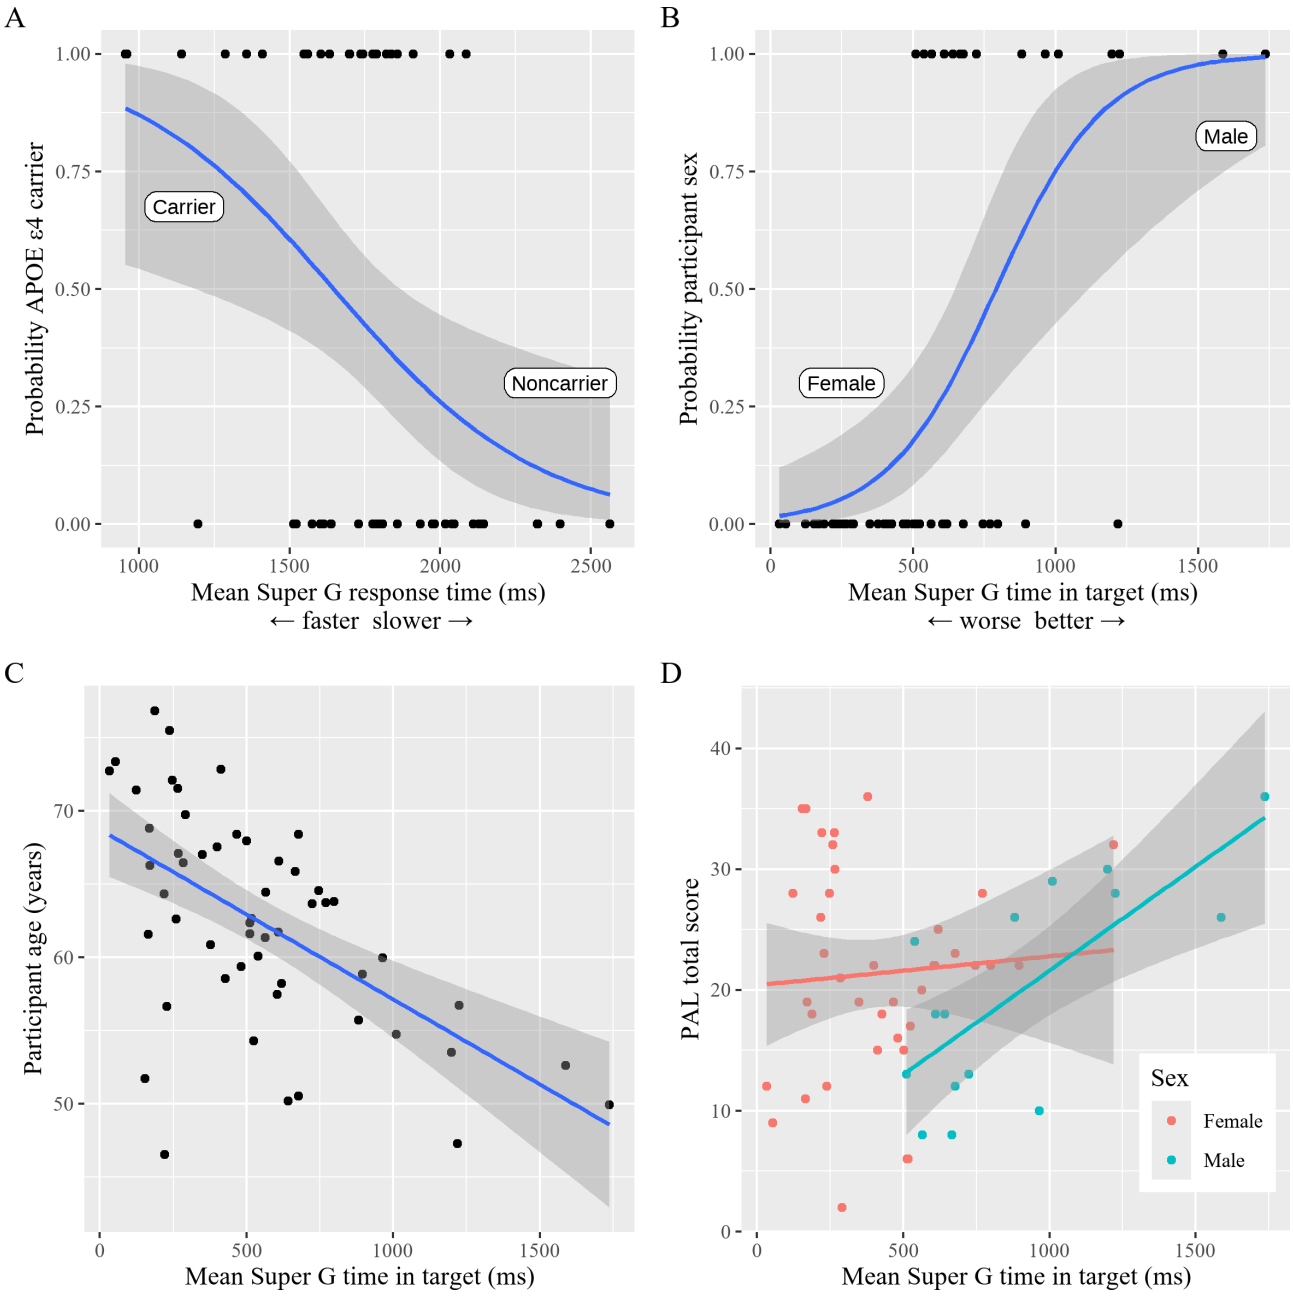
Relationship Between Super G Performance and AD Risk Factors

Within the *APOE* ε4 carrier status logistic regression (model 1) there was a significant association between *APOE* ε4 carrier status with Super G RT (OR 0.12, 95% CI 0.02-0.44; *P*=.006) (Figure 2A). Thus, a participant with a Super G RT that was 1 SD below the mean would have an 88% increase in odds of being an *APOE* ε4 noncarrier than carrier. Visual comparison between all Super G performance metrics and *APOE* ε4 can be visualized in Figure S3 in Multimedia Appendix 1. All other control variables, including PAL (*P*=.62) and svRT (*P*=.29),

were not significantly related to *APOE* ε4 carrier status. Within the participant age linear regression (model 3), Super G TinT was significantly associated with age (β −3.97, 95% CI −6.64 to −1.30; *P*=.005) (Figure 2C) and within the participant sex logistic regression (model 2), TinT was also associated with sex (OR 32.03, 95% CI 3.74-1192.61; *P*=.01) (Figure 2B), with lower TinT values (poorer performance) associated with being older and being female, respectively. This is consistent with our earlier work in other cohorts [27]. Visual comparison between all Super G performance metrics and sex can be visualized in Figure S4 in Multimedia Appendix 1.

Given that previous research in MindCrowd has demonstrated a main effect of sex on verbal learning (as measured with the PAL test) [26,28], and that TinT is also strongly linked with participant sex (Figure 2B), within the PAL linear regression (model 4), a sex-by-TinT interaction was also included to best model PAL [26]. Results from the PAL model demonstrated that age was associated with PAL (β −3.37, 95% CI −6.34 to −0.4; *P*=.03), indicating that older age was associated with lower PAL scores. There was also a main effect of participant sex (β_{Male} −7.73, 95% CI −14.98 to −0.45; *P*=.04). This result indicates that male participants scored an average of 7 points lower on the PAL than females. There was a significant sex-by-TinT interaction ($\beta_{Male:TinT}$ 6.77, 95% CI 0.34-13.19; *P*=.04). This result indicates that males with a mean TinT 1 SD greater than the group mean are associated with an increase of 6.77 points on the PAL compared with females with the same TinT performance (Figure 2D). Furthermore, in the PAL adjusted regression (model 5), where PAL scores are modified based on the time between PAL and Super G measures, the results are nearly identical to the raw scores (β_{age} −3.41, 95% CI −6.38 to −0.44; *P*=.03; β_{Male} −7.57, 95% CI −14.81 to −0.33; *P*=.04; $\beta_{Male:TinT}$ 6.72, 95% CI 0.31-13.14; *P*=.04; Figure S5 in Multimedia Appendix 1). The results of this adjusted analysis provide evidence that the delay between PAL and Super G measures does not significantly impact the observed relationship between PAL and TinT given participant sex.

Figure 2. (A) Mean Super G response time (ie, time at which Super G exits the start planet once the blue atmosphere disappears) between *APOE* ε4 noncarriers and carriers. Y-axis represents the probability a participant is classified as a carrier or noncarrier based on their mean response time. The blue line represents the binomial relationship between response time and carrier status with faster response time more associated with being a carrier and slower response time more associated with being a noncarrier. The gray ribbon represents the 95% CI of the estimated probability of binomial relationship. (B) Mean Super G time in target between female and male participants. Y-axis represents the probability a participant is classified as a male or female based on their mean time in target. The blue line represents the binomial relationship between time in target and sex with better time in target associated with being a male and worse time in target associated with being a female. The gray ribbon represents the 95% CI of the estimated probability of binomial relationship. (C) Linear relationship between participant age in years and their mean Super G time in target. The blue line represents the least squares line fitted between the variable and the gray ribbon about the line represents the 95% CI. (D)The relationship between mean Super G time in target to individual PAL total score stratified by sex (male in blue and female in pink). Given known sex differences between males and females on PAL and observed sex differences on mean Super time in target, such a stratification by sex was necessary to control for potential confounding of sex on the Super G to PAL relationship. The blue line represents the line of least squares for males and the pink line represents the line of least squares for females. The gray ribbon about each line represents the 95% CI. PAL: paired associates learning.



Discussion

This study tested whether motor skill acquisition, as assessed by the Super G task, was sensitive to known risk factors of AD, namely age, sex, *APOE* ε4 carrier status, and verbal learning. Results showed that better Super G performance was directly and independently associated with each of these risk factors, suggesting that Super G may be a sensitive digital biomarker of AD risk that can be remotely collected. Interestingly, TinT and RT were related to different AD risk factors (sex, age, and verbal learning vs *APOE* ε4 carrier status, respectively), likely reflecting how different aspects of motor skill map onto different AD risk factors. Our prior work showed that TinT is the product of optimal execution of SR and TR and best characterizes overall

skill compared with the other Super G variables [21], and it was related to age, sex, and verbal learning. However, RT is a performance characteristic of early skill acquisition, as it measures an individual's ability to anticipate when to initialize movement at the beginning of the trial, which was related to *APOE* ε4 carrier status. Although *APOE* ε4 carriers unexpectedly outperformed noncarriers in terms of early skill acquisition (ie, better RT performance), this opens up the possibility of using Super G as a prognostic enrichment strategy for enriching AD-focused cohorts with ε4 carriers [29].

The observed *APOE* ε4 benefit in this study is contrary to previous work where *APOE* ε4 carrier status leads to worse performance on memory tests in carriers compared with noncarriers [30-32]. However, the role *APOE* ε4 in aging independent of AD pathology may be significant [33], as a small but growing body of evidence in both cognitively unimpaired humans and rodents shows that visual working memory and learning is better among *APOE* ε4 carriers than noncarriers [34-36]. Although *APOE* ε4 is the primary genetic risk factor for AD [13], evidence suggests a possible benefit, or compensatory behavior [37], of learning at an earlier age while leading to impairments in later life [38,39]. Previous research has shown that cognitively unimpaired individuals who are *APOE* ε4 carriers have greater gray matter volume in frontal regions, can better allocate cognitive control, and possess better visual working memory and learning than *APOE* ε4 noncarriers [34,40,41]. Furthermore, task-based neuroimaging studies have associated better performance on visual working memory tasks among carriers with greater activation in frontal and parietal regions [34,36,42]. This leads to the hypothesis that increased frontal activation is a compensatory mechanism that modifies behavior in AD, given that frontal brain regions are relatively spared in AD [43,44]. Although these data do not provide direct support for the *APOE* ε4 compensatory mechanisms, it may be plausible that Super G may be able to measure a suspected *APOE* ε4 benefit. This interpretation is further supported by the fact that in-lab motor skill studies have associated greater skill with higher white matter integrity of frontoparietal tracts [45,46] in cognitively unimpaired older adults, which could serve as a candidate neural substrate for such a compensatory mechanism as proposed previously, but further study would be needed to confirm.

Prior research that has investigated sex differences in motor skill learning and performance has demonstrated a preferential advantage for males compared with females [47]. Similarly, this study revealed that males tended to perform better than females on Super G. The estimated effect size of mean time in target between males and females was very large, with Cohen *d*=1.66. This result is consistent with previous research using Super G, which also found large sex differences in performance [27]. Several factors may explain the observed sex differences in Super G performance. One possible biological explanation [48] may be due to early tau deposition which has been shown to be elevated in females compared with males, consistent with the higher risk for developing AD among females. Thus, a remote and unsupervised motor skill task that is sensitive to sex differences may aid in the detection of sex-specific changes in behavior due to disease in a scalable way. Moreover, there was an interaction between sex, verbal learning, and Super G performance, which suggests that motor skill in males (ie, Super G performance) may be linked to their verbal learning to a greater degree than in females. Larger sample sizes are needed to examine the interactions between sex and other behavioral variables in the context of AD [49,50].

Several limitations to this study should be acknowledged. First, the mean time between when the PAL and Super G was 5 years. Although this is a substantial delay between 2 variables of interest, there was no correlation between PAL score and this intertest interval. Furthermore, when PAL was adjusted for this delay, there was no change in the reported relationship between Super G and PAL regardless of whether raw or adjusted PAL scores were used as the dependent variable (Figure S5 in Multimedia Appendix 1). Thus, the reported result between PAL and Super G appears robust, even with such a delay between measures. Second, the study sample was all non-Hispanic White and highly educated (>80% with at least a college degree), preventing any analysis of interactions between race or ethnicity and *APOE* ε4. Analyses that consider the interaction between race and carrier status are important, given that the link between the *APOE* ε4 allele and the AD is weaker among Black/African American and Hispanic/Latino individuals despite their increased risk of developing AD overall [12,51,52]. In addition, the study sample size was relatively limited due to our required inclusion criteria, particularly the existence of *APOE* genotyping data. As such, future Super G research will recruit larger and more diverse samples. We plan to expand the size of this work with future collaborations, and it is important to note that the MindCrowd cohort itself has increased in size, in racial and ethnic diversity, and in the number of individuals in the cohort who have *APOE* genotyping data, suggesting a path to addressing this limitation in the future. Third, we did not collect participant data on previous video game experience, which may be a contributing factor to the observed relationship between Super G performance and sex [53]. Fourth, there is no defined minimal clinically important difference or clinical cutoff score for the PAL, making it difficult to determine the meaningfulness of the observed relationship between PAL and Super G performance. For example, it cannot be determined whether the predicted change in PAL of 6.5 points among males, in relation to TinT performance, is representative of a meaningful increase or decrease in verbal learning. Finally, with only an 8.1% response rate in this study (54 participants completed all trials of Super G out of the 662 contacted), there may be limited generalizability to the broader MindCrowd cohort or the general public. However, this response rate is similar to other web-based AD-focused cohorts such as the Alzheimer's Prevention Trials Webstudy [54], although the participants in this study were not paid to participate (in contrast to the Alzheimer's Prevention Trials Webstudy), were not actively seeking care, and were emailed only once during the recruitment process. It is noted that these are the factors that could influence participation rates. Despite these limitations, this study establishes the proof of concept that Super G may be a feasible skill-based digital biomarker of individual AD risk.

Acknowledgments

Abstract

Background: People living with dementia are at risk of getting lost and going missing due to memory loss, confusion, and disorientation. Missing person incidents involving people living with dementia are increasing. Alert systems such as Community ASAP can promote community engagement in locating missing persons with dementia and aid in search and rescue efforts. However, the implications of public disclosure of personal information such as name, age, sex, and physical description within such alert systems have yet to be explored.

Objective: This study aimed to identify and discuss the implications of public disclosure of personal information in Community ASAP for people living with dementia at risk of going missing.

Methods: This study used a qualitative descriptive research design drawing from naturalistic inquiry. A total of 19 participants including people living with dementia, care partners, first responders, and service providers were recruited from Ontario, Alberta, and British Columbia, Canada. Semistructured interviews were used to explore participants' perspectives on the perceived implications of the release of personal information when using Community ASAP. NVivo (version 12) was used to manage data, and conventional content analysis was conducted to identify key themes of the implications of public disclosure of personal information in Community ASAP.

Results: In total, 10/19 (53%) of the participants were women and 9/19 (47%) were men. Of the 19 participants, 3 (16%) were people living with dementia, 5 (26%) were care partners, 4 (21%) were first responders, and 7 (37%) were service providers. In total, 4 key themes were identified as implications of public disclosure of personal information in Community ASAP: *right to autonomy*, *safety versus privacy*, *informed and knowledgeable consent*, and *stigmatization.* Participants discussed how the public disclosure of personal information in Community ASAP could undermine a person's choice not to be found and contribute to stigmatization. Participants emphasized a need to balance safety and privacy concerns. Informed and knowledgeable consent is important when using an alert system to locate missing persons with dementia.

Conclusions: Community ASAP can promote community engagement in locating missing persons with dementia. However, the public disclosure of personal information in alert systems has implications. Users' right to autonomy, a balance between safety and privacy, informed and knowledgeable consent, and risks of stigmatization are perceived impacts of disclosure of personal information in alert systems.

Introduction

Background

Dementia is an increasing health problem affecting >55 million people worldwide [1]. People living with dementia are at risk of getting lost and going missing due to memory loss, confusion, and disorientation [2]. Missing person incidents involving people living with dementia have been increasing [3]. Missing persons with dementia are at risk of being exposed to injuries and death. If not found within 24 hours, half of missing persons with dementia will sustain serious injuries or be found deceased [4]. It is crucial to engage the community in locating missing persons and not view missing person incidents solely as a family issue [5]. This inclusive approach provides extra eyes on the ground. Strategies such as alert systems promote community engagement by encouraging community members to be on the lookout for missing persons. This, in turn, aids in search and rescue efforts and minimizes the risks associated with going missing [6].

Alert systems such as the United States' publicly funded Silver Alert program disseminate information about missing persons with dementia or other cognitive disabilities to the public through media broadcasts (eg, commercial radio and television stations) and electronic billboards [6]. The Silver Alert system has been implemented in all but 5 states [6]. However, there are limitations to these programs. The process of issuing Silver Alerts and the duration differ across states, and media broadcasts may reach fewer people due to an increase in the use of mobile devices to access information. Furthermore, there are concerns about declining media sensitivity due to alert fatigue [7].

In Canada, when a person living with dementia goes missing, police services alert the public about a missing person using social media such as Facebook and X (formerly Twitter) and not an emergency alert system such as an Amber alert [8]. Amber alerts notify the public about missing abducted children using Alert Ready. Alert Ready is Canada's emergency alert system that sends critical alerts about hazards or impending dangers (eg, floods, tornados, chemical spills, and fires) to Canadians through radio, satellite television, and compatible wireless devices [9]. As missing person incidents involving people living with dementia are more frequent than missing children and not typically related to a crime, the use of the Alert Ready system would not be appropriate [8]. Furthermore, the use of the Alert Ready system can desensitize the public to alerts and cause alert fatigue, which already exists with Amber alerts.

Ideally, programs that mitigate risks of going missing among people living with dementia would engage local communities but minimize alert fatigue and be location specific. For example, the community-led British Columbia Silver Alert program notifies community subscribers about missing persons with dementia, cognitive impairment, and autism using channels such as social media (eg, Facebook and X) and via email or SMS text message [10]. Interest in community alert systems in other Canadian provinces is growing, as evidenced by a recent national petition; amendments to Missing Persons (Silver Alert) Acts in Alberta, Manitoba, and Ontario [11-13]; and the launch of Silver Alert pilot projects in Quebec [14].

To date, a localized alert system based on volunteer subscription does not exist. To this end, our team developed a localized area alert app called Community ASAP, the first of its kind in Canada, with representatives of end users, including people living with dementia, care partners, and community organizations [3]. Community ASAP allows community volunteers, local businesses, and police services to work together to locate missing persons with cognitive impairment and is available as a mobile app. As a requirement in Canada, a Community ASAP coordinator from police services would initiate an alert when a person living with dementia is reported missing. Community volunteers who register with Community ASAP receive alerts about missing persons based on their geographic preferences. The alert includes a link to the missing individual's personal information, such as their first and last names, nickname, age, physical description (eg, height, weight, eye color, and hair color), mobile number (if any), and locations they typically visit [3].

Community ASAP and other public alert systems such as Silver Alerts and Amber alerts are designed to enhance public awareness of vulnerable missing persons, but they differ in their scope and approaches. Community ASAP is a subscription-based alert system that requires community engagement and provides real-time updates and geofencing features. For example, volunteers receive missing person alerts based on their geographic preferences, allowing them to choose up to 5 locations, such as home and work addresses, and set a radius (1, 3, 6, 12, or 25 km) for each location [3]. However, its effectiveness depends on widespread app adoption and access to mobile devices. In contrast, Silver Alerts and Amber alerts are government funded or community funded and broadcast information about missing persons through large-scale public channels such as highway signs, radio, and television, reaching a wider audience [6,15]. The activation of Community ASAP in Canada and public alert systems in the United States rely on police verification, which means that alerts are not triggered immediately when a missing person incident occurs [3,6,16].

This study was a part of the development and evaluation of the accuracy and usability of Community ASAP [3]. During the development of Community ASAP, we identified the need to understand how the rights of people living with dementia to self-determination and privacy are respected while using the alert system. The use of alert systems has raised ethical concerns about the privacy of people living with dementia [6,15]. Furthermore, there is limited knowledge about concerns related to using alert systems to locate missing persons with dementia [15], particularly how the release of personal information to the public may impinge on the human rights of vulnerable older adults [17].

Objectives

The purpose of this study was to identify and discuss the implications of public disclosure of personal information in an alert system called Community ASAP for people living with dementia at risk of going missing.

Methods

Research Design

This study used a qualitative descriptive research design drawing from naturalistic inquiry, which allows a phenomenon to be studied in its natural state [18]. This method is appropriate when the intent of the study is to provide a basic description and summary of people's experiences [19,20].

Recruitment

Purposeful sampling [21] was used to select participants who had professional and personal experiences on the topic to best provide insights into concerns that could arise from the release of information via Community ASAP. Specific strategies included intensity [21] and snowball [22] sampling. Intensity sampling was used to sample information-rich cases. In snowball sampling, participants helped share study information with other prospective participants whom they believed had knowledge or experience with the topic of interest. These strategies were chosen for practical reasons, including the challenges of selecting potentially difficult-to-access or vulnerable groups, such as people living with dementia. We aimed to include the perspectives of people living with dementia, who are often underrepresented in research. Studies have shown the importance of involving people living with dementia in research, highlighting their ability to provide reliable self-report information, personal perspectives, and valuable insights [23-25]. Inclusion of people living with dementia in this study was crucial to understanding their individual experiences with an alert system and enhancing their safety and well-being while using this program.

Participants (people living with dementia, care partners, first responders, and service providers) were recruited and identified via email or face-to-face conversations through our research team's existing professional networks serving people living with dementia, such as Alzheimer societies, dementia advocacy organizations, and first responders. Thus, some of the participants were known to the research team, and others were not. None of the participants were family members or friends of or had personal relationships with the researchers. All prospective participants who were invited to take part in the study enrolled. Participants had lived or professional experience with dementia and the use of technologies to manage the risk of going missing or responding to missing person incidents. During recruitment, participants were asked to self-identify their experience and knowledge of technologies. All participants had some level of familiarity or experience with technology. We did not inquire about the extent or specific type of their experience.

We selected participants from across 3 Canadian provinces (Ontario, Alberta, and British Columbia) where our professional networks were located and from 4 stakeholder groups: people living with dementia, care partners, service providers (eg, social workers, dementia educators, representatives from vulnerable person registries, and support workers), and first responders (eg, police and search and rescue managers). Inclusion criteria were to (1) be aged ≥18 years, (2) speak English, and (3) have lived or professional experience with or knowledge of the use of technologies to manage the risk of going missing or responding to missing person incidents. Exclusion criteria were having no understanding about technologies to manage the risk of going missing, inability to articulate perspectives due to impaired cognitive abilities, and severe visual or hearing limitations that could not be corrected with the use of an assistive device.

Ethical Considerations

Ethics approval was received from the University of Alberta Research Ethics Board (Pro00078537). All participants gave written informed consent prior to the study, were told that their participation is voluntary, and were informed of their right to withdraw at any time. People living with mild cognitive impairment or mild dementia who had the ability to consent as identified by our professional networks were invited to participate in this study. We used the teach-back method [26] to ensure that these participants had cognitive ability to engage in one-on-one interviews with research team members. The person living with dementia was asked an open-ended question about what they had read in the information letter to ensure that they understood the procedure, risks, and what to do should they wish to withdraw from the study. Transcripts were cleaned for accuracy and deidentified to maintain anonymity. Participants did not receive an honorarium.

Data Collection

Semistructured interviews [27] were conducted with each participant in person, via phone, or through Zoom (Zoom Video Communications) videoconference. The purpose of the interviews was to understand participant perspectives on the implications of public disclosure of personal information in alert systems. Each person selected a preferred mode of participation based on their geographical location and other time commitments. In total, we interviewed 19 stakeholders (n=16, 84% individual interviews and 1 group interview with n=3, 16% of the participants at their request). No other individuals (ie, care recipients or care partners) were present during the interviews with people living with dementia as these individuals had the ability to consent and respond to questions. Before the interview began, the researcher introduced herself, the overarching study [3] in which the current project was embedded, and the purpose and procedures, and written informed consent was obtained. An interview guide (Textbox 1) that contained 5 open-ended questions was used to elicit participants' perspectives on the possible implications of the release of information through Community ASAP. Probes were used to elaborate on participant responses and clarify meaning [22]. The interviews were conducted by female research team members (NN and CD) with backgrounds in occupational therapy, experience with qualitative research methods, and PhDs in rehabilitation science. Each participant was interviewed once, and the interviews were approximately 30 to 90 minutes in length. Interviewers documented their observations and any interruptions in field notes, and the interviews were digitally recorded and transcribed verbatim. Transcripts were not returned to participants as we did not use a member-checking approach to review the transcripts. NVivo (version 12; Lumivero) was used to manage the data.

Textbox 1. Interview guide questions.

Questions

- From your perspective as a (person with dementia or caregiver of a person with dementia, service provider, first responder, expert in ethics, or the law), what ethical concerns are associated with release of personal information in the C-ASAP system?
- From your perspective as a (person with dementia or caregiver of a person with dementia, service provider, first responder, expert in ethics, or the law), what legal concerns are associated with release of personal information in the C-ASAP system?
- How does the release of personal information in the proposed C-ASAP system compare with other registries such as MedicAlert Safely Home and various Vulnerable Persons Registries?
- What are the implications of having a missing person's name released to the public (and thus a part of the public record)? What is the balance (or tipping point) between privacy and safety?
- [For group interviews involving representatives from agencies that collect information about vulnerable persons and store them on registries]: What agreements are in place between the vulnerable person or their family and the agency upon signing on with a particular registry?

Data Analysis

Conventional content analysis [28] guided our analytic approach. A thematic approach is preferred when there is limited existing theory or research literature on a phenomenon, allowing for the identification of specific meanings and determination of appropriate categories and themes. A female doctoral candidate in public health sciences (AA) with a background in nursing and qualitative research methods analyzed the data. She immersed herself in the data by listening to the recordings while reading the transcripts and identifying initial reflections. Next, she coded the transcripts using keywords. Codes were described, and similar codes were grouped and refined to create categories. As new codes were generated, they were added to the framework, and transcripts that had been previously coded were updated to reflect hierarchy. Category descriptions were generated to describe their contents, and themes that represented the categories were created inductively. Analysis continued until saturation of the data was reached.

Data analysis was an iterative process. The coding hierarchy, categories, and themes were reviewed, scrutinized, and confirmed by the analyst and the 2 team members who conducted the interviews; that is, we used peer debriefing as a trustworthiness strategy [29]. This helped us improve clarity and the internal and external homogeneity of codes and categories [30] and consider alternative interpretations and explanations. Thus, the coding hierarchy and main themes were refined repeatedly, thereby enhancing credibility. Our process is consistent with the approach by Morse et al [31] to verification in which transcripts, codes, categories, and themes are rechecked.

Results

Overview

A total of 19 participants (n=10, 53% women and n=9, 47% men) were interviewed. Of these 19 participants, 3 (16%) were people living with dementia, 5 (26%) were care partners, 4 (21%) were first responders (search and rescue and police officers), and 7 (37%) were service providers. Participants were predominantly White individuals (17/19, 89%), and the remainder were Asian individuals (Korean and Filipino; 2/19, 11%; Table 1). All participants had some level of familiarity or experience with technology. In total, 58% (11/19) of the participants (first responders and service providers) had professional experience with technology to manage or respond to missing person incidents, such as alert systems, MedicAlert, and locator devices (GPS devices and Project Lifesaver). The remaining participants (people living with dementia and care partners; 8/19, 42%) had lived experience or familiarity these technologies.

Thematic Findings

Overview

Four key themes represent the implications of public disclosure of personal information in Community ASAP for people living with dementia who have gone missing: (1) right to autonomy, (2) safety versus privacy, (3) informed and knowledgeable consent, and (4) stigmatization (Textbox 2).

Textbox 2. Themes with participant quotes.

Right to autonomy

- "Depending on where the person is in their journey, what if they just wanted to be alone for a few days and then got this whole thing going on because someone decided that they've disappeared. That's a legal issue for me." [Person living with dementia 3, an experienced user of GPS devices who had previously been lost]
- "We locate a missing person, we let them know you've been reported missing, here's the person who's reported you missing...However, they do have a right to be missing so to speak." [First responder 4, an experienced police officer with expertise in search and rescue]
- "Is that what they wanted when they were in the real self before dementia, there is an ethical issue there because you're not honoring what the person wants in the moment." [Service provider 3, a service provider who worked directly with people living with dementia providing education and counseling]

Safety versus privacy

- "The more eyes the better. I think if you're missing, I don't think privacy should be an issue." [Person living with dementia 1, who had experience with MedicAlert]
- "I think that the tipping point is safety, and so that might be it is 30 to 20 degrees Celsius outside. It's not as extreme situation as it is 30 or minus 25. So, all of these things need to be taken into account." [Care partner 2, a family member who cared for a person living with dementia]
- "Some people aren't as open to having other people or the general public know a person with dementia has been missing more around, that they have the condition, they have dementia." [Service provider 6, a person with expertise in supporting the safety of vulnerable persons and who had experience with GPS locator devices for this population]
- "If they are making this phone call it's urgent enough, it's important enough that yes, we are willing to give up that right to this in order to find this person quickly." [First responder 1, an experienced search and rescue member who also provided education about locator devices]

Stigmatization

- "For a lot of people, I worry about their faces and the local papers, this stuff. And that still makes them very vulnerable, because someone recognizes them after the fact." [Person living with dementia 3, an experienced user of GPS devices who had previously been lost]
- "So, with my dad, we didn't want anybody to know that he had Alzheimer's. I think it's because there may be a stigma of Alzheimer's." [Care partner 3, a family member of a person living with dementia who got lost]
- "So, it's such a stigma, it's such a huge issue that sometimes you might think that having an alert system would be really useful for the community to know how to interact or to keep their eye out for somebody with dementia in the community. But is a stigma sort of perpetuating." [Service provider 7, a service provider who works directly with people living with dementia providing education and counseling]
- "The one thing we are always cognizant of in our media releases, is our management and our upper management are always cognizant of the...stigma." [First responder 3, a police officer with experience with missing persons]

Informed and knowledgeable consent

- "If the person is like me and can give consent, that would be OK...if I've already deteriorated, then I think it would be up to my family or my power of attorney because they know what my wishes are." [Person living with dementia 2, a person who was previously lost]
- "Whenever possible, that person who is actually living with dementia, I certainly would advocate and support their involvement from the get-go. No matter what the timeframe, I think you need to be respectful and try to include their voice as much as possible, knowing that cognitively that could change at any time, and if it does then I would hope that the person has the best interests for that individual." [Care partner 5, a family member of a person living with dementia who had experience with locator devices]
- "I think the idea of capacity and the ability to give informed consent is not an on/off button. And to always have that conversation as much as possible to the extent that it is possible for you and whether that's through care partners. I think it's really at the heart of it, really enabling that person to have the choice. But the challenge with that is that on one day the person might say 'yeah I'm completely fine with it' and then the next day they're like 'ugh, I'm not fine with it at all.'" [Service provider 7, a service provider who works directly with people living with dementia providing education and counseling]
- "Informed consent is the only consent that would certainly help alleviate some problems down the road, and I would think if the person can't give consent, because of their mental capacity, hopefully the caregiver would have that Power of Attorney to be able to make that decision for them, on their behalf." [First responder 2, an experienced police officer and search and rescue expert]

Right to Autonomy

This theme relates to concerns about how the release of personal information can compromise a person's choice not to be found. Participants discussed the importance of respecting people's autonomy and right to go missing without wanting to be found. People living with dementia also possess the rights of adults and have the right to be alone or go missing, whereas this does not apply to children. A participant (first responder 4) with many years of experience in search and rescue emphasized adults' rights to go missing. He expressed the following:

> *When we locate a missing person, we let them know you've been reported missing, here's the person who's reported you missing...However, they do have a right to be missing so to speak.*

Labeling intentionally missing persons as missing, especially those capable of decision-making, may raise ethical and legal concerns, as noted by some participants. This concern was further expanded by a participant living with dementia:

> *Depending on where the person is in their journey, what if they just wanted to be alone for a few days and then got this whole thing going on because someone decided that they've disappeared. That's a legal issue for me. Like where in the journey it is decided that someone...I don't even know how to explain that because like for me, it's not uncommon for me, I mean now I always tell somebody just because that's my life. I quite often go "Oh well I'm going to take off and go here for a couple of days."* [Person living with dementia 3, an experienced user of GPS devices who had previously been lost]

Participants pointed out that individuals' views on risk and outlook on life may change as their dementia progresses. Hence, it is crucial that the use of Community ASAP respects the preferences of those living with dementia. In addition, there might be a need to re-evaluate personal information disclosure preferences as dementia progresses. A service provider highlighted the importance of honoring the current wishes of people living with dementia when using Community ASAP:

> *Somebody's idea about what they consent to and what they want when they're first diagnosed might be different than what they want later on, and what's the record of truth. Is that what they wanted when they were in the real self before dementia, there is an ethical issue there because you're not honoring what the person wants in the moment.* [Service provider 3, a service provider who worked directly with people living with dementia providing education and counseling]

Safety Versus Privacy

This theme highlights concerns related to the balance between safety and privacy, acknowledging the diverse perspectives on how to maintain this balance for missing persons. While Community ASAP serves as a safety net, offering peace of mind to people living with dementia and their care partners, it also facilitates a sense of independence. However, some participants expressed concerns about privacy when it comes to sharing their personal information publicly. For many, safety was the tipping point as finding the missing person alive and minimizing the risks of harm is paramount. A care partner emphasized the urgency of finding missing persons promptly, especially in severe weather conditions in Canada:

> *I think that the tipping point is safety, and so that might be it is 30 to 20 degrees Celsius outside. It's not as extreme situation as it is 30 or minus 25. So, all of these things need to be taken into account.* [Care partner 2, a family member who cared for a person living with dementia]

Privacy concerns are influenced by culture as cultural beliefs play a key role in how individuals view privacy, particularly regarding the disclosure of certain information to the public. For instance, a Korean participant (care partner 3, a family member of a person living with dementia who got lost) shared cultural beliefs about having a "conservative background" and keeping his father's dementia diagnosis confidential within the family and refraining from sharing it with outsiders.

There are concerns regarding the permanence of personal information on the internet. Details such as a missing person's name, age, photo, and physical description shared with the public might linger on the internet even after the person is located. Some participants expressed unease about their personal information being public posthumously.

Participants also emphasized the importance of only sharing essential information, such as the person's name, age, photo, and physical description. While some information is necessary for community members (volunteers) to identify a missing individual, disclosing medical information (eg, cognitive impairment) could heighten the risks of fraud, identity theft, and abuse. One participant raised concerns about potential exploitation of people living with dementia when using Community ASAP:

> *The risk is that the volunteers would prey upon this person if he/she is found and returned home, identified to have dementia. They are already vulnerable to scammers, to people who would be able to redirect them and take advantage of them.* [Service provider 1, a service provider who worked directly with people living with dementia providing education and counseling]

Some participants expressed that a dementia diagnosis could make individuals vulnerable to exploitation regardless of whether their personal information is shared via an alert system such as Community ASAP. One participant (person living with dementia 1) stressed the significance of not disclosing banking details to the public:

> *You're not going to give out any information regarding bank accounts. If people want to take advantage of you, they're gonna do it anyways.*

Stigmatization

This theme discusses concerns about how the use of Community ASAP could lead to stigma for people living with dementia. People living with dementia may experience stigma due to their dementia diagnosis and assumptions about their abilities and behaviors. People may assume that individuals living with dementia do not have the capacity to make decisions for themselves. Therefore, sharing personal information such as a cognitive impairment or dementia diagnosis publicly could heighten the existing risk of stigmatization for people living with dementia. A police officer (first responder 3) with experience with missing persons expressed the following:

The one thing we are always cognizant of in our media releases, is our management and our upper management are always cognizant of the...stigma.

A service provider also explained the stigma associated with using alert systems:

> *So, it's such a stigma, it's such a huge issue that sometimes you might think that having an alert system would be really useful for the community to know how to interact or to keep their eye out for somebody with dementia in the community. But is a stigma sort of perpetuating.* [Service provider 7, a service provider who works directly with people living with dementia providing education and counseling]

Participants pointed out that the public may not understand how to approach people living with dementia or communicate with them, hence the need to address dementia-related stigma and misconceptions through public education and awareness campaigns. It was also noted that service providers and first responders should receive adequate training on recognizing, communicating with, and responding to missing persons with dementia. A service provider discussed the importance of using nonstigmatizing language when interacting with missing persons with dementia:

> *I think one of the issues we may see is how responsive behaviors are presented. So, if there are triggers, because I know it is important to communicate that to the community, like you know do not touch this person because they might respond in this way. How can we train coordinators to use language that is going to be non-stigmatizing but still express the nature of that behavior.* [Service provider 1, a service provider who worked directly with people living with dementia providing education and counseling]

Informed and Knowledgeable Consent

This theme focuses on concerns related to ensuring individuals' informed and knowledgeable consent when using Community ASAP. Participants highlighted the importance of people living with dementia having the capacity to understand the implications of an alert system, its objectives, and the reasons behind collecting and sharing their personal data. They emphasized the necessity of providing sufficient information about Community ASAP to those living with dementia and respecting their autonomy in decision-making. However, dementia can affect an individual's ability to process and understand information adequately, leading to challenges in decision-making regarding alert systems, which does not always align with a simple *present or absent* perspective. This concern was elaborated on by a service provider:

> *I think the idea of capacity and the ability to give informed consent is not an on/off button. And to always have that conversation as much as possible to the extent that it is possible for you and whether that's through care partners. I think it's really at the heart of it, really enabling that person to have the choice. But the challenge with that is that on one day the person might say "yeah I'm completely fine with it" and then the next day they're like "ugh, I'm not fine with it at all."* [Service provider 7, a service provider who worked directly with people living with dementia providing education and counseling]

For individuals with limited decision-making capacity, service providers should seek consent from their proxies or substitute decision makers (eg, relatives) and make decisions in their best interests. Participants emphasized the importance of a respectful decision-making process that considers the evolving wishes and preferences of individuals with dementia as the condition advances. A first responder discussed the significance of informed consent and ensuring that decisions made on behalf of an individual living with dementia align with their preferences:

> *Informed consent is the only consent and that would certainly help alleviate some problems down the road, and I would think if the person can't give consent, because of their mental capacity, hopefully the caregiver would have that Power of Attorney to be able to make that decision for them, on their behalf. What's the end goal? The end goal is to try and help that person the best you can, and if they are in a position that is maybe not good for them, at least hopefully we put enough checkmarks in place that they'll come out okay, and that's what you have to look at.* [First responder 2, an experienced police officer and search and rescue expert]

The need to involve people living with dementia in the decision-making process regarding the use of Community ASAP was discussed by participants. It was emphasized that involving the person with dementia in decisions at an early stage is crucial as dementia progression can greatly impact decision-making capacity. Care partner 5, a family member of a person living with dementia who had experience with locator devices, expressed the following:

> *You need to be respectful and try to include their voice as much as possible, knowing that cognitively that could change at any time, and if it does...I would hope that the person has the best interests for that individual.*

Discussion

Principal Findings

Our study aimed to identify the implications of public disclosure of personal information in an alert system called Community ASAP for people living with dementia who are at risk of going missing. The implications were discussed under 4 key themes: *right to autonomy*, *safety versus privacy*, *stigmatization*, and *informed and knowledgeable consent.*

Community ASAP differs from public alert systems for missing persons with dementia such as Silver Alerts. While Community ASAP is a subscription-based, localized alert system that provides real-time updates and geofencing features, Silver Alerts can be government funded or community funded and use large-scale channels such as highway signs and media to reach a wider audience [3,6]. Given the limited research on subscription-based, localized alert systems for missing persons with dementia, our references drew primarily from studies on Silver Alerts.

Participants raised concerns about respecting individuals' right to autonomy when using Community ASAP. The literature emphasizes the importance of honoring the autonomy of people

living with dementia in alert systems [17,32]. Autonomy, or self-determination, is a fundamental human right tied to a person's capacity to assess options, weigh risks, communicate choices, and act accordingly [33,34]. Unlike children requiring guardianship, adults with dementia, even those with appointed guardians, retain some decision-making capacity [33].

People living with dementia may go missing intentionally to avoid disclosing their location or unintentionally due to disorientation or difficulty recognizing familiar places [16,35]. Respecting the right to go missing intentionally is controversial as risk is often viewed negatively and people living with dementia are considered a vulnerable group needing protection [36,37]. The use of technology to locate missing persons raises ethical concerns about balancing autonomy and privacy with safety [6,17,34]. For example, dementia-related wandering is typically seen as "risky" due to potential harm, but it can also represent autonomy and agency and even provide health benefits as a form of exercise [38]. In care settings, health care providers may monitor "wandering" due to ethical responsibilities and potential litigation fears [39]. However, disclosing personal information can violate a person's autonomy [6]. It is crucial to balance safety with respect for autonomy, necessitating open discussions between people living with dementia and their care partners or health care professionals [39]. These conversations should focus on the person's values, care preferences, and ways to support their choices while living with risks.

The public disclosure of personal information in Community ASAP also raises concerns about balancing safety and privacy. While safety focuses on locating missing persons and minimizing risks of harm, privacy emphasizes the right to choose what information is shared with others [33]. Participants expressed that disclosing details such as dementia diagnoses could violate privacy rights. Similarly, Wasser and Fox [32] found in their analysis of Silver Alerts that such systems can unintentionally infringe on the privacy rights of individuals with dementia. In addition, cultural beliefs influence perceptions of dementia [40] and privacy as some cultures view such diagnoses as private. Understanding these cultural factors is essential when using alert systems while ensuring the privacy of people living with dementia.

For most participants, the safety of missing persons outweighs privacy rights. The literature shows that care partners often prioritize safety over privacy concerns [15,16]. Alert systems can serve as a safety net for people living with dementia, providing comfort and independence while easing care partners' worries. Balancing safety and privacy requires understanding individual preferences and the perceptions of risk. Disclosure of personal information may be necessary for safety, but technology can also create a false sense of security if it fails [8,16,33]. To reduce the risk of individuals going missing, additional measures such as GPS devices and return home interviews should be used alongside alert systems [8]. Informed dialogue among people living with dementia, care partners, and health care professionals is essential, along with effective policies to address these concerns [6,16,33].

Public disclosure of personal information in Community ASAP can contribute to the stigmatization and abuse of people living with dementia. Stigma can lead to delays in seeking help, exclusion from social activities, and reduced quality of life [41,42]. Participants in this study emphasized the need for dementia education and staff training to address stigma and improve communication regarding missing persons. Community education is also crucial to raise awareness about the risks associated with alert systems [6,8]. Furthermore, a participatory approach in the design, development, and evaluation of alert systems is necessary [3].

People living with dementia are at heightened risk of abuse due to their diagnosis [43,44]. Publicly sharing information such as dementia diagnoses and home addresses can lead to financial exploitation and other crimes. For example, the United States' Silver Alert may broadcast home addresses, license plates, and photographs of missing persons, unintentionally increasing risks of victimization or identity theft [7,16,17]. It is vital to limit the information shared in alert systems to what is necessary and implement safety measures such as using general locations instead of specific addresses and ensuring that sensitive data are controlled and removed promptly [3].

Another concern regarding the public disclosure of personal information in Community ASAP is informed and knowledgeable consent. Consent is considered knowledgeable if "the individual knows the purposes of the collection, use or disclosure and knows that they have the right to give, withhold or withdraw consent" [45]. Participants noted that people living with dementia may face challenges in providing informed consent for using alert systems, often due to assumptions about their capacity [6,17]. While dementia can impact decision-making capacity in some cases, individuals can still make decisions with support from family, friends, or health care professionals [33,46]. Assessment of decision-making capacity can be difficult as dementia-related cognitive fluctuations affect attention and memory [46,47]. A dementia diagnosis does not automatically imply incapacity [46], and capacity assessments should account for the person's stage of dementia and be conducted during moments when they are experiencing minimal confusion [47]. Continuous consent should be sought as the condition progresses, and early discussions are encouraged to address future decision-making needs. For those requiring substitute decision makers, involving them in decisions respects autonomy and dignity. Regardless of dementia progression, individuals should be included in conversations about their health and the use of alert systems, ensuring that their voices are considered in the design and implementation of these technologies.

Strengths and Limitations

While there is research on public alert systems such as Silver Alerts, little is known about the implications of public disclosure of personal information in subscription-based, localized alert systems. Our study addressed this gap by examining how Community ASAP may infringe on the rights of people living with dementia. Specifically, it highlights the need to understand and address end users' concerns about disclosure of personal information, the right to autonomy, the balance between safety and privacy, and informed and knowledgeable consent. Including participants with lived and professional experience

with dementia and technologies for managing risks of going missing provided diverse perspectives on a topic with limited existing research. The qualitative descriptive approach used in this study enabled an in-depth exploration of concerns associated with public disclosure of personal information in subscription-based, localized alert systems.

Community ASAP and this study have limitations. The subscription-based, localized design of Community ASAP and the small participant sample size for each category limit its generalizability. The subscription model may exclude lower-income users and create a self-selection bias, whereas the app's reliance on a high density of community users may reduce its effectiveness in underengaged or rural areas. These factors may have influenced participant responses and perspectives. To enhance broader applicability, addressing barriers such as cost, accessibility, and adoption in diverse communities would be essential in future research.

In addition, it was unclear how much experience participants had with localized alert systems. Thus, the concept of the release of personal information in such alert systems was hypothetical. Participants' perspectives may differ with real-world experience, and the abstract nature of the topic may have led to the generation of data that are somewhat limited compared to those that a more concrete topic would yield. Recruitment methods also presented a limitation, potentially privileging certain voices. Participants were predominantly White individuals, which does not represent the demographics of Canada. In addition, participants were recruited through the researchers' networks, likely including individuals who were more vocal, confident, or willing to participate. This may have excluded underrepresented perspectives such as those from ethnic communities where alert systems might be viewed differently or where stigma around dementia is more significant.

Conclusions

Localized alert systems such as Community ASAP differ from existing Silver Alert programs that push alerts to the public through the media. Instead, Community ASAP pushes alerts to targeted community members who volunteer to be extra eyes and ears on the lookout for missing persons with dementia. This can promote community engagement in locating missing persons with dementia. However, the public disclosure of personal information in alert systems has significant implications. Such disclosure can compromise an individual's right to autonomy and privacy and lead to stigmatization. The balance of privacy rights with safety concerns presents a challenge. Informed and knowledgeable consent should be a fundamental part of using alert systems. Regardless of the stage of dementia, individuals living with the condition have a right to be included in conversations about their health, including the use of alert systems. An understanding of these implications paves the way to respecting the rights of people living with dementia at risk of going missing and improving their safety and well-being.

Acknowledgments

This work was supported by the Centre for Aging + Brain Health Innovation and Aging Gracefully Across Environments Using Technology to Support Wellness, Engagement, and Long Life from the Networks of Centres of Excellence of Canada. Community ASAP was conceived by Ron Beleno, a caregiver for his father who lived with dementia. The authors thank the study participants for contributing their time and feedback, including the Calgary Missing Older Adult Resource Network, Alzheimer Society of Ontario, Alzheimer Society of Durham Region, and Coquitlam Search and Rescue, as well as Canadian police services in Durham, Ontario; Toronto, Ontario; and Calgary, Alberta, Canada.

Abstract

Background: The rapid advancement of technology has made mobile health (mHealth) a promising tool to mitigate health problems, particularly among older adults. Despite the numerous benefits of mHealth, assessing individual acceptance is required to address the specific needs of older people and promote their intention to use mHealth.

Objective: This study aims to adapt and validate the senior technology acceptance model (STAM) questionnaire for assessing mHealth acceptance in the Thai context.

Methods: In this cross-sectional study, we adapted the original, 38-item, English version of the STAM using a 10-point Likert scale for mHealth acceptability among the Thai population. We translated the mHealth STAM into Thai using forward and backward translation. A total of 15 older adults and experts completed the pilot questionnaire and were interviewed to assess its validity. The pilot items of the Thai mHealth STAM were then reworded and revised for better comprehension and cross-cultural compatibility. The construct validity of the Thai mHealth STAM was evaluated by a multidimensional approach, including exploratory and confirmatory factor analysis and nonparametric item response theory analysis. Discriminative indices consisting of sensitivity, specificity, and area under the receiver operating characteristic (AUROC) were used to determine appropriate banding and discriminant validity for the intention to use mHealth. Internal consistency was assessed using Cronbach α and McDonald ω coefficients.

Results: Out of the 1100 participants with a mean age of 62.3 (SD 8.8) years, 360 (32.7%) were adults aged 45-59 years, and 740 (67.3%) were older adults aged 60 years and older. Of the 40-item pilot questionnaire, exploratory factor analysis identified 22 items with factor loadings >0.4 across 7 principal components, explaining 91.45% of the variance. Confirmatory factor analysis confirmed that 9-dimensional sets of 22 items had satisfactory fit indices (comparative fit index=0.976, Tucker-Lewis index=0.968, root mean square error of approximation=0.043, standardized root mean squared residual=0.044, and R^2 for each item>0.30). The score banding D (low≤151, moderate 152-180, and high≥181) was preferred as the optimal 22-item Thai mHealth STAM cutoff score based on the highest sensitivity of 89% (95% CI 86.1%-91.5%) and AUROC of 72.4% (95% CI 70%-74.8%) for predicting the intention to use mHealth. The final Thai mHealth STAM, consisting of 22 items, exhibited remarkable internal consistency, as evidenced by a Cronbach α of 0.88 (95% CI 0.87-0.89) and a McDonald ω of 0.85 (95% CI 0.83-0.87). For all 22 items, the corrected item-total correlations ranged between 0.26 and 0.71.

Conclusions: The 22-item Thai mHealth STAM demonstrated satisfactory psychometric properties in both validity and reliability. The questionnaire has the potential to serve as a practical questionnaire in assessing the acceptance and intention to use mHealth among pre-older and older adults.

(JMIR Aging 2025;8:e60156) doi:10.2196/60156

Introduction

As the global population ages, the integration of technology into the lives of older adults becomes increasingly crucial for enhancing their quality of life, independence, and well-being [1]. An emerging technology that promotes healthy aging is mobile health (mHealth). mHealth refers to medical and public health services facilitated by mobile devices [2]. It can provide individualized care plans for older adults to sustain functional ability and enhance quality of life [3]. Examples of mHealth innovations for older adults include supporting services for age-friendly health and facilitating the establishment of behavioral changes [3,4]. However, the adoption of technology, for example, mHealth, among older adults remains a complex and multifaceted issue, influenced by various factors such as individual perception and experience, ease of use, technological support, and sociocultural contexts [5,6]. To address this challenge, numerous theoretical frameworks have been proposed to understand and predict older adults' acceptance of technology.

Assessing technology acceptance is essential for the successful implementation and use of mHealth technologies, as it directly influences user engagement, health outcomes, and health care delivery efficiency. Understanding acceptance helps developers create user-friendly applications [7,8], improves health outcomes through better adherence to interventions [9,10], and guides implementation strategies to address barriers effectively [11,12]. It also informs policy makers and administrators, enabling evidence-based decisions on mHealth investments [13,14]. Therefore, the lack of validated questionnaires for assessing technology acceptance could lead to a limited understanding of user needs and missed opportunities for improvement. Addressing this gap by developing and validating robust assessment is critical for maximizing the benefits of mHealth technologies and ensuring their effective adoption across diverse populations.

In the field of mHealth, various instruments and frameworks have been developed to assess adoption, intention to use, and acceptance. Established instruments like the Health Information Technology Usability Evaluation Scale (Health-ITUES) [15,16], System Usability Scale (SUS) [17,18], and mHealth App Usability Questionnaire (MAUQ) [19,20] provided insights focusing on user experiences and satisfaction. Broader frameworks include the unified theory of acceptance and use of technology (UTAUT) [21,22], which was extended to include additional factors relevant to mHealth, such as trust and perceived reliability, and was used in various studies to predict mHealth acceptance; the Fit between Individuals, Tasks, and Technology (FITT) Framework [23] is another, which was introduced to measure acceptance in clinical environments, emphasizing the alignment between user needs and technology capabilities. Despite their usability, these instruments and frameworks often lack specificity when addressing the unique needs of older adults.

The senior technology acceptance model (STAM) [24] stands out due to its tailored approach for older adults, which addresses their unique challenges and enhances the relevance of mHealth technologies for this population, making it more relevant than general models like the technology acceptance model (TAM) [25] or the UTAUT [26]. Furthermore, it emphasizes the role of social influence and support, which are critical for older adults who may rely on family and caregivers for technological adoption and addressing common health conditions in older adults, such as cognitive load and physical limitations.

The STAM was first proposed by Chen and Chan [24] in 2014 and has gained prominence for its focus on the unique needs and characteristics of older adults. This model was developed based on a study of 1012 older adults aged 55 years and older in Hong Kong, and it specifically targets older adults as its primary population of interest. The STAM integrates concepts from established technology acceptance frameworks, such as the TAM [25] and the UTAUT [26], tailored to address the specific considerations of older adults and provides a thorough framework for studying the factors that influence technological adoption in this age group. The study indicated 8 dimensions associated with technology acceptance in older adults, which included gerontechnology self-efficacy, gerontechnology anxiety, facilitating conditions, self-reported health conditions, cognitive ability, social relationships, attitude toward life and satisfaction, and physical functioning. Sociodemographic factors such as age, gender, education, and economic status are taken into account [24].

While the STAM has been used in different cultural contexts in other Asian countries, including Hong Kong [24] and South Korea [27], its applicability to the Thai population has not been validated. Thailand, like many other countries, is experiencing rapid population aging, emphasizing the urgency of understanding and promoting health technology acceptance among older adults [28]. However, cultural background, social norms, and technological infrastructures specific to Thailand may influence older adults' perceptions and behaviors toward technology differently than in other contexts. Therefore, this study aimed to adapt, validate, and define the interpretation of the STAM questionnaire for evaluating the acceptance and intent to use mHealth in Thailand.

Methods

Study Design and Study Population

The cross-sectional study was conducted from August 2022 to July 2023 through a nationwide, web-based survey and a community survey. Eligible criteria for the study were Thai citizens aged 45 years and older on the date of the survey who could read and communicate in the Thai language and had no underlying conditions or diseases that limited their ability to complete the survey or use mHealth apps (eg, dementia, active psychological problems, or severe visual problems). The web-based survey was disseminated through an assortment of social media platforms, including the department websites, Facebook, Line, Twitter (rebranded as X in 2023), and Instagram. The information on community survey setting and recruitment is described in the section below. For the survey data collection, the respondents to both the web-based and community surveys used the Research Electronic Data Capture (REDCap; Vanderbilt University) survey platform to self-complete the questionnaires. REDCap [21,22] is a secure, web-based software platform designed to support data capture for research studies, providing (1) an intuitive interface for validated data capture, (2) audit trails for tracking data manipulation and export procedures, (3) automated export procedures for seamless data downloads to common statistical packages, and (4) procedures for data integration and interoperability with external sources. All study data were collected and managed using REDCap tools hosted at the Faculty of Medicine, Chiang Mai University. All respondents provided their informed consent, which was included in the screening questionnaire and study information sheet, before participating in this survey. The study excluded incomplete respondents or participants who spent less than 2 minutes or more than 60 minutes on the survey. This study was reported in accordance with COSMIN (Consensus-Based Standards for the Selection of Health Status Measurement Instruments)

reporting guidelines for studies on measurement properties of patient-reported outcome measures [29].

Community Survey Setting and Recruitment

The community survey was distributed by the investigator team, consisting of medical students and health care personnel at primary care units from 10 subdistricts in Chiang Mai province. To identify eligible participants in the target area, officers from the subdistrict primary care units reviewed periodic health survey data for community-dwelling adults aged 45 years and older. Subsequently, patients' information was verified with the health-promoting hospital databases to exclude individuals with health conditions that impeded survey participation or mHealth use as described above. The subdistrict primary health care teams invited eligible individuals to participate in the study through individual contact by community health care volunteers, community radio announcements, and posters displayed at primary care units.

Ethical Considerations

The ethical consideration of the human subject research was approved by the Institutional Review Board of the Faculty of Medicine, Chiang Mai University (COM-2565-09079). All respondents provided their informed consent, as outlined in the screening questionnaire and study information page, before participating in this survey. For the web-based survey, respondents remained anonymous, and no identification data were recorded. In the case of the community survey, identification data of eligible participants were used solely for recruitment purposes within each target area and were not recorded in either the survey form or the study database. Participants received 100 Thai Baht (US $3) as compensation for answering the questionnaires.

Translation and Adaptation of the Thai mHealth STAM

The original, English, 38-item STAM is a 10-point Likert scale consisting of 10 subscales and 38 items that capture the acceptance of general technology use for the older adult population. The total ranges from 38 to 380 points, with a higher score indicating greater acceptance of technology. The validity and reliability of 38-item STAM have been established on a satisfactory scale in 1012 older adults aged 55 years and older in Hong Kong [24]. The construct validity of the STAM was also evaluated with the confirmatory factor analysis (CFA) and revealed a satisfactory model fit with the proposed structure (comparative fit index [CFI]=0.938, root mean square error of approximation [RMSEA]=0.054, and standardized root mean square residual [SRMR]=0.075). The reliability of each subscale with Cronbach α coefficients ranged from 0.67 to 0.95.

Translation and adaptation of the Thai mHealth STAM was performed in accordance with the second edition of the International Test Commission (ITC) Guidelines for Translating and Adapting Tests [30]. In accordance with the ITC precondition guidelines, permission from the holder of the intellectual property rights relating to the 38-item STAM was obtained before performing any translation and adaptation of the STAM. The forward and backward translation with an expert reconciliation design was performed as recommended by the ITC test development guidelines. Before beginning the forward translation process, we decided to include a new subscale, perceived barriers, in the Thai STAM version due to the findings from the previous scoping review [31] on adopting mobile apps for health-related interventions among older adults. It revealed that barriers to adopting mHealth apps among older adults were the most common topics identified in the included studies. Insufficient technological skills, perceived lack of capability and time, concerns regarding personal data privacy, and trust in mHealth providers were the four items comprising the perceived barriers subscale. Following the translation protocol, the original, English, 38-item STAM was adapted to specify mHealth apps in all items and then forward translated into Thai by a professional translator to ensure accuracy for the target audience. The expert panel, which included a digital health expert (family physician and epidemiologist), 2 gerontology physicians, and a public health expert in community medicine, reviewed the forward translation of the Thai STAM questionnaire to ensure readability and transcultural adaptation. The backward translation was done by another professional translator into English. Then, the expert panel reconciled the backward translation version with the original STAM version.

The investigator's team resolved any discrepancies by reaching a final consensus through discussions with the expert panel. To ensure the face and content validity of the proposed questionnaire, a literature review, an expert review, and public interviews were incorporated into the adaptation of the Thai mHealth STAM. In total, 15 older adults participated in this phase to complete the pilot 40-item Thai STAM. Participants were subsequently interviewed to assess the following: overall questionnaire readability, clarity of instructions and items/response options, comprehension of the questionnaire, and other feedback on each item. Then, the pilot 40-item Thai STAM was reworded and revised as recommended on input from both participants and expert interviews. Finally, the pilot 40-item Thai mHealth STAM was given to a group of 40 older adults to verify its reliability and scale usability.

Sample Size Estimation

The sample size was estimated based on three parameters, which are as follows: (1) a stable structure for an exploratory factor analysis (EFA) based on the rule of thumb, which is 10 cases per question; (2) expected CFI for a CFA based on the structural equation modeling; and (3) expected Cronbach α for the internal consistency of the questionnaire. For the first parameter, according to the rule of thumb, at least 440 respondents, accounting for 10% of the dropout rate, were required for an EFA. To achieve the expected CFI of 0.95 for a CFA, at least 459 respondents, accounting for 10% of the dropout rate, were required based on an average factor loading of 0.60 and an average factor correlation of .30 to ensure a .05 α (type I) error and power of 90% [32]. For testing overall reliability, at least 146 total respondents were required based on expected Cronbach α=0.80 (SD .05), a confidence level of 95%, and a dropout rate of 10% [33]. All sample size estimation was performed by the web-based sample size calculator [34]. Finally, the minimal required sample size for this study was 920, which was divided into 460 each for the EFA and CFA, respectively.

Statistical Analysis

Descriptive Analysis

All statistical analyses were conducted using Stata (version 17.0; StataCorp). A *P* value below .05 indicated statistical significance. Categorical data were presented as frequency and percentage, while continuous data were described using mean (SD). Univariable analysis for comparison was performed as appropriate. The Thai mHealth STAM item scores were summarized with central estimations, measures of variability, floor and ceiling effect, skewness, and kurtosis tests. The overall psychometric properties of the Thai mHealth STAM were evaluated for validity and reliability as follows:

Dimensionality

To explore and reduce the dimensionality of the proposed questionnaire, an EFA was performed using a principal component analysis (PCA). The selection of PCA over common factor analysis was based on its ability to enhance parsimony and aid in the selection of factors for CFA [35]. Communalities were initially evaluated, and then orthogonal rotation with the varimax criteria and oblique rotation with promax criteria of the component was conducted. The Kaiser-Meyer-Olkin (KMO) measure and the Bartlett test of sphericity were conducted to verify the appropriateness of using factor analysis. A KMO value greater than 0.8 [36] and a Bartlett test with a *P* value less than .05 [37] are suggested for assessing sample adequacy and the suitability of the data for factor analysis, respectively. Eigenvalues greater than 1, the cumulative percentage of variance, and the scree plot with the number of factors that explained more than 5% of the variance were used to determine the number of factors to be retained [38,39]. A parallel study was conducted to validate the optimal threshold for the number of included factors [40]. Then, we used the following criteria to evaluate the adequacy of the EFA results. First, each should be saliently loaded with at least three items to ensure reliability and stability. In case a factor contains only 2 items, the expert panel consensus will be reached to ensure that the factor is meaningful based on the context and theoretical basis. Second, each item should load saliently on only 1 factor without complex or cross-loadings. Third, each factor should demonstrate internal consistency reliability ≥0.70. Fourth, all factors should be theoretically meaningful [35,41,42].

Construct Validity

For a CFA, structural equation modeling using a maximum likelihood estimation was performed to assure the factor structure based on the exploratory factor, as described previously. To determine the appropriateness of the proposed model, the specific fit indices were evaluated as follows: RMSEA<0.100, SRMR<0.100, CFI>0.900, and Tucker-Lewis Index (TLI)>0.900 [43-45]. To establish acceptance of the final structure of the final model, the coefficient of determination (R^2) and item-scale correlation (standardized factor loading) should be at least 0.30 and 0.40, respectively. Finally, a nonparametric item response theory (IRT) analysis was done to confirm that the final Thai mHealth STAM had the unidimensional set for the relationship between the latent trait and the responses to the items [46]. The IRT analysis was assessed based on fundamental assumptions, including unidimensionality, local independence, and monotonicity. Loevinger H coefficients (H^s) less than 0.3, between 0.3 and 0.4, and greater than 0.4, as determined by the item traces, correspond to poor, medium, and strong scalability properties, respectively. The monotonicity assumption criterion was determined by a critical value of less than 80.

Discriminant Validity

To determine the discriminant validity of the final questionnaire, the intention to use mHealth, as indicated in the external question, "If there are available mHealth applications for you, do you want to use them? (yes/no)," was used as the anchor-based question. The discriminative indices, including sensitivity, specificity, and area under the receiver operating characteristic (AUROC), were used with the intention of determining the appropriate cutoff scores. The 6 proposed bandings for the Thai mHealth STAM scores are categorized into low, moderate, and high acceptance based on score tertiles. Associations between these bandings and the intention to use mHealth are presented by adjusted odds ratios (aORs) with 95% CI from a multivariable logistic regression adjusted for potential

confounders such as age, gender, education, income, and living alone.

Reliability

To estimate the correlation statistics for reliability, 95% CI using 1000 bootstrap resampling was presented alongside the reported correlation statistics. An internal consistency consisting of Cronbach α and McDonald ω coefficients was calculated for each item of the final questionnaire, as well as the entirety of the final questionnaire, to determine internal consistency, reliability, and the degree to which every item on a scale measures the same construct. The values of at least .70 indicated acceptable reliability of the questionnaire [47]. In addition, the item-total correlations and the corrected item-total correlations between .20 and .80 were considerably acceptable. A subgroup analysis of adults aged 45-59 years and adults aged 60 years and older was also performed, recognizing the importance of understanding the unique health needs and challenges faced by both current older populations and those who will age into this group in the future.

Results

Findings From the Translation and Adaptation of the Thai mHealth STAM

After reviewing the forward translation, the panel of experts decided to remove 2 items from the gerontechnology self-efficacy subscale, as they were redundant with the facilitating condition (FC) subscale (FC1 and FC2). Independent back-translation provided an additional check of the semantic equivalence of the translation. A total of 4 items, including PU2, PEOU2, P4, and P8, were modified based on the backward translation. For face and content validity, we conducted interviews with 15 older adults similar to the target population. Based on participants' feedback, 4 items (FC1, FC2, C4, and P2) were slightly modified for clarity. In addition, 2 gerontology experts suggested rephrasing 2 items (A1 and A2) regarding attitude to aging and life satisfaction due to the sensitive wording. Finally, the 40-item Thai mHealth STAM in the pilot group of 40 older adults indicated acceptable internal consistency (Cronbach α =0.91). The details of the full 40 items (10 dimensions) of the Thai mHealth STAM are presented in Table S1 in Multimedia Appendix 1.

Participant Characteristics

From the total of 1100 participants, the mean age was 62.3 (SD 8.8) years. The majority of participants were female (776/1100, 70.5%). Among the 1100 participants, 360 (32.7%) were adults aged 45-59 years, and 740 (67.3%) were older adults aged 60 years and older. Statistically significant differences in the characteristics between adults and older adults were observed in marital status (P=.003), education levels (P<.001), income (P<.001), underlying diseases (P<.001), and technology experience (P<.001). The characteristics of the participants of the study population are presented in Table 1. The derived data were randomly divided in a 1:1 ratio into 2 datasets in preparation for the EFA and CFA. The characteristics of the participants involved in the EFA and CFA are described in Table S2 in Multimedia Appendix 1.

Table 1. Participant characteristics of the study population.

Characteristics	Total (N=1100)	Adults (n=360)	Older adults (n=740)	*P* value
Age (year), mean (SD)	62.3 (8.8)	52.4 (5.5)	67 (5.5)	<.001
Male, n (%)	324 (29.5)	99 (27.5)	225 (30.4)	.32
Marital status, n (%)				.003
Single	96 (8.7)	43 (11.9)	53 (7.2)	
Married	747 (67.9)	250 (69.4)	497 (67.2)	
Separated, divorced, or widowed	257 (23.4)	67 (18.6)	190 (25.7)	
Education levels, n (%)				<.001
No education	18 (1.6)	1 (0.3)	17 (2.3)	
Primary school	725 (65.9)	160 (44.4)	565 (76.4)	
Secondary school	97 (8.8)	50 (13.9)	47 (6.4)

[b]mHealth: mobile health.

Dimensionality

According to the item analysis, we excluded 6 items from the physical function subscale (P2, P3, P4, P5, P7, and P8) due to a floor effect or ceiling effect of >80% (Table S3 in Multimedia Appendix 1). An EFA was conducted using PCA with 34 remaining items. The Bartlett test of sphericity obtained $P<.001$, indicating that the correlation matrix was not random [37]. The KMO statistic was 0.875, well above the minimum standard for conducting factor analysis [36]. Therefore, we determined that the input data were appropriate for EFA. Subsequently, the rotation of principal components was performed using both orthogonal rotation (varimax) and oblique rotation (promax) in an attempt to achieve a simple structure. Given the fact that an oblique rotation is generally recommended by measurement specialists to facilitate the emergence of factor intercorrelations [48-50], almost all social sciences measurements exhibit some degree of correlation [51]. In addition, the correlation matrix for the factors with oblique (promax) rotation indicated that the highest correlation was 0.445 (Table S3 in Multimedia Appendix 1); we thereby determined that the factors were correlated, and hence, oblique rotation was an appropriate approach. The results of parallel analysis (Table S4 in Multimedia Appendix 1) and PCA with or without oblique (promax) rotation all recommended the retention of 7 factors. According to the previous criteria, 2-item factors were identified, including factor 4 (PBR1 and PBR2) and factor 6 (S1 and S2). The internal consistency of seven factors demonstrated Cronbach α of 0.884 with 95% CI (0.875-0.894), which met acceptable thresholds. Within the context and theoretical framework of the STAM [24] and the UTAUT [11,21,26,52], social factors significantly influence behavioral intentions to use technology, particularly in the use of mHealth. Perceived barriers also play a role in determining intentions to use mHealth, as demonstrated by the aforementioned scoping review [31]. The inclusion of factor 4 and factor 6, which represented perceived barriers and social relationships, was considered appropriate. Based on the priori criteria and consensus of the panel experts, the EFA identified 22 candidate items (ATT1, ATT2, PU1, PU2, PU3, PEOU1, PEOU2, PB1, PB2, ANX1, ANX2, FC2, FC4, FC5, H1, H2, H5, C2, C3, C4, S1, and S2) with factor loadings greater than 0.4 that encompassed the 7 factors. The final EFA result is presented in Table 2.

Table 2. Exploratory factor analysis of the final 22-item Thai mobile health (mHealth) senior technology acceptance model (STAM).

Construct Validity

From the EFA, the 22 items of the 7-factor Thai mHealth STAM explained 91.45% of the variance. The unidimensionality of each factor (subscale) and the overall models were assessed by analyzing modification indices in the CFA. Of the 7 factors from the EFA, the CFA of each factor (subscale) showed that only 5 factors, consisting of cognitive ability (C2, C3, C4), perceived barriers (PB1 and PB2), facilitating conditions (FC2, FC4, and FC5), self-reported health conditions (H1, H2, and H5), and social relationships (S1 and S2), showed satisfactory information criteria indices of the CFA, as presented Table 3. Factor 1, which included items from the attitude toward using (ATT1 and ATT2), perceived usefulness (PU1, PU2, and PU3),

and perceived ease of use (PEOU1 and PEOU2), did not meet the CFA criteria due to over-factoring issues (Table S5 in Multimedia Appendix 1). Factor 2, combining perceived barriers (PB3 and PB4) and gerontechnology anxiety (ANX1 and ANX2), was unfit according to CFA criteria, with a low CFI (0.799), low TLI (0.698), and high RMSEA (0.306, 90% CI 0.293-0.319). Attempts to combine subscales also did not meet CFA criteria (Table S5 in Multimedia Appendix 1). However, when items were separated as in the original STAM, including attitude toward using (ATT1 and ATT2), perceived usefulness (PU1, PU2, and PU3), perceived ease of use (PEOU1 and PEOU2), and gerontechnology anxiety (ANX1 and ANX2), these separated factors showed a good fit with CFA criteria (Table S5 in Multimedia Appendix 1). Out of the 9 factors from the single latent factor analysis, 5 were 2-item factors. These were kept in the final CFA model because 3 factors (attitude toward using, perceived ease of use, and gerontechnology anxiety) were originally designed as 2-item factors, similar to the original STAM. The perceived barriers and social relationships were also retained because of their contextual relevance, as described above. Finally, the CFA confirmed 9-dimensional sets of 22 items with satisfactory fit indices, as shown in Table 3. The details of the CFAs of evaluated and reevaluated models are described in Table S4 in Multimedia Appendix 1.

A nonparametric IRT analysis also affirmed the unidimensionality, local independence, and monotonicity of the 22-item model with 8 factors (Table S6 in Multimedia Appendix 1). For the scalability, all 22 items of the Thai mHealth STAM had H^s coefficients over 0.4, which indicates medium to strong scalability properties (Table S6 in Multimedia Appendix 1). The correlation among the final 22-item Thai mHealth STAM subscales ranged from 0.040 to 0.685 (Table S7 in Multimedia Appendix 1). The final 22-item Thai mHealth STAM questions, along with the English version and modeling indices, are described in Table 4.

Each item is scored on a 10-point Likert scale from 1 (very unsatisfied or strongly disagree) to 10 (very satisfied or strongly agree), with reverse scaling for perceived barriers and gerontechnology anxiety.

Table 3. Confirmatory factor analysis of the final Thai mobile health (mHealth) senior technology acceptance model (STAM).

Factor	Number of items	Threshold for acceptable fit					Model fit

Discriminant Validity

Considering the absence of a reference standard, it is theoretically reasonable that more participants with higher STAM scores will result in greater acceptance and adoption of technology. The discriminative indices, including sensitivity, specificity, and AUROC, were used to determine the cutoff scores for the proposed questionnaire, considering the intention to use mHealth from the external question. The 6 proposed sets of the final 22-item Thai mHealth STAM bands were classified into low, moderate, and high acceptance, as presented in Table 5. The set D of the possible banding was preferred as the optimal 22-item Thai mHealth STAM cutoff score based on the highest sensitivity of 89% (95% CI 86.1%-91.5%) and AUROC of 72.4% (95% CI 70%-74.8%). This finding also confirmed the discrimination performance of the 22-item Thai mHealth STAM in identifying persons with and without the intention to use mHealth. For set D, low, moderate, and high scores are defined as ≤151, 152-180, and ≥181, respectively. In addition, we conducted a subgroup analysis based on age groups: pre-older adults (aged 45-59 years) and older adults (aged 60 years and older). The result revealed that the set D banding had robust discriminant validity in older adults (AUROC 73%, 95% CI 70%-76%), but the discriminant validity decreased in the pre-older adult group (AUROC 67.7%, 95% CI 63.3%-71.9%). The discriminant validity of the 22-item Thai mHealth STAM by the subpopulation cohorts is shown in Table S8 in Multimedia Appendix 1.

[a]The final 22-item Thai mHealth STAM is highlighted.

[b]aOR: adjusted odds ratio.

[c]AUROC: area under receiver operating characteristic curve.

[d]Ref: reference.

[e]All reported aORs were statistically significant with *P* value<.05. aORs were estimated using a multivariable logistic regression with adjustment for age, gender, education levels (no, primary, secondary, and university education), income levels (low: <10,000 baht, moderate: 10,000-30,000 baht, and high: >30,000 bath), and living alone.

Scale Reliability

Out of 1100 overall participants, the final 22-item Thai mHealth STAM demonstrated an excellent internal consistency in both the Cronbach α (0.88, 95% CI 0.87-0.89) and the McDonald ω coefficients (0.85, 95% CI 0.83-0.87), as shown in Table 6. By subpopulation, the Cronbach α and the McDonald ω coefficients were 0.88 (95% CI 0.86-0.90) and 0.84 (95% CI 0.81- 0.89) for adults aged 45-59 years and 0.88 (95% CI 0.86- 0.89) and 0.83 (95% CI 0.81-0.86) for older adults. All 22 items revealed the corrected item-total correlations ranging from 0.26 to 0.71, achieving a level of acceptance between 0.20 and 0.80 (Table 6).

Discussion

Principal Findings

The study aimed to adapt and validate the STAM questionnaire for assessing mHealth technology acceptance among pre-older and older populations regarding the use of health support. The results confirmed the scale's factor structure, supported an 8-factor model with 22 items, and showed good discriminant validity in predicting mHealth intention. The optimal version was a 22-item Thai mHealth STAM using the scoring cutoff (≥152). Subgroup analysis indicated no significant difference in discriminant validity between pre-older and older adults. The scale demonstrated strong internal consistency and stability, with reliability confirmed by Cronbach α and McDonald ω coefficients. This adapted 22-item version is more relevant for assessing mHealth intention among older adults and is suitable for public surveys and routine practice, which take less than 15 minutes to complete.

Our findings are consistent with the previous study conducted by the owner of the original STAM [53], which was subsequently developed into a brief form to save administration time and reduce the burden on respondents. The 14-item brief version of the STAM questionnaire consisted of a 4-factor structure: attitudinal beliefs, control beliefs, gerontechnology anxiety, and health. These findings are consistent with ours, reflecting the original STAM model constructs and the age-related health characteristics of older adults. We observed a decrease in discriminant validity within the pre-older adult group, indicating a need for additional factors to explain their behavioral intentions. For example, older adults with different genders, education levels, income, marital status, and ethnicity may have different intentions and purposes to use mHealth for their health [54].

Strengths and Limitations

On the strength side, this is the first Thai version of the STAM questionnaire suitable for evaluating technology acceptance in Thai older adults. The 22-item Thai STAM version demonstrates structural balance, reliability, and validity in assessing technology acceptance among older individuals. The evaluation process is time-efficient. In addition, this tool can be used with both pre-older adults and older adults to prepare them for engaging with technology in their future lives. Furthermore, the

evaluation takes into account the influence of Thai cultural norms on the adoption and acceptance of mHealth.

However, there are some limitations to consider. Although the psychometric properties of the 22-item Thai mHealth STAM are satisfied through transcultural adaptation in terms of validity and reliability in both the pre-older and older populations, this scale can be applied for use in a broad. However, our study participants may not be representative of the overall Thai pre-older and older populations, as almost all of the participants lived in the northern part of Thailand, particularly in Chiang Mai province. In order to address this concern, future studies, including those based on different regions of Thailand and other specific populations (eg, teenagers, vulnerable groups, minorities, and specific groups of patients) that could potentially derive advantages from mHealth usage, are recommended to expand the generalizability and usability of this scale. Finally, the 22-item Thai mHealth STAM was evaluated based on the board's definition of mHealth. It is possible that the proposed questionnaire may not be compatible with all of the existing mHealth technologies due to the diverse range of mHealth technologies in health care. The patient's choice may vary depending on several factors, such as health care providers, types of services, or the specific application. Hence, we suggest using this questionnaire to assess their acceptance and intention to use it in conjunction with the designated mHealth technology.

Practical Implications of the 22-Item Thai mHealth STAM

The 22-item Thai mHealth STAM offers a practical assessment of patients' acceptability—a crucial factor often overlooked, as evidenced by a recent systematic review of technology acceptability in health care, which revealed that only 10% (142/1219) of the reviewed studies examined patient acceptance [55]. This publicly available questionnaire has the potential to support health care professionals, policy makers, and developers in making informed decisions [56,57], particularly regarding the adoption and acceptance of mHealth within Thai cultural norms. This questionnaire can be incorporated into the research and development (R&D) processes of mHealth and used as a questionnaire to define the target population based on levels of acceptability, as well as ascertain the factors that encourage or hinder the adoption of their mHealth technologies [58,59]. This information is important for informing stakeholders and developers in advance of the mHealth R&D and implementation stages, which necessitate user data for resource allocation and planning in consideration of user requirements and experiences [60,61].

Conclusion

The increasing number of older people, along with their growing adoption of technology, indicates that mHealth technologies might offer a new approach to enhancing the health of older adults with lower health care expenses. Although there are many advantages to using mHealth apps, it is important to consider their acceptance and intention to use them for health-related objectives. We proposed the 22-item Thai mHealth STAM as the questionnaire to evaluate the levels of acceptability and intention to use mHealth in the Thai community of pre-older and older adults. The 22-item Thai mHealth STAM has demonstrated satisfactory psychometric properties in terms of validity and reliability. As a result, it is now feasible to use this questionnaire in a public survey to support stakeholders in making informed decisions. Nevertheless, to improve generalizability and long-term use, further study is needed to investigate the various demographic groups with the specific mHealth interventions.

Acknowledgments

This work was supported by the Faculty of Medicine, Chiang Mai University (grant no. 124-2565), and Chiang Mai University. We would like to express our gratitude to Ms Asapaporn Nimmannit from the Research Institute for Health Sciences at Chiang Mai University for her support in translating the questionnaire. We used QuillBot [62] to review grammar and edit language. We critically reviewed the feedback generated by QuillBot and, based on this, revised the writing using our own words and expressions.

Data Availability

The data sets generated and analyzed during this study are not publicly available due to the institutional policies for protecting participant confidentiality but are available from the corresponding author on reasonable request.

Abstract

Background: Persons living with dementia and their caregivers experience frequent emotional health challenges. Across the illness spectrum, engaging in shared pleasant activities is an important feature of well-being for persons living with dementia–caregiver dyads. Under the umbrella of virtual reality, immersive virtual environment technology (IVET) offers artificial sensory experiences and shows promise in this population. IVET development benefits from a user-centered design approach, and as an emerging field, preliminary testing of safety, usability, and engagement for person living with dementia–caregiver dyads is required.

Objective: We aimed to develop a preliminary IVET intervention for psychosocial health among person living with dementia–caregiver dyads. In doing so, we highlight design considerations and user preferences to ensure the safety and usability of technology-based interventions in the context of dementia.

Methods: We engaged 10 clinicians, 8 caregivers, and 3 persons living with dementia in 5 rounds of focus groups to evaluate the safety and usability of preliminary intervention features. Following prototype development, we engaged caregivers and persons living with dementia (n=9 dyads) in beta testing workshops to observe real-time user interaction with the intervention and guide refinements. Rapid data analysis was used to extract themes relevant to intervention development.

Results: The following themes emerged from focus groups to inform prototype development: (1) designing flexibly to allow users to tailor the intervention experience to their own environmental context and circumstance, (2) designing with the dyad's clinical and relational needs in mind, and (3) accounting for illness and aging-related challenges in design. The following themes emerged from workshops to inform prototype refinements: (1) increasing user support through more feedback and (2) increasing variety of visual and auditory feedback.

Conclusions: Using user feedback throughout the development process, we developed a prototype of an IVET intervention, Toolkit for Experiential Well-Being in Dementia (the Isle of TEND), tailored to the needs of persons living with dementia and their caregivers. Our prototype uses specific design features to promote safety, usability, and engagement in the context of dementia. Future feasibility testing of the intervention is warranted.

Introduction

Background

Throughout the course of dementia, emotional health challenges (eg, depression, negative affect, and worry) are common among both persons living with a dementia diagnosis and their informal caregivers (eg, family members and friends) [1,2]. Persons living with dementia and their caregivers present with different emotional needs throughout the course of dementia [3,4]; however, maintaining relationship quality within the context of changing interpersonal dynamics remains an important component of emotional health for both members of the person living with dementia–caregiver dyad [5].

Dyadic research is gaining popularity within the fields of emotional health and dementia care [6,7]. Dyadic research highlights the impact of interpersonal relationships and the transmission of emotional states between members of the person living with dementia–caregiver dyad, which influence the emotional health of each member [8]. For example, perceived relationship strain by the persons living with dementia is associated with increased emotional distress in their caregivers and vice versa [9,10]. Alternatively, positive affective states can be shared among dyad members (eg, laughter), increasing emotional health for both dyad members [11]. Indeed, relationships and the emotional health needs of persons living with dementia and caregivers often change throughout the course of dementia, especially in advanced stages, as cognitive and communication limitations are more common [4,12]. However, despite changes, the need for positive experiences shared between persons living with dementia and caregivers remains common and relates to fewer behavioral and psychiatric symptoms among persons living with dementia and less stress among caregivers [13]. Thus, shared pleasant activities are an important component of emotional health among person living with dementia–caregiver dyads that can be targeted at any stage of illness.

As dementia advances and cognitive impairments become more pronounced, identifying shared activities that can promote emotional health for both persons living with dementia and caregivers may become more challenging [14-16]. Indeed, many dyadic interventions in the context of dementia are concerned with systematic approaches to identifying and engaging in shared activities [17]. For example, the tailored activity program intervention helps dyads identify and engage in personalized shared activities to reduce agitation among persons living with dementia and improve well-being among caregivers [18,19]. However, many of these shared activity interventions rely heavily on caregivers to plan and initiate activities, which may reduce shared positive affective states due to the caregiver-care recipient role, rather than equitable activity engagement [11]. For example, caregivers may find themselves in the role of an “instructor” or “supervisor,” rather than fully engaging in and receiving the emotional benefits of an activity. Therefore, designing interventions that allow both persons living with dementia and caregivers to fully engage in shared activities may create a positive emotional experience for each dyad member, contributing to their emotional health. Technology may aid this endeavor by creating interactive experiences that minimize the need for caregiver initiation (ie, using a technology platform that engages and guides both members of the dyad through an activity, rather than relying on the caregiver to lead the activity). Immersive virtual environment technology (IVET) is one such option for engaging person living with dementia–caregiver dyads in an intervention together.

IVET exists under the umbrella of virtual and augmented reality [20] and is defined as an artificial sensory experience that users actively engage with as if it were a real experience [21]. IVET promotes active engagement between users and computer-simulated environments through multisensory user-driven experiences [13,21,22]. These methods align well with existing approaches to promoting positive affect among persons living with dementia (ie, multisensory stimulation and personalized activities) [23]. IVETs often follow the 3 I’s design framework [24], which suggests that user engagement is achieved through (1) immersion (ie, creating a feeling of presence within the virtual environment), (2) interaction (ie, creating a sense of agency and control over the virtual environment), and (3) imagination (ie, the potential to create new experiences within the virtual environment). In nondementia populations, IVET interventions have demonstrated positive effects on emotional health outcomes, such as positive affect and emotional health (eg, depression and stress) [25]. Importantly, IVET interventions vary in terms of the level of immersion, categorized as low (ie, screen-based intervention), medium (ie, cave automatic virtual environments and surrounding projection screens), or high (ie, head-mounted displays for isolation from physical reality) [25]. In nondementia populations, medium immersion produces the greatest results on emotional health, with little difference observed between low and high immersion [25]. However, given the potential safety risks, such as cybersickness, falls, and agitation associated with higher levels of immersion in the context of dementia [21,26], IVET with low immersion may be suitable for this population. Indeed, most IVET interventions tested within the context of dementia use lower levels of immersion [27].

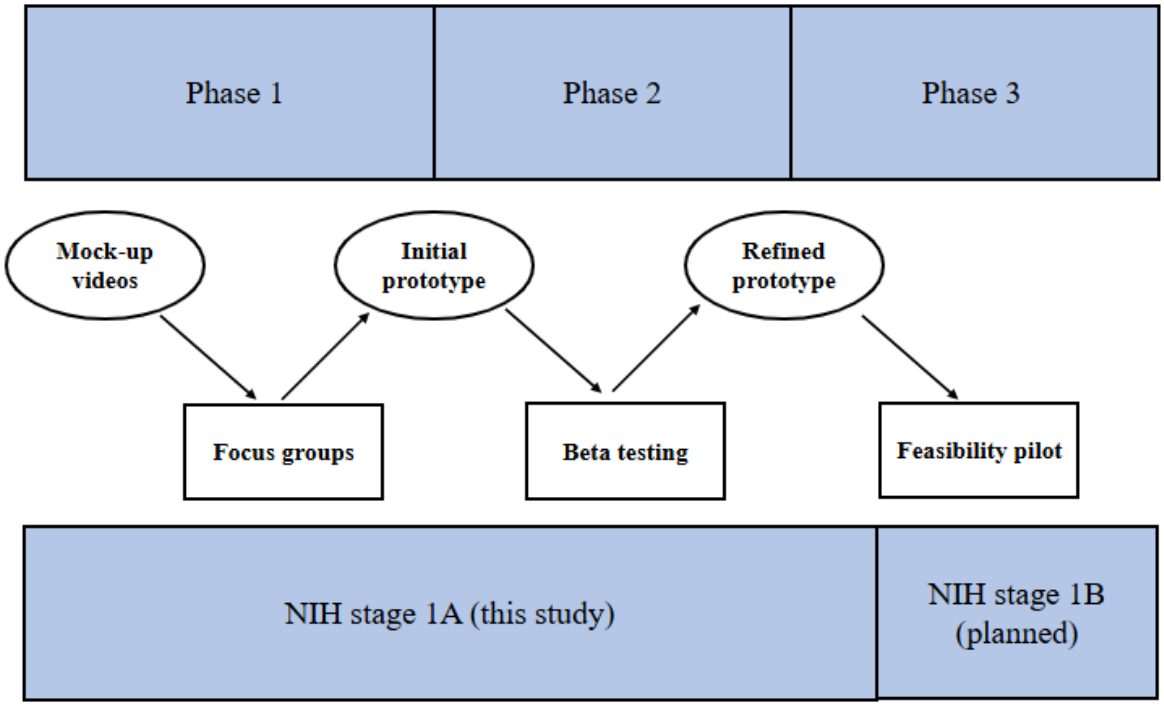
IVET interventions allow for multiple users to engage jointly (eg, persons living with dementia and their caregivers participate in shared activities) [21]. However, existing interventions have been tested primarily among persons living with dementia and caregivers individually [27-30]. For persons living with dementia, IVET interventions have demonstrated feasibility and usability, primarily targeting cognitive rehabilitation, exercise, or spatial navigation training [27]. For caregivers, IVET interventions have demonstrated feasibility and usability, often focused on caregiver education and skills [31,32]. Fewer IVET interventions have been developed for person living with

dementia–caregiver dyads to participate in jointly (ie, dyadically), with a focus on shared positive experiences for emotional health. SENSE-GARDEN is an example of a dyadic IVET intervention, which creates an immersive environment based on preferred autobiographical experiences, such as music, images, videos, and personal media (eg, family photos), for persons living with dementia who have moderate to severe cognitive limitations, allowing them to navigate along with their caregivers. The intervention is designed to support reminiscence between the persons living with dementia and caregivers in the present moment. Notably, caregivers have an active role in personalizing the information in SENSE-GARDEN but receive a lower "active dose" of the intervention (ie, fewer caregiver-focused experiences). Rather, caregiver benefit is conceptualized as arising from positive interactions with persons living with dementia. A clinical trial is currently underway for this intervention [33].

A major challenge to designing dyadic IVET interventions in the context of dementia is addressing cognitively mismatched dyads, which is more common as dementia advances. Promoting shared engagement among person living with dementia–caregiver dyads across the illness spectrum must embrace the 3 I's of design (ie, immersion, interaction, and imagination) for dyads with potentially different cognitive ability levels. While challenging from a design perspective, if achieved, this type of intervention would be an invaluable opportunity for dyad members to truly engage in shared activities together (ie, not initiated by the caregiver), helping them to briefly abandon the caregiver-care recipient dynamic and, in doing so, derive relational and emotional benefits. These types of more equitable interactions may promote positive affect and interpersonal connection among both persons living with dementia and caregivers, dignity for the persons living with dementia, and positive aspects of caregiving for the caregivers [34]. However, currently, guidelines for designing dyadic IVET interventions to promote shared engagement among person living with dementia–caregiver dyads are lacking, especially for dyads with mismatched cognitive abilities [6,35].

Additional work is needed to guide the development of dyadic IVET interventions throughout the course of dementia, especially in more advanced stages. For this endeavor, user-centered design approaches may be particularly important to ensure that interventions have the potential to be acceptable and feasible for both dyad members at various stages of illness. User-centered design is an iterative approach that centers the user experience early and often throughout the intervention development process [36]. The aim of user-centered design is to maximize the feasibility and acceptability of an intervention [37]. This study followed a multiphasic conceptual model of user-centered design rooted in human factors research, as outlined by Witteman et al [38]; refer to Figure 1. In phase 1, design teams engaged users and other knowledge holders with the goal of understanding user needs, goals, and strengths. In phase 2, design teams iteratively developed and refined an initial intervention prototype with user feedback. In phase 3, design teams observed users' naturalistic interactions with the initial prototype to inform additional refinements [38]. On the basis of user-centered design principles in the context of dementia [39], we prioritized the following factors across each design phase: understandability (ie, the user understands the intervention functions), learnability (ie, the user is able to easily learn the intervention), usability (ie, the user is able to participate in a task with minimal assistance), and safety (ie, tasks do not inadvertently lead to negative affect or other adverse outcomes).

Figure 1. User-centered iterative design to develop immersive virtual environment technology. Circles denote activities initiated by the design team, and rectangles denote activities designed to elicit user feedback. NIH: National Institutes of Health.



Purpose

This study aimed to develop a dyadic IVET intervention to support the emotional health of person living with dementia–caregiver dyads. Our design team represents an academic-industry partnership. In this study, we highlight our multiphasic user-centered design process [38], focused on the early stages of intervention development of a dyadic IVET intervention (phases 1 and 2 of user-centered design). First, we present data from focus groups with clinicians, caregivers, and person living with dementia–caregiver dyads to understand user needs, goals, strengths, and usability and safety concerns (phase 1). Then, we discuss the process of iteratively developing and refining an initial intervention prototype based on user feedback from multiple user workshops with person living with dementia–caregiver dyads (phase 2). The resulting dyadic IVET intervention prototype will be ready for pilot testing in a pilot feasibility trial (phase 3). In this study, by describing phases 1 and 2 of user-centered design, we highlight early design considerations for future teams focused on developing IVET or other novel technologies with person living with dementia–caregiver dyads across stages of dementia.

Methods

Study Design

This study followed a multiphasic user-centered design framework for the early stages of intervention development, as outlined by Witteman et al [38] and with the following dementia-specific considerations incorporated [39]: (1) understanding user needs, goals, strengths, limitations, and safety concerns; (2) iteratively developing and refining an initial prototype with user feedback; and (3) observing users' naturalistic interactions with the initial prototype. In phase 1, we conducted 5 focus groups with clinicians, caregivers, and person living with dementia–caregiver dyads to identify preferred activity features as well as design considerations for usability (ie, preferred intervention activities and accommodations) and safety in the context of dementia. The study team determined readiness to move to phase 2 after we believed that we understood major safety risks and could generate enough content for mock-ups of an intervention prototype. In phase 2, we conducted 8 beta testing workshops with person living with dementia–caregiver dyads to inform the development and refinement of an initial prototype. We determined readiness to move to phase 3 when usability concerns were sufficiently addressed, as evidenced by minimal usability issues reported by workshop participants. At the conclusion of phase 2, we had a finalized intervention prototype ready for feasibility testing in phase 3, which is not reported in this study. Phases 1 and 2 map onto stage 1A of the National Institutes of Health (NIH) Stage Model of Behavioral Intervention Development (ie, intervention generation, refinement, modification, and adaptation), and phase 3 maps onto stage 1B (ie, pilot testing) [40,41].

Phases 1 and 2 of intervention development were informed by our intervention conceptual model, as suggested by Rochon et al [42]. Specifically, we aimed to develop an IVET intervention that could promote sustained attention, positive emotions, and active engagement (ie, mechanistic targets) among both persons living with dementia and caregivers, leading to increased relationship satisfaction, decreased distress, and reduced agitation among persons living with dementia, as well as decreased burden among caregivers (ie, outcomes).

Ethical Considerations

Procedures were approved by the Massachusetts General Hospital Institutional Review Board (2022P001401). The information reported in this manuscript follows the Guidance for the Reporting of Intervention Development standards [43]. Potential clinician participants provided verbal consent before participating in focus group interviews. Caregivers provided verbal consent or e-consent during screening phone calls. A research assistant administered the University of California, San Diego Brief Assessment of Capacity to Consent Questionnaire (UBACC [44]) to persons living with dementia to determine their ability to provide consent. For those unable to provide consent, the persons living with dementia provided assent, and their caregivers provided surrogate consent to participate. All data were deidentified to protect anonymity. In phase 1, clinicians were compensated US $30, and persons living with dementia and caregivers were compensated US $50 each. In phase 2, persons living with dementia and caregivers were compensated US $50 each for their time.

Participant Recruitment

During phases 1 and 2, this study enrolled three categories of participants: (1) clinicians involved in dementia care, (2) caregivers of persons living with dementia, and (3) person living with dementia–caregiver dyads.

Clinicians were recruited via emails to dementia care clinics within the affiliated health care system. Clinicians were eligible if they (1) self-identified as dementia care providers and (2) were able to participate via Zoom (Zoom Communications). Of the 11 clinicians screened for focus groups, 1 (9%) did not participate due to a scheduling conflict.

Caregivers and dyads were both recruited via research registries (eg, study fliers). Recruitment materials were designed to target caregivers. Interested caregivers responded to the research team to obtain additional information about the study and review eligibility. Caregivers were eligible if they (1) aged >18 years, (2) self-identified as informal caregivers for a person living with dementia (eg, a family member or friend providing support), (3) could participate in English, and (4) had access to a video-enabled device for Zoom participation. Of the 31 caregivers screened for focus groups, 5 (16%) were ineligible due to not identifying as a caregiver of a person living with dementia, 13 (42%) had scheduling conflicts, and 5 (16%) could not be contacted.

For person living with dementia–caregiver dyads, caregivers were targeted using similar recruitment strategies discussed above. Interested caregivers identified and contacted their care recipient with dementia to participate in the study. Then, caregivers and persons living with dementia participated in a screening call together. Using the same eligibility criteria stated in the Participant Recruitment section, caregivers provided verbal consent or e-consent during screening calls. Eligibility

criteria for persons living with dementia included (1) having an informal caregiver participating in the study, (2) a self- or caregiver-reported dementia diagnosis, and (3) the ability to participate in an interview conducted in English. The UBACC uses 2 open-ended questions to assess the understanding of informed consent information (eg, "Can you briefly tell me what the purpose of the study is based on what I just read?"); scores range from 0 to 2, with scores <2 indicating lack of capacity to provide consent. The UBACC scores show a strong correlation with global cognition [45], suggesting that lower scores (ie, the inability to provide consent) are indicative of more advanced stages of dementia. Across stages, of the 12 persons living with dementia screened for this study, 8 (67%) scored a 0, a total of 2 (17%) scored 1, and 2 (17%) scored 2 (ie, able to consent independently). Of the 26 caregivers screened for workshops, 1 (4%) was ineligible due to not identifying as a caregiver, 4 (15%) had scheduling conflicts, 3 (12%) declined due to the care partner's worsening medical status, and 9 (35%) could not be contacted.

Phase 1: Focus Groups

Participants

There were 21 participants across 5 focus groups. A total of 10 clinicians participated across 2 clinician-only focus groups, representing the following professions: geriatric medicine (n=2, 20%), neurology (n=3, 30%), social work (n=2, 20%), occupational therapy (n=1, 10%), psychology (n=1, 10%), and psychiatry (n=1, 10%). Clinician degrees included Occupational Therapist (1/10, 10%), Licensed Psychologist (1/10, 10%), Master of Social Work (1/10, 10%), Licensed Clinical Social Worker (1/10, 10%), Licensed Independent Clinical Social Worker (1/10, 10%), Doctor of Medicine (6/10, 60%), Doctor of Science (1/10, 10%), and Doctor of Philosophy (PhD; 3/10, 30%). Participants reported an average of 10.95 (SD 10.20; range 2-20) years of experience in dementia care. The majority were women (6/10, 60%) and White (9/10, 90%) individuals.

A total of 4 caregivers participated in a caregiver-only group. Participants were primarily women (4/4, 100%), and half identified as White (2/4, 50%) individuals.

A total of 3 person living with dementia–caregiver dyads (n=6) and 1 solo caregiver (ie, the corresponding person living with dementia was unable to attend) participated across 2 dyad focus groups. Persons living with dementia were primarily men (2/3, 67%) and White (2/3, 67%) individuals. Caregivers were primarily women (4/4, 100%), and half identified as White (2/2, 50%) individuals.

Procedure

The sequence of focus groups was clinicians (n=2), person living with dementia–caregiver dyads (n=2), and caregiver-only (n=1) group. A PhD-level clinical psychologist with experience in dementia care and qualitative research led 4 focus groups with clinicians and person living with dementia–caregiver dyads. During dyadic focus groups, the facilitator made every effort to ensure active participation from persons living with dementia, including seeking collateral information from dyad members (eg, confirming caregiver statements with persons living with dementia), asking binary questions (eg, yes or no), rephrasing questions when needed, and making behavioral observations with verbal confirmations (eg, "I noticed you perked up when I mentioned music, do you enjoy listening to music?"). Two trained bachelor-level research assistants coled the caregiver-only group. None of the interviewers had previous relationships with the participants. Group sessions lasted an average of 54 (range 51–57) minutes. All focus groups were completed virtually over secure Zoom, audio recorded, and transcribed.

During each focus group, participants responded to semistructured interview questions targeting activity preferences, technology preferences, usability considerations, and safety concerns; refer to Multimedia Appendix 1 for example focus group questions. In addition, participants provided feedback on a series of mock-up videos (ie, disjointed visuals designed to elicit conceptual feedback and ideas for intervention modules), including passive nature views (ie, waves crashing and Northern lights), guided relaxation with nature background (ie, night sky with voice-over), and abstract color flow (ie, colorful viscous swirl). Mock-up videos were previously used by the design team to inform the development of other IVET platforms targeting nondementia populations. Videos were chosen to provide insight into design features that aligned with our proposed mechanistic targets of sustained attention, positive emotions, and active engagement [42]. Participant feedback was designed to elicit preferences, usability considerations, and safety concerns (eg, "What problems do you see with this experience?" and "Do you foresee any concerns for safety or otherwise?"). Consistent with an iterative process of design, videos and interview questions were updated between each round of focus groups, such that videos or topics that elicited concerns for usability (eg, querying about the utility of sensory kits of household items, such as spices, to accompany videos, which elicited concern for feasibility) or safety (eg, abstract color flows, which elicited concern about increasing agitation or confusion) were omitted, and others were added (eg, new nature scenes with multiple points of view).

During each focus group, 1 or 2 bachelor-level research assistants observed the interviews and completed live field notes using a standardized rapid data analysis (RDA) template created for use in this study; refer to Multimedia Appendix 1 for the RDA template. At the conclusion of each focus group, all facilitators and observers completed reflective field notes using a standardized form with categories similar to those in the RDA template.

Phase 2: Beta Testing Workshops

Participants

A total of 9 person living with dementia–caregiver dyad (n=18) participants were recruited across 8 beta testing workshops. Dyads were recruited separately for phases 1 and 2; none of the dyads who participated in phase 1 participated in phase 2. However, dyads enrolled in phase 2 were allowed to participate in multiple workshops if desired. Of the 9 dyads, most (6, 67%) participated in 1 workshop and 3 (33%) participated in 2 workshops; however, none participated in >2 workshops. Participants ranged from 1 to 4 dyads per workshop, with the majority consisting of 1 dyad (6/8, 75% workshops).

Across workshops, 100% (18/18) of participants identified as White individuals. Most persons living with dementia (7/9, 78%) identified as male, and most caregivers (7/9, 78%) identified as female. Caregivers provided proxy reports of dementia diagnoses, per their understanding of the medical records of the persons living with dementia, which included Alzheimer disease (2/9, 22%), unspecified dementia (4/9, 44%), Lewy body dementia (1/9, 11%), primary progressive aphasia (1/9, 11%), and frontotemporal dementia (1/9, 11%). Given that this study did not access medical records, caregiver reports were not confirmed, and the stage of illness was not reported. Multiple dyad relationship types were noted, including spousal (4/9, 44%), sibling (1/9, 11%), and adult child (1/9, 11%) caregivers.

Procedure

Beta testing workshops were led by members of the industry partner design team, with 1 to 2 trained research assistants in attendance to assist dyads in navigating the platform and to complete live field notes for RDA. All workshops were completed virtually over secure Zoom and recorded for the research team to review after session completion (eg, detailed feedback and behavioral observations). If multiple dyads engaged in 1 session, breakout rooms were used to enable private viewing experiences. Beta testing workshops lasted an average of 63 (range 34-103) minutes.

Workshops were completed via Zoom. At the start of each workshop, the design team shared a website link to the initial IVET intervention prototype with participants. Dyad participants were instructed to share their screen after opening the website. A workshop facilitator then prompted dyads to navigate the intervention both freely (eg, “As you explore the area, please share your thoughts out loud”) and with specific instructions (eg, “Can you figure out how to navigate back to the home screen?”). Participants started by freely navigating the prototype, providing live feedback on usability and acceptability (eg, confusing instructions and enjoyable features). Then, participants were presented with 1 to 3 modules to navigate, guided by facilitator prompts that primarily focused on usability and acceptability (eg, “Are there specific features on the island that drew your interest?” “What are your initial thoughts on the visuals of the activity?” and “Was navigating around the island intuitive or challenging?”). Dyads could choose the module they were most interested in navigating. In some situations, the second or third module was chosen for the dyad to ensure that feedback was gathered for each module. At the conclusion of each workshop, caregivers and persons living with dementia independently responded to quantitative measures assessing the perceived feasibility and usability of the platform. As workshops progressed, feedback became more targeted (eg, preference for specific images) than in earlier workshops (eg, preferred level of feedback from the platform), moving toward an initial prototype.

During workshops, research assistants completed observational field notes using a standardized template created for use in this study; refer to Multimedia Appendix 1 for the template. Field notes were used as part of RDA to inform intervention refinements between each workshop.

Measures

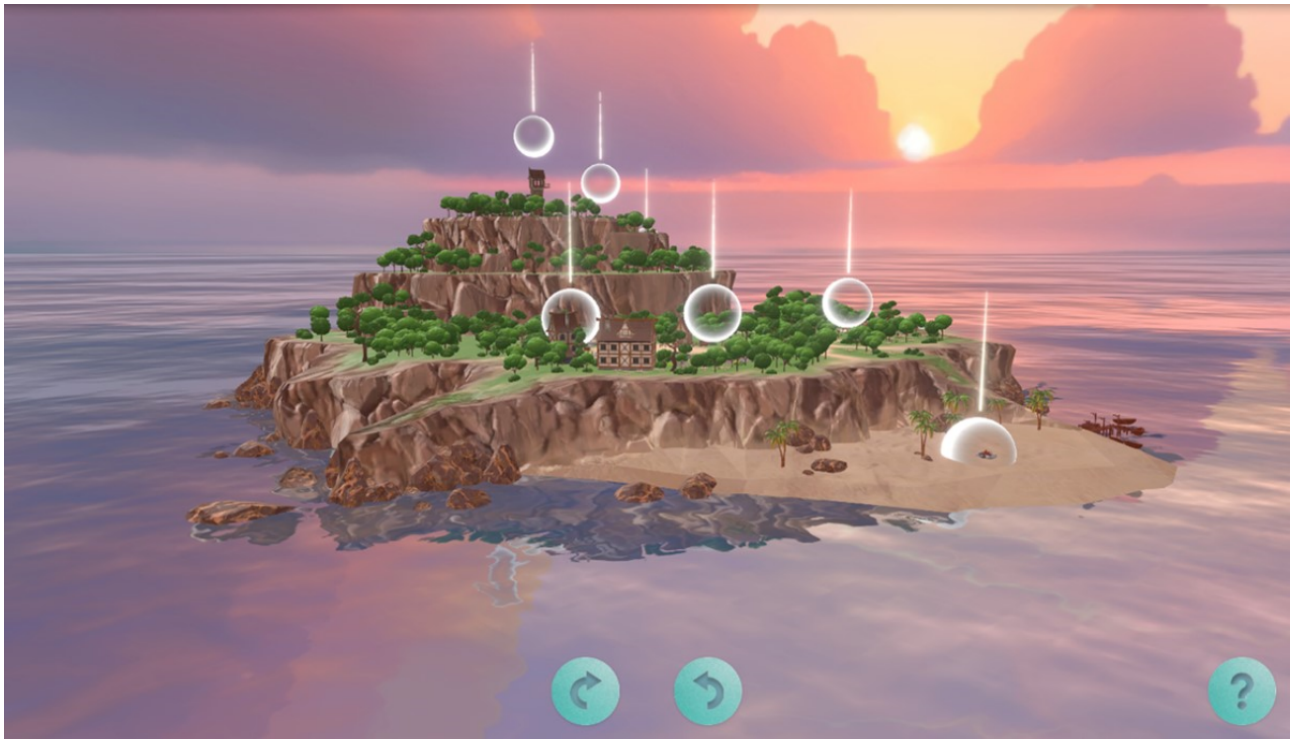
Usability was assessed using the System Usability Scale (SUS) [46]. The SUS consists of 10 items evaluating the perceived usability of technological platforms, including websites. The SUS is the most widely used scale to assess usability for technology-based interventions in the context of dementia, but self-report challenges may exist with more advanced cognitive limitations [47]. However, the SUS is primarily applied to persons living with dementia with mild cognitive impairments and lacks psychometric data across the full spectrum of dementia (ie, limited data available in advanced stages of dementia) [47]. Furthermore, the SUS uses 5-point Likert scale for response options [48,49]. Therefore, following best practices to reduce cognitive load and ensure that persons living with dementia could meaningfully participate, we adapted this scale to reflect yes or no response categories [47,50]. This decision increased the likelihood that persons living with dementia in this study could provide feedback independently.

A total of 3 additional study-specific feasibility questions targeted entertainment, safety, and control. These items were adapted from previous technology-based intervention studies with participants with mild cognitive impairment and their caregivers [48] and provided feedback salient to our conceptual model (eg, engagement and positive affect) and design aims (eg, safety). These items were also asked in a yes or no format to increase inclusivity for persons living with dementia.

Intervention Prototype

Activities outlined in Phase 1: Focus Groups and Phase 2: Beta Testing Workshops sections culminated in the development of an initial prototype of a web-based dyadic IVET intervention, referred to as the Toolkit for Experiential Well-Being in Dementia (Isle of TEND). The Isle of TEND website contained a home page (Figure 2) with the ability to navigate to 8 modules, which contained different shared activities; refer to Multimedia Appendix 2 for an overview of modules. Consistent with our conceptual model [42], each module in the Isle of TEND featured a shared activity intended to promote sustained attention, positive emotions, and active engagement with the intervention. The intervention was designed to be used by both persons living with dementia and caregivers together in the home.

Figure 2. The Toolkit for Experiential Well-Being in Dementia (Isle of TEND) home screen.



Data Analysis

This study used RDA as an analytic framework to identify themes from focus groups and workshops. RDA is used to quickly identify themes in qualitative data [51]. Rather than written transcriptions, this technique relies on live coding directly from interviews, such as taking observational notes during interviews or while listening to an audio recording [52-54]. For this study, RDA was chosen to identify specific feedback from participants related to preferences, usability, and safety that could guide prototype development and refinement. By quickly capturing this information, our research team was able to communicate findings back to our design team to iteratively respond to feedback and update the intervention prototype to gather more feedback from users.

Consistent with previous studies using RDA [55], we compiled RDA template notes from 2 to 3 team members (ie, 1 PhD-level clinical psychologist and 2 bachelor-level research assistants) into a single matrix for each focus group. Data from this matrix were used to guide discussions with the design team and informed design decisions toward initial prototype development.

At the conclusion of the study, matrices were combined and used to facilitate thematic analysis of focus groups and workshops separately. Focus group data were analyzed as a single dataset (ie, clinician, caregiver, and dyad focus groups analyzed together), such that we identified themes that emerged across groups. We did not compare themes across populations, as this was not consistent with the aims of this study. Two research assistants (ER and AT) trained in qualitative RDA methods independently reviewed matrices to identify codes. Coders met on multiple occasions during the coding process to resolve discrepancies. Codes were grouped by content to form themes. The thematic structure was iteratively developed and confirmed with a meeting between coders and a clinical psychologist on the study team with experience in dementia care (EP). After a thematic structure was agreed upon, the research assistants (ER and AT) reviewed transcripts to identify salient quotes for each thematic category. Both focus groups and workshops followed the same analytic steps. However, transcripts were only reviewed for focus groups because the data collected during workshops produced fewer exemplar quotes (eg, workshops contained more “thinking aloud” methods or behavioral observation, making data less relevant for exemplar quotations).

Results

Phase 1: Focus Groups

Three themes emerged from focus groups with clinicians, caregivers, and dyads: (1) designing flexibly to allow users to tailor the intervention experience to their own environmental context and circumstance, (2) designing with the dyad’s clinical and relational needs in mind, and (3) accounting for illness and aging-related challenges in the design.

Theme 1: Designing Flexibly to Allow Users to Tailor the Intervention Experience to Their Own Environmental Context and Circumstance

The ability for users to individualize their experience emerged as an important design feature to increase acceptability and usability as well as to empower choices among users. Participants noted that the option to individualize or tailor intervention content could help accommodate a larger range of users based on their access to and comfort navigating technology. In addition, participants recommended that the IVET intervention be accessible via various platforms. For example, a clinician noted the following:

> *[Consider] an app that is free, that can download the materials into [users] cell phone or their device so it doesn't depend on the Internet connection...and maybe having the option of audio only or audio plus visual.*

Participants also noted the importance of developing stimuli that were familiar to and pleasant for participants of various backgrounds, cohorts, and identities to promote individualization. Furthermore, participants noted that familiar stimuli may especially increase comfort, enjoyment, engagement, and safety for persons living with dementia. A caregiver highlighted the potential benefits of familiar stimuli:

> *Having an inspirational waterfall isn't necessarily going to put me at ease, but maybe hearing my family's familiar voice, or the clattering of my own kitchen, or having something that individualizes this to me would.*

Similarly, a clinician highlighted the need for inclusivity as follows:

> *I just wonder if the salience of some of the images might be different depending on the cultural groups. The aurora borealis is beautiful, but for maybe people who [are] not familiar with that part of the of the world...what are the scenes, the sounds that are most salient and comforting to that individual.*

Of note, related to the environmental context of an at-home IVET intervention, caregivers discouraged the use of a proposed sensory kit of household materials, citing feasibility issues with the ability for a range of users to locate these materials in their home (eg, spices).

Theme 2: Designing With the Dyad's Clinical and Relational Needs in Mind

Participants noted that designing an intervention with a specific purpose and orienting users to a rationale for using the intervention may increase usability. Specifically, participants suggested recommendations for appropriate times and intended outcomes of use (eg, using when calm and avoiding when agitated). For example, a clinician noted the potential clinical utility of an IVET intervention:

> *I think that [the calming sounds are] good, and it appeals to an inherent positive emotional experience which could also aid caregivers when they're trying to prep for redirection or transition. Basically, if we're trying to get somebody to do something that they may not necessarily want to do we're far more likely to be able to if a person is in a positive emotional state versus a negative one and so these types of things could aid in that process of prepping a patient for a transition.*

Caregivers believed that they would likely need to be present to initiate the intervention as well as to guide the persons living with dementia through some of the modules. For example, a caregiver noted the following:

> *[Caregivers] would have to be there to sort of guide [Person living with dementia] or kinda help them figure out what [the intervention] is.*

Participants were skeptical that an IVET intervention could be engaging for both dyad members, noting challenges of achieving sustained attention and immersion for both persons living with dementia and caregivers. This is highlighted by a caregiver who stated the following:

> *[Person living with dementia] loses interest pretty quick, and I think sometimes he has trouble following the storyline. So, it would be hard to find something that would be suitable for both of us, cause we're kind of in very different places now. And that's one of the things that's difficult is we don't have as many shared experiences as we used to.*

Participants recommended structured stimuli to quickly capture and sustain the attention of users, which they noted could be challenging in the context of dementia. For example, a caregiver stated the following:

> *Without having a clear beginning or end, [the person living with dementia] might get bored or discouraged, it needs to have more structure.*

Furthermore, participants emphasized that the IVET intervention would need to be designed to sustain attention and immersion without overstimulating or confusing users with cognitive challenges.

Theme 3: Accounting for Illness and Aging-Related Challenges in the Design

Participants noted the importance of ensuring the reduction, rather than an unintentional exacerbation, of behavioral and psychiatric symptoms of dementia, particularly agitation and hallucinations. This concern is highlighted by a clinician, who stated the following:

> *Dementias with any psychiatric component or psychotic features, paranoia, delusional thinking...you always want to be careful about providing stimulation when we don't know where that may lead the patient's train of thought.*

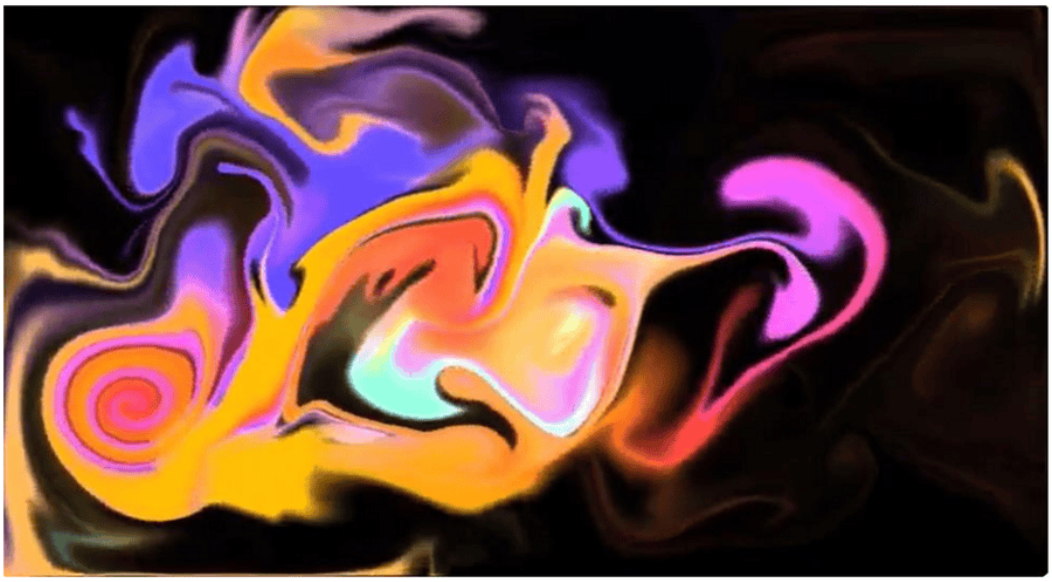
There were specific stimuli that participants recommended avoiding, such as 1 video with a moving (ie, swirling) bright color scheme against a black background (Figure 3), which participants suggested could potentially exacerbate psychiatric symptoms. For example, a clinician stated the following:

> *I think patients would not like [the swirling color video], they have a lot of visual spatial misperceptions.*

Furthermore, participants cautioned against dark backgrounds, which might increase psychiatric symptoms and confusion or disorientation. For example, a caregiver noted the following:

> *My husband is really paranoid, he thinks people are out to get him. I was thinking of the lighting, if there is darkness that might increase his paranoia.*

Figure 3. Swirling color scheme video.



Another caregiver noted the following:

> *The edges of my video were very dark. So, it gives you almost like that movie theater feel to it, which I worry, if you're immersed in something too much, do you have less grasp on here and now where you are.*

In addition, as noted across multiple themes, participants relayed that certain cognitive symptoms, especially attentional deficits and apathy, could pose a challenge to engagement and usability. One clinician stated the following:

> *I wonder if in some instances this [mock-up videos] may be a little too unstimulating to capture the patient's attention, unless they are really already very calm and wanting to be calm.*

Another clinician stated the following:

> *for images...it might be really, really simple ones, the less complicated you make it, the better received because [person living with dementia] cognitive abilities and processual abilities are impaired.*

Participants also noted that visual clarity was an important design feature and recommended that the IVET intervention accommodate for age-related changes and pathologies more common with older age. For example, 1 caregiver stated the following:

> *There's something about lighting that I would pay attention to for elders...I have another elder in my life who has glaucoma and she can't see things in depth of perception and other things.*

Phase 2: Beta Testing Workshops

Qualitative Results

Two main themes emerged from beta testing workshops with dyads that informed intervention refinement: (1) more feedback to guide using the intervention and (2) more variety of visual and auditory experiences.

Theme 1: Increasing User Support Through More Feedback

Participants noted that more purposeful or goal-directed actions within intervention modules could reduce confusion during use. When engaging with the intervention, caregivers and persons living with dementia frequently inquired about the end goal of modules, especially when feeling "lost" or "stuck." Relatedly, participants recommended more instructions, which, per observation, appeared to be related to participant concerns about making an error or doing the experience "wrong." Together, an open-ended module without clear directions, which was initially developed to increase exploration and reduce the need for caregiver instructions, actually increased confusion and perceived misuse of the intervention by users.

Furthermore, participants voiced the need for continuous instructions throughout use to understand next steps, which was particularly relevant in modules that included multistep tasks. For example, a module that developed a poem based on typed responses to multiple prompts caused some confusion among users because dyads were unsure of the task they were being prompted to complete (eg, not knowing that prompts would generate a poem) or the end goal of the multistep process (eg, the need to press next and respond to another prompt to develop the full poem). In addition to more prompts, participants suggested having multiple methods of engagement, such as a speech-to-text function, to promote accessibility and usability.

Theme 2: Increasing the Variety of Visual and Auditory Feedback

Participants recommended increasing the presence and variability of responsive sounds, background music, and interactive visuals. Caregivers and persons living with dementia both noted that alternating music or background colors might reduce redundancy after multiple uses and make the intervention more engaging. In addition to increasing engagement, dyads noted that sound effects, especially calming nature sounds, improved their experience by creating a sense of calm while using the intervention.

Quantitative Analysis

In general, users rated the intervention positively (Table 1). On the study-specific feasibility scale, 100% (11/11) of caregivers and 67% (6/9) of persons living with dementia (n=2, 22% were unsure or did not respond) felt that the program was safe to use, 82% (9/11) of caregivers and 100% (9/9) of persons living with dementia felt that the program was entertaining, and 82% (9/11) of caregivers and 89% (8/9) of persons living with dementia felt that the program helped them "feel in charge of their own experience." On the SUS, 82% (9/11) of caregivers and 89% (8/9) of persons living with dementia thought that the program was "easy to use," and 73% (8/11) of caregivers and 78% (7/9) of persons living with dementia "felt very confident using the program" (n=1, 11% were unsure or did not respond).

Table 1. Feasibility and usability results of beta testing workshops.

	Caregivers, (n=11), n (%)			Persons living with dementia (n=9), n (%)		
	Yes	No	Unsure or unable to answer	Yes	No	Unsure or unable to answer
"I think that I would like to use this program."	7 (64)	2 (18)	2 (18)	6 (67)	2 (22)	1 (11)
"I found the program unnecessarily complex."	1 (9)	10 (91)	0 (0)	1 (11)	8 (89)	0 (0)
"I thought the program was easy to use."	9 (82)	2 (18)	0 (0)	8 (89)	1 (11)	0 (0)
"I think that I would need the support of a technical person to be able to use this program."	4 (36)	7 (64)	0 (0)	3 (33)	4 (44)	2 (22)
"I found the various functions in this program were well integrated."	9 (82)	2 (18)	0 (0)	6 (67)	3 (33)	0 (0)
"I thought there was too much inconsistency in this program."	2 (18)	9 (82)	0 (0)	2 (22)	5 (56)	2 (22)
"I would imagine that most people would learn to use this program very quickly."	7 (64)	3 (27)	1 (9)	4 (44)	0 (0)	5 (56)
"I found the program very cumbersome to use."	0 (0)	11 (100)	0 (0)	1 (11)	5 (56)	3 (33)
"I felt very confident using the program."	8 (73)	2 (18)	1 (9)	7 (78)	1 (11)	1 (11)
"I needed to learn a lot of things before I could get going with this program."	1 (9)	10 (91)	0 (0)	2 (22)	4 (44)	3 (33)
"Was this program able to entertain your relative and you?"	9 (82)	2 (18)	0 (0)	9 (100)	0 (0)	0 (0)
"Did you feel that the program was safe to use for your relative and you?"	11 (100)	0 (0)	0 (0)	6 (67)	1 (11)	2 (22)
"The program helped my relative feel in charge of their own experience."	9 (82)	2 (18)	0 (0)	8 (89)	1 (11)	0 (0)

Feedback-Design Integration

Throughout intervention development, our academic-industry team met weekly to discuss results from focus groups and workshops and translate findings into pragmatic design elements. Often, the research team helped provide the context of findings within the illness context of dementia, as well as guide a systematic approach to intervention design that would prepare the team for a future, scientifically rigorous clinical trial. The industry design team often discussed the possibilities and limitations of an IVET intervention delivered with minimal equipment (ie, via a computer or tablet). These perspectives led to productive discussions about incorporating user feedback into intervention design. Together, this iterative process led to the end product of an IVET intervention ready for initial feasibility testing (NIH stage 1B) that was deemed safe and usable by end users (ie, person living with dementia–caregiver dyads). Feedback and design decisions are provided in Table 2.

Table 2. User feedback and design team responses.

User feedback	Design feature
Focus groups: initial prototyping	
Implement choice-based activities when possible.	The team decided on a web-based IVET[a] format so that users could guide themselves through the platform. The intervention was user driven, and users chose from various modules in the intervention, deciding the type and length of activity within each module.
Establish the ability to adjust audio or visuals depending on preferences.	Developers enabled access to the intervention on the user's own tablet or computer so that users could adjust the volume and brightness to their preference.
Include visuals or audio that are appealing and familiar to diverse populations.	The design team developed 8 different modules, including modules set in a forest, an ocean, a beach, and a lighthouse.
Integrate instructions for the intervention.	The design team included text instructions on the home screen to orient users when they logged into the intervention. The instructions reviewed how to navigate through the home screen and the modules.
Intervention can be used among people with and without cognitive impairment.	Modules were "error-free" so that users were unable to "fail" or choose the "wrong" option, halting the experience; regardless of user choice, the experience continued.
Include stimuli that are reactive to touch or hand or arm movement.	Developers created two activities, which accessed the device's camera to track and react to hand movement: (1) Sound Garden, which used hand movement to control the music pitch and volume in a garden scene, and (2) Art Studio, which used hand movement to create brush strokes on the screen to reveal an art piece.
Design modules that are grounded in reality (familiar structure and clear beginning and ending).	The team set the intervention in recognizable locations, such as a waterfall, a lighthouse, and a beach. The game had a clear beginning with text instructions when users logged on.
Avoid abstract images and darkness in visuals.	The team removed abstract "swirling colors" stimuli. The team discarded a video set in a dark forest environment and brightened the colors in the remaining modules.
Beta testing workshop: prototype refinements	
Clarify the end goal or purpose of the intervention. Include more goal-directed aspects to the intervention.	The design team added an introduction slide clarifying that the intervention was designed to create "shared adventures" between the dyad and "engage the senses and spark imagination." The team included a "help" button across all modules to guide users.
Implement different methods of engagement, such as a speech-to-text option instead of typing.	Developers included a speech-to-text function in modules that required users to type. These activities accessed the device microphone to capture spoken responses from the dyad and convert them into text. To increase engagement, developers created custom soundscapes for scenes and changed them based on the visual stimuli presented.
Add more instructions and audio-to-text instructions.	Developers added a module description when users hovered their mouse over each module location. The team added step-by-step tutorials, which isolated different interactive aspects of the experience when users clicked on each module. In addition, the team added voice-over to text as an accessibility option to all introductions and guides.
Increase the visual stimuli throughout use to reduce redundancy.	The team increased the visual options in modules throughout the experience by creating more artwork and audio clips. For example, in the Storytelling module Campfire Cove, the team increased the number of available pictures to choose from and created an accompanying story.
Include visual and audio stimuli, such as animation or music, in modules that lacked sounds or featured static images. Add calming music or nature audio when possible.	The design team added nature-based animation and sound on the home screen, including auditory and visual waves, so that when logging on, users were greeted with these stimuli. In addition, the design team added nature-based sounds to the background of module instructions, such as birds chirping and "calming" music.

[a]IVET: immersive virtual environment technology.

Discussion

Principal Findings

Following a multiphasic user-centered design framework with dementia-specific considerations [38], this study used focus groups and user workshops to develop and refine the initial prototype of a dyadic IVET intervention to support the emotional health of person living with dementia–caregiver dyads (ie, the Isle of TEND). The intervention was rooted in our conceptual model of shared activities that can promote sustained attention, positive emotions, and active engagement among both dyad members simultaneously [42]. The Isle of TEND is now ready for feasibility testing, consistent with NIH stage 1B.

Design Considerations

Overview

Across focus groups and workshops, we identified several key considerations for designing an IVET intervention for person living with dementia–caregiver dyads. Importantly, we did not constrict our intervention to a specific stage of illness. Rather, we engaged users, including those with cognitive limitations as evidenced by UBACC scores, and other knowledge holders who could provide feedback relevant to users with varying degrees of cognitive ability. This approach allowed us to capture multiple voices and perspectives to ensure that we are designing for all persons living with dementia, including those often not considered during the design stage due to significant cognitive impairment.

Personalization and Variety of Experiences

Consistent with previous research on technology-based interventions with persons living with dementia [56,57] and activity engagement in them [58], personalization and variety of experiences emerged as key design features for our intervention. This feedback is not surprising, given the heterogeneity of identities, preferences, and lived experiences of dyads managing dementia. Increasing the number of novel or rotating visuals and sounds in each module allowed for personalization and helped to reduce boredom with repeated use. Our design team was cautious to only make slight variations in activities (eg, sounds or storytelling prompts) to reduce boredom without increasing confusion. Consistently, participants noted that nature-based sounds and animation, such as waves or chirping birds, evoked positive emotions. Therefore, our design team focused on nature scenes for many of our modules. Previous research with persons living with dementia supports that nature sounds introduced through technology, referred to as a soundscape, are perceived positively with minimal safety concerns [59,60].

Optimizing Autonomy and Choice While Sustaining Ease of Use

Feedback related to personalization highlighted an important component of designing in dementia: optimizing autonomy and choice while sustaining ease of use. In addition to increasing acceptability, the ability to tailor interventions to personal preferences may create an opportunity for persons living with dementia to have more control over their user experience. This was important for both members of the dyad to promote a sense of accomplishment, autonomy, and confidence and, ideally, allow the dyad to break the care recipient-caregiver script, enabling both members to feel as though they have ownership of their own experiences with the intervention. Previous technology-based interventions developed for persons living with dementia with mild cognitive impairments also note the importance of prioritizing user control [48]. Furthermore, in the context of dyads, increasing autonomy and choice for persons living with dementia means reducing the need for the caregiver to "deliver" the intervention. While refinements to our prototype are still needed to fully achieve this outcome, it is an important endeavor for dyadic interventionists in the context of dementia, as allowing for a break in the care recipient-caregiver script may produce positive emotional benefits for both dyad members across all stages of illness.

Users consistently provided feedback that some user-driven choices in our platform were too open ended (eg, coming up with a poem without prompts), which could lead to confusion and produce the opposite emotional experience for dyad members than intended (ie, frustration with being "wrong" and the perceived need for caregiver-directed behaviors). To address this balance, our design team attempted to provide ample instructions and feedback for use while not imposing "rules" (ie, "error-free" design) and promoting exploration. For example, several of our modules initially present users with directions for navigating the activity and then provide participants with open-ended (ie, pictures of different scenes) and forced-choice (ie, multiple choices for storytelling) decisions to guide their experience based on their needs and preferences. In addition to providing directions throughout the module, as recommended by users, we developed responsive features to reduce cognitive load and avoid frustration. For example, following effective communication strategies in the context of dementia [61], if a dyad did not respond to a multiple-choice prompt within a period of time, a forced-choice option appeared (ie, this or that). Most users with dementia rated that they felt in control of their own experience and confident in using the Isle of TEND, which may be a product of these design features.

Maintaining Engagement Among Cognitively Mismatched Users

We set out to design an IVET intervention that can maintain sustained attention and engagement among cognitively mismatched dyad users while at the same time not overwhelming the persons living with dementia or underwhelming the caregivers. Participants recommended that to achieve this goal, we needed to have a clear structure, continuous feedback, and novel stimuli, which are consistent with theory (eg, flow) [62]. In response to these recommendations, our design team developed a home screen with an introduction to the IVET intervention, tutorials and instructions for each module, and a navigation guide that appears constantly. Furthermore, our design team developed several modules that are reactive to touch or movement. For example, 1 module, the Art Garden, accesses the device camera and uses hand movement as "brushstrokes" to paint a picture. Despite these features designed to promote sustained attention and engagement, user feedback in the workshops was still mixed regarding the ability to capture and

sustain engagement across cognitively mismatched dyads and reduce caregiver-directed behaviors (eg, caregiver reiterating directions). However, it is important to note that 82% (9/11) of caregivers and 100% (9/9) of persons living with dementia still found the intervention to be entertaining. The field still needs to address the important topic of designing for mismatched cognitive abilities, as there are potential clinical benefits associated with shared engagement for person living with dementia–caregiver dyads managing dementia throughout the course of illness (eg, emotional closeness and relaxation). It is possible that design teams need to attend to more nuanced interactions between users and platforms to evaluate common elements of sustained attention and engagement across users with varying cognitive abilities (eg, movement).

Not Exacerbating Behavioral and Psychiatric Symptoms of Dementia

Regarding safety concerns, participants flagged specific stimuli that could potentially lead to distress or exacerbate behavioral or psychiatric symptoms that accompany certain types of dementia. In particular, participants recommended avoiding abstract stimuli, bright colors, or moving objects against a dark background, as these could potentially increase adverse events (eg, agitation) in more advanced stages of dementia. These images may relate to overstimulation or confusion, which increases behavioral and psychiatric disturbances in the context of advanced dementia when persons living with dementia have increased vulnerability to environmental stressors [63]. Users suggested that, in general, simpler and easily recognizable images may be better received by both persons living with dementia and caregivers. Participants also identified dark or shaded visuals as potentially problematic (eg, blurriness and glare) for users with age-related or other visual impairments. In response to the feedback, the design team removed visuals and modules that relied on limited lighting and highly abstract images. Of note, there were no observed exacerbations of dementia-related behavioral or psychiatric symptoms during workshops.

Limitations

This initial intervention development study has several limitations to consider. First, our convenience sample of caregivers, dyads, and clinicians consisted of a majority of White participants. In future pilot testing, we will ensure that participants are more representative of the US population. Second, we did not administer cognitive assessments to describe the level of cognitive impairment of our sample. Therefore, we cannot empirically comment on the cognitive profile of participants with objective measurement, including the severity of cognitive impairment. This study used self-reports from persons living with dementia and caregivers to capture the presence of dementia, and the UBACC provides additional insight into the presence of cognitive limitations inhibiting the ability to provide autonomous consent. Indeed, dementia research must balance participant burden, the reality of difficulties obtaining a dementia diagnosis, and study goals. In line with our broader goal of offering TEND as a free intervention for individuals in community settings, we included participants with varying levels of cognitive ability, as reflected by the fact that only 17% (2/12) of our sample was able to provide independent consent. To circumvent challenges with reporting on quantitative surveys for those with more advanced dementia, our team took multiple steps to support persons living with dementia in reporting their own outcomes, including using binary scales and reading questions aloud. However, these methods may have reduced the validity of our measures, and we still cannot be sure that all items were fully comprehended. Finally, we chose RDA over other forms of qualitative analysis. For this study, prioritizing a quick summary of information and relaying this to our design team consistent with RDA was necessary, but this analytic approach may also be more susceptible to researcher bias.

Conclusions

The result of this multiphasic user-centered design study with an academic-industry design team was the development of an initial dyadic IVET intervention for persons living with dementia and their caregivers to use together at home. On the basis of our conceptual model, we aimed to promote sustained attention, positive emotions, and active engagement in both dyad members to increase relationship satisfaction and reduce psychosocial distress. In this study, we highlight early intervention development with a focus on designing for usability and safety. While some of our design considerations may be helpful for future investigators and design teams focusing on dyads managing dementia, we also recognize that there are gaps that still need to be filled, such as promoting mutual engagement among cognitively mismatched dyads.

Conflicts of Interest

Abstract

Background: The rising prevalence of dementia is a major concern, with approximately 45% of cases linked to 14 modifiable risk factors. The European project LETHE aims to develop a personalized digital intervention model to delay or prevent cognitive decline through risk factor management.

Objective: The objective of our study was to design a clinical trial platform for older individuals at risk of cognitive decline, including a mobile app for study participants and a clinical trial management system (CTMS) for health professionals.

Methods: Using a user-centered design approach, workshops and feedback rounds involved potential participants representing the target group and professionals. The LETHE app's usability was assessed among 156 older adults enrolled in a 2-year

multinational randomized controlled trial evaluating the feasibility of a digitally supported lifestyle program for dementia risk reduction. The randomized controlled trial is currently ongoing; the System Usability Scale (SUS) was administered 1 month after baseline to map first user experiences. Feedback on the LETHE CTMS was collected from 21 users.

Results: Of the 78 participants in the trial intervention group, 66 (85%) provided responses for the mobile app, with a median SUS score of 70 (IQR 55-82). Within the control group, 73% (57/78) of responses were received, with a median SUS score of 73 (IQR 63-90). For the CTMS, we received 71% (15/21) of responses, and the feedback was mostly positive. A ranking of the features that could be considered beyond state of the art showed that the integration of personalized activities (mean 2.23, SD 1.17) and real-time appointments (mean 2.46, SD 1.51) were considered the most novel ones.

Conclusions: The LETHE app and CTMS were developed to support a personalized digital intervention method within a study involving 156 participants. Limitations include participants having digital literacy and internet access, potentially impacting the generalizability of the findings. Despite these limitations, positive feedback and high usability scores suggest promising potential for the LETHE app and CTMS in supporting personalized interventions to prevent cognitive decline in older adults.

Introduction

Background

Overview

The rising prevalence of dementia, driven by sociodemographic changes, constitutes a significant global health challenge. Projections indicate a notable rise from 57 million affected individuals in 2019 to an anticipated 153 million by 2050 [1]. Notably, the Lancet Commission's report underscores that approximately 45% of all cases of dementia are associated with 14 potentially modifiable risk factors at different phases of the life span [2], and diet has also been suggested as an additional factor [3]. Previous multidomain intervention studies have demonstrated their positive impact on cognitive performance while simultaneously targeting various lifestyle domains, including diet, physical activity, cognitive training, management of cardiovascular risk factors, or social interaction [4-6].

Information and communications technology (ICT) solutions such as apps running on phones and tablets, as well as wearable devices that collect user-generated health data (digital biomarkers) in an automated way, could potentially help provide digitally supported interventions for a broader audience and groups at risk of cognitive decline. At the same time, these technologies can collect data to monitor progress and adherence to lifestyle interventions. Other research projects have shown that digital interventions can be effective and feasible for older adults, but this depends on several factors such as digital literacy, usability of the technology, and the design of the study with regard to human support (hybrid intervention) [7-9].

The Horizon 2020 LETHE project [10] has been initiated to provide such a personalized digital intervention model and components for reducing risk of developing cognitive decline by evolving the successful Finnish Geriatric Intervention Study to Prevent Cognitive Impairment and Disability (FINGER) multidomain intervention model [5]. Leveraging ICT-based methods and guided in-person as well as remote sessions, LETHE aims to prevent cognitive decline in at-risk older individuals by providing personalized feedback and intervention methods.

The LETHE project focuses on the aforementioned modifiable risk factors grouped into the following lifestyle domains: "Physical Activity," "Nutrition," "Cognitive Training," "Management of vascular/metabolic risk factors," "Sleep/Relaxation," and "Social Activity."

The LETHE study encompasses a currently ongoing 2-year randomized controlled multicenter, parallel-group feasibility trial (ClinicalTrials.gov; NCT05565170) involving 156 participants at risk of cognitive decline distributed across clinical centers in Austria (Medical University of Vienna), Finland (Finnish Institute for Health and Welfare), Sweden (Karolinska Institute), and Italy (University of Perugia). Participants were equally randomized to one of the study groups (intervention and control), both supported by digital tools (mobile app and smartwatch). At baseline, participants had a mean age of 68.8 (SD 4.5) years, with an average of 14.9 (SD 3.1) years of education. A total of 64.7% of the participants were women. Notably, most participants (84%) used their smartphones at least 6 times per day. Two-thirds of the participants had previous experience using their smartphones for health tracking, and approximately 48% had used lifestyle-related apps. In addition, 63% of the participants reported using the internet for eHealth-related tasks such as booking physician appointments or checking test results [11].

To provide intervention components and continuously collect data from the trial participants, a LETHE smartphone app was designed and implemented. Clinical data, including blood test results, are entered into the LETHE clinical trial management system (CTMS), which was also developed during the course of the project, by health professionals at each visit. The CTMS was developed to ensure seamless integration with the app, allowing all participant-entered data to be displayed for health professionals to review and respond accordingly. Furthermore, data and services from third parties have been integrated, including cognitive training data and data from Fitbit devices, which track steps, sleep, and physical activity. The feasibility

of other novel technologies (audio glasses and a robot that reflect the content of the smartphone app) is being investigated in a substudy.

This study aimed to describe the design and implementation of the LETHE technical components, which were carefully developed through a joint process involving potential users, clinical experts, and designers and technicians.

Hybrid Intervention Approach

LETHE adopts a hybrid intervention (blended therapies) approach, seamlessly integrating digital intervention sessions with in-person and group sessions led by a trained coach (eg, physiotherapist or nutritionist). This comprehensive strategy, meticulously managed by health professionals, is in harmony with the study's mobile app and CTMS concept.

The literature on hybrid interventions for older adults at risk of cognitive decline, incorporating technology with coaching and peer sessions in comparison to stand-alone technology interventions, is still developing and has so far mainly focused on already symptomatic individuals. Nevertheless, emerging studies indicate that fostering social connection and interaction can be pivotal for success in dementia interventions [12]. Digital health platforms, easily accessible via mobile technology, can be efficient and cost-effective tools for dementia prevention. They not only offer individualized cognitive training but can also provide an engaging user experience [13,14]. The currently ongoing prevention of dementia using mobile phone applications (PRODEMOS) study creates an evidence-based dementia prevention strategy using mobile health (mHealth) accessible to at-risk individuals [15]. In contrast, Maintain Your Brain was a completely online lifestyle intervention targeting modifiable risk factors for dementia that was delivered to the participants via a web interface [16]. Wesselman et al [17] conducted a comprehensive overview of web-based multidomain lifestyle programs, combining it with a meta-analysis to evaluate their effectiveness. Through a systematic literature research, they collected a wide range of web-based programs.

Other studies have provided app-supported self-regulation for older adults based on self-determination theory, with a tablet facilitating tailored exercise programs and playing a key role in action planning and execution of behaviors [18]. The involvement of a personal coach was pivotal, adapting exercises to individual preferences and providing motivating remote monitoring to empower older adults to enhance physical activity levels at home. The experience conveyed in the study by Mehra et al [18] emphasizes the value of the personal coach, particularly during the initial phases of goal setting, behavior execution, and evaluation in self-regulation to achieve specific goals by guiding one's own behavior. Their findings indicate that the availability of a personal coach remains crucial even when technology supports the intervention. Nevertheless, concerns about adherence and safety arose in the absence of instructor guidance [18].

The success of this hybrid intervention approach could be further supported by the seamless interaction of a mobile app and a web-based CTMS for professionals. This integrated system allows professionals to interact with and monitor patients' development, enabling timely interventions when needed.

Digital Intervention Applications

mHealth apps are increasingly used by individuals to engage in health behaviors, aid in the self-management of chronic conditions, or enact preventive measures [19]. These apps hold promise in personalizing and tailoring behavior change interventions based on real-time data, thereby enhancing health outcomes [20]. Another crucial consideration is the necessity for co-designing apps in collaboration with the end users and health professionals from the relevant sector [21]. This is particularly vital for older adults as their participation in the technological design process is pivotal for their acceptance and adoption of the technology [22].

Digital interventions, whether delivered through mHealth apps or computers, are subject to evaluation in randomized controlled trials (RCTs) targeting various conditions such as psychotic disorders [23,24], mental health [25-28], eating disorders [29], diabetes [30], chronic pain [31], insomnia [32], or speech disorders [33]. These interventions often incorporate features such as audio or video content for physical activity or relaxation [23,24,26,32]; mood tracking [23,25,26]; personal tasks [23,25,31]; questionnaires [25,27,29,31]; educational materials [23-26,32]; self-tracking of, for example, vital signs in the form of a diary [24,32]; and habit libraries for behavior changes [34].

An umbrella review comprising 48 systematic reviews concentrating on mHealth apps in RCTs across various health conditions such as diabetes or hypertension indicates the potential effectiveness of app-based health interventions [35]. This further strengthens the approach of delivering a mobile-based app for study participants.

CTMSs for Intervention Projects

Equally important when intervention apps are used in clinical trials or research settings is central monitoring and management by the study coordinator or a corresponding physician. Using a CTMS and the integration of electronic data capture has become commonplace to serve this purpose [36]. Such a platform should facilitate and effectively support the multidimensional data management process in clinical trials [37] throughout their phases, from participant onboarding to completion [38].

Electronic systems allow for streamlined data transfer from clinics to the CTMS, remote enrollment capabilities, greater transparency of trial conduct, timeline monitoring such as specific tasks, tracking of participant visits, enhanced research documentation, and robust reporting [36,38,39]. A CTMS presents a variety of advantages; for example, it enables research teams to access up-to-date study information and simplifies collaboration as all project members can work efficiently together on the same task [38]. Moving beyond traditional methods of data collection in clinical trials, which may involve manual completion of paper case report forms (CRFs), leads to increased accuracy in findings, enhanced productivity as all necessary elements for managing the trial are consolidated in a single location, and higher data quality and compliance while reducing the risk of bias in clinical outcomes [36]. Important

considerations when selecting a CTMS include the feature set, usability, customization, and cost [38].

A systematic review of 19 research papers examining the technical features of clinical data management systems revealed that most of these systems were developed on a web-based platform to meet the individual needs of specific clinical trials within a short time frame [40]. Reportedly, such systems used in research centers showed limitations and inability to fully support the automation of all dimensions of the clinical data and workflow management process. In addition, the review found that most of the systems lacked flexibility and extensibility for further system development.

Health professionals such as study nurses, who are key members of the clinical research team and one of the targeted user groups for CTMSs, play a critical role in achieving accurate outcomes for clinical research studies. Furthermore, the effective implementation of a CTMS in RCT studies can have multiple benefits, including improved completion rates and increased fidelity while ensuring the safety of individual research participants [36].

The studies mentioned in this section collectively underscore the value of CTMSs in enhancing the efficiency and effectiveness of complex multisite intervention projects.

Objectives

This paper describes the iterative design process and reports on the technical implementation of the LETHE app and the LETHE CTMS within the context of a multifaceted and hybrid intervention to prevent cognitive decline in older adults. By sharing the results, we aim to contribute valuable insights to the field of dementia prevention and risk factor management through personalized ICT-supported hybrid intervention methods. We collaborated intensively with end users and health professionals to design the clinical trial platform. In addition, in this study, we evaluated how the trial participants and clinicians accepted the developed applications by using subjective usability assessments. This helped us to understand whether such digital tools keep the participants more engaged and identify directions for further improvement.

Methods

Design of a Mobile App and Clinical Trial Platform

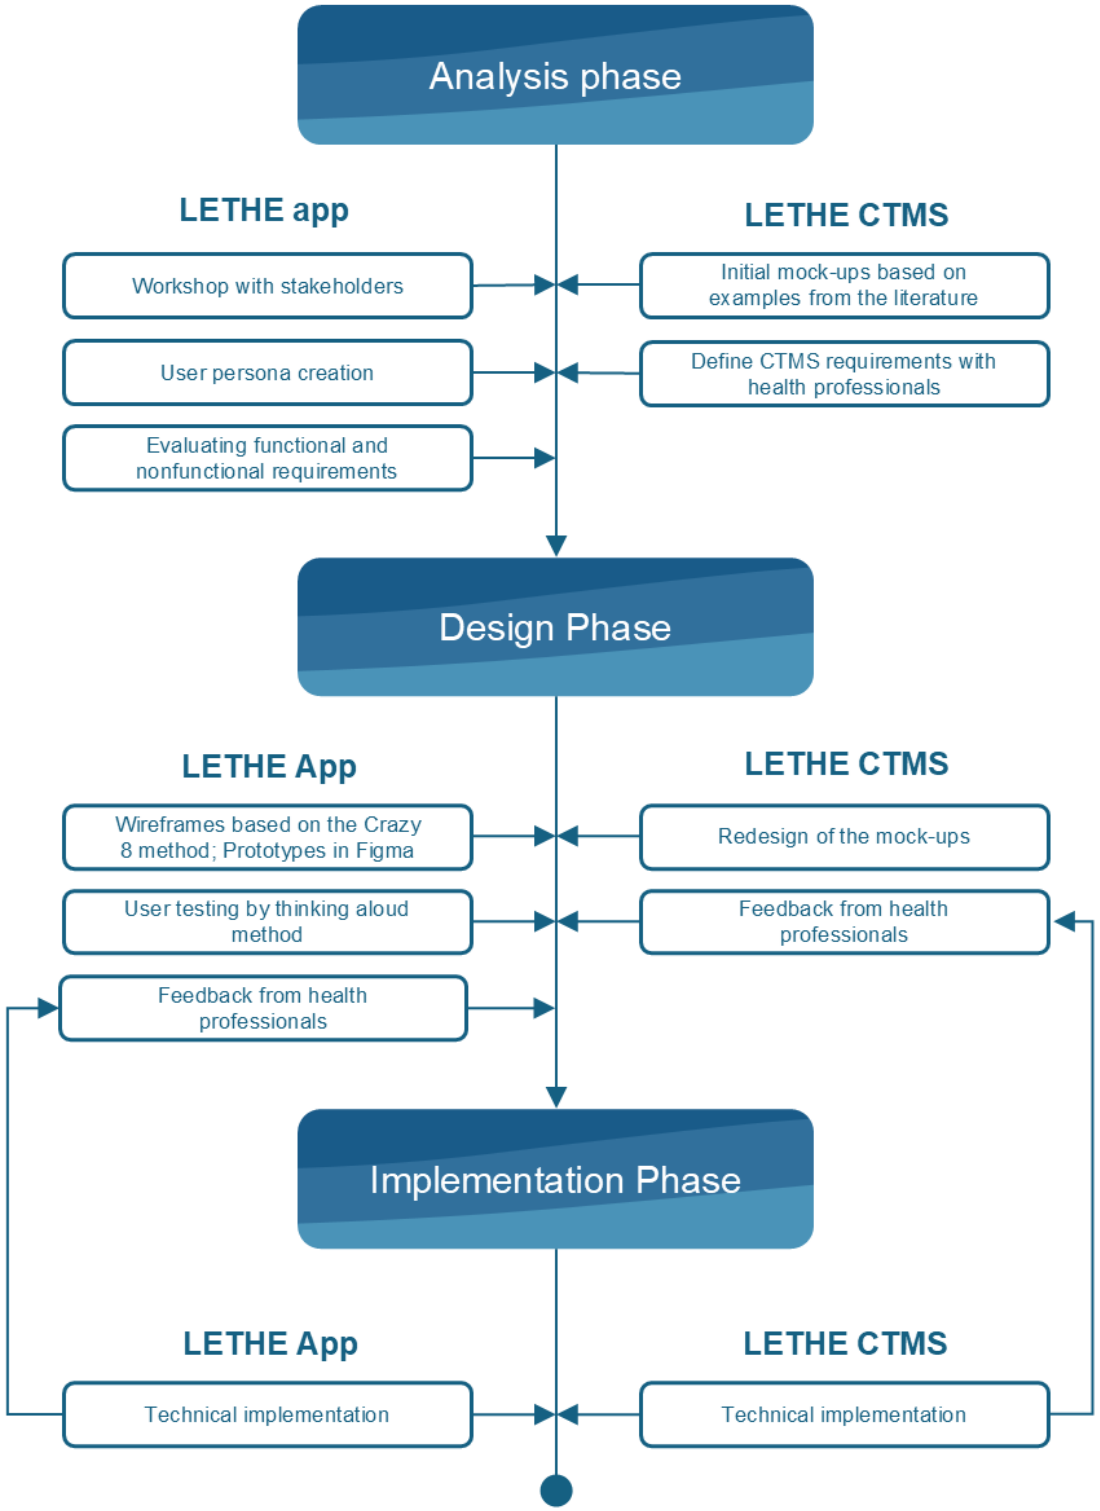
Overview

To ensure high usability, the user-centered design (UCD) approach was chosen for the LETHE app as well as for the CTMS design process. The UCD process involves the participation of end users (in our case, older individuals at risk of cognitive decline and health professionals supporting them during a preventive lifestyle intervention using the CTMS) to define key user requirements. The design approach consists of 3 main phases: analysis, design, and implementation [41].

The UCD approach encompasses 5 key principles: defining user requirements, gathering and considering feedback from users to specify requirements, involving users from the outset to evaluate design iterations, consistently adhering to UCD, and using an iterative design process [42].

Figure 1 illustrates the different design phases of the LETHE app and the LETHE CTMS.

Figure 1. Different phases for the design and development of the LETHE app and LETHE clinical trial management system (CTMS).



Requirement Analysis and Design of the LETHE App

First, a requirement workshop, which was held online, was carried out with the goal of listing requirements for the entire LETHE ecosystem and especially for the LETHE app. A total of 21 individuals from the LETHE project, including clinicians, behavioral experts, and representatives of public involvement in dementia, were invited to the workshop.

During the workshop, 3 user personas [43] were created, which represented typical end users of the LETHE app. General requirements were evaluated via open-ended questions from a clinical view. Specific requirements such as the design or the scientific use were ranked according to importance. The functional requirements of the LETHE app included, on the one hand, the content features according to the FINGER lifestyle domains; on the other hand, general digital requirements were collected from professionals during the workshop. The design

of the digital intervention was based on established behavior change theories to ensure that the app's features were effective. We focused on understanding relevant psychological factors that influence behaviors related to dementia risk [44,45] by relying on multiple behavior change theories to achieve a comprehensive understanding [46]. We used intervention mapping elements [47] and relied on a behavior change taxonomy [48] to select strategies that would best target relevant psychological factors to promote behavior change. Methods such as self-monitoring, setting clear goals, and planning for challenges were built into the app's features. Throughout the design process, a collaboration with health professionals and an advisory board of older adults at risk of or living with dementia was established. The results of this workshop were collected via online collaborating tools such as Mentimeter [49] and Padlet [50].

Afterward, wireframes based on the requirements and identified personas were created. During the user experience design, the method "The crazy 8" for wireframing was used to create as many screens as possible [51]. This method is a fast-sketching method to engage designers in sketching 8 distinct ideas in 8 minutes. In the next step, the wireframes were built using Figma (Figma, Inc) [52] as clickable prototypes to obtain continuous feedback from the involved health professionals.

In addition, a first user test with 4 German-speaking citizens aged between 65 and 85 years was carried out at the Department of Neurology at the Medical University of Vienna, and results were integrated during the implementation phase. One participant had a diagnosis of dementia, whereas the other 3 had no diagnosis. The user tests were conducted using the wireframes as clickable prototypes. First, participants explored the prototype using the thinking-aloud method [53]. Afterward, they were asked to perform 2 specific tasks (ie, choosing among a prepopulated list of pieces of advice for lifestyle improvement and setting them as goals for personal change and entering self-measured blood pressure values). Finally, participants provided verbal feedback and shared ideas and recommendations to further improve the prototypes.

When an implementation-ready design was obtained after the workshop and the user test, the implementation phase (including translation tasks) involved continuous feedback from professionals. Textbox 1 summarizes the phases for creating the design of the LETHE app.

Textbox 1. Phases for creating the design of the LETHE app, with steps 4 and 5 being recurring.

- Workshop for creation of user personas and functional and nonfunctional requirements (step 1)
- Creation of wireframes and clickable prototypes based on the workshop (step 2)
- User testing with potential end users (step 3)
- Adaption of wireframes and implementation phase (step 4)
- Continuous improvement, modification, and development after feedback from professionals and suggestions by study participants and advisory board members (step 5)

Requirement Analysis and Design of the LETHE CTMS

In the initial phase of our UCD methodology, an interactive workshop dedicated to the analysis of user requirements for the LETHE CTMS was conducted. The workshop was held online via Microsoft Teams (Microsoft Corp) with 13 health professionals as participants from different study centers located in Finland, Italy, Sweden, and Austria, as well as technical partners involved in the LETHE project. The professionals of the study centers included neurologists, gerontologists, public health experts, and professionals in the field of quality of life and dementia who represented the end users of the CTMS. The aim was to collaboratively identify the essential features and functionalities required for the LETHE CTMS. The workshop used the Mural tool [54], facilitating the creation of digital whiteboards using sticky notes for brainstorming in smaller breakout rooms consisting of 3 to 4 persons. In those breakout rooms, initial design considerations were discussed. Those considerations included general thoughts on a CTMS, an overview of the participants, data entering, and an artificial intelligence (AI) risk simulation. The process behind the design of the CTMS is described in Textbox 2 [55-57].

The results of the workshop influenced the subsequent design phase, during which multiple design proposals were iteratively developed incorporating feedback from clinical professionals. Once the design phase concluded, we transitioned into the implementation phase.

Textbox 2. Process to design the LETHE clinical trial management system, with steps 3 and 4 being recurring steps.

- Creation of initial mock-ups based on examples from the literature [55-57] and the study protocol of the LETHE trial for workshops together with clinical and technical partners (step 1)
- Conduction of the workshops to gather feedback and potentially missing features (step 2)
- Redesign of the mock-ups and technical implementation (step 3)
- Feedback on the redesign (step 4)

Evaluation of the Mobile App and Clinical Trial Platform

Overview

This section provides a detailed overview of the methodology used to analyze user perspectives within the currently ongoing 2-year clinical feasibility trial, focusing on both the LETHE app and the LETHE CTMS (or LETHE dashboard). The aim was to gather insights on basic usability assessments, encompassing considerations such as satisfaction with the applications.

The analysis was conducted using R (version 4.3.2; R Foundation for Statistical Computing) [58]. The normality test for the data was carried out using the Shapiro-Wilk test (α=.05). To assess the difference in the System Usability Scale (SUS) scores [59] between the study groups, the Mann-Whitney *U* test was used. For pairwise comparisons of the various countries, the Kruskal-Wallis test followed by the Dunn post hoc test with Bonferroni correction was used.

Evaluation of the LETHE App

Older adults who participated in the LETHE RCT provided feedback within the LETHE app through a structured questionnaire, "Experiences with LETHE app," consisting of 10 closed-ended questions based on an adapted version of the SUS, which was simplified for older adults and adults with cognitive impairment [60]. Using a Likert Scale [61] with 5 points ranging from "Strongly Disagree" to "Strongly Agree," participants expressed subjective feelings about the frequency of LETHE app use, perceptions of app complexity, and their need for assistance or confidence in navigating the mobile app. The questionnaire can be found in Multimedia Appendix 1.

This survey will be administered at 3 distinct time points throughout the study: 1 month, 6 months, and 24 months after randomization. Participants have 4 weeks to complete the survey at each time point. This timeline allows for the observation of participant sentiments over an extended duration, offering insights into the subjective aspects of use patterns and the perceived complexity of a mobile app specifically designed for older individuals. As the trial is still ongoing, this study focused on data from the first time point. As a result, we share participants' initial user experiences at this stage.

The LETHE app exists in 2 versions: one for the intervention group and one for the control group. Due to the limited functionality of the version for the control group, which lacks more sophisticated features such as personalized or intervention activities, the analysis was conducted separately for the intervention and control groups.

Within the LETHE trial, 156 study participants were invited to complete the questionnaire, with 78 (50%) in the intervention group and 78 (50%) in the control group. The calculated SUS was assigned a grade [62] as shown in Table 1, with "C" as the average grade and 68 as the center of the range.

Table 1. Interpretation of the System Usability Scale (SUS) score based on a grading scale by Sauro and Lewis [62].

SUS range	Grade	Percentile range
84.1-100	A+	96-100
80.8-84	A	90-95
78.9-80.7	A–	85-89
77.2-78.8	B+	80-84
74.1-77.1	B	70-79
72.6-74	B–	65-69
71.1-72.5	C+	60-64
65-71	C	41-59
62.7-64.9	C–	35-40
51.7-62.6	D	15-34

Evaluation of the LETHE CTMS

To obtain a comprehensive understanding of perspectives from relevant health professionals who used the LETHE CTMS, a 41-question online survey was conducted including both open- and closed-ended questions via Microsoft Forms (Microsoft Corp). The survey was distributed 10 months after the start of the study, and users were given 3 weeks to complete it. The primary objective was to gather feedback on the functionalities of the LETHE CTMS and assess user satisfaction with its implementation. The survey aimed to provide insights essential for mitigating common bottlenecks in the future development of similar tools. Notably, the survey was self-administered and structured into different parts, starting with a brief introduction outlining its objective before participants provided information about their role in the project. Subsequently, general inquiries about the CTMS, such as the onboarding process and overall experience, were posed. Participants then provided feedback on each functionality. Finally, recommendations, challenges, and additional comments were solicited.

All users of the LETHE CTMS were invited to participate and were informed about the survey duration.

The mixing of open- and closed-ended questions served a dual purpose. Closed-ended questions, including Likert scaling and ranking formats, enabled the quantification of participant sentiments, whereas parallel open-ended inquiries facilitated the collection of qualitative feedback. Noteworthy is the

inclusion of a single ranking question designed to identify the beyond-state-of-the-art features of the LETHE CTMS.

Moreover, a 5-point Likert scale [61] was used for closed-ended questions, encompassing the following response options: “Strongly Agree,” “Agree,” “Neither Agree nor Disagree,” “Disagree,” and “Strongly Disagree.”

The structure of the survey can be found in Multimedia Appendix 2.

Ethical Considerations

The trial has been approved by ethical committees in Austria (Ethics Committee of the Medical University of Vienna; 1392/2022), Finland (Hospital District of Helsinki and Uusimaa Ethical Committee; HUS/13675/2022), Italy (Regional Ethics Committee Umbria; 25723/22/AV), and Sweden (Swedish Ethical Review Authority; 2022-03961-01). All participants provided written informed consent before enrollment. The data used in this study for analysis were anonymized. Study participants received a wearable device, and a phone if they chose to have one. Some of those in the intervention group were additionally provided with a tablet for use during the trial.

Results

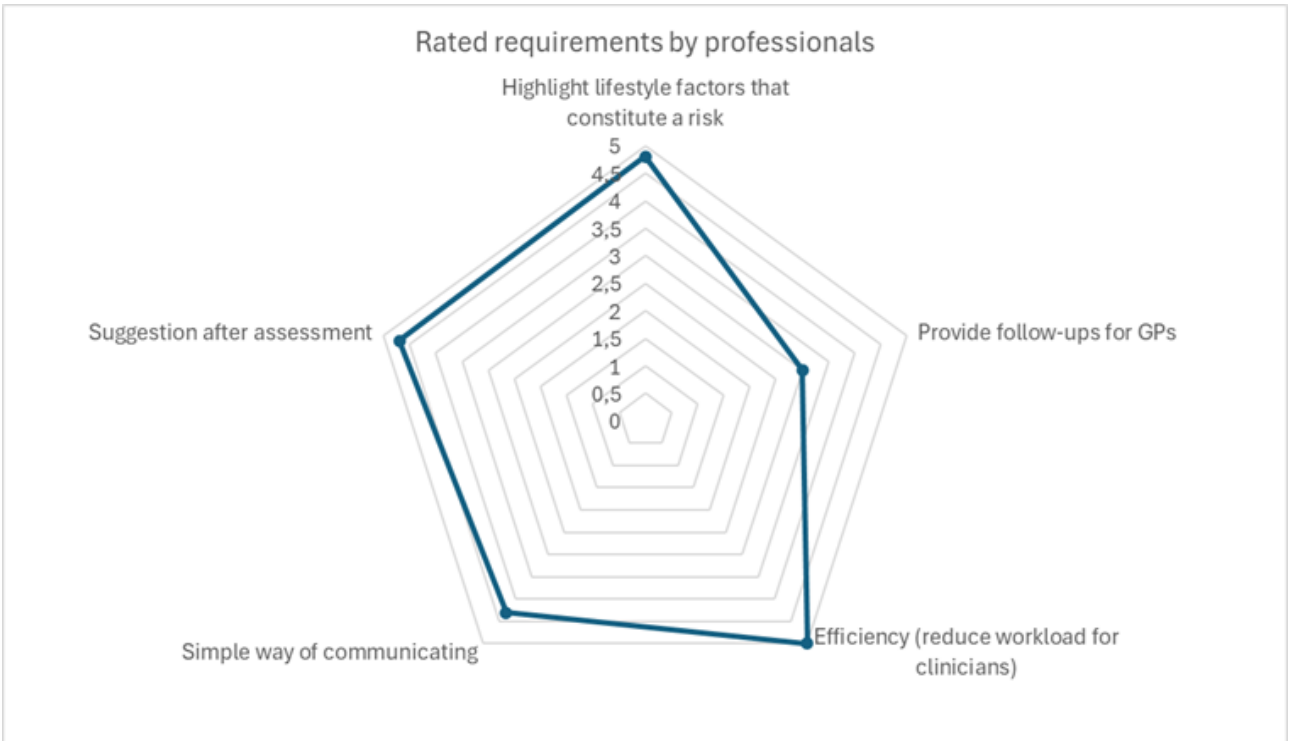
Design, Functionalities, and Evaluation of the LETHE App

Results of the Requirement Workshop and End-User Testing

The workshop together with the clinical and technical partners identified several requirements regarding the LETHE app, including the highlighting of lifestyle factors that constitute a risk or where the participant could improve. Additional observations include the LETHE app’s provision of guidelines to identify and flag study participants who are not using it. The communication between the specialists and the study participants should be simple. There was also an emphasis on data transfer and data sharing, highlighting that study participants can independently input data without professional assistance, such as for questionnaires.

The identified requirements were categorized and ranked via a survey. The main outcomes for the LETHE app are summarized in Figure 2. The highest-ranked requirements were to reduce the workload for professionals and highlight the lifestyle factors that constitute a risk. The least important requirement was to provide follow-ups for general practitioners. Those main findings were considered when designing the prototype.

Figure 2. Categorized and ranked requirements for the LETHE app. GP: general practitioner.



While conducting the user evaluation with the 4 participants at the Department of Neurology at the Medical University of Vienna, several key findings were obtained. The size of the user interface elements was criticized as being too small, and the tiles were not understood as large buttons. A section about the summary of the previous week as well as the share function of third-party apps (eg, for cognitive training or videos), which allows users to view content on another device via a QR code or by emailing it to themselves, was not considered intuitive to understand. The given tasks were missing additional information and were not clear without further explanation. Suggestions from the user testing included adding a notification for remembering to eat vegetables and fruits, as well as the marking of special input data values.

Functionalities of the LETHE App

Overview

The trial incorporates the LETHE app, an Android-native app using Java, to facilitate digital aspects and streamline data collection from study participants. The LETHE app has been released through the Google Play Store and is publicly available for download. However, access to the app's content is restricted to authorized study participants. Data storage and retrieval are managed through a .NET 7 (Core; .NET Foundation) application programming interface, which exposes data via GraphQL (Meta Platforms) protocols for external interaction with a PostgreSQL database (PostgreSQL Global Development Group). Figure 3 illustrates the modules of the LETHE app and the interaction with the LETHE CTMS.

The LETHE app correspondingly aligned the lifestyle domains with a specific digital feature based on the FINGER study [5] and included the additional domains of *sleep/relaxation* and *social activity*. Figure 4 illustrates a comparison between the in-person and digital components of the lifestyle intervention trial.

Figure 3. Overview of the modules, functionalities, and interactions between the LETHE app and the LETHE clinical trial management system (CTMS).

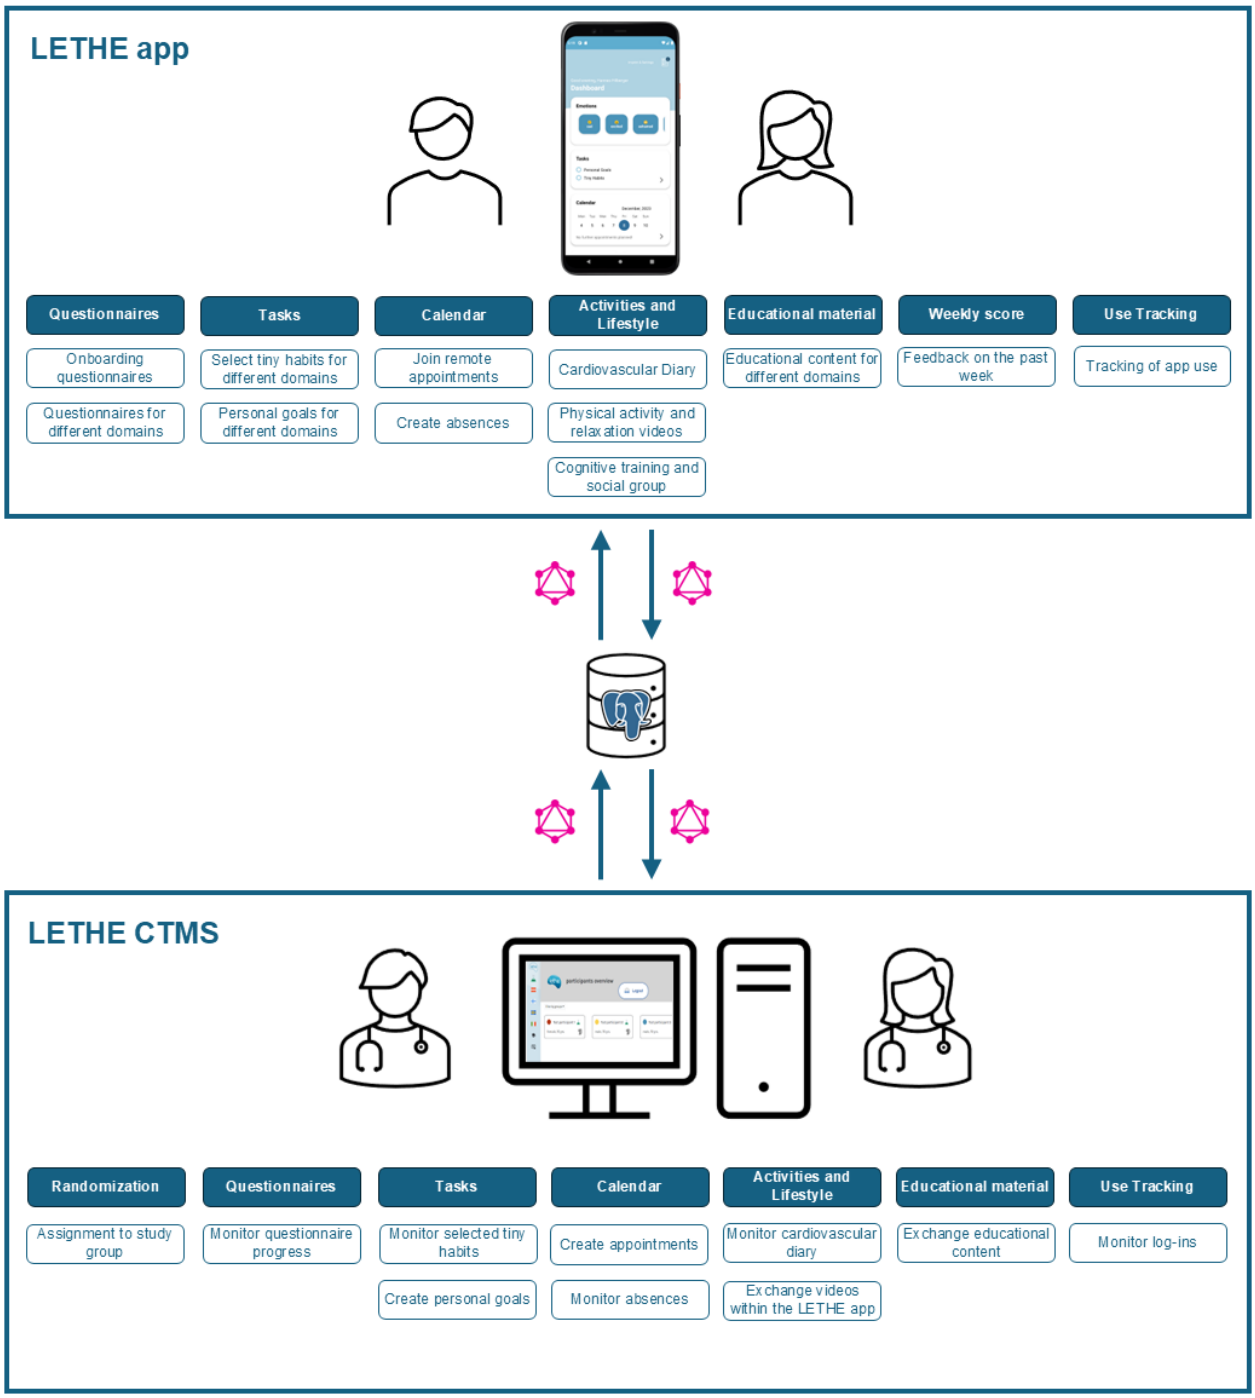


Figure 4. Comparison between in-person and digital components for each lifestyle domain.

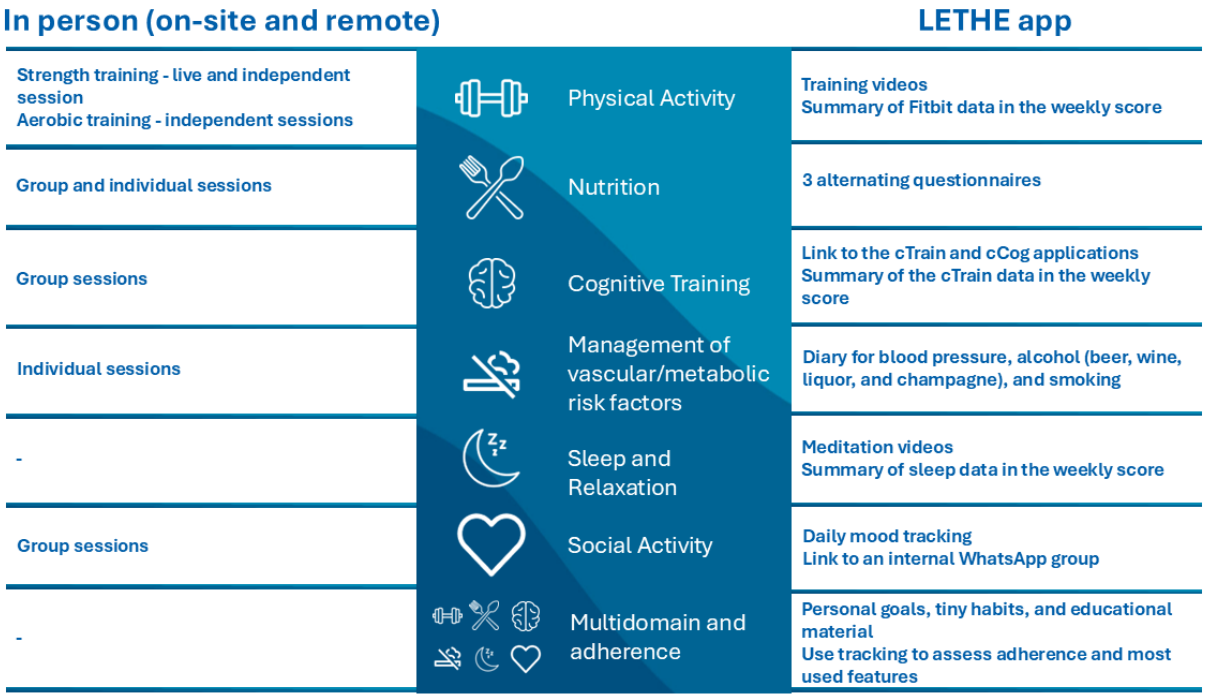

After completing the baseline study visit and initial questionnaires through the LETHE app, participants are randomly assigned to either the intervention or control group through the LETHE CTMS. Subsequently, the LETHE app dynamically adjusts the content based on group assignment. Both groups have access to the calendar, settings, questionnaires, mood tracking, and educational content. However, the intervention group has additional functionalities, such as personalized activities and the LETHE lifestyle program.

The LETHE app supports 5 languages (English, Finnish, Italian, Swedish, and German), with translations provided by the study centers. To enhance flexibility for features such as tiny habits and questionnaires, most of the translated content is dynamically retrieved, facilitating faster translation adjustments and content extensions. The translation process involved preparing an initial draft in English, which was then translated by native speakers at the clinical centers. The translations were reviewed to ensure accuracy for each region.

Designed with an older population in mind, the LETHE app uses a tile-based approach with large tiles as entry points for each functionality. This design allows individual elements to be hidden, shown, or reused, creating a modular structure. Following this approach, each component could be packaged independently, facilitating potential reuse in other research projects with similar requirements. Screenshots of each functionality of the LETHE app can be found in Multimedia Appendix 3.

Questionnaires

The questionnaires may be completed at single or multiple time points, with variations based on study group or participant gender. Each questionnaire consists of a title, due date, progress bar, and background color divided into green, yellow, and red, indicating the time remaining to complete the questionnaire. Participants can answer questions across multiple sessions, with answers cached on the device and sent only upon completion. The technical structure adheres to the Fast Healthcare Interoperability Resources (FHIR) standard [63], ensuring interoperability with other systems and enabling the questionnaire module's reuse by incorporating different FHIR questionnaires while maintaining the same structure.

LETHE App Dashboard

Once assigned to either the intervention or control group, participants unlock access to the LETHE app dashboard, which consists of different tiles to access various functionalities. Participants can choose here how they feel daily. Each possible mood item is accompanied by a short description and an emoticon for visualization. The list of the available mood items is dynamically adaptable and could expand in future development based on participant feedback.

Tasks

The *Tasks* section encompasses the personalized intervention module, comprising 2 distinct areas: personal goals and tiny habits. Personal goals are collaboratively established with clinical professionals during visits, targeting specific lifestyle domains for personalized interventions. Personal goals follow the specific, measurable, achievable, realistic, and time-bound principle [64]. Unlike tiny habits, personal goals are not predefined, but they can be packaged as a future library of personalized objectives. These goals can be set daily, weekly, or monthly, offering frequency flexibility, including options such as bidaily or biweekly. Study participants can mark goals as completed or incomplete. Each personal goal is bound to a lifestyle domain, providing participants with an indication of their personal domains for lifestyle improvement.

Tiny habits provide practical everyday tips and behavioral suggestions to help individuals implement manageable healthy

habits [65,66] and is adapted from the StopDia library [34], which is available in Finnish under a CC BY 4.0 license [67]. Tiny habits can be individually set by participants and are available for all lifestyle domains. Each tiny habit includes a description of the activity, a health fact about its benefits, and a place where it should be performed. There are >500 tiny habits in total to choose from, and they are assigned to a lifestyle domain. Given the subjective nature of tiny habit completion, participants are asked weekly about their success based on perceived completion in a questionnaire.

Calendar

The calendar displays all study-related appointments, both remote and in person, with a monthly and daily view. Remote visits can be joined directly from the daily view, which features larger tiles for individual appointments tailored to the target group. Participants can add vacation or unavailability periods, marking them as absences in the calendar. The absence menu is distinct in contrast to all other functionalities, providing a holiday like feel for participants.

Activity and Lifestyle

This section encapsulates the comprehensive LETHE app lifestyle program, featuring various activities tailored to distinct lifestyle domains. In the "Diary" section, study participants can log different health metrics such as blood pressure, alcohol consumption, and daily cigarette intake, directly contributing to the "Management of vascular/metabolic risk factors" lifestyle domain.

A range of activities aligned with different lifestyle areas unfold in the horizontal list at the top of the screen. It starts with a variety of videos dedicated to the areas of "Physical Activity" and "Relaxation." For the "Cognitive Training" domain, there is a link to an external application called cTrain, a cognitive training game package encompassing games similar to those used in the original FINGER study [5,68].

For the "Social Activity" domain, participants from the intervention group can engage with a country-specific and internal WhatsApp group facilitated by clinical staff, ensuring exclusivity for trial participants. The last tile in the list serves as an educational hub, presenting web resources including web feeds provided by professionals via the LETHE CTMS for each lifestyle domain.

Weekly Scores

The weekly score with motivational feedback messages offers participants feedback on the previous week. The feedback message adjusts if the score increased or decreased. The score displays 3 rings representing "App Data/Lifestyle," "Fitness," and "Brain Training." The "App Data/Lifestyle" category includes how often the LETHE app is used. The "Fitness" section displays Fitbit data, including step count, sleep duration, and individual fitness sessions, whereas "Brain Training" presents an overview of cognitive training data.

Use Tracking

To obtain insight into participants' adherence and identify features of particular interest to older individuals in a lifestyle intervention app, a mechanism for use tracking was developed. Each time a participant opens the LETHE app, a unique ID is assigned for the session. Every screen is assigned to an event, and each event is saved with new time stamps when navigating through screens until the participant closes the app. This monitoring technique aims to understand useful features and incorporate measures for adherence analysis [69].

Evaluation of the LETHE App

Overview

Overall, of the 156 participants, 123 (78.8%) provided responses. The distribution of SUS scores in both the intervention group (P=.03) and the control group (P=.02) deviated significantly from normality. However, there was no significant difference in SUS scores between the groups (P=.18).

Intervention Group

A total of 78 participants from the intervention group were invited for the SUS, and 66 (85%) responses were received. Of these 66 participants, 12 (18%) did not answer all the questions. The analysis revealed that the highest satisfaction levels were associated with learning how to use the app, whereas the lowest satisfaction levels were linked to the integration of various components, as shown in Figure 5 and Multimedia Appendix 4. The integration of the various components also received the most neutral responses among the questions. The question regarding the need for assistance when using the app generated the most disagreement, whereas learning about the app before use had the smallest response rate of 85% (56/66) for all questions.

Multimedia Appendix 4 provides an additional analysis for all 4 countries. Finland achieved the highest response rate (19/20, 95% of participant responses), and Sweden achieved the lowest response rate (12/18, 67%).

As 18% (12/66) of the participants did not provide complete answers, missing values were replaced with the neutral value of 3 following the approach outlined by Lewis [70] to calculate the SUS. Figure 6 highlights the presence of 1 outlier with a total score of 0, which was not excluded.

The median SUS score was 70 (IQR 55-82), which is above the average score and qualifies the app for a grade C, as shown in Table 2.

Figure 5. System Usability Scale (SUS) responses for the LETHE app in the intervention group. Panel (A) shows positively formulated questions, whereas panel (B) highlights negatively formulated questions. Green indicates high user satisfaction, and red indicates low user satisfaction. Q: question.

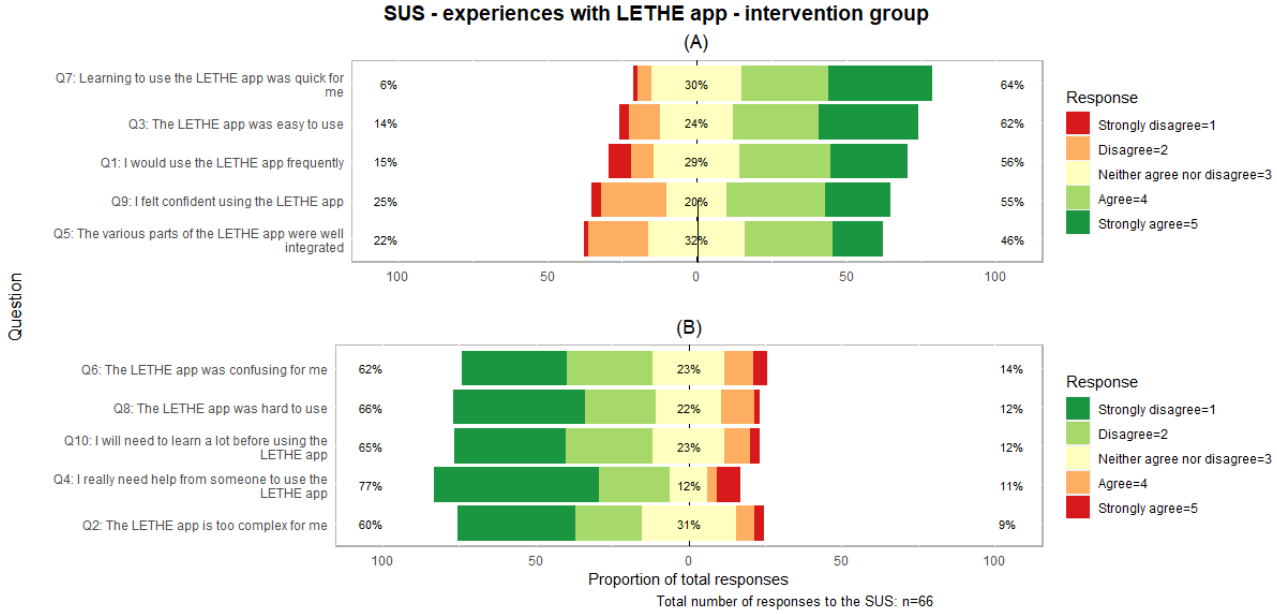

Figure 6. Box plot of the System Usability Scale (SUS) scores for each country in the intervention group.

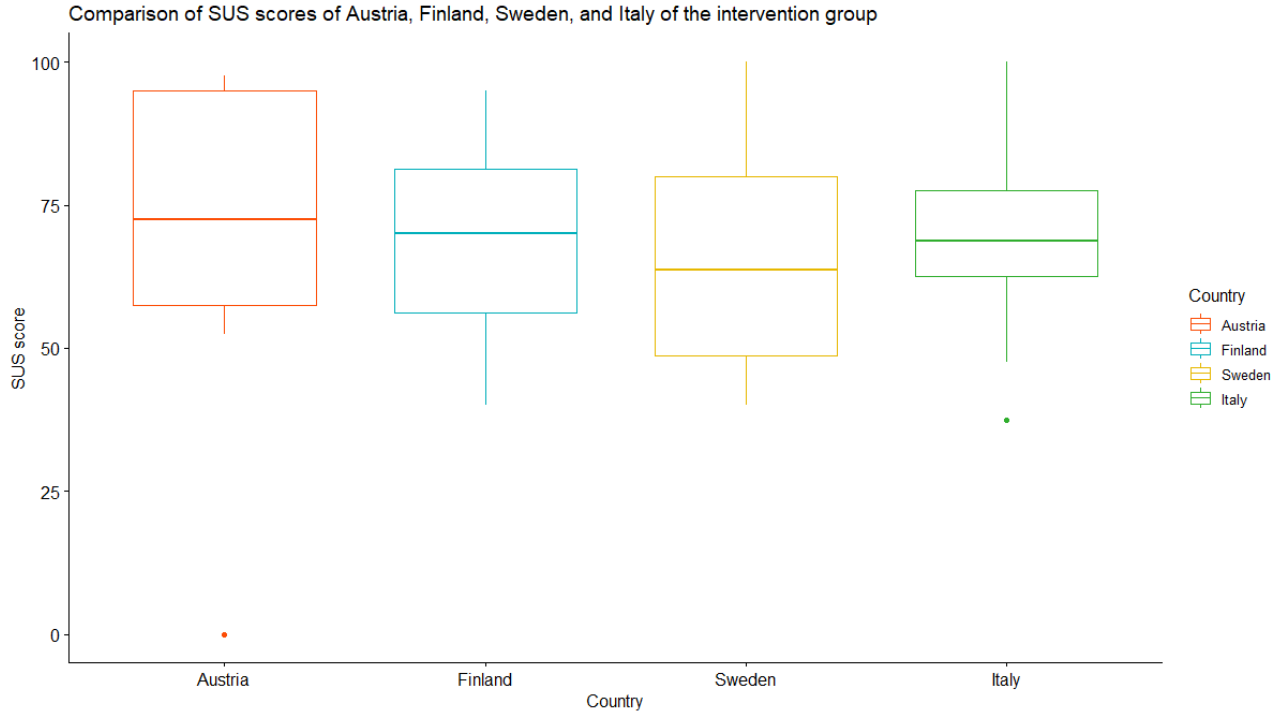

Table 2. Scores on the System Usability Scale (SUS) and its subscales for study participants in the intervention group.

	Measure[a]	Values, median (IQR)	Grade
Total (n=66)	SUS	70 (55-82)	C
Austria (n=17)	SUS	73 (58-95)	C+
Finland (n=19)	SUS	70 (57-82)	C
Sweden (n=12)	SUS	64 (49-80)	C–
Italy (n=18)	SUS	69 (63-78)	C

[a]The SUS ranges from 0 to 100, with 100 as the highest score.

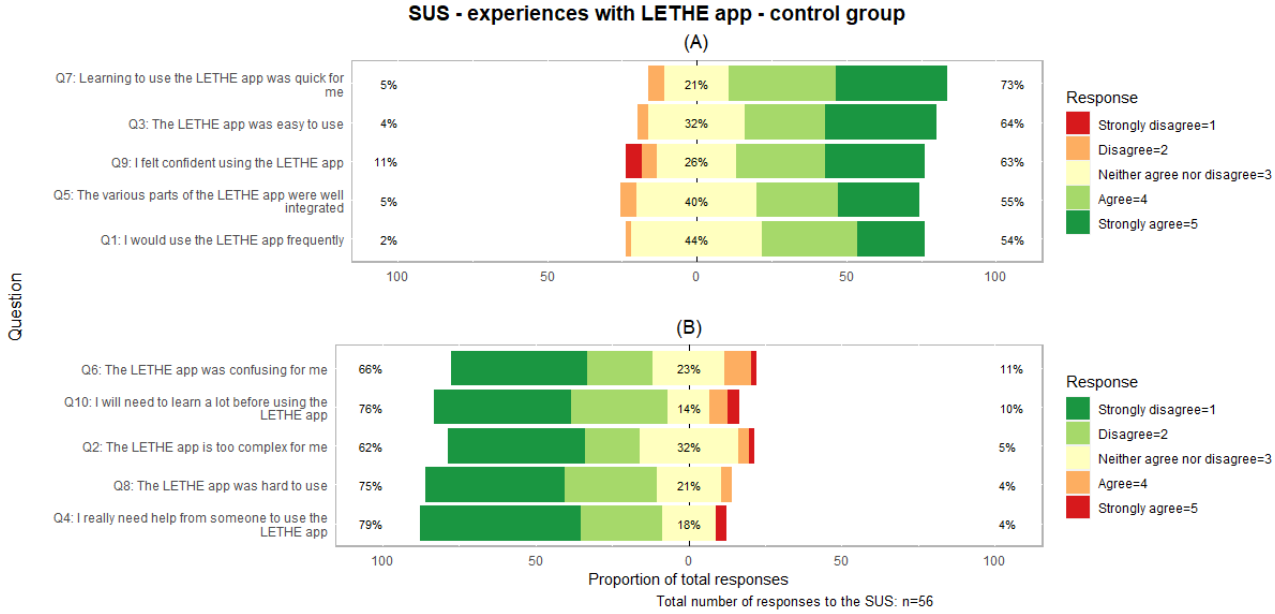
Austria achieved the highest median SUS score at 73 (IQR 58-95), whereas Sweden recorded the lowest median score at 64 (IQR 49-80). Austria was the only country where the app received a C+ score, distinguishing it from the others. Austria had 1 participant who was classified as an outlier with a total score of 0 but was still included in the analysis.

The distribution of SUS scores in Austria departed significantly from normality (P=.01). The distribution of SUS scores in Finland (P=.66), Sweden (P=.19), and Italy (P=.94) did not show evidence of nonnormality. The median SUS score did not differ significantly between the countries in the intervention group (P=.74).

Control Group

For the limited version of the LETHE app, 73% (57/78) of the study control group participants responded. Notably, 18% (10/57) of the respondents did not answer all questions. Figure 7 and Multimedia Appendix 5 indicate that the highest satisfaction was achieved in terms of how quickly participants could learn to use the LETHE app, followed by its ease of use. The only instance of a "Strongly disagree" response was regarding the confidence in using the LETHE app. The question about the LETHE app's frequent use gathered the most neutral responses, possibly due to its limited functionalities compared to the intervention version. A total of 79% (44/56) of the participants disagreed with the idea of needing help from others while using the LETHE app. Similarly to the intervention group, the question about learning about the LETHE app before using it received the smallest response rate of 98% (56/57) of all questions.

Figure 7. System Usability Scale (SUS) responses for the LETHE app in the control group. Panel (A) shows positively formulated questions, whereas panel (B) highlights negatively formulated questions. Green indicates high user satisfaction, and red indicates low user satisfaction. Q: question.



In the control group, Italy exhibited the lowest response rate, with 60% (12/20) of the participants responding, whereas Austria had the highest response rate, with 85% (17/20) of the participants responding. A detailed breakdown of responses per country is available in Multimedia Appendix 5.

To calculate the SUS, all missing values were substituted with the neutral value of 3, mirroring the approach taken with the intervention group. Table 3 illustrates that the median SUS score was 73 (IQR 63-90), corresponding to a B– grade.

Table 3. Scores on the System Usability Scale (SUS) and its subscales for study participants in the control group.

	Measure[a]	Values, median (IQR)	Grade
Total (n=57)	SUS	73 (63-90)	B–
Austria (n=17)	SUS	90 (73-95)	A+
Finland (n=16)	SUS	69 (65-76)	C
Sweden (n=12)	SUS	64 (50-84)	C–
Italy (n=12)	SUS	78 (54-90)	B+

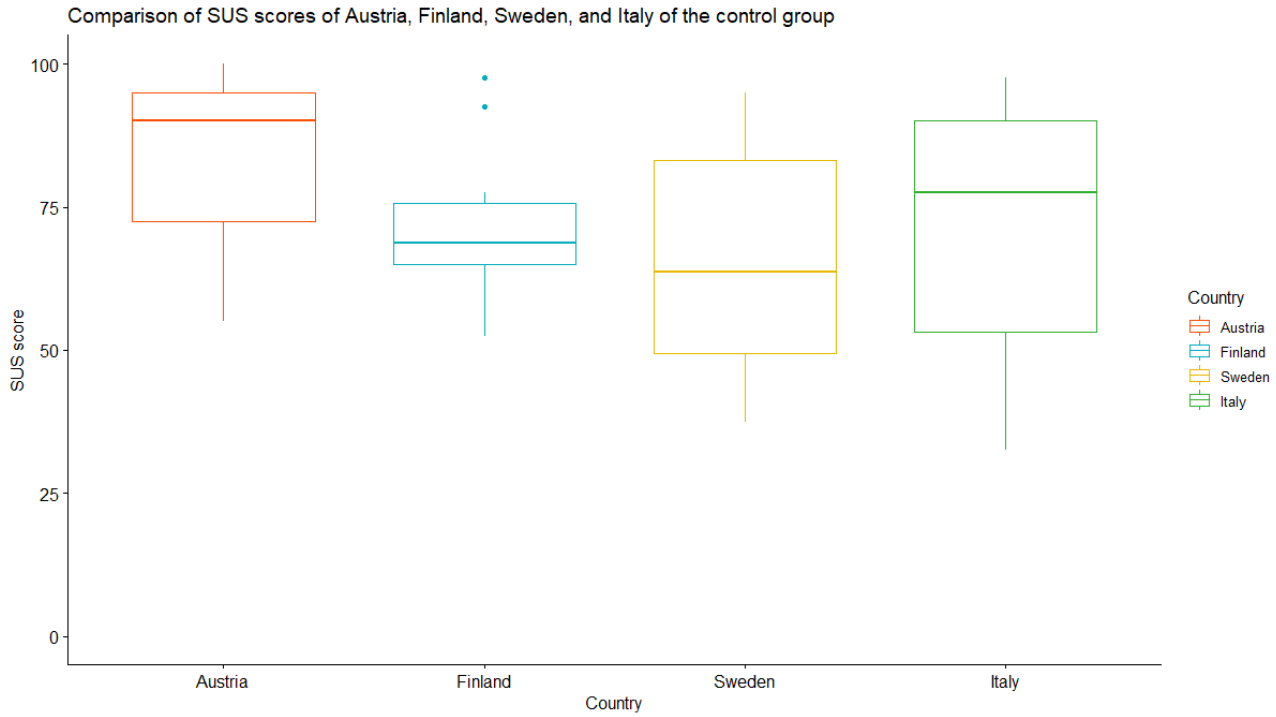
[a]The SUS ranges from 0 to 100, with 100 as the highest score.

Austria had the highest median SUS score at 90 (IQR 73-95), giving the app an A+ grade, whereas Sweden had the lowest median score at 64 (IQR 50-84), giving the app a C– grade. The app obtained a C grade in Finland and a B+ grade in Italy, with median scores of 69 (IQR 65-76) and 78 (IQR 54-90), respectively. Notably, in contrast to the intervention group, the

median SUS score was higher in Austria and Italy and lower in Finland, and it stayed the same in Sweden. Figure 8 visualizes the box plot for each country.

The SUS scores of Austria (P=.03) and Finland (P=.047) departed significantly for normality. The distribution of the SUS scores of Sweden (P=.41) and Italy (P=.11) did not show evidence of nonnormality. The SUS scores did differ between the countries in the control group (P=.03). Pairwise comparisons showed that the median SUS score of Austria was significantly different than the median SUS score of Sweden (P=.02). For the other pairwise comparisons, no significant difference was found. Specifically, the comparisons between Austria and Finland (P=.33), Austria and Italy (P=.36), Finland and Sweden (P=.99), Finland and Italy (P=.99), and Sweden and Italy (P=.99) all yielded P values greater than the threshold for statistical significance.

Figure 8. Box plot of the System Usability Scale (SUS) scores for each country in the control group.



Design, Functionalities, and Evaluation of the LETHE CTMS

Feedback From the Workshop

After an examination of the LETHE study protocol and the examples from the literature [55-57] for a design perspective, initial mock-ups for the LETHE CTMS, a web application, were created. The mock-ups were kept very general and built the foundation for the discussions in the workshop with health professionals. These mock-ups encompassed (1) an overview page featuring details on all study participants, (2) a dedicated view for an individual study participant, (3) the conceptualization of an AI simulation, and (4) a data entry page aligned with the study protocol.

The feedback on the mock-ups included the exclusion of real names given that all study participants would be collectively visible on one page in the mock-up. Emphasis was placed on the immediate visibility of adherence using colors (eg, green, yellow, and red) and dropouts. In addition, diverse roles were implemented to restrict access to sensitive information, such as ensuring that health professionals could only view data related to their own country as well as a blinded role to not see the group of the study participants. Workshop participants also expressed the desire for a descriptive overview of the dataset variables.

Subsequently, the discussion turned to the overview page, where all study participants are listed. Key considerations included the inclusion of adherence information and the need for clear differentiation between participants from the intervention and control groups. Given the sizable participant list of 156 individuals, there was a request for sorting and search functionalities.

During discussions regarding the page presenting information for an individual study participant, workshop participants advocated for distinct perspectives tailored to individuals in the intervention and control groups, emphasizing adherence and dropout summaries. Further dialogues included role-specific views, aiming for the visibility of only relevant data. The workshop participants also expressed a preference for a comprehensive presentation of lifestyle categories, including detailed information and distinct sections for different clinical professionals as well as additional risk factors such as the consumption of alcohol or cigarettes. Requests for additional functionalities included the presentation of the Clinical Dementia Rating [71], allergies, questionnaire responses and scores, notes on participant interactions, details of adverse events such as muscle pain after a prescribed aerobic workout, and automated calculations such as BMI. Another necessity identified was the inclusion of a data export functionality.

When considering the AI dementia risk simulation, there was a discussion about whether it could be used during the study intervention or solely for research purposes. The AI risk simulation is currently available only to researchers due to ethical considerations. As the models used in the simulation have not yet been fully tested or validated, they were not implemented with real participants at this stage. Moreover, the risk information generated by the simulation is not disclosed to participants. Should the disclosure of this risk information be considered in the future, it would require careful evaluation. This process would involve consulting with both the participants and experts in ethics to assess the potential psychological impacts and the broader ethical implications of sharing risk-related information with participants.

The workshop discussed the insertion of all CRF data into the LETHE CTMS, encompassing visit-related data and scores such as the Clinical Dementia Rating and Neuropsychological Test Battery as in the FINGER study. Workshop participants underscored the inclusion of medications, validation checks, and prefillable fields. The study protocol served as a reference for defining the data entry page fields.

Following the conclusion of the workshop, participants were given a clickable prototype. Subsequently, a follow-up workshop was conducted to incorporate adaptations based on the initial workshop insights. The most significant modification was made to the data entry page, necessitating a complete restructuring due to a higher-than-anticipated number of data fields. After several iterations, a design for the beginning of the study was proposed.

Functionalities of the LETHE CTMS

Overview

Following the completion of the LETHE CTMS design, pivotal components were identified to commence the clinical trial. This included an overview of all study participants, a detailed view of a study participant, and the data input portal for clinical professionals. The LETHE CTMS was developed as a web application using React and uses the same backend infrastructure as the LETHE app. The LETHE CTMS is deployed as a Docker container (Docker, Inc). Once a new version is pushed to the main branch of the GitLab repository, a Continuous Integration/Continuous Delivery or Deployment (CI/CD) pipeline is automatically triggered, handling the build, release, and deployment process. After the container is pushed to the GitLab container registry, deployment is carried out using an Ansible playbook (Ansible Inc).

The LETHE CTMS has a consistent design throughout the application, achieved by using a fundamental page structure featuring headers, card-based content representation, a uniform color scheme inspired by the LETHE project colors, and font selection. Ensuring that the data are relevant only to the relevant users was achieved through ongoing communication with end users, and various roles were defined. There are roles that have access to all participants from all study centers; roles that are blinded and, therefore, can only enter visit forms; and roles that are not blinded and can have access to all participant details from their study center.

The LETHE CTMS underwent iterative modifications over time driven by continuous user feedback and evolving requirements. In particular, each section has been given a standardized nomenclature. At the moment, the following sections are included: overview page, detail page, clinician data entry page (containing the electronic CRF [eCRF]), and the configuration pages to adapt the content in the LETHE app. For now, the AI risk simulation is only available for research purposes and not visible to the end users, so a further description is not provided. Screenshots of the different pages can be found in Multimedia Appendix 6.

Overview Page

The overview page serves as a visual representation of all study participants within the selected country. Upon initializing this page, the study participants are loaded based on the study site affiliation of the clinical professional. The header features a legend outlining variables encompassing distinct adherence pathways and the respective participant groups. Color-coded adherence pathways range from “low” (red) to “medium” (yellow) to “high” (green) and include a category of “not calculated.” These pathways are grouped into distinct types, with more details provided on the detail page.

The central section of the page displays all participants from the current site within individual rounded boxes, which encompasses variables such as the participant’s ID, and other essential participant information, including adherence, group affiliation, age, and gender, is also presented.

There is also the possibility to access the configuration pages, allowing for the modification of content related to educational material and videos on the LETHE app.

Detail Page

Upon selecting an individual on the overview page, a more detailed view is presented, encompassing comprehensive data on that particular participant.

The detailed view interface is organized into 3 columns, each with functional components. In the first column, baseline visit data are featured, encompassing demographics, cardiovascular metrics, comorbidities, medications, allergies, and blood values. Users can review completed and pending questionnaires as well as access the responses and corresponding scores. This column concludes with a messaging feature that allows professionals to schedule notifications directly sent to study participants’ smartphones.

The second column commences with notes about adverse events, the entering and tracking of personal goals, and the monitoring of the selected tiny habits and cardiovascular risk factor data entered into the LETHE app. Professionals can also view participant absences to adjust appointment scheduling and reschedule personal goals accordingly.

In the last column, professionals can schedule recurring remote or in-person meetings with study participants together with reminders. Each meeting can be marked as completed to help track the adherence. Participant-professional contacts are recorded, and additional information is displayed, including last

LETHE app log-in, participant consent status, and participation in substudies.

At the bottom of the page, adherence to various categories, such as app use, cognitive activity, diet, and physical activity, is visually displayed, providing an overview of the participant's engagement with key aspects of the study protocol. Table 4 shows the thresholds used to assign each pathway to one of the adherence levels. On the basis of adherence and lifestyle domain, participants receive tailored messages on specific weekdays: physical activity on Mondays, app use on Tuesdays, diet on Wednesdays, cognitive activity on Thursdays, cardiovascular risk factors and social interaction on Fridays, and relaxation and sleep on Saturdays. Participants consistently in the red pathway receive domain-specific or holistic messages. In addition, tiny habit messages are sent on Mondays, Wednesdays, and Thursdays based on reported engagement.

Table 4. Adherence pathways and thresholds for different categories.

	Data type	Instrument used to measure the data and frequency of measurement	Green threshold	Yellow threshold	Red threshold
Physical activity	Activity min and frequency (moderate to vigorous intensity)	Fitbit; weekly (Mondays); passive	Months 1-3: 30-45 min (1 time per wk); months 4-6: 30-45 min (2-3 times per wk); months 7-9: 30-60 min (3-4 times per wk); months 10-24: 45-60 min (3-5 times per wk)	Months 1-3: 15-29 min (1 time per wk); months 4-6: 15-29 min (1 time per wk); months 7-9: 15-29 min (1-2 times per wk); months 10-24: 15-44 min (1-2 times per wk)	1 wk with 0 min or 3 weeks in a row in the yellow path
App use	Changes between the screens within the LETHE app	App; weekly (Tuesdays); passive	≥3 screens (4-7 d)	≥3 screens (0-3 d)	0 screens for 14 d
Diet patterns	Completing food-monitoring item questionnaire within the LETHE app (3 alternating questionnaires)	App; weekly (Wednesdays); active	2/3 or 3/3 blocks completed (in 3 wks)	1/3 blocks completed (in 3 wks)	0% completed (in 3 wks)
Cognitive training	Use of cognitive training program	cTrain; weekly (Thursdays); active	2-3 times per wk	0-1 times per wk	0 times for 3 wk

Data Entry Page

Diverging from the workshop, a series of design iterations led to the decision that the data entry page would act as a repository for information gathered from all study visits, whereas tasks such as contacting study participants and scheduling appointments were moved to the detailed view of an individual participant.

Within the eCRF, each primary section, covering screening, baseline, and subsequent visits, contains subforms that address different documentation areas (eg, forms to report results for blood tests, medication use, and neurological assessments such as the Mini-Mental State Examination [72]).

Each subform within the eCRF incorporates features such as automatic calculations and validation checks, whereby abnormal values trigger a visual highlighted in yellow. This ensures data accuracy and enhances the efficiency of data entry. The eCRF design, embedded with these functionalities, serves as a comprehensive and streamlined platform for recording and managing diverse aspects of study visit documentation.

Evaluation of the LETHE CTMS

Overview

This section analyzes the feedback from the CTMS survey completed by health professionals. First, user-specific details, such as their role in the project and within the application are presented. Second, the quantitative and qualitative feedback for each of the functionalities and the design is analyzed. Finally, a ranking of the state-of-the-art features is presented. The survey refers to the LETHE CTMS as *LETHE dashboard*, but both terms are interchangeable.

Users of the LETHE CTMS

The survey targeted all users of the LETHE CTMS, gathering general information such as their role in the project, their function within the application, and the frequency of their application access. When the survey was conducted, 21 users had access to the LETHE CTMS, and 15 (71%) responded to the survey. The summarized results are presented in Table 5. Most respondents held roles as coordinators or in unblinded positions, with access to almost all features. Of the 15 respondents, 12 (80%) accessed it at least once a week.

Table 5. Role of professionals in the LETHE project and in the LETHE clinical trial management system (CTMS) and frequency of CTMS use (N=15).

Answer option	Professionals, n (%)
"Could you please describe your role in the project?"	
Coordinator	1 (7)
Digital coach	2 (13)
Neuropsychologist	3 (20)
Nutritionist	2 (13)
Physiotherapist	1 (7)
Principal investigator	1 (7)
Study nurse	4 (27)
Study physician	1 (7)
"What dashboard role do you have?"	
Blinded role	1 (7)
Coordinator role	6 (40)
Unblinded role	8 (53)
"How frequently do you access the dashboard?"	
Daily	1 (7)
More than once a week	6 (40)
Once a week	5 (33)
More than once a month	1 (7)
Once a month	2 (13)

Feedback on the Design and Functionalities of the LETHE CTMS

Figure 9 and Table 6 indicate that the highest level of user satisfaction was related to the comprehensive display of relevant participant information in an easily understandable way, with a score of 100% above neutral. A detailed breakdown of all quantitative responses can be found in Multimedia Appendix 7. Overall, feedback was positive, reflecting successful integration of design approaches from workshops and feedback. Users found the LETHE CTMS intuitive, with a visually appealing and clear layout featuring consistent colors, logically divided sections, and pictograms. Pop-ups during item saving aided navigation and provided feedback on actions. Suggested improvements included reducing the steps to move between participants, addressing inconsistencies in single- and double-click requirements, and ensuring visibility of study participant phone information on the participant overview page.

Figure 9. Survey responses for the LETHE clinical trial management system from health professionals. Green indicates high user satisfaction, and red indicates low user satisfaction.

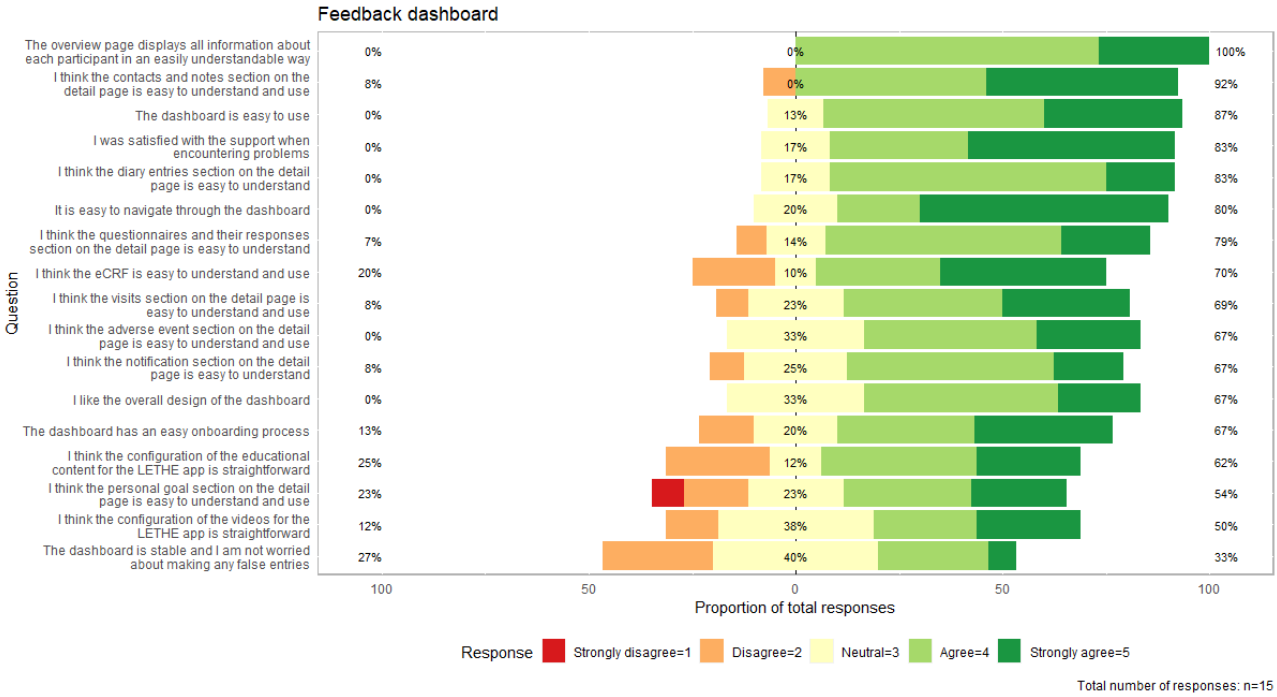


Table 6. Means and SDs of the LETHE clinical trial management system feedback survey targeting the different functionalities.

	Values, mean (SD)[a]
“The overview page displays all relevant information about each participant in an easily understandable way” (n=15)	4.27 (0.46)
“I think the Contacts/Notes Section on the Detail Page is easy to understand use” (n=13)	4.31 (0.85)
“The Dashboard is easy to use” (n=15)	4.20 (0.68)
“I was satisfied with the support when encountering problems” (n=12)	4.33 (0.78)
“I think the Diary Entries Section on the Detail Page is easy to understand” (n=12)	4.00 (0.60)
“It is easy to navigate through the Dashboard” (n=15)	4.40 (0.83)
“I think the Questionnaires and their Responses Section on the Detail Page is easy to understand” (n=14)	3.93 (0.83)
“I think the eCRF is easy to understand and use” (n=10)	3.90 (1.20)
“I think the Visits Section on the Detail Page is easy to understand and use” (n=13)	3.92 (0.95)
“I think the Adverse Event Section on the Detail Page is easy to understand and use” (n=12)	3.92 (0.79)
“The Dashboard has an easy onboarding process” (n=15)	3.87 (1.06)
“I like the overall design of the Dashboard” (n=15)	3.87 (0.74)
“I think the Notification Section on the Detail Page is easy to understand” (n=12)	3.75 (0.87)
“I think the configuration of the Educational Content for the LETHE App is straightforward” (n=8)	3.63 (1.19)
“I think the Personal Goal Section on the Detail Page is easy to understand and use” (n=13)	3.46 (1.27)
“I think the configuration of the Videos for the LETHE App is straightforward” (n=8)	3.63 (1.06)
“The Dashboard is stable and I am not worried about making any false entries” (n=15)	3.13 (0.92)

[a]The scale ranges from 1 (*Strongly disagree*) to 5 (*Strongly agree*). A higher level of agreement indicates greater satisfaction.

Concerning the onboarding process, users expressed that it involved multiple steps and should be streamlined further. However, once granted access, the general opinion was that the process was straightforward. The lowest satisfaction regarding functionalities was observed in the educational content and video configuration, where users missed options for uploading videos and materials instead of web links. The stability and prevention of false entries, particularly in the eCRF, received the lowest satisfaction rating. Users reported issues with scrolling affecting eCRF values and occasional problems with

saving values. Suggestions included implementing a log to track data edits for added transparency, a measure already in place but not visible to users. Another notable disagreement in the *Personal Goals* section was that users found it difficult to set goals at regular intervals, and the lifestyle domain associated with each personal goals was not visible in the detailed view of a study participant.

Feature suggestions included displaying follow-up data, editing values in different sections, providing additional Fitbit data insights, and summarizing clinical test names and scores at the bottom of the eCRF page. Positive aspects highlighted satisfaction with support, emphasizing quick response times, correction of implementations, and clear explanations.

Other feedback suggested the ability to send messages to groups of study participants as well as create group meetings. Overall, those surveyed commented on the effectiveness of the LETHE CTMS for study staff and participants, noting a continuous improvement since its first use.

Ranking the Most Useful and Beyond-State-of-the-Art Features

One of the survey questions asked respondents to rank various features integrated into the LETHE CTMS based on their perceived usefulness and how they surpassed state-of-the-art capabilities. As shown in Table 7, the integration of personalized activities (mean 2.23, SD 1.17) and real-time appointment planning (mean 2.46, SD 1.51) stood out as the most impactful features. An additional comment from a respondent highlighted the novelty of the interplay between the LETHE CTMS and the LETHE app, with a note that further optimization was needed. In addition, the LETHE CTMS holds the potential to serve as both an eCRF and a tool to assist in intervention delivery. This dual functionality was seen as a valuable development for the future to meet the evolving needs of professionals conducting clinical trials.

Table 7. Ranking of different features based on surpassing state-of-the-art capabilities, with R1 being the best-ranked feature and R7 being the worst-ranked feature.

	Choices (n=13), n (%)							Total (n=91), n (%)
	C1[a]	C2[b]	C3[c]	C4[d]	C5[e]	C6[f]	C7[g]	
R1	2 (15)	2 (15)	1 (8)	0 (0)	1 (8)	4 (31)	3 (23)	13 (14)
R2	1 (8)	0 (0)	0 (0)	0 (0)	1 (8)	4 (31)	7 (54)	13 (14)
R3	1 (8)	0 (0)	2 (15)	4 (31)	3 (23)	2 (15)	1 (8)	13 (14)
R4	0 (0)	3 (23)	3 (23)	3 (23)	1 (8)	2 (15)	1 (8)	13 (14)
R5	1 (8)	1 (8)	3 (23)	2 (15)	5 (38)	0 (0)	1 (8)	13 (14)
R6	2 (15)	5 (38)	1 (8)	3 (23)	1 (8)	1 (8)	0 (0)	13 (14)
R7	6 (46)	2 (15)	3 (23)	1 (8)	1 (8)	0 (0)	0 (0)	13 (14)
Total (n=91)	13 (14)	13 (14)	13 (14)	13 (14)	13 (14)	13 (14)	13 (14)	91 (100)

[a]Overview page of different study participants in different countries, including their digital intervention adherence pathways (mean 5.08, SD 2.43).

[b]Direct notifications to study participants via the dashboard (mean 4.84, SD 1.99).

[c]Electronic case report form (mean 4.69, SD 1.80).

[d]Immediate results of onboarding and questionnaires on the dashboard (mean 4.54, SD 1.40).

[e]Configuration of the content of the app via the dashboard (mean 4.15, SD 1.68).

[f]Real-time planning of appointments within the dashboard for the app (mean 2.46, SD 1.51).

[g]Integration of personalized intervention tasks (*Personal Goals*; mean 2.23, SD 1.17).

Discussion

Principal Findings

This paper outlines the design process, functionalities, and evaluation of the digital intervention study components within the LETHE project, focusing on older individuals at risk of cognitive decline and clinical professionals. The design process involved multiple sessions with potential end users and clinical experts. Furthermore, the setup is currently being evaluated in a 2-year intervention study, and the first results have been presented [11,69].

The original FINGER multidomain trial, along with related studies, demonstrated that cognitive benefits can be achieved through a 2-year intervention. As a result, this duration was established as the timeline for the LETHE trial. However, there is only limited information available on longer studies supported by ICT components, such as digital apps requiring daily interactions and wearable devices.

These requirements made it necessary to carefully design the study in terms of human support and create user-friendly ICT components for both participants and clinical professionals. The learnings regarding ICT use in clinical studies, as well as data collected in intervention studies (clinical data and digital biomarkers), are essential and can influence future studies and clinical trial setups using ICT.

To emphasize the importance of user-friendly design, this paper presents the process from requirement gathering to the design of the components. The findings will be evaluated and will inform further improvements to the setup.

Overall, the median SUS score of the intervention group of 70 (IQR 55-82) was comparable to that of the control group of 73 (IQR 63-90). The slightly higher median score of the control group might be attributed to the less complex functionalities compared to those of the intervention group version, specifically the absence of personalized and intervention activities. However, both median scores surpassed 68, indicating above-average user acceptance and satisfaction according to SUS guidelines [62]. Given that the initial user experience for the control group was quite positive even with fewer features, there is hope that they will remain engaged throughout the trial. It is anticipated that these values will improve as participants gain more experience with the LETHE app during the 2-year RCT [73]. Evaluating the other time points will give us more information about the longer-term usability and user engagement.

Noteworthy is the variation in median SUS scores between countries, with Austrian participants providing the highest scores (intervention group: median 73, IQR 58-95; control group: median 90, IQR 73-95) and Sweden providing the lowest scores (intervention group: median 64, IQR 49-80; control group: median 64, IQR 50-84). Performing a pairwise comparison using the Dunn test, a significant difference in median SUS scores between Austria and Sweden was found (P=.02).

While the LETHE lifestyle intervention program is centrally coordinated, and the activities in the 4 countries are harmonized to ensure comparable content, certain local adaptations are allowed to optimize feasibility (eg, in the detailed intervention delivery [balance between in-person and digital sessions] and how the digital components are leveraged). A qualitative study is currently underway to collect additional data on the barriers to and facilitators of the use of digital tools among participants in the LETHE trial.

Overall, users expressed satisfaction with the LETHE CTMS, and workshops on design, usability, and functionality proved beneficial. However, clarity regarding the purpose of an AI risk simulation and addressing user concerns about inaccurate data entry emerged as key challenges during the design process. Further exploration into user satisfaction with the intervention's introduction by clinical professionals across different countries is warranted for future research.

Research should investigate reasons behind decreased personal engagement in long-term ICT-supported studies. The LETHE protocol, with its 2-year ICT-supported design, offers a unique contribution to support cognitive health in older individuals.

In terms of future research, several key directions should be explored. First, a thorough evaluation of the platform's use and usability after the completion of the full 2-year trial would provide valuable insights into its long-term effectiveness. Second, further investigations could focus on the AI-driven risk simulation within the CTMS, with a particular emphasis on its potential role in guiding future interventions. Finally, exploring the adaptability of the LETHE platform among populations with low digital literacy and assessing the feasibility of a hybrid approach would be an important area for future research.

We are confident that LETHE app's diverse features, together with high retention, positive feedback and frequent use [11,69], provide promising directions for future hybrid multimodal interventions.

Strengths and Limitations

This study has several strengths, particularly in how the LETHE app and CTMS incorporate perspectives from both northern and southern Europe. This allows for a broader range of views to be considered. Moreover, this study is regularly improved through feedback from professionals, suggestions from study participants, and input from advisory board members, ensuring ongoing refinement and relevance. One limitation lies in assuming that all participants have sufficient digital skills and internet access, which was an inclusion criterion for the RCT. However, according to a recent study, the gap in digital health trends between younger and older people may vanish in 10 years as today's individuals aged <65 years are highly adapted to digital solutions [74].

Furthermore, all participants were provided with introductory materials and manuals for the LETHE app to facilitate use. Those factors could impact their ratings. Moreover, the subjective nature of the SUS, which relies on participants' self-reported perceptions of usability, might not fully grasp the nuanced usability challenges, especially among older users who may have varying cognitive and physical abilities. Another limitation is that the LETHE app content (eg, educational materials or videos) varies between countries and may influence the ratings.

Another consideration is that the initial user testing involved a small sample size, with only 4 German-speaking participants for the first user testing. However, the evaluation of the LETHE app is part of a study in which health professionals and 156 study participants are included.

The LETHE app was developed exclusively for the Android platform. This decision was based on practical considerations, including resource constraints, time limitations, and the need for a streamlined pilot phase. Focusing on a single operating system allowed for a more efficient development, testing, and release process, ensuring that the feasibility trial could be completed within the available time frame. Android was chosen due to its widespread use and compatibility with various devices, facilitating broader accessibility. To mitigate potential accessibility barriers, participants who did not have an Android device were given the option to receive one for the study. This approach enabled a standardized evaluation of the app's functionality and user experience. Future iterations of the app may consider cross-platform availability, including an iOS or web version.

Regarding the LETHE CTMS, a limitation of the survey is that most users held roles with the highest level of privileges in terms of functionalities, with frequent role changes occurring throughout the project. Improved planning of roles is advisable for future applications to mitigate this issue.

Comparison With Prior Work

Previous studies indicate declining user engagement with mHealth interventions over time due to multiple factors, such as unengaging content, complex protocols, or poor design. For instance, studies such as predictive model-based decision support for diabetes patient empowerment (POWER2DM) [75] have investigated ICT-supported health systems integrating features such as shared decision-making, personal goal setting, mood tracking, and exercise components, which is similar to the interaction between the LETHE app and LETHE CTMS but within the context of diabetes self-management.

Compared to existing digital interventions for dementia prevention, such as PRODEMOS [15] and Maintain Your Brain [16], LETHE introduces several additions and refinements. LETHE builds on standard goal setting but also includes the tiny habits method as an add-on. It also covers additional lifestyle domains, including social engagement and sleep, which are not included in PRODEMOS but are, meanwhile, part of the Lancet Commission's report [2].

In terms of data collection, LETHE uses Fitbit devices to passively monitor physical activity and sleep, whereas PRODEMOS relies on self-reported step counts. Both interventions use a hybrid approach, but LETHE's study duration is extended to 24 months (compared to 18 months in PRODEMOS) and builds on the successful FINGER protocol [5].

LETHE differs from Maintain Your Brain by offering immediate access to all modules rather than introducing them sequentially. Although LETHE does not include a separate mental health module, it collects related information through questionnaires. Maintain Your Brain, compared to LETHE, is entirely internet based and spans 3 years, with only quarterly booster activities after the first year and yearly follow-up assessments for the remaining 2 years.

Finally, unlike both PRODEMOS and Maintain Your Brain, a primary outcome of LETHE is the feasibility of a digitally supported multimodal lifestyle intervention, assessed through participant engagement with the LETHE app and a Fitbit device, attendance to study activities, and implementation of a hybrid approach that combines active and passive data collection across 4 countries.

One significant factor contributing to the unsatisfactory use of ICT components in ICT intervention studies is the usability of the functions provided. This paper provides a comprehensive account of the design process for both the app and the CTMS, aiming to maximize their usability. Subsequent publications will detail the outcomes concerning use and user satisfaction. Identified gaps in involving older adults in the design process of digital health technologies shed light on issues such as the exclusion of individuals with low digital skills during recruitment, emphasizing the importance of using diverse methods such as focus groups, interviews, or workshops [76]. While both the LETHE app and LETHE CTMS design processes incorporated various methods to solicit continuous feedback from diverse user populations, they did not explicitly include persons with low digital skills.

Conclusions

In summary, this paper presented and evaluated the design and functionalities of a comprehensive clinical trial system involving a mobile app tailored for older individuals at risk of cognitive decline. The LETHE app and a web-based monitoring and configuration system for clinical professionals, the LETHE CTMS, were thoroughly evaluated through survey-based assessments. Overall, our approach facilitates real-time interaction, providing 2 distinct applications for professionals and study participants. The results elucidated the design principles, stakeholder involvement, and essential functionalities of such an eHealth system. Subsequent research will delve into the posttrial use of the LETHE app over the 2 years, shedding further light on its effectiveness and user engagement.

Acknowledgments

The LETHE project has received funding from the European Union's Horizon 2020 research and innovation program under grant agreement 101017405 [77] (accessed on January 31, 2024). FM is also supported by an ALF (Region Stockholm) grant. This research is supported by a larger consortium, including FH JOANNEUM GmbH, Medical University of Vienna, University of Perugia, Karolinska Institute, Finnish Institute for Health and Welfare, Alzheimer Europe, Foundation for Research and Technology–Hellas, Maastricht University, Kaasa solution GmbH, Innovation2Grow, the EGI Foundation, Extra Red SRL, Infotrend Innovations Company Limited, Combinostics Oy, and the Lisbon Council for Economic Competitiveness asbl.

Abstract

Background: Cognitive impairment in older adults reduces independence and raises health care costs but can be mitigated through stimulating activities. Based on network theory, intricate relationships within and between clusters of instrumental activities of daily living (IADLs) and cognitive domains suggest the existence of central IADLs and cognitive domains, as well as bridge IADLs. Modifying these can significantly enhance daily living activities and cognitive functions holistically.

Objective: This study aims to identify central IADLs (key activities within the IADL network), central cognitive domains (key domains within the cognitive network), and bridge IADLs (linking IADL and cognitive networks). These insights will inform targeted interventions to effectively improve IADL and cognitive well-being in older adults.

Methods: A cross-sectional analysis of adults aged 65 years and older in the United States focused on 5 IADLs and 6 cognitive domains from the National Health and Aging Trends Study (NHATS). Network analysis identified central and bridge variables. Nonparametric and case-dropping bootstrap methods checked network stability. Network comparison tests assessed sex differences with Benjamini-Hochberg adjustments.

Results: Of the 2239 participants, 56.4% were female (n=976). We computed and tested 3 networks: IADL, cognition, and bridge-with correlation stability coefficients of 0.67, 0.75, and 0.44, respectively (all>0.25). Meal preparation was identified as the central IADL, with a centrality index of 3.87, which was significantly higher than that of other IADLs (all P<.05). Visual attention emerged as the central cognition domain, with a centrality index of 0.86, which was significantly higher than that of other cognition domains (all P<.05). Shopping was determined to be the bridge IADL, with a centrality index of 0.41, which was significantly higher than that of other IADLs (all P<.05). Notably, gender differences emerged in the IADL network, with stronger associations between laundry and meal preparation in females (1.69 vs males: 0.74; P=.001) and higher centrality in meal preparation among females (difference=1.99; P=.007).

Conclusions: While broad enhancements in all IADL and cognitive domains are beneficial, targeting meal preparation, visual attention, and shopping may leverage their within-network influence to yield a more pronounced improvement in holistic IADL, holistic cognition, and holistic cognition function through IADL interventions among older adults. Notably, meal preparation interventions may be less effective in males, requiring tailored approaches.

Introduction

Cognitive function encompasses mental processes such as acquiring knowledge, manipulating information, and reasoning, including perception, memory, learning, attention, decision-making, and language abilities [1]. Globally, cognitive impairment in older adults has a prevalence ranging from 5.1% to 41%, with incidence rates around 53.97 per 1000 person-years [2]. This impairment not only predicts older adults' future incidence of dementia, but also significantly reduces functional independence and quality of life [2]. Beyond the individual level, economically, cognitive impairment incurs 44% higher direct medical costs and significantly increases the need for

informal care [3]. Given these consequences, early detection and proactive management are essential to mitigate impacts and prevent progression to more severe conditions and greater health care burdens.

Instrumental activities of daily living (IADLs) encompass complex tasks necessary for independent living, such as cooking, cleaning, transportation, laundry, and financial management [4]. These activities assessment sometime adjusted by country or age will include driving or medication management [5,6] and demand cognitive skills like planning, memory, and problem-solving, linking their performance closely to cognitive well-being [4]. In performing these tasks, individuals engage in practical cognitive training that builds cognitive reserve and supports overall brain health. Furthermore, regularly performing IADLs provides ongoing cognitive training that builds "cognitive reserve," a concept suggesting that mentally stimulating tasks strengthen neural connections, thereby enhancing brain resilience [7]. Although other pursuits, such as employment or volunteering, also require high-level cognition, IADLs foster daily independence in older adults, and their everyday, repetitive occurrence makes them an ideal approach for continuous cognitive training. However, current interventions usually target specific IADL domains, such as shopping or meal preparation, highlighting the challenges and resource demands of broad IADL interventions [8].

A significant research gap exists in identifying the most impactful IADL component that can efficiently enhance global cognitive function, particularly crucial in resource-limited settings. This need is supported by complex interactions between IADLs and cognition [9-12], correlations within individual IADL domains (eg, between laundry and meal preparation due to similar cognitive and physical demands) [13], and relationships within cognition domains (between psychomotor function and visual attention stemming from their joint role in tasks requiring quick coordination and responses) [14]. Notably, the cognitive demands of specific IADLs vary; for instance, shopping necessitates skills in navigation, selection, and financial transactions, whereas meal preparation involves planning, execution, and presentation. Such distinctions suggest the existence of certain IADLs that are more closely linked to multiple cognitive domains. Traditional analytic methods, which often isolate relationships or assume predictor independence, may overlook the nuanced, simultaneous interactions among nodes. In contrast, network analysis captures these complex dynamics by representing variables as nodes interconnected by edges [15]. This approach not only elucidates direct interactions but also reveals broader network structures, thereby identifying "central" nodes-those exerting significant within-group influence-and "bridge" nodes that connect disparate networks [15]. Specifically, within our framework, a central IADL is defined as the activity with the highest connectivity within the IADL network, while central cognition refers to the cognitive domain with the most extensive links. A bridge IADL, by linking the IADL and cognitive networks, may have an outsized impact on overall function when its performance changes. Such insights can inform target interventions and strategic resource allocation aimed at enhancing both daily living activities and cognitive function [15]. Furthermore, gender-specific differences in cognitive decline and IADL performance further complicate this landscape. Women generally demonstrate superior executive function and memory; however, their executive function appears to decline more rapidly than that of men, while memory trajectories remain similar between sexes. In contrast, difficulties in financial management and medication adherence are more predictive of dementia in men, whereas transportation challenges serve as stronger indicators in women [16,17]. Consequently, a nuanced exploration of these differences is critical for developing targeted intervention strategies.

This study aimed to identify the central IADL and cognition domains within their respective networks, pinpoint the bridge IADL most substantially linked to overall cognitive function, and examine sex differences in these variables. We hypothesized the existence of central, bridge variables and sex-based differences affecting them. The findings are expected to reveal network dynamics, pinpoint key intervention targets for effectively enhancing holistic IADL and cognitive functions in the elderly, and indicate the necessity of sex-specific interventions.

Methods

Study Design and Data Source

This cross-sectional analysis used waves 11 and 12 (2021 - 2022) of the National Health and Aging Trends Study (NHATS), a nationally representative longitudinal database of Medicare beneficiaries aged 65 years and older. Waves 11 and 12 of NHATS were chosen for their comprehensive 6-domain cognitive assessment, unlike earlier waves that measured only episodic memory, executive function, and orientation. Data were gathered during in-home interviews by NHATS interviewers. For those included in both waves, only data from wave 12 were retained to ensure the latest cognitive assessments were used. The reporting of this study followed the CHERRIES checklist [18].

Participants and Sample Size Calculation

Eligible participants were cognitively intact individuals aged 65 years and older, not residing in nursing homes, and without signs of cognitive impairment. Cognitive intactness was determined by absence of potential or probable dementia. According to previous NHATS literature, potential dementia was defined by scores≤1.5SDs below the mean in one cognitive domain, while probable dementia was indicated by similar scores in at least two domains, meeting AD8 criteria, or having a clinical dementia diagnosis [19]. To ensure adequate statistical power, our network analysis of 11 nodes and 55 edges required a minimum of 165 participants, adhering to the 3-participants-per-parameter rule [20].

Measures

Cognitive performance was assessed across six domains: (1) Episodic memory, scored 0 - 20 from immediate and delayed recall of 10 words; (2) executive function, scored 0 - 5 by the clock drawing test; (3) orientation, scored 0 - 8 from knowledge of the current date and names of the president or vice president; (4) psychomotor function, measured by reaction speed in log-transformed milliseconds from the cogstate detection task,

where participants respond when a card turns face up; (5) visual attention, assessed by reaction speed for correct responses in log-transformed milliseconds from the cogstate identification task, where participants decide if a card is red or black; and (6) working memory, evaluated by accuracy in the cogstate one card back task, asking participants to remember if they have seen a card before. Cogstate, a tablet-based test used since wave 11 in NHATS, includes card detection, identification, and one card back activities, expanding cognitive assessments beyond traditional tests. This computerized assessment has been validated against traditional paper-based cognitive tests, demonstrating adequate reliability and validity in differentiating adults with cognitive impairment from those without [21]. Further details are available in the NHATS Cogstate user guide [22].

IADLs were assessed via self-reports on managing medication, laundry, shopping, meal preparation, and banking. Participants reported performance over the past month using 5 options: “1” Did not do by self last month; “2” Did by self last month with no difficulty; “3” Did by self last month with difficulty; “4” -Don’t know or refuse, with no difficulty; and “5” Don’t know or refuse, with difficulty. We dichotomized responses rather than using a Likert scale because the options do not form a natural continuum, but instead distinguish independent performance from any difficulty. Participants with no difficulty (responses “2” or “4”) were classified as “no difficulty,” while those with difficulty or inability (responses “1,” “3,” or “5”) were classified as “difficulty.” This binary approach preserves the key distinction in functional independence and aligns with previous research [23].

Sociodemographic variables included age (70 - 74, 75 - 79, 80 - 84, 85 - 89, and 90+ years), sex (female or male), living arrangement (alone, with others), race (Hispanic, non-Hispanic Black, non-Hispanic White, and other non-Hispanic), income status (poverty, low income, and normal), and self-rated health (poor, fair, good, very good, and excellent). Income status was defined according to federal guidelines from the Office of the Assistant Secretary for Planning and Evaluation at the US Department of Health and Human Services (ASPE HHS, 2024 version) as follows:≤100% Federal Poverty Level (FPL), >100% to≤200% FPL, and>200% FPL, replacing the previous labels of “poverty,” “low income,” and “normal.” Self-rated health was measured using a single 5-point Likert-scale item (1=poor, 5=excellent): “Would you say that, in general, your health is poor, fair, good, very good, or excellent?”

Statistical Analysis

Data were organized in a Microsoft Excel database and subjected to rigorous quality control checks. The analysis was carried out using R statistical software (version 4.1.1; R Core Team). Descriptive statistics summarized participant demographics and performance in IADLs and cognitive functions. Continuous variables were checked for normality with P-P plots and described using mean and SD; categorical variables were presented as frequencies and percentages. To maintain consistency across all nodes within the IADL and cognition networks, necessary reverse coding adjustments were made to ensure that higher scores consistently indicate diminished capabilities. Network analysis proceeded through 5 phases: evaluating topological overlap, estimating the network, assessing network stability, calculating centrality and bridge centrality indices, and conducting network comparison tests.

Checking Topological Overlap

We used the R package *network tools*’ goldbricker function to identify unique variables and avoid artificial relationships from symptom similarity in our network analysis. A significance threshold of 0.25 and a *P* value<.01 determined statistical significance [24].

Network Estimation

We developed 3 networks for our study: an IADL network for all 5 IADL domains, a cognitive network for all 6 cognitive domains, and a bridge network linking both. Each network consisted of nodes (items within each domain) and edges (relationships between items). For the cognition network with continuous data, we applied the EBICglasso method, which used the Extended Bayesian Information Criterion (EBIC) with the least absolute shrinkage and selection operator (LASSO) for partial correlation analysis, reducing confounding by shrinking coefficients and zeroing smaller correlations. The IADL network, based on binary data, was analyzed using the IsingFit method, which used logistic regression to adjust node states and determine conditional probabilities. The bridge network was assessed using the “mgm” method, designed for mixed data types, using conditional independence tests tailored to heterogeneous data. Network visualization was performed using R packages *bootnet* and *qgraph*, where edge thickness represented association strength—blue for positive and red for negative associations [25].

Network Stability

The *bootnet* package was used to assess edge and centrality stability in each network [25]. Edge stability was evaluated through nonparametric bootstrap, with 95% CIs reflecting accuracy; narrower CIs indicate higher network reliability [25]. Centrality stability was measured with a case-dropping subset bootstrap, as reflected by the correlation stability coefficient (CS-C); values above 0.25, ideally over 0.5, denote optimal stability [25].

Central Node, Centrality, Bridge Node, and Bridge Centrality

A central node in a network has substantial influence due to its extensive connections with other nodes [26]. Bridge nodes connect different communities or clusters within a network, facilitating interactions that would otherwise not occur [27]. Centrality measures in network analysis typically include strength, betweenness, closeness, and expected influence; however, due to the instability of betweenness and closeness, and because strength ignores negative edges (summing only absolute values), we exclusively used expected influence for central nodes and bridge expected influence for bridge nodes [28]. The expected influence index, which accounts for both positive and negative edge values, was calculated using the *qgraph* package in R [26,27]. Similarly, the top bridge node was identified through the highest bridge expected influence (1-step) index, which sums the edge values connecting the node

to those outside its community, determined by the *networktools* package in R [26,27]. Differences in node centrality were analyzed using Wilcoxon tests with 1000 bootstrapped indices from the bootnet package in R, applying Benjamini-Hochberg corrections for multiple comparisons [29].

Network Comparison Test

To analyze gender differences across 3 networks, we used the *network comparison test* package in R. This involved performing both a network invariance test, which identified significant variations in edges among subgroup networks, and a global strength invariance test, which evaluated the total weighted sum of all edges to measure the connection strength among network variables. Should the network invariance test yield significant results, we then conducted an edge invariance test to pinpoint specific edge pairs that varied between subgroups. In addition, we compared node centrality between men and women. To adjust for multiple comparisons at the level of individual edges and centralities, the Benjamini-Hochberg correction method was used.

Ethical Considerations

This secondary analysis of the NHATS dataset relies on publicly available data. The original data collection, which obtained informed consent from all participants, was approved by the Johns Hopkins University IRB. As no restricted data were used, further IRB review was not required.

Results

Sample Characteristics and Descriptions of IADL and Cognitive Domains

Of the 2239 participants (1194 from wave 12 and 245 from wave 11), 1263 were female (56.41%), and 1720 (76.82%) were White. The predominant age group was 75‐79 years, representing 748 participants (33.41%). Detailed sociodemographic data, as well as descriptions and abbreviations of the IADL items and cognitive domains, are provided in Table 1.

Table . Demographics, descriptions, and abbreviations of instrumental activities of daily living (IADL) and cognitive domain items (N=2239).

Items Remained After Redundancy Check

The Goldbricker analysis confirmed no redundancy in the IADL and cognitive domains, thus all items were retained.

Stability of IADLs, Cognition, and the Bridge Networks

The bootstrapped 95% CI analysis revealed narrow CIs across all 3 networks (IADL, cognition, and bridge), indicating precise edge-weight estimates (Figures S1, S3, and S5 in Multimedia Appendix 1). In addition, CS-C values for the IADL, cognition, and bridge networks were 0.67, 0.75, and 0.44, respectively, all surpassing the recommended threshold of 0.25, confirming the networks' interpretability and reliability (Figures S2, S4, and S6 in Multimedia Appendix 1).

IADL Network

Figure 1A illustrates the IADL network, with all edges (10/10, 100%) nonzero, indicating strong connectivity among nodes. The most robust connections were between I3 and I4 (I3: shopping-I4:meal, edge weight 1.38), I2 and I4 (I2: laundry-I4:meal, 1.33), and I1 and I5 (I1: medication- I5: banking, 1.08). Logistic regression coefficients for other edges are detailed in Table S1 in Multimedia Appendix 1. Figure 2A shows that node I4 (meal) had the highest expected influence of 3.87. Figure 2B's centrality bootstrapped difference test highlights I4's (meal's) significantly higher influence (all $P<.05$ after Benjamini-Hochberg corrections), underscoring its central role in the network.

Figure 1. Network structure of instrumental activities of daily living (IADL) network, cognition network, and the bridge network.

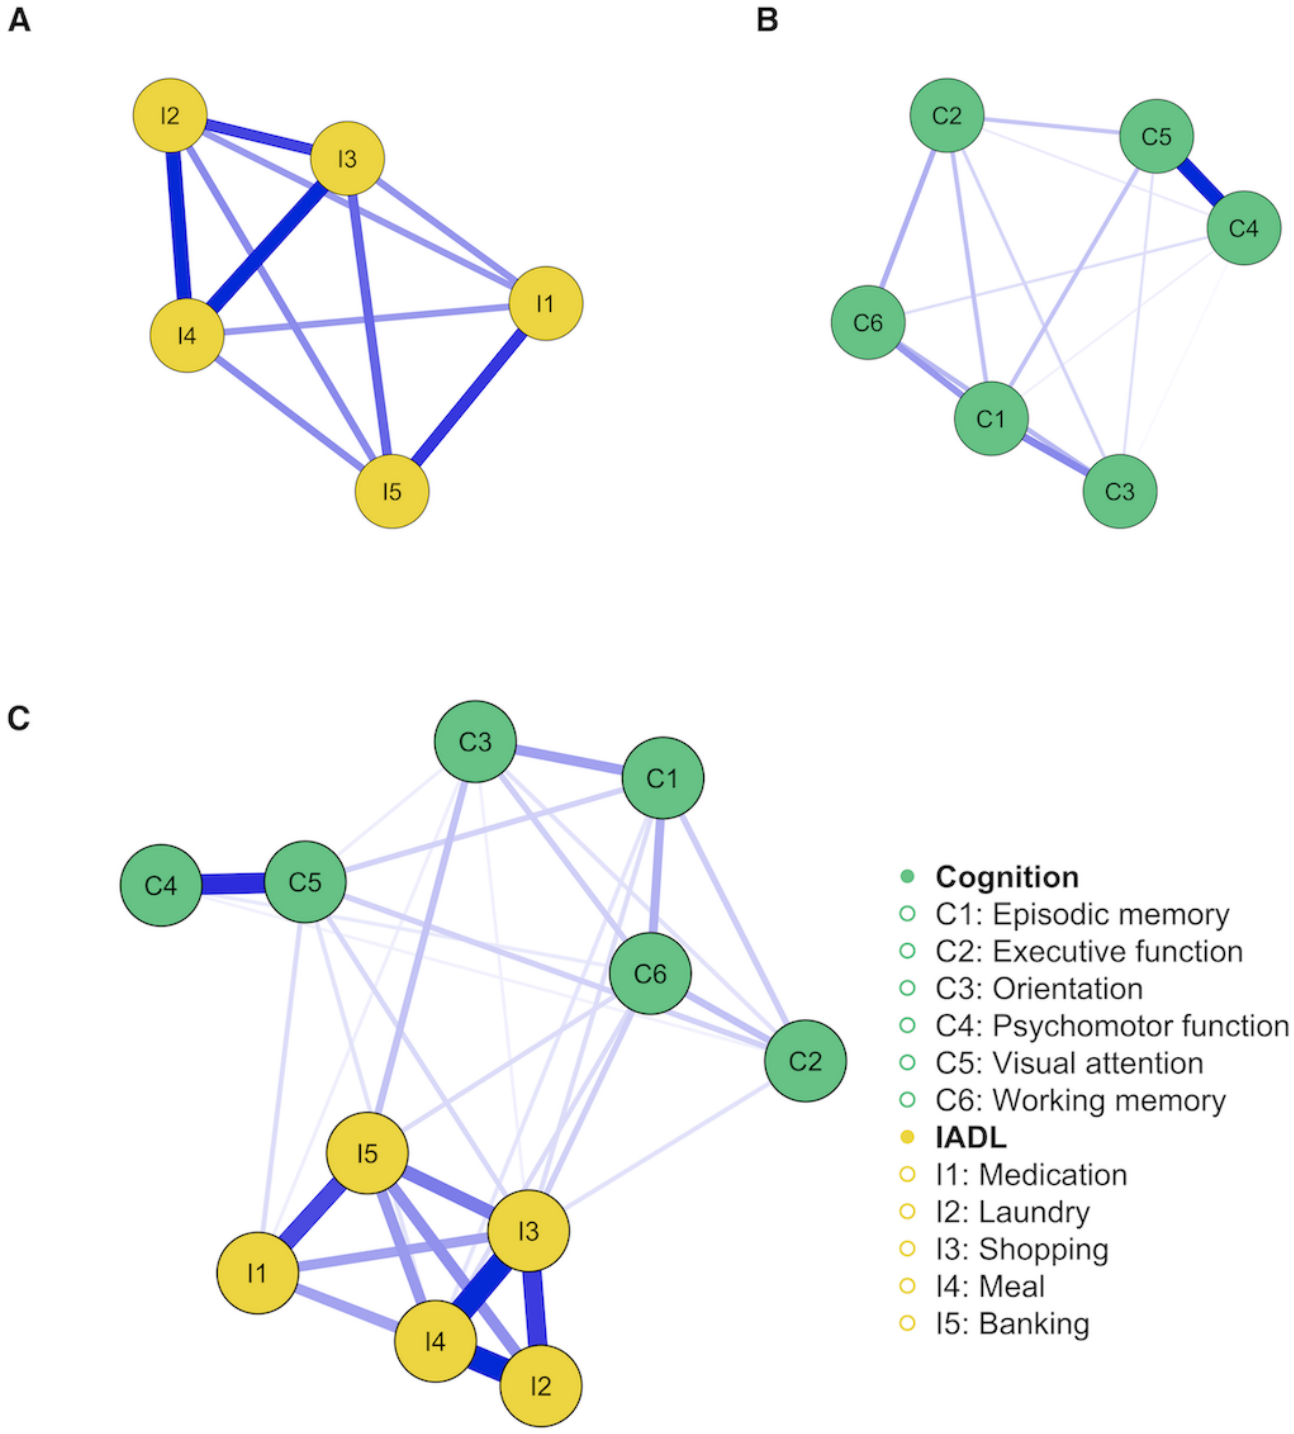

Figure 2. Expected influence centrality index and centrality bootstrapped difference tests for variables in the IADL network (Pane A and Panel B) and the cognition network (Panel C and Panel D). Gray boxes indicate variables that do not significantly differ from one-another. Black boxes represent variables that differ significantly from one another (α=.05). White boxes show the values of bridge expected influence. I1: difficulty in managing medication; I2: difficulty in managing laundry; I3: difficulty in managing shopping; I4: difficulty in managing meals; I5: difficulty in managing banking; C1: episodic memory; C2: executive function; C3: orientation; C4: psychomotor function; C5: visual attention; C6: working memory.

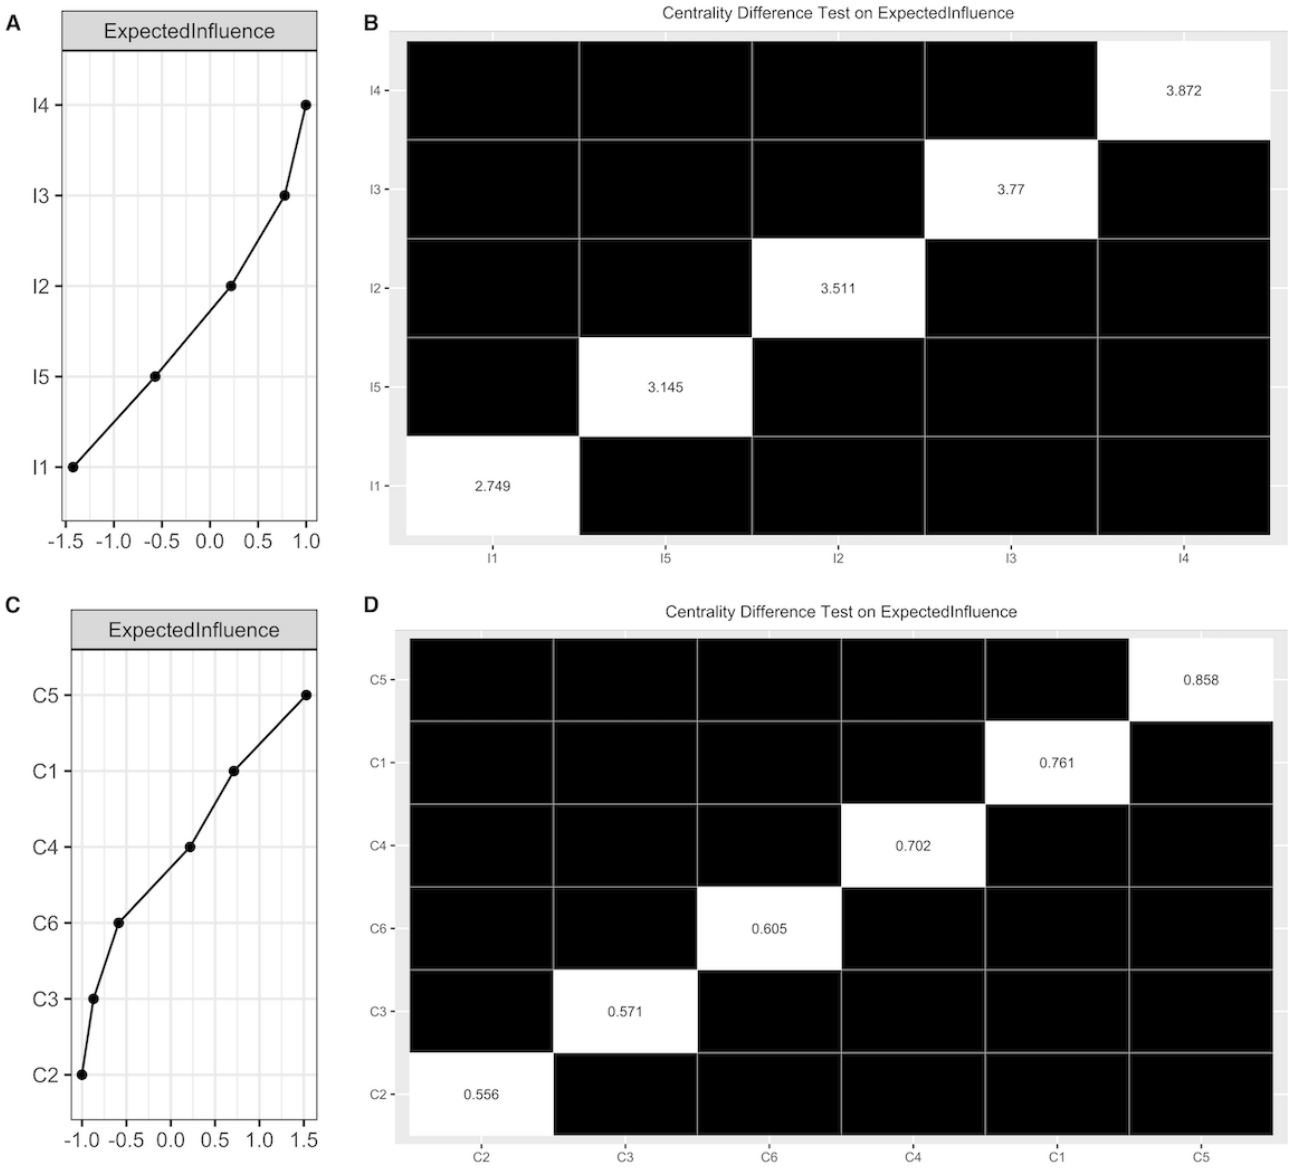


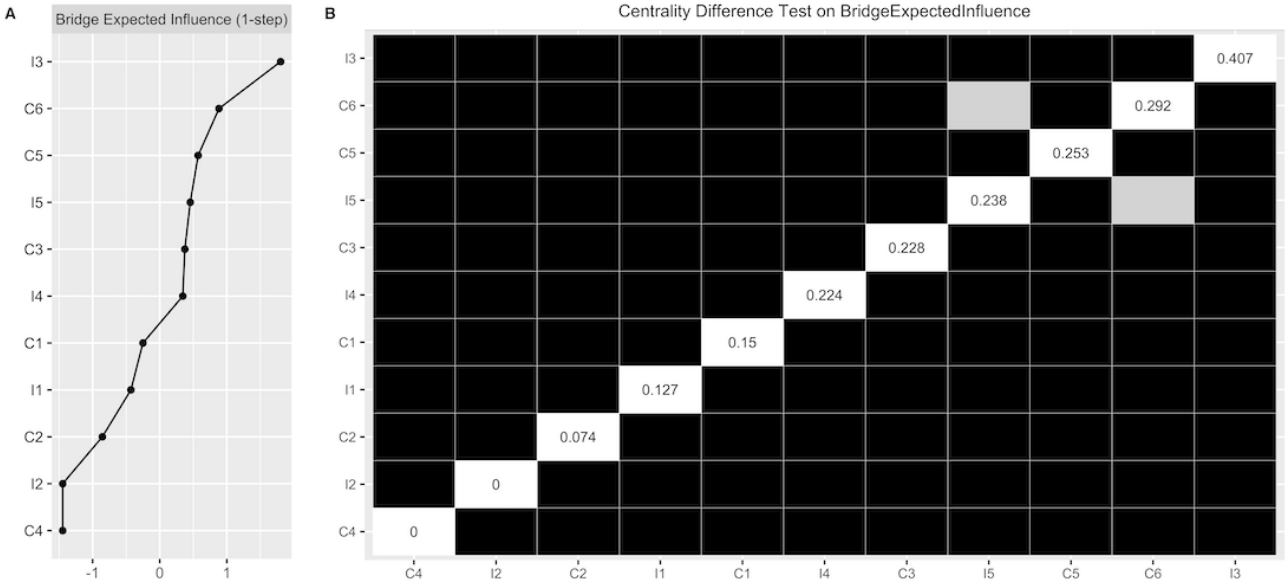
Cognition Network

Figure 1B shows the cognition network structure, with 14/15 edges (93.33%) nonzero, reflecting strong connectivity among nodes. The strongest connections were C4-C5 (C4: psychomotor function-C5: visual attention; edge weight 0.54), C1-C3 (C1: episodic memory-C3: orientation, 0.25), and C1-C6 (C1: episodic memory-C6: working memory, 0.22). The partial correlation matrix for other edges is in Table S2 in Multimedia Appendix 1. Figure 2C displays the expected influence index for all nodes, with C5 (visual attention) having the highest at 0.86. Figure 2D's centrality bootstrapped difference test underscores C5's (visual attention's) significant influence within the cognitive domains (all P<.05 after Benjamini-Hochberg corrections).

Bridge Network

Figure 1C shows the bridge network between IADL and cognition, with 34/55 edges (61.82%) nonzero, indicating strong connectivity. Details on all edges are in Table 3 in Multimedia Appendix 1. Figure 3A highlights the bridge expected influence index, with I3 (shopping) recording the highest at 0.41, followed by I5 (banking, 0.24) and I4 (meal, 0.22). Significant bridge edges include I3-C6 (I3: shopping-C6: working memory, edge weight: 0.12), I5-C3 (I5: banking-C3: orientation, edge weight: 0.15), and I4-C6 (I4: meal-C6: working memory, edge weight: 0.09). Figure 3B's centrality bootstrapped difference test confirms I3's (shopping's) prominent role in connecting IADL and cognitive domains (all P<.05 after Benjamini-Hochberg corrections).

Figure 3. Bridge expected influence centrality index (Panel A) and centrality bootstrapped difference tests (Panel B) for variables in the bridge network. Gray boxes indicate variables that do not significantly differ from one-another. Black boxes represent variables that differ significantly from one another (α=.05). White boxes show the values of bridge expected influence. I1: difficulty in managing medication; I2: difficulty in managing laundry; I3: difficulty in managing shopping; I4: difficulty in managing meals; I5: difficulty in managing banking; C1: episodic memory; C2: executive function; C3: orientation; C4: psychomotor function; C5: visual attention; C6: working memory.



Sex Differences in Networks

Network invariance and global strength tests revealed no significant sex differences in the cognition network (*M*=0.07, *P*=.64; *S*=0.10, *P*=.21). Conversely, significant sex differences were evident in the IADL and bridge networks, confirmed by network invariance tests (IADL: *M*=0.95; *P*=.005 and bridge: *M*=0.49; *P*=.002) and global strength tests (IADL: *S*=1.94; *P*=.001 and bridge: *S*=1.79; *P*=.002). Following these findings, further edge and centrality invariance tests were conducted for the IADL and bridge networks between sexes. In the IADL network, edge invariance tests identified significant sex disparities between I2 (laundry) and I4 (meal), with females demonstrating stronger associations (female 1.69, male 0.74; *P*=.001) and greater centrality in I4 (meal: difference=1.99; *P*=.007). However, in the bridge network, no significant sex differences were detected through further edge and centrality invariance tests (all *P*>.05 after Benjamini–Hochberg corrections).

Discussion

Principal Findings

Using network analysis, the main findings of this study elucidates the detailed interactions within and between IADL and cognitive domains in older adults, identifying 3 key variables as predictive markers and potential intervention targets for enhancing global IADL and cognitive function, while also noting sex differences. First, meal preparation difficulty and visual attention are central nodes within their respective IADL and cognition networks, with higher levels predictive of better functionality; targeted modifications could significantly improve overall functionality. Secondly, shopping difficulty within the IADL network has the strongest association with global cognition. Given the cause-and-effect relationship between IADL and cognitive function, early interventions targeting shopping difficulties could effectively boost global cognition. Finally, a sex difference was observed, with meal preparation exerting a greater influence in the IADL network among females than males, suggesting its higher predictive relevance and intervention efficacy for females.

Within the IADL network, the biggest 3 connections include those between shopping and meal preparation, laundry and meal preparation, and medication management and banking. The strong link between shopping and meal preparation is due to their shared planning, organization, and physical demands necessary for food tasks [30-32]. Likewise, laundry and meal preparation share organizational and physical demands [13]. The link between medication management and banking stems from their reliance on the same executive functions and working memory [33,34]. Importantly, meal preparation is central in the IADL network, perhaps due to impacts on other domains like medication, shopping, and banking owning to necessary executive skills such as multitasking and planning [35,36]. Data from our cross-sectional analysis indicate that meal preparation is the most central node within the IADL network. This finding suggests that same unite improvement in meal preparation ability can yield the largest overall enhancement in IADL performance relative to other tasks. Therefore, targeted interventions—such as the integration of assistive kitchen technologies or cognitive orthoses—may be especially effective in promoting independent cooking and, by extension, broader functional independence [37,38].

In the cognition network, the strongest connections are between psychomotor function and visual attention, and between episodic memory, orientation, and working memory. The link between psychomotor and visual attention is due to their roles in coordinated, rapid response tasks [14]. Significant correlations also exist between episodic memory and gray matter volume in the bilateral hippocampus and parahippocampal gyrus, which are key for orientation [39]. Furthermore, the association

between episodic memory and working memory is supported by evidence that working memory capacity and prefrontal cortex executive functions are essential for episodic memory formation and retrieval [40]. Importantly, visual attention, the most central node in the cognitive network, is crucial for selective focus necessary for advanced cognitive processes like reasoning and problem-solving [41], and it enhances complex task execution through interactions with working memory [42]. Studies show that enhancing visual attention can lead to sustained improvements in cognitive performance [43,44], supporting its pivotal role in overall cognition and highlighting the need for targeted interventions to enhance focus and processing of visual stimuli. Potential interventions include computer-based training programs, video games, mindfulness exercises, and virtual reality applications specifically designed for visual tracking tasks, all of which may contribute to enhanced cognitive function [45-48].

In the bridge network, which integrates both IADLs and cognition, connectivity is notably high, with 61.82% (34/55) of edges being nonzero. This finding indicates a robust interconnection among multiple cognitive domains and IADLs, suggesting that daily tasks rely on a synergy of cognitive processes rather than on any single discrete skill [49,50]. Such an observation aligns with mounting evidence that real-life cognition operates as an integrated set of processes-often termed functional cognition [51,52]. While traditional neuropsychological models emphasize isolated cognitive constructs, functional cognition highlights how domains such as attention, executive function, and memory converge to support everyday activities [53]. By adopting this framework, our findings on the specific links (“edges”) between each cognitive domain and each IADL can offer theoretical guidance for real-world functional cognition rehabilitation or training aimed at improving IADL performance. Importantly, the prominent bridge edge was identified between shopping and working memory. When considering the overall impact on global cognition, shopping ranked first as the bridge IADL, followed by banking and meal preparation. These latter activities are also highly demanding cognitively and should be targeted in interventions. However, if resources are limited, prioritizing shopping may yield the greatest benefits in enhancing overall cognitive function. Notably, shopping functions as a bridge IADL because it draws on a broad range of cognitive skills: episodic memory for recalling past purchases and layouts; executive function for planning and budgeting; spatial orientation for navigation; psychomotor skills for handling products and carts; visual attention for identifying items; and working memory for tracking purchases and costs [33,54-57]. To leverage its bridge position, shopping tasks could be integrated into routine cognitive assessments, and regular shopping activities could be encouraged to maintain cognitive function. Virtual reality simulations of shopping tasks, artificial intelligence-powered service robotics, and the use of audio recorders as assistive technology to enhance shopping independence among older adults [58,59], can leverage the bridge IADL role of shopping to effectively improve global cognitive function.

Sex differences within the IADL network show females with a stronger association between laundry and meal preparation and a higher centrality of meal preparation. These patterns likely result from societal norms assigning women more IADL responsibilities, especially laundry and meal preparation [17,60,61]. The elevated centrality of meal preparation in women’s IADL networks suggests a ripple effect where challenges in meal preparation deplete time management, mental energy, and physical resources, reducing efficiency in other tasks. This ripple effect also explains the stronger association between meal preparation and laundry among women compared with men. Previous studies indicate that IADLs do not measure equivalently for men and women [61]; our study finds that meal preparation has a lower predictive value for overall IADL function in males than in females. Interventions to improve IADL performance through meal preparation should be tailored with an awareness that these activities vary in importance and difficulty between sexes.

Limitations

Several limitations are worth mentioning. First, the assessment of IADL relied on self-reported data, which, while expedient, may compromise reliability and necessitate cautious interpretation of the findings. Future research should use more objective measures to validate these results. Second, the cross-sectional design precludes the establishment of causality and does not capture the temporal dynamics between IADL capabilities and cognitive function, underscoring the need for longitudinal approaches. Third, we excluded older adults with dementia, as dementia-related deficits may mask subtle variations in both cognition and IADL performance, which is critical for identifying central or bridge nodes in network analysis. Consequently, our findings should be interpreted primarily for community-dwelling older adults with relatively preserved cognitive function. Future research should incorporate participants with more severe cognitive impairments to validate whether our findings remain consistent. Fourth, although we set eligibility at ≥65 years, all final participants were aged 70+ years, likely because those aged 65 - 69 years in earlier waves either dropped out or turned 70 years old by Waves 11 - 12. This may limit the generalizability of our findings to younger older adults. Fifth, our study relies on the NHATS dataset, which limits the assessment to a select set of IADL and cognitive domains. Sixth, one limitation of our study is that the network analysis did not adjust for external confounders (eg, age and cultural background). Network models focus solely on the relationships among the included nodes and do not account for factors outside the network. Future research might address this limitation by residualizing each node on confounders before constructing the network, or by using subgroup or multigroup analyses to examine how these factors influence network structure. While these measures capture key aspects of functioning, we acknowledge that not including additional, more nuanced domains may affect the generalizability of our findings. Finally, the generalizability of our findings is limited to the American population studied; it remains unclear if these results can be generalized to populations with differing cultural, economic, or health system backgrounds. Further studies should

expand the demographic scope to determine if these findings hold across diverse populations.

Conclusions

The central IADL, central cognitive domain, and bridge IADL connecting global cognition were meal preparation, visual attention, and shopping, respectively, underscoring the need for targeted interventions to maximize resource efficiency and effectiveness. Specifically, enhancing meal preparation in older adults may significantly boost holistic IADL capabilities through interventions such as cooking classes, nutritional education, and tailored tools, along with support services such as interdisciplinary collaboration, caregiver training, and smart appliances. Similarly, focusing on visual attention training through methods such as computer-based programs, neurofeedback, and mindfulness exercises may substantially improve global cognitive function. Given the link between IADL performance and cognitive function, interventions centered on shopping are expected to be highly effective. This can be achieved by integrating shopping tasks into cognitive assessments and promoting regular shopping activities. Technological aids such as GPS, virtual reality simulations, and caregiver education on the cognitive benefits of shopping can further support elderly care and quality of life. In addition, observed sex differences suggest that meal preparation interventions may vary in effectiveness, with potentially lower efficacy among males, highlighting the need for tailored strategies to maximize outcomes.

Abstract

Background: Cognitive training for older adults is crucial before cognitive impairment emerges. During periods of social distancing like the COVID-19 pandemic, cognitive stimuli are lacking. Online dual-task training is proposed as a solution to address these needs.

Objective: We aimed to explore the feasibility, acceptance, and potential effects of online group-based dual-task training as an intervention for enhancing cognitive function among community-dwelling older adults.

Methods: A randomized controlled feasibility study was conducted with 76 participants in Hong Kong, randomly assigned to the intervention and attention control groups in a ratio of 2:1 (n=50, 66% and n=26, 34%, respectively). The intervention group underwent 60-minute online dual-task training sessions twice a week for 12 weeks, incorporating cognitive components (upper limb and finger movement, arithmetic operation, and verbal fluency) and physical components (chair-based exercises) developed through a co-design approach. The attention control group received online health talks. Outcomes related to feasibility and acceptance included class attendance and self-reported satisfaction. Main outcomes related to potential effects included the Memory Inventory in Chinese and the Montreal Cognitive Assessment 5 Minutes (Hong Kong Version) at baseline, 6 weeks (midintervention), 12 weeks (postintervention) and 18 weeks (follow-up). Descriptive statistics and linear mixed effects models were used. Effect size was described with Cohen *d*. Qualitative feedback was collected from 12 informants and analyzed by thematic analysis.

Results: About 72% (36/50) of the participants in the intervention group and 62% (16/26) in the control group attended over 75% of the classes. In total, 44 (88%) participants from the intervention group provided acceptance feedback; 82% (36/44) were satisfied and 84% (37/44) would recommend the training to others. Improvement in the Memory Inventory in Chinese score in the intervention group was observed at midintervention, postintervention, and follow-up, with a medium-to-large effect size (*d*=0.65, 0.43 and 0.85, respectively). Adjusting for baseline values, the between-group differences in the Montreal Cognitive Assessment 5 Minutes (Hong Kong Version) score attained a small-to-medium effect size at midintervention (*d*=0.34) and postintervention (*d*=0.23). Qualitative feedback highlighted the timesaving and convenient aspects of online dual-task training, with participants finding the sessions challenging and enjoyable, and reporting benefits across cognitive, physical, and psychosocial domains. However, a preference for traditional in-person training was noted among the older adults despite the advantages of online training.

Conclusions: Online dual-task training is a feasible intervention accepted by the older adults, with potential benefits in cognitive abilities. Online training may complement in-person sessions. Further investigation in a full-scale randomized controlled trial is warranted to comprehensively explore its effects and address areas for improvement.

Introduction

Cognitive Decline

The cognitive health of older people is critical to aging in place. Even among healthy older adults, about one-third may experience cognitive decline within 18 months [1], impacting decision-making and daily activities like managing finances, medications, transportation, and meal preparation [2]. Cognitive decline is also linked to decreased physical performance and psychosocial issues, such as loneliness and depression [3]. The health care burden may thus increase in the long run [3].

Existing Dual-Task Interventions

Interventions to enhance cognitive function or to prevent decline are essential for healthy aging. When older adults have limited capacity in performing both functional tasks and cognitive tasks, they tend to prioritize the former over the latter because of the lower chance of being injured [4]. Dual-task training, which involves combining cognitive and physical training components, has been shown to improve physical and cognitive performance, including, but not limited to, gait, balance, and memory and cognitive function [5]. Compared with training with single components, dual-task training tends to have potentially greater benefits [6,7]. Dual-task training has been widely applied among populations with clinical conditions, such as stroke, Parkinson disease, and cognitive impairment. A systematic review of 13 randomized controlled trials (RCTs) on stroke survivors reported that dual-task training could improve walking and balance function [8]. A recent meta-analysis of 14 RCTs estimated a small-to-moderate effect in improving cognitive function among stroke survivors [9]. Meanwhile, a meta-analysis of 17 RCTs on people with Parkinson disease revealed positive effects in physical performance, such as gait and balance, with effect size varying from small to large [10], and a narrative review of 3 studies reported potential improvements in cognitive function among this group, although statistical significance was not always achieved [11]. A 2022 network meta-analysis concluded that dual-task training was promising for addressing the cognitive and motor symptoms of patients with Parkinson disease [12]. The benefits of dual-task training for cognitive function were commonly investigated among cognitively impaired people. A review of 18 RCTs on those with dementia or mild cognitive impairment reported improvements in overall cognitive function, attention, and functional mobility [7]. Another meta-analysis of 21 RCTs reported small-to-moderate effects in global cognitive function, memory, executive function, and attention in cognitively impaired people [13]. A recent meta-analysis of 20 RCTs also reported benefits for global cognition, executive function, and working memory with effect sizes that were moderate, small to moderate, and moderate to large, respectively [14]. There is growing literature on studies targeting cognitively healthy older people. A meta-analysis of 8 controlled trials on cognitively healthy older adults reported improvement in cognitive functions, such as global cognition, working memory, and executive function [15]. The same review also reported no statistically significant difference in efficacy between cognitively healthy older adults and those with mild cognitive impairment [15].

Service Gaps

In practice, motivating healthy older adults to engage in cognitive training can be challenging, especially when they perceive no immediate risk of decline. Presenting interventions as recreational and stimulating can enhance participation. Compared with solely cognitive training, dual-task training may address this need. Meanwhile, when there was social distancing, such as during the COVID-19 pandemic, older adults lost their opportunity to exercise and interact with others. Reductions in physical activity and social interaction not only challenged their physical and psychological health but also challenged their cognitive performance. Although group-based dual-task training could be beneficial, existing dual-task training programs have been conducted face-to-face, which limits their application during times of social distancing, prompting the exploration of online delivery methods. As the participants could join the training in their own homes, the training components had to be specially designed to simultaneously ensure safety, enjoyment, and efficacy. Hence, as an initial step, the feasibility, acceptability, and potential effects of the proposed intervention had to be investigated through a feasibility study.

Aim and Objectives

This study aimed to explore the feasibility, acceptance, and potential effects of online group-based dual-task training as an intervention for enhancing cognitive function among community-dwelling older adults. To accomplish this aim, we had three objectives: (1) to develop the intervention through a co-design approach, (2) to explore its feasibility and acceptance among older adults, and (3) to examine its potential effects in terms of the cognitive, physical, and psychosocial status of the intervention group before and after the intervention and in comparison with the control group. We hypothesized that online based dual-task training would be feasible for healthy older adults.

Methods

Study Design

This was a randomized controlled feasibility study with 2 parallel arms. The trial was registered at ClinicalTrials.gov (NCT05573646).

Ethical Considerations

Ethics approval was obtained from The University of Hong Kong/Hospital Authority Hong Kong West Cluster Institutional Review Board (UW22-038).

Setting

This study was conducted in both online and community settings across Hong Kong. Data collection was conducted at older adults community centers, an older adult educational center, and a university campus, and the intervention was delivered online.

Target Population and Sample

The target population comprised community-dwelling older adults. The inclusion criteria were (1) age ≥65 years, (2) no communication problems, and (3) ability to use an online meeting platform. The exclusion criteria were (1) contraindications to chair-based exercises and (2) engagement in any kind of cognitive training 3 months before the study or during the study period.

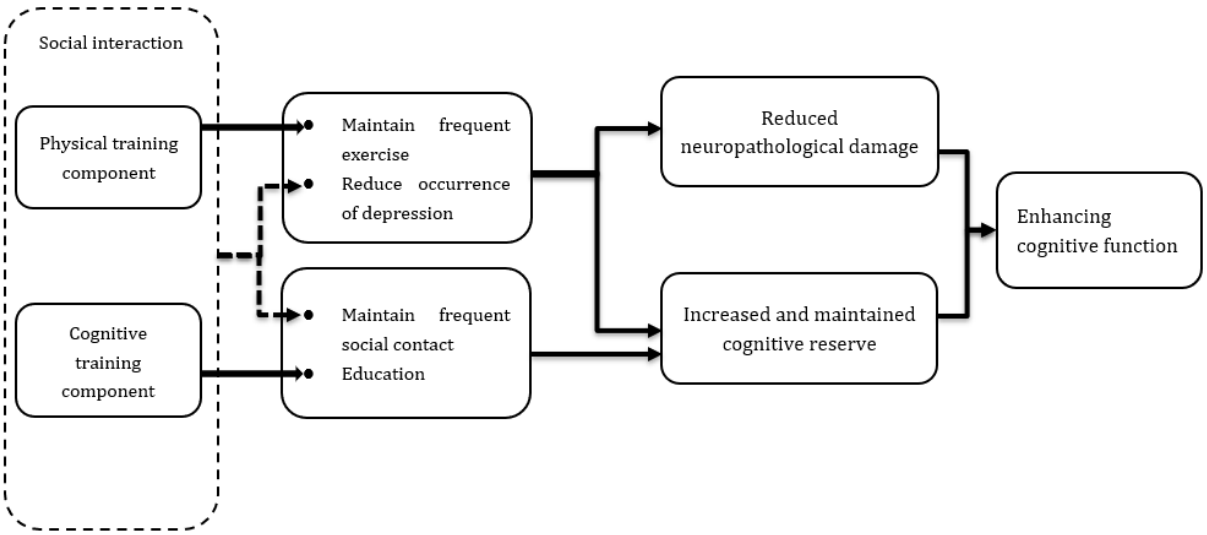
According to the literature, for a main trial designed with 80% power and 2-sided 5% significance to detect a small-to-medium effect (Cohen *d* between 0.1 and 0.3), a sample size of at least 20 per treatment arm is needed for a pilot study [16]. Meanwhile, to allow the sample to detect a medium within-group effect size in the intervention group (d=0.5) with 80% power and 2-sided 5% significance, a sample size of 34 was required for the intervention group. Taking both scenarios and 20% attrition into account, 50 participants in the intervention group and 25 participants in the control group were required.

Intervention: Online Group-Based Dual-Task Training

Participants in the intervention group received a 1-hour online group-based dual-task training session twice a week for 12 weeks, resulting in a total intervention time of 24 hours. Such frequency and duration were within the range of 4 to 25 weeks and 30 to 240 minutes per week, as used in previous dual-task training programs for healthy older adults [6].

Figure 1 shows the conceptual framework underpinning the development of the intervention based on the 2020 Report of the Lancet Commission on dementia prevention, intervention, and care [17]. The framework proposed that modifiable risk factors prevent dementia through reduction of neuropathological damage and increase and maintenance of a cognitive reserve. Among these factors, maintenance of frequent exercise and reduction of depression act on both paths, while maintenance of frequent social contact and education act on the cognitive reserve path. In our intervention, the physical training components helped to maintain frequent exercise (at least twice weekly) and the cognitive training component mimicked the education effect. The social interaction via group Zoom (Zoom Communications, Inc) classes maintained frequent social contact for at least twice a week and thus could help to relieve depression symptoms.

Figure 1. Conceptual framework.



In the development of the cognitive training component, various factors were considered, including the lower education level of the local older adults, the online delivery format of the intervention, the cultural appeal to the local older population, and the effectiveness and safety of the training. A diverse set of training components were incorporated, such as upper limb and finger movements, arithmetic operations, and verbal fluency exercises, based on their proven efficacy in previous dual-task training studies [18,19]. A co-design approach was adopted to develop the dual-task training components. In total, 9 participants from the target population were invited to a trial run to provide feedback on their interests, challenges, and suggestions for tasks they preferred. The suggested tasks were then reviewed by the project team to assess their intensity and potential impact on training outcomes. Considering what would be acceptable and effective, 18 upper limb and finger movement games, 22 arithmetic operation games, and 6 verbal fluency training components were finalized (Textbox 1). During the 1-hour training session, participants engaged in different tasks according to a predefined schedule (Table 1). Specifically, participants spent 12 minutes on upper limb and finger movement exercises, 15 minutes on arithmetic operations, and 15 minutes on verbal fluency tasks. Each game started at the easiest level, with the facilitator adjusting the cognitive demand

as participants progressed. For each game, the facilitator would start with the easiest level first. To sustain motivation and enjoyment, the difficulty level of each component increased when participants demonstrated mastery, typically indicated by 3 consecutive rounds without losing a game.

Textbox 1. Examples of cognitive training components.

Upper limb and finger movements

- Goal-directed finger movements, such as counting and reverse counting with the fingers and making motions in different directions with different hands
- Forming patterns in the air

Arithmetic operation

- Counting
- Reverse counting
- Counting or reverse counting with subtraction or addition
- Clapping at specific numbers or multiples

Verbal fluency

- "Jie Long" (a well-known Chinese word chain game)
- Naming games (particularly on Chinese cultural concepts, such as Chinese dim sum and greetings in the Chinese new year)
- Memory games (participants needed to recap the previous terms presented by others and then add their own)

Table 1. Dual-task training schedule for each 60-minute session.

Time (minutes)	Dual-task training	
	Physical components (chair-based)	Cognitive components
5	Warm-up exercise	Safety reminder or casual chit-chat
3	Toes raises	Upper limb and finger movement 1
3	Heel raises	Upper limb and finger movement 2
3	Toes raises	Upper limb and finger movement 3
3	Heel raises	Upper limb and finger movement 4
3	Break	Break
3	Stepping	Arithmetic operation 1
3	Rest	Arithmetic operation 2
3	Stepping	Arithmetic operation 3
3	Rest	Arithmetic operation 4
3	Stepping	Arithmetic operation 5
3	Break	Break
3	Stepping	Verbal fluency 1
3	Clam exercise	Verbal fluency 2
3	Stepping	Verbal fluency 3
3	Clam exercise	Verbal fluency 4
3	Stepping	Verbal fluency 5
3	Clam exercise	Verbal fluency 6
4	Cool-down exercise	Safety reminder

For the physical training component, we selected chair-based exercises, which were chosen due to their suitability for the limited space available in most local households. Chair-based exercises offer various benefits, such as improving mood and well-being, enhancing certain activities of daily living, promoting social interaction, and increasing muscle strength [20]. Alongside the cognitive training games, participants engaged in exercises like toe or heel raises on alternate sides,

stepping, and clam exercises (Table 1). The exercises were performed at a low frequency, such as 60 steps per minute. To ensure safety, participants were permitted to use their hands for balance support during stepping or clam exercises. Therefore, when upper limb and finger movement tasks were involved, only toe or heels raise were performed.

A group-based training approach was adopted as group-based cognitive training might yield greater interaction and cognitive benefits than individual-based training [21]. Group-based exercise was also reported as having the additional advantage of creating a social support environment that could enhance psychosocial well-being [22]. Moreover, group-based interventions tend to have higher adherence rates than general exercise programs due to the motivational support provided by group dynamics [23]. To encourage interaction among participants and enable close monitoring by the facilitator, a group size of less than 10 people was used.

Zoom was selected as the training platform due to its widespread use and familiarity among local older adults. Throughout the session, participants were instructed to sit on a sturdy chair with a back rest in front of a desktop computer, laptop, tablet, or mobile phone securely placed on a table. Mobile device users were provided with stands for better posture (all participants received the stand as a souvenir). To allow enough space for movement, the chair and table needed to be positioned 60 cm apart. Participants were encouraged to turn on their cameras during the session to facilitate interaction with one another. They were also asked to keep their audio on to actively participate in the cognitive tasks by verbalizing their answers.

The sessions were led by a trained facilitator. The facilitator did not need to be health professional, but they were required to undergo necessary training to ensure they had the knowledge and skills to effectively work with older adults [20]. A written manual with all the rules and regulations of the training was provided. During the initial sessions of the intervention, the project lead provided on-site supervision of the facilitator to ensure that the intervention was delivered according to the protocol. In addition, random spot checks were conducted by the project lead to ensure strict adherence to the protocol.

Attention Control: Interactive Health Talks

In line with recommendations for attention control groups [24], participants in the control group underwent 8 one-hour online group-based interactive health talks on food label knowledge and its practical applications. These sessions were led by a facilitator with nutrition training.

Outcome Measures

The primary outcomes were related to feasibility and acceptance. Feasibility was reflected by class attendance. Reasons for absence were documented when available. There was no consensus on the definition of high attendance [25]. We took 75% attendance as high attendance, as a review reported 3 of 11 studies on exercise interventions adopted this definition [25]. The proportion of participants with high attendance was calculated using the number of participants randomized to the group as denominator. A review of group exercise interventions for older adults reported that in 4 of 6 studies, 65% to 67% of participants adhered to the program [22]. Hence, our study considered over 65% of participants completing at least 75% of the classes as feasible.

Acceptance was reflected by 5-point Likert scale questions on the level of satisfaction with the intervention (“Are you satisfied with this training?”) and the level of likeliness of recommending the intervention to other people (“Would you recommend this training to friends and family”), with answers collected at the end of the intervention via instant text messaging. The proportion of respondents providing a positive response was calculated. As a conservative estimate, another proportion was calculated by assuming those who did not provide feedback as not being satisfied and not likely to recommend the intervention, with the number of participants randomized to the group as the denominator.

The secondary outcomes were related to potential effects, which included subjective memory complaints, cognitive status, working memory, executive function, physical function, instrumental activities of daily living, happiness, and social networks.

Subjective memory complaints were assessed using the Memory Inventory in Chinese (MIC) [26]. This scale consists of 27 items on memory concerns related to daily activities in the past month. Responses are rated on a scale from 0 (none) to 4 (once or more per day or continuously), with scores totaling between 0 and 108. A higher score indicates a greater frequency of memory concerns.

Cognitive status was assessed using the validated Montreal Cognitive Assessment 5 Minutes (Hong Kong Version) (HK-MoCA 5-Min), which covers 4 domains, namely, attention, executive functions or language, orientation, and memory [27]. The total score ranges from 0 to 30, with a higher score indicating better cognitive status.

Working memory was assessed by Digit Span Test [28]. Participants were required to repeat progressively longer series of digits. The test began with 2 digits and increased in length, with a maximum of 8 digits for the forward test and 7 digits for the backward test. The participant’s ability to recall the longest digit series in forward and backward order was recorded as the forward and backward scores, respectively. A higher score indicated a better working memory capacity.

Executive function was assessed by the Chinese version of the Victoria Stroop Test [29]. The test consisted of 3 parts, each presenting different stimuli: colored dots, common words unrelated to color, and color words. Participants were required to name the color in which the stimuli were printed. Inference scores were calculated based on the difference in completion time between the word or color test and the dot test, with a longer completion time indicating a poorer condition.

Lower-limb muscle strength was assessed by the 5-time chair stand task [30]. Participants were timed on how long it took them to complete the task, with a longer time indicating poorer performance. If participants were unable to finish the task within 1 minute, the test was stopped, and a time of 60 seconds was imputed for analysis purposes.

Instrumental activities of daily living were assessed by Lawton's 8 selected tasks, which include telephone use, shopping, food preparation, housekeeping, laundry, transportation, medicine use, and handling finances [31]. Participants rated their level of dependence in performing each task on a 5-point Likert scale. The score was the sum of all items, ranging from 0 to 8, with a higher score indicating greater independence.

Happiness was assessed by the Chinese version of the validated 4-item Subjective Happiness Scale [32]. Participants rated their responses on a 7-point Likert scale. The score was the average of the 4 items, ranging from 1 to 7, with a higher score indicating a higher level of happiness.

Depressive symptoms were assessed by the Patient Health Questionnaire-9 (PHQ-9) [33]. PHQ-9 was validated as a reliable tool for evaluating depression among older adults. The scale ranged from 0 to 27, with a higher score indicating a higher level of depressive symptoms.

Social networks were assessed by the Chinese version of the 6-item Lubben Social Network Scale [34]. Participants rated their responses on a 5-point Likert scale. The total score ranged from 0 to 30, with a higher score indicating a stronger social network.

All effect-related outcomes were assessed at recruitment (T0, baseline), 6 weeks after baseline (T1, midintervention assessment), 12 weeks after baseline (T2, postintervention assessment), and 18 weeks after baseline (T3, follow-up assessment). Demographic, medical and lifestyle information, such as age, gender, education level, exercise habits (measured by the International Physical Activity Questionnaire-Short Form), frailty status (measured by the FRAIL scale, which consists of 5 items, namely, fatigue, resistance, ambulation, illnesses, and loss of weight) and comorbidity (coexistence of 2 or more chronic illnesses) were collected at baseline. For participants who could not undergo face-to-face assessment for reasons such as quarantine or sickness, the 5-time chair stand task was not administered and was regarded as missing data.

Qualitative feedback was collected from a purposive sample at the end of the follow-up period through phone interviews. A semistructured interview guide was used to explore reasons for participating in the intervention, perceived difficulties encountered, logistical aspects of the intervention, and strengths and limitations perceived by participants. Prompts were provided as appropriate. Participants who exhibited varying degrees of change in the MIC score were invited to ensure diverse perspectives. Data saturation was achieved with 12 informants.

Procedure

Participants were recruited through social media and nongovernmental organizations in Hong Kong. They were randomly assigned to the intervention or control groups at a ratio of 2:1. As a strategy to enhance recruitment, a ratio of 2:1 was proposed for the number of people in the intervention and control groups, such that less participants would be disappointed with the allocation to the control group. A face-to-face orientation session was conducted to guide participants on using the Zoom platform and provide them with mobile device stands. Furthermore, for intervention group participants, demonstrations of the chair-based exercises were provided as they were unable to observe lower-limb movements on Zoom.

Randomization and Concealment

Block randomization with varying block sizes was used to generate the allocation sequence. An independent research assistant generated the sequence using an online platform and prepared sequentially numbered opaque sealed envelopes. These envelopes were opened in front of the participants immediately after obtaining informed consent.

Blinding

This was a single-blinded study as participants and interventionists could not be blinded. Trained research assistants involved in assessing outcomes related to potential effects were blinded to the allocation.

Data Analysis

The participants' characteristics were summarized using descriptive statistics. Attendance statistics, regarding the percentage of scheduled classes attended, were calculated. The percentage of participants satisfied with the intervention and those who would recommend it to others were also calculated. Adopting intent-to-treat, linear mixed effects models were used to analyze effect-related outcomes, adjusting for sociodemographic characteristics, medical history, and lifestyle patterns. A significance level of 5% was used. However, given the small sample size, focus was placed on effect size with the corresponding 95% CI. A Cohen *d* of 0.2 was considered clinically meaningful [35]. Missing outcome measures were not imputed as the linear mixed effects models could handle missing data. Statistical analyses were performed using SPSS version 28.

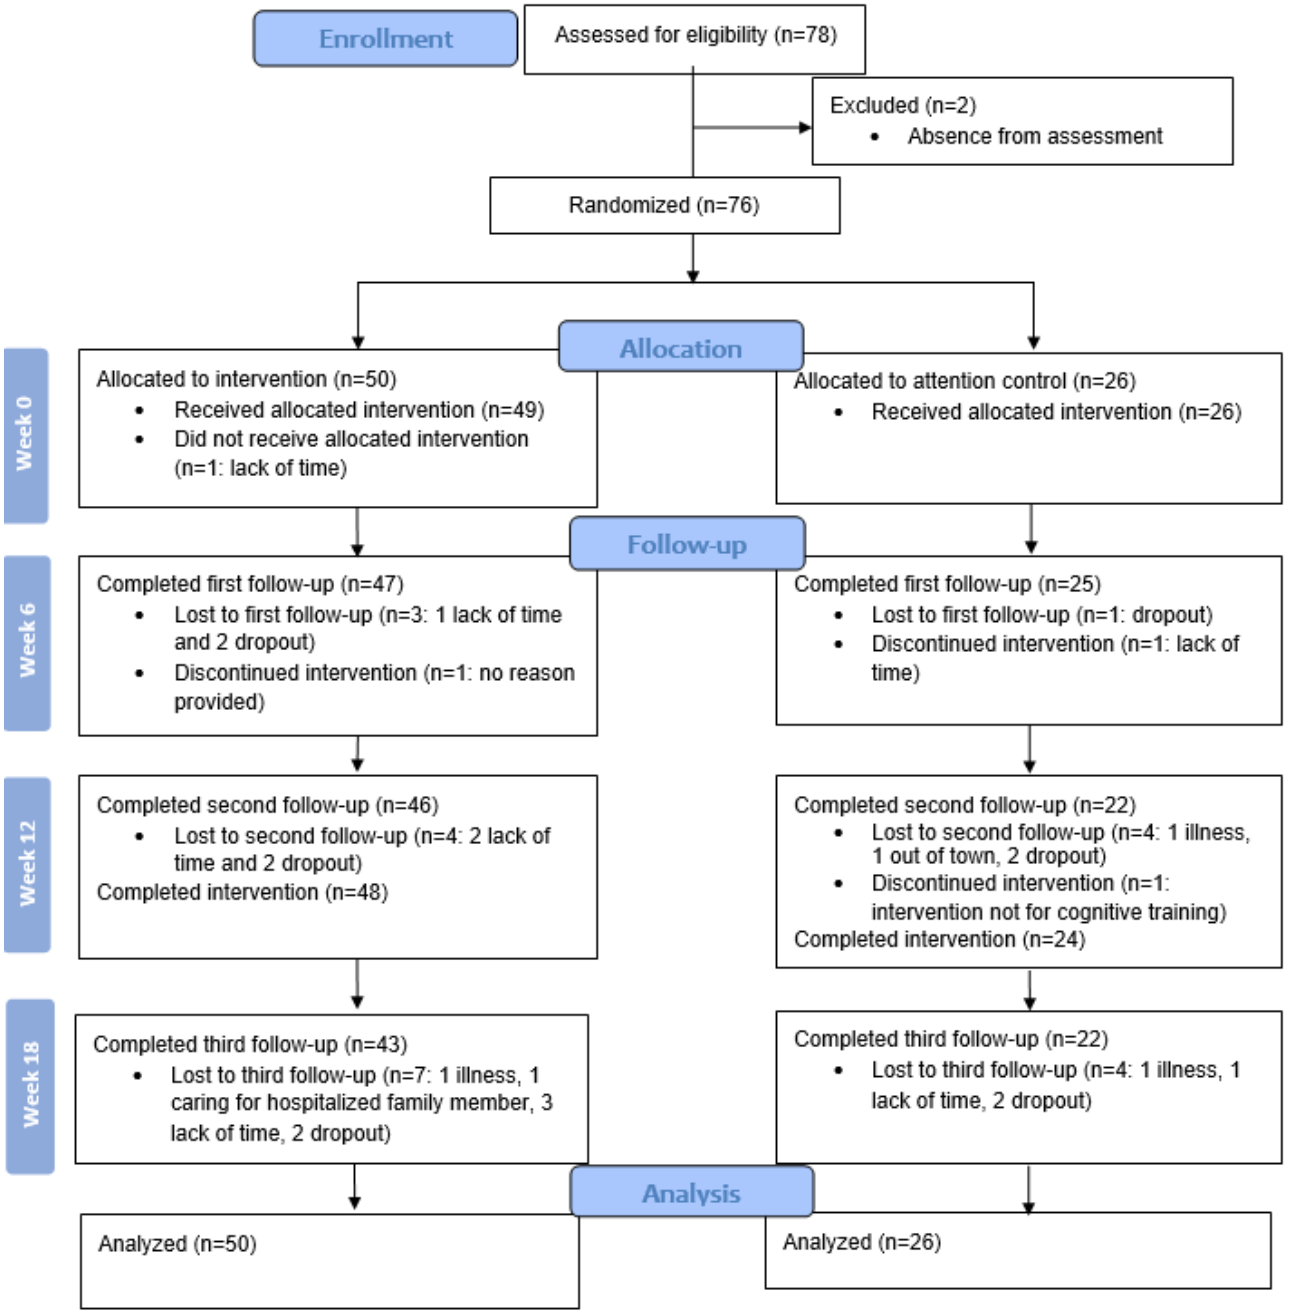
As for the qualitative interview, the audio recordings were transcribed verbatim for thematic analysis [36]. First, 2 researchers read the transcripts several times and conducted the systematic coding independently. They proceeded to generate the initial codes and the recurrent pattern within the data and identify and name the themes and subthemes according to the underlying meaning. Then, a third researcher checked for the consensus on the themes and subthemes and discussed with the team accordingly. They also worked together to identify the common threads that extend across the interviews of the participants. Analyses were performed manually without the aid of software.

Results

Overview

In total, 76 participants were recruited from October 2022 to May 2023 (Figure 2). To manage class sizes, the 50 participants in the intervention group were divided into 8 subgroups, each with 24 classes, and the 26 participants in the attention control group were divided into 2 subgroups, each with 8 classes. Overall, 48 (96%) participants from the intervention group and 24 (92%) from the control group completed the assigned intervention.

Figure 2. CONSORT (Consolidated Standards of Reporting Trials) diagram.



The mean ages of the participants in the intervention and the control groups were 71.5 (SD 5.2) and 71.1 (SD 6.0) years, respectively. There were 64% (32/50) female participants in the intervention group and 88% (23/26) in the control group. One-fifth (15/76, 20%) of the participants had a primary level of education or below. About 44% (22/50) of the participants in the intervention group and 54% (14/26) in the control group had multimorbidity. Most participants in both groups (30/50, 60% and 16/26, 61%) had low levels of physical activity. Prefrailty was observed in about 38% (19/50) of intervention-group participants and 50% (13/26) of control-group participants. Table 2 shows the characteristics of the participants.

Table 2. Baseline characteristics of participants (N=76).

Characteristics	Intervention (n=50)	Control (n=26)
Age (y), mean (SD)	71.5 (5.2)	71.1 (6.0)
Sex, n (%)		
Male	18 (36)	3 (11)
Female	32 (64)	23 (89)
Education level, n (%)		
Primary or below	10 (20)	5 (19)
Secondary	27 (54)	14 (54)
Tertiary or above	13 (26)	7 (27)
Multimorbidity[a], n (%)		
No	28 (56)	12 (46)
Yes	22 (44)	14 (54)
Physical activity level (measured by IPAQ[b]), n (%)		
Low	30 (60)	16 (61)
Moderate	15 (30)	9 (35)
High	5 (10)	1 (4)
Frailty status (measured by FRAIL[c] scale), n (%)		
Robust	31 (62)	13 (50)
Prefrail	19 (38)	13 (50)

[a]Multimorbidity is defined as the co-existence of at least 2 of the following long-term health conditions: hypertension, heart disease, high cholesterol, cancer, osteoporosis, and other chronic illnesses, as reported by the participants.

[b]IPAQ: International Physical Activity Questionnaire.

[c]FRAIL: Fatigue, Resistance, Ambulation, Illnesses, and Loss of weight.

Feasibility

In the intervention group, 36 (72%) participants attended over 75% of the 24 classes. For the attention control group, 16 participants (61%) attended over 75% of the 8 classes. Common reasons for absence in both groups included time clashes with medical appointments, illness, or other prior commitments.

Acceptability

Among 44 participants who provided acceptance feedback on the intervention, 82% (36/44) expressed being very satisfied or satisfied with the intervention, and 84% (37/44) indicated they would be very likely or likely to recommend the intervention to others. Assuming that those who did not provide feedback were not satisfied and were not likely to recommend the intervention, the satisfaction rate was 72% (36/50) and the recommendation rate was 74% (37/50).

Potential Effects

Regarding the effect-related outcomes, owing to the pilot nature of the trial, statistical significance was not the primary focus, instead, the effect size was noted. Within-group changes were explored and are presented in Multimedia Appendix 1. For the intervention group, the effect size of the MIC improvements at midintervention, postintervention, and follow-up compared to baseline were 0.65, 0.43 and 0.85, whereas the estimates for the control group were 0.51, 0.37 and 0.78, respectively. Similarly, both groups experienced an increase in HK-MoCA 5-Min score with moderate to large effect sizes. However, changes in working memory, as assessed by the Digit Span Test, did not consistently show the same direction in both groups. The intervention group showed a moderate improvement in executive function, as shown by the inference score for color from the Victoria Stroop Test, while the control group showed a small-to-large improvement in the inference score for words. Improvement was not observed for other outcomes in both groups.

Between-group differences, adjusting for the baseline differences, were explored and are presented in Multimedia Appendix 1. The intervention group did not outperform the control group in the MIC, but it showed better performance in the HK-MoCA 5-Min at the midintervention and the postintervention assessments (effect size 0.34 and 0.23, respectively). Meanwhile, a medium effect size was observed for between-group difference in the Digit Span Test at the follow-up. However, the findings for the Victoria Stroop Test were inconsistent. Details on other outcomes are presented in Multimedia Appendix 1.

Comparing the effect-related outcomes between participants with high attendance (≥75% of class) and low attendance in the intervention group (Multimedia Appendix 1), those with high attendance had fewer subjective memory complaints than those

with low attendance at midintervention and postintervention, with effect sizes of 1.18 and 1.53, respectively. At the follow-up assessment, the between-group difference was observed to be in favor of the high-attendance group in the Digit Span Test, inference score for color, and PHQ-9 score.

Qualitative Feedback

Table 3 shows the demographic characteristics of the 12 informants. Table 4 shows the 5 identified themes and the corresponding subthemes derived from the qualitative feedback, along with the significant quotes. The themes are summarized as presented in Textbox 2.

Table 3. Characteristics of the 12 informants providing qualitative feedback.

Informant	Sex	Age group (y)	Education level
A	Female	65-74	Primary
B	Female	65-74	Secondary
C	Male	≥75	Primary
D	Female	65-74	Secondary
E	Female	65-74	Secondary
F	Female	65-74	Tertiary
G	Female	≥75	Secondary
H	Female	65-74	Secondary
I	Female	65-74	Secondary
J	Male	65-74	Tertiary
K	Male	65-74	Primary
L	Male	65-74	Tertiary

Table 4. Five identified themes and the corresponding subthemes from the qualitative feedback and the significant quotes.

Themes and subthemes	Significant quotes by informants
Perceived strength of the training (before participation)	
Arousing curiosity and motivation to join	• "I heard an introduction at the elderly community center, and I want to learn more." [Informant A] • "Curious about online dual task training." [Informant B]
Giving them hope to slow down cognitive decline	• "I am taking precautions because I don't know if I will have cognitive impairment in the future. I just want to prevent it. Early prevention is better." [Informant D] • "I want to maintain, not improve, cognitive ability." [Informant L]
Offering opportunity for social interaction	• "I want to make new friends." [Informant C]
Save travel time	• "No need to spend time going back and forth; you can stay at home. Nowadays, we mostly go to centers to learn things. In-person is much better, but it takes more time to get there and back." [Informant E] • "But overall, I think online is good for participants, as it saves travel time." [Informant J]
Positive experience from the training	
Comprehensive training	• "I think the course is quite good and comprehensive; it does not just focus on those with cognitive impairment." [Informant I]
Challenging training	• "There is some difficulty; sometimes I forget, like moving a hand or getting distracted and forgetting to do the stepping. You need to stay focused to complete it." [Informant B] • "At the beginning, I feel a bit frustrated when playing. However, it has its benefits. If everything were easy, there would be no need for training." [Informant G] • "If you have to move both your foot and hand, you often end up neglecting one. Sometimes, you also have to keep track of numbers, so you need to pay attention to what the other participants are saying." [Informant K]
Engaging facilitator	• "The host guided us with patience." [Informant A] • "Overall, I think the team is very dedicated. Sometimes when we can't hear, she [the facilitator] reminds us. Or when we can't think of an answer, she gives us hints at the right time. I think the whole process is very smooth." [Informant I]
Peer support and encouragement during the training	• "We encourage each other during the training." [Informant L]
Enjoy the convenience at home environment	• "I can start the training right after breakfast. When we have breaks, we can go to the washroom and drink water at home. After the session ends, we can prepare lunch ourselves." [Informant A]
Challenges encountered with online training	
Constrained supervision and intensity of training	• "At least with Zoom, the camera cannot capture my feet, so you cannot tell if participants are doing stepping. I think in-person is ultimately more useful because you can see everyone's movements." [Informant B] • "Because in-person, you can immediately see everyone's performance." [Informant D]
Harder to follow the sequence if the training involved taking turns	• "Because it is online and most participants are women, it is hard for me to know that it is my turn unless there is a man preceding my turn. But after a few sessions, everyone starts to get familiar with each other, and we build up rapport about the sequence." [Informant J]
Less concentrated and less cordial	• "During training, some might not be able to concentrate, for example, if there are things happening at home." [Informant A] • "It's not as easy to get distracted if it is in-person." [Informant D]
Class atmosphere not comparable to in-person class	• "But in-person is more enjoyable, with more group interactions, which makes it more fun." [Informant G]
Technical issues encountered	• "The display is limited in size, and there might be some lag time." [Informant J] • "The problem is that some resource-limited families don't have Wi-Fi at home, so they have to go to the center to access it, which is less convenient." [Informant K]

Themes and subthemes	Significant quotes by informants
Perceived benefits of the training	
Improved cognitive ability (including attention and concentration)	• "Initially, I felt very unfamiliar with it, but after a few more sessions, I absorbed new knowledge and it made my mind more agile." [Informant G] • "I think I can use my brain more, as I usually don't use it much." [Informant H] • "My memory has been maintained without much decline." [Informant L]
Improved coordination and physical flexibility	• "After participating, my knowledge has broadened, and both my hands and mind have become more agile." [Informant C] • "I find that after training, the coordination of my hands and feet has become a bit more agile compared to before." [Informant L]
Improved communication skills	• "It can train an older person to handle different communication demands." [Informant J]
Promotion of positive mood and social interactions	• "Someone accompanies you. I also find it fun and enjoyable." [Informant F]
Learn new skills for self-practice in future	• "I have not experienced this kind of hand-eye coordination, but now I do. Sometimes, when I'm alone, I practise the movements." [Informant E] • "I'll go back and practise it myself." [Informant K]
Increased self-efficacy and self-confidence	• "My brain is now willing to exercise and let me do calculations." [Informant F] • "I actually feel quite happy and it gives a sense of accomplishment because you can achieve your goals and meet the training requirements, so there is a sense of success." [Informant J]
Self-explanation of less benefit from "cheating"	• "I do not feel like I have gained much. Maybe I prepare the answers in advance. For example, knowing that the next lesson will involve 'clapping on 7,' I will prepare the answers beforehand. But if it is in-person, it is harder to cheat." [Informant I]
Suggestions for improvements	
Continue the training (beyond 12 weeks)	• "I think I need to keep doing it consistently to see improvement. But I understand it is difficult if resources are lacking. Once the training stops, like now, I have forgotten a lot." [Informant K]
Booster training	• "Suggest to add online virtual courses. Each session would be half an hour, allowing students to choose their own study times." [Informant K] • "If possible, it would be best to have a booster session once a month to refresh what we have learned." [Informant L]
Consider in-person mode (but reduced frequency to accommodate time and venue constraints)	• "I think in-person sessions are ultimately more useful because you can see everyone's movements. In-person sessions could be held once a week, not too frequently, since not everyone can attend twice a week, and the center might not be able to provide the space for two days of training." [Informant B]

Textbox 2. Summary of the themes and subthemes derived from qualitative feedback.

- Perceived strength of the training (before participation): informants found dual-task training to be a novel approach, which interested them and motivated them to participate. They expected the training would help to slow down cognitive decline. The online format of the training saved them travel time but could still offer social interaction.
- Positive experience from the training: informants described the training comprehensive and challenging. The engaging facilitator increased their adherence. The group training enabled peer support, enhancing their training experience. Informants also found having the training at home very convenient.
- Challenges encountered with online training: supervision and the intensity of training was limited by the online format. Some informants found it harder to follow the sequence if the training involved taking turns. Some found the home environment made them less concentrated and the class atmosphere was not comparable to in-person class. The quality of the experience was also influenced by the display size of their device, Wi-Fi speed, and more importantly accessibility to a stable internet connection.
- Perceived benefits after the training: informants perceived benefits in cognitive ability, coordination, physical flexibility, communication skills, positive moods, and social interactions. Some valued acquiring new skills that could enable future self-practice. Some mentioned increased self-efficacy and self-confidence. Meanwhile, one mentioned the use of a cheat sheet as related to the negligible improvement.
- Suggestions for improvements: informants expressed a desire to continue the training by either extending the training period or offering regular booster sessions. However, informants generally preferred in-person training, although they acknowledged limitations regarding time and venue.

Discussion

Principal Findings

This study demonstrated feasibility and explored potential effects of an online dual-task training for community-dwelling older adults. The innovative aspects of the online dual-task training included (1) the delivery mode, allowing for uninterrupted training even during a pandemic, (2) chair-based exercises suitable for home-based practice, (3) cognitive training tailored to the needs of Chinese older adults with lower education levels, and (4) a co-design approach that considered the preferences and interests of the participants when designing the training components.

This study was launched at the end of 2022 when the COVID-19 pandemic was still ongoing. While there was no citywide quarantine policy in place, there was still a home quarantine policy for those who were infected and their close contacts. Older adults tended to limit their outings to reduce the risk of infection, as well as chance of becoming close contacts. The older population had experienced a lack of activities for a prolonged period, potentially leading to a faster decline in cognitive performance. The group-based online dual-task training addressed this gap by offering training that the participants could participate in at home.

The findings of our pilot study showed the intervention was highly feasible, as 72% (36/50) of the participants in the intervention group attended over three-quarters of the classes, which was above the target of 65%. The intervention was also well received by the participants; 82% (36/44) of the participants were satisfied with the intervention and 84% (37/44) would recommend the intervention to others. Even adopting the most conservative approach, such figures remained high at 72% (36/50) and 74 (37/50), respectively. The dual-task training successfully attracted some relatively cognitively healthy participants to join and could be continued irrespective of the pandemic situation. This initiative addressed the existing gap in services by providing online cognitive training for community-dwelling older adults.

Within-group improvement was observed in subjective memory complaints and cognitive function in the intervention group. Such improvements became evident at midintervention and persisted until the final follow-up, showing a medium-to-large effect size. Despite the qualitative feedback indicating self-perceived benefits, other outcomes did not consistently favor the intervention. Controlled for the baseline outcomes, small-to-medium effects ranging from 0.23 to 0.34 were observed in cognitive function for the between-group difference in midintervention and postintervention assessments. These findings are consistent with previous literature reporting small effects of 0.22 to 0.29 for dual-task training over control groups [37,38]. Nevertheless, inconsistent results were reported for other outcomes. Moreover, the fluctuation in the magnitude of the improvement was unexpected. Although possible self-practicing of the dual-task training after the intervention period might explain the increase in within-group improvement at the follow-up, the drop at the postintervention assessment was unexpected. There were factors that might have affected the evaluation. For example, engagement in the environment might influence achievement in relation to the effects of cognitive training [39], but the social context of the participants was not assessed. Another possibility might be COVID-19 infection, which might influence the performance of the participants not only during the infection period but afterward [40]. Moreover, some assessments could not be performed face-to-face but were conducted via Zoom; the different modes of data collection might have also influenced their performance. After the pandemic, a proper RCT should be conducted.

Meanwhile, within-group improvement was observed for the attention control group. The attention control condition consisted of a series of interactive health talks focusing on nutrition and food labeling. Participants memorized the contents delivered in each talk so they could answer the instructors' questions. Moreover, some participants had to learn to operate the Zoom platform as it was new to them. The learning process might also be beneficial to the participants, as some calculation was involved in comparing food labels using different units. In future trials, usual care control may be adopted.

Qualitative feedback highlighted the strength of the training regarding convenience, innovation, and comprehensiveness. In contrast, participants expressed a preference for in-person interactions. Hence, online training could be considered as a potential alternative or complement to traditional in-person training. Participants engaged in the training before receiving a cognitive impairment diagnosis, indicating that dual-task training could motivate early engagement in cognitive training. The facilitator leading the training does not necessarily be a health professional [20], and it is the engaging nature of the training, as revealed from the feedback, that the participants highly valued. This makes implementation of the intervention more feasible. Apart from the cognitive training, the participants also treasured social interactions and peer support during the class, and these further support the need to organize group-based training.

Implications

Dual-task training offers sufficient challenges to community-dwelling older adults; they found it interesting and reported that it boosted their motivation to participate in cognitive training. The contents of the training were comprehensive, covering motion, arithmetic operations, and verbal fluency. The training was conducted in a stimulating and recreational atmosphere, which was well received by the participants.

Online training offers the advantage of saving time and being convenient. However, it is not intended to replace traditional in-person training, as older adults generally prefer face-to-face interactions. Nonetheless, online training can be viewed as an alternative or complement to in-person sessions. Participants highlighted that organizing training twice a week in-person would be challenging, indicating a potential solution of combining one day of in-person training with one day of online training to maintain a twice-weekly training frequency. As older adults become more accustomed to online training, it can serve as a viable option during situations like a pandemic, enabling

training to continue even when older adult community centers are closed or during citywide quarantine measures.

When considering the implementation of in-person or hybrid mode training, it is essential to conduct research studies to assess their effectiveness. If in-person dual-task training is to be provided, incorporating more physical components could be beneficial. Similarly, any modified training approaches should undergo evaluation before being integrated into routine services. Future research studies could involve including a usual care control group or a waitlist control group to accurately determine the true impact of the training, building upon the improvement areas identified in this study. For instance, potential strategies for future interventions may involve implementing a 6-week intervention period, as some participants in the outcome evaluations exhibited positive effects as early as 6 weeks after the intervention; combining both in-person and online training modalities; and incorporating booster sessions. The exclusion criterion regarding engagement in any form of cognitive training 3 months before or during the study period may pose challenges once activities return to normal after the pandemic. Therefore, future trials should take a pragmatic approach, ensuring that any benefits derived from the intervention are in addition to participants' existing daily lifestyle routines.

Strengths and Limitations

The strength of this study included the integration of both quantitative and qualitative outcomes, which would reflect the feasibility and perceived benefits more holistically. The multiple outcome domains also helped to examine the potential effects more comprehensively. The multiple assessment points (4 time points) would facilitate the exploration of potential effects relative to the dosage of the intervention. The innovation components of the interventions were not restricted to the local context but could largely be applied to other regions.

Nevertheless, there were some limitations. The use of an attention control group might have limited the examination of potential effects from the intervention. Moreover, COVID-19 infection among the participants or their family members and the overall social environment during the study period were not documented, limiting the ability to control for the influences from these factors on the study outcomes. The cognitive domains assessed were limited to attention, verbal fluency, orientation, working memory, and executive function. Other cognitive domains, such as perceptual-motor control and social cognition, that might benefit from the intervention were not evaluated. User satisfaction was based on a self-developed question, and a validated scale could be considered in future. Owing to the nature of the feasibility study, the sample size was small, and a proper trial is needed in the future involving larger sample size.

Conclusions

Online dual-task training was shown to be a feasible intervention and was well received by older adults during the pandemic. Within-group improvement was observed in subjective memory complaints and cognitive function, with a medium-to-large effect size in the intervention group. Further investigation in a full-scale RCT is required to fully explore the intervention's potential effects.

Acknowledgments

This project was supported by the Health and Medical Research Fund (19200991) under the Food and Health Bureau of the government of the Hong Kong Special Administrative Region. The authors would like to thank the New Territories West Elder Academies Cluster and Hong Kong Sheng Kung Hui Welfare Council for their support and the older adults for their participation.

Abstract

Background: The utility of aging metrics that incorporate cognitive and physical function is not fully understood.

Objective: We aim to compare the predictive capacities of 3 distinct aging metrics—motoric cognitive risk syndrome (MCR), physio-cognitive decline syndrome (PCDS), and cognitive frailty (CF)—for incident dementia and all-cause mortality among community-dwelling older adults.

Methods: We used longitudinal data from waves 10-15 of the Health and Retirement Study. Cox proportional hazards regression analysis was employed to evaluate the effects of MCR, PCDS, and CF on incident all-cause dementia and mortality, controlling for socioeconomic and lifestyle factors, as well as medical comorbidities. Discrimination analysis was conducted to assess and compare the predictive accuracy of the 3 aging metrics.

Results: A total of 2367 older individuals aged 65 years and older, with no baseline prevalence of dementia or disability, were ultimately included. The prevalence rates of MCR, PCDS, and CF were 5.4%, 6.3%, and 1.3%, respectively. Over a decade-long follow-up period, 341 cases of dementia and 573 deaths were recorded. All 3 metrics were predictive of incident all-cause dementia and mortality when adjusting for multiple confounders, with variations in the strength of their associations (incident dementia: MCR odds ratio [OR] 1.90, 95% CI 1.30 - 2.78; CF 5.06, 95% CI 2.87 - 8.92; PCDS 3.35, 95% CI 2.44 - 4.58; mortality: MCR 1.60, 95% CI 1.17 - 2.19; CF 3.26, 95% CI 1.99 - 5.33; and PCDS 1.58, 95% CI 1.17 - 2.13). The C-index indicated that PCDS and MCR had the highest discriminatory accuracy for all-cause dementia and mortality, respectively.

Conclusions: Despite the inherent differences among the aging metrics that integrate cognitive and physical functions, they consistently identified risks of dementia and mortality. This underscores the importance of implementing targeted preventive strategies and intervention programs based on these metrics to enhance the overall quality of life and reduce premature deaths in aging populations.

Introduction

The aging process encompasses various physiological declines across multiple systems. As the global population ages, the prevalence of dementia is rising, expected to reach 131 million individuals by 2050. This increase poses a significant economic challenge, potentially equating to 1.1% of the global gross domestic product by 2030 [1]. The lack of curative treatments for dementia and its substantial public health impact underscore the necessity for early detection to mitigate or delay its onset. Given dementia's heterogeneous and lengthy preclinical phase, early screening and diagnosis in at-risk individuals are vital for disease management and caregiver preparedness [2].

Cognitive and physical declines with age often occur simultaneously, suggesting shared underlying mechanisms [3]. Researchers have developed metrics across molecular, phenotypic, and functional areas [4] to reflect the complex nature of aging accurately. Cognitive deterioration typically

precedes dementia by several years, with evidence indicating that motor decline, especially in walking speed, can precede cognitive decline by over a decade [5,6]. Thus, composite aging metrics, encompassing both physical and cognitive functions, offer a promising method to gauge the functional status of the aging population. A meta-analysis highlighted an increased dementia risk in individuals with both physical frailty and cognitive impairment compared to those with cognitive impairment alone [7]. Therefore, composite aging metrics may serve as focal points for interventions aimed at preventing or delaying disability onset and enhancing the healthy lifespan of the elderly [8,9].

An ideal dementia screening tool for primary care should be brief, easily administered, acceptable to older individuals, and exhibit high sensitivity and specificity. Research on aging metrics that incorporate both cognitive and physical functions is gaining traction in gerontological studies due to their strong predictive power for adverse health outcomes. Various metrics have been introduced, such as cognitive frailty (CF) [10], motoric cognitive risk syndrome (MCR) [11], and physio-cognitive decline syndrome (PCDS) [12]. Despite their conceptual similarities, detailed assessments of their definitions and attributes are scarce, hindering their application in research and clinical settings.

Research has shown an increased incidence of concurrent gait and cognitive impairments in older adults susceptible to dementia [5]; however, the specific clinical traits of those experiencing both declines are not well-defined, and direct comparisons between different aging metrics have not been made. Additionally, the effectiveness of these metrics in identifying at-risk individuals and assessing the risk of adverse health events within the same population is not well understood. This lack of knowledge is clinically important for effectively categorizing older adults and identifying potentially reversible conditions in individuals with concurrent declines, thereby informing targeted strategies to slow dementia progression or reduce mortality rates. Consequently, our study seeks to fill these voids by comparing the risk of future dementia and all-cause mortality across 3 aging metrics and examining the predictive abilities of MCR, PCDS, and CF for adverse events among community-dwelling older adults without dementia at baseline, employing data from a broad population-based cohort.

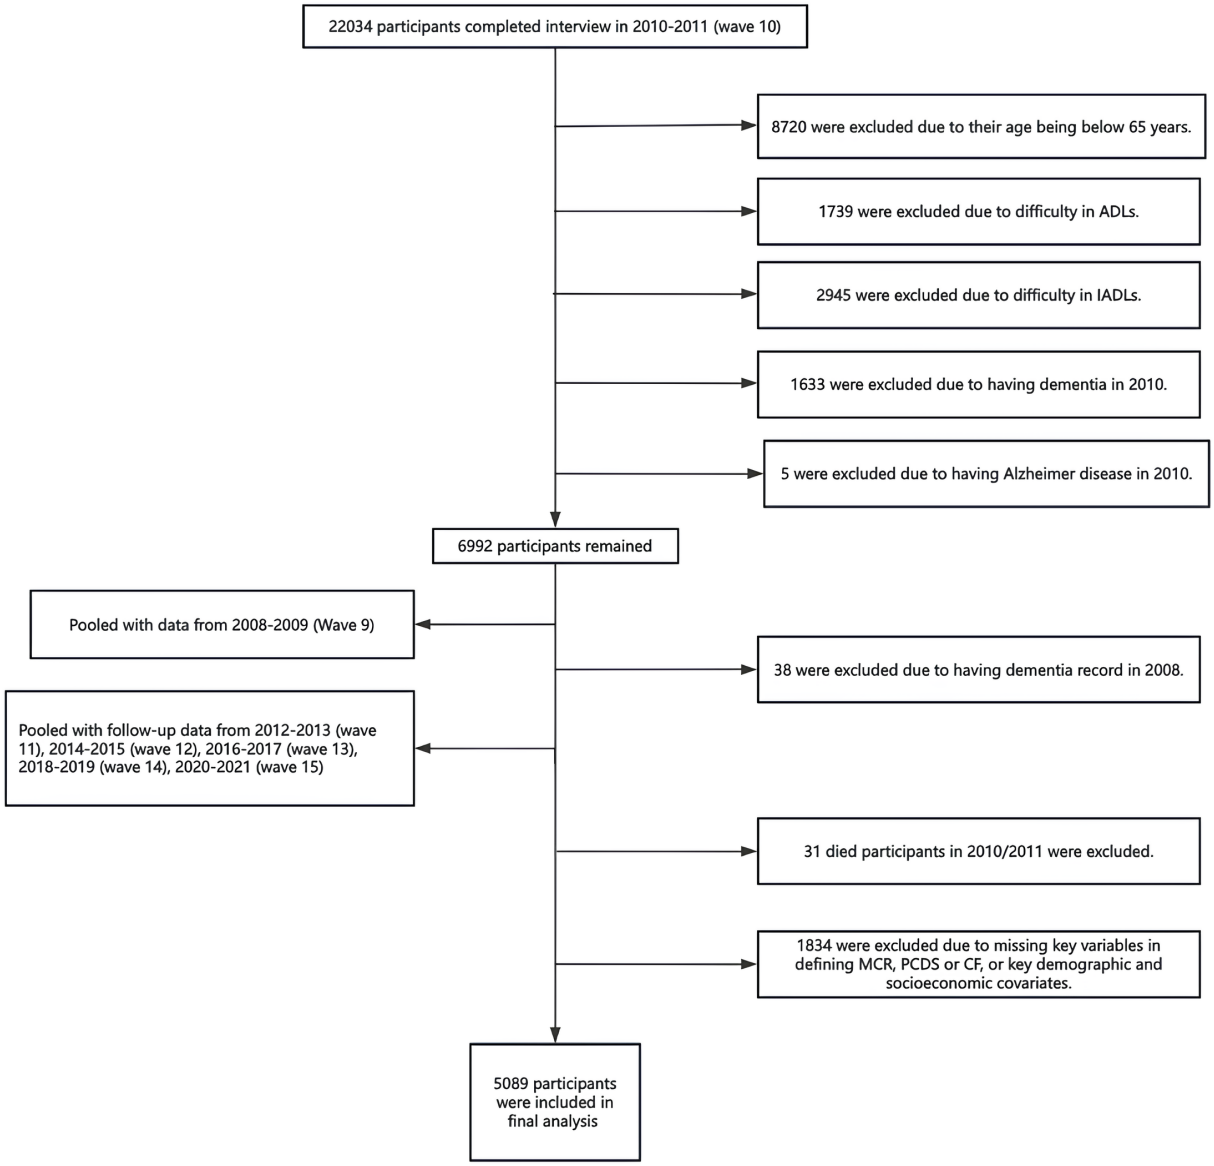
Methods

Sample

This study analyzes data from waves 10 - 15 of the Health and Retirement Study (HRS), the most extensive longitudinal study examining the aging experiences of Americans aged 51 and older. The HRS uses multi-stage probability sampling of U.S. households to obtain a nationally representative sample of adults in this age group [13]. It collects self-reported data on demographics, chronic health conditions, daily activities, disability status, and other health determinants at baseline and every 2 years thereafter. In 2006, the HRS began conducting enhanced face-to-face interviews that included physical performance assessments, biomarker collections, and a leave-behind questionnaire on psychosocial topics. Half of the households were chosen randomly for the enhanced interview in 2006, with the remainder selected in 2008, a process that continues in subsequent waves. Further information on the HRS's recruitment strategies and design is detailed in previous literature [13].

The baseline for this analysis combined data from the 2008 - 2009 (wave 9) and 2010 - 2011 (wave 10) waves, marking the initial occasion respondents were asked about diagnoses of Alzheimer disease or dementia, instead of a "memory-related disease." Mortality data has been available since 2011. A total of 22,034 individuals completed wave 10 and were followed biennially through to 2020 - 2021 (wave 15). This study is a secondary analysis of the de-identified HRS public data, and the original HRS was approved by the University of Michigan Institutional Review Board. All participants signed the informed consent at the time of participation. Our final sample consisted of 2372 individuals who (1) were 65 years or older, (2) had complete baseline data on MCR, PCDS, and CF measures, (3) reported no difficulty with any activities of daily living and instrumental activities of daily living at baseline, (4) did not have Alzheimer disease or dementia at baseline, and (5) were alive in 2010 and 2011. Figure 1 shows the participant flow through each selection stage according to the inclusion criteria.

Figure 1. Study flowchart of participant selection. ADL: activity of daily living; IADL: instrumental activity of daily living; CF: cognitive frailty; MCR: motoric cognitive risk syndrome; PCDS: physio-cognitive decline syndrome.



Measures

Cognitive Function

Biennial cognitive function tests were administered by trained HRS interviewers either in-person or via telephone using the Modified Telephone Interview for Cognitive Status (TICS-m), a global cognition test modeled on the Mini-Mental State Examination. The TICS-m comprises immediate and delayed 10-noun free recall tests (score range: 0 - 10 for each), a serial 7 subtraction test (score range: 0 - 5), and a test of counting backward from 20 (score range: 0 - 2). Higher scores denote better cognitive performance. During each assessment, HRS participants were categorized into normal cognition, mild cognitive impairment (MCI), or dementia based on established thresholds and comprehensive evaluations, including expert clinician adjudication from the Aging, Demographics, and Memory Study, a dementia sub-study within the HRS framework. Cognitive status was categorized into 3 distinct groups based on continuous scores [14], where scores from 12 to 27 indicated no impairment; scores between 7 and 11 signified cognitive impairment without dementia or MCI; and scores from 0 to 6 suggested dementia [15].

Motoric Cognitive Risk Syndrome

MCR was defined by subjective cognitive complaints coupled with slow gait in older adults who did not have a mobility disability or dementia [16]. In the HRS, gait speed (measured in meters per second) was determined from the time taken (in seconds) to walk a 2.5-meter course at a normal pace within participants' homes. A slow gait was defined as performance ≥1 SD below the mean for the participant's age and sex, a criterion previously used in HRS to identify MCR [17].

Subjective cognitive complaints were assessed using 2 questions: 1. "How would you rate your memory at the present time? Would you say it is excellent, very good, good, fair, or poor?" and 2. "Compared with the previous interview, would you say your memory is better now, about the same, or worse now than it was then?" Responses of 'fair' or 'poor' to the first question,

or 'worse' to the second, were considered indicative of cognitive complaints.

Cognitive Frailty

CF was defined as the co-occurrence of physical frailty and MCI [18]. The concept of frailty was identified using the 5 criteria outlined by Fried et al [19] in the Cardiovascular Health Study: unintended weight loss, physical inactivity, exhaustion, weakness, and reduced speed. Unintended weight loss is recognized as either a 10% or greater reduction in BMI since the last measurement in 2008 or a current BMI less than 18.5 kg/m^2. Physical activity levels were quantified by averaging the frequencies of activities at 3 levels of intensity—mild, moderate, and vigorous—weighted by the average metabolic equivalent of task (MET) scores for each intensity level: mild (1 - 3 MET), moderate (4 - 6 MET), and vigorous (7 - 10 MET). Participants were deemed physically inactive if their average physical activity fell within the lowest 20%. Exhaustion was determined based on responses to 2 questions from the Center for Epidemiologic Studies Depression scale [20], including, "I could not get going" and "I felt that everything I did was an effort." Muscle strength was assessed through the average of 2 grip strength measurements using a dynamometer on the dominant hand. Weakness was determined by grip strength falling below thresholds adjusted for BMI and gender, as established in the CHS. Reduced speed or slowness was defined as a speed <0.762 m/s for women taller than 159 cm or men taller than 173 cm and as <0.653 m/s for women 159 cm tall or less or men 173 cm tall or less, measured on a 2.5-m course [19,21]. Participants were considered to have missing data for physical measures if they were unable to perform the assessments due to the absence of suitable facilities or equipment or recent surgery. The diagnosis of frailty was based on the number of these criteria fulfilled, with those meeting 3-5 criteria classified as frail.

Physio-Cognitive Decline Syndrome

PCDS was defined as slowness or weakness (using cutoffs from the 2019 consensus update by the Asian Working Group for Sarcopenia), accompanied by cognitive performance that is at least 1.5 standard deviations below the mean for age-, sex-, and education-matched controls across all cognitive domains [12,22]. This assessment is based on comprehensive objective neuropsychological tests.

All-Cause Dementia and Mortality

The diagnosis of dementia was based on physician-diagnosed dementia and TICS scores ranging from 0 to 6. Mortality data were recorded, including the year and month of death, obtained from an exit interview or a spouse or partner's core interview.

Covariates

Covariates included sociodemographic factors, clinical characteristics, and health-related lifestyle behaviors, all of which were assessed at baseline. Sociodemographic characteristics included age (in years), sex (male or female), educational background (primary school or below, high school or equivalent, college and above), and marital status (married vs unmarried). Health-related lifestyle behaviors included excessive drinking, defined as more than 14 drinks per week for men and more than 7 drinks per week for women. Alcohol consumption was calculated by multiplying the number of days per week that alcohol (drink liquor or beer or wine or rice) was consumed by the number of drinks (liang or bottles or mugs) per day. Clinical characteristics included history of hypertension, diabetes, and heart disease. Hypertension was defined as systolic blood pressure ≥140 mm Hg, diastolic blood pressure ≥90 mm Hg, physical diagnosis, or antihypertensive medication use [23,24]. Diabetes was defined as having a diabetes diagnosis by a physician, being on treatment for diabetes, and having a fasting glucose level greater than or equal to 126 mg/dL and HbA_{1c} >6.5%. The presence of heart disease was determined via a physician's diagnosis obtained through an in-person visit with study personnel via a questionnaire.

Statistical Analysis

The incidence rates of all-cause dementia and mortality were calculated as the number of incident cases divided by the number of person-years of follow-up within the observation year (from 2008 to 2021). Differences between the MCR and non-MCR groups, PCDS and non-PCDS groups, and CF and non-CF groups were assessed using a 2-sided, independent *t*-test and the χ^2 test. To evaluate the impact of MCR, PCDS, and CF on the occurrence of all-cause dementia and mortality, we employed Cox proportional hazards regression analysis. The observation period extended from the index date to the earliest of the following: onset of dementia, death, or the conclusion of the observation period (December 31, 2018). Adjusted hazard ratios (AHRs) for MCR, PCDS, and CF in predicting the onset of dementia and all-cause mortality were calculated, accounting for covariates in an initially unadjusted model. Subsequent adjustments for covariates were made in 2 stages: Model 1 adjusted for age and gender; Model 2 further incorporated socioeconomic (education level and marital status), lifestyle (excessive drinking), and medical conditions (hypertension, diabetes, heart disease, and stroke). To assess and compare the predictive accuracy of all models, discrimination, defined by the model's ability to differentiate between individuals who develop dementia and those who do not, was quantified using Harrell C-statistic, taking survival into account.

Several sensitivity analyses were conducted to verify the stability of our findings. First, to focus on new cases and reduce reverse causation bias, individuals diagnosed with dementia or who died within 2 years of follow-up (sensitivity analysis I) were excluded. Second, to address the competing risk of death for dementia occurrences, Fine and Gray competing risk models were used [25], comparing these to the results from Cox proportional hazards regression models (sensitivity analysis II). The sub-distribution hazard function, defined at time *t*, represents the immediate risk of event *k* among individuals not previously experiencing event *k*. Third, to minimize selection bias, associations within individual samples with complete data on MCR, PCDS, and CF were analyzed separately (sensitivity analysis III). Statistical analyses were performed using 2-tailed tests with a significance level of $P<.05$ and 95% CIs, employing Stata (version 17) for all statistical procedures.

Ethical Considerations

This investigation has been conducted in accordance with the ethical standards of the Declaration of Helsinki, as well as national and international guidelines. The study has been approved by the Institutional Review Board at the University of Michigan (approval number: HUM00061128). All participants were provided with detailed information about the study, including its purpose, procedures, potential risks and benefits, and their rights to withdraw at any time. Written informed consent was obtained from all participants prior to their involvement in the study. To ensure privacy and confidentiality, all data collected were anonymized and deidentified. No identifying information was retained or published. Protective measures were in place to safeguard participant information, including secure storage of data and restricted access to study records. Participants were not compensated for their involvement in this study. The research was conducted on a voluntary basis, and no financial or other incentives were provided.

Results

Baseline Characteristics

The study participants' baseline characteristics are outlined in Table 1. The initial cohort comprised 2367 individuals, featuring prevalence rates for MCR, PCDS, and CF at 5.4% (n=121), 6.3% (n=140), and 1.3% (n=31), respectively. Among these, CF patients were the oldest on average (75.7, SD 6.1 years), with the distribution of men being 52.89% (64/121) in the MCR group, 47.14% (66/140) in the PCDS group, and 58.06% (10/31) in the CF group. During the follow-up, 573 (24.2%) patients died. The proportions of all-cause dementia for MCR, PCDS, and CF were 24.8% (30/121), 33.6% (47/140), and 41.9% (13/31), respectively.

Relationships of MCR, PCDS, and CF With Incident Dementia and All-Cause Mortality

Overall, there were 341 incident dementia cases during follow-up, for an overall incidence rate of 19.52 (95% CI 17.56-21.71) per 1000 person-years. There were 573 cases that died during follow-up, for an overall incidence rate of 30.14 (95% CI 27.77-32.71) per 1000 person-years (Table 2). The incidence rates of all-cause dementia among MCR, CF, and PCDS patients were 38.04, 108.11, and 55.80 per 1000 person-years, respectively—significantly higher than those observed in the relatively healthy control group. Similarly, the incidence rates of all-cause mortality were 47.99, 100.79, and 44.70 per 1000 person-years for MCR, CF, and PCDS patients, respectively—again, markedly higher than in the healthy controls. Table 2 also demonstrates significant associations of the 3 conditions with increased risks of incident dementia and all-cause mortality in various models (all *P* values <.001). CF had the highest AHR for both outcomes (5.06; 95% CI 2.87-8.92 for dementia, and 3.26; 95% CI 1.99 - 5.33 for mortality). Participants with dual decline experienced a two to threefold increased risk of dementia progression (AHR: 1.90 - 2.22 in the MCR group; 3.21 - 3.35 in the PCDS group) compared with those without dual decline. The AHR for all-cause mortality ranged from 1.60 to 1.84 in the MCR group and from 1.56 to 1.63 in the PCDS group. The trend was consistent across models: AHRs for dementia and mortality increased from the unadjusted model to adjusted model 1, then decreased upon further adjustment for covariates, including socioeconomic status, lifestyle factors, and medical comorbidities. Sensitivity analyses I (Table S1 in Multimedia Appendix 1) and III (Table S2 in Multimedia Appendix 1) consistently showed an elevated risk of dementia and mortality for MCR, CF, and PCDS. However, in sensitivity analysis II, the standardized hazard ratios for MCR and CF were not statistically significant post-adjustment (Table S3 in Multimedia Appendix 1).

Table . Associations between 3 aging metrics, incident all-cause dementia, and all-cause mortality.

	Total sample	MCR[a]		CF[b]		PCDS[c]

Discriminations of MCR, PCDS, and CF for All Outcomes

The discrimination abilities of MCR, PCDS, and CF regarding all-cause dementia and mortality are detailed in Table 3. The C-index for PCDS in identifying all-cause dementia was 0.732 (95% CI 0.703-0.760), outperforming the C-indices for MCR and CF (PCDS vs MCR: 0.012, 95% CI −0.001 to 0.025; *P*=.08; CF vs MCR: 0.005, 95% CI −0.004 to 0.013; *P*=.35). In contrast, MCR's C-index for identifying all-cause mortality was the highest among the 3, at 0.727 (95% CI 0.706-0.748). Similar to the case with incident dementia, the differences in discrimination ability among MCR, PCDS, and CF for all-cause mortality were not statistically significant.

Table . Harrell C-index for Cox regression models predicting incident all-cause dementia, and all-cause mortality.

	C-index[a]	95% CI	*P* value	Difference	*P* value
Incident all-cause dementia					
MCR[b]	0.7194	0.6915 to 0.7472	<.001	Reference	
PCDS[c]	0.7315	0.7028 to 0.7602	<.001	0.0121 (−0.0009 to 0.0252)	.08
CF[d]	0.7239	0.6959 to 0.7520	<.001	0.0046 (−0.0038 to 0.0129)	.35
All-cause mortality					
MCR	0.727	0.7061 to 0.7479	<.001	Reference	
PCDS	0.7259	0.7048 to 0.7469	<.001	−0.0012 (−0.0054 to 0.0030)	.59
CF	0.7254	0.7044 to 0.7465	<.001	−0.0016 (−0.0054 to 0.0022)	.41

[a]All indexes were estimated in models adjusted for age, gender, educational background, marital status, excessive drinking, hypertension, diabetes, and heart disease

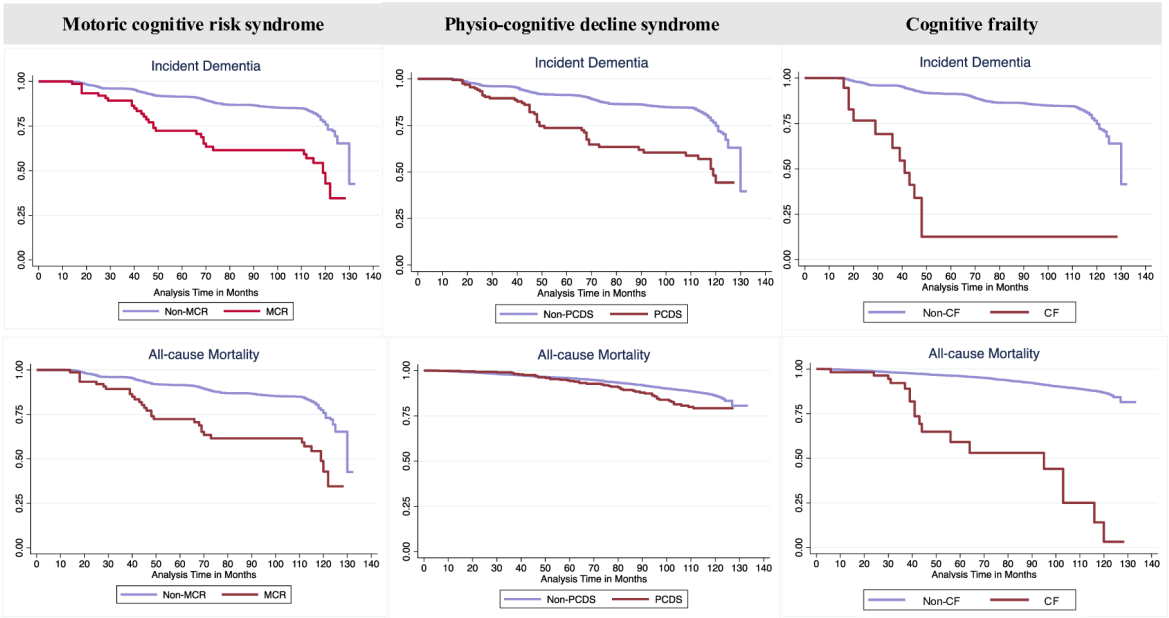
[b]MCR: motoric cognitive risk syndrome.

[c]PCDS: physio-cognitive decline syndrome.

[d]CF: cognitive frailty.

The Kaplan-Meier curve, depicted in Figure 2, shows the duration to incident dementia or all-cause mortality, stratified by MCR, PCDS, or CF, and healthy controls, with adjustments made for all covariates. Both curves demonstrate a decline over the follow-up period, with a notably pronounced decrease observed among patients (all *P* values for log rank <.001).

Figure 2. Kaplan-Meier survival curve depicting the proportion of participants remaining dementia-free or surviving during follow-up, comparing motoric cognitive risk syndrome (MCR), physio-cognitive decline syndrome (PCDS), and cognitive frailty (CF) patients with their respective healthy control groups.



Discussion

Principal Findings

Analyzing data from a large-scale cohort in the United States, this study is the first to illustrate that MCR, PCDS, and CF have significant associations with incident dementia and all-cause mortality within the same population, despite the inherent heterogeneity of these metrics. Among them, CF emerged as the highest-risk group for both dementia and mortality, with markedly elevated incidence rates and the highest AHRs (5.06 for dementia and 3.26 for mortality), identifying CF as the most vulnerable subgroup. These findings offer valuable insights into the future health trajectories of frail individuals with cognitive impairments and highlight the need for targeted interventions and early health education to mitigate dementia and mortality risks in later life at lower costs. While PCDS showed the strongest predictive ability for dementia and MCR for mortality, the differences in predictive accuracy were not statistically significant. Implementing appropriate management strategies can help alleviate the health care burden for individuals with varying cognitive and physical conditions.

To forestall unhealthy aging, health care systems need to identify individuals at risk of functional declines that are still preventable or reversible. Our results are in line with prior studies, indicating that MCR syndrome is linked with a 90% increased risk of incident dementia and a 60% higher risk of mortality, even after adjustments for demographics, SES, and cardiovascular comorbidities (hypertension, diabetes, and heart disease). Consistent with research from Chung et al, the prevalence of hypertension and heart disease was significantly higher in the MCR group, highlighting the importance of regular screening to manage cardiovascular risk factors and delay dementia onset [26,27]. These observations further emphasize the potential neurodegenerative nature of MCR pathologic changes [28].

CF has been associated with an increased risk of dementia and mortality, as demonstrated by a meta-analysis revealing that older adults with CF face higher mortality and dementia risks than their healthier counterparts [29]. However, the absence of a standardized assessment tool for CF hampers its use in widespread epidemiological studies. Using the frailty phenotype alongside the MMSE, although common, proves to be time-intensive and presents challenges for deployment in community and hospital settings [30]. Furthermore, the lower prevalence of CF compared to other measures (1.31% for CF vs 5.91% for PCDS vs 5.11% for MCR) in the community-dwelling older adult cohort indicates difficulties in identifying a substantial number of at-risk individuals for interventions in similar groups.

In contrast to CF, PCDS, with its precise definition encompassing physical decline and cognitive impairment, provides a more targeted approach. By focusing on the mobility aspects of frailty linked to worse cognitive outcomes and increased mortality risk, researchers can more accurately identify the target population, concentrating on specific causal mechanisms [31,32]. PCDS serves as an advantageous focus for multidomain interventions, integrating physical activity, cognitive training, nutritional counseling, and disease management education to improve the condition of vulnerable but potentially reversible older individuals [33]. A recent Singapore study that used a 12-week dual-task exercise program to examine the potential reversibility of CF, MCR, and PCDS also found clinical improvements in PCDS, but the longer-term effects remain uncertain [34]. Nonetheless, Lee et al [35] demonstrated that PCDS was related to a 6-year, but not 3-year, incidence of dementia, even when using inverse probability weighting analysis to account for bias from missing data. This finding implies a latency period for the development of dementia, highlighting this interval as potentially crucial for preventive interventions.

While PCDS demonstrated the best predictive performance for incident dementia, MCR emerged as a superior predictor for all-cause mortality. The choice between these 2 metrics may depend on practical considerations, with MCR offering several unique advantages for clinical use. MCR is simpler and more efficient to assess, unaffected by education levels or learning effects, which enhances its credibility and reliability as a screening tool. In contrast, the comprehensive cognitive assessments required for PCDS diagnosis can be labor-intensive and require specific skills, which may limit their use in community or primary care settings. Given MCR's higher predictive accuracy for all-cause mortality and its ease of implementation, it is well-suited for use in routine health care assessments, particularly in primary health care settings. Additionally, research suggests that while handgrip strength declines earlier in aging, walking speed in later life is a stronger predictor of mortality [36]. This further supports MCR's higher predictive accuracy for all-cause mortality.

Despite representing a prodromal phenotype of accelerated aging, MCR remains an important target for intervention to prevent poor outcomes in older adults. MCR offers incremental validity in predicting dementia beyond what is provided by MCI subtypes [16] and individual components such as subjective cognitive complaints or slow gait [16,37]. Our findings suggest that MCR could serve as a simpler, more efficient tool to identify individuals at higher risk for dementia, especially given its independence from educational background or learning effects. The motor components of MCR, such as the time-up-and-go test or one-leg-standing test, are reliable and valid methods for quantifying motor function, making MCR an easily implementable screening tool in various health care settings. However, one study has shown that the MCR subtype defined by the 5-times-sit-to-stand test, which also includes a balance component, was less effective in predicting cognitive decline compared to MCR defined by slow gait [38]. Further research is needed to determine how different gait and balance assessments influence the identification of individuals at risk for dementia, and whether integrating MCR into routine geriatric assessments could enhance early intervention strategies in aging populations.

Early and appropriate intervention might postpone the onset of dementia or reduce its risk, particularly given the lengthy incubation period associated with the development of dementia. Our results could aid clinicians in the early implementation of screening and prevention strategies and inform government decisions on community health prevention. The strength of this

study lies in its extensive, well-delineated cohort, featuring longitudinal assessments, uniform measures, and verified outcomes. To our knowledge, this is the first study to assess the predictive accuracy of MCR, PCDS, and CF regarding dementia incidence and all-cause mortality within the same cohort. The reliability and consistency of our findings, supported by sensitivity analyses, bolster the study's validity. Nonetheless, several limitations should be acknowledged. First, the study lacked objective neuropsychological testing [39] and did not account for some potential confounding factors, such as *APOE* genotype or imaging biomarkers [40,41]. However, our sensitivity analysis—excluding participants diagnosed with dementia or those who died within 2 years of the index date—strengthened the robustness of our conclusions. Second, while we used data from a large longitudinal cohort, the final sample size of 2372 individuals may limit the representativeness of our findings. Additionally, the prevalence rates of MCR (5.4%), PCDS (6.3%), and CF (1.3%) in our sample may be higher than those in the general older population, introducing potential selection bias. To address this, sensitivity analyses were conducted within individual subgroups with complete data on MCR, PCDS, and CF. These analyses included larger sample sizes and showed lower prevalence rates for the 3 conditions, aligning more closely with those observed in the general population. The robustness of these results further confirmed our conclusions, enhancing their validity and generalizability while mitigating potential selection bias. Future research could benefit from larger, more diverse, and representative samples to enhance generalizability. Third, the potential influence of mortality on dementia risk assessment must be considered. Individuals who died during follow-up could bias dementia outcome evaluations. To address this competing risk, we employed Fine and Gray competing risk models and compared the results with those from Cox proportional hazards regression models as part of our sensitivity analysis. This approach ensured that our findings remained robust and accounted for the impact of mortality on dementia risk associations. Finally, variations in syndrome definitions and differences in the prevalence of the 3 aging metrics within the population could affect their predictive power for adverse outcomes. This variability may limit the generalizability of our results to other populations. To mitigate this, sensitivity analyses within subgroups with complete data on MCR, PCDS, and CF were conducted, reinforcing the reliability of the associations between these aging metrics and adverse health outcomes.

Conclusions

The integration of cognitive and physical functions into aging metrics consistently indicates risks for incident dementia and all-cause mortality, despite their significant differences, underscoring their utility for effective risk stratification in research and clinical settings. Patients with CF represent the most vulnerable subgroup, highlighting the need for prioritized preventive strategies and interventions. Meanwhile, MCR emerged as a particularly efficient and accurate screening tool for both dementia and mortality. These findings emphasize the importance of implementing targeted prevention and intervention programs based on these metrics to enhance quality of life and reduce premature mortality among aging populations. Further research on the longitudinal dynamics of these aging metrics in relation to dementia, mortality, and other outcomes is essential for a deeper understanding of their long-term impact.

Abstract

Background: The number of centenarians worldwide is expected to increase dramatically, reaching 3.4 million by 2050 and >25 million by 2100. Despite these projections, depression remains a prevalent yet underdiagnosed and undertreated condition among this population that carries significant health risks.

Objective: This study aimed to identify and achieve consensus on the most representative signs and symptoms of depression in near-centenarians and centenarians (aged ≥95 years) through an e-Delphi study with an international and interdisciplinary panel of experts. Ultimately, the outcomes of this study might help create a screening instrument that is specifically designed for this unique population.

Methods: A modified e-Delphi study was carried out to achieve expert consensus on depressive symptoms in near-centenarians and centenarians. A panel of 28 international experts was recruited. Consensus was defined as 70% agreement on the relevance of each item. Data were collected through a web-based questionnaire over 3 rounds. Experts rated 104 items that were divided into 24 dimensions and 80 criteria to identify the most representative signs and symptoms of depression in this age group.

Results: The panel consisted of experts from various countries, including physicians with experience in old age psychiatry or geriatrics as well as nurses and psychologists. The response rate remained consistent over the rounds (20/28, 71% to 21/28, 75%). In total, 4 new dimensions and 8 new criteria were proposed by the experts, and consensus was reached on 86% (24/28) of the dimensions and 80% (70/88) of the criteria. The most consensual potentially relevant dimensions were *lack of hope* (21/21, 100%), *loss of interest* (27/28, 96%), *lack of reactivity to pleasant events* (27/28, 96%), *depressed mood* (26/28, 93%), and *previous episodes of depression or diagnosed depression* (19/21, 90%). In addition, the most consensual potentially relevant criteria were *despondency, gloom, and despair* (25/25, 100%); *depressed* (27/27, 100%); *lack of reactivity to pleasant events or circumstances* (28/28, 100%); *suicidal ideation* (28/28, 100%); *suicide attempt(s)* (28/28, 100%); *ruminations* (27/28, 96%); *recurrent thoughts of death or suicide* (27/28, 96%); *feelings of worthlessness* (25/26, 96%); *critical life events* (20/21, 95%); *anhedonia* (20/21, 95%); *loss of interest in activities* (26/28, 93%); *loss of pleasure in activities* (26/28, 93%); and *sadness* (24/26, 92%). Moreover, when assessing depression in very old age, the duration, number, frequency, and severity of signs and symptoms should also be considered, as evidenced by the high expert agreement.

Conclusions: The classification of most elements as *relevant* highlights the importance of a multidimensional approach for optimal depression screening among individuals of very old age. This study offers a first step toward improving depression assessment in near-centenarians and centenarians. The development of a more adapted screening tool could improve early detection and intervention, enhancing the quality of mental health care for this population.

Introduction

Background

The centenarian population is growing significantly and is projected to increase sharply in the coming decades. As of 2024, there were approximately 722,000 centenarians worldwide, with Japan, the United States, and China having the highest numbers [1]. This figure is expected to rise to 3.4 million by 2050 and exceed 25 million by 2100 [2,3]. In Europe, notable examples include France, Italy, and Greece, each with >20 centenarians per 100,000 inhabitants registered already in 2011. Portugal also stands out with a density of 14.4 centenarians per 100,000 inhabitants that same year, ranking it among the top 15 in Europe [4]. In Switzerland, the centenarian population more than doubled from 787 in 2000 to 1948 in 2022, reaching a noteworthy prevalence of 22.1 per 100,000 inhabitants [5].

Amid extreme longevity, individuals' health experiences vary significantly, from robust health to substantial declines [6-8]. Depression, a prevalent mood disorder among older adults [9], emerges as a major public health concern [10]. The *International Classification of Diseases, 11th Revision* characterizes a depressive episode as "a period of depressed mood or diminished interest in activities occurring most of the day, nearly every day during a period lasting at least two weeks accompanied by other symptoms such as difficulty concentrating, feelings of worthlessness or excessive or inappropriate guilt, hopelessness, recurrent thoughts of death or suicide, changes in appetite or sleep, psychomotor agitation or retardation, and reduced energy or fatigue" [6]. However, this definition broadly encompasses the general population and may not fully address the possible difference and heterogeneity of depressive symptomatology in older adults, potentially leading to diagnostic imprecision.

Accurate diagnosis is crucial as depression should not be misconstrued as an inherent aspect of aging even in very advanced age [11,12]. A systematic literature review reported substantial variations in depression prevalence among near-centenarians and centenarians across countries, such as 12.8% in Italy, 13.5% in Australia, 20% in the United States, and 29% in Mexico [13]. These differences may reflect cultural, health care, and socioeconomic influences as well as methodological variations in study conduct [13,14]. Interestingly, comparisons between centenarian cohorts and younger groups have shown inconsistent findings, with half of the studies reporting higher rates of depressive symptoms among centenarians [13]. This highlights the diversity of aging experiences and suggests that mental health may not necessarily worsen with age. Particularly noteworthy are the findings from Sweden, where near-centenarians and centenarians exhibited almost double the depression rates of older adults aged 85 years at 32.3% versus 16.8%, respectively. These statistics highlight the need not only for careful mental health evaluations among individuals of very old age but also for prompt discussion on tailored approaches to support mental well-being in this population [13,15].

Depression can lead to severe physical, cognitive, and psychological effects. Physically, it can cause malnutrition, falls, delirium, functional decline, and increased mortality [13,16-20]. Cognitively, depression has been connected to cognitive decline and dementia [21-25]. Psychologically, it has been associated with anxiety and suicidal ideation [26,27]. Furthermore, depression places a significant burden on caregivers and health care systems [16-18,28,29], increasing costs and resource demands. These consequences underscore the critical need for early detection and intervention. Therefore, proactive measures such as regular mental health screenings are essential to prevent the severe impact of depression on individuals' quality of life and alleviate its wider societal effects [11]; however, these are not part of the current practice in most countries worldwide.

Addressing this gap in care is difficult as depression in older adults frequently remains underdiagnosed and undertreated, in part because its manifestations are often misinterpreted as natural aspects of aging [18,19,30,31]. Studies have estimated that approximately half of depression cases are not identified by frontline health care providers [16,18], and of those detected, approximately half do not receive adequate treatment [16]. The challenge in detecting late-life depression (LLD) stems from its sometimes subtle, hidden, or atypical signs and symptoms [30,32]. Physical manifestations such as weight loss, psychomotor retardation, and exhaustion, as well as emotional manifestations such as loss of interest in activities, heightened anxiety, or irritability, might overshadow the typical sadness often associated with depression [9,18]. This complexity requires greater clinical vigilance. Moreover, the possible overlap of symptoms between depression and dementia adds another layer of diagnostic difficulty as both conditions can present with symptoms such as memory impairment, psychomotor retardation, and reduced motivation [9]. Beyond dementia, several other medical conditions can mimic or exacerbate depressive symptoms. Chronic pain, thyroid dysfunction, Parkinson disease, stroke, and medication side effects—particularly in polymedicated individuals—can contribute to *depression-like* symptoms, including fatigue, apathy, functional dependence, memory impairment, and

disturbances in mood and sleep [33-38]. These overlapping symptoms underscore the need for a comprehensive assessment to distinguish LLD from other conditions, aiming for an accurate differential diagnosis. The wide range of signs and symptoms associated with LLD can extend beyond the conventional diagnostic criteria for depressive disorders. Symptom clusters not fully meeting the diagnostic criteria for depression may still carry significant clinical importance due to their link to reduced quality of life and increased disability [9,18].

Objectives

Given the prevalence of depression among individuals of very old age, better detection of early signs and symptoms is crucial. However, despite the availability of various screening tools, to the best of our knowledge, none have been specifically validated for near-centenarians and centenarians (aged ≥95 years). Therefore, our study aimed to compile a comprehensive range of potentially relevant depressive features that have been documented in scientific literature. These features were then submitted to an international panel of experts to achieve consensus on the most representative signs and symptoms of depression in individuals of very old age. The outcomes of this approach are 2-fold. First, by systematically examining and integrating diverse diagnostic criteria and screening tools, this study aimed to contribute to the ongoing debate about the complexities and challenges of effectively diagnosing depression in individuals of very old age. Second, achieving expert consensus is central to developing a new screening instrument specifically tailored to this unique population. This effort might be an important first step toward early detection and effective intervention, which might lead to better outcomes and enhanced general well-being for this age group, and seeks to contribute to promoting mental health and supporting optimal care for individuals of very old age.

Methods

Study Design

We conducted a modified e-Delphi study to systematically combine expert opinions and achieve an informed group consensus on the symptomatology of depression in very old age. The Delphi technique is an established approach in which a panel of experts is asked to provide their opinions on a given issue over the course of several rounds [39]. In each round, the questions are informed by the findings of the previous one, allowing the study to evolve over time based on the collected data [39].

Given the prevalence of depression among older adults and the complexities of its diagnosis, the Delphi technique is particularly useful for gathering expert consensus on this issue. In our study, we used an e-Delphi approach to involve experts from different locations and facilitate efficient data collection through electronic communication methods. To adapt the traditional Delphi approach to the specific requirements of our study, we implemented several modifications (referred to as a *modified e-Delphi study*). To keep the focus on the items rather than on the degree of agreement, experts were informed at the start of each new round about which items had reached consensus without being given the precise consensus rates. In addition, for items on which consensus had already been reached, experts were unable to review their previous responses. This decision was made to avoid revisiting settled issues and manage the large number of items efficiently, ensuring the stability of agreed-upon elements. An additional aspect of our modified methodology was a final evaluation of open issues by the steering committee. This last step took place to discuss the items that had not achieved consensus over the e-Delphi rounds, ensuring a thorough examination of these elements.

The materials presented to the e-Delphi panel were based on a comprehensive analysis of the existing literature on depression in very old age (personal communication by Gomes da Rocha et al, 2023). This ensured that the expert panel's input was based on a thorough understanding of the relevant literature, thereby enhancing the validity of the final consensus, which may be seen as a lever to encourage scientific debate and foster new developments toward an effective diagnosis of depression in very old age [40].

This study adhered to the Conducting and Reporting Delphi Studies guidelines [41,42].

Steering Committee

The steering committee for this e-Delphi study based in Western Switzerland comprised 4 members: 2 physicians who are old age psychiatrists and senior researchers (AvG and PV), 1 clinical nurse specialist in geriatric care and a senior researcher skilled in the e-Delphi technique (HV), and 1 clinical nurse specialist in geriatric care who is also a junior researcher (CGdR). The committee was responsible for overseeing the study design, ensuring ethical compliance, and guiding the iterative process of questionnaire refinement and consensus building. Meetings were held monthly, with methodological decisions made based on discussion. The committee played a crucial role in maintaining the study's rigor, managing data collection and analysis, and addressing any lack of consensus among panelists.

Selection of Experts

In the Delphi approach, nonprobability sampling methods are used through the purposive selection of an expert panel. However, clear selection criteria were applied to limit researcher bias based on a five-step procedure [43]:

1. *Identifying the most appropriate categories of experts for the panel:* we identified experts from 3 main professional categories—physicians, nurses, and psychologists—each with a minimum of 5 years of professional experience and competencies in LLD. These professionals were selected for their specific work experience or contact with individuals of very old age in clinical, research, or teaching domains within the fields of old age psychiatry or geriatrics. In addition, our recruitment strategy aimed for a broad geographical representation by including experts from various continents (ie, Asia, Australia, Europe, and North America) to enrich the panel with diverse perspectives and, thereby, enhance the global view on depression screening among individuals of very old age.
2. *Identifying experts:* names were compiled from various sources, including previous research involvement, publications on the subject, professional email lists,

professional associations or societies, and boards of professional organizations. This method aimed to create a list of potential panelists recognized for their expertise and contributions to the field that was as comprehensive as possible.

3. *Contacting some readily reachable experts from each professional category to nominate other experts:* initial contact was made with experts who were easily accessible. These experts were then asked to nominate additional professionals whom they believed could contribute valuable insights to the study, thereby using a snowball sampling technique to ensure a wide and diverse pool of expertise.
4. *Creating sublists for each professional category and ranking experts based on specific criteria:* experts were organized into sublists by professional category and ranked according to their representation of professional role or specialty and their field of practice. This was a strategic approach intended to foster a diverse and balanced panel that reflects a broad spectrum of experiences and viewpoints, contributing to the robustness and credibility of the consensus process.
5. *Inviting the experts.*

The Delphi method offers no consensus on an ideal sample size as the focus is on qualitative depth and the use of expert judgment for a comprehensive exploration of specific topics rather than on statistical representativeness [44]. Usually, a panel comprises 7 to 15 experts to facilitate effective information processing and decision-making; however, some studies may involve up to 30 experts for broader perspectives [44]. For our study, we aimed to assemble a convenience sample of at least 20 experts from various countries.

Recruitment Procedure

On the basis of the predefined selection of potential panelists, we emailed invitation letters to a total of 84 experts. These letters outlined the study's objectives, described the e-Delphi context, detailed the questionnaire (eg, language, type of questions, and estimated completion time), and clarified what was expected from the participants, ensuring that they understood the significance of their contributions to the study. Interested parties could access the questionnaire through a direct URL to the survey. Anticipating a 25% to 30% response rate for the first-round questionnaire, we expected approximately 20 to 25 experts to participate. We aimed to retain these experts across all subsequent rounds, planning for a maximum of 4 rounds.

Data Collection Procedures

The SurveyMonkey tool (SurveyMonkey Inc) was used as the survey software as it facilitates secure and efficient data collection. In accordance with literature recommendations [43], each e-Delphi round remained open for a minimum of 4 weeks, during which up to 3 automatic reminder emails were dispatched to nonrespondents. At the start of each new round, experts were provided access to the overall results from the previous round, including a list of items for which consensus was either *achieved* (≥70% agreement) or *not achieved* (<70% agreement) [43]. The items that did not reach consensus were integrated into the current round for further deliberation, along with any new items that emerged from panel suggestions through open-ended questions.

Measures

The questionnaire was divided into 3 sections.

e-Delphi Section

This section aimed to achieve consensus on the topic under study and consisted of 104 items. These were divided into 24 dimensions (eg, *impaired concentration* and *lack of hope*) and 80 criteria (eg, *impaired ability to think or concentrate* and *hopelessness*), which experts rated according to their relevance using a Likert scale from 1 (*Not relevant*) to 4 (*Very relevant*). Experts also had the possibility to comment on their answers and suggest additional items that they considered relevant to the topic for subsequent rounds.

In addition to rating the relevance of each item, experts were asked to indicate the most suitable type of assessment for each criterion: self-assessment, hetero-assessment, or both. This was intended to identify preferred methods of assessing potential depressive signs and symptoms. The aim was not to achieve a stringent consensus of 70% as with the relevance ratings but to capture a broad spectrum of expert opinions on assessment approaches.

The initial selection of 104 items was based on a comprehensive review of existing instruments widely used in research to screen for and evaluate depressive signs and symptoms among near-centenarians and centenarians [13] supplemented by additional insights from recent analysis (personal communication by Gomes da Rocha et al, 2023). We started with all items available in these measures to be as comprehensive as possible. These instruments included self-assessment tools such as the Geriatric Depression Scale–30 [45], the Center for Epidemiologic Studies Depression Scale [46], the depression-related items from the Brief Symptom Inventory [47], and the Hospital Anxiety and Depression Scale [48], as well as the Montgomery-Åsberg Depression Rating Scale [49], which is administered by a professional rater. Furthermore, given the significant prevalence of neurocognitive disorders in our aging population and the need for reliable assessment of depressive symptoms in individuals with cognitive impairments, we also considered instruments specifically designed for such assessments: the Cornell Scale for Depression in Dementia [50,51] and the depression section of the Neuropsychiatric Inventory [52,53]. In addition, we included the *International Classification of Diseases, 11th Revision* and the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition* diagnostic criteria to anchor our selections in the gold standards for depression diagnosis [6,54]. To complete the pool of items, the Depression Rating Scale from the Resident Assessment Instrument was also retained given its widespread use among adults of old and very old age in diverse settings, such as private homes (Resident Assessment Instrument–Home Care) or long-term care facilities (Resident Assessment Instrument–Long-Term Care Facilities) [17,55-57]. After compiling all items from the selected instruments, we checked for overlap and excluded identical items, which led to the final selection of 104 items. For instance, items such as "Do you feel

that your situation is hopeless?" from the Geriatric Depression Scale–30 and "Feeling hopeless about the future" from the Brief Symptom Inventory necessitated thematic grouping under a unified dimension (*Lack of Hope* in this example). This process enabled us to construct more general items designated as *dimensions* that reflected the essence of the criteria within each group, thereby streamlining the questionnaire without compromising the depth of depressive symptom screening. The list of all selected instruments and original items can be found in Multimedia Appendix 1.

In summary, this strategic selection of items aimed to cover a broad spectrum of relevant criteria for the screening of depressive signs and symptoms, ensuring the questionnaire's comprehensive scope and its applicability to adults of very old age with varying levels of cognitive functioning.

Sociodemographic and Professional Characteristics

This section included questions designed to capture the sociodemographic and professional characteristics of the panelists in round 1, including age, gender, nationality, profession, years of professional experience, and their country and field of practice. In subsequent rounds, only essential information (age, gender, nationality, and profession) was collected to ensure continuity and to accurately link responses from the same panelists across all rounds.

Contact With Individuals of Very Old Age

Although this could be considered part of professional characterization, this section specifically gathered information on the frequency of the panelists' experiences or interactions with individuals of very old age (aged ≥85 and ≥95 years). It was specific to the first round, aiming to inform the context of their responses. While this study's target population was defined as near-centenarians and centenarians (≥95 years), there is only a limited number of experts focusing on this exact population. However, most experts working with individuals aged ≥85 years have regular contact with near-centenarians and centenarians. Thus, these experts were also invited provided that they felt confident in drawing on their experiences and perceptions relevant to the population aged ≥95 years.

Pretest

Before launching round 1, the questionnaire was pretested with a small purposive sample of 5 professionals (nurses, psychologists, and a physician) to verify its clarity and comprehensibility, with only a minor adjustment made based on 1 expert's suggestion to include specific examples for certain items. Despite the positive outcomes of the pretest, experts were invited to rate the questionnaire at the end of round 1 for comprehensiveness, readability, and clarity.

Overall, 93% (26/28) of the experts participating in round 1 rated the questionnaire as *Comprehensive* or *Very comprehensive*, and 86% (24/28) found it *Easy* or *Very easy* to read and understand. Due to this positive feedback, no further structural adjustments were implemented before proceeding to the subsequent rounds.

Data Analysis

Data collected via SurveyMonkey were transferred to a Microsoft Excel spreadsheet (Microsoft Corp) and examined for any potential errors or missing data. They were then imported into the SPSS Statistics software (version 29.0; IBM Corp) for analysis [58]. Descriptive statistics were computed to characterize the panel from a sociodemographic and professional perspective using means and SDs as well as medians and interquartile ranges for quantitative variables and frequency distributions and percentages for qualitative variables. The level of agreement among experts required to achieve consensus on a given item was set at 70% for each round. This threshold is commonly used in Delphi studies [59-61] as it allows for the inclusion of minority viewpoints in the early rounds, ensuring that diverse perspectives are considered before achieving final consensus. This is particularly relevant in the context of depressive symptom screening given the challenges associated with detecting LLD, as previously mentioned. Hence, this consensus rate is considered acceptable for preserving methodological rigor, as supported by the literature [43], which indicates that such a threshold aligns with norms for ensuring reliability and validity in the context of an iterative, consensus-building approach. The consensus rate for each item was calculated using a 4-level Likert scale (1=*Not relevant*, 2=*Somewhat relevant*, 3=*Relevant*, and 4=*Very relevant*). In the first step, these responses were recoded into 2 levels: values of 1 and 2 were recoded as "0" (*Overall not relevant*), and values of 3 and 4 were recoded as "1" (*Overall relevant*). Next, we aggregated the recoded responses for each item to determine consensus, which was achieved when the percentage of experts identifying an item as *Overall relevant* or *Overall not relevant* met or exceeded the predefined threshold of 70%.

After the first e-Delphi round, items that did not reach the consensus level were carried forward to the subsequent round. At the beginning of each subsequent round, experts were given the opportunity to review the general outcomes from the previous round (ie, *consensus achieved* or *consensus not achieved* for each evaluated item). Items that achieved consensus were not included again in subsequent rounds. After conducting 3 rounds with the participating panel and observing only limited changes in the consensus rate after the third round, we decided to proceed with the last round, which involved a final evaluation of unresolved aspects by the steering committee. This last step aimed to gain a deeper understanding of the reasoning behind the outcomes and further refine the consensus process. Items that still did not achieve consensus after the 3 e-Delphi rounds were thoroughly examined during this phase.

Ethical Considerations

The Ethics Commission on Human Research of the Canton of Vaud was consulted and confirmed that this project fell outside the scope of the Swiss Human Research Act (Req-2023-00844; Multimedia Appendix 2) as the study did not involve the collection of health-related personal data or biological material.

All participants received detailed information about the study, including its aim and relevance, what to expect, a description of the questionnaire, instructions for participation, and contact information for the main researcher, along with the invitation

email. The questionnaires for all rounds (1, 2, and 3) included an introductory section emphasizing the voluntary nature of participation in the study, as well as specific information regarding confidentiality, data protection, risks, and benefits and a statement on ethical considerations. Participants were explicitly informed that, by answering the questionnaire, they were implicitly providing consent to take part in the study. They did not receive any compensation for their participation. Each participant received a survey link for accessing the questionnaire, and their IP addresses were not recorded to ensure confidentiality. The collected data were deidentified, with no personal identifiers retained. Responses stored on SurveyMonkey were deleted after transferring the data to the Microsoft Excel spreadsheet. All data are securely stored on a password-protected institutional server to comply with Swiss data protection regulations and will be definitively deleted after 5 years.

Results

Expert Participation and Sociodemographic and Professional Characteristics

A total of 84 experts were invited to this modified e-Delphi study. Of these 84 experts, 28 (33%) participated in the first round, forming the baseline panel. This group (n=28) was consequently invited to the second and third rounds, for which the participation rates were 75% (21/28) and 71% (20/28), respectively.

The panel exhibited sociodemographic and professional diversity, including different nationalities, professions, and fields of practice. The average age ranged slightly between 44.1 (SD 10.6) and 46.7 (SD 11.4) years over the rounds. A majority of women participated in the first and second rounds (17/28, 61% and 13/21, 62%, respectively), whereas men were more prevalent in the third round (11/20, 55%). Swiss and Portuguese nationalities were the most represented (12/20, 60% to 18/28, 64%), with the nursing profession being predominant (9/20, 45% to 12/21, 57%), followed by the medical profession (5/21, 24% to 8/20, 40%). The average professional experience was 19.4 (SD 8-9) years, with nearly 80% (22/28, 79%) of the experts being engaged in purely clinical activities or a combination of clinical and academic activities, among others (eg, service organization). More than 80% (23/28, 82%) reported having regular or very regular contact (daily, weekly, or monthly) with individuals aged ≥85 years, and 75% (21/28) reported having regular or very regular contact with individuals aged ≥95 years (Table 1).

[e]One expert commented the following: "Not yearly, but once in a while."

Questionnaire Completion Times

The completion dates and the mean time taken for participants to complete the questionnaires in each round are summarized in Table 2. Globally, the e-Delphi rounds took place between August 2023 and February 2024, with an overall weighted mean completion time of 16 minutes and 40 seconds (SD 11 min and 27 s).

Table 2. Summary of overall consensus achievements across e-Delphi rounds regarding potential dimensions and criteria for depression screening.

	Questionnaire completion dates	Questionnaire completion time, mean (SD)	Dimensions analyzed	Consensus achieved (dimensions), n (%)	Consensus not achieved (dimensions), n (%)	New dimensions proposed	Criteria analyzed	Consensus achieved (criteria), n (%)	Consensus not achieved (criteria), n (%)	New criteria proposed

Overall Consensus Achievements

A consensus threshold of ≥70% was established for both dimensions and criteria, as previously described.

Depression Screening: Potentially Relevant Dimensions

In round 1, experts assessed 24 dimensions, reaching consensus on 13 (54%). In addition, 4 new dimensions were suggested by the experts and incorporated in round 2: *underlying cognitive disorder* (dimension 25), *previous episodes of depression or diagnosed depression* (dimension 26), *personal care (eg, poor hygiene)* (dimension 27), and *language/speech (eg, poor speech)* (dimension 28). Thus, 15 dimensions (n=11, 73% without consensus and n=4, 27% new proposals) were reassessed in round 2, with consensus achieved on 10 (67%). In round 3, a total of 5 dimensions were revisited, with consensus reached on only 1 (20%; Table 2).

Table 3 summarizes the consensus rates for the 28 dimensions assessed across the 3 e-Delphi rounds. A total of 14% (4/28) of the dimensions failed to reach the ≥70% consensus threshold: memory problems (dimension 21), mood-congruent delusions (dimension 22), reduced adaptation capacity (dimension 24), and language/speech (eg, poor speech) (dimension 28)—the only newly suggested dimension without consensus. Of the dimensions on which consensus was achieved, all were considered relevant for screening for depression in individuals aged ≥95 years except for increased appetite (dimension 8), which was deemed not relevant. Notably, several relevant dimensions reached ≥90% consensus: lack of hope (dimension 20; 21/21, 100%), loss of interest (dimension 4; 27/28, 96%), lack of reactivity to pleasant events (dimension 5; 27/28, 96%), depressed mood (dimension 1; 26/28, 93%), and previous episodes of depression or diagnosed depression (dimension 26; 19/21, 90%).

Figure S1 in Multimedia Appendix 3 provides an overview of the consensus rates for the potentially relevant dimensions for depression screening.

Table 3. Consensus level on potential dimensions for depression screening[a].

	Round 1 (n=28)			Round 2 (n=21)			Round 3 (n=20)		
	Level of consensus at ≥70%	Result	Participants, n (%)	Level of consensus at ≥70%	Result	Participants, n (%)	Level of consensus at ≥70%	Result	Participants, n (%)

Depression Screening: Potentially Relevant Criteria

In round 1, a total of 80 criteria were assessed, with consensus reached on 49 (61%). In addition, 8 new criteria emerged from suggestions by the panel and were incorporated in round 2: *critical life events (eg, loss of a child or another loved one)* (criterion 81), *emotional indifference* (criterion 82), *anhedonia* (criterion 83), *afraid of being alone* (criterion 84), *resurfacing of "old wounds" (eg, long-standing conflicts with children)* (criterion 85), *feeling of accomplishment throughout life* (criterion 86), *closeness with family and significant others* (criterion 87), and *subjective health* (criterion 88). As a result, 39 criteria (n=31, 79% without consensus and n=8, 21% new proposals) were reassessed in round 2, with consensus achieved on 12 (31%). In round 3, a total of 27 criteria were revisited, with consensus reached on 9 (33%; Table 2).

The consensus rates for the 88 criteria assessed across the 3 e-Delphi rounds are presented in Multimedia Appendix 4. In total, 20% (18/88) of the criteria failed to reach the ≥70% consensus threshold: *easily annoyed* (criterion 20); *short-tempered* (criterion 21); *staying home instead of going out and doing new things* (criterion 26); *psychomotor agitation* (criterion 29); *significant unintentional weight gain (more than 5% in a month)* (criterion 33); *restless sleep* (criterion 35); *full of energy* (criterion 42); *feels as good as other people* (criterion 51); *pessimism* (criterion 52); *thinks most people are better off than him/her* (criterion 56); *finding life exciting, wonderful, and enjoyable* (criterion 58); *getting bored often* (criterion 62); *feeling fearful* (criterion 64); *feeling that people are unfriendly or dislike him/her* (criterion 66); *memory problems* (criterion 69); *the mind is as clear as it used to be* (criterion 70); *having a sense of direction and purpose in life* (criterion 79); and *afraid of being alone* (criterion 84)—the only newly suggested criterion without consensus. Of the criteria on which consensus was achieved, all were considered *relevant* for screening for depression in individuals aged ≥95 years except for *hard to get started on new projects* (criterion 28), *fear of dying* (criterion 75), and *sufficient financial resources* (criterion 77), which were considered *not relevant*. Notably, several *relevant* criteria reached a ≥90% consensus: *despondency, gloom, and despair* (criterion 5; 25/25, 100%); *depressed* (criterion 6; 27/27, 100%); *lack of reactivity to pleasant events or circumstances* (criterion 25; 28/28, 100%); *suicidal ideation* (criterion 45; 28/28, 100%); *suicide attempt(s)* (criterion 46; 28/28, 100%); *ruminations* (criterion 14; 27/28, 96%); *recurrent thoughts of death or suicide* (criterion 43; 27/28, 96%); *feelings of worthlessness* (criterion 47; 25/26, 96%); *critical life events* (criterion 81; 20/21, 95%); *anhedonia* (criterion 83; 20/21, 95%); *loss of interest in activities* (criterion 23; 26/28, 93%); *loss of pleasure in activities* (criterion 24; 26/28, 93%); and *sadness* (criterion 4; 24/26, 92%).

Figure S2 in Multimedia Appendix 3 provides an overview of the consensus rates for the potentially relevant criteria for depression screening.

Signs and Symptoms of Depression: Duration, Number, Frequency, and Severity

In round 1, experts (n=28) were asked about the importance of considering the duration of depressive signs or symptoms in addition to their presence. It is important to note that, for the purpose of this assessment, they were instructed not to consider *suicidal thoughts or ideation* as these require immediate attention and, thus, were deliberately excluded from the duration criteria. All participants (28/28, 100%) agreed on its importance. When specifically asked about the minimum duration for considering these signs or symptoms as clinically significant, 25 experts provided their insights—21 (84%) suggested a range from *a few days* (1 to 3) to *4 weeks*, with *2 weeks* being the most cited (n=9, 36%).

In addition, 7% (2/28) of the experts suggested differentiating the duration of signs or symptoms between recurrent episodes in chronic depression and new-onset cases. For this reason, a question addressing this specificity was introduced in round 2 (n=21), with 62% (13/21) supporting the distinction. For recurrent episodes, most experts favored a minimum duration

of *2 weeks* (9/13, 69%), whereas for a new onset, opinions varied, with "4 weeks" (5/13, 38%) being the most cited.

In round 2 (n=21), 62% (13/21) emphasized the importance of considering the number of signs or symptoms during screening. Of the 12 experts who specified a threshold, 7 (58%) favored a minimum of 3 symptoms.

Regarding sign or symptom frequency, all experts who provided an opinion in round 2 (20/20, 100%) considered it relevant. Of these 20 experts, 19 (95%) specified a particular frequency, of whom 9 (47%) suggested a frequency of *several times per day*, 3 (16%) suggested a frequency of *nearly daily*, and 6 (32%) suggested a frequency of *several times per week*.

For severity, 90% (18/20) considered it an important factor. Moreover, on a severity scale from 0 to 10 (with 10 being the most severe), the average threshold for clinical concern was 4.9 (SD 1.4), with a median of 5.0 (IQR 2.0).

Further details regarding the results described previously can be found in Multimedia Appendix 5.

Steering Committee's Decision on Dimensions and Criteria Lacking Consensus After 3 e-Delphi Rounds

The steering committee conducted 2 additional rounds of discussion to decide on the relevance of the 4 dimensions and 18 criteria that did not reach a consensus of ≥70% among the panelists during the 3 e-Delphi rounds.

In the first round of discussion, committee members reviewed the panelists' comments and agreement levels for each dimension and criterion, analyzing potential reasons for the lack of consensus and considering the clinical implications. Each member shared their perspectives drawing on their clinical expertise. In the second round, the committee revisited the dimensions and criteria after reflecting on the insights from the first round, aiming to resolve any remaining uncertainties and reach a collective decision. Consensus was prioritized, with majority voting used when necessary.

A summary of the committee's final determinations is provided in Multimedia Appendix 6, where the rationale behind the inclusion or exclusion of each dimension and criterion is detailed.

Table 4 presents an overview of the consensus levels reached in each e-Delphi round and the final decisions made by the steering committee.

Table 4. Steering committee's decision on the dimensions and criteria lacking consensus after 3 e-Delphi rounds.

Types of Assessment for Potential Depression Criteria: Self-Assessment, Hetero-Assessment, or Both?

In addition to assessing the relevance of each criterion, the panel provided opinions on the preferred assessment method (self-assessment, hetero-assessment, or both). Rather than seeking strict consensus, the goal was to identify general trends. Using a 50% threshold as an example, 35% (28/80) of the criteria were deemed suitable for *self-assessment* only, 4% (3/80) of the criteria were deemed suitable for *hetero-assessment* only, and 40% (32/80) of the criteria were deemed suitable for both methods. Detailed information is available in Multimedia Appendix 7, whereas Figure S3 in Multimedia Appendix 3 provides an overview of the consensus rates for these assessment methods.

Discussion

Principal Findings

This modified e-Delphi study aimed to identify and achieve consensus on the most representative signs and symptoms of depression in very old age, focusing on near-centenarians and centenarians.

Our results revealed that most of the items proposed—86% (24/28) of the dimensions and 80% (70/88) of the criteria—which had been assembled based on a literature review, were considered *relevant* for depression screening in very old age. This highlights the importance of a multidimensional approach and acknowledges the complexity of accurately diagnosing depression in this population.

Most Consensual Potentially Relevant Depressive Signs and Symptoms

Focusing on items with the highest consensus rates (≥90%), some overlap between dimensions and criteria was observed, which was expected as dimensions grouped related criteria.

For example, the *depressed mood* dimension was widely considered *relevant*, aligning with criteria such as *depressed*; *sadness*; and *despondency, gloom, and despair*, which reflect the emotional core of depressive disorders [6,54]. Similarly, *loss of interest in activities*, *loss of pleasure in activities*, *lack of reactivity to pleasant events or circumstances*, and *anhedonia* also achieved broad consensus as critical indicators of depression [6,54,62-64]. Collectively, these signs and symptoms highlight the significant impact of depression on a person's capacity for joy and engagement with life, underscoring their relevance in depression screening.

Criteria such as *ruminations* and *feelings of worthlessness* equally achieved a strong consensus due to their role in the negative cognitive and emotional patterns of depression. Previous research has shown that *ruminations* exacerbate psychopathology, including depression, by intensifying and extending negative mood states, thus interfering with problem-solving and perpetuating physiological stress responses [65]. Similarly, *feelings of worthlessness* are strongly linked to self-blame, lack of hope, and an increased suicide risk even after depressive episodes remit [66,67]. Building on this, the *lack ofhope* dimension achieved unanimous consensus (21/21, 100%) as a relevant element, reflecting its importance as a significant predictor of psychological well-being [68]. Within this broader dimension, the *hopelessness* and *hopeful about the future* criteria also showed high consensus (24/27, 89% and 16/21, 76%, respectively), emphasizing their important role in depression screening in individuals of very old age whether as a negative indicator or a positive resource.

Furthermore, *previous episodes of depression or diagnosed depression* were also identified as relevant, highlighting the importance of considering an individual's psychiatric history as past experiences with depression increase the risk of recurrence [69]. In addition, *critical life events* perceived as negative were recognized for their significant association with higher levels of depressive symptoms in a recent meta-analysis [70].

Finally, the strong agreement on severe criteria such as *recurrent thoughts of death or suicide*, *suicidal ideation*, and past *suicide attempt(s)* underscores the critical need to address these factors due to their immediate risk to individuals' safety [26].

Most Consensual Potentially Relevant Depressive Signs and Symptoms in the Context of Old Age

Having established the most consensual depressive features, it is essential to explore how these characteristics manifest specifically in older adults as unique age-related factors may shape their expression and impact.

As individuals age, they may face different challenges, some of which are particularly relevant to LLD. These include agism; loss of income; the death of loved ones; and the risk of isolation, functional limitations, multimorbidity, cognitive decline, and institutionalization [71]. Such multidimensional challenges can impact well-being and mental health, contributing to reduced aging satisfaction and increased loneliness, including near-centenarians and centenarians [71,72]. While the cumulative effect of these difficulties can increase the risk of LLD, it is important to note that experiencing them does not necessarily lead to the development of a depressive state [72].

The dimensions and criteria that achieved high consensus, as previously discussed, clearly represent central elements in depression screening across all age groups, aligning with current diagnostic standards [6,54]. Our findings confirm their importance for accurate diagnosis in individuals of very old age, underscoring their transversality across generations and relevance even in the final stages of life. While depression in very old age may have unique aspects, some of the core signs and symptoms of the disorder remain consistent and should not be overlooked, including in near-centenarians and centenarians. However, these signs and symptoms may carry additional significance due to the unique psychosocial and physical challenges faced by these individuals [72].

For instance, *loss of interest in activities*, *loss of pleasure in activities*, *lack of reactivity to pleasant events or circumstances*, and *anhedonia* may highlight a deeper disengagement from life that can be difficult to detect in older adults. These symptoms are often masked by typical aging challenges such as physical decline, social isolation, or even cognitive issues, complexifying their identification. In addition, *feelings of worthlessness* and

the negative impact of *critical life events* may be particularly relevant in late-life contexts, where significant life changes and losses are common [67,73]. As highlighted in a meta-synthesis [74], older adults often experience declines in physical and cognitive abilities, leading to feelings of disconnection and a perception of being unneeded by their communities. This sense of being unneeded can foster feelings of isolation and insignificance, thereby triggering or exacerbating depressive symptoms. Moreover, societal changes and loss of social roles further deepen these feelings of worthlessness, underscoring the importance of addressing these issues in older populations [74].

While the high consensus on many classic criteria suggests their continued relevance across the life cycle, our findings also point to unique aspects of depression in very old age that may not be fully captured by current approaches. For example, the unanimous agreement on the relevance of *lack ofhope* highlights its particular significance in this age group. Unlike other factors typically associated with normal aging processes, low levels of hope have been identified as a significant risk factor in older adults, reflecting a deeper sense of despair with potentially serious consequences. A systematic review [75] underscored that lack of hope is closely linked to negative outcomes in older populations, including an increased risk of depression and poorer overall health outcomes.

Moreover, the strong agreement on severe symptoms such as *recurrent thoughts of death or suicide*, *suicidal ideation*, and past *suicide attempt(s)* underscores the importance of also addressing these factors in very old age, where such topics often remain taboo [76]. Reluctance to discuss or acknowledge these symptoms may lead to underdiagnosis and inadequate treatment, emphasizing the need for sensitive and proactive approaches in this age group. Recent qualitative research [76] has revealed that suicidal thoughts in later life are often subtly expressed and normalized in everyday conversations, making them difficult to detect. However, the extent to which this applies to centenarians is unclear. Previous research suggests that only a minority of centenarians express a wish to die [77,78], making explicit suicidal thoughts likely rare and not always linked to depressive states. Nonetheless, feelings of life being *completed and no longer worth living* reflect a deeper disconnection from life, characterized by aching loneliness, feelings of not mattering, and a physical and mental tiredness [79]. Creating safe spaces for informal—yet meaningful—discussions is essential, alongside strategies for timely recognition and management of these symptoms [76].

Potentially Not Relevant Depressive Signs and Symptoms in the Context of Old Age

The *increased appetite* dimension may have been considered *not relevant* as it can result from situational factors such as attending a day center or moving to a nursing home, where tailored meals and social dining often enhance the willingness to eat, contributing to an increased appetite. Similarly, the *significant unintentional weight gain* criterion was likely deemed *not relevant* for related reasons as previous research has found no association between weight gain and incident depressive symptoms in older adults [80].

Certain cognitive dimensions such as *memory problems* and *language/speech (eg, poor speech)* were also classified as *not relevant*, likely due to their overlap with nondepressive phenomena commonly observed in older adults. This highlights the need for tailored screening protocols that can effectively differentiate between depression and cognitive impairment, conditions that often coexist in individuals of very old age and require distinct therapeutic strategies [81,82]. The criterion *the mind is as clear as it used to be* was likely deemed *not relevant* for the same reasons.

Criteria such as *hard to get started on new projects*; *staying home instead of going out and doing new things*; *finding life exciting, wonderful, and enjoyable*; *easily annoyed*; and *getting bored often* may be more closely related to motivational factors, social involvement, social support, or underlying health conditions rather than directly indicating a depressive state [83,84]. Similarly, criteria such as *thinks most people are better off than him/her*, *feeling that people are unfriendly or dislike him/her*, and *feels as good as other people* may reflect personality traits, which are relatively stable over the life span and may not necessarily reflect a change in mental health status [85].

Symptoms such as *psychomotor agitation* illustrate the challenge in differentiating between depression-related symptoms and those arising from other geriatric conditions such as dementia or delirium [86], suggesting that certain depressive features may be less applicable or not sufficient for individuals of very old age [87]. In addition, the *full of energy* criterion, typically seen as a positive indicator, was not deemed relevant, possibly because it is rare for a near-centenarian or centenarian without depression to report feeling full of energy. This likely reflects their overall physical condition rather than a depressive state, and the absence of this criterion may often be confounded with physical exhaustion linked to frailty [88].

The *fear of dying* criterion was also classified as *not relevant*. Although it might be assumed that individuals in the final stage of life would fear death, previous research suggests that death anxiety is generally low among older adults, who are more often concerned with the dying process rather than death itself [89]. Similarly, *sufficient financial resources* was deemed *not relevant*. While financial difficulties can impact mental health, their link to psychological distress in older adults appears to be more influenced by underlying factors such as mastery and self-esteem rather than acting as a direct indicator of depression [90].

The Specificity of Near-Centenarians and Centenarians

Research on near-centenarians and centenarians has predominantly focused on physical, cognitive, and social health, with less attention paid to psychiatric aspects [13]. Studies on depression in this population often rely on overall assessment scores from standardized instruments rather than detailed analysis of individual items [72,87,91-94]. This gap, alongside the variety of existing tools for screening for depression in very old age, also motivated this study.

Notably, one study conducted a detailed item-level analysis using a 14-item version of the Geriatric Depression Scale in

Portuguese centenarians [88] and found that 51.4% reported *feelings of worthlessness*, supporting the relevance of this specific criterion in our e-Delphi study. In addition, only 12.3% reported having more *memory problems*, 43.3% expressed a preference for *staying home instead of going out and doing new things*, 39.8% reported *getting bored often*, and 33.3% agreed with the statement *thinks most people are better off than they are* [88]. Globally, these findings align with our results, where these criteria were considered not relevant in this age group.

While these findings suggest reduced presence of symptoms established for younger populations, it remains unclear whether depression in near-centenarians and centenarians significantly differs from that in other older individuals, such as octogenarians; the key features of depression may not vary meaningfully. Therefore, it is worth questioning whether the development of a tool specifically designed for very old age, including the near-centenarian and centenarian population, is truly necessary. Nevertheless, psychological resources such as resilience appear to be particularly strong in near-centenarians and centenarians [77,95]. These protective characteristics may lead traditional depression screening tools to overlook subtle signs of depression that are masked by these strengths. A tool specifically designed for this age group could better capture the subtle differences and specific needs, enhancing the accuracy and effectiveness of depression screening.

Duration, Number, Frequency, and Severity of Depressive Signs and Symptoms and Type of Assessment

Our findings emphasize the importance of considering the duration, number, frequency, and severity of depressive signs and symptoms in near-centenarians and centenarians. Notably, experts differentiated between chronic and new-onset depression, advocating for a nuanced approach that may significantly impact clinical assessments and interventions. This aligns with existing literature documenting distinct clinical profiles for persistent and nonchronic depressive disorders in adults aged 18 to 79 years [96,97], with persistent cases often involving earlier onset, more severe symptoms, and greater treatment resistance [96]. While these findings are based on younger individuals, they reinforce the necessity of a personalized life span approach that includes rigorous screening and comprehensive clinical strategies for the oldest age groups.

Furthermore, experts in our study highlighted the potential value of combining self- and hetero-assessment techniques to screen for depressive signs and symptoms in very old age. However, this approach may require further consideration. Cognitive limitations at this age may affect the reliability of self-reports, complicating the integration with caregiver observations. Developing strategies to reconcile these differing perspectives—such as guidelines for interpreting discrepancies—could ensure that assessments are accurate and sensitive to the unique challenges faced by individuals of very old age. Flexible, combined approaches remain relevant as research suggests that they enhance diagnostic accuracy and patient engagement [98].

Further Considerations

Given the findings of our study, a more comprehensive approach to depression screening in near-centenarians and centenarians may be advantageous. The high consensus among experts regarding certain depressive features highlights their relevance and significance for this particular age group. Importantly, the diagnosis of LLD in adults of very old age can be particularly complex due to overlapping symptoms with other mental or somatic conditions, as previously outlined. This overlap necessitates a differential diagnostic approach that integrates a broader perspective. This emphasizes the need for screening tools that are both comprehensive and sensitive to the unique experiences and needs of individuals of very old age. Implementing such tailored screening methods could contribute to improved mental health outcomes within this population.

Our work extends existing literature by providing a comprehensive overview of a wider range of depressive features, including considerations of their duration, number, frequency, and severity—factors that are less considered in standard depression screenings. This highlights the complexity of diagnosing depression in adults of very old age and confirms the necessity of incorporating these specific aspects into the screening process.

While the e-Delphi method was valuable for identifying key elements in detecting depressive signs and symptoms in those of very old age, a separate validation study is necessary to confirm whether the extended screening process would be more effective compared to current tools. Nonetheless, this study hopefully represents a meaningful step forward in improving the detection of depressive signs and symptoms in this population.

Limitations

We acknowledge several limitations. First, despite the international and professional diversity of the expert panel, it may not have captured the full spectrum of clinical practices or cultural perceptions related to aging and depression. The relative overrepresentation of nurses among the panelists in rounds 1 and 2 may have introduced a bias toward nursing-specific priorities, such as a stronger focus on the practical applicability of screening criteria in daily care. However, this also reflects their pivotal role in direct care for individuals of very old age, making their insights particularly relevant for developing pragmatic screening criteria. Given this, a *groupthink* effect in which the dominant profession influenced the consensus cannot be excluded. In addition, our panel lacked experts from Asian countries despite notable recruitment efforts even though these regions have some of the highest proportions of centenarians worldwide. This absence may have introduced a bias toward Western perspectives. At the same time, the concept of depression in very old age may be less clearly defined in some Asian cultures due to cultural background. Second, the selection of a 70% consensus threshold may have influenced the interpretation of the results as it reflects a compromise between inclusivity and stringency, subtly shaping the scope of the consensus achieved. Third, the structured nature of the e-Delphi process may have limited the exploration of nuanced symptoms critical to understanding depression in individuals of very old

age, a population whose cognitive decline may complicate symptom presentation. Fourth, some overlap between dimensions and criteria was observed, which may be perceived as a limitation to some extent. However, the steering committee was aware of this overlap and intentionally decided to retain it to confirm certain trends in consensus on specific items.

Despite these challenges, this study's insights have the potential to stimulate discussions on improving mental health strategies for older populations, especially those of very old age. The diverse and interdisciplinary composition of the panel further contributes to the generalizability of the findings, offering valuable insights to health care professionals and researchers worldwide.

Future research should aim to develop and validate a screening tool specifically designed for depressive signs and symptoms in very old age, including near-centenarians and centenarians. A validation study comparing the extended method with established tools or a *gold standard* diagnostic reference is crucial to determining its efficacy. In addition, it is important to assess the tool's effectiveness across different cultural contexts to ensure its broad applicability. The incorporation of Patient-Reported Experience Measures in future developments would also be beneficial in capturing the lived experiences and perceptions of this age group.

Conclusions

This expert consensus could significantly contribute to enhancing early detection and intervention for depression in individuals of very old age, notably by informing the creation of a new screening tool. The findings have the potential to improve diagnostic accuracy and, consequently, allow for the personalization of treatment plans tailored to the unique needs of individuals of very old age.

In conclusion, this study used expert consensus to establish a foundational step toward enhancing the detection and treatment of depression among individuals of very old age, including near-centenarians and centenarians. This study emphasizes the need for cautious, multidimensional, and multidisciplinary approaches to depression screening in this age group, advocating for the continuous refinement of screening tools to address the complex nature of very old age effectively.

Acknowledgments

This work was supported by the Swiss National Science Foundation through the Sinergia grant CRSII5_186239/1 (SWISS100). The authors gratefully acknowledge the contributions of all the experts who participated in this study. They recognize those who agreed to be publicly acknowledged: Alcina Matos Queirós, Department of Health and Social Welfare, Canton of Vaud, Switzerland; Carina Santos, Riviera-Chablais Hospital, Switzerland; Christophe Nakamura, Lausanne University Hospital, Switzerland; Eivind Aakhus, the Norwegian National Centre for Ageing and Health, Vestfold Hospital Trust, Norway; Filipa Pereira, School of Health Sciences, University of Applied Sciences and Arts Western Switzerland Valais-Wallis, Switzerland; Jean Roche, Lille University Hospital, France; Kim Uittenhove, Swiss Federal Institute of Technology in Lausanne, Switzerland; Nancy A Pachana, the University of Queensland, Australia; Oscar Ribeiro, University of Aveiro, Portugal; Raquel Neves, Almoosa Rehabilitation Hospital, Kingdom of Saudi Arabia; Sofia Fernandes, School of Health Sciences, University of Applied Sciences and Arts Western Switzerland Valais-Wallis, Switzerland; Sylvain Nguyen, Riviera-Chablais Hospital, Switzerland; Sylvie Bonin-Guillaume, Aix-Marseille University, University Hospital of Marseille, France; and Tiago Ferreira, Lausanne University Hospital, Switzerland. The authors also extend their sincere appreciation to the experts who preferred to remain anonymous. Their equally valuable contributions were central in shaping this study's outcomes.

Authors' Contributions

CGdR, AvG, and HV contributed to the conceptualization of the study. AvG, PV, and HV provided methodological input. AvG, PV, DSJ, OR, and HV contributed scientific input. CGdR was responsible for data collection, data analysis, and writing the original draft. CGdR, AvG, PV, DSJ, OR, and HV reviewed and edited the manuscript. AvG and HV supervised the study.

Abstract

Background: Cyberchondria is the compulsive searching for health information online that continues despite harmful effects. It leads to increased health anxiety and lower health-related quality of life (HRQOL). Older adults face higher risks of cyberchondria due to their limited digital literacy skills and more frequent health concerns. However, researchers have not thoroughly studied how cyberchondria affects this age group.

Objective: This study aimed to explore cyberchondria in the older population and investigate its relationship with cognitive fusion (ie, the tendency to become entangled with thoughts and perceive them as literal truths that dictate behavior), HRQOL, and mental well-being.

Methods: A web-based, cross-sectional survey was conducted in May 2024 with a sample of 638 participants from China aged ≥60 years recruited through the online panel of a survey company. The participants completed questionnaires assessing cyberchondria (using the Cyberchondria Severity Scale-12 [CSS-12]), cognitive fusion, HRQOL, and mental well-being. Structural equation modeling (SEM) was used to assess the hypothesized mediation model, and standardized estimates and their 95% CIs were calculated for all structural paths.

Results: Participants had a mean CSS-12 score of 40 (SD 8.5), suggesting a fairly high level of cyberchondria in this sample. Participants with a higher socioeconomic status tended to report lower levels of cyberchondria. The SEM showed that cyberchondria was positively associated with cognitive fusion (β=0.505, *P*<.001 for both models) and negatively associated with HRQOL (β=–0.221, *P*<.001) and mental well-being (β=–0.212, *P*<.001). The mediation model showed a good fit and demonstrated that cognitive fusion fully mediated the total effect of cyberchondria on HRQOL and mental well-being.

Conclusions: Cyberchondria may be more prominent in older Chinese adults, especially those residing in rural areas and with a lower socioeconomic status. Additionally, cyberchondria can enhance cognitive fusion, contributing to poor HRQOL and mental well-being. Interventions focused on “defusing” cyberchondria-relevant thoughts may help reduce maladaptive behaviors associated with cyberchondria and improve the overall well-being of older populations.

Introduction

Background

The internet can amplify health anxiety by creating an environment in which distinguishing credible online health information from that derived from unreliable sources may be difficult, often leading to confusion and fear [1,2]. Cyberchondria refers to excessive or repeated online health information seeking that persists despite negative consequences and is associated with increased health anxiety [3] and decreased health-related quality of life (HRQOL) [4,5], with its toll including diminished well-being and compromised daily functioning. Cyberchondria and health anxiety are closely intertwined, and studying this link is crucial to address the growing impact of cyberchondria. The rise of cyberchondria is intimately linked to the digital revolution, and online misinformation and worst-case scenarios often lead to catastrophic interpretations that exacerbate anxiety. The internet also facilitates confirmation bias, allowing individuals to seek information that aligns with their existing fears, reinforcing anxiety. Easy access to information facilitates compulsive checking behaviors, which provide temporary relief but ultimately perpetuate anxiety. This creates a vicious cycle, in which increased anxiety leads to more compulsive online health information seeking [4,6,7].

Cyberchondria in Older Adults

Older adults face heightened vulnerability to cyberchondria. Their vulnerability stems not only from lower digital literacy and more frequent health concerns [8,9] but also from their generation's unique beliefs and life experiences [10]. Older adults, particularly those from generations that emphasized deference to authority figures, may uncritically accept health-related information presented in an authoritative tone, even from unreliable online sources [11]. This attitude, coupled with passive health information-seeking habits developed in an era of limited access to medical knowledge, heightens susceptibility to misinformation and catastrophic health interpretations.

Moreover, older age brings an expectation of decline, a psychological state shaped by imminent health risks, accumulated losses, and direct experiences with chronic illness [12]. These experiences may foster hypervigilance toward bodily changes, prompting compulsive online searches that reinforce anxiety through confirmation bias. The interplay of factors, such as cohort beliefs, anticipatory health anxiety, and cumulative adversity, may create a unique pathway for cyberchondria in older adults, distinct from younger populations. Despite these risks, limited research has focused on cyberchondria in this age group, even as studies highlight their frequent use of the internet for health information, which may increase their anxiety and distress [12-14].

HRQOL and Cyberchondria

HRQOL is a multidimensional construct that encompasses an individual's physical health, mental health, social functioning, and role functioning [15]. HRQOL is particularly affected by cyberchondria, as the anxiety and stress from constant health-related searches have a negative impact on emotional well-being. This anxiety can also manifest as psychosomatic symptoms, affecting physical health and daily functioning.

Unravelling the mechanisms linking cyberchondria to HRQOL is essential, as individual differences in coping strategies, digital literacy, and pre-existing health conditions interact dynamically with the aforementioned specific vulnerabilities in older adults. As cyberchondria becomes more prevalent [16], targeted interventions must address not only the skill gaps but also the ingrained cognitive and emotional patterns that predispose older adults to its harms, ultimately safeguarding their well-being in an increasingly digital health landscape.

Mental Well-Being and Cyberchondria

Mental well-being and HRQOL are distinct concepts that address different dimensions of human experience. Unlike HRQOL, which quantifies the impact of health on physical, social, and role functioning, mental well-being focuses on emotional and psychological states and encompasses positive aspects such as happiness, life satisfaction, resilience, and a sense of purpose [17]. Rooted in frameworks like positive psychology, mental well-being relates to the presence of flourishing mental states (eg, optimism, self-acceptance) and absence of psychological distress (eg, anxiety, depression). Cyberchondria can jeopardize mental well-being by heightening anxiety about one's health [18]. It can also destabilize emotional health, trigger obsessive thought patterns, and impair resilience, ultimately eroding the core components of mental well-being and leaving individuals trapped in a cycle of distress and hypervigilance [19].

Elucidating the mechanisms connecting cyberchondria to mental well-being is vital, especially for older adults who face unique risks due to diminished digital literacy, heightened health concerns, and reduced adaptability to stress [20]. Factors such as pre-existing anxiety, limited ability to critically evaluate online content, and a propensity for catastrophic thinking can intensify cyberchondria's impact, making older adults particularly susceptible to its psychological toll [21]. With the growing prevalence of digital health-seeking behaviors, research must prioritize these interactions to inform robust, tailored interventions, combining enhanced digital education with cognitive-behavioral strategies, to break the cycle of anxiety and safeguard mental well-being in this vulnerable population [22].

Cognitive Fusion and Cyberchondria

Cognitive fusion refers to the tendency for behavior to be overly regulated and influenced by cognition. Cognitive fusion occurs when individuals get overly entangled with their thoughts, treating them as literal truths rather than just mental phenomena [23]. Although cognitive fusion is primarily a state phenomenon, some individuals may experience it more persistently, leading to patterns that resemble a trait. This means that certain people might be more prone to cognitive fusion across various situations, making it appear as a stable, trait-like characteristic [24]. Studies have shown that cognitive fusion is strongly associated with health care avoidance and weight stigma [25] and that higher levels of cognitive fusion are associated with

increased anxiety and depression and poorer HRQOL [26,27]. Cognitive fusion is also related to rumination, shame, and reduced self-compassion [28]. Cognitive fusion involving anxious thoughts can exacerbate anxiety-related maladaptive behaviors, such as avoidance, checking, and reassurance seeking. The inability to distance oneself from such thoughts perpetuates the anxiety cycle and strengthens the perceived validity of the thoughts [29].

Previous studies have shown an association between cyberchondria and metacognitive beliefs [30,31], a concept potentially linked to cognitive fusion. Although metacognitive beliefs refer to ways of appraising one's thoughts and other cognitive functions, cognitive fusion is about a strong attachment to one's thoughts and their perceived truth. Compared with cognitive fusion, metacognitive beliefs reflect a broader construct, can be either positive or negative, and lack an element of attachment to one's own thoughts, regardless of the nature of these thoughts. Both constructs influence how individuals experience and respond to their thoughts, but considering the potential role that cognitive fusion can play in psychopathology, it has not received sufficient attention from researchers in the context of cyberchondria.

Although cognitive fusion can affect people of all ages, older adults may be more severely impacted than their younger counterparts, given their thoughts about numerous life transitions, including retirement, loss of loved ones, high risks of social isolation, and declining health [32]. Cognitive fusion may amplify health-related anxiety of older adults by making it difficult for them to separate their concerning health-related thoughts from the reality about their health. However, limited empirical evidence exists on the relationship between cognitive fusion and health anxiety among older adults [33]. Studying cognitive fusion in this demographic may help develop tailored interventions to enhance coping mechanisms of older adults and improve their mental health and overall HRQOL [34].

The relationship between cognitive fusion and cyberchondria can be understood through the lens of cognitive processes and reinforcement. Cognitive fusion may contribute to negative perceptions of online health information [35]. In other words, the threatening thoughts about online health information, especially if this information is ambiguous or incongruent, are experienced as real and not a product of one's own interpretation or perception. This increases anxiety and makes a person search compulsively for health information in an effort to alleviate the sense of threat, thus leading to cyberchondria [29,36]. However, such behavior only reinforces the sense of threat, especially in the long run. For older adults whose health-related searches are often driven by anticipatory anxiety [12], seeking ambiguous or alarming information may deepen cognitive fusion ("I must be ill because I keep reading about symptoms"), creating a feedback loop. This aligns with studies showing that repetitive behaviors amplify cognitive rigidity in aging populations [33]. Thus, we hypothesized cyberchondria as a behavioral trigger that intensifies cognitive fusion, which in turn erodes HRQOL.

Research Questions and Hypotheses

Research Questions

Drawing from the theoretical and empirical considerations outlined earlier, this study proposed 2 research questions to guide the investigation. First, what are the levels of cyberchondria and cognitive fusion among older adults, and which sociodemographic factors correlate with these constructs? Second, how are cyberchondria, cognitive fusion, HRQOL, and mental well-being interrelated in older adults? To address the second question, 5 hypotheses were formulated. The conceptual framework is presented in Multimedia Appendix 1.

Hypothesis 1

Prior research has demonstrated that cyberchondria contributes to functional impairment and diminished quality of life [18]. In older adults, this effect may be amplified due to age-related vulnerabilities, such as reduced online health literacy and the presence of chronic illnesses, which heighten susceptibility to health anxiety and its consequences [37]. Therefore, we proposed, as hypothesis 1 (H1), that cyberchondria negatively impacts HRQOL in older adults.

Hypothesis 2

Studies have shown that excessive online health information seeking is linked to increased psychological distress, including heightened anxiety and reduced emotional well-being [38,39]. Older adults may be particularly vulnerable to these effects due to declining physical health, reduced resilience to stress, and limited digital literacy, which can exacerbate the psychological toll of cyberchondria. Thus, we hypothesized, as hypothesis 2 (H2), that cyberchondria negatively impacts mental well-being in older adults.

Hypothesis 3

Research has indicated that cognitive fusion, characterized by entanglement with thoughts and treating them as literal truths, is associated with anxiety-driven behaviors [40]. Cyberchondria, as a behavioral pattern driven by health anxiety, may similarly foster cognitive fusion by reinforcing rigid and catastrophic thought patterns about health. Accordingly, we proposed, as hypothesis 3 (H3), that cyberchondria positively impacts cognitive fusion in older adults.

Hypothesis 4

The theoretical framework of acceptance and commitment therapy, supported by studies, suggests that cognitive fusion amplifies the negative effects of maladaptive thoughts on well-being, including health-related outcomes [41]. In the context of cyberchondria, older adults who excessively seek online health information may develop rigid, catastrophic cognitions that impair HRQOL through cognitive fusion [42]. Therefore, we hypothesized, as hypothesis 4 (H4), that cognitive fusion mediates the negative impact of cyberchondria on HRQOL in older adults.

Hypothesis 5

Evidence from prior research indicates that cognitive fusion intensifies the emotional impact of anxiety-driven behaviors, mediating the association between repetitive thought patterns

and psychological distress [40]. For older adults, cyberchondria may similarly exacerbate emotional distress through cognitive fusion, undermining mental well-being [23]. Thus, we proposed, as hypothesis 5 (H5), that cognitive fusion mediates the negative impact of cyberchondria on mental well-being in older adults.

Methods

Data and Participants

This study used data from a web-based cross-sectional survey conducted between April 2024 and May 2024 to examine the health and social status of China's older population. The participants were recruited through Wenjuanxing, a Chinese survey company with an online panel of over 2.6 million members. The inclusion criteria were as follows: (1) age ≥60 years, (2) ability to read and speak Mandarin, (3) absence of cognitive impairments, and (4) ability to provide informed consent. Eligible participants were invited to complete a series of questionnaires starting with an informed consent form. Only those who consented to participate then completed the questionnaire. Several measures were implemented to ensure data quality. First, we used CAPTCHA (Completely Automated Public Turing test to tell Computers and Humans Apart) to prevent bot submissions, ensuring that only genuine human respondents participated. We also conducted a time analysis to exclude implausibly rapid responses, which could indicate a lack of thoroughness. Additionally, we limited submissions to one per IP address within a set time frame to prevent duplicate entries. To further enhance data integrity, we identified and filtered parallel response patterns, including both consistent and repetitive patterns, which could suggest inattentive or automated responses.

Measures

The standard and validated Chinese versions of all instruments were administered. The English versions are included in Multimedia Appendix 2 for reference only.

Cyberchondria

The severity of cyberchondria was measured using the Cyberchondria Severity Scale-12 (CSS-12). It possesses good psychometric properties, comparable to those of the original version, and has been validated in the Chinese population [43]. The CSS-12 items were rated on a Likert-type scale ranging from 1 (never) to 5 (always). The total score ranges from 12 to 60, with higher scores indicating higher levels of cyberchondria.

Cognitive Fusion

The Cognitive Fusion Questionnaire (CFQ) was designed to measure the extent to which individuals are entangled in their thoughts [23]. It consists of 7 items, each rated on a 7-point Likert scale ranging from 1 (never true) to 7 (always true). Total scores range from 7 to 49, with higher scores reflecting a higher level of cognitive fusion. The psychometric properties of the CFQ have been reported to be satisfactory in the Chinese population [44].

HRQOL

The EQ-5D-5L was used to measure HRQOL in this study. It comprises 5 health-related items (mobility, self-care, usual activities, pain or discomfort, and anxiety or depression), each rated on a 5-point Likert scale ranging from 1 (no problems) to 5 (extreme problems) [45]. To reflect HRQOL, all health states described by the descriptive system can be converted into a single utility score using a scoring algorithm based on public preferences. This study used the EQ-5D-5L China value set and scoring algorithm [46].

Mental Well-Being

The World Health Organization-5 Well-Being Index (WHO-5) is a widely recognized and validated tool for assessing subjective psychological well-being [47]. It consists of 5 questions that measure positive mood, vitality, and general interest over the past 2 weeks. Each item is rated on a 6-point Likert scale ranging from 0 (not present) to 5 (constantly present), allowing for a maximum score of 25. Higher scores indicate better well-being. The psychometric properties of the WHO-5 in the Chinese population have been reported to be satisfactory [48].

Statistical Analysis

Descriptive statistics were used to analyze participants' sociodemographic characteristics. Continuous variables (eg, age) were analyzed using means and SDs, whereas categorical variables (eg, sex) were analyzed using frequencies and percentages. Pearson correlation coefficients (r) were calculated to determine associations between variables, with r values ≥0.3 and ≥0.5 indicating moderate and large effects, respectively [49]. ANOVA was conducted to assess the differences in CSS-12 scores across different socioeconomic groups.

We used structural equation modeling (SEM) with full-information likelihood estimation to assess the hypothesized mediation model. Latent variables for cyberchondria (CSS-12), HRQOL (EQ-5D-5L), mental well-being (WHO-5), and cognitive fusion (CFQ) were created based on the sum score of the 4 instruments. Respondents' characteristics (ie, sex, age, education level, and presence of a chronic condition) were included in the model for adjustment. To assess the direct, indirect, and total effects, we used 5000 bootstrapped samples, derived effect estimates, and bias-corrected 95% CIs [50]. We assessed model fit using a Tucker-Lewis index>0.90, comparative fit index>0.90, root mean square error of approximation<0.05, and standardized root mean square residual<0.05 [51]. We set significance at P<.05 (2-tailed) and conducted all statistical analyses using R software [52].

Ethical Considerations

This study was performed in line with the principles of the Declaration of Helsinki. The study protocol and informed consent were approved by the Institutional Review Board of Hong Kong Polytechnic University (reference ID: HSEARS20230502006). Informed consent was obtained from all the participants. All data were anonymized to protect participants' privacy and ensure confidentiality.

Results

Participants' Sociodemographic Characteristics

Table 1 presents the sociodemographic characteristics of the 638 survey participants. The majority were men, comprising 64.1% (409/637) of the sample. In terms of educational background, 51.4% (328/637) had a high school education or less, 25.9% (165/637) had attended college, and 22.7% (145/637) held a university degree. Regarding their household registration, 37.5% (239/637) were from rural areas, while 62.5% (399/637) were from urban areas. When asked about their perceived socioeconomic status, 11% (70/637) considered themselves below the local average, 79.1% (505/637) felt they were equal to it, and 9.9% (63/637) viewed themselves as above it. Moreover, 60.7% (387/637) were long-term caregivers, and 55.3% (353/537) had chronic conditions.

Table 1. Participants' demographics and socioeconomic status (n=637).

Characteristics	Results, n (%)
Sex	
Male	409 (64.1)
Female	229 (35.9)
Age (years)	
60-65	533 (81.6)
66-79	105 (18.4)
Educational level	
High school or less	328 (51.4)

Yes	353 (55.3)
No	285 (44.7)

Profiles of Cyberchondria, HRQOL, Mental Well-Being, and Cognitive Fusion and Associations Between Them

Table 2 presents the participants' scores on the 4 assessment instruments, while Table 3 shows the correlations among the instruments. The average CSS-12 (cyberchondria) score was 40 (SD 8.5) points. The mean WHO-5 (mental well-being) score was 20.4 (SD 5.0) points, the mean EQ-5D-5L (HRQOL) score was 0.8 (SD 0.19) points, and the mean CFQ (cognitive fusion) score was 36.8 (SD 12.3) points. The Cronbach α coefficients for all 4 instruments were above 0.8, indicating good internal consistency and reliability.

Table 2. Measure profiles.

Measures	Mean (SD)	Median (range)	Cronbach α
CSS-12[a]	40 (8.5)	42 (12-58)	0.87
WHO-5[b]	20.4 (5.0)	21 (5-30)	0.87
EQ-5D-5L	0.8 (0.19)	0.88 (0.08-1)	0.83
CFQ[c]	36.8 (12.3_	39 (9-63)	0.94

[a]CSS-12: Cyberchondria Severity Scale-12.

[b]WHO-5: World Health Organization-5 Well-Being Index.

[c]CFQ: Cognitive Fusion Questionnaire.

Table 3. Correlations between the measures.

Measures	CSS-12[a]	WHO-5[b]	EQ-5D-5L	CFQ[c]
CSS-12				
r	—[d]	–0.20	–0.30	0.50
P value	—	<.001	<.001	<.001
WHO-5				
r	–0.20	—	0.36	–0.42
P value	<.001	—	<.001	<.001
EQ-5D-5L				
r	–0.30	0.36	—	–0.48
P value	<.001	<.001	—	<.001
CFQ				
r	0.50	–0.42	–0.48	—
P value	<.001	<.001	<.001	—

[a]CSS-12: Cyberchondria Severity Scale-12.

[b]WHO-5: World Health Organization-5 Well-Being Index.

[c]CFQ: Cognitive Fusion Questionnaire.

[d]Not applicable.

Mental well-being (WHO-5) was positively correlated with HRQOL (EQ-5D-5L; r= 0.36, P<.001), suggesting that greater well-being aligns with better HRQOL. Conversely, mental well-being was negatively correlated with cognitive fusion (CFQ; r=–0.42, P<.001), indicating that higher well-being corresponds with reduced cognitive fusion. Similarly, HRQOL was negatively correlated with cognitive fusion (r=–0.48, P<.001), demonstrating that better HRQOL is linked to lower cognitive fusion. Cyberchondria (CSS-12) had negative associations with mental well-being (r=–0.2, P<.001) and HRQOL (r=–0.3, P<.001) and a positive association with cognitive fusion (r=0.5, P<.001). These results suggest that elevated cyberchondria is associated with poorer mental well-being, diminished HRQOL, and heightened cognitive fusion (Table 3).

Differences in Cyberchondria Across Sociodemographic Groups

Table 4 illustrates the differences in cyberchondria (CSS-12) scores across various sociodemographic groups. Although no statistically significant differences were observed between the sexes, substantial variations were evident in all other group comparisons. Notably, individuals with higher educational levels, who resided in urban areas, who were younger, who had a higher socioeconomic status, who did not need caregivers, and who had no chronic conditions had lower cyberchondria scores.

Table 4. Participants' responses on the Cyberchondria Severity Scale-12 (CSS-12) and Cognitive Fusion Questionnaire (CFQ), stratified by demographics.

Demographic characteristics	Cyberchondria (CSS-12)		Cognitive fusion (CFQ)	
	Mean (SD)	*P* value	Mean (SD)	*P* value
Sex		.36		.72
Male	39.8 (8.8)		37.0 (12.4)

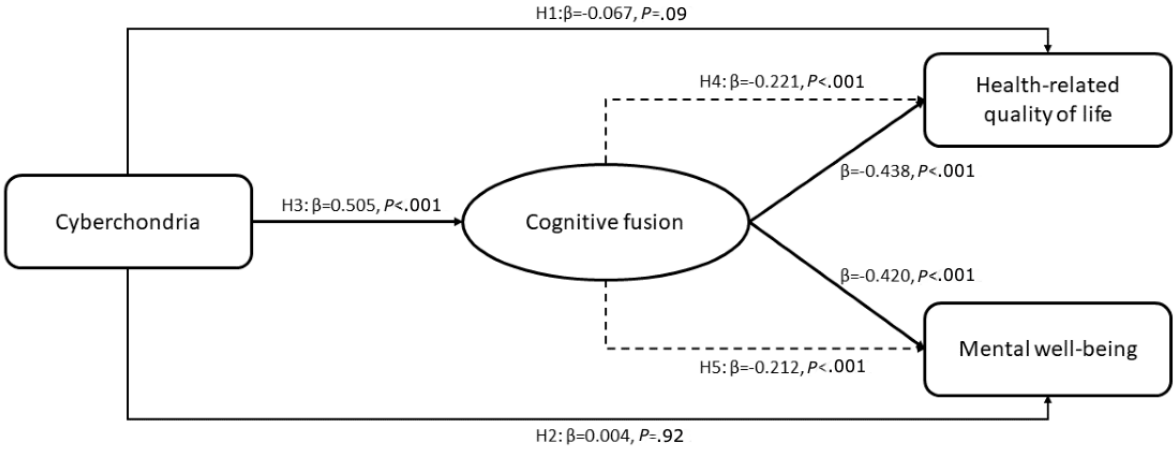
Differences in Cognitive Fusion Across Sociodemographic Groups

The differences in respondents' cognitive fusion across socioeconomic groups were similar to those found for levels of cyberchondria. Participants exhibited significantly higher cognitive fusion if they had lower educational levels, lived in rural areas, were older, had a lower socioeconomic status, and had caregivers or chronic conditions (Table 4).

Results of the Hypothesized Mediation Model

Figure 1 shows the results of the SEM analysis. The mediation model, adjusted for sex, age, and education level, demonstrated acceptable model indices (comparative fit index=0.997, Tucker-Lewis index=0.993, root mean square error of approximation=0.017), suggesting that unmeasured potential confounders were relatively unlikely to affect the results. Outcomes of the SEM analysis showed the lack of statistically significant direct effects between cyberchondria and HRQOL (β=–0.067, *P*=.09; H1 is not supported) and between cyberchondria and mental well-being (β=0.004, *P*=.92; H2 is not supported). The coefficients of the mediation paths were statistically significant. Cyberchondria was significantly positively associated with cognitive fusion (β=0.505, *P*<.001; H3 is supported) with significant negative indirect associations with HRQOL (β=–0.221, *P*<.001; H4 is supported) and mental well-being (β=–0.212, *P*<.001; H5 is supported).

Figure 1. Results of mediation analysis.



Discussion

Principal Findings

This study demonstrates that the levels of cyberchondria in the sample of older Chinese adults were rather high. Our participants had an average score of 40 (of the maximum score of 60) on the CSS-12, which surpassed the mean scores found in earlier research [53-56]. According to the CSS-12 cutoff value established by Xu [57], 60% of our participants exhibited significant features of cyberchondria. These results provide empirical evidence that internet-related mental health issues affect older adults, challenging the belief that such problems are mainly of relevance for younger individuals [58,59]. Additionally, the mediation analysis revealed that associations between cyberchondria and both HRQOL and mental well-being were complex, as no significant direct effects were observed in the model (H1 and H2 were not supported). However, cyberchondria appeared to have a negative and indirect effect on HRQOL and mental well-being by enhancing cognitive fusion among older adults (H3, H4, and H5 were supported). This highlights the importance of addressing cyberchondria not just as a mental health issue but also as a broader HRQOL concern. Interventions that aim to improve overall well-being, not just reduce anxiety, in this population should be encouraged. However, since the significant associations disappeared in the mediation models, the mechanisms relating cyberchondria to HRQOL and mental well-being might be complex and call for further research scrutiny.

The factors contributing to the high levels of cyberchondria are complex. Our study found that older adults with a lower socioeconomic status reported significantly higher cyberchondria levels than those with a higher socioeconomic status. This finding is consistent with results of previous studies conducted in other populations. For example, a Turkish study revealed a significant relationship between cyberchondria levels and family income among adolescents [60]. Several reasons may help explain this. Older individuals with a lower socioeconomic status often have limited access to health care resources, poor internet connectivity, and lower eHealth literacy [61,62]. These factors may compel them to rely heavily on potentially unreliable online health information. Moreover, older individuals with a lower socioeconomic status are more likely to experience social isolation and have smaller support networks [63,64], which may exacerbate their health anxiety and lead to higher levels of cyberchondria. Given these complexities, cyberchondria should be studied within the broader context of psychosocial determinants of health rather than as a simple health-related phenomenon.

A significant difference in CSS-12 scores emerged between urban and rural residents. Older urban residents exhibited lower levels of cyberchondria than their rural counterparts. Although a previous study found that health anxiety is more prevalent and severe in rural areas than in urban areas [65], the study empirically confirmed that the variation in cyberchondria levels was linked to household registration. The reasons for the striking difference in cyberchondria levels between urban and rural older adults largely overlap with the aforementioned reasons for the difference in cyberchondria levels between older individuals with higher and lower socioeconomic statuses. In addition, the urban migration of younger generations in China often leaves older family members in rural areas, which can hinder older people's access to direct support for using digital technologies [66]. Thus, a shift to digital health information, emphasized by the government, may become a challenge for rural residents [67,68].

The cognitive fusion scores in our sample of older adults were slightly higher than those reported in younger populations [32,69] but lower than those in populations with mental health problems, such as depression [70] and suicidal intention [71]. Gillanders et al [26] found that cognitive fusion is negatively associated with HRQOL, which is consistent with our findings. Additionally, we found a significant association between cognitive fusion and education; older respondents with higher educational levels had lower levels of cognitive fusion. Previous studies indicated that education often enhances cognitive flexibility [72], improves critical-thinking skills [73], and boosts problem-solving abilities [74]. These factors may help better-educated individuals avoid rigid thought patterns, thus reducing their proneness to cognitive fusion.

The mediation model revealed that cyberchondria may increase cognitive fusion, leading individuals to become overly entangled with their thoughts about online health information. Heightened

cognitive fusion can negatively impact HRQOL and mental well-being by making it challenging for older individuals to manage their distressing thoughts and emotions. This finding provides support to H2 of this study and partially aligns with the findings of previous studies showing that cognitive fusion significantly mediates the relationship between individual well-being and other health-related factors [75-78].

Building on previous research and clinical findings, our study extends the understanding of how cognitive fusion may serve as a potential mechanism by which cyberchondria causes negative health outcomes [79]. These findings provide valuable insights into how excessive online health information seeking may affect mental health and other functions. This study has clinical implications, as it suggests that interventions targeting cognitive fusion may be effective in mitigating the impact of cyberchondria on HRQOL and mental well-being.

As populations worldwide age, many countries are experiencing a surge in internet use among older adults, driven by increased access to smartphones and online platforms. The rising trend of cyberchondria among Chinese older adults found in this study is very relevant for other regions with aging populations, such as Japan, the United States, and much of Europe, where older adults increasingly turn to the web for health information [80]. The internet's role in amplifying anxiety through misinformation and compulsive online behavior is a universal concern [81]. Other countries can learn from China's experience to prepare for similar challenges, particularly where health care systems might struggle because of the increasing number of older patients with high levels of health anxiety and cyberchondria.

Strengths and Limitations

This is the first study conducted in China to specifically examine cyberchondria and its sociodemographic correlates in the older population. The novelty of this study lies in its examination of previously overlooked relationships between cyberchondria, cognitive fusion, HRQOL, and mental well-being in this population. The findings of this study enhance our understanding of cyberchondria by linking a specific cognitive construct (ie, cognitive fusion) with behavioral aspects (ie, excessive online health information seeking).

However, this study has several limitations that warrant consideration. First, our web-based sampling method, despite using various quality assurance techniques, may have introduced selection bias. Individuals unfamiliar with online surveys or those not part of the company's panel may have been excluded, potentially limiting the generalizability of our findings. Second, although national census data for the population aged 60 years and older was unavailable, our sample was representative only to some extent of the demographic characteristics of China's older population, as reported in previous studies. Specifically, our sample had higher proportions of educated individuals, men, and urban residents. These sampling differences may introduce bias in our findings. Third, our reliance on self-reported measures means that participants' subjective views may have influenced their responses. Fourth, the study did not assess some potentially important variables, such as digital literacy. This was due to the limited length of the study questionnaire and the need to reduce the cognitive burden on older respondents. Variables like digital literacy may affect cyberchondria, and their direct or moderating effects should be explored in future studies. Fifth, our decision to model HRQOL using the EQ-5D-5L single utility score as a manifest variable in the SEM analysis deviates from conventional SEM practices. An alternative approach, such as conceptualizing HRQOL as a latent construct with the five EQ-5D-5L dimensions as formative indicators, might better capture the multidimensional nature of HRQOL. Although this alternative does not align with the standard use of the EQ-5D-5L utility score, it might reflect the differential contributions of each dimension and adhere more closely to typical SEM frameworks. Our approach may have constrained the model's ability to account for the nuanced interplay of HRQOL dimensions, and future research should consider latent variable modeling to address this limitation. Last, our study used a cross-sectional design. Although SEM can offer some insights into potential causal relationships between variables, longitudinal data will be necessary in the future to establish definitive causal links.

Conclusion

This study shows that almost two-thirds of the older Chinese online population might exhibit features of cyberchondria. Higher levels of cyberchondria were observed among older adults living in rural areas and those with lower socioeconomic status. Targeted educational programs could be useful for empowering older adults to better navigate cyberspace and identify credible online health information. Cyberchondria can enhance cognitive fusion in older populations, resulting in poorer HRQOL and mental well-being. Interventions aimed at "defusing" cyberchondria-relevant thoughts and breaking the cycle of anxiety-fueled, excessive online health information seeking can help reduce cyberchondria and improve the overall well-being of older populations.

Abstract

Background: Health data are growing rapidly, and the processing of such data is evolving. Research on data governance in older persons' health care is unexplored, providing little guidance for practice and future studies.

Objective: This scoping review aimed to synthesize available information on data governance in the context of older persons' health based on evidence from literature.

Methods: The study followed the methodological framework of Arksey and O'Malley and PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses Extension for Scoping Reviews). Online databases, namely, PubMed, Cochrane, Ovid, ACM, IEEE Xplore, and Google Scholar were searched by 2 independent reviewers (AG and AMB) for studies on older persons' health data governance published from January 2000 to April 2024. The independent reviewers performed the search, screening, data extraction, and review of full-text papers. A third reviewer (YP) made the final decision for unresolved discrepancies between the first 2 reviewers. The framework by the World Health Organization Pan American Health Organization, a high-level framework for planning and implementing data governance in public health, was used in the data extraction and analysis. Descriptive statistics were used, and a descriptive approach was used to summarize the results of the scoping review.

Results: A total of 9840 titles were identified and 57 papers were included. Of these, 35 (61.4%) focused on technology, 19 (33.3%) on processes, and 3 (5.3%) on people. Data controller, processor, researchers, data subject or patient (including family or relatives), and relevant organizations were involved in older persons' data governance. Data governance frameworks were designed and implemented by reviewing the current evidence, involving the stakeholders throughout the process, implementing specific procedures (eg, collection and aggregating health data), and monitoring and evaluating them.

Conclusions: The review underscores the importance of the involvement of relevant stakeholders and the use of various innovative tools and approaches in governing data related to the health of older persons. Meanwhile, research specifically addressing data governance for older persons' health conditions is limited. To enhance health outcomes for older persons, effective data governance is essential, alongside further research on relevant policies and practices.

KEYWORDS

older persons; health; data governance; scoping review; medical records

Introduction

Data governance is a management discipline and an emerging data management approach in health care. It is defined within the context of information technology as specifying the framework for decision rights and accountabilities to vitalize desirable behavior in the use of data [1]. Data governance highlights the responsibilities of those with authority in the organization [2], internal and external stakeholders [3], such as data stewards [4], civic society, public bodies [5], professional bodies [6], and the individuals who contributed their data [4], in managing data through its life cycle to generate quality information that can inform decision-making. Data life cycle begins with the capture or collection to the processing, use, storage, and disposal of data [7].

Data governance is also important in health systems as it is considered by many organizations as a promising method of maintaining health data [8]. Health data are considered an important asset to improve health through their use in public health, epidemiology, and health informatics [9]. Governance of such data allows health organizations to successfully manage, protect, maintain, and use data to generate information that

improves health care quality, health outcomes, and health system performance [10].

Real-time generation and efficiency in obtaining knowledge are possible when data governance principles are applied in health care [3]. In contrast, the absence of data governance could lead to failure in decision-making and addressing the individual needs of the public sector [11]. Literature underscores the impact of data governance on a nation's health care system, and the need to collect the right data, effectively process it to generate quality information for evaluating the health system, and identify where and when it is not functioning well [12]. Available evidence calls for the need to establish, streamline, and institutionalize a strong and comprehensive data governance process [5,13-19].

Data governance is essential in digital transformation initiatives of organizations as it improves data quality and accuracy and facilitates real-time data exchange [20]. One of the principles of the global health sector's digital transformation is accelerating progress toward inclusive digital health with emphasis on the most vulnerable populations [15]. These vulnerable populations include the older persons. The potential of data governance in the field of older persons' care has been highlighted by the World Economic Forum by presenting a new approach to data governance [21]. It emphasized that the combination of caregiver skills, for example, with the older persons' data such as their specific care needs, can result in better and more precisely tailored care for older persons.

The state of research on data governance in the health care of older persons is unexplored locally and internationally. This leaves little guidance for its application in practice and for future research on the topic. Thus, this scoping review aimed to map out the available literature on data governance in the context of older persons' health. Specifically, this review sought to answer the following questions: Who is involved in the planning and implementation of data governance ("people")? How are data governance frameworks designed and implemented? What are the governance processes that lead to the improvement of older persons' health ("process")? What tools and technologies are used to effectively govern data ("technology")?

Methods

Study Design and Framework

This scoping review followed the methodological framework of Arksey and O'Malley [22] and PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses Extension for Scoping Reviews) [23]. The review questions were informed by the data governance framework in public health by Pan American Health Organization (PAHO), a high-level framework for planning, implementing, and continuously improving data governance [10]. The framework highlights the involvement of 3 components: people, processes, and technology. The people component includes establishing decision-making structures (eg, both the executive decision-making and the technical bodies); defining roles and responsibilities of those involved in the management of data throughout its life cycle; communicating these roles and responsibilities, data-related decisions, policies, and processes; and ensuring transparency on adherence to standards. Processes include managing data assets, enabling processes and standard operating procedures, and establishing processes for policy management and ensuring standards. The technology component pertains to identifying and implementing tools and technology required to manage data such as hardware and software; ensuring quality, availability, and security of information systems; and ensuring performance of the tools [10].

Aside from the framework for planning and implementing data governance, the data governance functions throughout the data life cycle also guided this scoping review. Data governance should address and include defining accountabilities, prioritizing investment requirements, establishing policies, implementing processes, setting standards, managing risks, and monitoring performance related to data throughout its life cycle. The data life cycle is as follows: data collection; data aggregation; data quality assurance and monitoring; data storage; data protection; data access, use, and disclosure; and data retention and destruction [10].

Sources of Information

Six databases, namely, PubMed, Cochrane, Ovid, IEEE Xplore, Association for Computing Machinery (ACM), and Google Scholar were searched. PubMed, Ovid, and Cochrane contained a vast collection of health literature. IEEE Xplore and ACM digital libraries contained resource materials from the fields of electrical engineering, information technology, computer science, and electronics, which capture the technology-related aspect of this review. Google Scholar indexes the full text or metadata of scholarly literature and contains a wide variety of disciplines and sources.

Search Strategy

The strategy was developed in consultation with an academic librarian and the search terms used were "data governance," "health data governance," "older person," "older people," "older adult," "elderly," "senior citizen," and "aged." Boolean operators were used to filter search results (Table S1 in Multimedia Appendix 1).

This review also included evidence from nonresearch sources [24] such as reports, projects, and economy papers from Google Scholar. Moreover, experts in data governance, eHealth, and geriatrics were consulted to explore additional literature sources. The experts were identified through the existing networks of the investigators and organizations relevant to digital health. Searching the reference list of the identified data governance literature was also conducted.

All the literature searched through the online databases, digital libraries, consultation with experts, and reference listing was uploaded in a shared Google Drive folder accessible only to the reviewers using their official university email addresses. The titles were encoded using Google Sheets to identify and remove duplicates.

Selection Process

Considering that data governance was introduced in 2000 and literature on the topic started to be published around the same

time [1,2,25], the search was filtered by publication dates between January 1, 2000, and April 22, 2024. The papers that meet the following criteria were included: (1) topic related to data governance including people, processes, or technology, (2) topic relevant to older persons' health care, (3) peer-reviewed publications, reports, policies, programs, and policy briefs, and (4) in the English language. Resources that were not related to data governance and older persons' health, conference abstracts, and published in languages other than English were excluded.

Following the eligibility criteria, 2 reviewers (AG and AMB) independently searched databases, screened papers for eligibility, reviewed the full texts, and extracted data from the included studies. If the reviewers are unable to screen papers based on the title alone, abstract screening was done to check whether the papers are related to health, data governance, and older persons. Initial data extraction from the abstracts was done to document the topic they covered using a data extraction form.

The reviewers independently documented the search yields and listed the titles obtained per online database using Google Sheets. The search yields of each reviewer per online database were compared as a form of initial validation. To ensure consistency among the reviewers, the procedures from searching to data extraction were pilot tested using 10 randomly selected samples. Reviewers proceeded with the next phases only upon reaching 75% agreement [24].

For each phase, the reviewers documented the reasons for exclusion and settled discrepancies by discussing them throughout the selection process. The reviewers met online and conferred about the discrepancies, which led to an amendment of the eligibility criteria. Based on the initial assessment of the abstracts and available full texts, there were various papers with mixed populations as their study samples (eg, 18 years and above). Considering the focus of this review, the reviewers decided to only include papers with older persons explicitly stated in their titles or abstracts or representing more than 50% of the study sample. Meetings between the reviewers were conducted to discuss which of the papers would be included in the review.

Data Extraction

Once the list of included studies was finalized, the 2 reviewers (AG and AMB) independently extracted the relevant information using an extraction tool in Google Sheets. Information such as authors, citation, publication year, type of publication, research design, setting of care, population, data governance function and component, and outcomes of the study and the technological intervention, among others, were extracted for further analysis. The reviewers conducted regular meetings to discuss and reconcile differences in the extracted data. Any disagreements that remained unresolved were discussed with a third reviewer (YP) to arrive at a consensus. The third reviewer made the final decision for the unresolved disagreements between the first 2 reviewers.

Data Management and Analysis

The search results and study selection process are documented in this scoping review report and presented using a PRISMA-ScR flow diagram. All data were documented in a Google Sheets document and exported into an Excel file after the entire process ended. For the unstructured texts in the data extraction form, a qualitative content analysis was conducted to describe how data governance is planned and implemented in the care of older persons. The data were coded according to the framework components involved, namely, person, processes, and technology, and data governance functions. A descriptive approach was used to summarize the result of the scoping review. Numerical or categorical data were presented using counts and proportions. Tables and a figure were used to present the extracted data for each extraction category.

Ethical Considerations

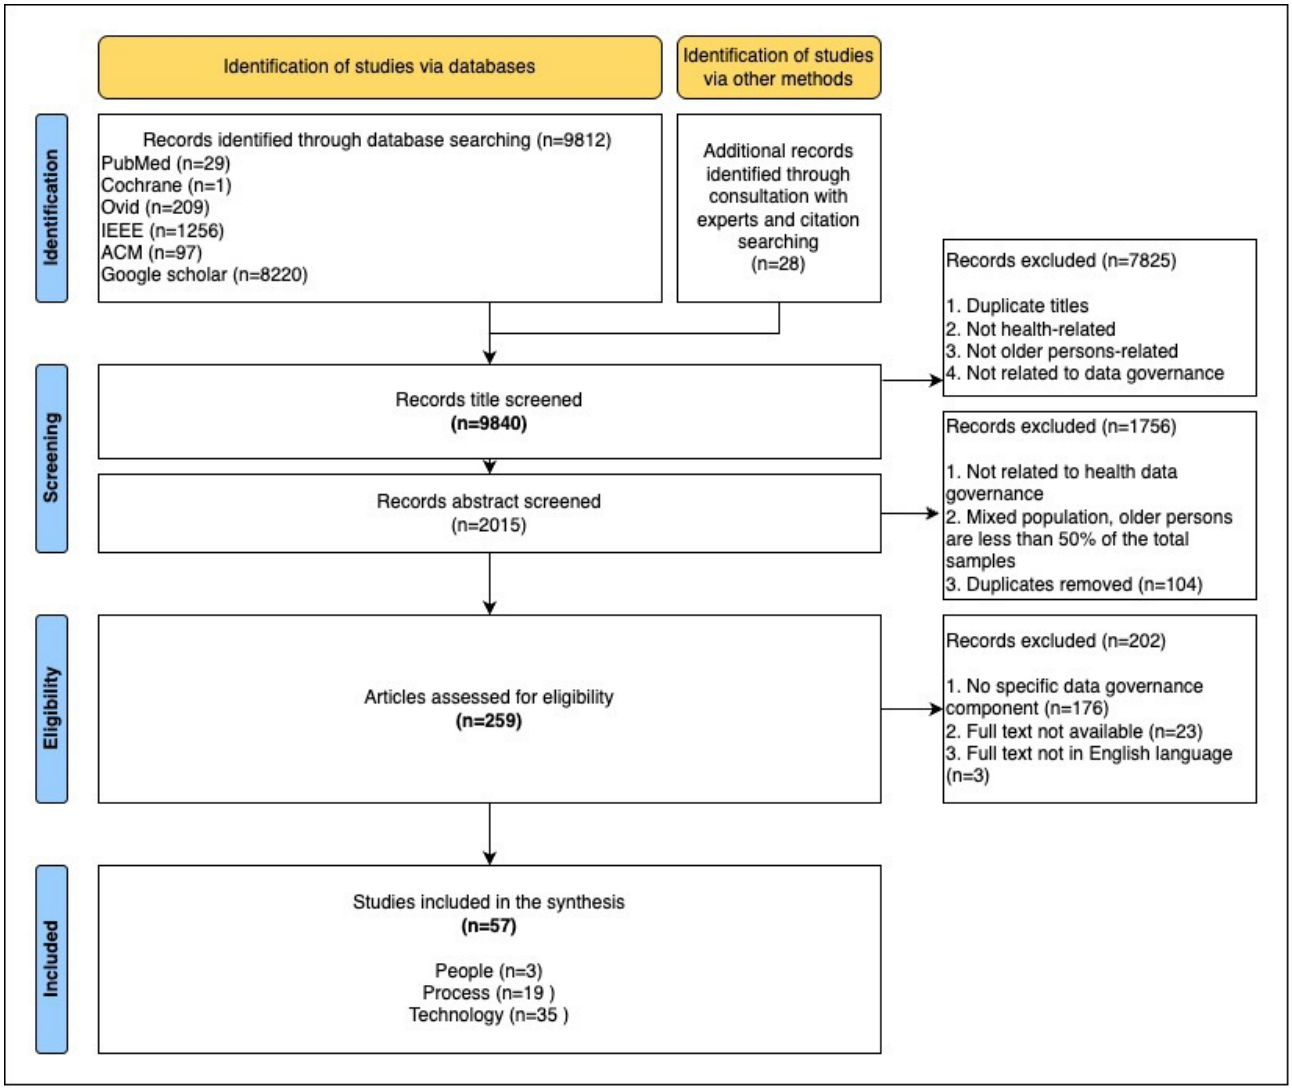
The study was monitored and classified as exempt from ethics review (UPMREB 2023 - 0864-EX) by the University of the Philippines Manila Research Ethics Board.

Results

Overview

A total of 9840 titles were identified from 6 databases, consultation with 3 experts, and reference listing (Figure 1). Duplicates and all papers not related to older persons, health, and data governance, and those with mixed populations were removed during the screening phase, leaving a total of 259 papers assessed for eligibility. Of these papers, 202 were removed due to the unavailability of full texts, non-English language, and lack of specific data governance components. A total of 57 (22%) papers met the criteria for inclusion in the synthesis.

Figure 1. PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses Extension for Scoping Reviews) diagram.



Description of Included Studies

The included studies were published between 2003 and 2024; 56.1% (32/57) of these were published in the year 2020 onwards. The majority (32/57, 56.1%) of the included studies were from the IEEE digital library. Most (47/57, 82.5%) were journal papers, followed by conference proceedings (7/57, 12.3%). These conference proceedings were peer-reviewed full papers from IEEE and ACM (Table 1).

In terms of study design, 36.8% (21/57) were observational, followed by 29.8% (17/57) classified as experimental studies. These experimental studies are subdivided into 2 groups, namely, technology development and randomized controlled trials. About 30% (16/57) of the studies did not specify their design.

The studies were conducted mostly in home settings (11/57, 15.8%), followed by those conducted in multiple settings of care such as home and hospital, community and hospital, and hospital and long-term care facilities. More than 30% of the included studies did not specify their study setting. In terms of geographic coverage, most were conducted in Europe, followed by Asia and those with multicountry sites. There were no included studies that covered the following continents: Africa, Middle East, and South America (Table 1).

Sixty-seven percent of the included studies provided information about the study population, particularly, the age group, mean age, or age range they covered. Although 33.3% (19/57) did not indicate the specific age of their study population, the technology or the data governance component being relevant to older persons was explicitly stated in the title, abstract, and full text. Due to the variation of available information on age and unavailability of other information, the overall mean age cannot be computed.

About 70% of the included studies specified the sample size. A study had 1 older person sample, which was about a novel cloud-based framework for the older adult health care services [26]. The largest sample size among the included studies was 591,726 electronic health records of primary care patients aged 65 years and older [27].

Data Governance Components and Functions

A majority (35/57, 61.4%) of the included studies were largely related to technology, tools and technology, in particular (Table 2). This is followed by processes (19/57, 33.3%), which are mostly centered on enabling processes and standard operating procedures. Only 3 papers were focused on people, particularly, roles and responsibilities and decision-making structure.

Interestingly, there were no included studies on communication and transparency under the people component, standards and policy management in the process component, availability and security, and performance alone in the technology component (Table 2).

Table 2 also shows that the data governance function of the included studies mostly focused on implementing processes, while only a few covered monitoring performances [27-30], defining accountability [31-33], setting standards [34,35], and managing risks [36].

Designing and Implementing Data Governance

The identified actors involved in designing and implementing data governance related to the health of older persons include data controllers, processors, and subjects. Specific data controllers identified in this review include a hospital [32], researchers [33], and a steering committee [37]. The data subjects were patients [32], persons with dementia [33], nursing home residents [37], friends or relatives [32], legally authorized representatives [33], and hospital staff [32]. The data processors were a platform service provider [32], research team members [33], and privacy, scientific expert, and data access committees [37].

All included studies on the people component of data governance highlighted the crucial roles of relevant stakeholders (eg, controllers, processors, and subjects) in planning, designing, and implementing data governance [27,32,33]. Moreover, the composition, roles, and accountabilities of these stakeholders vary depending on the settings (eg, hospital, research, and nursing home).

An example specifying the roles and responsibilities of people involved in data governance was highlighted by Bernsmed [32] in the context of medical data collected from sensors that are exchanged between the older persons, their families and friends, and health personnel. The roles of data controller, processor, and subject were defined, and the accountability obligations were outlined. A data controller, which can be a person, public authority, agency, or other actors, determines the purposes and means of personal data processing. The data processor processes the personal data on behalf of the controller. Meanwhile, a data subject is a person who can be identified directly or indirectly through a reference identification number. In the study, the patients and relatives or friends, as well as the hospital staff, were the data subjects, while the hospital is the controller of its patients' and personnel's data. The data controller (hospital) is accountable to patients, relatives or friends, and hospital staff (data subjects) in informing and obtaining consent for the collection, processing, and management of their data [32].

A total of 10 papers provided information on how frameworks related to data governance of older persons' health data are

designed and implemented [26,32,33,35,37-42]. Specific examples of the use of data governance frameworks were related to addressing a particular issue such as fall detection [41], dementia care mapping [42], depression risk prediction [35], cardiac image processing [40], and digital twin health care for real-time supervision and crisis warning [43].

Conceptual content analysis of the methods using the PAHO framework emphasized the involvement of relevant stakeholders, implementation of specific processes, and conduct of literature review, demonstrating the feasibility or testing of the developed framework and defining the roles and accountabilities of the actors or stakeholders (Table S2 in Multimedia Appendix 1).

Data Governance Processes, Tools, and Outcomes

A total of 19 papers provided information on the specific processes or interventions relevant to older persons' health [26,30,34,35,38,39,41-53]. Majority focused on implementing processes pertaining to data collection, aggregation, and access, use, and disclosure. One study covered 6 data life cycles from data collection up to disclosure [44]. There were no papers that covered the process of defining accountability, managing risks, prioritizing investment, and establishing policy (Table 2).

Several tools and technologies were identified and used for data governance throughout the data life cycle. A total of 35 papers provided information on the specific technologies relevant to older persons' health [27-29,36,40,54-82]. Most of the identified technologies focused on implementing processes while only a few were related to use of technology in monitoring performance, defining accountability, and managing risks. Furthermore, these technologies are mostly involved in data collection.

In implementing data governance processes, various tools and technologies are used in collecting data for the assessment and monitoring of health needs; assessment of fall risk and detection of fall; identification of mental health–related issues such as mild cognitive impairment, dementia, stress, loneliness, and depression; and improvement of lifestyle and health (Table S2 in Multimedia Appendix 1).

In terms of specific outcomes of the technology component of data governance, a total of 34 papers provided information on these. Most of the outcomes were process-related, such as efficient data access; quality control; communication and care support; recognition, detection, and prediction of various conditions; monitoring; and others. Only 2 included papers provided information on health outcomes among the older person samples, namely, improvement of quality of life [62] and cognitive skills and function [68] (Table S2 in Multimedia Appendix 1).

Older Persons' Health Care Data Governance

Figure 2 summarizes the results of this scoping review following the data governance framework in public health by PAHO [10].

Figure 2. Older person's health care data governance based on the available literature. Discussion

Principal Results

This scoping review aimed to synthesize available information on how data governance is planned and implemented in the context of older persons' health based on evidence from literature. Specifically, it aimed to answer the following questions: Who are involved in the planning and implementation of data governance (people)? How are data governance frameworks designed and implemented? What are the governance processes that lead to the improvement of older persons' health (process)? What tools and technologies are used to effectively govern data (technology)?

Findings show that available studies related to the health of older persons covered mostly data governance components related to technology and process. Moreover, data governance is designed and implemented by initially examining the current evidence and existing regulatory frameworks, involving all relevant stakeholders and defining their roles and accountabilities, implementing specific processes following the focused issue, and testing and monitoring the governance framework. Various data governance processes, tools, and technologies are used and contribute to the improvement of older persons' health. The use of these mostly leads to process outcomes.

This review emphasizes the involvement of stakeholders, particularly in technology development and testing process [40,41], sharing perspectives on digital transformation of public health services [39], and mapping of service users [42]. Moreover, the accountability of data controllers, processors, and subjects was outlined [32,33,37]. This underscores the data governance responsibilities of those with the authority in the organization [2] (data controller), the internal and external stakeholders (data processors and subjects) [3-6], and, ultimately, the data subjects who contributed their data [4] in

managing data through their life cycle to inform decision-making.

Limitations

This review included literature only on data governance relevant to older persons published from the past 2 decades and those peer-reviewed publications, reports, policies, programs, or policy briefs written in English language. Identified studies eligible for review but without full texts were excluded from the synthesis. Despite the efforts of the reviewers and consultant librarian in accessing the papers, 23 full texts were not retrieved. These papers were mostly from ACM and Google Scholar, published 2021 and beyond, included conference proceedings, and focused on the technology component of data governance. These exclusions might have affected the comprehensiveness of the reported findings on technology.

Many included studies did not specify the study design, setting, geographic coverage, age of the study population, and sample size. It would be helpful if this information were available to provide a complete description of the state of data governance literature for older persons. Moreover, the assessment or appraisal of the included studies for methodological rigor and quality was not performed as this review aimed to describe information only on data governance in the context of older persons' health.

Various processes and technologies aimed to contribute to the improvement of older persons' health based on their objectives and purpose were identified. However, since most of the included studies are related to technology, at their preclinical stage of technological development, and focused only on data collection, limited information on the actual health outcomes of data governance specific to older persons was collected.

Comparison With Prior Work

Studies related to health information systems included in this review [27,60,79] also support data governance as an important player in the health system, a promising method of maintaining health data [8], and recognize its potential in the field of older persons' care [83,84]. Various processes, tools, and innovative approaches in governing health data of older persons were explored in this review. Available evidence suggests that the use of these tools and technologies supports data governance, leading to positive health outcomes and better processes [27,31,61-63,68,75-77]. Although positive health outcomes were noted, further interventional studies with utilization of a data governance framework are essential to determine its direct effects on actual health outcomes among the older population.

In terms of processes, findings in this review are consistent with Cave [85] where strategies for implementing data governance were explored through a qualitative case study. These strategies include structured oversight with committees and boards, obtaining stakeholder buy-in, and benchmarking and standardization. Benchmarking and standardization through review of current evidence and existing regulatory frameworks were identified to be important steps in planning and implementing data governance [32,33,35,38,39,42]. These preliminary steps are crucial in ensuring a well-designed and effective governance framework.

Strategies for effective and strategic communications and compliance with regulations were not adequately covered in this review due to the lack of studies on this topic. Communication and transparency, as well as compliance with standards and policies, should be considered in implementing data governance. This is to ensure the protection of people, promotion of health value, and prioritization of equity, which are the key health data governance principles [86]. Moreover, although there were no papers that covered the processes of defining accountability and managing risks, these were discussed in the literature in terms of the role of persons involved in data governance and as integral components of designing and implementing data governance.

Various geriatric syndromes, such as falls and fall risk [54,55,65,69,71,73,74], mild cognitive impairment and dementia [33,42,53,64,66,75,82], frailty [29,80], loneliness, social isolation, and depression [56,57], were the focus of the studies included in this review. However, there were no included studies related to other geriatric syndromes such as functional decline, incontinence, delirium, pressure ulcers, polypharmacy, malnutrition, sleep problems, and others. These geriatric syndromes are common health conditions among older persons [87-90], often having multifactorial causes, and may have a major impact on their quality of life and disability [90]. Data governance covering these conditions can also generate information on strategies to address the needs of older persons and provide quality care to improve their health and quality of life.

Only 1 paper explicitly proposed a data governance framework specific for older persons, which was published a decade ago [38]. The proposed framework was drawn from the Data Management Body of Knowledge of the DAMA International, Inc [2,91] and the work of Cleven and Wortmann [92]. Dahlberg's [38] motive for proposing this specific governance framework was the fragmentation of older persons' data and the necessity to consolidate these data to make it more useful. The paper defined the types and sources of data that exist about older persons, and how these can be integrated into a comprehensive framework. It suggested defining the data categories, attributes, and sources of data first to improve data governance of older persons. There is no evidence that the framework has been validated. Hence, testing this framework is essential to determine its value in data governance for older persons.

It is notable that the included papers that provided information on designing and implementing data governance mostly came from high-income countries such as Australia, United States, Canada, United Kingdom, Japan, Singapore, Netherlands, and other countries in Europe. These countries are actively implementing digital health care solutions in the forms of telemedicine, electronic records, mobile health, and other digital tools for diagnosis and management, hence, the availability of data governance frameworks. On the other hand, no studies were included in the review from Africa, Middle East, and South America. This can be attributed to the challenges experienced in digital health, such as limited infrastructure, affordability issues, and data privacy concerns, especially in low-income and middle-income countries [93-95]. While others have established

and are implementing data governance, the rest are yet to address the challenges of digital health transformation.

The need for data governance in general [14] and in the care of older persons has been highlighted by the reviewed papers specifically on dementia research [42,53], health care applications for geriatric clinical care [49], and nursing homes for quality improvement [37]. New paradigms on the use of big data in dementia research and clinical care [42], as well as international dementia care mapping, require data governance [53]. Likewise, the standardization of machine learning approaches tailored to health care applications is required to evaluate whether these applications improve clinical care for older persons [49]. In nursing homes, literature suggests the need for enhancing transparency, specifically in presenting understandable information to the residents and their representatives on which data will be used, how they will be used, and for what purposes [37].

Findings agree with other papers not included in this review such as the call for institutionalizing a strong and comprehensive data governance process [5,10,12-19,96-98], a national health data governance framework to ensure availability and use of personal health data for public interest [99], and data governance for learning health systems to reduce concerns about privacy and trust in the system [100,101].The included studies were analyzed according to the data life cycle, data governance function, and components they covered to identify research gaps. The people data governance component covered only data access, use, and disclosure. Information on how people are involved, their roles and responsibilities, and communication and transparency during data collection, aggregation process, quality assurance, storage, data protection, retention, and destruction, is lacking. In terms of the process component, limited studies were related to data quality, storage, and protection, and none for defining accountability and managing risk. Meanwhile, no tools and technology were identified from the studies that covered data aggregation, data quality, data protection, and setting standards.

Studies on data governance in health care of older persons are largely focused on various forms of technology followed by process. The major research gap across all data governance components was the lack of included studies on data retention and destruction, prioritizing investments, and establishing policy (Table S3 in Multimedia Appendix 1). Findings and gaps that were identified from this review inform future research directions and practices of older persons' health data governance.

Conclusions

This review highlighted the importance of benchmarking, involvement of relevant stakeholders, and the use of various innovative tools and approaches in governing data related to the health of older persons. However, studies that are explicitly centered on data governance of older persons' health data, their common health conditions, or other geriatric syndromes, are limited. Likewise, identified research gaps include the lack of studies on data retention and destruction, establishment of policy, prioritizing investment, and communication and transparency.

Available studies on the health of older persons covered mostly technology and process data governance components. Only a few focused on people, which were identified to have crucial roles in designing governance frameworks, planning, and implementing data governance. To optimize the use of data in improving the health and quality of life of older persons, a well-designed process that considers the essential data governance components, functions, and principles should be developed and implemented.

Recommendations

Effective governance of older persons' health data requires a multisectoral approach. Benchmarking, utilization of innovative tools and approaches, and collaboration between relevant stakeholders, including policy makers, program planners, health facility administrators, health care providers, information and communication technology and digital health experts, data privacy and legal experts, and, ultimately, the older persons and their families, are essential in designing and implementing data governance.

In establishing health data governance policies or incorporating them into the national standards, legislations, and organizational policies, the key governance principles, components, functions, and data life cycle should be considered. In practice, health settings and personnel should ensure the involvement of the patients (including their families and relatives) in collecting and processing their data. The practical application of data governance frameworks and technologies in the care of older persons is essential to support favorable health outcomes. Further studies on the governance of data on common health conditions of older persons to inform clinical practice, health data retention schedules and destruction methods, and data governance policies and investments are recommended.

Acknowledgments

This scoping review was funded by the National Institutes of Health (NIH), University of the Philippines Manila through the NIH Commissioned Grants 2023 (project code: NIH 2023-027). The project team would like to thank and acknowledge the following: the NIH Executive Committee for funding this scoping review; Dr Shelley Ann de la Vega, director of the Institute on Aging, for her valuable support to the project especially during the funding application; Ms Vivian Biala for providing research grant administrative support; CAMP Research Committee for carefully reviewing and providing technical approval of the proposal; UP Manila Research Ethics Board for exempting the study from ethical review; experts consultants (Dr Alvin Marcelo, Dr Evelyn Hovenga, and Dr John Richard Hizon) for providing valuable insights based on their expertise; Mr Cristopher Naguit for helping the team process the salary and disbursement documents; and, finally, to the UP Manila channels for the processing of administrative,

legal, financial, and technical documents needed for this project. This project would not have been completed without the support of the above personalities and offices. All authors declared that they had insufficient or no funding to support open access publication of this manuscript, including from affiliated organizations or institutions, funding agencies, or other organizations. JMIR Publications provided APF support for the publication of this paper.

Data Availability

All study data are present in this paper and the supplementary materials.

Authors' Contributions

AG performed protocol development, data collection, analysis, manuscript writing, review, and approval of the paper; AMB performed data collection, analysis, manuscript writing, review, and approval of the paper; and YP performed protocol development, data analysis, manuscript writing, review, and approval of the paper.

Conflicts of Interest

None declared.

Abstract

Background: As the global population ages, the prevalence of dementia is expected to rise significantly. To alleviate the burden on health care systems and the economy, it is essential to develop effective strategies to enhance cognitive function in older adults. Previous studies have shown that combined nonpharmacological interventions can improve cognition across various domains in older individuals. However, there is no established gold standard for the exact combination and duration of these interventions, which makes it challenging to assess their overall effectiveness.

Objective: Given the diversity of nonpharmacological multimodal interventions aimed at preventing cognitive decline in older adults with mild cognitive impairment (MCI), this scoping review sought to identify and summarize the characteristics and outcomes of these interventions.

Methods: We adhered to the Arksey and O'Malley methodological framework and the PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses Extension for Scoping Reviews) and searched 4 electronic databases (MEDLINE, PsycINFO, CINAHL, and Web of Science) systematically on July 6, 2023, and updated the search on April 17, 2024, using specific terms and keywords.

Results: This review included 45 studies from 18 countries with 4705 participants from 2014 to 2024 encompassing different combinations of physical training (PT), cognitive training (CT), nutrition intervention, psychosocial intervention, social activities, and electrical stimulation. There is a growing numbers of studies combining PT and CT for MCI treatment, with additional modalities often added to address various aspects of the condition. Compared to single-modal interventions and usual care, multimodal approaches demonstrated significantly better improvements in cognition domains such as attention, global cognition, executive function, memory, processing speed, and verbal fluency. Technology has been instrumental in delivering these interventions and enhancing the effects of PT and CT. Multimodal interventions also show promise in terms of acceptability and user experience, which can improve treatment adherence.

Conclusions: Research is limited regarding the cost-effectiveness and optimal dosage of these interventions, making it difficult to assess the additional benefits of incorporating more modalities. Future research should examine the long-term effects of incorporating multiple modalities, using standardized MCI criteria and outcome measures.

Introduction

Overview

Mild cognitive impairment (MCI) represents a transitional stage between normal aging and dementia, characterized by cognitive decline greater than expected for age, impacting one or more domains such as attention, memory, orientation, executive functioning, language, and visuospatial skills [1,2]. However, the decline does not significantly interfere with daily activities [3]. The lifetime prevalence of MCI in individuals aged above 60 years is estimated to be 15% to 20% [4], with this prevalence increasing with age. The annual transition rate from MCI to various subtypes of dementia ranges from 10% to 15% and can reach up to 25.2% for adults aged 80 to 84 years [5,6]. Older adults with MCI are 46% more likely to develop dementia within 3 years compared to just 3% in the normal-aging population [7].

The trajectory for individuals with MCI may vary, leading to dementia, stable cognition, or a return to normal cognition function [6]. Untreated MCI may progress to dementia, a neurodegenerative disease that significantly impacts daily functions and affects one's physical, psychological, social, and economic aspects. Dementia also directly affects one's caregivers, families, and society [8]. With the global population of individuals aged 60 years and above projected to double from 1 billion in 2020 to 2 billion by 2050 [9], there is mounting concern regarding the rising prevalence of dementia and the urgent need for preventive measures to address the associated social and economic burdens. Factors, such as modifiable risk factors, genetics, and interventions, can affect MCI progression [10]. Therefore, understanding various interventions and their effectiveness in preventing progression from MCI to dementia is crucial given the rising prevalence of dementia among older adults.

Currently, there is no gold standard for treatments or interventions to manage MCI. The American Academy of Neurology guidelines indicate insufficient empirical evidence to support pharmacological treatments for MCI in older adults [11]. Conversely, numerous studies have advocated nonpharmacological interventions, such as physical training (PT) or cognitive training (CT), as effective strategies for managing MCI [11-13].

Nonpharmacological Interventions

PT, including aerobic, strengthening, and balance exercises, has been shown to stimulate norepinephrine release in the brain, promote brain plasticity, increase brain volume, and enhance cerebral blood flow [14]. These effects are crucial for improving cognition, mood, and physiological abilities [15]. Combining aerobic and strengthening exercises has been identified as particularly effective for cognitive improvement [16].

On the contrary, CT primarily uses cognitive stimulation and repetitive tasks to enhance various cognitive domains, particularly memory, attention, and executive function [17]. The effectiveness of CT in improving cognition lies in its capacity to strengthen the functioning and plasticity of neural networks and cognitive reserves [17]. Research suggested that memory-focused CT increased activation and connectivity in the frontal, temporal, and occipital brain regions [18]. These areas are crucial for memory, motor function, processing, attention, language, mood, and problem-solving. Therefore, CT shows promise for improving overall cognition in older adults with MCI.

Given that both PT and CT can enhance brain plasticity and stimulate brain regions responsible for various cognitive functions, their combined application, whether delivered separately or through dual tasking, is the most common approach for managing cognitive impairment in MCI. This multifaceted approach effectively targets different aspects of cognitive decline, countering cognitive decay and neurodegeneration.

Growing evidence suggests that engaging in more social activities (SA) can lower the risk of cognitive decline in individuals with MCI [5], making SA a potential key modality for MCI management. SA involves participation in activities that allow interactions or engagements with others [5]. Karp et al [19] found that older adults with MCI who participated in a broader range of activities, including mental stimulation, physical activities, and social recreation, had a lower risk of developing dementia than those who participated in fewer or no such activities. On the other hand, beyond PT, CT, and SA, emerging evidence suggests that modifiable lifestyle factors, including diet and nutritional intervention (NI), electrical stimulation, or psychosocial intervention (PI) may also improve cognitive functions in this population [10,20].

Multimodal Interventions

A multimodal intervention, integrating various methods such as PT, CT, SA, NI, electrical stimulation, and PI, either sequentially or simultaneously, addresses cognitive decline across different domains of MCI. This approach has been proven effective in managing MCI in older adults, enhancing cognitive abilities, mood, sleep, activities of daily living, functional capacities, and physical abilities, with benefits lasting up to 2 years [14]. A systematic review and meta-analysis [21] showed that combining 2 or more interventions had small to medium effects on global cognition, memory, executive function, and verbal fluency, demonstrating a synergistic effect. Studies also showed that multimodal interventions outperformed single-modal interventions in managing MCI [15,16]. Another systematic review and meta-analysis [22] also supported that combined PT and CT had a small to medium effect on global cognition than various types of cognitive-only interventions in older adults with MCI. However, these reviews solely focused on the effects of combined PT and CT [22] or compared the

effectiveness of multimodal interventions only with single-modal interventions [21], thus lacking direct comparisons between various types of multimodal interventions to inform researchers or clinicians regarding which combinations of multimodal interventions would yield better results. In addition, previous reviews did not consider the user experience of multimodal interventions, which limits the clinical applicability of their findings and important factors to determine the feasibility of multimodal interventions. Thus, a comprehensive evaluation of multimodal interventions should include both feasibility and user experience to optimize benefits.

Optimizing Multimodal Interventions: Technology, Dosage, and Cost-Effectiveness

The increasing adoption of digital health care technology in managing MCI [23] could enhance the delivery and reduce the costs of interventions, especially benefiting those in remote areas [24]. Given the high prevalence and economic burden of MCI on communities and health care systems, technology such as the use of computerized CT (CCT) can help mitigate costs associated with nonpharmacological interventions, addressing the shortage of trained professionals. While previous systematic reviews and meta-analyses have acknowledged the role of technology in MCI management, they mainly focused on CCT [24-26] without considering the broader potential of technology beyond CCT.

Addressing the impact of different dosages of nonpharmacological interventions for MCI is crucial for developing effective and sustainable therapeutic strategies. This involves determining the optimal frequency, intensity, type, and duration of interventions to maximize cognitive benefits while balancing time and financial costs [27]. A study [27] highlighted that CT, PT, NI, and the majority of combined PT and CT significantly improved cognition in individuals with MCI, with particularly effective doses being 1 to 2 sessions per week with 60 to 120 minutes per session and interventions lasting over 12 weeks. However, as this study focused on only one type of multimodal intervention (combined PT and CT), the dosage effects of other nonpharmacological multimodal interventions remain uncertain. Therefore, this scoping review aimed to summarize dosage effects from the literature on multimodal interventions.

In addition, managing cognitive decline imposes a significant global economic burden. The cost-effectiveness of multimodal interventions varies by region because of the differences in health care resources. Although previous research supported the effectiveness of multimodal interventions for cognitive decline, their adoption of multiple modalities often increases cost. However, no prior review has summarized the cost-effectiveness of these interventions, so this scoping review aimed to address this important gap to inform clinical decision-making.

Rationale for a Scoping Review

Considering the variety of multimodal MCI interventions, both with and without technology, and the diverse methodologies and research focus of the existing literature, a scoping review is warranted to identify the current research gaps to inform future research and clinical practice. The complexity and heterogeneity of the interventions, coupled with the rapidly evolving nature of this field, make a systematic review less feasible for comprehensively mapping the use of different types of multimodal interventions and investigating the current research trends. As such, this scoping review aimed to map and describe the latest development in MCI interventions and provide researchers and clinicians with insights into current trends and limitations of the existing approaches and studies. Specifically, this review mapped the current landscape of nonpharmacological multimodal interventions for older adults with MCI, identified and summarized the components of these interventions, research trends, and the use of different outcome measures. It aimed to enhance the understanding of MCI management and provide future research directions on multimodal interventions.

Methods

Overview

This review adhered to the Arksey and O'Malley methodological framework [28] and the PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses Extension for Scoping Reviews) [29]. The protocol was registered on the Open Science Framework platform [30]. The review process involved five key steps: (1) formulating the research questions; (2) devising the search strategy; (3) identifying and selecting relevant studies; (4) data charting; and (5) synthesizing and presenting findings.

Identified Research Questions

This review explored the following research questions:

1. What are the research trends in multimodal interventions for older adults with MCI?
2. What components were included in these multimodal interventions? What results have been reported?
3. How cost-effective were the identified multimodal interventions?
4. What role did technology play in these interventions for older adults with MCI?
5. What insights were available regarding the acceptability, user experiences, and dose responses of these interventions?

Identifying and Selecting Relevant Studies

We conducted a search across 4 databases—MEDLINE, PsycINFO, CINAHL, and Web of Science—on July 6, 2023, and updated the search on April 17, 2024, using specific Medical Subject Headings terms and keywords such as "combine," "multi," "dual," "mix interventions, and "mild cognitive impairment" (Multimedia Appendix 1). Although quality assessment is optional for scoping reviews [31], this review included only randomized controlled trials to enhance study quality. Two independent reviewers (JHSZ and RCFC) screened titles, abstracts, and full texts against the eligibility criteria (Textbox 1). Disagreements were resolved by consensus or by consulting a third reviewer (AYLW). The interrater reliability of the screening process as measured by the kappa coefficient was 0.87.

Textbox 1. Selection criteria for the scoping review.

Inclusion criteria

- Participants: diagnosed with mild cognitive impairment (MCI) by clinicians or psychologists using well-established criteria
- Intervention: at least one combination of a nonpharmacological multimodal intervention in managing older adults with MCI
- Control: received at least one or multiple forms of an intervention, a placebo or sham training, health education, or treatment as usual
- Outcome: must use at least one well-established measurement for testing cognitive outcomes
- Study design: must be an experimental study (randomized controlled trial or quasi-experimental study)
- Other: full-text and peer-reviewed study written in English

Exclusion criteria

- Participants: diagnosed with dementia or the cognitive impairment resulted from drug use or psychiatric or other neurological disorders (eg, bipolar disorder, schizophrenia, stroke, Parkinson disease, or epilepsy)
- Intervention: pharmacological interventions or nonpharmacological experimental studies with a single-modal intervention
- Study design: systematic reviews, scoping reviews, opinion letters, conference proceedings, dissertations, and research design protocols
- Other: gray literature

Definition of Types of Intervention and Control Groups

The included studies featured diverse intervention components and control groups. Detailed operational definitions for these interventions and control groups are provided in Textbox 2.

Textbox 2. Operational definition of the intervention and control groups in the included studies.

Interventions

- Physical training: activities, exercises, or training that required older adults to do physical activities with or without the guidance or supervision of a professional trainer or clinician
- Cognitive training: activities or training that used a standardized systematic cognitive stimulation, rehabilitation task, and training to improve cognitive function
- Nutrition intervention: the use of any type of dietary supplement, including herb extract, or any form of dietary counseling
- Psychosocial intervention: the use of activities, training, counseling, therapy, or education that aimed to improve psychological well-being, including music therapy and mindfulness
- Social activities: activities that encourage social engagement or facilitate social interaction between older adults
- Electric current stimulation: the use of current stimulation including transcranial alternating current stimulation and transcranial direct current stimulation

Control groups

- Active control: a group of participants who received at least one form of intervention
- Placebo control: a group of participants who received a placebo or sham training
- Health education control: a group of participants who received health education
- Inactive control: a group of participants who received no additional treatment, treatment as usual, or only health advice

Data Extraction

Relevant data, including authors, publication year, country, place of recruitment, diagnostic criteria, participants, intervention types, outcomes, treatment frequency and duration, follow-up time points, use of measurement tools, control group characteristics, results, and interpretations of findings, were extracted by 2 independent reviewers (JHSZ and RCFC). All extracted findings were compared. Discrepancies were reconciled by consensus or through consultation with a third reviewer (AYLW).

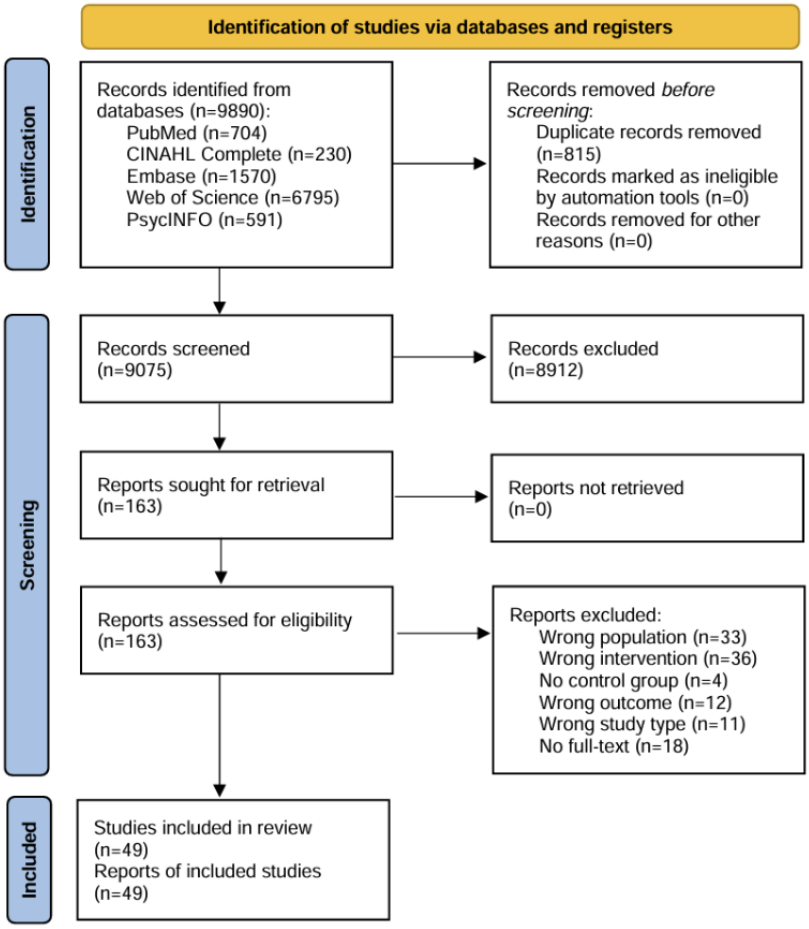
Results

Study Selection and Characteristics

The initial search identified 9890 articles. After removing 815 duplicates, 9075 titles and abstracts were screened; 163 out of 9075 titles and abstracts were selected for full-text screening. Studies based on the same cohort were counted as a single study, including 4 studies by Hagovská and Nagyova [32], Hagovská and Olekszyova [33,34], and Hagovská et al [35] and 2 studies by Liao et al [36,37]. Exclusions were made for reasons

including incorrect target population (n=33), absence of multimodal intervention (n=36), lack of a control group (n=4), different study outcomes (n=12), absence of cognitive outcomes (n=11), and unavailability of full text (n=18). Ultimately, 45 studies from 49 articles published between 2014 and 2024, encompassing a total of 4705 participants, were included in this review. A detailed description of the study selection is presented in Figure 1.

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) 2020 flow diagram of literature search and screening.



The characteristics of the included studies, including participant characteristics, intervention tasks, treatment duration and frequency, and assessment time points, are presented in Multimedia Appendix 2. These studies used various criteria to diagnose MCI, such as the Peterson criteria (n=14) [15,16,38-49], the Albert criteria (n=5) [50-54], and cutoff scores from established screening tools like the Alzheimer Disease Assessment Scale–Cognitive subscale (cutoff score not provided) [38,40], Mini-Mental State Examination between 20 and 27 [55], Montreal Cognitive Assessment with scores up to 28 [15,23,36,37,52,56-65], Clinical Dementia Rating scores from 0.5 to less than 1 [45,60,66], or direct diagnoses from professional psychologists. Table 1 provides a detailed description of the diagnostic criteria used for a comprehensive reference.

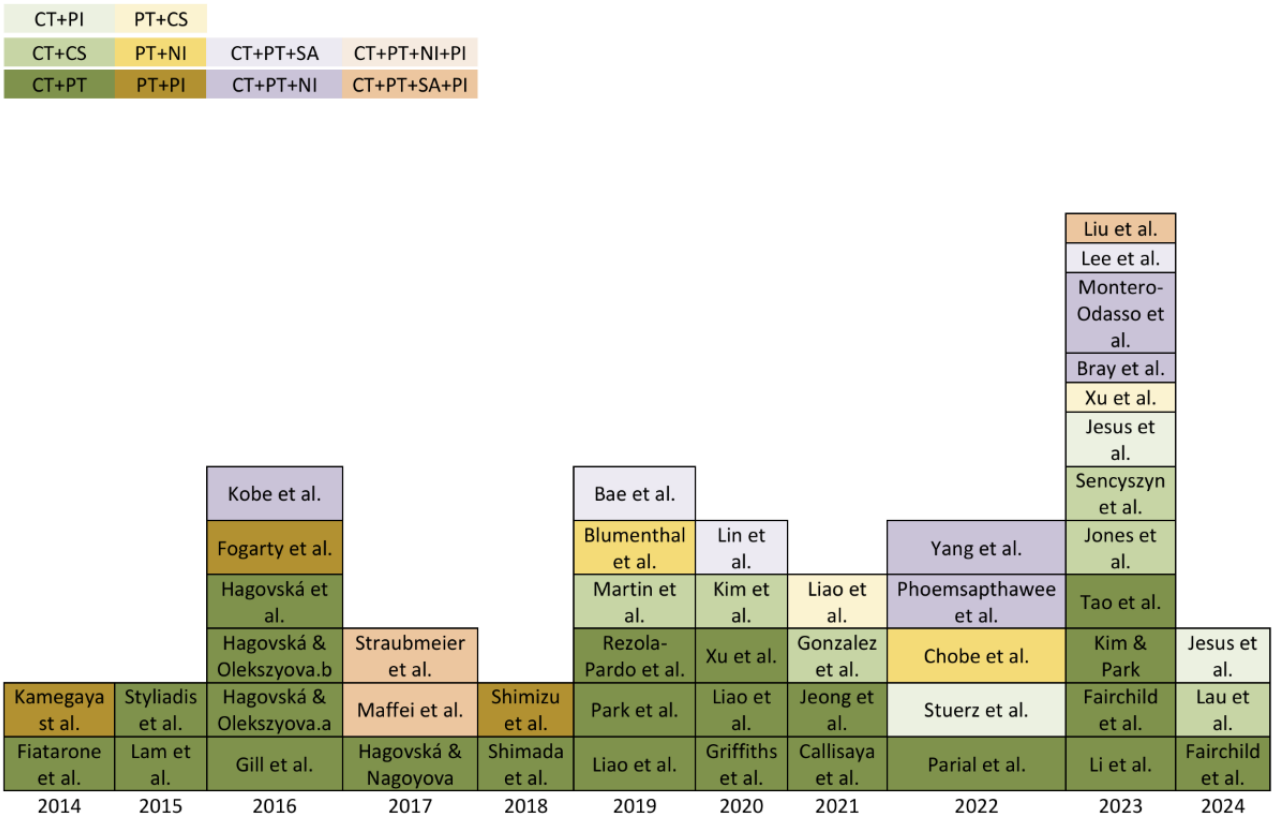
Table 1. Diagnostic criteria used in the included studies.

Criteria	Definition
Peterson criteria [11]	• Self-report cognitive decline • Objective cognitive impairment compared with age • No impact on daily functioning • No dementia
Albert criteria [3]	• Cognitive change reported by the patient, informant, or clinician • Objective evidence of cognitive impairment in one or more domains (typically 1 to 1.5 SDs below the mean when compared with their peers with matched age and education level) • Independent in functional abilities • No dementia

Publication or Study Trend

There has been a noticeable increase in both the number of studies and the variety of multimodal intervention combinations from 2014 to 2024 (Figure 2 [15,16,32-78]). Specifically, studies incorporating NIs as part of multimodal MCI interventions grew from 1 in 2016 to 3 in both 2020 and 2023. In addition, the use of technology in delivering multimodal interventions has gradually increased from 1 study in 2015 to 5 in 2023.

Figure 2. The number of studies that incorporated multimodal interventions for mild cognitive impairment throughout the years. CS: current stimulation; CT: cognitive training; NI: nutritional intervention; PI: psychosocial intervention; PT: physical training; SA: social activities.



Types of Multimodal Interventions

The included studies used combinations of 2, 3, and 4 types of interventions. Although most included studies primarily focused on combining PT and CT, there is an increasing number of studies integrating additional interventions to address the multifaceted nature of MCI. The following section details these specific combinations, the types of control groups used, and the overall outcomes across cognitive domains, such as attention, executive function, global cognition, memory, processing speed, and verbal fluency. Comprehensive outcomes, measurement tools, and targeted cognitive domains of the included studies are summarized in the following sections.

Bimodal Interventions

Overview

Most studies that used combined PT and current stimulation [45,67], or PT and NI [56,58] reported significantly greater improvements in various cognition domains compared to active control groups, while the use of combined CT and PI [61,68,69] reported significantly greater improvements compared to inactive control groups. However, studies with combined PT and CT showed mixed results. Conversely, most studies comparing combined PT and PI [39,41,48], CT and electroacupuncture [42], or CT and current stimulation [44,47,53,60,62] with an active or inactive control intervention found little to no significant advantage in the intervention groups (Table 2).

Table 2. Studies that incorporated a bimodal intervention and outcomes (n=35).

Study	Sample size (control or controls sample size)	Control or controls	Measured cognitive domains	Clinical outcomes
PT[a]+CT[b]				
Callisaya et al [57], 2021	44 (49)	• IN[c]	• GC[d] (COWAT[e], DSCT[f], HVLT[g], TMT-A[h], TMT-B[i], and SCWT[j])	• No significant difference between the two groups for all tests (*P*>.05)

The Combination of PT and CT

Among these 18 studies, 4 used a single-modal active control group [34,59,63,70], 3 compared against a health education group [15,40,71], and 5 used a passive control group [51,52,57,72,73]. Two studies used both a single-modal active control and a passive control group [65,66]. One study compared results with 2 single-modal active controls and a placebo group [38], while another used 3 single-modal active control groups [74]. In addition, 1 study contrasted results with 2 single-modal active controls, a health education group, and a passive control group [16]. Another study used a bimodal active control group [36].

Among these studies, 7 reported significantly greater improvements in all measured cognitive functions within the bimodal intervention groups [15,35,40,52,59,63,72]. Three studies revealed improvements in both bimodal intervention and control groups [16,37,61,70]. One study found greater improvements in executive function, global cognition, and verbal fluency within the PT-only control group, whereas attention and processing speed improved significantly across all groups [38]. Another study reported no changes in cognitive function across any group [57]. In addition, 1 study observed improvements in attention, episodic memory, and working memory across all groups but no changes in global cognition [74]. Finally, 1 study reported greater improvement in global cognition within the NI-only control group [65].

Three Studies Investigated the Combination of PT and PI

Among these 3 studies, 2 studies compared results with a single-modal active control group [39,48], and one compared with a passive control group [41]. One study found that both the bimodal intervention and control groups enhanced attention, memory, and processing speed, but only the intervention group significantly improved executive function [39]. Another study

revealed improvements in global cognition only within the bimodal intervention group, although both groups improved in executive function [41]. In addition, one study reported significantly greater improvements in global cognition exclusively in the bimodal intervention group [48].

Two Studies Investigated the Combination of PT and NI

One study compared the intervention group with 2 single-modal active control groups and a health education control group [56]. It found that both the bimodal intervention and PT-only groups showed greater improvements in executive function and global cognition, although no gains were observed in memory or verbal fluency across groups [56]. Conversely, another study contrasted the intervention group with 2 single-modal active control groups [58] and revealed improvements in global cognition in all groups [58].

One Study Investigated the Combination of CT and Electroacupuncture

This study compared the intervention group with a single-modal active control group. It found that all groups demonstrated significant improvements in global cognition [42].

Three Studies Investigated the Combination of CT and PI

One study compared a reverse sequential control group [68], whereas 2 studies compared results with a passive control group [61,69]. Results from the latter 2 studies revealed significantly greater improvements in attention, episodic memory, and global cognition in the bimodal intervention group [61,69]. Conversely, the study with a reverse sequential control group found enhanced global cognition in both groups. Notably, the group starting with the PI showed more significant attention improvements after the initial training, while the group beginning with CT exhibited greater improvements following the second, combined training phase [68].

Five Studies Investigated the Combination of CT and Current Stimulation

Two of these studies compared the intervention group with a bimodal active control group [53,62]. One study contrasted the intervention group with a single-modal and a bimodal active control group [60]. Another study used a combination of CT and sham current stimulation as a control group [44]. One study included a current stimulation–only group, a sham current stimulation–only group, and a sham current stimulation control group [47].

One study observed improvements in everyday memory and global cognition across all groups, with attention improvements unique to the bimodal intervention group [60]. However, the CT-only control group showed greater working memory improvements than the bimodal intervention group [60]. Notably, transcranial direct current stimulation (tDCS) appeared to enhance the efficacy of CT in processing speed [60], despite not being a direct target. Another study showed that the bimodal intervention group demonstrated more significant attention improvements than both the placebo and CT groups [62]. In addition, 1 study found improvements in attention; processing speed; subjective cognitive functioning; and verbal, visual, and working memory across all groups [53]. Another study revealed improvements in episodic memory, executive function, and visual memory in both bimodal and active control groups [44].

Two Studies Investigated the Combination of PT and Transcranial Brain Stimulation

One study compared the intervention group with a bimodal active control group (PT and sham brain stimulation) [45], while another study used 2 bimodal active controls (PT and sham stimulation and sham PT with brain stimulation) along with a passive control group [67].

Results showed improvements in episodic memory, executive function, global cognition, and visual working memory in both the bimodal intervention and control groups [45]. However, the bimodal intervention group displayed greater enhancements across all cognitive functions compared to the control groups [67].

Trimodal Interventions

Overview

Studies comparing combined PT, CT, and SA with health education controls reported significantly better cognitive improvements, especially in the memory domain [55,75,76]. Similarly, 3 out of 5 studies using combined PT, CT, and NI [46,49,54] showed significantly greater improvements in global cognition compared to control groups (Table 3).

Table 3. Studies that incorporated trimodal intervention and outcomes (k=8).

Study	Sample size (control sample size)	Control	Measured cognitive domains	Clinical outcomes

Five Studies Investigated the Combination of PT, CT, and NI

One study compared the trimodal intervention group with an NI-only active control group [43], another compared it with both a PT-only active control and a placebo group [46], and a third study used an inactive control group [49]. One study contrasted outcomes with 4 control groups: combined PT and CT with placebo NI; combined PT and NI with sham CT; combined PT with sham CT and sham NI; and an inactive control group [54]. The fifth study compared the trimodal intervention with various combinations of PT, CT, and NI placebos [50].

In the first study, the trimodal intervention group study reported no substantial changes in cognitive functions across all groups [43]. Conversely, the second study found the intervention group showed significantly greater improvements in all cognitive functions compared with the placebo group, but not when compared to the PT-only control group [46] and the third study observed more significant enhancements in global cognition in the trimodal intervention group [49]. The fourth study also found greater improvements in global cognition in the trimodal intervention group, but no significant changes in other measures [54]. In the last study, the trimodal intervention group showed no significant difference compared to the controls [50].

Three Studies Investigated the Combination of PT, CT, and SA

All 3 studies contrasted the intervention group with a health education control group, revealing significant improvements in global cognition and memory for the trimodal intervention group [55,76]. In addition, 1 study found significant enhancements in memory compared to control groups [55], while another reported significant improvements in both attention and executive function during a 12-month follow-up in the intervention group [76].

Quadrimodal Interventions

Most studies incorporating quadrimodal interventions reported small to moderate effects across various cognition domains, especially in global cognition (Table 4).

Table 4. Studies that incorporated quadrimodal interventions and outcomes (n=3).

Study	Sample size (control sample size)	Control	Measured cognitive domains	Clinical outcomes
PT[a]+CT[b]+PI[c]+SA[d]

[k]MoCA: Montreal Cognitive Assessment.

[l]AVLT: Auditory Verbal Learning Test.

[m]PALT: Paired Associative Learning Test.

Two Studies Investigated the Combination of PT, CT, PI, and SA

The 2 studies compared a quadrimodal intervention group with a passive control group [64,77]. One study found significantly greater improvements in global cognition in the quadrimodal intervention group [77]. In contrast, the other study reported no significant improvement in cognitive function within the intervention group, but the control group experienced deterioration [64].

One Study Investigated the Combination of PT, CT, PI, and NI

Compared to a passive control group, the quadrimodal intervention group showed significantly larger posttreatment improvements in global cognition and memory. However, these effects showed no difference between the two groups at the 12-month follow-up [78].

The Use of Technology in MCI Interventions

Between 2015 and 2024, a total of 16 studies incorporated technology to enhance intervention delivery. The Nintendo Wii (n=1) was first used as a hardware platform for delivering PT [16]. Subsequent studies used various technologies, including virtual reality (VR) technology (n=1) for combined PT and CT intervention [37]; Nintendo Switch (n=1) [44]; and iPad (n=2) [50,57] for sensorimotor, visuomotor [54], and CT [50], respectively.

In addition, 13 studies used a range of computerized programs for CT targeting functions such as attention, memory, and executive function. These included AKL-T01 (n=1) [62], Brain Fitness (n=1) [16], COGPACK (n=2) [53,68], CogniPlus (n=1) [32], NeuronUP (n=1) [60], Neuropeak (n=1) [54], and RehaCom (n=3) [42,47,63] and 2 studies with no specified programs [44,49]. In addition, 1 study used the FitForAll program [16] for PT. Studies that incorporated CCT alongside other modalities showed significantly better improvements, particularly in global cognition, than studies with either active and inactive control groups. Details on tasks, duration, and major findings of these programs are presented in Multimedia Appendix 3.

Five studies incorporated tDCS with CT [44,47,53,60,62], while 2 studies combined tDCS with PT [45,67]. Specifically, they applied 1.5mA to 2 mA of tDCS to the left dorsolateral prefrontal cortex (DLPFC) or 1.5 mA of transcranial alternating current stimulation (tACS) on the prefrontal cortex [62].

Acceptability and User Experience

User compliance is influenced by the acceptability and experience of treatments. Four studies indicated high acceptability and positive user experiences regarding multimodal interventions. Jesus et al [61] reported that 24 out of 27 participants demonstrated a 97% acceptability rate for the treatment effect and frequency of a combined CT and PI. Another study on a combined PT, CT, and PI intervention reported that 78% (39/50) of participants rated the program as “very good,” 20% (10/50) rated it as “good,” and 2% (1/50) rated it as “pleasurable” [68]. In addition, a study on a combined PT, CT, and SA program showed that 86% (35/41) of

participants were satisfied with the intervention duration and 81% (33/41 participants) expressed a desire to continue [55].

Similarly, a study on a combined PT and CT intervention reported that 39 out of 44 (89%) participants perceived subjective benefits. In terms of overall satisfaction, 14 out of 44 (32%) participants rated it as "very good," 24 out of 44 (54%) participants rated it as "good," and 6 out of 44 (13%) participants rated it as "neither good nor bad." In addition,12 out of 44 (27%) participants considered the user-friendliness of the intervention as "very good" [57].

Dosage Effect and Health Economics

While treatment dosage may affect clinical outcomes, only 1 study evaluated the dosage effects of a quadrimodal intervention (combined PT, CT, PI, and SA) [64]. It found that 1 to 2 sessions per week of the quadrimodal intervention in daycare centers yielded no significant difference in cognitive outcomes compared with 3 to 5 sessions per week [64]. As such, the study suggested that less-frequent sessions (1-2 wk) might be as effective as more frequent sessions, thus further studies are warranted to validate these findings and test with other multimodal interventions.

In addition, while the cost-effectiveness of multimodal cognitive interventions is important for clinical practice, none of the included studies examined the cost-effectiveness of the identified intervention.

Discussion

Overview

This scoping review examines the current research landscape on nonpharmacological multimodal interventions for MCI, highlighting publication trends, intervention types, technology use, user experience, and dosage effects. Over the past decade, the variety of multimodal intervention combinations has increased. The most common interventions combine PT and CT, with additional components, such as NI, electroacupuncture, PI, and current stimulation. Cognitive outcome measures are diverse, targeting various domains. Bimodal and trimodal interventions generally outperform single-modal ones in improving global cognition, attention, and executive function. Notably, PT with current stimulation and PT with NI often demonstrate better cognitive improvements compared to active controls, while CT with PI shows more improvements compared to inactive controls. However, most studies on combined PT and CT report mixed results. Quadrimodal interventions also show superior improvements, although their long-term effect remains uncertain. This review, following the Arksey and O'Malley framework, did not conduct a meta-analysis or risk of bias assessments. The included studies suggested that trimodal and quadrimodal interventions, especially those including SA, might offer better cognitive outcomes, but findings should be interpreted cautiously due to the limited number of studies. Technologies, such as VR, gaming, computerized programs, and transcranial stimulation, are increasingly adopted in MCI interventions. Although technology-assisted training showed significant improvements in various cognitive domains comparable to traditional trainings, results should be interpreted with care given the limited studies. Future research should investigate whether technology-assisted training, with or without additional modalities, offers significantly better cognitive improvements than traditional training. Although only 4 included studies assessed the acceptability of multimodal interventions, they were generally well-received by users. Only 1 included study evaluated the dosage effects of a quadrimodal intervention, suggesting that 3 or more sessions per week may not be beneficial, although this finding should be interpreted cautiously. As none of the included studies evaluated the cost-effectiveness of these interventions, future studies should address this gap.

Types of Modalities

Aside from traditional PT like aerobic and stretching exercises, recent research has been expanding to explore various PT types beyond traditional methods, including mind-body exercises such as tai chi [66], yoga [58], and dancing [15] as viable components in multimodal interventions for managing MCI.

Mind-body exercises, which engage the mind to influence bodily functions, are popular among older adults, partly due to cultural preferences in certain populations. The effectiveness of such exercises, such as tai chi, varies between Asian [74,79] and Western populations [39], highlighting cultural influences. tai chi, for instance, demands whole-body coordination, rhythmic movements, dynamic weight shifting, single-limb support, integrating movement recall (memorization and concentration), spatial orientation, and cognitive activities such as attention and executive control. This provides simultaneous PT and CT that could be beneficial for older adults with MCI [20,66]. In addition, these mind-body exercises offer relaxation and social support in group settings, potentially improving mood and motivation to participate in activities. Given their multifaceted benefits, mind-body physical activities may be incorporated into multimodal interventions for MCI.

With the growing interest in multimodal interventions, there is a noticeable increase in incorporating various interventions in addition to combined PT and CT. Modifiable lifestyle factors, including NI, are crucial for cognitive improvements among older adults with MCI. However, the effectiveness of NI as a standalone intervention has yielded mixed results for cognitive outcomes. Different dietary patterns and supplements have been suggested to promote cognitive health. For instance, the Mediterranean-Dietary Approaches to Stop Hypertension Intervention for Neurodegenerative Delay diet is popular. However, a large-scale study found that the Mediterranean-Dietary Approaches to Stop Hypertension Intervention for Neurodegenerative Delay diet was not significantly superior to a control diet with mild caloric restriction over 3 years [80]. In addition, systematic reviews suggest that certain single-nutrient supplements, such as folate, vitamin E, omega-3 fatty acids, and probiotics, show promising but preliminary results, often based on weak evidence or low-quality studies [81-83].

NI has drawn attention to its potential in multimodal interventions for MCI. All the included studies that incorporated NI demonstrated promising outcomes when combined with PT and CT compared to the control groups. However, some studies

lacked detailed descriptions of their use of dietary guidelines, limiting the understanding of whether the specific dietary changes could be contributed to cognitive improvement. The current findings suggest that while a single NI may offer limited results, a combination of different modalities can provide a synergistic protective effect, highlighting the effectiveness of a multimodal approach over a single intervention.

In addition, there is an increasing use of PI and SA as supplementary components. Previous studies suggested that engaging in SA could help delay the development of dementia and cognitive decline [84,85]. SA and leisure activities not only have therapeutic benefits but also allow participants to engage with peers, fostering long-term adherence to interventions. It is important to note that the number of studies that incorporated the use of PI and SA is still relatively small; more studies are warranted to strengthen whether the implementation of additional PI and SA might provide additional benefits in a multimodal intervention for MCI.

Collectively, all the aforementioned intervention components play a role in enhancing mental health and cognitive functions across various aspects of MCI, suggesting that a larger number of combined modalities could be beneficial. This aligns with a previous systematic review that suggested an increased number of modalities might yield greater improvement in cognition [21]. Indeed, most of the included studies incorporating 3 or 4 modalities reported notable improvements in various cognitive domains, especially when additional modalities (including SA, NI, and PI) were combined with PT and CT. However, there is no consensus regarding the optimal number or combinations of modalities for multimodal interventions. Furthermore, it is worth noting that adopting multiple lifestyle changes may pose challenges for older adults. As Schneider and Yvon [86] suggested, such changes are more feasible for older adults in better health and with higher education levels. In current MCI management, while health advice is important, it may not sufficiently inform or motivate individuals with MCI to adopt new management strategies. Therefore, health education emerges as a crucial component for the successful implementation of lifestyle changes because it provides vital information on lifestyle modifications and guides the execution of physical or cognitive exercises at home.

Nonetheless, it is noteworthy that most of the included studies only compared the effectiveness of 3 or more modal combinations with single-modal interventions, health education, or passive control groups. It remains unclear whether there are more modalities or specific combinations that would offer greater benefit to individuals with MCI.

The Current Use of Technology

Beyond traditional interventions, technology is increasingly embraced by researchers for its potential as a valuable asset in delivering multimodal interventions for clinicians and researchers from 2015 (n=1) [16] to 2023 (n=4) [47,54,62,63]. CCT comprises guided drill-and-practice on standardized tasks aimed at various cognitive domains that gradually progress with adjustable difficulty based on user performance. This approach is both cost-effective and safe for widespread use [87].

This review identified several computer programs that provide personalized CCT targeting various cognitive domains. Our findings concur with a previous systematic review, showing CCT and VR-CT as effective in enhancing attention, executive function, global cognition, memory, processing speed, verbal fluency, and visuospatial ability in older adults at risk of cognitive decline [25]. These outcomes are on par with traditional in-person PT and CT, suggesting CCT and VR-CT as promising ways for broad-scale cognitive intervention delivery.

Interactive video game–like programs offer training across multiple cognitive domains, including attention, executive function, processing speed, and visuomotor and visuospatial abilities, providing more engaging and motivating experiences for older adults with MCI than traditional face-to-face CT [26,88-90]. These programs also facilitate PT through diverse hardware. For instance, one included study used Nintendo Wii, Wii Remote, and Wii Balance Board for physical exercises (eg, aerobic exercises) [16]. Advanced technologies such as the latest Nintendo Switch, which tailored physical exercise games and hardware (eg, Ring Fit Adventure), adapt challenges to individual capacities, progressively improving cognitive function in older adults with MCI.

In addition to the computerized training program, the included studies that incorporated VR technology in delivering combined PT and CT demonstrated significant improvement in executive function and global cognition. These improvements were greater and consistent with the improvements from the combined PT and CT control group without the use of VR [36,37]. This positions VR as a promising tool for integrated therapy. As suggested by recent systematic reviews, VR could act as an assistive device to deliver training and help improve executive function and global cognition in individuals with MCI [25,88]. Compared to traditional PT and CT, VR-PT and VR-CT offer accessibility, cost-effectiveness, and immersive personalized experience to facilitate skill transfer to activities of daily living [36,37,90]. With advancements in technology, VR equipment has become more user-friendly, affordable, and suitable for home use and rehabilitation, benefiting older adults with mobility issues. However, potential side effects such as stimulator sickness, discomfort, tiredness, mood change induced by immersive experience, and some health-related issues from wearing the VR headgear [90] highlight the need for clinician oversight to adjust treatment as necessary.

Although the development of computerized training programs can be costly, the potential for widespread deployment can offset the expenses of hiring numerous qualified assessors or clinicians and the costs associated with traveling for face-to-face training. Future research should explore integrating these programs with multimodal interventions, such as NI, to enhance their effectiveness and improve the overall well-being of individuals with MCI.

MCI affects multiple cognitive functions. The DLPFC plays a crucial role in functional connectivity with other brain regions and controls various cognitive functions, including attention, decision-making, planning, and working memory. Research has found that individuals with MCI exhibit functional disconnection

in the left DLPFC, leading to attention and working memory deficits [60]. This review included studies that used noninvasive brain stimulation techniques (eg, tDCS [45,53,60] targeting the left DLPFC and tACS targeting the prefrontal cortex); results from these studies suggested that using tDCS or tACS alongside PT or CT could enhance the effectiveness of PT or CT by improving cognitive capacity and reducing the load needed to perform cognitive tasks, thereby increasing processing speed and potentially serving as a viable component in future studies.

Taken together, technology stands as a valuable adjunct in administrating PT and CT, offering standardized, cost-effective, and assessable personalized experiences. Such technological integration could help researchers develop comprehensive management strategies for the widespread treatment of MCI in older adults.

Acceptability and User Experience

Acceptability and user experience are pivotal for the success of interventions aimed at managing MCI, which directly influence its adherence rates. Adherence, in turn, significantly affects the effectiveness of multimodal interventions. Therefore, the interplay between user experience, acceptability, and adherence is vital in developing and implementing MCI interventions. However, most included studies have not investigated these factors, which may hinder clinicians or senior management in choosing or recommending treatment options. One included study suggested that the low adherence rate in older adults might be attributed to family responsibilities, health issues, and social commitments. Leveraging technology, particularly eHealth and mHealth tools, could improve adherence by alleviating barriers to adherence [65]. These tools could be used to facilitate easier implementation and monitoring of interventions, thereby reducing the time and cost required for broader deployment across various populations and regions [91]. Although none of the included studies have implemented such technological applications, future research should explore the potential of mobile technology in enhancing adherence in older adults with MCI.

Limitations and Future Directions

While this scoping review offers a comprehensive overview of current study directions in multimodal interventions for MCI management, it has several limitations. First, by focusing solely on experimental studies with control groups, it may have overlooked relevant insights from qualitative research and gray literature. Second, this scoping review only included English articles, which may introduce cultural bias. Third, this review concentrated exclusively on the cognitive outcomes, omitting physical and psychological outcomes that might be crucial considerations for policy or clinical decisions. Fourth, several included studies had relatively small sample sizes, ranging from 19 to 27 participants [16,43,45,62,65]. Therefore, results should be interpreted with caution. Fifth, adhering to the Arksey and O'Malley framework and PRISMA-ScR guidelines meant no risk of bias assessments or evidence syntheses were conducted. Future systematic reviews or network meta-analyses should aim to summarize evidence regarding the relative effectiveness of different combinations of various multimodal interventions for MCI management.

While the current American Academy of Neurology guidelines for MCI management only recommend PT or CT, recent studies highlight the potential benefits of NI, PI, and SI for MCI management. With the annual conversion rate of MCI to dementia ranging from 10% to 15% per year [7], further research should explore various multimodal intervention combinations, focusing on follow-up, treatment duration, and frequency to potentially reduce or delay conversion rates. Although some included studies used brain imaging, most relied on self-reported or assessment scores, which might not accurately reflect real-world improvements. Future research should incorporate brain imaging technologies to validate results more robustly and elucidate the mechanisms underlying clinical improvements in cognitive function.

Considering the limited research on the cost-effectiveness of multimodal interventions for older adults with MCI and the growing aging population, future studies should investigate the economic viability of these interventions. In addition, the unclear dosage effects of different multimodal intervention combinations warrant investigation. Only one included study revealed that attending 1 or 2 sessions per week of a quadrimodal intervention was not significantly different from 3 to 5 sessions per week, suggesting that fewer sessions of quadrimodal intervention (PT, CT, PI, and SA) might still significantly improve global cognition [64]. However, this finding from a single study is not conclusive, further research is needed to determine the optimal dosage and combination of modalities to optimize the effectiveness of multimodal interventions for MCI.

Previous studies highlight the potential of lifestyle modifications such as dietary patterns in managing cognitive decline in older adults [92-94]. However, these studies used diverse nutrition supplements or dietary patterns. Similarly, while social engagement could help manage MCI [5], there is a dearth of studies on its effectiveness in enhancing physical and emotional well-being in older adults with MCI.

Finally, the included studies used diverse diagnostic criteria and cognitive measurements with different cutoff scores, potentially resulting in heterogeneous participant cohorts that could affect the results. An international consortium should be formed to develop standardized outcome measures for consistent outcome comparisons.

Conclusions

This scoping review provides a comprehensive update on the use of multimodal interventions for improving cognitive functions in older adults with MCI. It presents study directions, multimodal intervention types, respective findings in the included studies, the role of technology in these interventions, and potential research directions. The most common multimodal intervention combines PT and CT. However, various types of interventions such as NI, PI, SI, and brain stimulation have also been incorporated into multimodal interventions more recently. Given the capacity of these interventions to stimulate multiple cognitive domains, the effectiveness of various combinations of modalities should be explored. The research gaps highlighted in this review pave the path for future large-scale clinical trials to help develop more effective management strategies for cognitive decline in older adults with MCI.

Acknowledgments

The authors would like to thank the authors and participants of the included and referenced studies in this scoping review. In addition, they would like to thank the Health and Social Science faculty librarian at the Hong Kong Polytechnic University for her help with our search terms. This scoping review was supported by funding from the Research Institute for Smart Ageing at The Hong Kong Polytechnic University (grant 1-CD4Z). David Ho-Keung Shum is supported by the Yeung Tsang Wing Yee and Tsang Wing Hing Endowed Professorship.

Abstract

Background: Using remote monitoring technology in the context of Alzheimer disease (AD) care presents exciting new opportunities to lessen caregiver stress and improve patient care quality. The application of wearables, environmental sensors, and smart home systems designed specifically for patients with AD represents a promising interdisciplinary approach that integrates advanced technology with health care to enhance patient safety, monitor health parameters in real time, and provide comprehensive support to caregivers.

Objective: The objectives of this study included evaluating the effectiveness of various remote sensing technologies in enhancing patient outcomes and identifying strategies to alleviate the burden on health care professionals and caregivers. Critical elements such as regulatory compliance, user-centered design, privacy and security considerations, and the overall efficacy of relevant technologies were comprehensively examined. Ultimately, this study aimed to propose a comprehensive remote monitoring framework tailored to the needs of patients with AD and related dementias.

Methods: Guided by the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) framework, we conducted a systematic review on remote monitoring for patients with AD and related dementias. Our search spanned 4 major electronic databases—Google Scholar, PubMed, IEEE Xplore, and DBLP on February 20, 2024, with an updated search on May 18, 2024.

Results: A total of 31 publications met the inclusion criteria, highlighting 4 key research areas: existing remote monitoring technologies, balancing practicality and empathy, security and privacy in monitoring, and technology design for AD care. The studies revealed a strong focus on various remote monitoring methods for capturing behavioral, physiological, and environmental data yet showed a gap in evaluating these methods for patient and caregiver needs, privacy, and usability. The findings also indicated that many studies lacked robust reference standards and did not consistently apply critical appraisal criteria, underlining the need for comprehensive frameworks that better integrate these essential considerations.

Conclusions: This comprehensive literature review of remote monitoring technologies for patients with AD provides an understanding of remote monitoring technologies, trends, and gaps in the current research and the significance of novel strategies for remote monitoring to enhance patient outcomes and reduce the burden among health professionals and caregivers. The proposed remote monitoring framework aims to inspire the development of new interdisciplinary research models that advance care for patients with AD.

Introduction

Background

Alzheimer disease (AD) is the most generic form of dementia, and significantly affects the brain cells, declines cognitive abilities, and makes it difficult to perform daily tasks [1]. The main effects of the disease are loss of memory, inability to use problem-solving and logical thinking skills, anxiety, depression, and confusion [2]. AD has remained the leading cause of death among people aged >60 years. The main cause of AD is the accumulation of abnormal proteins such as β-amyloid and microtubule-associated tau protein in the brain; the aggregation of these proteins causes synaptic disintegration and neural loss, which characterize AD [3,4]. Disturbingly, it is estimated that the number of AD cases could grow to 13.8 million by 2060. The pervasive nature of this disease underscores the pressing need for continued research, intervention strategies, and support systems to address the growing challenges posed by AD in an aging population [5,6].

Caring for individuals with AD is an enduring and demanding journey, often placing a significant burden on family members who become primary caregivers or on those who opt to hire professional caregivers [7]. The responsibilities encompass a spectrum of care, requiring a deep commitment to providing the essential support needed for patients with AD to navigate their daily lives. Caregivers play a crucial role in assisting individuals with AD in tasks integral to their routine while also implementing lifestyle adjustments aimed at alleviating stress, confusion, anxiety, and agitation. The caregiving journey involves fostering an environment that promotes mental, physical, and social well-being. This includes implementing tailored strategies to keep patients with AD mentally engaged, encouraging physical activities that align with their abilities, and facilitating social interactions to prevent isolation. However, continuous monitoring and provision of care for patients with AD causes a substantial burden on both the family members and caregivers [8,9]. This responsibility often causes a lot of stress and depression among those providing care. Family members and caregivers find themselves dealing with the progressive loss of individuals with AD. In addition to that, they must navigate between caregiver responsibilities and sustaining a work-life balance. Disputes between family members, financial burdens, and escalating medical expenses extend the challenges that those undertaking caregiver roles face [10]. While existing research has identified various scales to measure the burden on family members, there is a notable gap in the literature concerning effective strategies to alleviate this burden. Manzini and do Vale [11] and Liao et al [12] address this critical gap by exploring remote monitoring methods facilitated by ITs. By leveraging innovative approaches, the research seeks to enhance the quality of care provided to patients with AD and substantially reduce the burden experienced by family members and caregivers. Through the implementation of such technological solutions, the aforementioned studies [11,12] aspired to contribute valuable insights into improving the overall well-being of both patients with AD and those entrusted with their care.

Despite the growing body of research on remote monitoring for AD and related dementias (ADRD), significant gaps remain in the literature, particularly regarding interdisciplinary integration. Previous reviews have primarily focused on individual aspects of remote monitoring, such as wearable devices [13-16], smart home sensors [17-19], or privacy and security considerations [20,21], often in isolation. However, the effectiveness of these technologies depends on a holistic approach that integrates expertise from health care, computer science, cybersecurity, and user-centered design. The lack of interdisciplinary research has led to fragmented solutions that may not fully address the practical needs of patients and caregivers. This review sought to bridge these gaps by offering a comprehensive assessment of remote monitoring technologies while emphasizing their usability, security, and ethical implications. Therefore, we formulated four research questions (RQs) to explore existing remote monitoring technologies and their applications, assess their needs and advantages, examine privacy concerns related to remote monitoring, and investigate technology adoption among older adults:

- RQ 1: What are the primary remote monitoring technologies to capture different behavioral, physiological, and environmental data?
- RQ 2: To what extent do these existing remote monitoring technologies achieve an optimal balance of efficiency, practicality, and empathy in addressing the needs of both patients and caregivers?
- RQ 3: What are the critical security and privacy considerations and concerns involved in these remote monitoring technologies?
- RQ 4: What are the critical design considerations and technology components for a comprehensive remote monitoring framework specifically tailored to patients with AD?

While this review focused on remote monitoring for individuals with AD, it is important to acknowledge that many of the challenges, technologies, and solutions discussed are also relevant to other dementia subtypes. Conditions such as vascular dementia [22,23], Lewy body dementia [24], and frontotemporal dementia [25] share overlapping symptoms [26,27], including cognitive decline, behavior changes, and mobility issues, which can similarly benefit from remote monitoring interventions. However, our decision to center this review on AD was guided by its high prevalence and the significant body of research available on remote monitoring solutions tailored specifically to ADRD. The insights presented in this paper may be broadly applicable to dementia care, although future research should further explore technology adaptations for different dementia subtypes.

The remainder of this paper is divided into 3 key sections. Section 2 outlines the methodology, comprising 3 subsections that detail the scoping criteria, literature search strategy, and

data analysis procedures. Section 3 addresses the RQs in depth. Finally, section 4 concludes the literature review, summarizing the key findings and their implications.

Objectives

Our objective with this paper was to critically assess the effectiveness of various remote sensing technologies in enhancing patient outcomes, particularly for individuals with ADRD, while also identifying strategies to reduce the burden on health care professionals (HCPs) and caregivers. To perform this assessment, the research comprehensively examined key factors essential for the successful implementation and adoption of these technologies. These factors include patient and caregiver compliance, ensuring that the technologies are used consistently and effectively; user-centered design, which focuses on creating accessible and intuitive systems tailored to the specific needs of end users; privacy and security concerns, addressing the safeguarding of sensitive patient data and ensuring adherence to ethical and regulatory standards; and the overall efficacy of these technologies, evaluating their accuracy, reliability, and impact on patient care.

Methods

Overview

In the landscape of AD care, this review undertook a comprehensive examination of the complex dynamics introduced by remote monitoring technologies. We focused on different remote monitoring technologies, types of algorithms used to process the data, issues and concerns related to security and privacy, caregiver burdens, and specific monitoring frameworks for patients with AD. We conducted an extensive search to identify relevant research papers across multiple disciplines from 2011 to 2024. Our search encompassed a diverse array of digital libraries, including Google Scholar, IEEE Xplore, PubMed, and DBLP on February 20, 2024, with an updated search on May 18, 2024, to ensure coverage across multidisciplinary domains, including health care, engineering, and computer science. These databases were selected based on their relevance to remote monitoring technologies, security and privacy considerations, and AD care. While Scopus, Embase, and Cochrane are widely recognized for systematic reviews in clinical and biomedical research, our focus on technological, interdisciplinary, and engineering aspects made IEEE Xplore and DBLP particularly valuable sources. In addition, PubMed was included to ensure coverage of relevant medical and health care studies. Google Scholar was used to capture a broader range of studies, including conference proceedings and gray literature, which are crucial for emerging technologies. On Google Scholar, the search string used was *"Remote monitoring technologies" AND "Wearable sensors" AND Alzheimer AND "Privacy concerns,"* ensuring a broad examination of related literature. PubMed and IEEE Xplore were queried using the search string *(Remote monitoring technologies) AND Alzheimer AND ("Privacy concerns")* to capture articles with a focus on technical and medical perspectives. In addition, DBLP was queried using the search string *Alzheimer AND "Remote monitoring"* to include publications emphasizing computer science and engineering insights. In addition, we cross-referenced the citations of each article to uncover additional relevant articles or government reports aligning with our inclusion criteria. Notably, we imposed some constraints on the period during which the papers were published, and only English-language papers were considered. In total, we identified 31 articles that fulfilled our inclusion criteria.

Our search strategy included keywords such as "Remote monitoring technologies" AND "Wearable sensors" AND "Alzheimer" AND "Privacy concerns" to ensure the inclusion of studies addressing security and data protection—critical challenges in adopting remote monitoring solutions. However, we acknowledge that this keyword choice may have limited the retrieval of studies focusing on broader aspects, such as clinical effectiveness, usability, and caregiver perspectives. While our selection process incorporated additional screening to identify studies covering a wider range of topics, future research could benefit from refining the search terms to ensure a more balanced representation of different remote monitoring challenges.

Study Identification and Selection

A total of 79 papers were initially identified based on their titles and abstracts that were deemed to be potentially relevant to the research topic. Of the 61 records assessed for eligibility, 30 (49%) were excluded for various reasons: 7 (23%) were books, 6 (20%) were partial articles, and 17 (57%) were out-of-context studies. Finally, 31 papers were identified to extract information and insights related to the RQs. These papers were thoroughly analyzed to identify common themes, methodologies, findings, and gaps in the existing literature. This analysis provided a deeper understanding of the current research and valuable insights to guide this review. This systematic approach to literature review and analysis enhanced the validity and reliability of the research, contributing to its overall credibility.

In the following sections, the findings from the papers are presented and discussed. The results are organized based on the information identified in the literature review with respect to the RQs.

Results and Discussion

Primary Remote Monitoring Technologies (RQ 1)

Overview

Remote monitoring technologies using wearable and portable device–based sensors have revolutionized health care by enabling continuous and real-time tracking of various physiological and environmental parameters. These sensors, embedded in devices such as smartwatches, fitness bands, and portable health monitors, can measure heart rate, blood pressure, glucose levels, temperature, and physical activity [28,29]. They offer significant advantages in managing chronic conditions, detecting early signs of health deterioration, and providing personalized care. Wearable sensors are particularly beneficial in monitoring older patients and individuals with chronic diseases, allowing for prompt interventions and reducing hospital visits. Furthermore, the integration of these devices with mobile health (mHealth) apps and cloud-based platforms facilitates seamless data collection, analysis, and sharing with

health care providers, enhancing patient engagement and improving health outcomes. The subsequent subsections provide a detailed description of the various aspects of remote monitoring technologies. To ensure a systematic approach, a thorough review of the literature was conducted following the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) framework [30,31] (Multimedia Appendix 1), as shown in Figure 1. Figure 2 illustrates the integration and synergy of different remote monitoring technologies based on relevant parameters. These are further elaborated on in the following subsections and in Multimedia Appendices 2-5 [14,32-52].

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flow diagram for the study selection in the literature review.

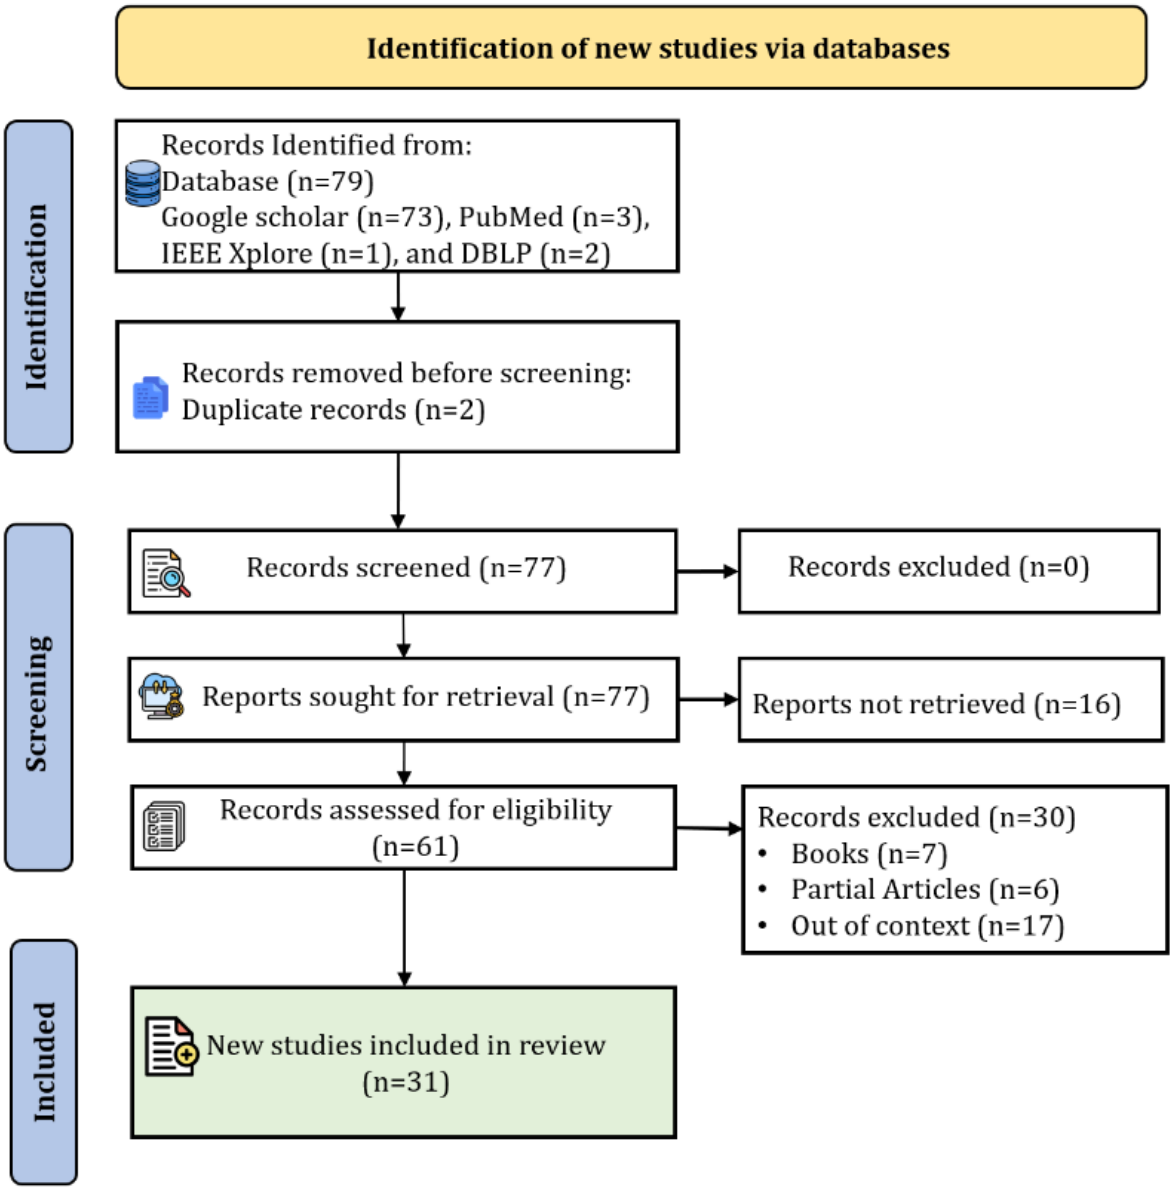

Figure 2. Integration and synergy of different remote monitoring technologies. AI: artificial intelligence; AR: augmented reality; IoT: Internet of Things; ML: machine learning; MR: mixed reality; VR: virtual reality.

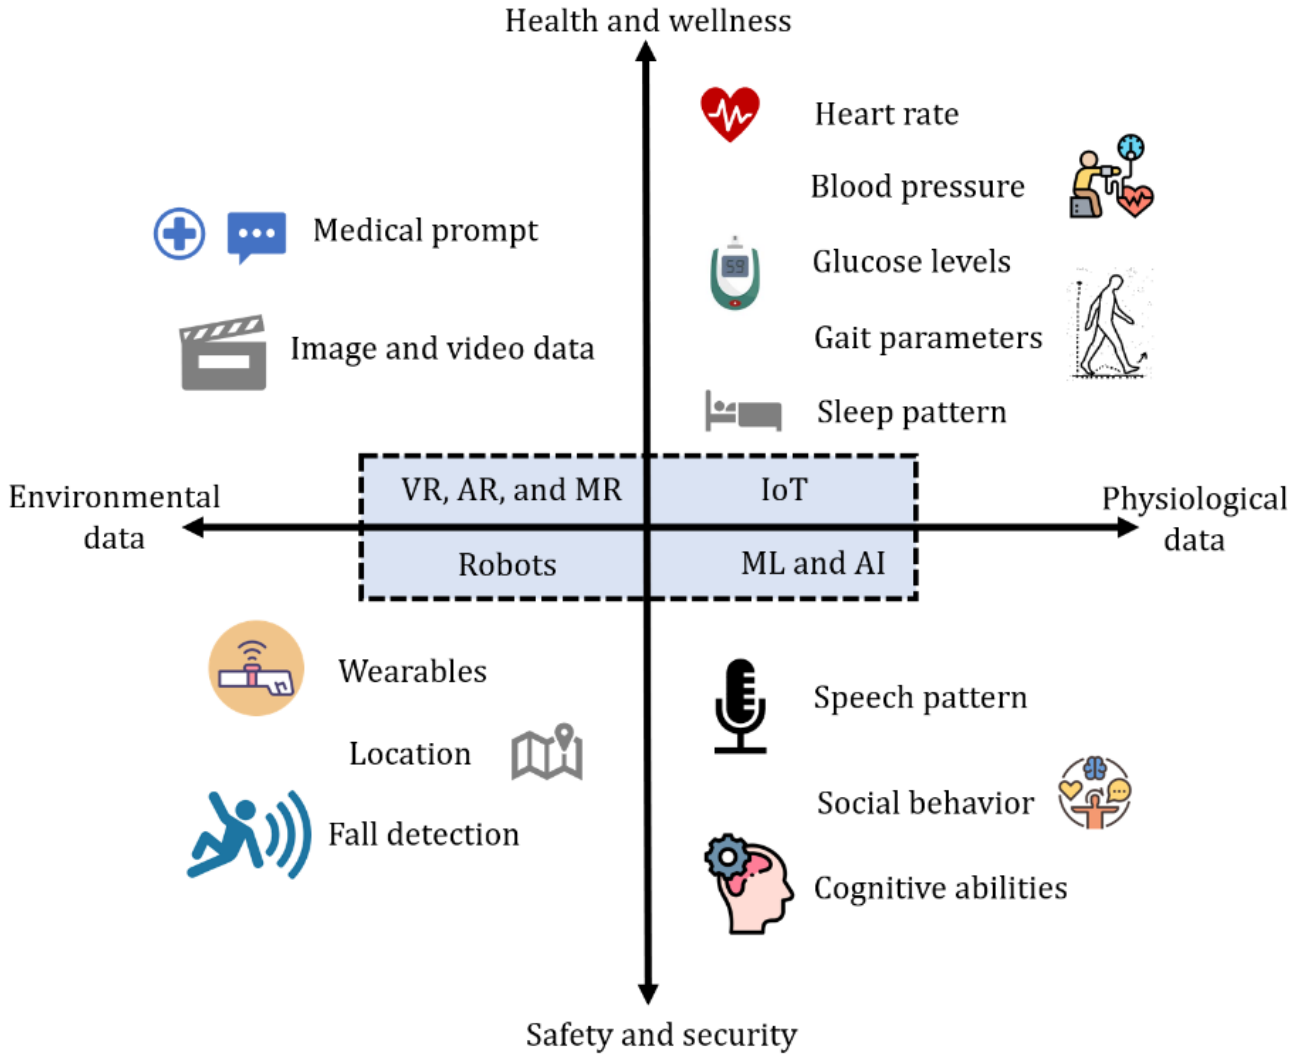


Wearables

Wearable technologies refer to devices worn on the body either as an accessory or as clothing. Devices embedded with an accelerometer and gyroscope, such as wrist or ankle devices, are used for analyzing gait parameters such as speed, variability, and stride length [32]. There are also wearable devices that capture physical activity data, including steps taken, intensity, and duration, aiding in tracking physical activity, which helps the patient with AD be physically active and slow down the progression of the disease [32]. In addition, wrist devices and smart clothes are equipped with sensors, whereas various wearables, including wristbands, smartwatches, and chest straps, collect different data such as physiological signs, posture, gait, movement, and sleep data, and enable the continuous monitoring of blood pressure. Devices such as the Basis Health Tracker, Misfit Shine, Fitbit Flex, Withings Pulse O2, and Actiwatch Spectrum actigraph are used for sleep detection and monitoring daily activities [53-57]. These devices enable continuous monitoring of vulnerable patients, offering medical specialists a comprehensive view of the patients' health for more accurate diagnosis and treatment [33,34]. Moreover, dream headbands are used to record and store physiological data in real time during sleep, facilitating the monitoring of daily sleep patterns and enabling patients and caregivers to access their reports freely [35]. Further details are provided in Multimedia Appendix 2 [32-35,37-45] and Multimedia Appendix 3 [32-34,36-38,42,45-47].

Environment and Home Sensors

Remote monitoring through advanced environment and sensor technology provides a promising approach to enhancing care, monitoring daily activities, and detecting early signs of cognitive decline. In the context of home-based remote monitoring, various sensors are used to capture and analyze vital health and activity data. Infrared sensors strategically placed throughout the home facilitate gait analysis by detecting individual movements and providing insights into gait characteristics such as walking speed, rhythm, and variability [32]. Wireless mattress sensors and ambient sensors are used to monitor sleep time, movements, and patterns, aiding in the early detection of mild cognitive impairment (MCI) and AD. In addition, night monitoring systems equipped with motion detectors are used to monitor sleep patterns and alert caregivers to unusual nighttime behavior [32]. In the case of continuous physical activity monitoring, infrared sensors are used to collect internal

movement data, which allows for the assessment of activity level without the need for active participation of the individual [32,36]. A multisensory approach, including sound sensors, video cameras, radio-frequency identification readers, pressure sensors, light sensors, proximity sensors, temperature sensors, humidity sensors, and location trackers, has been applied to many activities and environmental conditions in the home [33]. This rich dataset facilitates the assessment of disease progression and provides valuable information about changes in daily activities and environmental factors. Behavior patterns are tracked using sensors installed in various areas of the home, including the kitchen, bedroom, and bathroom, along with fall detection sensors. These sensors help monitor mobility, stability, frequency, and time spent in different areas, contributing to a deeper understanding of daily routines and potential risks [32]. Microsoft Kinect cameras are specifically used for gait monitoring to detect and assess falls among older individuals, with the collected video data aiding in fall prevention efforts [37].

Finally, motion sensor–activated light paths and bed pressure sensors are used for fall prevention and sleep problem detection, respectively. These sensors provide an additional layer of safety and monitoring, enhancing the overall effectiveness of the remote monitoring system [34].

Personal Devices

Personal devices, specifically, smartphones equipped with advanced sensors such as accelerometers, gyroscopes, and magnetometers, play a pivotal role in gait analysis and physical activity monitoring. Apps installed on these smartphones analyze the sensor data to determine various gait characteristics, including stride length, walking speed, and rhythm, providing valuable insights into mobility patterns [32]. Moreover, waist-worn accelerometers facilitate continuous monitoring of physical activity parameters such as movements and acceleration, aiding individuals in maintaining optimal levels of physical activity and energy use [32]. In addition to physical activity monitoring, smartphones serve as effective tools for assessing social behavior. By monitoring calls, SMS text messages, and internet-browsing activities, these devices offer insights into an individual's social activity levels and patterns. This information is crucial for health care providers and caregivers to understand the social interactions of individuals, identify potential signs of isolation, and implement interventions to promote social engagement and well-being [37].

Machine Learning and Artificial Intelligence

Machine learning and artificial intelligence (AI) play a pivotal role in health care by leveraging diverse data sources to enhance diagnostic capabilities, predict disease progression, and support clinical decision-making. Driving patterns collected through GPSs are analyzed to detect early signs of preclinical AD. These patterns are compared with disease progression to identify behavior changes linked to AD [32]. Activity data from sensor-embedded devices such as wearables are used for data mining and predictive modeling, aiding in identifying potential health issues and informing health care decisions [46]. Sleep patterns collected from these devices offer valuable insights into an individual's health status, providing clinicians with early warnings of health deteriorations or relapses and enabling timely interventions to improve patient outcomes [47].

Speech pattern analysis using data from health records, including calls and SMS text messages, offers diagnostic capabilities for neurodegenerative diseases such as Parkinson disease and AD, enabling early detection and intervention [38]. In addition, AI-powered image and video processing techniques assist in diagnosing various conditions, such as cancer from x-ray and computed tomography scans and degenerative diseases from fundus photography, enhancing diagnostic accuracy and treatment planning [38]. Furthermore, data collected from wrist-worn actigraphy devices such as the ActiGraph wGT3X are analyzed using a variety of machine learning algorithms, including logistic regression, random forest, gradient-boosting machine, and support vector machine. These algorithms help predict the risks and progression of disease, providing valuable insights for personalized health care management and intervention strategies [45].

Robots

Robots such as Nao, Pepper, Paro, Stevie, Zoro, Mini, and Tangy are emerging as valuable tools in health care settings, particularly for supporting the needs of older adults. These robotic companions engage older individuals through interactive activities such as conversations, quizzes, tongue twisters, and arithmetic calculations, demonstrating promising results in enhancing social engagement and alleviating feelings of isolation [46]. AI-powered robots equipped with advanced sensors and algorithms can access environmental data and user-specific characteristics to deliver personalized medical prompts and emotional support. These robots play a crucial role in physical rehabilitation, reducing feelings of isolation and promoting overall well-being by providing companionship and interactive engagement [38,42]. Furthermore, specialized robots such as Nao, Pepper, and Paro are designed to cater to the unique needs of patients with dementia with cognitive impairment. These robots offer a comprehensive range of services, including behavioral monitoring, physical exercise tutoring, recreational activities, stress management, and medication reminders. By providing multifaceted support, these robotic companions significantly enhance the quality of life of older adults and contribute to improved health care outcomes [34]. Robots named Stevie and Zoro are specially tailored to support caregivers and older adults with memory loss. These robots offer care support, entertainment options, cognitive engagement activities, and social connectivity features. Their interactive nature stimulates older adults through engaging exercise and interaction, fostering a sense of community and connection [32]. Robots such as Mini and Tangy enhance cognitive abilities in older adults using educational games and imitation learning, aiming to improve memory, cognitive function, and mental agility through innovative stimulation and support [37].

Internet of Things

The Internet of Things (IoT) has revolutionized health care monitoring by using novel sensors and wireless communication methods such as Bluetooth, Wi-Fi, near-field communication, and Zigbee to access and securely store real-time data on vital signs, including temperature, blood pressure, heart rate, and

glucose levels, in the cloud. This advancement facilitates effective device management and real-time data monitoring and offers a secure storage solution, enhancing patient care and treatment outcomes [47]. Furthermore, the integration of multiple sensors into wearable devices, environment monitoring systems, and in-home setups provides pervasive and unobtrusive intelligence to support individuals proactively in their daily lives. These sensors enable continuous monitoring of various parameters, including temperature, humidity, and blood pressure, offering valuable insights for personalized health care interventions [39,42].

IoT-based tools such as smart pillboxes assist individuals in medication management by sending reminders according to prescribed medication plans, ensuring adherence to treatment regimens, and improving medication compliance [39]. Moreover, the implementation of semantic frameworks and advanced data processing techniques enables the collection and analysis of multi-sensor data to determine disease progression and provide timely alerts through real-time monitoring. This approach aids in the early detection of health deterioration, facilitating timely interventions and improved patient outcomes [40]. In addition, the DCARE model used a computational approach to process data from monitoring devices, incorporating content prediction, behavior recognition, and content recognition. This model serves as a comprehensive solution for general monitoring, data processing, and sending alerts to caregivers in case of potential risks or emergencies, enhancing patient safety and care coordination [41].

Virtual, Augmented, and Mixed Reality

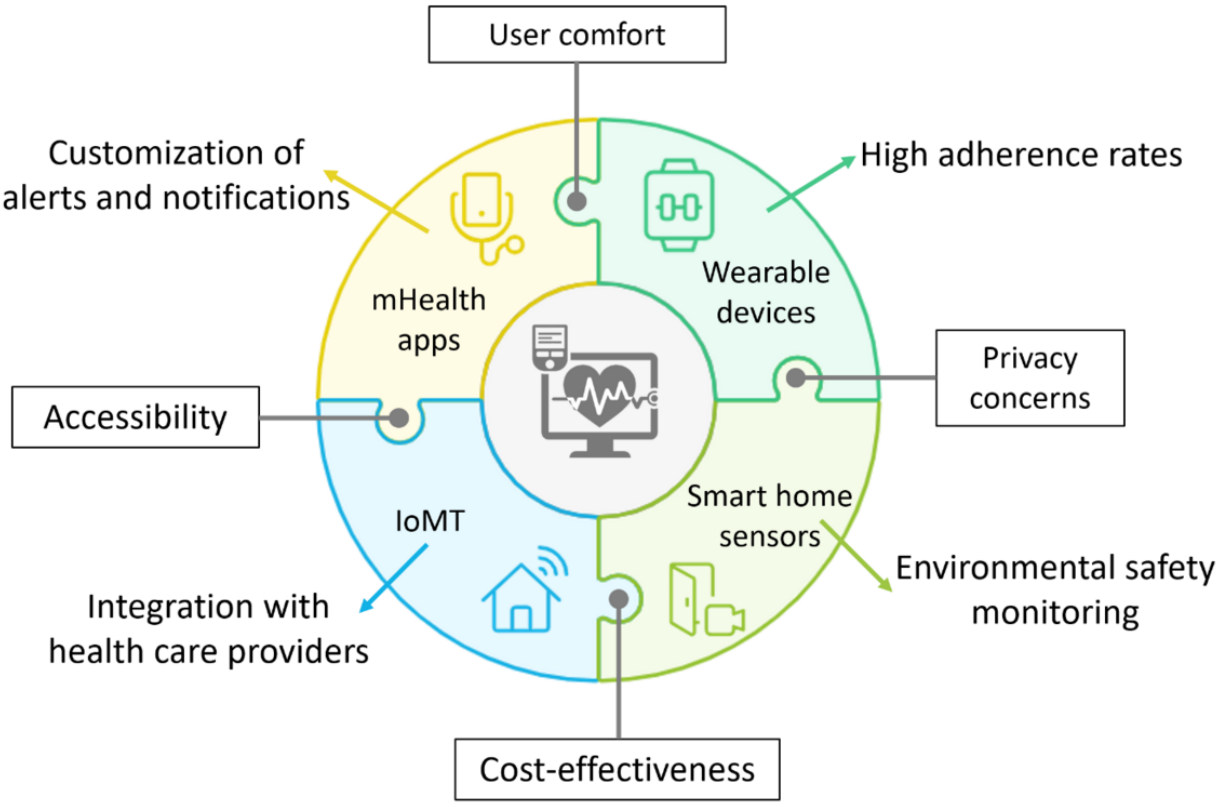
Virtual reality, augmented reality, and mixed reality technologies, facilitated by devices such as headsets, smart glasses, and next-generation smartphones, offer an immersive experience that extends beyond entertainment to include web-based home shopping, leisure activities, and communication, enriching both social interaction and physiological well-being [42]. Smart spectacles equipped with machine learning algorithms for face and object recognition enable personalized video and image playback, assisting patients with dementia and memory loss by stimulating memory recall and cognitive engagement [43]. In addition, GPS and device tracking functionalities, combined with medication reminders via Bluetooth connectivity, empower caregivers to monitor patient locations and medication adherence, ensuring timely interventions and enhancing patient safety [44].

Effectiveness of Remote Monitoring Technologies (RQ 2)

Overview

In addressing RQ 2, which investigated the effectiveness of remote monitoring technologies for individuals with ADRD, a thorough review of previous research papers was conducted. The findings are synthesized and summarized in Multimedia Appendix 4 [14,32,33,36-38,42,45,46,48-52] and Figure 3, providing a detailed comparison of various monitoring methods, their advantages, and their limitations. This comprehensive assessment helps achieve an optimal balance in addressing the needs of both patients and caregivers. The following subsections delineate different aspects pertaining to RQ 2.

Figure 3. Key features and considerations of different remote monitoring technologies. IoMT: Internet of Medical Things; mHealth: mobile health.



Wearable Devices

Wearable devices have emerged as valuable tools for remote monitoring of various health conditions, including cerebrovascular diseases, neurodegenerative diseases, and MCI. Godkin et al [48] investigated the adherence value of wearable devices focusing on 3 key aspects—adherence based on sensor location, time of day, and wear location—and participant and study partner acceptance of continuous multi-sensor wear for a week-long period. The outcomes of this study demonstrated the feasibility of a continuous multi-sensor approach to remote monitoring for individuals living with cerebrovascular diseases and neurodegenerative diseases, showing high adherence rates during both day- and nighttime wear throughout the study period. The aforementioned study also addressed concerns related to device discomfort, including itchiness, catching on clothing during dressing or on bed sheets during sleep, device size, and appearance.

Similarly, a comprehensive investigation conducted by Stavropoulos et al [14] focused on public involvement activities to capture the preferences, priorities, and concerns of people with AD and their caregivers regarding the use of monitoring wearables. Face-to-face discussions with the patient advisory board revealed varying levels of acceptance toward new technologies among older individuals, highlighting concerns regarding the cost of devices, adaption to modern technologies, and potential difficulties in operating technology. Furthermore, Stavropoulos et al [14] used a questionnaire to understand the specific requirements, preferences, barriers, and daily obstacles faced by individuals with MCI, their caregivers, and HCPs in using wearables. The Human Factors and Technology Requirements Questionnaire collected survey responses to various types of questions, such as open-ended, multiple-choice, and closed-ended questions, and the importance of user-centered design for assistive technologies using wearables and highlighted the implications for future research. The aforementioned study provided valuable insights into the perspective of individuals with MCI, caregivers, and HCPs regarding the use of assistive technologies with wearable trackers, emphasizing the need to consider privacy and ethical issues in the technology design and the disadvantages of traditional record-keeping methods.

Smart Homes (Multiple Sensors)

Smart home technologies equipped with multiple sensors have shown promising benefits in remote monitoring, particularly through video monitoring methods. However, there is a growing interest in exploring novel remote monitoring technologies beyond traditional video monitoring, emphasizing the need to diversify research in this area [36]. Despite the potential advantages, there is limited evidence to conclusively determine the acceptance of these remote sensing technologies, indicating a gap in understanding alternative methods [36]. In a comprehensive systematic review, it was highlighted that smart home remote monitoring has the potential to support older persons and caregivers by addressing individual family needs [49]. Nevertheless, critical barriers need to be addressed for successful adoption and implementation, including concerns about the time, training, and technical challenges associated with smart home technologies [49]. These challenges include issues with battery life, unstable wireless connectivity, and incompatibility, which have raised concerns about potential feelings of loneliness and isolation among older people with cognitive impairments [49]. Furthermore, there is a need for more research on alternative remote sensing technologies, such as vibration and acoustics technologies, to better understand their potential applications and effectiveness [36].

Addressing stigma and negative associations with disability through appropriate design and customization of sensing technologies, such as the use of smart fabric sensors, could help mitigate privacy concerns and enhance acceptability [36]. Future research should focus on understanding end-user conditions for acceptability and addressing various barriers, including usability, technical issues, cost concerns, and social implications, to facilitate the broader adoption of smart home technologies in health care settings [36,49].

Multimode Sensor (Machine Learning Approach)

In addressing the challenges of predicting and managing the behavioral and psychological symptoms of dementia (BPSD), multimode sensor technologies coupled with machine learning approaches have emerged as promising tools [45]. These approaches leverage diverse data sources to offer valuable insights into the relative contributions of various factors, such as caregiver-perceived triggers, cognitive and functional status, personality traits, and actigraphy-derived parameters, in predicting BPSD. However, the efficacy of these technologies can be compromised by challenges related to the improper wear of devices, leading to limited data availability for accurate prediction [45]. Despite these obstacles, machine learning models have demonstrated their capability to effectively predict different subsyndromes of BPSD. Such predictive capabilities hold significant potential to inform personalized interventions tailored to individual symptom profiles, thus facilitating timely and targeted care.

Nevertheless, it is essential to acknowledge the existing limitations and gaps in current research [45]. Cho et al [45] emphasize the need for future studies to address these challenges. This includes validating findings in larger and more diverse populations, integrating objective monitoring technologies, and developing more precise prediction algorithms to enhance the accuracy and reliability of these predictive models. Such advancements could significantly contribute to improving the quality of care and support provided to individuals living with dementia and their caregivers.

Patient and Public Involvement Survey

Patient and public involvement surveys emphasize the importance of prioritizing user-friendly design and personalized approaches when developing mHealth apps tailored for individuals with cognitive impairment [50]. Survey findings in the study by Lazarou et al [50] highlighted participants' keen interest in brain games aimed at memory enhancement, showcasing a strong demand for cognitive support tools. In addition, the participants expressed a desire for medication reminders and GPS tracking functionalities within mHealth apps, demonstrating the potential utility of such features in enhancing daily living and emergency response for individuals

with cognitive impairment [50]. Despite these valuable insights, it is important to acknowledge the survey's limitations. The research was conducted among a limited population, potentially introducing self-bias and not capturing the full spectrum of needs and preferences across diverse groups [50]. To address these challenges, future research should aim to explore more diverse populations and incorporate a broader range of user perspectives. This will help in developing more inclusive and effective mHealth interventions that cater to the diverse needs of individuals with cognitive impairment, caregivers, and HCPs.

Internet of Medical Things and Robots

The Internet of Medical Things (IoMT) is revolutionizing the health care landscape by integrating advanced technologies into smart health care systems. In the study by Mathkor et al [52], the authors provided a comprehensive overview of IoMT, highlighting its role in current and future biomedical systems. The study emphasized the integration of technologies such as deep learning, machine learning, blockchain, AI, radio-frequency identification, and Industry 5.0. These technologies hold immense potential in enhancing patient care, improving diagnostic accuracy, and streamlining health care operations. However, the implementation of IoMT systems presents several challenges that need to be addressed for successful adoption. High costs associated with device development, infrastructure setup, and connectivity solutions can pose financial barriers. In addition, many IoMT devices operate on battery power, leading to concerns about battery life and continuous operation. Data quality issues, including noise, biases, and inaccuracies, can also arise due to device limitations or environmental factors. To fully realize the benefits of IoMT, it is crucial to address these challenges and develop robust, scalable, and secure solutions. Companion robots have emerged as potential tools to address the social and emotional needs of older adults, particularly those with dementia.

In the study by Pou-Prom et al [51], the authors conducted an experiment involving 19 participants diagnosed with AD to explore the feasibility of using conversational companion robots. The study revealed that, while some participants enjoyed interacting with the robots, others expressed doubtfulness and reluctance. Technical limitations such as speech recognition challenges, lack of dialogue context, and keyword matching were identified as barriers to seamless communication. Furthermore, the absence of features such as miscommunication and acoustic features hindered the assessment of dementia-related symptoms through robot interactions. The mixed reactions from participants highlighted the importance of ongoing research to refine companion robot technologies. Future work should focus on addressing the identified limitations, exploring the trade-off between autonomous and semiautonomous approaches, and optimizing the design and functionality of these robots to better support the well-being of older adults. Collaborative efforts involving HCPs, engineers, and end users are essential to develop more effective and user-friendly companion robot solutions that can have a meaningful impact on the lives of older adults with dementia.

Cognitive Monitoring for Dementia Care

Advancements in remote monitoring have enabled the integration of cognitive assessment tools to track disease progression and evaluate treatment effectiveness in dementia care. Digital cognitive assessments such as smartphone-based memory and attention tests offer frequent, scalable evaluations that provide real-time insights into cognitive changes. In addition, AI-driven speech and typing analysis can detect subtle linguistic and motor impairments associated with cognitive decline, enabling early intervention and treatment adjustments. Gaze tracking and eye movement analysis further enhance cognitive monitoring by assessing reading patterns, recognition abilities, and attention shifts, which may indicate neurological changes over time. Meanwhile, wearable electroencephalography devices and neurofeedback tools provide continuous, objective measurements of brain activity, allowing researchers and clinicians to assess how therapeutic interventions impact cognitive function. These emerging technologies hold great promise for improving personalized treatment strategies, monitoring drug efficacy, and facilitating early diagnosis, ultimately enhancing the quality of care for individuals with dementia.

Privacy and Security in Remote Monitoring (RQ 3)

Overview

When examining the critical security and privacy considerations involved in remote monitoring technologies, particularly for patients with AD, it is essential to delve into several layers of complexity that encompass data security, privacy regulations, ethical issues, and the unique vulnerabilities of the patient population. Remote monitoring technologies, including smartphones, wearables, and environmental sensors, offer significant benefits for managing AD by enabling continuous health monitoring and early detection of anomalies and providing valuable data for research. However, these benefits come with substantial security and privacy challenges. Different aspects of privacy and security concerns are summarized in Multimedia Appendix 5.

Data Types and Associated Risks

First, the nature of the data collected by these devices—ranging from personal details to medical records, geolocation, and behavioral patterns—makes them highly sensitive. Ensuring data security is paramount as it requires robust encryption methods to protect data both in transit and at rest. Encryption safeguards the data from unauthorized access during transmission and storage. Equally important is implementing strong access control measures, ensuring that only authorized individuals such as health care providers and approved caregivers can access the patient data. Regular security audits and vulnerability assessments are crucial to identifying and addressing potential security gaps, thereby maintaining the integrity of the monitoring systems.

Privacy concerns are equally critical, particularly given the stringent requirements set forth by regulations such as the General Data Protection Regulation (GDPR) in Europe and HIPPA (Health Insurance Portability and Accountability Act) in the United States [58-60]. These regulations mandate that

patients' personal health information be protected and that individuals have control over their data. Adherence to these regulations involves ensuring that patients (or their legal guardians) provide informed consent for data collection and use. This consent process must be clear and comprehensive, detailing what data will be collected, how they will be used, who will have access, and how long the data will be retained. Data minimization principles should be applied, collecting only the necessary data required for the intended purpose, thus reducing the risk of unnecessary exposure. Patients with AD may not fully understand the implications of data collection and their rights regarding data privacy. Therefore, it is imperative to involve caregivers or legal guardians in the consent process to ensure that the patients' rights and preferences are respected. Furthermore, patients with AD are particularly vulnerable to exploitation and abuse. Continuous monitoring can inadvertently infringe on their privacy and autonomy, raising ethical concerns. Balancing the need for constant monitoring to ensure safety with the patients' rights to privacy and dignity is a delicate task. Ethical considerations must guide the implementation of these technologies, ensuring that monitoring practices do not become overly intrusive.

Device and IoT Security

From a technical perspective, the integration of various monitoring devices such as smartphones, wearables, and environmental sensors introduces additional security challenges. Each device and sensor can be a potential entry point for cyberattacks. IoT devices are often targeted due to their typically lower security standards. To counteract these risks, it is crucial to ensure that all devices are secured against tampering and hacking. This involves regular firmware updates to patch vulnerabilities, the use of strong authentication mechanisms to prevent unauthorized device access, and the use of data anonymization techniques to protect patient identity in the event of a data breach [41,61].

Furthermore, the use of advanced technologies such as AI and machine learning in processing and analyzing the collected data presents its own set of risks. While these technologies can enhance the accuracy and efficiency of health monitoring, they also require access to large datasets, which can exacerbate privacy concerns if not handled properly. Ensuring that AI and machine learning models are trained on anonymized data and that they adhere to strict privacy standards is essential to mitigate these risks. Potential attackers pose significant threats to the security of remote monitoring systems. These attackers might attempt to intercept data transmission, gain unauthorized access to monitoring devices, or exploit vulnerabilities to extract sensitive information. Addressing these threats requires a multilayered security approach, including end-to-end encryption, secure communication protocols, and robust incident mechanisms to quickly address and mitigate breaches when they occur [47].

Balancing Safety and Patient Autonomy

While remote monitoring offers substantial benefits for managing AD, it also presents critical security and privacy challenges that must be carefully addressed. Ensuring robust data security through encryption, access controls, and regular audits; complying with privacy regulations; obtaining informed consent; and addressing the unique vulnerabilities of patients with AD are essential components of a secure and ethical monitoring system [62,63].

Balancing safety and patient autonomy in remote monitoring for AD care presents a complex challenge that requires a nuanced approach. While the technology offers substantial benefits, such as continuous health monitoring, early anomaly detection, and timely interventions, it must be implemented thoughtfully to prevent undue intrusion. The need for constant observation can infringe on the patients' sense of independence, raising ethical questions about dignity and consent. To address these concerns, remote monitoring systems should integrate customizable privacy settings that allow caregivers to modify the monitoring level based on the patients' current health status and preferences. Noncritical data anonymization and local data processing using edge computing can significantly reduce the sense of surveillance, ensuring that only essential information is transmitted to central servers [64].

Obtaining informed consent from patients with AD is another critical aspect due to cognitive impairments that often affect their decision-making capabilities. In such cases, involving caregivers or legal guardians becomes essential to uphold the patients' rights while ensuring that their best interests are protected [65,66]. Technologically secure consent management systems can be used to store and track consent records digitally. Leveraging blockchain technology for tamper-proof consent logs can enhance transparency and accountability, making it clear who has agreed to data collection and how the data will be used. This approach ensures compliance with regulations such as the GDPR [60] and HIPAA [58,67], reinforcing trust among patients, caregivers, and health care providers.

Adaptive monitoring systems that support variable levels of oversight can help maintain patient autonomy by shifting from comprehensive tracking to minimal oversight as needed. This adaptability allows caregivers to balance the safety needs with the patients' right to privacy. Moreover, implementing user-controlled privacy features empowers patients and their caregivers to configure data sharing preferences, such as choosing which types of data are collected and how frequently they are transmitted. This flexibility can significantly improve user satisfaction and trust in the monitoring system.

AI integration into monitoring systems should prioritize ethical standards, ensuring that data handling is minimal and transparent. For instance, using federated learning allows algorithms to be trained directly on local devices, avoiding the need to transfer raw data to external servers [68]. This method safeguards privacy while maintaining the system's ability to deliver valuable insights. In addition, explainable AI frameworks can provide justifications for alerts and decisions, ensuring that caregivers understand the reasoning behind the system's actions [69]. Such transparency bolsters confidence in the technology and facilitates informed decision-making.

To enhance safety protocols without compromising privacy, remote monitoring systems should use multilayered privacy protocols that combine encryption, robust user authentication, and differential privacy [70]. By injecting noise into datasets,

differential privacy makes it difficult to trace data back to individual patients while allowing for meaningful analysis. Regular security audits and ethical reviews should also be conducted to ensure that monitoring practices do not become overly invasive. Independent ethics committees can provide oversight, ensuring that the technology aligns with patient-centric values and preserves autonomy.

Maintaining patient dignity is paramount, especially when using advanced monitoring technology. Nonvisual sensors such as microradar [71] systems can detect falls and wandering without capturing images or videos, offering a less invasive alternative to camera-based surveillance. Moreover, patients and caregivers should have the option to customize notification settings, choosing to receive only high-priority alerts to minimize stress. This selective alert system can enhance quality of life by allowing patients to maintain a degree of normalcy and autonomy in their daily lives.

Potential Remote Monitoring Framework for Patients With AD (RQ 4)

Overview

Critical design considerations for a potential remote monitoring framework for patients with AD include ensuring privacy and data security to comply with HIPAA regulations, using nonintrusive monitoring technologies such as microradar sensors to maintain patient dignity, and incorporating AI-driven analytics for accurate detection of falls and wandering. The system should offer real-time alerts to caregivers, be user-friendly for both patients and caregivers, and integrate with existing health care platforms for seamless data sharing. In addition, providing customizable and scalable features can accommodate diverse patient needs and facilitate broader adoption.

The development of our proposed remote monitoring framework was directly informed by the insights gained from our literature review. Our findings revealed that existing monitoring solutions such as wearable sensors and camera-based systems present significant limitations in terms of user compliance, privacy concerns, and real-time responsiveness. Wearable devices require active patient participation, which may not always be feasible for individuals with ADRD, whereas camera-based systems raise ethical and privacy concerns. In response, our framework integrates microradar technology, which allows for the nonintrusive monitoring of falls and wandering behaviors without compromising user privacy. In addition, AI-powered analytics enhance the accuracy of detection by processing microradar data to identify anomalies in movement patterns. To support real-time caregiver intervention, our system uses Web Real-Time Communication (WebRTC) and peer-to-peer (P2P) communication for seamless alerts. By addressing these limitations and leveraging interdisciplinary advancements, our framework offers a comprehensive, privacy-conscious, and scalable solution for the monitoring of patients with ADRD. Different aspects pertaining to RQ 4 are discussed in the following subsections.

Ensuring Patient Safety

Patient safety is the cornerstone of any remote monitoring system for patients with AD. Wearable devices such as smartwatches and fitness trackers can monitor crucial health indicators such as gait, sleep patterns, physical activity, and falls. Environmental sensors placed in the patient's home can track temperature, motion, and other conditions to detect unusual behavior, such as wandering or falls, ensuring that immediate action can be taken [72].

Given the sensitivity of health data, robust security measures are essential. Data from wearable devices and sensors must be encrypted to prevent unauthorized access. Compliance with regulations such as the GDPR and HIPAA is necessary to protect patient privacy. Strong authentication methods and regular software updates can help maintain data integrity and security.

Ease of Use for Caregivers

The system must be user-friendly, as caregivers for individuals with ADRD may not be technologically savvy. A simple, intuitive interface is crucial, allowing for straightforward navigation and clear, actionable alerts to reduce ambiguity and stress. Customizable notifications and automated alerts ensure that caregivers are informed of critical issues without needing to constantly monitor the system while minimizing false alarms to avoid unnecessary stress. In addition, providing educational resources within the system helps caregivers understand how to best use the monitoring tools and improve their caregiving skills. This approach empowers caregivers, enhances efficiency, and improves patient safety by facilitating timely interventions [73,74].

Ethical Considerations

Ethical considerations for a potential remote monitoring framework for patients with AD include ensuring informed consent and respecting patient autonomy. Considering cognitive impairments, obtaining informed consent must involve patients as much as possible as well as legal representatives or caregivers when necessary to ensure understanding and voluntary participation. Privacy and confidentiality are paramount, requiring compliance with data protection regulations and secure data handling practices. The system should be minimally intrusive, using discreet technologies to balance safety with patient dignity and avoiding constant visible monitoring that could lead to a loss of independence. Transparency in communication about the system's operation and data use, as well as providing feedback mechanisms, builds trust and addresses concerns. Ethical design principles involving user-centered approaches and bias mitigation in AI, alongside regular ethical reviews and oversight by ethics committees, ensure that the system remains respectful and patient centered while enhancing safety [75,76].

Compatibility With Existing Systems

To be effective, the remote monitoring system for patients with AD must integrate seamlessly with existing health care infrastructure, such as electronic health records (EHRs) [77]. This integration ensures that all relevant health data from the monitoring system are accurately and efficiently captured within the broader health care framework. Using standardized protocols

and application programming interfaces is critical for facilitating data sharing and interoperability [78]. These standards, such as Health Level Seven Fast Healthcare Interoperability Resources, ensure that data from the monitoring system can be easily and securely exchanged with different EHR systems and other health IT platforms [79]. Seamless integration allows physicians, specialists, and other clinicians to access comprehensive, up-to-date information about patients, promoting coordinated care. For instance, if a remote monitoring system detects a fall or wandering incident, this information can be automatically logged in the patient's EHR, alerting HCPs in real time. This ensures that primary care physicians, specialists, and hospital staff have a unified view of the patient's health status and recent events, enabling more informed decision-making and timely interventions.

Moreover, compatibility with existing systems helps in reducing duplication of efforts and minimizes the risk of errors. HCPs can avoid manually entering data, which not only saves time but also reduces the likelihood of transcription errors. By ensuring that the remote monitoring data are automatically integrated into EHRs, the system enhances the accuracy and reliability of patient records. In addition to technical interoperability, organizational processes and workflows must be considered to ensure smooth integration. Training for physicians, nurses, and other HCPs on how to use the new system and interpret its data within the context of existing EHRs is essential. Developing clear protocols for how and when data from the monitoring system should be used in patient care can help ensure that the system is used effectively. By enabling seamless data sharing and integration, the system supports a more coordinated and comprehensive approach to health care, ultimately improving outcomes for patients with AD and reducing the burden on caregivers and medical professionals.

Scalability and Flexibility

A scalable system is essential for accommodating the increasing number of patients with AD who require care. As demand for remote monitoring solutions grows, the system must expand without compromising performance or reliability. This need involves designing the system architecture to support a larger user base and additional data processing and storage capabilities. Scalable infrastructure ensures that the system can handle a surge in the number of patients and caregivers, allowing health care providers to maintain high standards of care even as the user population increases. Moreover, incorporating standardized interfaces and protocols such as application programming interfaces and interoperability standards ensures that the system can easily connect with new devices and technologies, facilitating continuous improvement and innovation [80].

Flexibility in the remote monitoring system is equally important. The system should have a modular architecture that allows for the easy integration of new sensors and technologies as they become available. This modular approach ensures that the system can adapt to technological advancements and incorporate innovative solutions without requiring a complete redesign. It should also be configurable to meet the specific requirements of various health care settings, such as in-home care, assisted living facilities, or hospitals, providing tailored solutions that address the unique challenges of each environment. The system's scalability and flexibility ensure that it adapts to evolving health care needs, enhancing patient care and supporting the growth of remote monitoring technologies [80].

Technology Components

Wearable technology is essential for health monitoring, allowing for the real-time tracking of multiple health variables such as heart rate, physical activity, sleep habits, and location [56,72]. These devices help monitor the patient's daily routines and identify emergencies such as falls. Environmental sensors also enhance the patient's living environment by monitoring door activity, motion, and room temperature to detect unusual activity. For instance, if a patient leaves the house at an unusual time, an alert can be issued to the caregiver. Smartphone apps enable caregivers to easily monitor and receive notifications, enter observations, create personalized alerts, and access learning materials. Continuous connectivity ensures that caregivers are always informed about the patient's status.

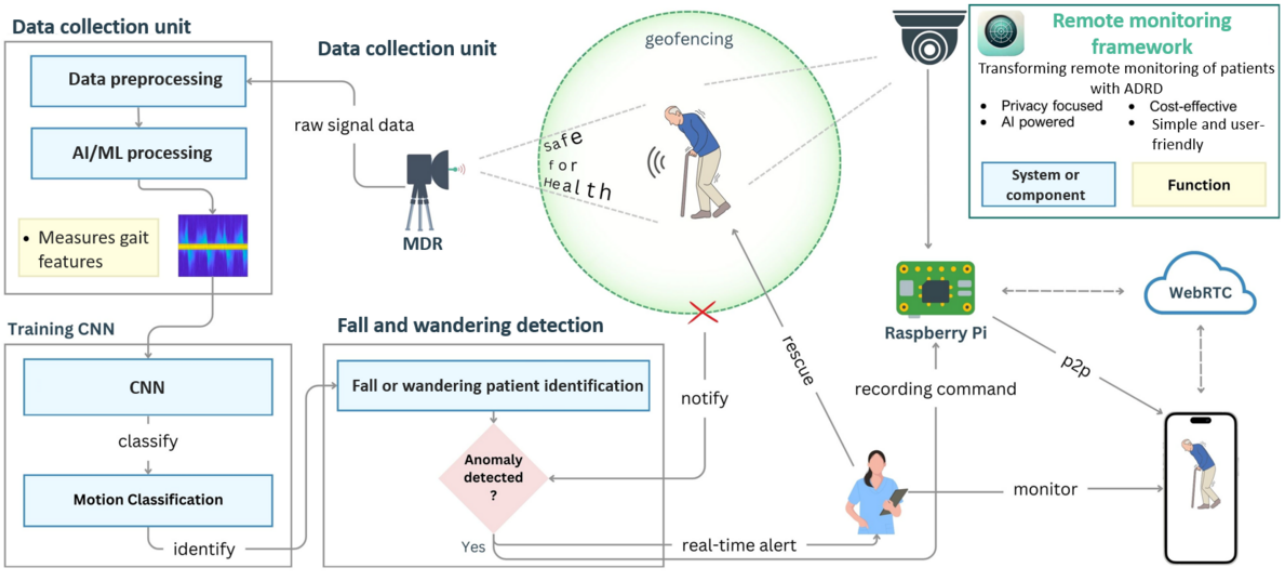
Implementing AI and machine learning algorithms to analyze data collected from wearables and other devices allows for the identification of trends indicating potential health issues. These predictive analytics enable caregivers to anticipate problems and take preventive measures before they become critical, thus improving patient care and safety. Moreover, an IoT infrastructure is essential for ensuring seamless data transfer between all connected devices, with cloud computing offering scalable processing and storage capacity and edge computing minimizing delays by processing data locally. Effective data management is crucial for making sense of the vast amounts of data generated by the system, allowing for trend analysis and informed clinical decisions. Advanced analytics techniques can also provide personalized patient care. In addition, robust security technologies such as intrusion detection systems, firewalls, and encryption methods are vital to protect the system from threats, with frequent maintenance and updates ensuring ongoing security

Comprehensive Framework

Overview

On the basis of the discussions in the previous subsections and the findings of previous studies, we propose a comprehensive remote monitoring framework, as shown in Figure 4, by incorporating the use of wearable technologies, sensors, AI-powered analytics, and a safe IoT infrastructure. The elements in the schematic framework are intricately connected and together create a comprehensive system for the remote monitoring of patients with AD. The framework is designed with a strong focus on health and safety. The use of microradar technology ensures that monitoring is nonintrusive and safe for patients, reducing the stress associated with traditional monitoring systems. This framework not only enhances patient safety but also alleviates the burden on caregivers by providing reliable, real-time support and intervention tools. The following is a detailed discussion of how each point contributes to the overall monitoring framework.

Figure 4. Schematic framework for remote monitoring of patients with Alzheimer disease. ADRD: Alzheimer disease and related dementias; AI: artificial intelligence; CNN: convolutional neural network; MDR: micro-Doppler radar; ML: machine learning; P2P: peer to peer; WebRTC: Web Real-Time Communication.



Data Collection

The data collection unit is the central component of the monitoring system and is responsible for gathering and processing the data required to track the patient's movements and health status effectively. At its core, the unit uses micro-Doppler radar technology to capture raw signal data by continuously monitoring the patient's movements in a nonintrusive manner [81]. This technology is crucial as it does not require the patient to wear any devices or interact with the system, thereby preserving the patient's privacy and minimizing any stress or discomfort that might arise from traditional monitoring systems. The raw data collected by the micro-Doppler radar undergoes a critical preprocessing stage in which essential gait features are extracted. This step is vital in filtering out noise and isolating the most relevant aspects of the patient's movements that could signal potential risks. Once preprocessed, the data are fed into advanced AI and machine learning algorithms, which analyze the extracted features to identify patterns in the patient's movements. This sophisticated processing enables the system to distinguish between normal daily activities and potentially hazardous situations such as falls or wandering, thereby enhancing the system's ability to ensure the patient's safety while maintaining their dignity and comfort.

Data Processing

The data processing component plays a critical role in enhancing the system's ability to accurately classify various patient movements, which is fundamental to ensuring effective monitoring and maintaining the safety of individuals with ADRD. The process begins with preprocessed data being fed into a convolutional neural network [82], a powerful AI model specifically designed to recognize and analyze patterns within the input data. This network is trained to classify different types of motions, enabling it to distinguish between normal daily activities such as walking or sitting and potentially hazardous incidents that may require immediate intervention, such as falls or wandering outside a designated safe zone. The convolutional neural network's ability to make these distinctions is vital to the system's overall accuracy and reliability as it allows for the early detection of unusual or dangerous behaviors. This, in turn, facilitates timely alerts and responses, ensuring that caregivers can intervene quickly and appropriately to protect the patient's well-being. Through this advanced data processing approach, the system not only enhances patient safety but also provides peace of mind to caregivers through the knowledge that the system is capable of accurately monitoring and responding to the specific needs of patients with ADRD.

Fall and Wandering Detection

The fall and wandering detection component is a critical part of the monitoring system, designed to ensure the continuous safety of patients by closely tracking their movements and identifying any signs of falling or wandering outside a predefined safe area. The system uses a geofencing approach in which a *defined* boundary or safe zone is established around the patient's environment. This safe zone is carefully configured based on the patient's needs and typical movement patterns. The system continuously monitors the patient's movements within this boundary using sophisticated pattern identification techniques. By analyzing these movement patterns in real time, the system can quickly detect any deviations from the norm. For example, if the patient crosses this virtual boundary or exhibits movements that suggest a fall, such as a sudden loss of balance or an abrupt change in posture, the system immediately flags this behavior as an anomaly. This continuous, vigilant monitoring is essential for identifying potential risks before they can lead to serious harm.

Once an anomaly is detected, the system's response should be both swift and automated. The anomaly detection process should be finely tuned to recognize specific triggers, such as the patient moving outside the safe zone or experiencing a fall. When such an event is identified, the system automatically triggers an alert, ensuring that caregivers are notified in real time. These alerts should be designed to reach caregivers through various channels,

such as mobile notifications or direct messages, providing them with immediate information about the patient's situation. This real-time notification system is crucial for enabling caregivers to respond promptly and appropriately to any incidents, whether it involves assisting the patient after a fall or guiding them back to safety after wandering. The combination of continuous monitoring and instantaneous alerting forms a robust safety net, significantly reducing the risks associated with falls and wandering in patients with ADRD.

Caregiver Notification and Support

The caregiver notification and support component is designed to empower caregivers with the tools and information they need to effectively monitor and respond to the needs of patients in real time. Central to this component are real-time alerts, which are instantly sent to caregivers' devices, ensuring that they are always aware of the patient's status. These immediate notifications are particularly crucial in emergency situations, such as when a fall or wandering event occurs. By receiving alerts the moment an anomaly is detected, caregivers can intervene promptly, providing necessary assistance or preventing further harm to the patient. This real-time communication is key to maintaining the safety and well-being of patients with ADRD.

In addition, the system is equipped with a recording command and rescue feature facilitated by a Raspberry Pi module. This module plays a vital role by capturing and recording the event as soon as an anomaly is detected. The recorded data are automatically sent to caregivers, offering them detailed insights into the incident. This documentation not only aids in immediate rescue actions but also serves as a valuable resource for later analysis. By reviewing recorded incidents, caregivers and medical professionals can better understand the circumstances leading up to the event, which is essential for medical evaluations and refining future care strategies. The ability to document and analyze these events ensures that care can be continuously improved, ultimately enhancing the quality of life of both patients and caregivers.

WebRTC and P2P Communication

The framework integrates advanced communication technologies to ensure seamless monitoring and interaction between caregivers and the system, providing a reliable and immediate connection regardless of location. A key component of this system is the use of WebRTC technology, which facilitates real-time P2P communication [83,84]. This technology allows caregivers to monitor the patient from their smartphones or other devices with ease and without delay, ensuring that they remain connected to the patient's status at all times. The use of WebRTC ensures that the communication is not only immediate but also direct, reducing latency and enhancing the responsiveness of the system.

This capability significantly enhances patient safety as it allows caregivers to maintain a continuous, real-time connection with the system, enabling them to respond quickly to any situation that may arise. Whether it is monitoring routine activities or responding to alerts triggered by the system, WebRTC ensures that caregivers can provide timely and effective interventions. The seamless monitoring facilitated by this technology is crucial for reinforcing the safety net around patients with ADRD, giving caregivers the confidence and tools they need to manage their loved ones' care effectively, no matter where they are.

Conclusions

This study highlights the revolutionary potential of remote monitoring technologies in AD care, emphasizing the critical balance among innovation, practicality, and empathy. The comprehensive analysis revealed that, while wearable devices and ambient sensors significantly enhance the ability to track and support patients with AD, they also introduce challenges related to privacy, data security, and user acceptance. The findings stress the necessity of involving patients and caregivers in the design process to ensure that these technologies meet their specific needs and regulatory requirements, which is crucial to the successful implementation of these technologies.

The proposed remote monitoring framework integrates cutting-edge microradar technology with AI-powered processing to create a nonintrusive, privacy-conscious solution for monitoring patients with AD and dementia. By focusing on real-time data processing, caregiver notification, and seamless communication, the system not only enhances patient safety but also provides critical support to caregivers, ultimately improving the quality of care for individuals with ADRD. Future research can focus on refining these systems to enhance their usability, accessibility, and security, thereby improving the overall caregiving experience and patient well-being. By advancing remote monitoring practices, we can create a supportive environment that alleviates caregiver burdens and promotes a higher quality of life for individuals living with AD.

Abstract

Background: With the rapid expansion of wearable technologies, there is increased interest in their utility for passive data collection applications in research on aging. Wearables can be beneficial for research with people with dementia and their families, who have burdens that can make both study participation and reliable data collection more difficult, especially as dementia progresses, but their use also has challenges. Population-specific issues affecting the success of wearables for data collection can include remembering to wear a device, fluctuating acceptance of the device or study participation, and reliance on already strained caregivers.

Objective: This study aimed to systematically evaluate contemporary wearables research to describe persons with dementia's experiences with wearables, their desired qualities, and protocol needs to enhance participant buy-in and sustained wearing for better quality dementia research.

Methods: We used the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) 2020 checklist for systematic reviews and searched 3 scholarly databases using Medical Subject Headings (MeSH) terms for papers published since 2018 featuring the use or discussion of wearable devices for persons with dementia. We screened 1757 abstracts and retained 58 for full-text review.

Results: We present synthesized preferences, barriers, and facilitators to buy-in and adherence to wearables in dementia research. A total of 29 factors were categorized into 4 overarching categories aligned with study development: device selection, protocol considerations, enhancing recruitment, and promoting adherence.

Conclusions: These findings inform researcher guidelines for wearable device selection and protocol design to enhance the utility of wearables in future longitudinal research featuring persons with dementia and their caregivers.

Introduction

Background

The growing prevalence of dementia and its substantial economic and social impacts have led to increased attention and funding allocations for research supporting persons living with dementia and their caregivers as well as dementia prevention research [1]. Obtaining the perspective of persons living with dementia and their caregivers is critical to advancing our understanding of dementia to not only find effective treatments but also to address burdens often associated with providing care to this population [2,3]. Engaging persons living with dementia and their caregivers in research studies can be challenging for many reasons, including the fluctuating cognitive capacities of individuals with dementia, the logistical and emotional demands placed on caregivers, and the need for research protocols that accommodate the specific needs and

limitations of this population [3]. Innovative methods to increase meaningful engagement in research studies involving persons living with dementia and their caregivers are warranted.

Meeting Researcher Needs

Wearable technology is a noninvasive, passive way to collect a variety of data over long periods and offers the potential benefit of enhancing care and prevention efforts [4-6]. Remote data collection, such as that offered by wearable technology, has many potential benefits, including reducing recall bias and decreasing the burden placed on participants owing to frequent contact for research purposes. Identifying wearables and research protocols that meet both researcher and participant needs will help wearable technology be more effectively used in longitudinal dementia studies [7]. As the wearable technology market is expected to continue growing substantially [8], guidance for researchers to optimize the selection of devices to enhance buy-in and adherence in their studies is necessary. Wearable devices and research strategies tailored to persons living with dementia and their care providers are crucial for optimizing long-term research with this population [9].

Currently, longitudinal dementia research with wearables faces 3 overarching challenges. First, the challenges particular to persons with dementia and their caregivers and health care professionals must be considered to gain long-term buy-in and use, especially as dementia progresses and caregiving burdens increase [10,11]. Population-specific issues include remembering to wear or charge the device, ethical informed consent [12], and privacy concerns [13,14] that may differ from cognitively intact older adults [15,16]. Second, there is a multitude of wearables on the market with a variety of features and hardware forms at various costs that have not been evaluated in terms of this population's usability and adherence factors. Third, wearables must also provide consistent, accurate, and useful data that meet researcher needs (eg, activity monitors, GPS, and location information) and have limited or easily resolvable technical problems, user-related issues, or data access factors [17].

To date, there has not been a systematic evaluation of wearables for research that holistically examines whether wearables meet the needs of persons with dementia, their caregivers, and researchers to enhance participant buy-in and research utility. Moreover, with the rapid expansion and advancement of wearable technology in the last few years, new research on participant experiences and desires for wearables is necessary. Recent wearables research with this population has featured focus group discussions with limited representation of persons with dementia and their caregivers [10,18], as compared to the experiences of older adults without dementia [19]. Observational research that could inform wearable acceptance and adherence strategies has often been limited to very short-term evaluation periods (typically up to 7 days) with a handful of activity monitoring devices [20-22]. Identifying factors related to wearables that are acceptable to persons living with dementia and their care providers, as well as population-specific support systems, is necessary to strengthen the quality of research requiring long-term adherence [7].

Objectives

This study aimed to conduct a systematic review of dementia-related preferences, barriers, and facilitators to using wearables in research studies to inform future study development, including device selection and participant support protocols.

Methods

Data Sources

This systematic review followed the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) 2020 checklist (Multimedia Appendix 1) [23]. Original research studies were identified from the PubMed, MEDLINE, Scopus, and CINAHL databases (all last consulted in January 2023) and Google Scholar. In March 2024, approximately 500 results were reviewed to capture additional references since the 2023 search. The search strategy included a combination of Medical Subject Headings (MeSH) terms and keywords. Categorized according to the PICO (population, intervention, comparison, and outcomes) framework, search terms were used in OR statements in combination for the population ("dementia," "Alzheimer* Disease," "memory loss," and "cognitive impairment") and the intervention or indicator ("wearable*," "wearable sensor*," "tracker*," "biosensor*," "Fitbit," "wearable electronic*," "remote monitoring," and "pedometer"). Regarding comparison, the inclusion criteria did not require intervention trials, whereas for outcomes, the inclusion criteria did not specify the outcomes of the studies.

The full text of the relevant articles was retrieved from the Web of Science, Google Scholar, and library access at the University of Michigan. The articles were reviewed for additional related references.

Study Selection

The selection criteria for the literature search included (1) full-text data from primary peer-reviewed journal articles, commentaries, and conference proceedings; (2) use of remote monitoring via electronic devices that captured data of persons; (3) enrollment of, or reference to, populations living with Alzheimer disease, dementias, or chronic memory impairment or loss impairment; (4) publication in English from January 2018 to March 2024; and (5) documentation of any preferences, barriers, or facilitators to wearables device use. Notably, research featuring Huntington or Parkinson disease was included if participants were experiencing dementia-type impairment and otherwise met the inclusion criteria. Studies were excluded if they (1) did not meet the inclusion criteria, (2) used an implantable wearable or a device not intended for data collection (eg, hearing aids), (3) reported only a study protocol, or (4) included no person interaction (eg, device development without consulting with the population considered affected). Dissertations, books, book chapters, other reviews, and single-case studies were excluded.

CMP searched independently, and CMP and CF reviewed titles and abstracts for relevance and subsequently conducted the full review. CMP manually searched the reference sections of these full-text articles and key reviews for additional citations. RMSL

independently reviewed the search criteria and list of full-text articles to meet the eligibility criteria. The authors used EndNote (Clarivate), a bibliographic tool that allowed them to organize PDFs of articles by topic, along with other data about each article.

Data Extraction and Analysis

Data extracted (by CMP) from the full text of the eligible studies included, when available, publication details, study location, study design, study population, device type and location worn, and device-wearing duration. For the focus of this study, we extracted information related to the preferences, barriers, and facilitators of the use, adoption, maintenance, and adherence of wearable electronic devices by persons with dementia, including ideal device qualities and protocol needs for persons living with dementia and their caregivers. This information could come from the researchers (eg, procedures and processes attempted), persons with dementia (eg, reported preferences and difficulties inhibiting ongoing use), or persons caring for those living with dementia, whether health professionals or informal family caregivers (eg, encouraging persons to wear the device).

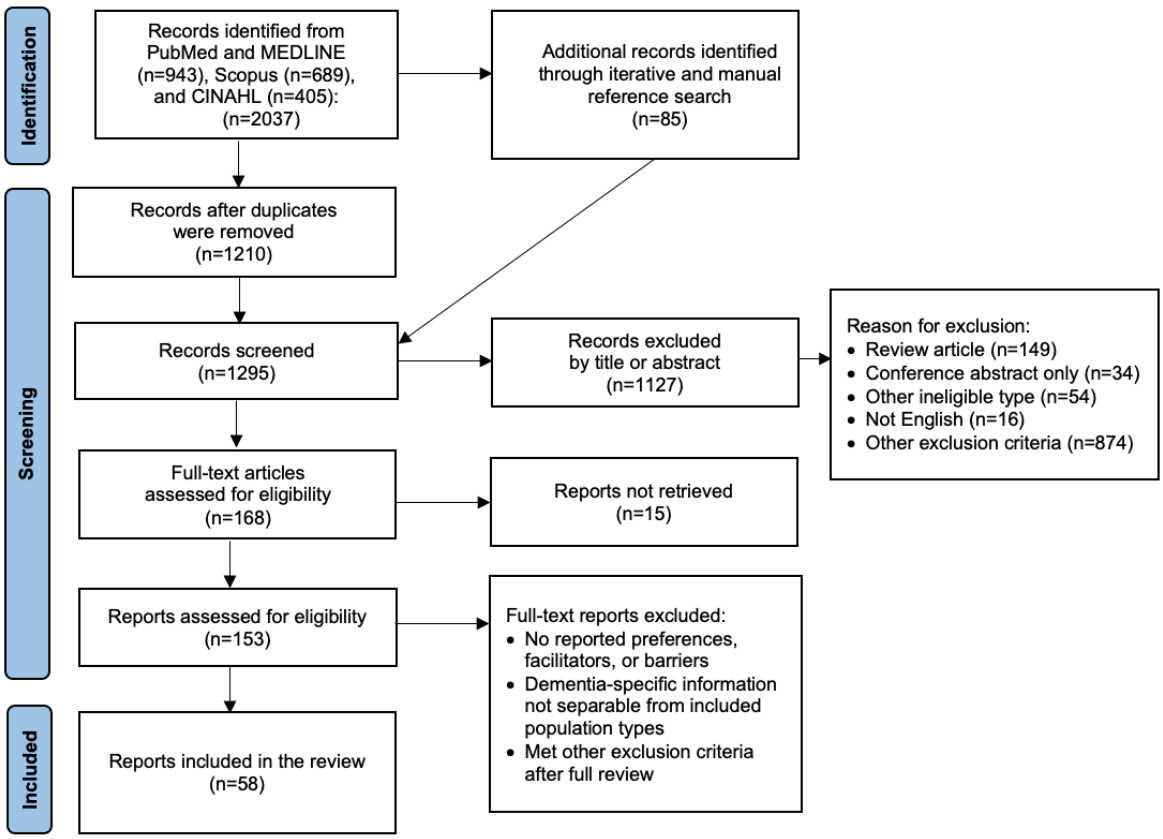
The extracted qualitative data on preferences, barriers, and facilitators were reviewed and initially synthesized for each study by CMP into a common factor coding structure using a grounded theory qualitative research approach [24]. This approach does not presuppose findings but relies on iterative "constant" comparison of collected data to develop codes and overarching themes. RMSL reviewed the summaries and factor synthesis, which CMP and RMSL then independently assigned to each study. The factor assignments were reviewed, and discrepancies were adjudicated together. We report the descriptive frequencies of the factors identified and noted in at least 5 studies and provide a qualitative synthesis of their implications for optimizing long-term dementia research.

Results

Overview

This systematic review identified 1757 studies through the databases as well as iterative and manual reference searches. After the eligibility criteria were applied, 3.3% (58/1757) of the studies were retained for data extraction analysis (Figure 1 [23]). Most studies (1127/1295, 87.03%) were excluded based on the abstract review because the device evaluated was not a wearable or the population had some cognitive impairment but did not specifically include dementia. The studies were primarily observational (eg, feasibility studies) and qualitative (eg, using interviews or focus groups), with only 19% (11/58) featuring some type of trial. Participants were most often persons living with dementia in the community (as opposed to residential care), their informal family care partners, and paid dementia care health professionals. The duration for which persons living with dementia were asked to wear the study device ranged from a few hours over several days to 12 months, though 7 days was a common wear period. Information pertaining to the individual studies, including the type of wearable, is summarized in Multimedia Appendix 2 [9,10,18,20,22,25-60].

Figure 1. PRISMA 2020 flow diagram for the systematic review of wearables in dementia research.



Barriers, facilitators, and preferences from the 58 studies were qualitatively synthesized into a total of 29 factors that fit into 4 overarching themes. These themes are categorized by issues dementia researchers should consider from study development to deployment: device selection, protocol considerations, enhancing recruitment, and promoting adherence. Although we categorized these factors by greatest relevance to a particular study section, it should be recognized that many of the factors are interconnected and related. The frequency and proportion of studies featuring each factor are detailed in Table 1. The factors present in each study and their cross-reference numbers are available in Multimedia Appendix 3 [9,10,18,20,22,25-77]. As we describe the factors in the results, we use the term caregivers inclusively to mean both informal (ie, unpaid, often family members) and paid caregivers (eg, health professionals and residential care staff) and provide relevant quotes that capture participant experiences. In the Discussion section, we offer a synthesis of recommendations for researchers planning to conduct longitudinal research with populations with dementia.

Table 1. Presence of synthesized factors across the studies (N=58).

Factor	Count, n (%)
Device selection	
Easy to use	21 (36)
Smaller size or weight	18 (31)

Remembering the device	12 (21)
Independence	10 (17)
Self-removal	7 (12)

Device Selection

Easy to Use

Given the care burden of family members or paid caregivers in residential settings, a wearable's ease of use was paramount when asking caregivers to be involved in a study. It was the most frequently identified factor in studies, with 36% (21/58) of studies mentioning it. The wearable device must be easy to use [25-27,61-65] with an intuitive interface and features [28-31]. The device should require little maintenance or technical support for everyday use, and any interaction with the device required by the study should be simple [10,28,32-35,66]. Some studies explicitly noted that perceived ease of use was associated with more positive attitudes toward wearing the device and less effort or sense of inconvenience in participation [27,36-39]. As a person living with dementia exclaimed in the study by Gris et al [38], "Older people need to use simple things!"

Smaller Size and Weight

Almost without exception, participants desired smaller and lighter wearables or expressed discontent about the size and weight of the device they were asked to wear in the study [34,35,40-42,63,64,66-68]. The influence of a wearable's size and weight was the most frequent physical form factor, with 31% (18/58) of the studies including comments about it, and it was the fourth most common factor identified overall. While rare, there were some exceptions to participants desiring smaller devices overall. Some suggested enlarging certain facets of a device, such as having a larger face or font to read [43] or larger buttons to interact with [27].

Comfort

The physical ease of wearing the device was important [28,31-33,38,41,44,67,69], with discomfort specifically cited as a reason why participants removed the device in several studies [34,45,66]. *Comfort* was sometimes explicitly linked with *unobtrusive*, as complementary qualities [20,29,61]. Nevertheless, prototype devices that were bulky or wearables with a more invasive application (eg, required taping to limbs or backs) were mostly tolerated in the short term. However, simply put, "If residents would show discomfort related to the wearable, the wearable would not be used" [61].

Fits Into Routine

Studies found that if a device type was already familiar or similar to what caregivers and persons living with dementia already used regularly, the wearable could be seen as convenient and more easily fit into a participant's lifestyle [10,30,32,33,46,67,70]. Wristwatches were the most frequently cited as meeting these criteria [20,29,35,38,41,47]. At the same time, devices might also be removed if accessory removal is also part of a participant's routine [20,32,41]: "To tackle such barriers [to using mHealth devices] will likewise require (informal) caregivers to change their attitudes towards using digital technologies and the integration of these technologies into routine care" [30].

Unobtrusive

A wearable that is not obvious or can be hidden was considered a distinct positive [25,29,35,38,70,71]. Having the ability to conceal a wearable alleviated some worry about a person living with dementia being resistant to wearing the device or removing it (refer to the Self-Removal subsection), which could be especially pertinent in studies involving individuals with more advanced stages of dementia [61,66,68]. Unobtrusive devices were also seen as reducing the potential of drawing attention to themselves or experiencing stigma associated with wearing a device [10,42,61] (refer to the Stigma subsection). Like the *fits into routine* factor, wristwatches were commonly cited as an unobtrusive solution [10,20], but something that could be slipped onto a belt or into a shoe was also noted as a viable option [10,29].

Tailorable

Having the option to use a wearable in a way that fits a person's particular style preferences was desired, from format (eg, neck pendant or watch) to style (eg, colors and design) [10,29,34,35,38,61,62,71], as some had concerns with the particular format that was provided in the study and desired a different way to wear the device [26,31,68]. Alternative device forms can include a spectrum of participants and their day-to-day presentations (eg, gender and culture) [10,18]. Offering a wearable in several different forms could help a device suit the *fits into routine* factor, but the *tailorable* factor highlights that singular forms may not fit into everyone's routine equally: "Several members in all four groups expressed a desire for more options in device styles...all groups asked if alternative styles could include a broach, belt clip, small bracelet, or ankle bracelet" [31].

Materials

Nonspecific material concerns or durability were cited as important considerations for wearables to be satisfactory to participants and researchers alike [29,41,63]. Specific material issues such as softness [34,63,66] and the need to make wearables safe for those with skin sensitivities or allergies were also mentioned [10,28,34,61]. Some participants stopped wearing the device altogether because it caused irritation [22] or even skin abrasions [48].

Aesthetics

The general appearance of the device design in its look and feel could be a barrier to everyday use and, thus, adherence [41,43,47,63,64]. Size, form, color, and device material all play a role in the aesthetic attractiveness of a wearable [31,34,35]. For example, participants in the study conducted by Jacklin et al [31] were dissatisfied with the prototype wearable they were testing, describing it as "big and clumsy looking" and "rubbery."

Easy to Wear

Diminishing fine motor skills in persons living with dementia made *easy to wear*, or how simply one can put on or take off the wearable, an issue for day-to-day use [10,62,65]. Wearables that were difficult for the wearer to put on or take off by themselves required caregiver support that could add stress to both the person living with dementia and their caregiver,

creating participation burden and a sense of lack of independence [34,48]. Some wearables were slightly more complicated and required specific sensor placement, which was either difficult to apply correctly or failed to remain securely attached [34,49,50].

The factor *easy to wear* is distinct from *easy to use* and may not play a role if a wearable is designed to be worn continuously. For example, a family caregiver reported that an accelerometer was "a little bit difficult to put on, so [the persons living with dementia] did do it but...it's not easy." The researchers echoed that "the wristband of the accelerometers could be difficult to fasten" but reported that afterward, "the accelerometers were not burdensome to wear" [65].

Water Resistant

Water-resistant or waterproof wearables were recommended [28,61,64] to minimize potential disruptions to data collection. Along with charging the device, a common point of noncompliance occurred when participants forgot to put the wearable back on after removing it for bathing (refer to the Remembering the Device subsection) [29,34]. By selecting a waterproof device and asking participants not to remove it, study protocols do not have to rely on persons living with dementia or their caregivers remembering to take off the device during bathing and, therefore, can reduce the number of study *task requirements* and related *burden impact* [44,63]. Cruz-Sandoval et al [29] suggested that minimizing the need to remove a device can reduce instances of "resistance" from persons living with dementia, and therefore, waterproof devices "can ease some of the burden on caregivers" as well.

Protocol Considerations

Privacy Concerns

Many studies noted that privacy was an issue, with participants voicing concerns about data security and who had access to the wearable's data [10,18,26,31,38,63,68,71]. For example, a caregiver's spouse worried about third-party breaches of her wearable data, explaining that "privacy and security are important to his wife because '...she understands just how easily those systems can be hacked'" [71].

At the same time, some persons living with dementia and their caregivers stated explicitly that privacy concerns were outweighed by the personal or societal benefits of their study participation [25,33], or they reported no privacy concerns [27]. Participants understood that data sharing was often necessary to meet the goals of the study, and privacy concerns were ameliorated when researchers established trust around data management: "Both informal caregivers and the nursing staff were not concerned about privacy issues regarding the wearable, as they consider biomedical variables as de-individualized values. The participants trusted the researchers and nursing home regarding good data handling, as they felt well-informed" [61].

Researchers were able to build trust and attenuate privacy concerns through transparency about data access and security measures during the informed consent processes and throughout the study [61,72]. Empowering participants to have control over privacy options (eg, allowing the collection of some but not all data) and offering the ability to turn off or select what data to monitor also helped [51,73].

Consent Capacity

The ability of persons living with dementia to understand and actively affirm their study participation is an ethical imperative but was specifically mentioned as a potential difficulty by several studies [38,71]. Especially in longer-term studies, seeking ongoing consent to participate was highlighted as necessary, with suggestions to check in regularly to assess the cognitive capacity of the persons living with dementia and their willingness to participate [20,51,74]: "Fluctuating cognition can be a significant barrier to the remote monitoring of isolated patients as forgetting about one's motivations to be monitored can lead to anxiety and agitation for being watched and, consequently, the disablement or destruction of equipment" [74].

At odds with fully informed consent was the general awareness of persons living with dementia regarding their participation or the device [32,43]. At this level of impairment, consent from a caregiver or another proxy for the persons living with dementia was sometimes sought instead, which could be an appropriate barrier to inclusion [22,69,70]. Another major challenge is reconciling what to do when a person living with dementia desires conflict with the caregiver's desire for them to engage in the study and wear the device [10,68]. Under consideration is the issue of dignity, respect for autonomy, and how ignoring these or not obtaining assent could lead to agitation: "In one case, [the study staff] visited the participant after he had refused to wear it on his wrist, saying his wife was tagging him 'like a dog'" [68]. In another study [10], a caregiver reported "[My husband] would have never given his consent even at the beginning—he liked the independence of making his own decisions and doing what he wanted. And I would have had to do it without his consent."

It was recommended that, when possible, researchers, caregivers of persons living with dementia, and their proxies should attend to their care recipient's wishes, whether from an explicit advanced directive [73] or knowledge of their comfort with similar technology [30].

Battery

The longevity of battery life and the ease of charging were noted as concerns for both researchers and participants [9,28,38,63,64,75]. Wearables with a battery life of at least several days were ideal [28,29,52,63], decreasing the need for participants to remember to charge the device [9,10,72] (ie, simplifying *task requirements*), which also minimized data collection interruptions for researchers. Low battery warnings from the device or study staff were seen as a useful tool to ensure an adequate charge of the battery [10,32,68]. Necessarily, the burden of charging was exacerbated when a caregiver was not on site to physically assist or when the charging mechanism was difficult to implement [35].

Adjustment Period

Participants may need time to acclimate to wearing the device (eg, establish wearing routines) and to resolve technical issues before consistent adherence and, therefore, consistent data quality, as adherence tended to improve after an initial period [9,29,32,33,41,53,61]. On the other hand, some studies found better compliance earlier in a study period [42,54,65], perhaps because of novelty. Adjustment periods featuring cognitive aids such as instructional pamphlets and study staff check-ins provided early troubleshooting and time to build new routines [9,29,33].

Task Requirements

Cognitive impairment and caregiving burden were barriers to protocol adherence when participants were asked to do more than simply wear the device [55,56,74,75]. When a study protocol required additional activity from either the persons living with dementia or a caregiver, such as completing bedtime and wake-up event markers, they were less likely to remember or be able to comply [9,50,57,72].

Enhancing Recruitment

Technical Anxiety

Although many interacted with the study wearables and related technology platforms successfully, participants' sense of a lack of technical proficiency and negative attitudes about technology were reported as a perceived barrier to enrollment [10,18,27,37,38,41,71] and adherence during the study [29,53,62]. Caregivers and persons living with dementia alike expressed concern about the complexity or technical know-how needed to operate the wearables [29,36,53,63,74]. Technical anxiety could present as worrying about damaging or losing the device [20,29,34]. The level of technical anxiety and attitudes toward the technology were related to age qualitatively and statistically [10,27,38,53,62] and previous experience with devices [36,46,76]. Participants in a study actually rated themselves as less technologically proficient at the end of the study because of difficulty with the wearable [42].

Multifunctional

Participants saw the potential for the device and platform to offer more information or other uses to the wearer as a benefit of being involved in the research [27,71]. Being able to track their health and activity, signal health events or emergencies (eg, wandering or fall alerts), provide directions, or offer location services, among others, were cited as desirable features [10,25,27,29-31,34,63,64,67,74]. Simpler functions such as information about time, date, and alarm capacity were also ideal wearable facets [10,32,35,41,52,63]: "Participants with dementia indicated that multiple purposes for the locator device, such as being able to measure heart rate, blood pressure and activity level, is advantageous as it would streamline the number of devices that they and their caregivers must contend with" [10]. Stavropoulos et al [63] reported, "Feedback suggested that some people with dementia may be more willing to accept technology that supports them in their daily functioning, in addition to assessing it."

Burden Impact

Caregivers especially liked the potential the wearables offered in terms of supporting their caregiving role and tasks, which, in turn, reduced related burden and stress [27,32,39,64,69]. Factors such as a wearable's capacity for *remote monitoring* and *providing health insights* could improve quality of life or provide peace of mind [33,39,63,67,72]. However, when the wearable was technically difficult to use (*easy to use)* or researchers required additional time or study activity (refer to the Task Requirements subsection), being involved in the study was perceived as a cause of additional burden and a deterrent to both enrollment and continued participation [29,32,33,58,59,61,70,74]. Notably, participants in several studies reported experiencing a mix of both reduced and heightened burden, which varied according to specific facets of the research or from using the wearable [32,33,65,69]: "The nursing staff indicated that they did not want to spend valuable care-time if the foreseen benefit of the wearable for the specific resident was not evident to them. Likewise, also informal caregivers found it important to know the potential individual benefits, before deciding whether to bother the resident with the wearable, as they anticipated some level of resistance to wearing the wristband by the residents" [61].

Stigma

Caregivers and persons living with dementia expressed concerns about the stigma associated with the wearable and the wearable identifying their care recipient (or themselves) as affected by the hidden disability [10,18,30,64]. There was concern about social acceptance and the visibility of the device, as well as the perceptions or comments that it might engender (eg, that they are under surveillance or need to be monitored) [33,34,61,72]. On the other hand, "social influence" was often a positive, with care providers or fellow persons living with dementia offering positive comments or encouraging the use of the wearable [29,37,39,76].

Families and professional care providers alike were sensitive to the negative connotation that some wearables might cause. An Alzheimer Society staff member reported that some families might avoid incorporating a MedicAlert bracelet in their care management plans because "It's a signifier or something that's perceived to bring stigma—[the persons living with dementia] don't want to be out there clearly marked in some way, that there's something wrong with them. Nor does the family" [18].

Caregiver Buy-In

Caregiver buy-in underlies many facets of wearable studies featuring persons living with dementia, as many studies relied on caregiver commitment and coordination with the researchers to do study activities (refer to the Caregiver Support subsection) [20,36,57,61,70]. Moreover, they played significant roles in facilitating understanding of the study by persons living with dementia [29,47] and in encouraging them to wear the device [39,41]. Some studies specifically cited the need for caregivers to have perceived usefulness or reasons to commit to reducing perceived potential burden or risks to enroll themselves and their care recipient in the study [61,72,76]. Gaining caregiver buy-in could be enhanced by reducing participation burdens

(eg, fewer *task requirements*, *easy-to-use* devices, and offering ongoing *technical support*) and experiencing personal benefit from the study (eg, *remote monitoring* and *providing health insights*).

Connectivity

Passive, remote monitoring is the defining advantage of wearable device studies. However, technical connectivity requirements can be a barrier to enrollment [10,31,61,69,74] and may create logistical problems for data transmission [18,31,56,77]. For example, requiring faster Wi-Fi or consistent Bluetooth linkage with a smartphone for more frequent data uploads [67,75,77] may introduce recruitment bias to individuals of higher socioeconomic status and those who are already technically inclined: "The lack of internet connection in patient homes and of funding for caregivers and family member to purchase assistive or communication devices are frequently coupled with skepticism or low abilities to engage with digital products" [74].

Promoting Adherence

Remote Monitoring

Remote monitoring was the most frequently cited desirable and useful feature (mentioned in 19/58, 33% of studies) when engaging in a wearable study among populations with dementia [10,25,27,34,59,61,69,76]. Geolocation-based remote monitoring enabled caregivers to track the movements of persons living with dementia when they were not present, including movement outside the home. Remote monitoring was also seen as a way to know about the well-being of persons living with dementia, for example, by the identification of agitated movement or interrupted sleep [32,40,77]. Remote monitoring enhanced the *independence* of the person living with dementia [27,38,63] while providing informal caregivers with peace of mind regarding the safety of persons living with dementia (eg, reduces *burden impact*) [46,63,64,67,72].

For some participants, the utility of the benefits of geolocation services conclusively outweighed potential *privacy concerns* [25,42]. However, for some, introducing the idea of being monitored could be seen as an infringement on autonomy and privacy [25,31], such as when "some participants feared that proud Anishinaabe older adults would be offended by the idea that their movements would be tracked" [31].

Provide Health Insight

Providing health insight to the participants was one of the top factors mentioned as a benefit to ongoing participation and use of a study's wearable. Paralleling the *multifunctional* factor as an aid to enrollment incentives, health insights included, for example, information on blood pressure, heart rate, sleep quality, and steps. Having ongoing access to this health data motivated participants' personal activity, helped caregivers monitor for health crises, and provided more general insight into the well-being of persons living with dementia [10,25,27,29,32,33,38,53,54,58,61,63,69,74,77]. In addition, they appreciated that this health information could be useful to residential staff and physicians in informing care decisions [25,27,32,34,61,64,69]. A caregiver in the study by Lazarou et al [25] said that with the information from the wearable, "we could monitor her daily activity and communicate any problems to the doctors. It helped us a lot to understand what is going on."

Technical Support

As *technical anxiety* was a barrier, providing initial technical training and ongoing technical support was identified as a complementary facilitator [20,26,37-39,50,74]. Staff availability to provide training at enrollment, support during an adjustment period, and assistance as needed throughout the study helped improve adherence [29,33,77]. Stand-alone instructional materials and cognitive aids were useful to participants who sought to troubleshoot issues on their own [9,10,47,66]. Along with data monitoring, regular proactive check-ins with participants made (or would have made) staff aware of technical problems and helped maintain better compliance [29,45,53,68,77].

For example, Gelonch et al [33] provided caregivers with initial training and ongoing technical assistance, and consequently, they supported their care recipient's use of a lifelogging camera: "The [persons living with dementia] said that the support and supervision provided by their caregiver in certain tasks or actions, such as connecting and loading the camera, were also key for them continuing with the experiment."

Even when apprehensive about using the technology (refer to the Technical Anxiety subsection), participants commonly showed a readiness to learn how to operate the wearable devices and follow study protocol. As recounted by Anderson et al [36], "Many were not necessarily technologically proficient caregivers, but they wanted to be useful. None of the caregivers implied that the research should not continue to be refined."

Caregiver Support

While the importance of *caregiver buy-in* was highlighted in recruitment, in this section, we underscore the importance of caregivers and their investment in the study for continued wearables adherence [36,39,71,77]. Many research protocols required caregiver activity to accomplish their goals by having them be the primary study participant or helping persons living with dementia complete study tasks [29,44] and, importantly, charging the wearable [35,77]. Many factors depend on the caregiver, such as helping persons living with dementia *remember the device* [20,41], assisting with putting it on (refer to the Easy to Wear subsection) [34,48], or understanding how to operate the wearable [33]. In addition, caregivers could be instrumental in explaining facets of the study and, in other ways, facilitating communication of research needs to their care recipient throughout the study [29,68].

Notably, relying on caregiver support can be a major ask (ie, increase *burden impact*): "The caregivers were able to be present almost all the time. They demonstrated personal investment in the care that the person living with dementia received. Their willingness to participate in, work with researchers, and use technology 24 hours a day for 30-60 days was a significant commitment" [36].

Safety

Broadly speaking, wearable technologies were seen as an instrument for enhancing the safety of persons living with dementia [45,46,71,72]. This potential positive was specifically identified as an ongoing benefit, often in tandem with or implied within *remote monitoring* and *providing health insight*. Wearables offer a sense of security to persons living with dementia and their care providers, aiding aging in place by alerting caregivers to life events or potential crises (eg, elopement or fall monitor) and detecting changes in health or behavioral patterns [28,31,34,59].

On rare occasions, the device itself was harmful, such as when an over-ear device caused skin abrasions [48] or when participants desired a different product or sensor design for safety reasons [69]. In contrast to other participants in their study, a caregiver in the study by Snyder et al [71] explained that they felt the wearable, an emergency response pendant, gave a false sense of security, saying, "My reluctance is that it doesn't seem...It can't stop something from happening to her. It just alerts you maybe if something does."

Remembering the Device

Adherence in wearable studies was affected by persons living with dementia's ongoing ability to remember what the device was for [22,29,42]. Not remembering the purpose of the device could also result in "confusion and agitation" [43]. More commonly, persons living with dementia simply forgot to wear the device [10,20,63,75], especially after removing it for bathing (if not *water resistant*) or sleep, often resulting in failure to put it back on [34,65]. Better adherence was reported earlier in the day [53,77], potentially because of sundowning: "Due to memory impairment participants had to be constantly reminded to wear the device and they could change their opinion from one day to the other. Activities that made wearing the device more salient, such as the need to take it off to charge it or bathing, proved challenging with some participants" [20].

Independence

Whether the device provided geolocating, physical activity monitoring, or health alerts, participants, especially caregivers, saw these devices and platform features as enhancing the independence and autonomy of persons living with dementia [10,27,39,63,67,71]. Participants' ongoing access to the data and ability to turn off data collection at their discretion contributed to a sense of agency within the study itself [33,38]. Similar to the potential harms of *remote monitoring*, Synder et al [71] framed this positive as part of the "conundrum between the benefits of having peace of mind, a sense of self-efficacy, and greater independence versus perceiving (remote monitoring technologies) as an invasion of privacy, a security risk, a false sense of security, and a distraction."

Self-Removal

Taking off the device when not instructed was an issue in several studies [44,60]. This could be temporary, such as during bathing, or routine, such as removing accessories before sleep [32,72]. In some cases, removal was longer term, often due to agitation (possibly related to sundowning) or discomfort [22,32,66]. Some researchers and care providers suggested or chose to put the wearable out of reach (eg, on their back) to prevent self-removal by persons living with dementia [60,61].

Discussion

Principal Findings

Overview

This review identified barriers, facilitators, and preferences that could improve the quality of research studies featuring wearable devices and persons living with dementia. The review included studies encompassing a variety of study designs and perspectives from researchers, persons living with dementia, and their caregivers (both unpaid family members and paid professionals), ensuring broad inclusion of research experiences. We offer a qualitative synthesis of these findings to enhance enrollment and adherence in long-term wearable research featuring persons living with dementia. Recommendations for future research fall within 3 main categories: device selection, ethical study design, and technical and data management plans.

Device Selection

Dementia Impairment Level Requires Different Devices

We identified the importance of selecting multifunctional devices with the capacity for participants to monitor their own or their care recipient's data, whether on the device itself or via a dedicated platform. However, what persons living with dementia and their caregivers preferred in terms of devices was sometimes different depending on the advancement of dementia in their target population. In earlier stages, persons living with dementia themselves were more engaged and desired more interactive, multifunctional devices that provided personal benefit to them. However, persons living with more severe dementia, from their perspective and their caregivers' perspectives, desired or interacted with only simpler wearable form factor and features (eg, just used the clock feature) [77]. Even less obtrusive devices or ones out of reach may also be warranted if they are more likely to remove the device themselves as dementia progresses.

The growing ubiquity of remote monitoring and wearable devices for everyday use likely makes stigma less of a concern as we move into the future because an older adult will not stand out when wearing something such as that, especially if it is unobtrusive or looks like an everyday wristwatch. The availability of the devices likely also drives expectations of what participants will personally gain from being in a research study, as people are more familiar with what type of information gathering is theoretically possible, and participants may expect to have access to that information too.

Wristwatches Fits Into Routine but Could Also Be Problematic

Wristwatch wearables were highly recommended as they are part of normal wear for many and offer different levels of multifunctionality. In addition, their unobtrusiveness can reduce stigma [10]. However, habitual device removal during sleep and bathing often conflicted with the research protocols requiring participants to wear the devices all the time [32,41]. Waterproof forms, along with clear instructions for the caregiver

and persons living with dementia to avoid removal in these situations, are useful. Researchers should understand that adjustment periods may be warranted with proactive reminders as participants acclimate to the newer routine and have fewer persistent issues [41].

Ethical Study Design

Attend to Fluctuating Consent Capacity in Persons Living With Dementia

Persons living with dementia feel actively engaged in the research and empowered over their health status when they can see their health data and decide when to engage in the study. However, progressive impairment can mean a person living with dementia may experience fluctuating ability to consent and understand the protocol for a long-term study. Researchers in longer-term studies should establish ongoing communication to monitor possible changes in device preferences or needs. Advanced cognitive decline from dementia can mean decision-making and consent ability are totally compromised for the person living with dementia. Reliance on a caregiver or another surrogate for consent is common, but studies emphasized that if the person living with dementia has given their thoughts on similar situations before, those preferences should be prioritized. Respecting participants' agency is paramount; recognizing and responding to the issues of ongoing consent in this population is key to conducting an ethical study. Actively checking in with participants on a regular basis in long-term studies to gain assent or consent for continued data collection is ethical and may also be required by institutional review boards, given expected cognitive changes.

Promote Inclusivity With Wearable and Protocol Choices

Researchers should be aware of how their study protocol and wearable device requirements may impact who can or would enroll in their study. Some studies, such as that by Cohen et al [53], suggested screening participants for technical knowledge and ability as a way of ensuring compliant participants are enrolled. However, this is not inclusive and could result in bias in recruitment. Instead, preexisting technology and connectivity needs (eg, stable Wi-Fi) should be minimized or eliminated to enhance distributive justice [73,78] and increase the representativeness of the study results. Researchers can reduce the burden and increase equity by not requiring constant wireless connectivity or by supplying the technology to participants. However, intermittent data collection may be at odds with proactive data monitoring for troubleshooting purposes. Staff phone calls or other lower-technology check-ins are recommended in this case.

If possible, different formats and styles (eg, watch vs pendant and watchband options) that are familiar and fit a participant's personal, cultural, and gender preferences should be offered [79]. However, it is important to balance these preferences with the type and quality of data that each format can reliably collect [34]. As evidenced by this review and other research efforts, user-centered codevelopment of wearables with persons living with dementia for research purposes is feasible [38,80] and should continue to be explored to enhance recruitment and adherence in longitudinal studies featuring persons living with dementia.

Data Management

Implement Data Management Plans

We categorized a total of 29 factors into 4 categories that aligned with study development (device selection, protocol considerations, enhancing recruitment, and promoting adherence). However, a fifth category—data management—was largely left uncommented on, as studies were primarily focused on the needs and preferences of the participants rather than the researchers. Participants may report ongoing adherence, but making sure a wearable is not only worn but also collecting data is paramount to conducting quality longitudinal research.

Researchers' data management plans should comprise data collection, storage, and processing for analysis [29,73]. For example, researchers conducting long-term studies should know how long their device batteries will last under their protocol and have procedures in place to limit both data loss and participant burden (eg, reminders to participants to charge their devices). By regularly checking data for completeness, researchers can identify technical problems and offer troubleshooting to resolve missing data issues. Researchers should also have a loss prevention plan for the wearable to reduce missing or inactive devices and the resulting data loss.

For example, Cruz-Sandoval et al [29] had a comprehensive data management plan for a wearable study in an assisted living setting. They combined weekly program visits with battery charging, data collection (ie, upload and synchronization with the study server), and addressed technical troubleshooting needs. They also reviewed the uploaded data for abnormal data patterns and double-checked with caregivers "as soon as possible" to understand if the abnormal data were valid or if they should flag it for deletion. As a loss prevention plan, the researchers also asked the staff to report on the location of the device at the end of each work shift. Particular data management plans could also influence device options; Muurling et al [81] recommended that real-time participant access to device data could both increase adherence and help alert researchers to data issues in close to real time.

Collective Data Management Efforts Could Enhance Support for Wearables Research

To reduce researcher data burden in individual studies, research groups could build infrastructure and codebases to share collectively in an open-access format (eg, on GitHub). Although researcher perspectives on the use of the devices and subsequent data management were generally missing in the studies, 1 study reported that their experience organizing, cleaning, and analyzing Fitbit data were "onerous and time consuming" and recommended that others use automated data management software [77]. Researchers should be aware that many commercial, proprietary wearables may not offer researchers access to the raw data, which may limit secondary utility and increase reliance on the original developers for measure validation. Other collective data enhancements include setting standard definitions or ideal compliance goals, which varied across studies or were not reported at all. Clear, agreed-upon

definitions for adherence and reporting standards are critical for improving long-term dementia research with wearable devices [9,47]. Indeed, a lack of specific, consistent adherence and attrition data from many studies made quantitative comparisons related to the factors impossible. When combined with real-time data monitoring, shared data expertise can help researchers determine whether seemingly incoherent data result from technical issues, allowing for timely resolution [81], or from changes in cognitive function and life circumstances as dementia progresses [82].

Informing Wearable Technology Adoption and Use Models

This systematic review evaluated preferences, barriers, and facilitators to wearables in a study setting, so everyday technology adoption measures may not be entirely applicable. Indeed, caregivers and persons living with dementia may endure adjustment periods, committing themselves to using difficult technologies if the knowledge gained will advance dementia prevention efforts or benefit other caregivers [82]. However, because of the lack of consistent quantitative data, we could not assess factor relationships quantitatively with wearable technology adoption and use models such as the unified theory of acceptance and use of technology model [83], its extended version—the unified theory of acceptance and use of technology 2 model [37], the wearable acceptance in health care model [84], or the technology acceptance model 3 [85]. These measures may also need to be updated as overall perceptions of technology change and its use becomes more ubiquitous, even among older adults. Surveys and other marketing research indicate that although fewer older adults use wearables compared to other age demographics, approximately 25% of US adults aged ≥65 were using wearables in 2023 [86], a rapid increase even in just the last few years [87]. Moreover, these measures relate to technology acceptance in general, while motivations underlying intentions and actual use of wearables may be different, especially as noted within research contexts. A research-specific technology acceptance questionnaire could help researchers understand perceptions directly related to their needs and identify additional barriers to recruitment and adherence.

There is also utility in a more systematic assessment of wearable device qualities themselves and how they relate to adherence. The use of measures such as the Quebec User Evaluation of Satisfaction With Assistive Technology (QUEST; version 2.0) can simplify device comparisons and inform future wearable choices or commercial development. Future reviews could also benefit from standard reporting of why particular devices were chosen in original studies.

Clinical Implications

We have reviewed and identified factors related to the use of wearables in long-term dementia research. However, wearables are also a potentially viable way to gather data for clinical decision-making because they can offer a way for clinicians to proactively monitor health data and circumvent some of the challenges around gathering a patient history from someone with dementia [64,88]. Supporting this potential, a large cohort study of cognitively healthy participants showed that changes in long-term 24-hour activity patterns were associated with elevated risk for the onset of Alzheimer disease, Parkinson disease, and cognitive decline [89]. Moreover, as wearable devices are being used more by the general population, clinicians are experiencing patients coming in with questions about what they have learned from their own wearable devices. Improving research in this area can help clinicians think about how they can interpret and use wearable data in a meaningful way (eg, personalized medicine). Clinicians could use the results of this paper to guide a conversation with their patients about selecting a wearable that is beneficial for meeting the needs of both the patient and their health care team, which could also enhance adherence.

Limitations and Strengths

Our findings are generally agnostic of cognitive impairment status or degree of dementia, reflecting the participant mix seen in the studies, which also often did not disambiguate by the severity or type of dementia (eg, Alzheimer disease and Lewy body disease), which may influence findings as well as the generalizability of findings. Because our analysis was not limited to specific device types or study goals (eg, physical activity or dementia prevention), not all factors may be applicable to all future research applications. We did not perform a formal risk of bias assessment because of the heterogeneity of the study types included, and we note that many studies may be considered at high risk of bias because of smaller sample sizes. However, considering the outcomes of interest for this study were qualitative in nature, the samples were considered sufficient.

Because our extraction captured all reported barriers and facilitators regardless of their origin, we identified the holistic perspective of researchers, persons living with dementia, and their care providers, including unpaid family members or paid health professionals. We systematically coded barriers, facilitators, and perspectives using a grounded, qualitative approach, which did not presuppose expected outcomes, allowing for new or unexpected insights. We offer a comprehensive synthesis of multiple types of studies featuring many wearables and outcomes of interest, identifying overarching themes core to long-term wearable research featuring populations with dementia.

Conclusions

We described factors critical to enhancing dementia study recruitment and wearable adherence, emphasizing how those factors should be considered collectively in an ethical context to meet both researcher needs and participant desires. Organized by study design order and literature prevalence, dementia researchers can use the findings of this systematic review to thoughtfully design quality, long-term wearable studies. The incorporation of wearable technology in dementia research presents a promising pathway to surmount traditional challenges associated with studying persons living with dementia and their caregivers. By leveraging these noninvasive tools, researchers can obtain continuous, objective data for use in advancing treatment, care, and prevention efforts. The results of this evaluation will facilitate quality improvement in ongoing research efforts and contribute to a more person-centered approach to developing effective interventions and prevention strategies.

Abstract

As the aged care sector undergoes digital transformation, greater attention is needed to development of digital health capability in its workforce. There are many gaps in our understanding of the current and future impacts of technology on those who perform paid and unpaid aged care work. Research is needed to understand how to make optimal use of both digital resources and human resources for better aged care. In this Viewpoint, we reflect on a workshop held during an international conference that identified shared concepts and concerns to shape further research into workforce capability. Digital technologies and digital data can increase quality of care in a system that operates through partnerships among service providers, service users, and community members. To realize this potential, digital health learning and development are needed in the aged care workforce. As digital dimensions of aged care services expand, the sector needs clearer direction to implement approaches to workforce learning and development. These must be appropriate to support the safe and ethical performance of care work and to increase the satisfaction of those who care and those for whom they care.

Why Focus on a Digitally Capable Aged Care Workforce?

The aged care sector is in the spotlight around the world due to the increasing health and well-being needs of aging populations. Examples are the Australian Royal Commission into Aged Care Quality and Safety [1], Japan's Social Welfare for the Elderly Act [2], and Germany's national report examining the human rights of older persons in long-term care [3]. Comparisons of aged care systems internationally focus on a variety of issues [4,5].

In such reports, the aged care workforce emerges as an essential factor. One part of this workforce is paid, structured, and regulated (eg, registered nurses) and formally counted in the health and care workforce. Another part of this workforce is informal—often unpaid and not structured or regulated (eg, relatives as unpaid caregivers) but contributing in incalculable ways [6]. Both parts operate under conditions that can be inequitable, inefficient, uncertain, and unsatisfactory. The overall situation of the aged care workforce demands widespread improvements in recruitment and retention, practice standards, skill levels, recognition, and reward [7].

Digital maturity in aged care service provider organizations lags behind mainstream health care services; there are differences between the two also in terms of information needs, technologies of interest, and administration. The medico-legal record for aged care services works differently from hospitals and primary care services, making data and information standardization problematic [8]. Robotics, sensors, and virtual reality have been

explored for over a decade in many countries for their potential to augment human care-giving, but with little opportunity for uptake due to cost and complexity [9]. Telehealth has been shown to have a promising place in aged care, especially since the COVID-19 pandemic, but funding and service supply remain problematic [10]. Nevertheless, digital transformation of the aged care sector is underway [11,12].

Despite this, digital skills of any kind rarely appear in aged care job descriptions or training programs. Further, national workforce strategies related to digital health capability scarcely address the digital skill shortages in the aged care sector. On one hand, there is hope that the sector will find the "right" staff for digitally enabled aged care and find ways to assure them of technology's quality and trustworthiness [13,14]. On the other hand, there is uneasiness that roles and responsibilities may become invisible, peripheral, or "care-adjacent" in the process of moving to technological efficiency and sustainability [15,16]. In short, the introduction of technology has still-unknown implications for the evolution of work in the aged care sector, with possible effects ranging from displacing workers to supporting productivity in current roles or to elevating responsibilities and recognition. However, much of the research to date into aged carers' digital experiences and expectations has had a short-term focus on technology implementations rather than consequences and outcomes [17,18].

Working with technology in particular ways can support specific well-being factors, including positive emotions, self-awareness, mindfulness, empathy, and compassion—so-called positive computing [19]—and there are reports that this approach can benefit aged care organizations and their workers [20]. But there is no guarantee that this will happen without a deliberate workforce strategy. This raises questions about how to proceed, which shape the aims of further research: How can digital transformation of the aged care sector be optimized through greater investment in the digital knowledge, skills, attributes, and attitudes of its workforce? How can such investment in turn improve working conditions and job satisfaction in the aged care workforce?

The authors explored these questions during a workshop that we facilitated at the July 2023 MedInfo conference in Sydney, Australia. There we presented our view that workforce research and development is needed to achieve optimal outcomes for workers in order to achieve these for service users as the aged care sector moves toward digital maturity. The ensuing discussions with workshop delegates contributed to refining the viewpoint we outline here.

What Knowledge and Skill Building Is Required for Digital Aged Care Work?

Digital aged care work is likely to deliver the greatest benefits when needs for fundamental, complementary digital knowledge and skills are met in both paid and unpaid workers. Table 1 summarizes and juxtaposes the capabilities that we propose.

Table 1. Digital capabilities needed in the aged care workforce.

For paid work	For unpaid work
Knowing about developments in the digital environment in which health and care operate	Knowing about the existence of digital systems and tools, and the ways they can support care users and workers
Knowing how to adopt digital tools to help with care coordination and monitoring	Knowing how to use tools to support care closer to home and enhance care provision
Knowing the importance for care quality of collecting and interpreting digital data collected during episodes of care	Knowing how to navigate a complex aged care system across multiple digital platforms
Ability with general digital proficiency and literacy, including information security	Ability with general digital proficiency and literacy
Ability to evaluate online information critically	Ability to access and interpret information from multiple online sources
Ability to consider usability and empathy when using digital tools with patients and clients	Ability to learn to engage with technology and be comfortable with technology
Ability to interpret biometric data and help the patient or client to understand it	Ability to be connected and share health data between care consumers and providers
Ability to judge when technology is not needed as well as when it is	Ability to access and use technology to overcome isolation

There are parallel aspects of capability, with different levels of sophistication, in the needs of paid and unpaid workers. Accordingly, paid workers must be cognizant of not only their own capabilities, but also the capabilities of the unpaid workers with whom they partner. Aside from the digital capabilities of direct consumers of aged care services, paid workers must consider and collaborate with the capabilities of volunteer carers among family, friends and community members. Thus, to build the digitally capable human resources that will support healthy and dignified aging for all, the sector certainly must increase levels of digital literacy in the paid workforce; digital literacy being defined as the ability to use technology to communicate, retrieve, and evaluate information to make decisions [21]. However, the sector also must increase levels of active engagement in digital citizenship among both paid and unpaid workers; in the concept of digital citizenship, people are increasingly expected to use a range of technologies to access services of all kinds and to participate on all levels in society [22].

Various approaches are possible to support digital knowledge building and skill building for the paid workforce. There seem to be gaps and requirements in terms of both formally accredited

training programs and less formal continuing professional development, as well as for both workplace-based learning and workplace-independent learning. The diverse and differentiated methods needed to uplift the digital capabilities of the unpaid workforce are an even broader challenge. Strategy and culture will have to change in the aged care sector to create an environment that encourages and supports all those who do the work to embrace learning and development for positive uses of technology. Among service providers, technology suppliers, industry and community associations, and government agencies, it is not yet clear where roles and responsibilities should sit for planning, implementing, and evaluating the changes that are needed to create and support a digitally capable aged care workforce.

Although these themes are similar to those arising in the mainstream health care workforce in some respects, they also recognize that the aged care ecosystem is distinctive and heterogeneous in terms of the array of partnerships among service providers, service users, and community members [23]. It may be useful to build a more detailed understanding of the digital capability gaps and needs in this sector by overlaying two other system-level concepts onto the idea of the aged care ecosystem—care ecosystems and workforce ecosystems. A care ecosystem is defined as an approach to configuring paid and unpaid workers, ambient assistive technologies, and digital data sharing as work-arounds for intractable workforce shortages in care, particularly in situations that do not call for advanced or intensive clinical services [24,25]. A workforce ecosystem is characterized by employees and contractors working interdependently with automated processes to achieve the goals of an organization and their personal goals; it is considered a guiding concept for the challenges of human resources management as artificial intelligence changes industries and societies [26,27]. A whole-system approach that acknowledges these concepts could provide a coherent framework to plan, implement, and evaluate the range of complementary measures that are needed for digitally enabled aged care work.

Conclusions and Next Steps

Digital technologies and digital data have the potential to improve many aspects of the experiences of the people who receive aged care and the people who provide it. The context in which we seek to develop the digital capabilities of the aged care workforce is challenging. There are strong sustainability pressures on service providers. Public policies, strategies, and sentiments favor innovative, distributed care. Social and technological services and solutions are not joined up. Workers across the sector are stretched thin, whether they are highly trained professionals (eg, registered nurses), minimally trained caregivers (eg, health and personal care assistants), or informal caregivers (eg families, friends, and neighbours).

Understanding how to build digital capability in this workforce is complex and multifaceted, with many unknowns. Inclusion is one: What learning and development methods are most efficient and effective to enable digital skills across the entirety of this workforce? Empowerment is another: How can aged care workers be enabled to advocate for and implement digital improvements that bring positive changes to care? Expertise is another: What career opportunities and leadership roles are appropriate to motivate digital aged care specialists and sustain their attention to workforce development?

Next steps for the work in this field include reviewing the literature to distill evidence from reports of small-scale efforts, workforce research, and development that engages real-world settings and stakeholders, as well as trials of scalable learning and professional and community development programs. To progress this research requires new collaborations among aged care workers, service provider organizations, aged care technology vendors, and digital health workforce researchers. We can improve the current standing of digital skills in the aged care workforce only if we first clarify what the workforce needs from education providers, employers, technology suppliers, and policy makers to enable and motivate them to use existing and emerging technologies safely and wisely. This work will provide important information to design learning and development that enhances digital capability, and it will establish expectations that allow us to evaluate changes in workforce status and performance as an integral part of the digital transformation of aged care.

Acknowledgments

We are grateful to the convenors of the MedInfo 2023 conference for the opportunity to conduct our workshop and to the delegates who attended and engaged in discussion. The 3 authors prepared the workshop together. To set up the workshop discussion, each author presented on a viewpoint of the topic, followed by KB-H and KD cochairing the discussion. All 3 authors contributed to writing and editing this Viewpoint and signed off the paper as ready for submission.

Conflicts of Interest

None declared.

Abstract

Digital twins—dynamic and real-time simulations of systems or environments—represent a paradigm shift in emergency medicine. We explore their applications across prehospital care, in-hospital management, and recovery. By integrating real-time data, wearable technology, and predictive analytics, digital twins hold the promise of optimizing resource allocation, advancing precision medicine, and tailoring rehabilitation strategies. Moreover, we discuss the challenges associated with their implementation, including data resolution, biological heterogeneity, and ethical considerations, emphasizing the need for actionable frameworks that balance innovation with data governance and public trust.

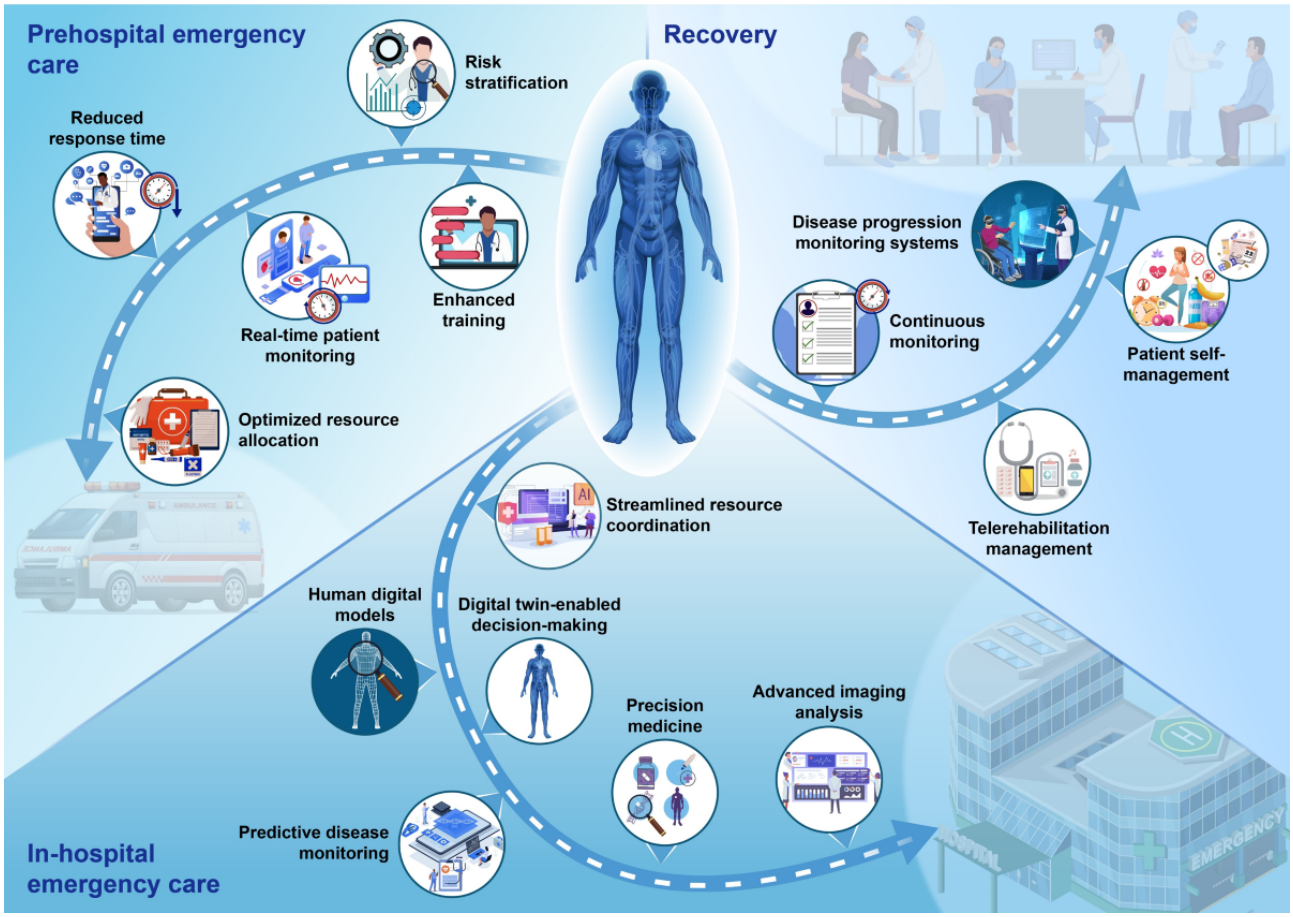
emergency care; digital twin; prehospital emergency care; in-hospital emergency care; recovery

Introduction

The concept of digital twins—dynamic, real-time simulations of processes, systems, or environments—has garnered increasing attention across various domains, from urban planning to medical monitoring [1]. Unlike predictive analytics and artificial intelligence (AI)–driven simulations, digital twins construct dynamic mirror models of physical entities through real-time data synchronization and simulation technologies, emphasizing virtual to physical mapping and closed-loop feedback to support full lifecycle management. In contrast, predictive analytics focus on trend forecasting based on historical data, whereas AI-driven simulations concentrate on multiscenario modeling of complex systems. The advantages of digital twins lie in their real-time capabilities, dynamic optimization, and potential for cross-system collaboration, enabling a closed-loop process from monitoring to decision-making, significantly enhancing efficiency and precision [2]. Emergency care, characterized by its demand for timeliness, precision, and adaptability, provides an ideal testing ground for this transformative technology. By bridging prehospital care, in-hospital management, and recovery, digital twins promise to reshape emergency medical systems for the future (Figure 1). Textbox 1 provides an explanation of the application of digital twins in prehospital first aid, in-hospital first aid, and rehabilitation.

Figure 1. The role of digital twins in transforming emergency medicine.



Textbox 1. The application of digital twins in prehospital first aid, in-hospital first aid, and rehabilitation.

Prehospital emergency care

- Optimized resource allocation: simulation of real-time first-aid scenarios to assess urban emergency needs and spatial distribution of resources, allowing for evidence-based planning and improved efficiency in resource use
- Reduced response time: minimization of procedural delays through real-time data sharing, enabling seamless communication and critical data updates across emergency personnel and systems
- Real-time patient monitoring: leveraging of wearable devices and sensors to create dynamic health profiles, facilitating immediate assessments and predictions of patient conditions (eg, vital signs such as heart rate and blood pressure)
- Risk stratification: aggregation and analysis of patient data to provide superior accuracy in predicting acute events (eg, cardiac arrests), outperforming traditional clinical risk assessments
- Enhanced training: use of simulation-based training environments to strengthen emergency response protocols, improve decision-making, and foster team coordination under high-pressure conditions

In-hospital emergency care

- Advanced imaging analysis: integration of multidimensional data to overcome sample limitations in medical imaging, enabling the development of robust diagnostic models
- Precision medicine: combination of genomic, environmental, and lifestyle data for tailored risk assessments and personalized treatment plans, empowering informed clinical decision-making
- Human digital models: use of digital replicas of anatomical structures to plan surgeries and minimize risks during procedures by simulating operations beforehand
- Digital twin–enabled decision-making: facilitation of real-time analysis and expert-guided interventions (eg, cardiopulmonary resuscitation and drug administration) via remote systems, reducing disparities in emergency care accessibility
- Predictive disease monitoring: use of Internet of Things devices and wearables to continuously monitor patient status, identifying early signs of complications and supporting timely interventions
- Streamlined resource coordination: ensuring efficient resource distribution and effective communication among health care teams through unified, up-to-date patient data sharing

Recovery

- Continuous monitoring: use of sensors and wearable devices to track recovery progress and dynamically adjust treatment plans to optimize outcomes
- Telerehabilitation management: enabling remote monitoring of patients through digital twins, providing clinicians with tools to assess and adjust rehabilitation remotely, particularly for mobility-impaired individuals
- Patient self-management: sharing digital twin insights with patients to encourage active participation in health management through lifestyle modifications and adherence to care plans
- Disease progression monitoring systems: integration of real-time monitoring data to predict the risk of disease exacerbations or complications, thereby intervening in time and triggering early warnings, allowing physicians to adjust treatment during critical windows and improve outcomes.

Prehospital Emergency Care

Current prehospital emergency care systems often struggle with suboptimal resource allocation due to their reliance on simplified decision-making models that fail to account for the complex, dynamic nature of urban environments [3]. Digital twins address these limitations by unifying diverse data streams into a single, adaptable model that enables real-time optimization of emergency resource allocation. These models incorporate multiple layers of data, from historical emergency call patterns to real-time traffic conditions, enabling more nuanced and effective resource deployment decisions.

Digital twins prove particularly valuable in prehospital emergency care, where time-sensitive decisions directly impact patient outcomes. By incorporating high-resolution information about building layouts, land use, population density, and traffic patterns, digital twins create actionable urban simulations that allow emergency response teams to plan and execute their operations with unprecedented efficiency. The integration of these various data sources enables more sophisticated approaches to emergency resource management than previously possible with traditional systems.

This transformation in emergency care delivery demonstrates the broader potential of digital twin technology to revolutionize urban health care systems through data-driven, predictive approaches to resource management. Moreover, wearables in ambulances provide dynamic health profiles, supporting real-time monitoring and accurate risk stratification for acute events. Simulation-based training environments can help improve emergency team readiness and coordination under high-pressure conditions.

In-Hospital Emergency Care

In hospitals, digital twins are redefining precision medicine by integrating diverse data sources to enable robust diagnostics, personalized treatments, and streamlined workflows [4]. By synthesizing real-time patient data with historical health records and predictive algorithms, digital twins facilitate more accurate disease modeling, enhancing clinical decision-making and tailoring interventions to individual patient profiles. This data-driven approach supports the early detection of complications, optimization of treatment pathways, and improvement of patient outcomes.

Preoperative simulations represent a critical application of digital twins in surgical care. By creating highly accurate digital replicas of patient anatomy, clinicians can simulate surgical procedures, anticipate potential challenges, and refine techniques before making the first incision. These virtual rehearsals significantly reduce surgical risks, improve procedural efficiency, and enhance patient safety. Complementing this, predictive monitoring through Internet of Things (IoT) devices enables the continuous assessment of patient vital signs, offering early warnings of complications such as sepsis or cardiac arrest. These alerts allow medical teams to respond swiftly, averting adverse outcomes and saving lives.

An emerging and transformative application is the development of medical device twins (MDTs), which provide virtual counterparts for critical hospital equipment, including ventilators, defibrillators, infusion pumps, and imaging devices. MDTs are created through digital twin technology and are consistent with the actual medical device in terms of function, performance, and status. They can be updated in real time to reflect the actual operation of the medical device. These digital twins continuously monitor device performance, tracking metrics such as wear and tear, calibration accuracy, and operational efficiency. By identifying potential failures before they occur, MDTs facilitate proactive maintenance, reducing downtime and ensuring the reliability of life-saving equipment during critical emergencies.

Beyond maintenance, MDTs contribute to resource optimization. By analyzing use patterns and forecasting demand surges, these systems can dynamically allocate equipment to areas of highest need, such as during mass casualty incidents or seasonal patient influxes. This predictive capability not only prevents bottlenecks in care delivery but also enhances hospital operational efficiency, ensuring that critical resources are always available when and where they are needed.

Recovery

In recovery, digital twins play a transformative role by enabling personalized and adaptive rehabilitation processes. These advanced systems integrate comprehensive patient data, including clinical records, biometric parameters, and lifestyle information, to develop dynamic treatment plans tailored to individual needs. Wearable devices continuously monitor patient progress in real time, providing crucial data to adjust therapies dynamically, ensuring that interventions remain effective and responsive to changes in a patient's condition [5,6]. This real-time feedback loop facilitates precision rehabilitation, minimizing setbacks and promoting steady recovery trajectories.

Telerehabilitation further amplifies these benefits by offering remote monitoring and therapy-adjustment capabilities. Patients can receive professional guidance and care modification without frequent in-person visits, reducing logistical burdens and enhancing access to rehabilitation services. Moreover, digital twins empower patients by offering insights into their recovery progress, encouraging active engagement in health management and fostering adherence to prescribed care plans.

A significant breakthrough in the recovery phase is disease relapse prediction and early warning, a feature that underscores the predictive power of digital twins. By leveraging longitudinal patient data and advanced predictive analytics, digital twin systems can detect subtle patterns indicative of potential disease recurrence. These insights enable the generation of real-time alerts for health care providers, prompting timely interventions that can mitigate complications and prevent hospital readmissions. For instance, changes in respiratory patterns or biomarkers could signal the early stages of a relapse, allowing for preemptive adjustments in treatment strategies.

Digital Twins in Real-World Applications

Currently, the application of digital twins in emergency care remains in its early developmental stages, with significant room for growth, yet they have already demonstrated potential in real-world scenarios. For instance, Pfizer and IBM's collaborative Project BlueSky focuses on developing remote patient monitoring systems that use wearable devices and environmental sensors to track disease symptoms in real time, capture dynamic data, and automatically identify abnormalities for timely intervention [7]. Similarly, Digital Orthopaedics and Dassault Systèmes jointly created a clinical decision support system capable of generating patient-specific computational models to reduce trial-and-error risks and achieve precision treatment [7]. During public health crises like COVID-19, digital twins have proven effective in enhancing emergency response capabilities by simulating real-time data collection and vaccination processes to identify optimal resource allocation strategies and refine contingency planning. These examples underscore the transformative role of digital twin technology in advancing emergency care efficiency and resilience [8].

In the cases mentioned above, digital twins have demonstrated significant advantages over current public health systems. Digital public health enables optimized resource allocation, reduces waste, and enhances emergency response efficiency, and it allows real-time monitoring of patient anomalies to accelerate emergency interventions. Centered on data-driven and intelligent capabilities, these advancements markedly improve the efficiency of resource allocation, response speed, and decision-making precision in emergency care.

In summary, digital twins represent a reliable tool in the era of digital intelligence, becoming increasingly feasible in the current data-rich context. The emergency response system serves as an excellent testing ground for digital twin applications, offering

significant potential across areas such as emergency resource planning, patient monitoring, and rehabilitation. However, the implementation of digital twins in the emergency domain is not a task to be completed overnight. It necessitates advancements in complementary fields, including urban modeling, wearable technology, and the IoT, to fully realize its potential. Despite their promise, the application of digital twins in emergency care faces substantial challenges. Currently, many medical digital twins remain confined to visualization, providing static representations rather than actionable tools for decision-making. For full realization, these systems must evolve beyond visualization to actionable frameworks. A second critical hurdle is data quality and resolution. Biological heterogeneity significantly influences disease progression and treatment outcomes, requiring vast, high-resolution datasets to build robust, accurate models. Lastly, ethical, privacy, and security concerns pose significant barriers to the adoption of digital twins in health care [9]. The integration of sensitive patient data with urban-level modeling raises important questions about data governance, requiring careful consideration to balance innovation with public trust. To address the aforementioned challenges, it is necessary to systematically overcome existing bottlenecks through technological optimization, privacy protection, ethical governance, and multiparty collaboration. On the privacy and security front, full lifecycle data protection must be strengthened by leveraging differential privacy and blockchain technology to anonymize sensitive information and enable traceable storage while implementing dynamic access controls to restrict unnecessary data access. Ethically and legally, clear boundaries and transparent guidelines for technology use must be established. Additionally, collaboration among governments, medical institutions, and technology companies is needed to develop unified technical standards and security evaluation systems alongside public education to build societal trust and ensure patient consent and data authorization. Only through parallel advancements in technology, regulatory frameworks, ethical constraints, and social collaboration can the safe implementation and sustainable development of digital twin technology in emergency scenarios be achieved.

Abstract

Background: The global cancer burden is rapidly increasing, with 20 million new cases estimated in 2022. The world population aged ≥65 years is also increasing, projected to reach 15.9% by 2050, making cancer control for older patients urgent. Surgical resection is important for cancer treatment; however, predicting postoperative disability and mortality in older patients is crucial for surgical decision-making, considering the quality of life and care burden. Currently, no model directly predicts postoperative functional disability in this population.

Objective: We aimed to develop and validate machine-learning models to predict postoperative functional disability (≥5-point decrease in the Barthel Index) or in-hospital death in patients with cancer aged ≥ 65 years.

Methods: This retrospective cohort study included patients aged ≥65 years who underwent surgery for major cancers (lung, stomach, colorectal, liver, pancreatic, breast, or prostate cancer) between April 2016 and March 2023 in 70 Japanese hospitals across 6 regional groups. One group was randomly selected for external validation, while the remaining 5 groups were randomly divided into training (70%) and internal validation (30%) sets. Predictor variables were selected from 37 routinely available preoperative factors through electronic medical records (age, sex, income, comorbidities, laboratory values, and vital signs) using crude odds ratios (P<.1) and the least absolute shrinkage and selection operator method. We developed 6 machine-learning models, including category boosting (CatBoost), extreme gradient boosting (XGBoost), logistic regression, neural networks, random forest, and support vector machine. Model predictive performance was evaluated using the area under the receiver operating characteristic curve (AUC) with 95% CI. We used the Shapley additive explanations (SHAP) method to evaluate contribution to the predictive performance for each predictor variable.

Results: This study included 33,355 patients in the training, 14,294 in the internal validation, and 6711 in the external validation sets. In the training set, 1406/33,355 (4.2%) patients experienced worse discharge. A total of 24 predictor variables were selected for the final models. CatBoost and XGBoost achieved the largest AUCs among the 6 models: 0.81 (95% CI 0.80-0.82) and 0.81 (95% CI 0.80-0.82), respectively. In the top 15 influential factors based on the mean absolute SHAP value, both models shared the same 14 factors such as dementia, age ≥85 years, and gastrointestinal cancer. The CatBoost model showed the largest AUCs in both internal (0.77, 95% CI 0.75-0.79) and external validation (0.72, 95% CI 0.68-0.75).

Conclusions: The CatBoost model demonstrated good performance in predicting postoperative outcomes for older patients with cancer using routinely available preoperative factors. The robustness of these findings was supported by the identical top influential factors between the CatBoost and XGBoost models. This model could support surgical decision-making while considering postoperative quality of life and care burden, with potential for implementation through electronic health records.

KEYWORDS

older patients with cancer; postoperative outcomes; functional disability; machine learning; decision-making

Introduction

The global cancer burden is rapidly increasing, with an estimated 20 million new cases and 9.7 million deaths in 2022 [1]. In Japan, the lifetime risk of being diagnosed with cancer is approximately 65.5% and 51.2% for men and women, respectively [2].

In addition, the global population is aging rapidly, with the proportion of those aged ≥65 years expected to increase from 9.1% in 2019 to 15.9% by 2050 [3]. Japan faces the most advanced stage of this demographic shift, with the population of older adults expected to increase from 28.8% in 2020 to 37.7% by 2050 [4]. Thus, cancer control for older patients has become an urgent issue worldwide, including in Japan.

Older patients with cancer often face challenges such as frailty [5], comorbidities [6-8], and socioeconomic status [6], which affect treatment outcomes and quality of life (QOL). Surgical resection is a key treatment, which requires careful consideration in older patients with cancer due to concerns about postoperative functional disability and its impact on long-term outcomes [9]. Some factors may influence surgical outcomes in older patients, including age [9], anemia [10], BMI [11,12], dementia [6,7], frailty [5], low household income [6], malnutrition [13], and smoking [14].

Considering the postoperative QOL and care burden on patients' families and society, it is important to predict not only postoperative mortality but also functional disability [15]. Hospital-associated disability, defined as functional disability following acute hospitalization, is recognized as a crucial outcome in older patients with significant impact on health care costs and long-term prognosis [16,17]. Some models can predict postoperative mortality [5,13]; however, few have addressed functional disability. A model after lower-extremity surgery [6] could predict the risk of in-hospital mortality and discharge to a nursing home, which is a surrogate for functional disability, in patients admitted from home. Currently, no model can directly predict functional disability after cancer surgery.

Therefore, this study aimed to develop a machine learning–based model for predicting postoperative functional disability and in-hospital mortality in patients with cancer aged ≥65 years using data from 70 hospitals across Japan. This approach will enable patients and their families to make informed decisions about undergoing cancer surgery, considering their postoperative QOL and care burden.

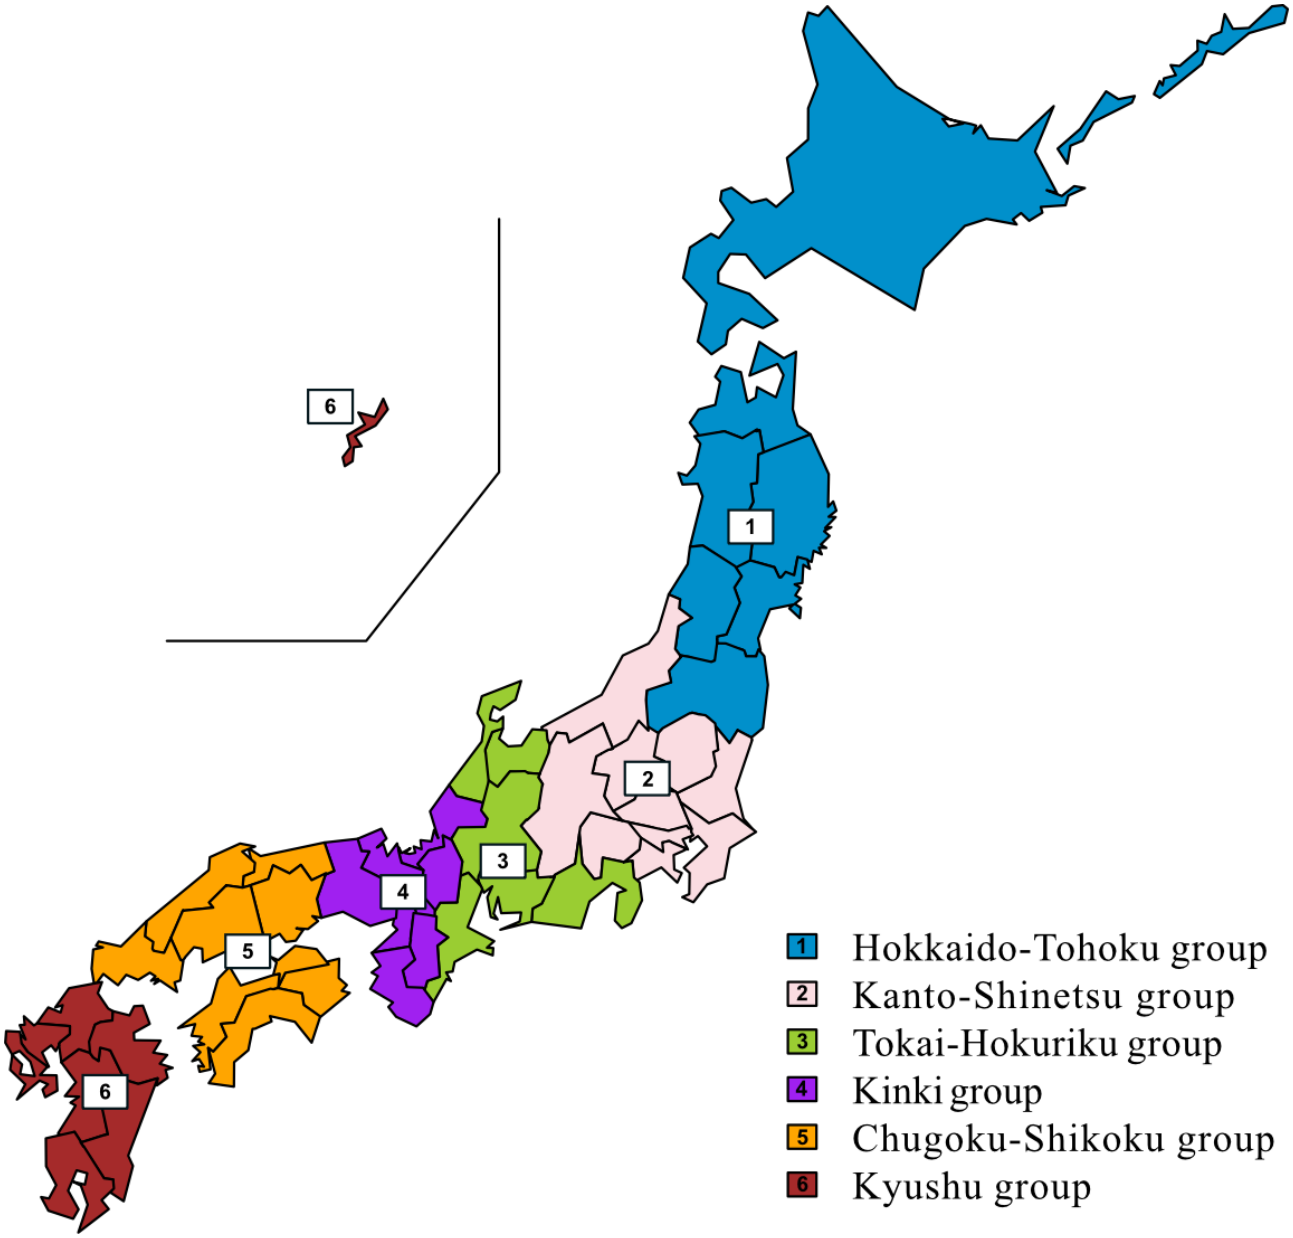
Methods

Study Design and Data Source

We conducted a retrospective cohort study to develop machine-learning models for predicting postoperative functional disability and in-hospital mortality in older patients with cancer. This study used data between April 2016 and March 2023 from 70 Japanese hospitals within the National Hospital Organization (NHO) database across 6 regional groups: Hokkaido-Tohoku group, Kanto-Shinetsu group, Tokai-Hokuriku group, Kinki group, Chugoku-Shikoku group, and Kyushu group (Figure 1) [18].

The NHO maintains 2 databases: (1) an administrative claims database based on the Diagnosis Procedure Combination–based Per-Diem Payment System [19] and a clinical information database based on the standardized structured medical record information exchange [20]. The administrative claims database contains patient information, such as age, sex, cost, comorbidities, complications, diagnosis, medical procedures, and medications. The clinical information database includes medical charts, laboratory data, and vital signs on a daily basis.

Figure 1. A total of 6 National Hospital Organization regional groups across Japan.



Participants

The study included patients aged ≥65 years who were admitted to NHO hospitals between April 2016 and March 2023 and underwent surgery for major cancers, including lung, stomach, colorectal, liver, pancreatic, breast, and prostate cancers. These cancer sites were selected because of their high incidence [2] and mortality rates [21] in Japanese and global cancer statistics [1]. The surgical procedures included both scopic and open surgeries under general anesthesia.

We excluded patients who had missing Barthel Index data at admission or discharge, were first included in the database at admission (no medical history available), underwent surgery more than 1 week after admission, or had the Barthel Index of 0 at admission. These exclusion criteria were applied because: (1) patients missing Barthel Index data could not be evaluated for outcome, (2) most of the predictor variables were missing if patients had no medical history, (3) we eliminated the effect of hospitalization on physical function from admission to surgery, and (4) the Barthel Index change from admission to discharge was an outcome variable, but patients with a minimum score of 0 at admission cannot show further decline [22].

Outcome Variables

The primary outcome was worse discharge, defined as either in-hospital death or postoperative functional disability. Postoperative functional disability was characterized as hospital-associated disability [16] (≥5-point decrease in the Barthel Index between admission and discharge) [17]. The Barthel Index consists of 10 items, including transfer, bathing, and stair climbing, used to evaluate activities of daily living on a scale of 0 - 100, with lower scores indicating a decline in physical function.

The secondary outcomes were health care costs and postoperative length of stay (LOS) in patients predicted to be at high risk and low risk for worse discharge. The optimal cut-off point for high-risk or low-risk classification was

determined using the Youden index [23] on the receiver operating characteristic (ROC) curve.

Predictor Variables

We identified the following 37 potential predictors of worse discharge based on previous studies: age (65 - 74, 75 - 84, and ≥85 years) [9], sex [24], underweight (BMI <18.5 kg/m^2) [12] and obesity (BMI ≥30 kg/m^2) [11], route of admission (home or nonhome), emergency admission, an estimated household income in the lowest tertile based on post-code (low income) [6], smoking (Brinkman Index ≥200) [14], functional dependence (Barthel Index ≤60) [22], surgical factors (open surgery, scopic surgery, and combined general and epidural anesthesia), the presence of gastrointestinal cancer (colorectal, liver, pancreas, and stomach), the cancer staging (0–II or III–IV) [25], the presence of recurrent cancer, Charlson Comorbidity Index (CCI) ≥3 [26,27], Hospital Frailty Risk Score (HFRS) ≥5 [28], comorbidities common in older patients (cerebrovascular disease, chronic pulmonary disease, congestive heart failure, dementia [8], diabetes, liver disease, myocardial infarction, peptic ulcer disease, peripheral vascular disease, and renal disease), medical history about cancer within 8 weeks before surgery that allowed the evaluation of preoperative chemotherapy [29] and radiotherapy [30] (chemotherapy, radiation, and surgery), vital signs (body temperature ≥38°C [31], systolic blood pressure >180 mm Hg [32]), and laboratory test values (albumin <3.5 g/dL [13], total bilirubin ≥2.0 mg/dL [33], creatinine ≥ 2.0 mg/dL [33], platelet <10^5/μL [33], and hemoglobin <11 g/dL [10]).

These predictors were measured as follows: age, sex, BMI, route of admission, emergency admission, income, cancer staging evaluated using the Tumor Nodes Metastasis (TNM) classification system [34], the presence of recurrent cancer, Brinkman Index, and Barthel Index were assessed at admission. Surgical factors were assessed during the surgery. The type of cancer was determined during the surgery using the *International Statistical Classification of Diseases and Related Health Problems, 10th Revision* (*ICD-10*) coding system [35]. Comorbidities were identified from *ICD-10* codes within 8 weeks before surgery (Table S1 in Multimedia Appendix 1). Notably, dementia was determined if it was either identified from *ICD-10* codes within 8 weeks before surgery or documented in the clinical summary at admission, as Japanese hospitals are required to include the dementia status of inpatients aged ≥65 years at admission [8]. Vital signs were measured closest to surgery after admission, and laboratory values were obtained using those measured closest to surgery within 8 weeks before surgery.

Statistical Analysis

We randomly selected one of the 6 NHO regional groups for the external validation set [36], while hospital data from the remaining 5 groups were randomly divided into the training (70%) and the internal validation (30%) sets [37]. The missing predictor variables were imputed using the "missRanger" [38], which is a random forest–based algorithm [39], assuming that the data are missing at random.

To summarize patient characteristics, continuous variables were expressed as mean (SD) or median (IQR), depending on the distribution of variables. The Wilcoxon rank-sum test or the Welch test was used to assess between-group differences. Categorical variables were expressed as proportions and compared using the χ^2 test.

In the training set, a double penalty was implemented by eliminating unnecessary variables to create a more practical model for clinical use [40]. The first penalty involved selecting predictor candidates with a crude odds ratio (OR) at P<.1 [41]. The second penalty to further narrow down the predictor candidates used the least absolute shrinkage and selection operator (Lasso) method, which allowed for the selection of clinically relevant variables with consistent relationships [36,42].

The selected factors were incorporated into 6 machine learning models: category boosting (CatBoost) [36,43], extreme gradient boosting (XGBoost) [36,42], logistic regression, neural networks [44], random forest [36], and support vector machine (SVM) [36]. Model performance was evaluated using the area under the ROC curve (AUC) with 95% CIs). Similarly, we calculated the accuracy, sensitivity, specificity, F_1-score, and the area under the precision-recall curve (PRAUC) to assess the performance of the models [36,37]. The precision-recall curve of the models was also shown.

We used the synthetic minority oversampling and random undersampling techniques to avoid overfitting owing to the imbalance between the positive and negative events [45]. The minority class was oversampled at 50%, 100%, and 200% of its original size, followed by random undersampling of the majority class to achieve equal numbers between classes. The models were trained using 10-fold cross-validation with grid search for hyperparameter optimization. Of these sampling ratios and hyperparameter combinations, those yielding the largest AUC were selected. We ranked the predictor variable using the Shapley additive explanations (SHAP) method [46] to assess the contribution of the predictors to the models. Moreover, considering higher cancer stages are associated with poorer postoperative outcomes [25], a multiple logistic regression was conducted to evaluate the interaction between cancer staging and other predictor variables using OR (95% CI). We examined interactions between cancer stage III–IV and the top 5 features based on the mean absolute SHAP value.

We analyzed the AUC difference between the models using the DeLong method [47], which was based on the model with the largest AUC in both internal and external validation. Sensitivity analyses were used to assess the impact of missing data and assessing 2 outcomes simultaneously (death or functional disability) on the models. For missing values, a complete case analysis was performed to confirm the robustness of the results obtained from the imputed data set. We also evaluated the AUC of the models when the models predicted only death in all patients or functional disability in patients with survival discharge. We conducted subgroup analyses by LOS, cancer type (breast, colorectal, liver, lung, pancreas, prostate, or stomach), and cancer staging (stage 0–I, II, III, or IV). For the LOS analysis, we calculated the 75th percentile of LOS for each cancer type separately and divided patients into LOS for each

cancer type <75th percentile (short-stay) and LOS ≥75th percentile (long-stay) groups [48].

For the analysis of secondary outcomes, we compared LOS and health care costs between patients at high and low risk based on the model with the highest AUC in both internal and external validation. Health care costs were assessed across various categories, including total, medical consultation, medication, medical procedure, surgical procedure, laboratory tests, hospital stay, and others. The currency conversion rate was 150 JPY to US $1.

All hypothesis tests had a 2-sided significance level of .05. All statistical analyses were performed using R version 4.3.1 (R Foundation for Statistical Computing) .

Ethical Considerations

Our study was approved by the Institutional Review Board of Showa University (approval number 2023 - 129-A). Individual consent was not required because this was an opt-out study. This study conforms to the principles outlined in the Transparent Reporting of a multivariable prediction model for Individual Prognosis or Diagnosis (TRIPOD) statement.

Results

In total, 54,360 patients from 70 hospitals were included in this study (Figure 2): 6711 in the external validation set from Kinki group, 33,355 in the training set, and 14,294 in the internal validation set from the remaining 5 regional groups. In the training set, 1406/33,355 (4.2%) patients experienced worse discharge (Table 1). These patients were older (24.5% [344/1406] vs 5.8% [1864/31,949] for age ≥85 years), more likely to be admitted from nonhome (8.1% [114/1406] vs 0.9% [281/31,949]), and had higher prevalence of dementia (28.7% [403/1406] vs 5.6% [1783/31,949]), gastrointestinal cancer (64.3% [904/1406] vs 41.7% [13,326/31,949]), and advanced cancer stage (32.6% [458/1406] vs 24.2% [7716/31,9] for stage III–IV).

In the training set, we selected 31 predictor variables for worse discharge using crude OR (Table S2 in Multimedia Appendix 1). Further selection using the Lasso method resulted in 24 factors: age (75 - 84 y and ≥85 y), male sex, BMI <18.5 kg/m^2, nonhome admission, emergency admission, low income, Barthel Index at admission ≤60, open surgery, gastrointestinal cancer, cancer stage III–IV, HFRS ≥5, cerebrovascular disease, congestive heart failure, dementia, diabetes, liver disease, myocardial infarction, medical history of chemotherapy, systolic blood pressure ≥180 mm Hg, albumin<3.5 g/dL, creatinine ≥ 2.0 mg/dL, platelet <10^5/μL, and hemoglobin <11 g/dL. All 6 models were developed using these 24 variables.

Furthermore, the AUCs were 0.81 (95% CI 0.80 - 0.82) for CatBoost, 0.81 (95% CI 0.80 - 0.82) for XGBoost, 0.79 (95% CI 0.78 - 0.80) for random forest, 0.79 (95% CI 0.78 - 0.80) for neural networks, 0.78 (95% CI 0.77 - 0.80) for SVM, and 0.78 (95% CI 0.77 - 0.80) for logistic regression (Figure 3). CatBoost and XGBoost were the 2 models with AUC ≥0.80 and showed similar values with relatively high accuracy (0.76), sensitivity (0.72), specificity (0.76), F_1-score (0.20), and area under the precision-recall curve (PRAUC) (0.22). The performance metrics and precision-recall curves for all models are shown in Table S3 and Figure S1 in Multimedia Appendix 1, respectively. In the top 15 influential factors based on the mean absolute SHAP value, the CatBoost and XGBoost models had the same combination for the 14 features: dementia, age ≥85 years, age 74 - 85 years, gastrointestinal cancer, albumin <3.5 g/dL, open surgery, male sex, hemoglobin <11 g/dL, low income, nonhome admission, Barthel Index at admission ≤60, BMI <18.5 kg/m^2, diabetes, and stage III–IV (Figure 4). There were no significant interactions between stage III–IV and the top 5 influential features that both models shared (Table S4) in Multimedia Appendix 1.

For both the internal and external validation set, the CatBoost model had the largest AUCs among the 6 machine- learning models: 0.77 (95% CI 0.75 - 0.79) and 0.72 (95% CI 0.68 - 0.75), respectively (Figure 5). In sensitivity analysis, all 6 models maintained comparable performance to the main analysis (Table S5 in Multimedia Appendix 1). The CatBoost model achieved relatively high AUCs and showed consistent performance in complete cases (0.78, 95% CI 0.76 - 0.80; 0.72, 0.68 - 0.76), death only (0.77, 0.71 - 0.82; 0.73, 0.65 - 0.81), and functional disability only (0.77, 0.75 - 0.79; 0.71, 0.68 - 0.75) for internal and external validation, respectively.

In subgroup analyses, the models maintained consistent performance for LOS and cancer staging (Table S5 in Multimedia Appendix 1). However, the performance varied based on cancer types: the CatBoost model achieved a larger AUC in patients with stomach cancer (internal: 0.80, 95% CI 0.76 - 0.84; external: 0.81, 95% CI 0.69 - 0.92) but a smaller AUC in patients with prostate cancer (0.53, 95% CI 0.40 - 0.66; 0.46, 95% CI 0.28 - 0.63) than the main analysis.

Based on the CatBoost model, patients at high risk had significantly longer LOS (internal: median 13, IQR 9 - 19 d vs median 9, IQR 7 - 13 d; external: median 13, IQR 10 - 19 d vs median 10.0, IQR 7.0 - 14.0 d) and higher total health care costs (internal: median US $11,048, IQR US $9191 - 13,106 d vs median US $10,092, IQR US $7894 - 11,893; external: median 11,069, IQR US $9401 - 13,499 vs median US $10,371, IQR US $8820 - 11,936) than patients at low risk (all P<.01). However, the high-risk group had slightly lower surgical procedure costs than the low-risk group in internal validation and was comparable to the low-risk group in external validation (Table 2).

Figure 2. Flow diagram of enrollment of study participants.(a) “Missing BI” means patients with missing Barthel Index at admission or discharge. (b) “No medical history” means patients included in the database within 8 weeks preceding surgery. (c) “More than 1 week” means patients who underwent surgery more than one week after admission. (d) “BI at admission=0” means patients with BI of 0 at admission. BI: Barthel Index; NHO: National Hospital Organization.

Others	0 (0-137)	100 (0-212)	<.01	0 (0-120)	0 (0-177)	<.01

[a]Functional disability" means a decrease in the Barthel Index by ≥5 points at discharge compared with admission.

[b]LOS: length of stay.

Discussion

Principal Findings

In this study, we developed and validated machine-learning models to predict postoperative functional disability and mortality in older patients with cancer. Our CatBoost model achieved good performance using routinely available preoperative factors from electronic health records, indicating the potential for clinical implementation. Although ethical training for hospital staff is essential to prevent unauthorized disclosure of prediction results, implementing this model within closed electronic health record systems could provide protection for patient privacy.

The previous model for lower-extremity surgery had an AUC of 0.72 in external validation [6], similar to our model; however, our model directly predicted functional disability using the Barthel Index rather than using nursing home discharge as a surrogate. The model performance remained consistent across sensitivity analyses for death and functional disability separately, and complete cases, indicating the robustness of our findings. Notably, the model demonstrated higher predictive performance in patients with stomach or colorectal cancer than the other cancers, making it especially valuable for surgical decision-making in these patients.

The CatBoost model identified patients at high risk who had longer LOS and higher health care costs; however, surgical procedure costs were comparable between patients at high and low risk. These findings suggested that the increased cost was based on the varying postoperative course. Our model can support decision-making for older patients with cancer and their families regarding cancer surgery by providing insights into potential postoperative QOL and care burden. Moreover, if patients at high risk choose to undergo cancer surgery, our model may enable health care providers to implement targeted interventions such as intensive postoperative rehabilitation. Early identification of patients at high risk, such as those aged ≥85 years with dementia, can help health care providers prepare support systems, including caregiver education, social work consultation for home health support, and coordination with multidisciplinary teams [15]. This proactive approach may help reduce caregiver burden and improve outcomes for both patients and their families.

Of the 6 machine-learning models, the CatBoost and XGBoost models, with AUC ≥0.80, had the same combination of 14 features in the top 15 influential factors. These factors include established risk factors for poor postoperative outcomes in older patients as identified in previous studies: dementia [7], older age [9] (≥85 y and 75 - 84 y), male sex [24], anemia [10] (hemoglobin <11 g/dL), low income [6], underweight [12] (BMI <18.5 kg/m²), diabetes [49], and cancer staging [25]. In addition,

several factors serve as proxies for known risk factors. For frailty [5], the factors include (1) open surgery, which generally results in a more pronounced postoperative functional disability compared with scopic surgeries; (2) nonhome admission, likely indicating that patients are too frail to live independently; and (3) Barthel Index ≤60 at admission, indicating severe dependence [22]. For malnutrition [13], the proxies are (1) albumin <3.5 g/dL, a marker of malnutrition, and (2) gastrointestinal cancer, which often involves a long time to restart food intake after surgery, increasing the risk of malnutrition compared with other cancer types. The consistency between the 2 models in identifying these factors further validates their importance in predicting postoperative outcomes. Although chemotherapy and creatinine ≥2.0 mg/dL were not common in both models, these factors, identified as influential factors in previous studies [33,50], might also be included as predictor variables in future models. Moreover, our models included several factors associated with social vulnerability, such as age ≥85 years, dementia, and low income. Without ensuring model transparency to health care providers, our model could unconsciously contribute to reduced surgical care access for vulnerable populations. Therefore, when implementing our model in clinical practice, health care providers should consider these model characteristics to ensure fair allocation of health care resources [51].

Limitations

Our study has some limitations. First, we only validated all models using Japanese data. While our CatBoost model showed moderate accuracy (AUC: 0.7 - 0.9) [52] in both internal and external validation, the AUC in the external validation was lower than that in the internal validation as observed in a previous study [6]. Further studies using data from other countries and ethnic groups are necessary to evaluate model robustness, including potential bias and overfitting [51], and confirm their applicability to different health care systems. However, our study used data from 70 hospitals across Japan, which may enhance generalizability within the country. In addition, considering the global trend of population aging, our models may prove valuable for other countries in the future, particularly when these countries reach levels of demographic aging similar to Japan's current situation.

Second, we did not have information on predictor variables such as marital status [6] because of the retrospective nature of the study. Despite this limitation, our models had good predictive performance in the validation sets. While our analysis showed no significant interactions between stage III–IV cancer and the top features, future studies incorporating additional variables may evaluate such interactions to enhance the predictive performance of models.

Finally, the long-term prognosis of patients classified as high-risk by our models remains unclear. Further research is required to determine the extent of functional recovery and mortality in these patients. At a minimum, postoperative functional disability in patients at high risk indicates an increased immediate post-discharge burden on family caregivers and health care resources.

Conclusions

Our CatBoost model achieved good performance for predicting postoperative functional disability and mortality in older patients with cancer. This model could support surgical decision-making for patients and families while guiding targeted interventions by health care providers. This model, which is based on routinely available preoperative factors, has the potential for implementation in clinical settings through electronic health records.

Abstract

Background: Alzheimer disease and related dementias (ADRD) exhibit prominent heterogeneity. Identifying clinically meaningful ADRD subtypes is essential for tailoring treatments to specific patient phenotypes.

Objective: We aimed to use unsupervised learning techniques on electronic health records (EHRs) from memory clinic patients to identify ADRD subtypes.

Methods: We used pretrained embeddings of non-ADRD diagnosis codes (*International Classification of Diseases, Ninth Revision*) and large language model (LLM)–derived embeddings of clinical notes from patient EHRs. Hierarchical clustering of these embeddings was used to identify ADRD subtypes. Clusters were characterized regarding their demographic and clinical features.

Results: We analyzed a cohort of 3454 patients with ADRD from a memory clinic at Massachusetts General Hospital, each with a specialist diagnosis. Clustering pretrained embeddings of the non-ADRD diagnosis codes in patient EHRs revealed the following 3 patient subtypes: one with skin conditions, another with psychiatric disorders and an earlier age of onset, and a third with diabetes complications. Similarly, using LLM-derived embeddings of clinical notes, we identified 3 subtypes of patients as follows: one with psychiatric manifestations and higher prevalence of female participants (prevalence ratio: 1.59), another with cardiovascular and motor problems and higher prevalence of male participants (prevalence ratio: 1.75), and a third one with geriatric health disorders. Notably, we observed significant overlap between clusters from both data modalities (χ^2_4=89.4; P<.001).

Conclusions: By integrating *International Classification of Diseases, Ninth Revision* codes and LLM-derived embeddings, our analysis delineated 2 distinct ADRD subtypes with sex-specific comorbid and clinical presentations, offering insights for potential precision medicine approaches.

Introduction

Background

Alzheimer disease (AD) is a neurodegenerative condition which affects more than 55 million people globally [1], and it is the seventh leading cause of death in the United States [2]. Despite its substantial public health burden, AD remains poorly understood, with limited treatment options available. AD and related dementias (ADRD) is an umbrella term that refers to multiple dementing illnesses, including AD, frontotemporal dementia (FTD), Lewy body dementia (LBD), and vascular dementia. AD is the most prevalent, accounting for around 60% to 80% of all dementia [2]. While these diseases have distinct clinical and neuropathological criteria, there is substantial overlap in both clinical presentation and autopsy findings at the individual patient level. For example, AD is clinically characterized by an amnestic-predominant dementia and neuropathologically defined by the build-up of amyloid beta (Aβ) plaques and neurofibrillary tangles formed by hyperphosphorylated tau protein [3]; however, these lesions are frequently accompanied by cerebrovascular disease (CVD) [4] or Lewy body pathology [5], which can influence clinical presentation. Likewise, LBD is defined by Lewy bodies but is also associated with plaques and tangles [6], which may accelerate the rate of cognitive decline [7]. This clinical and neuropathological heterogeneity limits our ability to target disease-modifying drugs to each specific neuropathological lesion. The so-called *amyloid hypothesis* has prevailed as the leading explanation of AD disease etiology, where it is held that Aβ toxicity leads to tau hyperphosphorylation, synaptic dysfunction, and neurodegeneration [8]. However, treatments targeting this hypothesis only show limited efficacy, which may stem in part from the clinical and neuropathological comorbidities [9], highlighting the need for a tailored approach to identify potential subtypes of disease and develop more effective targeted treatments.

Previous approaches to AD subtyping have focused on RNA expression, as well as brain imaging and cognitive assessments. Neff et al [10] identified 5 molecular subtypes of AD using RNA-sequencing signatures, characterized by different dysregulated pathways related to tau-mediated neurodegeneration, Aβ neuroinflammation, synaptic signaling, immune activity, mitochondria organization, and myelination. The Subtype and Stage Inference algorithm, applied to magnetic resonance imaging and positron emission tomography imaging data, identified distinct AD trajectories based on the rate and sequence of brain atrophy [11] and tau deposition [12]. Cognitive subtypes have also been identified based on memory, visuospatial and linguistic capabilities, and executive function [13-15]. These studies were limited to research cohorts with specific selection criteria, and it is unclear whether these subtypes can be extended to larger samples.

In contrast, real-world data, such as, electronic health records (EHRs), provide readily accessible large observational datasets and have been used for clustering AD or ADRD subtypes [16]. Unsupervised learning approaches on EHR datasets have revealed latent structure in conditions, such as autism [17,18] and Parkinson disease [19]. For AD subtyping, EHR-based approaches have used the *International Classification of Diseases* (*ICD*) or similar diagnostic codes, showing varying success depending on the methodology and population. Xu et al [20] used hierarchical clustering on EHR data from patients with AD, identifying subtypes related to CVD, mental illness, age of onset, and sensory problems. Alexander et al [21] found the following 5 patient subtypes: mental health, nontypical AD, typical AD, CVD, and men with cancer. They later identified a consistent subtype with early-onset AD, predominantly female participants, with a faster rate of progression using various machine learning methods [22]. Landi et al [23] used unsupervised deep learning to encode EHRs with temporal information, identifying early-onset AD, later-onset AD with mild comorbidities, and typical-onset AD with moderate symptoms. He et al [24] applied spectral clustering to EHRs of patients with AD, discerning 4 subtypes with significant demographic, mortality, and medication use differences. Tang et al [25] analyzed comorbidity patterns in EHRs of patients with AD, revealing sex-dependent variations. In another study, Tang et al [26] used EHRs with knowledge networks to predict AD onset and identify sex-specific genetic markers. These studies collectively highlight the varied methodologies and results in EHR-based research, emphasizing the complexity and potential of these approaches for a deeper understanding of AD.

However, none of these prior studies leveraged the richer representation of EHR data by embedding full sequences of clinical text. Transformers have emerged as state-of-the-art architecture for language modeling and are broadly characterized by the concept of attention [27]. Attention, named for its similarity to cognitive attention, enables the sharing of contextual information among word representations without directly encoding their sequence. The transformer used in this work is a version of the Bidirectional Encoder Representations from Transformers (BERT) architecture [28]. This architecture consists of an encoder which can be fine-tuned on downstream applications and domains. Specifically, we use Clinical BERT [29], which is pretrained on a large corpus of clinical notes from the critical care database Medical Information Mart for Intensive Care (MIMIC) [30].

Objectives

In this work, we used both pretrained embeddings of *ICD-9* code diagnostic data and transformer-derived embeddings of clinical notes. This dual approach addresses the limitations of previous studies by incorporating structured *ICD* codes, which allow us to study subtypes of patients with similar *ICD* codes (non-ADRD diagnosis in charts), and unstructured clinical notes, which capture detailed clinical history and manifestations provided by specialists. By combining these 2 modalities, we aimed to enhance the clustering of patient ADRD subtypes.

Methods

Cohort Selection Process

Patients were selected from the Massachusetts General Hospital (MGH) EHR database. The selection criteria included patients who had at least 2 MGH memory clinic visits (either an in-person office visit or a video telemedicine visit) from August

2015 to June 2022, were aged >50 years at their first visit, and had progress notes of substantial length (≥512 characters). These criteria were chosen due to the richness of the notes for the clustering analysis and the high quality of the ADRD diagnosis from specialists. From the identified patient cohort, 2 datasets were extracted as follows: one containing structured diagnostic *ICD* code data from the patients' entire medical history and another consisting of unstructured clinical notes authored by memory clinic specialists, limited to the most recent visit. We chose only the most recent visit note because it typically consolidates the patient's prior history, thereby reducing redundancy and providing a focused, up-to-date clinical snapshot. In addition, the dataset was filtered to exclude patients who did not have ADRD diagnoses (Multimedia Appendix 1), as well as those who lacked non-ADRD *ICD* codes (ie, patients who only had ADRD *ICD* codes were excluded).

Ethical Considerations

This study was approved by the Mass General Brigham Institutional Review Board (protocol 2015P001915), which granted a waiver of informed consent for secondary analysis of electronic health data. No participant compensation was provided. Electronic health data was queried from Epic and securely stored on servers within the Mass General Brigham firewall. Access was restricted to authorized study personnel, in full compliance with institutional privacy and data security policies.

Embedding Methodology

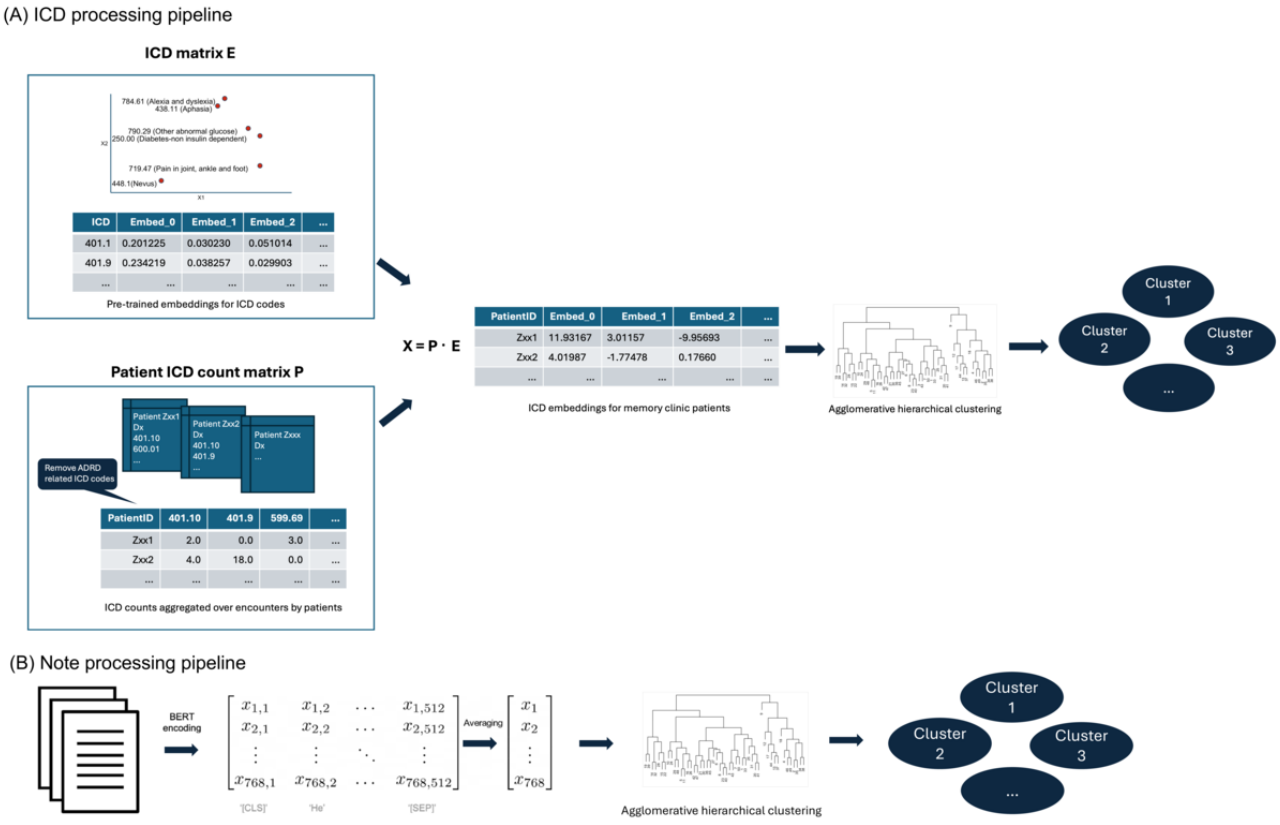
ICD Codes

Before clustering, it was necessary to derive a patient-level representation that encoded information relevant to phenotype in a single vector. While some prior work has relied on one-hot encoding (where categorical data are converted into binary vectors) of clinical data to represent patient phenotype, we leverage existing pretrained embeddings that capture relevant biomedical semantics in their latent representations of clinical concepts. In particular, we use a set of 300-dimensional embeddings for *ICD-9* codes, derived from prior work by Choi et al [31].

For a count-based encoded representation of *m ICD-9* codes across our cohort, $P \in R^{3454 \times m}$, and an embedding matrix, $E \in R^{m \times 300}$, our design matrix for clustering, $X \in R^{3454 \times 300}$, is given by the following matrix multiplication: $X = P \cdot E$.

This matrix multiplication sums the non-ADRD *ICD* embeddings across a patient record, and the resultant embedding is directly affected by the number of times each code appears in a patient's history. ADRD codes were dropped from the matrix *P* to not confound clustering based on structured ADRD phenotype. A schematic depicting the *ICD* representation pipeline is provided in Figure 1A.

Figure 1. Visualization of the clustering pipeline for (A) International Classification of Diseases (ICD) codes and (B) notes. For each subfigure, the workflow goes from left to right. BERT: Bidirectional Encoder Representations from Transformers.



Clinical Notes

Clinical notes were encoded using Clinical BERT before clustering. To derive patient-level representations of clinic notes, several preprocessing steps were undertaken. First, unwanted delimiter characters were stripped from patient notes, and notes were chunked into contiguous sections of up to 1024 characters. This resulted in a distribution of token numbers of ~200 to 300 per note following BERT's WordPiece encoding of input sequences. After passing through the transformer encoding, we took the final layer representation averaged over the 12 attention heads, such that each note was represented by a matrix of dimension (768, n), corresponding to each of the n input tokens having a 768-dimensional contextual vector representing it. Following this encoding, the representation was averaged over the token dimension to arrive at a single 768-dimensional vector for the whole note. This was explored using both simple averaging (arithmetic mean) over the token dimension, as well as attention-weighted averaging based on row-wise entropy of the final layer attention matrix. Attention-weighted averaging was used in patient representations due to the resultant lower inertia and increased silhouette score on average. A schematic depicting the note representation pipeline is provided in Figure 1B.

Attention-Weighted Averaging

For a given input sequence of length n, the final layer representation in a transformer model has an associated self-attention matrix, $A \in R^{n \times n}$. For BERT-based models, n is ≤512 due to the constraint on the length of the context window. To provide weights for averaging the embedding, $E \in R^{768 \times n}$, over the token dimension, we compute the row-wise differential entropy of the attention matrix, given in equation (1). Differential entropy is the continuous analog of Shannon entropy, which is usually only defined for discrete random variables [32]. In particular, the method described in Ebrahimi et al [33] is used to approximate the differential entropy, implemented in the Python (Python Software Foundation) library *SciPy version 1.7.3* [34], as the closed-form expression for the attention distribution for a given row $f(x)$ is not known analytically from the values of attention sampled. The differential entropy for a row i is given by

and the corresponding vector $h \in R^{n \times 1}$ corresponds to the entropy across every row. From the row-wise entropy, this vector is softmaxed to obtain the corresponding weights, $w \in R^{n \times 1}$, as follows:

The resultant embedding for a note sequence, $N \in R^{768 \times 1}$, is then given by the matrix multiplication as follows:

and the final patient-level representation is the simple average over all note fragments for a given patient, for their most recent encounter. A visualization of attention matrices with varying row-wise entropy and thus varying weighting per token is provided in Figures S1 and S2 in Multimedia Appendix 2.

Hierarchical Clustering

Clustering analysis was performed on *ICD-9* embeddings and clinical text representations to identify ADRD subtypes. We selected hierarchical agglomerative clustering with Ward linkage due to its ability to capture the hierarchical structure of clinical data, as seen in *ICD-9* codes (eg, metabolic disorders branching into type 1 and type 2 diabetes) and clinical notes (eg, cognitive impairment branching into memory loss and aphasia). Cluster quality was evaluated using elbow plots and silhouette scores, with implementation via *Scikit-learn v1.0.1* [35].

Optimal Transport

To address provider-specific effects in embeddings of clinical notes, we first applied Uniform Manifold Approximation and Projection (UMAP) to reduce the dimensionality of the data and then applied the earth mover distance transport approach using the Python *Optimal Transport* package [36]. *Optimal Transport* provides a mathematical framework to minimize the cost of transforming one distribution into another, which can address the problem of domain adaptation [37]. Domain adaptation involves adjusting data from different sources to make their data distributions more comparable, ensuring that models trained on these data perform well across various settings. In this context, the earth mover distance method was used to align the embeddings from various providers to a standard reference. This alignment ensured that the subsequent clustering analysis was less skewed by provider-related differences, allowing a more accurate interpretation of the underlying phenotypic variation.

Enrichment Analysis: ICD Clusters

ICD clusters were phenotypically characterized by testing for enrichment of *ICD-9* codes within each cluster. For each cluster, a 2×2 contingency table was generated for each *ICD-9* diagnosis code, comparing counts of patients with that code within cluster to counts of patients with that same code in other clusters. A chi-square test for enrichment was performed; the prevalence ratio (PR), calculated as the prevalence of each code in one cluster divided by its prevalence in the rest, was calculated to measure the strength of the association. A Bonferroni correction was applied to the resultant P values to correct for multiple comparisons, and *ICD* codes in each cluster were ranked by corrected P value to characterize the most significant enrichments. All P values in this investigation were two-sided, with a postcorrected α of 0.05 to determine significance. The top-10 significant diagnoses with the highest PR were extracted from each cluster for interpretation. If a cluster lacked significant diagnoses, the top diagnoses with the highest PR among the nonsignificant ones were selected. The enrichment analyses were conducted in Python version 3.8.15.

Topic Modeling: Note Clusters

We used BERTopic [38], using the Python package *BERTopic* v0.16.0, to identify representative topics and key terms within each note cluster. Embeddings obtained through optimal transport were directly used for clustering and topic assignment, bypassing the need for additional embedding and dimensionality

reduction steps. Before conducting cluster-based term frequency–inverse document frequency (TF-IDF) for topic assignment, the clinical text was preprocessed using a vectorizer to remove stop words and exclude common terms that appeared too frequently across most notes. Furthermore, to fine-tune and enhance the word representation of topics, we applied the KeyBERTInspired model, which extracts keywords by leveraging embeddings and cosine similarity to find the words with the closest semantic relationship to the note texts, thereby making them more representative of the topics. Following the extraction of representative terms within each cluster, we used GPT-4 (OpenAI) [39], a state-of-the-art large language model (LLM), to enhance interpretability. GPT-4 summarized the representative words provided by BERTopic into coherent themes with greater clinical significance, such as specific medical conditions, treatments, and medications. The PR, calculated as the prevalence of each word in one cluster divided by its prevalence in the rest, was calculated to measure the strength of the semantic relationship. The BERTopic modeling and analyses were conducted in Python version 3.9.6.

ADRD Diagnosis Categorization

The categorization of ADRD diagnoses was conducted using an extensive list of diagnostic names based on disease etiology. This list was meticulously reviewed for each unique diagnosis name recorded for the MGH memory clinic patients in the EHR system. The ADRD diagnoses categories included AD; dementia unspecified; FTD; LBD; vascular cognitive impairment (VCI); and others, such as posterior cortical atrophy (PCA), progressive supranuclear palsy, corticobasal degeneration, and primary progressive aphasia. An expert behavioral neurologist (JRD) provided critical input during this process, helping to develop a comprehensive mapping list that correlates specific diagnosis names with their corresponding ADRD categories. The application of this mapping to the data was performed using R version 4.3.2 (R Foundation for Statistical Computing). The full list of diagnosis names corresponding to ADRD diagnosis categories is provided in Multimedia Appendix 1.

Cluster Characterizations

To assess associations between clusters and sex, as well as ADRD diagnoses, we used the chi-square test. For each cluster, a 2×2 contingency table was generated for each variable, comparing the counts of patients with the characteristic within the cluster to those in other clusters. The PR, defined as the prevalence of a characteristic in one cluster divided by its prevalence in the remaining clusters, was calculated to measure the strength of the association: 1 indicates no difference in prevalence between the 2 groups, >1 indicates higher prevalence in the first group, and <1 indicates lower prevalence in the first group. In addition, to examine variations in the age of onset across clusters, we initially conducted a Kruskal-Wallis Rank Sum Test using the *stats* package from R. η^2 (calculated by subtracting the number of groups from the Kruskal-Wallis H statistic plus one, and then dividing this result by the total number of observations minus the number of groups) based on the H statistic was reported as the effect size: values closer to 0 indicate a smaller effect and values closer to 1 indicate a larger effect. Following significant findings, further post hoc analyses using the Dunn test were performed to delineate differences between groups. The *P* values were adjusted for multiple comparisons using the Benjamini-Hochberg method to control the false discovery rate (FDR). Age-of-onset data were rigorously annotated by human experts reviewing clinical notes; where notes did not specify an exact age of onset, the age at the first clinical visit within the memory clinic was used as an approximation. Finally, we conducted a chi-square test between *ICD* clusters and note clusters to test whether patient cluster assignment was consistent across note and *ICD* representations. If the contingency table was larger than 2×2, Cramér V (calculated as the square root of the chi-square statistic divided by the product of the sample size and the minimum dimension minus one) was reported as the effect size: 0 indicates no association and 1 indicates a strong association. Standardized residuals (standardized differences between the observed count and the expected count) were reported for each cell: values close to 0 indicate the observed count is close to the expected count, positive values indicate the observed count is higher than expected, and negative values indicate the observed count is lower than expected. All statistical analyses were conducted in R version 4.3.2.

Results

Study Population

Our final study population consisted of 3454 patients from the MGH tertiary care memory clinic with clinical notes and *ICD* codes in the EHR system. The average age of onset for patients was 72.1 (SD 9.5) years, with 1678 (48.58%) being female. The majority were White (n=3059, 88.56%), followed by Asian (n=90, 2.61%), Black or African American (n=77, 2.23%), American Indian or Alaska Native (n=4, 0.12%), and Native Hawaiian or Other Pacific Islander (n=1, 0.03%). In addition, 103 (2.98%) identified as belonging to other races, and race data were not available for 120 (3.47%) patients. Regarding ethnicity, 3020 (87.43%) identified as non-Hispanic, 106 (3.07%) as Hispanic, and ethnicity data were not available for 328 (9.5%) patients. AD was the most prevalent diagnosis, affecting 1317 (38.13%) patients, followed by dementia unspecified, which accounted for 1101 (31.88%) patients. Each encounter recorded only one diagnosis name, and only the most recent encounter was used. The patient selection details are illustrated in Figure 2. The demographic and ADRD diagnosis breakdowns are provided in Table 1 and ADRD categorization details are provided in Multimedia Appendix 1.

Figure 2. CONSORT (Consolidated Standards of Reporting Trials) diagram illustrating the selection of patients from the Massachusetts General Hospital (MGH) electronic health record (EHR) system. ADRD: Alzheimer disease and related dementias; Dx: diagnosis; ICD: International Classification of Diseases.

[a]AD: Alzheimer disease.

[b]FTD: frontotemporal dementia.

[c]LBD: Lewy body dementia.

[d]VCI: vascular cognitive impairment.

[e]Includes posterior cortical atrophy, progressive supranuclear palsy, corticobasal degeneration, and primary progressive aphasia.

[f]Age of onset was manually annotated by experts viewing clinical notes; for notes without age of onset, we approximated with the age of first encounter.

ICD Clustering

To investigate the clinical heterogeneity within ADRD, we clustered the embeddings of non-ADRD *ICD* codes assigned to this tertiary care sample from the MGH ADRD cohort. We hypothesized that this approach would reveal distinct clinical subtypes based on clinical comorbidities, which were associated with demographics (ie, age of onset and sex). The hierarchical agglomerative clustering method revealed 3 distinct clusters in the embeddings of non-ADRD *ICD* codes, as determined by the silhouette score. Figure 3A depicts a heatmap of enriched *ICD* codes across each cluster, and a 2D UMAP projection of these *ICD* code embeddings, colored by cluster, is displayed in Figure 4A. The distribution of patients across the clusters was as follows: cluster 1 included 1501 (43.46%) patients, cluster 2 included 1597 (46.24%) patients, and cluster 3 included 356 (10.31%) patients. Detailed summary statistics for these clusters are presented in Table 2.

Figure 3. Heatmap of enrichment in International Classification of Diseases (ICD) clusters and topics in note clusters. (A) This heatmap displays the enrichment of ICD-9 codes across ICD embedding clusters. Cluster 1 is primarily dominated by skin-related and certain cardiovascular conditions. Cluster 2 is marked by its exclusive and high prevalence ratios (PR) in psychiatric and behavioral conditions. Cluster 3 shows a diverse set of conditions with a significant prevalence of respiratory, pain-related, and complicated diabetic mellitus. (B) This heatmap displays representative words for each note cluster identified through topic modeling. Cluster 1 is primarily dominated by psychiatric manifestations and medications. Cluster 2 highlights cardiovascular, motor, and sensory issues. Cluster 3 covers a variety of symptoms and conditions, including autoimmune issues, behavioral and movement disorders, sleep disturbances, etc. In both (A) and (B), the color intensity of each code or word-cluster pairing reflects the PR (prevalence of code or word in observed group divided by prevalence in other groups) associated with that code or word. Words colored as exclusive were only present in one cluster.

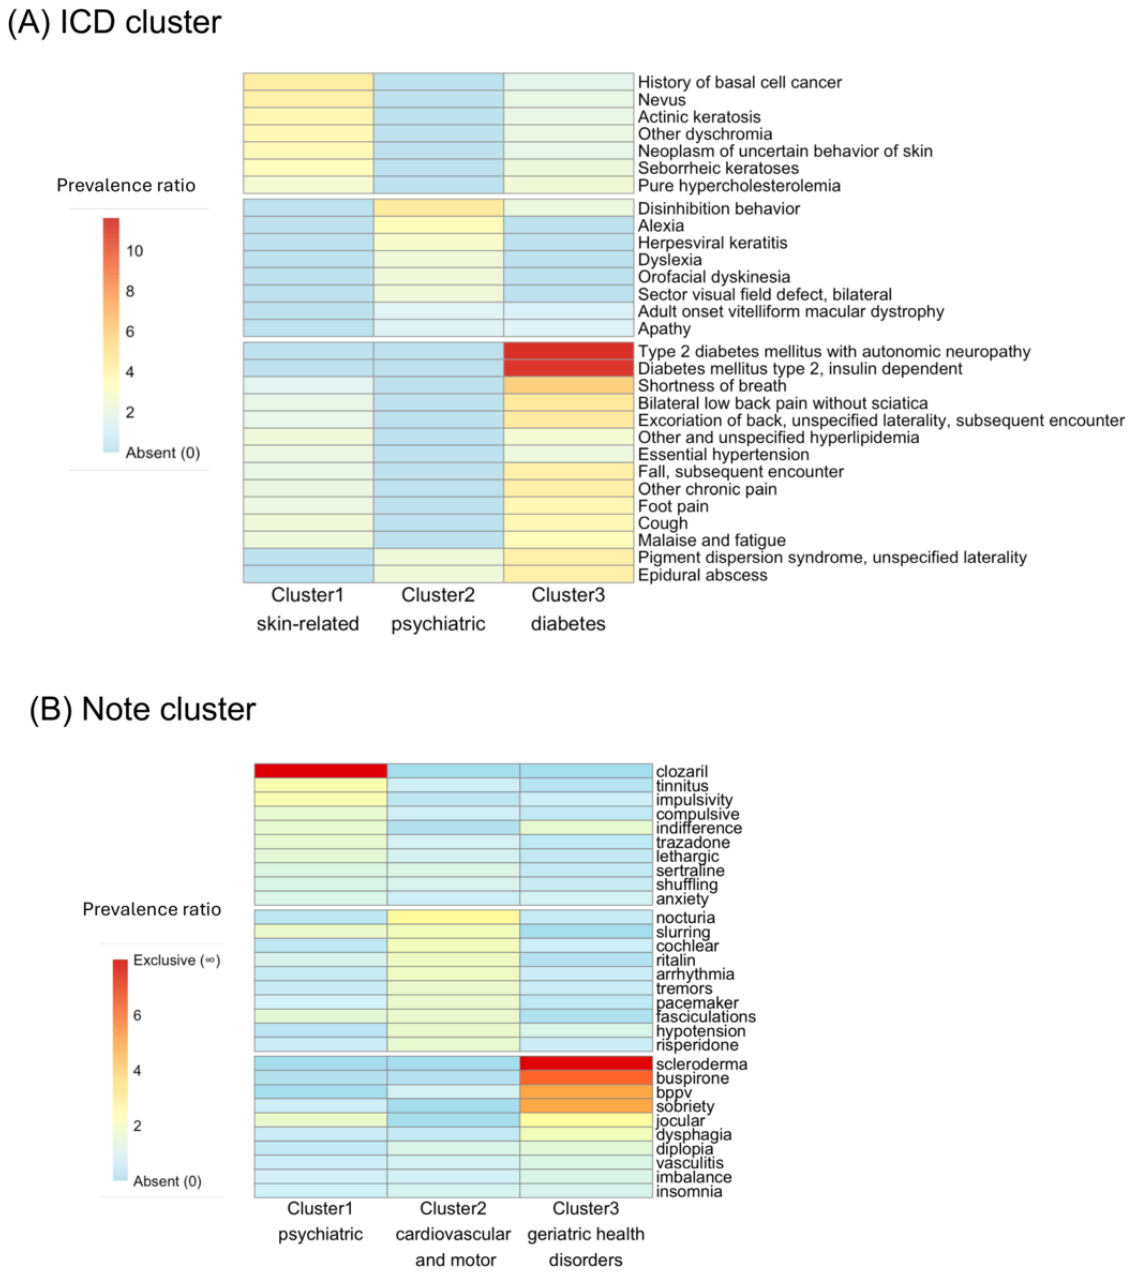

Figure 4. Clustering of International Classification of Diseases (ICD) embeddings and their demographic and diagnostic associations. (A) Uniform Manifold Approximation and Projection (UMAP) visualization of ICD embeddings were characterized by 3 clusters: cluster 1 includes 1501 (43.5%) patients, cluster 2 comprises 1597 (46.2%) patients, and cluster 3 contains 356 (10.3%) patients. (B) Bar plot showing prevalence for sex by cluster, significance based on a chi-square test. Notably, cluster 3 has a significantly higher proportion of female participants compared to male participants (P_{FDR}=.009). (C) Violin plot illustrating the distribution of age of onset across clusters. Each violin plot shows the kernel density estimate of the data, with the center line representing the median age of onset. Box plot elements are overlaid, where the box limits indicate the upper and lower quartiles, and the whiskers extend to 1.5 times the IQR. Individual points are hidden for clarity. Significant differences are observed, with cluster 2 showing the earliest average age of onset at 69.8 (SD 9.6) years, and cluster 3 the latest at 75.5 (SD 8.1) years (P<.001). (D) Heatmap showing prevalence ratio for Alzheimer disease and related dementias (ADRD) diagnoses across clusters, significance derived from a chi-squared test. Clinical diagnoses include Alzheimer disease (AD); dementia unspecified; frontotemporal dementia (FTD); Lewy body dementia (LBD); vascular cognitive impairment (VCI); and others such as posterior cortical atrophy (PCA), progressive supranuclear palsy (PSP), corticobasal degeneration (CBD), and primary progressive aphasia (PPA). Significant distribution variations are evident across clusters. The circle size, color, and number indicate the magnitude of the prevalence ratio. Blue indicates underrepresentation while red indicates overrepresentation. *P* values were corrected with false discovery rate adjustments.

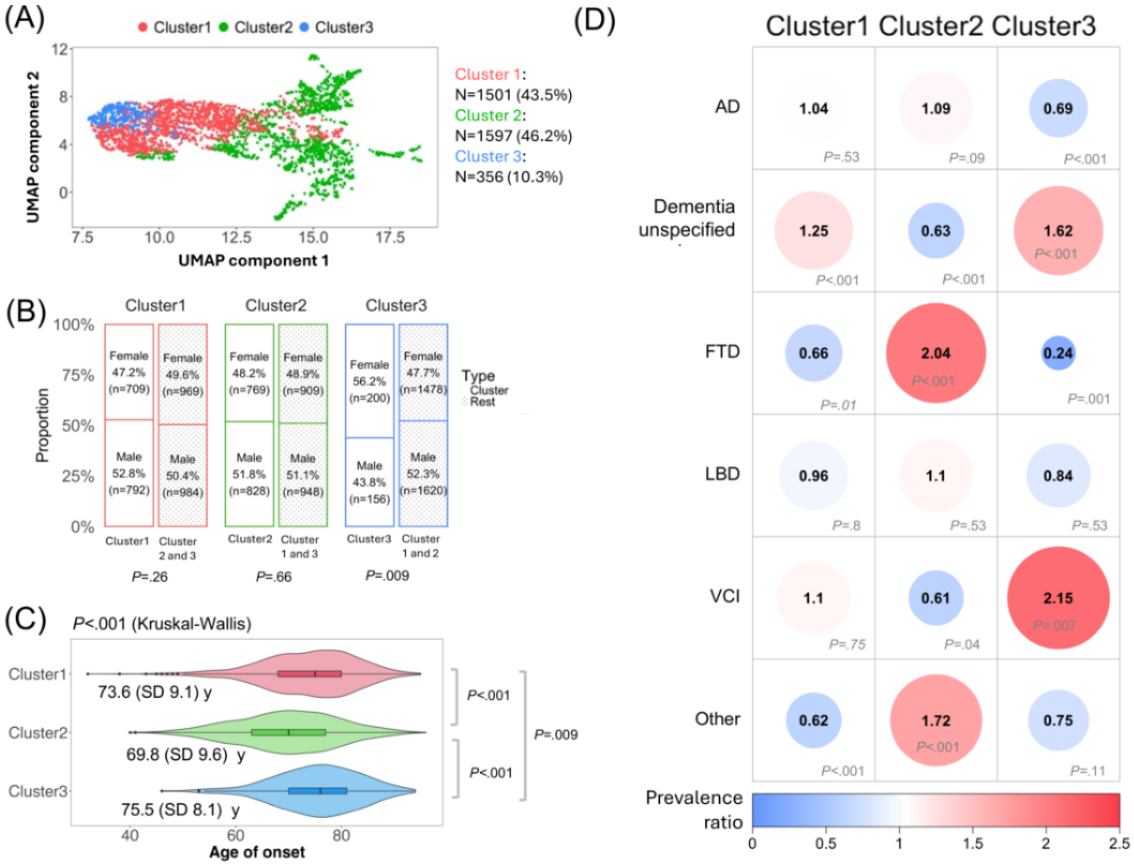

We examined differences in non-ADRD *ICD* code frequency across patient *ICD* embedding clusters (Figure 3A). In cluster 1, diagnoses, such as seborrheic keratoses (χ^2_1=243.15; P_{FDR}<.001; PR=3.32), actinic keratosis (χ^2_1=236.53; P_{FDR}<.001; PR=3.91), pure hypercholesterolemia (χ^2_1=199.13; P_{FDR}<.001; PR=2.71), history of basal cell cancer (χ^2_1=196.22; P_{FDR}<.001; PR=4.45), and nevus (χ^2_1=184.53; P_{FDR}<.001; PR=4.23), show notably high PRs. These diagnoses largely fall into skin-related disorders (such as various types of skin cancer and keratoses). Cluster 2 appears to be unique, with top PRs noted only for clinical signs, such as disinhibition behavior (χ^2_1=1.14; P_{FDR}=.99; PR=4.65), alexia (χ^2_1=0.426; P_{FDR}=.99; PR=3.49), and orofacial dyskinesia (χ^2_1=0.017; P_{FDR}=.99; PR=2.33), suggesting behavioral and psychiatric manifestations which are consistent with the FTD enrichment and earlier onset noted above. Notably, although these diagnoses did not reach significance in cluster 2, they were absent in the other clusters. Moreover, many diagnoses in cluster 2 were marked with a lack of PR, indicating a lower relevance of these diagnoses compared to clusters 1 or 3. Cluster 3 exhibited significant increases in diagnoses from a variety of categories, including respiratory issues (eg, cough: χ^2_1=339.47; P_{FDR}<.001; PR=3.77 and shortness of breath: χ^2_1=306.60; P_{FDR}<.001; PR=6.03), chronic pain (χ^2_1=460.55; P_{FDR}<.001; PR=4.80), musculoskeletal problems (eg, bilateral low back pain without sciatica: χ^2_1=456.91; P_{FDR}<.001; PR=4.80 and foot pain: χ^2_1=372.91; P_{FDR}<.001; PR=3.86), and complications of diabetes mellitus. Notably, diabetes mellitus (type 2 with autonomic neuropathy: χ^2_1=322.98; P_{FDR}<.001; PR=11.60 and insulin-dependent diabetes: χ^2_1=308.96; P_{FDR}<.001; PR=11.30) had exceptionally high PRs, suggesting a very strong association with these severe diabetes conditions in cluster 3.

Table 2. Summary statistics of International Classification of Diseases clusters.

Characteristics	Total (N=3454)	Cluster 1 (n=1501)	Cluster 2 (n=1597)	Cluster 3 (n=356)
Age of onset[a] (y), mean (SD)	72.1 (9.5)	73.6 (9.1)	69.8 (9.6)	75.5 (8.1)

Hispanic or Latino	106 (3.07)	45 (3)	42 (2.63)	19 (5.3)
Unavailable	328 (9.5)	98 (6.53)	229 (14.34)	1 (0.3)
ADRD Dx[b], n (%)				
AD[c]	1317 (38.13)	584 (38.91)	636 (39.82)	97 (27.2)
Dementia unspecified	1101 (31.88)	540 (35.98)	388 (24.3)	173 (48.6)
FTD[d]	190 (5.5)	64 (4.26)	121 (7.58)	5 (1.4)
LBD[e]	261 (7.56)	111 (7.4)	127 (7.95)	23 (6.5)
VCI[f]	96 (2.78)	44 (2.93)	33 (2.07)	19 (5.3)
Other[g]	489 (14.16)	158 (10.53)	292 (18.28)	39 (11)

[a]Age of onset was manually annotated by experts viewing clinical notes; for notes without age of onset, we approximated with the age of first encounter.

[b]Dx: diagnosis.

[c]AD: Alzheimer disease.

[d]FTD: frontotemporal dementia.

[e]LBD: Lewy body dementia.

[f]VCI: vascular cognitive impairment.

[g]Includes posterior cortical atrophy, progressive supranuclear palsy, corticobasal degeneration, and primary progressive aphasia.

Furthermore, statistical analyses revealed significant associations between ICD cluster membership, demographic variables, and diagnostic categories. Cluster 3 had an overrepresentation of female participants relative to clusters 1 and 2 (χ^2_1=8.8; P_{FDR}=.009; PR=1.178); however, clusters 1 and 2 showed no significant differences in sex distribution (cluster 1: χ^2_1=1.8; P_{FDR}=.26 and cluster 2: χ^2_1=0.2; P_{FDR}=.66; Figure 4B). In addition, the age of onset varied significantly among the ICD clusters (Kruskal-Wallis χ^2_2=182.6; P_{FDR}<.001, η^2=0.052). Cluster 2, with a mean age of onset of 69.8 (SD 9.6) years, had a significantly earlier age of onset compared with clusters 1 (Z=10.13; P_{FDR}<.001) and 3 (Z=−8.83; P_{FDR}<.001). Moreover, cluster 1 (mean 73.6, SD 9.1 years) had an earlier onset than cluster 3 (mean 75.5, SD 8.1 years; Z=−2.61; P_{FDR}=.009; Figure 4C). Cluster 1 was significantly enriched by dementia unspecified (χ^2_1=20.2; $_{FDR}$<.001; PR=1.252); cluster 2 was significantly enriched by FTD (χ^2_1=23.9; $_{FDR}$<.001; PR=2.039) and other rare ADRDs (χ^2_1=41; $_{FDR}$ <.001; PR=1.724); and cluster 3 was significantly enriched by VCI (χ^2_1=8.6; $_{FDR}$=.007; PR=2.147) and dementia unspecified (χ^2_1=50.2; $_{FDR}$<.001; PR=1.622). In contrast, no cluster was significantly enriched by AD, though AD was significantly underrepresented in cluster 3 (cluster 1: χ^2_1=0.6; $_{FDR}$=.53; cluster 2: χ^2_1=3.5; $_{FDR}$=.09; and cluster 3: χ^2_1=19.4; $_{FDR}$<.001; Figure 4D) or LBD (cluster 1: χ^2_1=0.1; $_{FDR}$=.80; cluster 2: χ^2_1=0.5; $_{FDR}$=.53; and cluster 3: χ^2_1=0.5; $_{FDR}$=.53; Figure 4D). Additional visualizations of

the UMAP projections colored by sex, age of onset, and ADRD diagnoses are available in Figures S3A, S3B, and S3C, respectively, in Multimedia Appendix 2.

Note Clustering

Initially, a provider effect was detected in the UMAP projection of note embeddings from the latest clinical notes of 3454 patients (Figure S4A in Multimedia Appendix 2). To address this, we used an optimal transport method, aligning the embeddings from all providers to the 2D embedding of a selected reference provider (Figure S4B in Multimedia Appendix 2). Following this alignment, hierarchical agglomerative clustering was applied to the adjusted note embeddings, revealing 3 distinct clusters, as determined by the silhouette score. The adjusted UMAP projection, color coded by cluster, is presented in Figure 5A. The patient distribution within these clusters was as follows: cluster 1 included 1280 (37.06%) patients, cluster 2 included 1161 (33.61%) patients, and cluster 3 included 1013 (29.33%) patients. Detailed summary statistics for each cluster are outlined in Table 3.

Figure 5. Clustering of note embeddings and their demographic and Alzheimer disease and related dementias (ADRD) diagnosis associations. (A) Uniform Manifold Approximation and Projection (UMAP) visualization of note embeddings characterized by 3 clusters: cluster 1 includes 1280 (37.1%) patients, cluster 2 includes 1161 (33.6%) patients, and cluster 3 includes 1013 (29.3%) patients. (B) Bar plot showing prevalence for sex by cluster, with significance based on chi-square tests. Notably, cluster 1 and cluster 3 were both enriched by female participants (P<.001) while cluster 2 was enriched by male participants (P<.001). (C) Violin plot illustrating the distribution of age of onset across clusters. Each violin plot shows the kernel density estimate of the data, with the center line representing the median age of onset. Box plot elements are overlaid, where the box limits indicate the upper and lower quartiles, and the whiskers extend to 1.5 times the IQR. Individual points are hidden for clarity. Significant differences are observed, with cluster 2 showing the latest average age of onset at 72.8 (SD 9.2) years, and cluster 1 the earliest at 71.5 (SD 9.3) years (P<.001). (D) Heatmap showing prevalence ratio for ADRD diagnoses across clusters, with significance derived from a chi-square test. Diagnoses include Alzheimer disease (AD); dementia unspecified; frontotemporal dementia (FTD); Lewy body dementia (LBD); vascular cognitive impairment (VCI); and others such as posterior cortical atrophy (PCA), progressive supranuclear palsy (PSP), corticobasal degeneration (CBD), and primary progressive aphasia (PPA). No significant distribution variations are observed across clusters (P>.05). The circle size, color, and number indicate the magnitude of the prevalence ratio. Blue indicates underrepresentation while red indicates overrepresentation. *P* values were corrected with false discovery rate (FDR) adjustments.

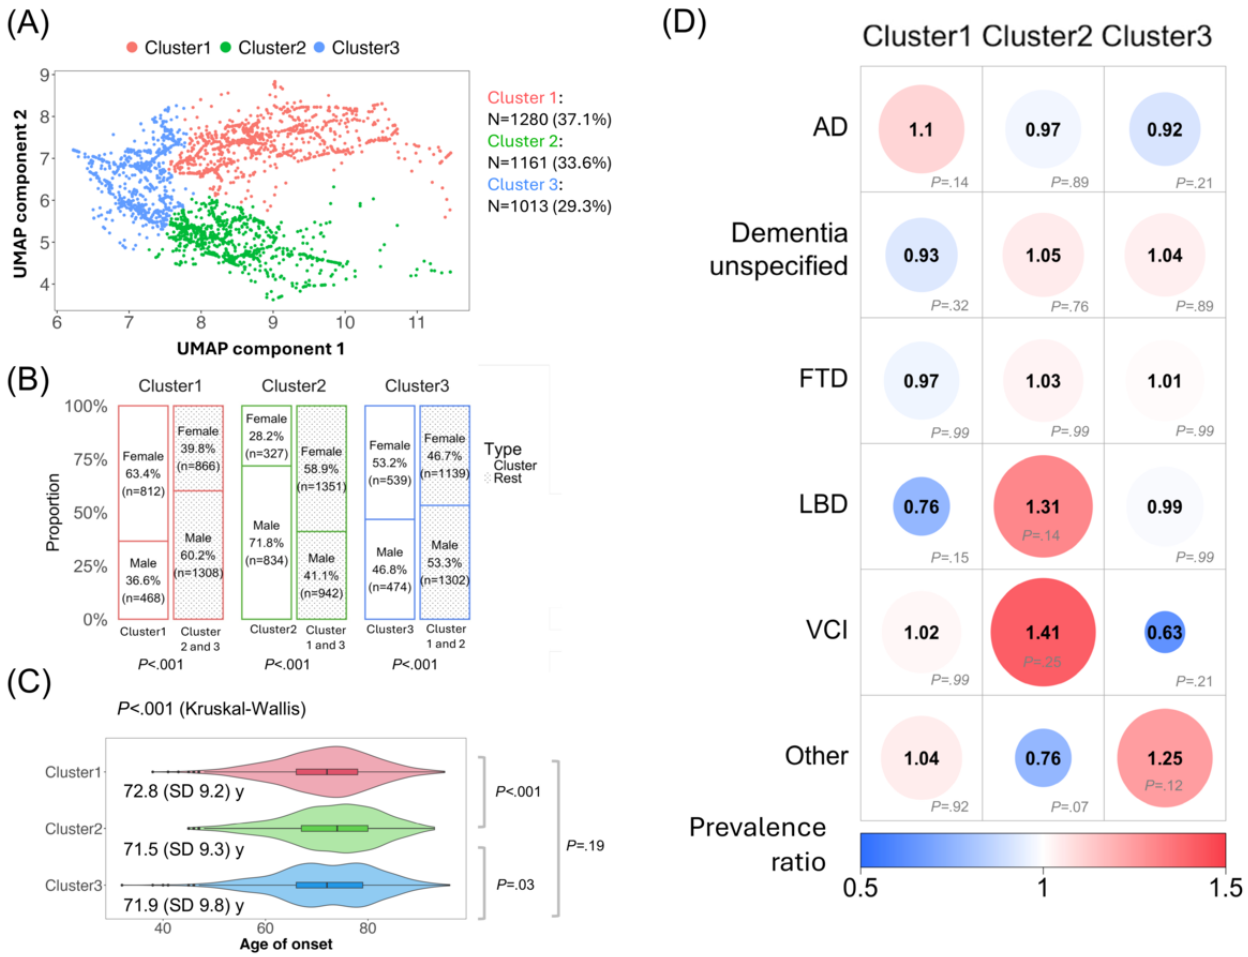

Table 3. Summary statistics of note clusters.

Characteristics	Total (N=3454)	Cluster 1 (n=1280)	Cluster 2 (n=1161)	Cluster 3 (n=1013)

Other[g]	489 (14.16)	186 (14.53)	136 (11.71)	167 (16.49)

[a]Age of onset was manually annotated by experts viewing clinical notes; for notes without age of onset, we approximated with the age of first encounter.

[b]Dx: diagnosis.

[c]AD: Alzheimer disease.

[d]FTD: frontotemporal dementia.

[e]LBD: Lewy body dementia.

[f]VCI: vascular cognitive impairment.

[g]Includes posterior.

We extracted common topics from each note cluster using topic modeling and examined the distribution of ADRD diagnoses across these clusters. In cluster 1, we found more terms related to psychiatric manifestations (eg, compulsive, indifference, and anxiety) and medications (eg, clozaril, trazodone, and sertraline), with a slight but nonsignificant enrichment in AD diagnosis (χ^2_1=4.9; P_{FDR}=.14; PR=1.10). Cluster 2 had more terms related to cardiovascular issues (eg, pacemaker, hypotension, and arrhythmia) and motor and sensory issues (eg, slurring, cochlear, and tremors), with a slight but nonsignificant enrichment in LBD (χ^2_1=4.6; P_{FDR}=.14; PR=1.31) and VCI (χ^2_1=2.5; P_{FDR}=.25; PR=1.41) diagnoses. Cluster 3 encompassed a wide variety of symptoms and conditions common in geriatric populations, including autoimmune (eg, scleroderma and vasculitis), behavioral changes and movement (eg, usual jocular behavior and imbalance, dysphagia), sleep (eg, insomnia), and sensory (eg, diplopia) problems, with a slight but not-significant enrichment in rare ADRD diagnoses (χ^2_1=3; P_{FDR}=.12; PR=1.25). Figure 3B depicts the list of representative words from each cluster and their PR, and Figure S5D in Multimedia Appendix 2 illustrates sentence examples from each cluster.

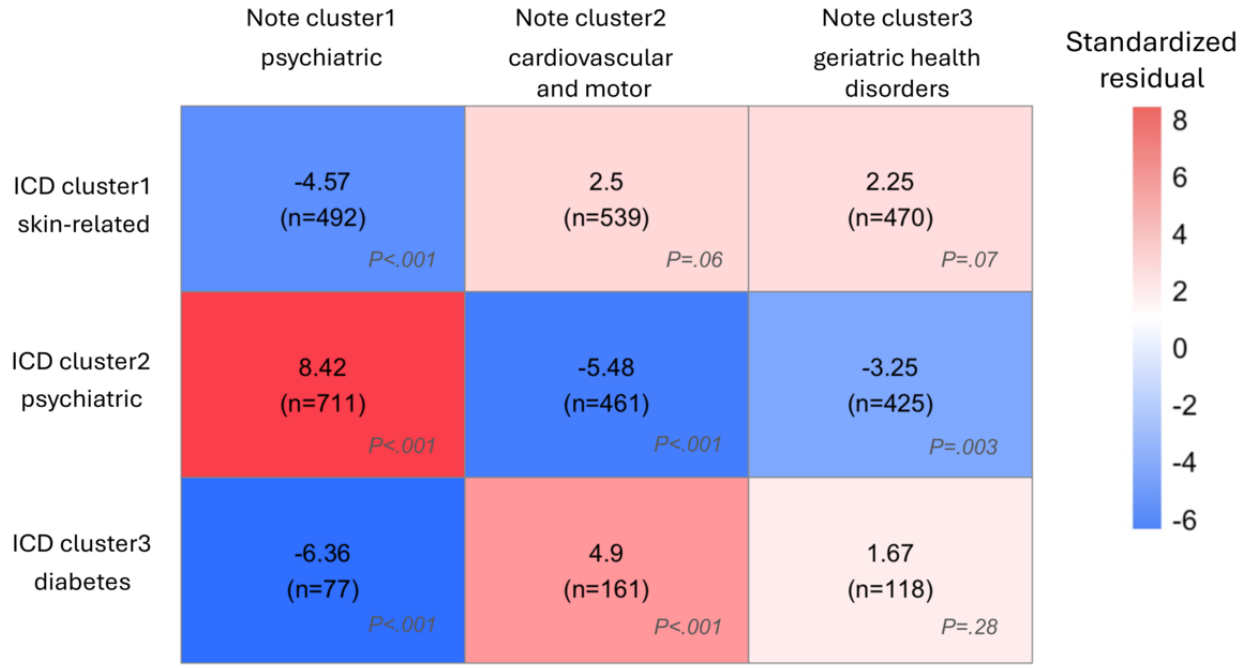
Furthermore, statistical analyses revealed significant associations of note cluster membership, with demographic variables, but not with ADRD diagnoses. First, both cluster 1 and 3 were significantly enriched by female participants (cluster 1: χ^2_1=178.7; P_{FDR}<.001; PR=1.593 and cluster 3: χ^2_1=12; P_{FDR}<.001; PR=1.14) while cluster 2 was enriched by male participants (χ^2_1=290.5; P_{FDR}<.001; PR=1.749; Figure 5B). In

addition, age of onset varied significantly among the note clusters (Kruskal-Wallis χ^2_2=14.9; P<.001; η^2=0.004), with cluster 2 (mean 72.8, SD 9.2 years) having a significantly later age of onset compared to cluster 1 (Z=−3.82; P_{FDR}<.001) and cluster 3 (Z=2.31; P_{FDR}=.03), while cluster 1 (mean 71.5, SD 9.3 years) and cluster 3 (mean 71.9, SD 9.8 years) did not differ (Z=−1.33; P_{FDR}=.19; Figure 5C). However, no association was observed between note cluster membership and ADRD diagnoses (Cluster 1-AD: χ^2_1=4.9; P_{FDR}=.14; Cluster 1-dementia unspecified: χ^2_1=1.9; P_{FDR}=.32; Cluster 1-FTD: χ^2_1=0.02; P_{FDR}=.99; Cluster 1-LBD: χ^2_1=4.1; P_{FDR}=.15; Cluster 1-other: χ^2_1=0.19; P_{FDR}=.92; Cluster 1-VCI: χ^2_1<0.001, P_{FDR}=.99; Cluster 2-AD: χ^2_1=0.3; P_{FDR}=.89; Cluster 2-dementia unspecified: χ^2_1=0.6; P_{FDR}=.76; Cluster 2-FTD: χ^2_1=0.01; P_{FDR}=.99; Cluster 2-LBD: χ^2_1=4.6; P_{FDR}=.14; Cluster 2-other: χ^2_1=8.3; P_{FDR}=.07; Cluster 2-VCI: χ^2_1=2.5; P_{FDR}=.25; Cluster 3-AD: χ^2_1=3.1; P_{FDR}=.21; Cluster 3-dementia unspecified: χ^2_1=0.4; P_{FDR}=.89; Cluster 3-FTD: χ^2_1<0.001; P_{FDR}=.99; Cluster 3-LBD: χ^2_1<0.001; P_{FDR}=.99; Cluster 3-other: χ^2_1=6.1; P_{FDR}=.12; Cluster 3-VCI: χ^2_1=3; P_{FDR}=.21; Figure 5D). Additional visualizations of the UMAP projections colored by sex, age of onset, and ADRD diagnoses are provided in Figures S5A, S5B, and S5C, respectively, in Multimedia Appendix 2.

Comparison Between ICD Clusters and Note Clusters

Statistical analysis demonstrated significant associations between *ICD* and note clusters (χ^2_4=89.43; P<.001; Cramér V=0.114). Specifically, note cluster 1, characterized by more female participants (PR=1.593) and terms related to psychiatric manifestations and medications, significantly overlapped (standardized residual=8.42; P_{FDR}<.001) with *ICD* cluster 2, which is noted for the earliest onset of disease (mean 69.8, SD 9.6 years) and a higher prevalence of psychiatric disorders and higher proportion of patients with FTD (PR=2.039). In addition, note cluster 2, which had higher proportion of male participants (PR=1.749) and terms related to cardiovascular and motor issues, overlapped significantly (standardized residual=4.90; P_{FDR}<.001) with *ICD* cluster 3, which is marked by the oldest onset of disease (mean 75.5, SD 8.1 years), a higher occurrence of VCI (PR=2.147), and dementia unspecified (PR=1.622) and had high prevalence of diabetes. These findings suggest a meaningful pattern of cluster correspondence across modalities (Figure 6).

Figure 6. Heatmap of the association of International Classification of Diseases (ICD) clusters with note clusters. Heatmap of the association of ICD clusters with note clusters. ICD clusters were significantly associated with note clusters (P<.001). Post hoc analyses revealed that note cluster 1 was positively associated with ICD cluster 2 (standardized residual=8.42, P<.001) and negatively associated with ICD clusters 1 and 3 (cluster 1: standardized residual=−4.57, P<.001; cluster 3: standardized residual=−6.36, P<.001). Furthermore, note cluster 2 was positively associated with ICD cluster 3 (standardized residual=4.9, P<.001) and negatively associated with ICD cluster 2 (standardized residual=−5.48, P<.001). Finally, note cluster 3 was negatively associated with ICD cluster 2 (standardized residual=−3.25, P=.003). Each cell displays standardized residuals (standardized differences between the observed count and the expected count) along with the count of overlapping patients (n). Color bar represents the value of the standardized residual. P values were corrected with false discovery rate adjustments.



Discussion

Principal Findings

This study aimed to characterize the clinical heterogeneity across ADRD by applying representation learning techniques on patient EHRs in a tertiary care clinic. We used pretrained *ICD* code embeddings, a transformer architecture for encoding clinical notes, and unsupervised learning to identify distinct ADRD subtypes. This work represents the first example of clustering patients with ADRD using embeddings derived directly from an LLM, without prior rule-based extraction of relevant medical concepts from the clinical note. The *ICD* codes allowed us to investigate subtypes of patients with similar *ICD* codes (non-ADRD diagnosis in charts), while the clinical notes allowed us to capture clinical history and presentation recorded by memory specialists. Our results demonstrate distinct patterns of disease manifestation with significant overlap between the *ICD* and note clusters. The overlap of clusters between the 2 approaches suggests that the subtypes may reflect common underlying clinical heterogeneity, as distinct subtypes can be identified through different data modalities.

Our choice of hierarchical agglomerative clustering was guided by the hierarchical nature of our data, empirical evidence from prior dementia subtyping studies, and theoretical limitations of alternative algorithms. Alternative methods, such as K-means, Gaussian mixture models [40], and density-based spatial clustering of applications with noise (DBSCAN) [41], face theoretical limitations: K-means assumes spherical clusters that is difficult to satisfy in high-dimensional embeddings; DBSCAN relies on density thresholds that break down in such spaces; and Gaussian mixture models can be unstable with overlapping subtypes. In contrast, hierarchical clustering preserves these nested relationships, resulting in more homogeneous [42] and reproducible [43] clusters.

In our study, we identified 3 clusters from *ICD* embeddings, each characterized by distinct health conditions. Cluster 1 predominantly featured issues related to skin health, with a commonality of dementia unspecified diagnoses and an average age of onset in the early 70s. The association between skin health and dementia in this cluster may be attributed to age, as both conditions become more prevalent with advancing age. This aligns with findings from previous studies, which reported an increase in the prevalence of actinic keratosis [44] and seborrheic keratosis [45], as well as AD [46], with age. Cluster 2 is marked by early-onset, psychiatric and behavioral manifestations; enrichment in FTD and other less common forms of ADRD; and the earliest age of onset among our clusters, typically in the late 60s. This cluster extends the characterization found in previous studies that described a behavioral symptom subtype in patients [20,21] by demonstrating similar characteristics in a broader population of patients with ADRD. Cluster 3 encompasses a broad array of conditions like respiratory issues and severe diabetes, affecting older patients, more female participants than male participants, with a higher incidence of VCI and dementia unspecified, and an age of onset in the mid-70s. Reflecting the AD subtype identified by previous researchers, this group was characterized as being overall older and having more comorbidities [20]. Landi et al [23] further differentiated patients with AD by onset timing, which we also observed but across a more diverse set of ADRD diagnoses. Notably, our *ICD*-based clustering did not reveal clearly separated clusters in the 2D UMAP projections. While UMAP aims to preserve both local and global relationships when reducing high-dimensional data to a lower-dimensional space, some distortions may inevitably occur during dimensionality reduction. Alternatively, the overlapping clusters could reflect the complexity of comorbid conditions in ADRD, which may not form clearly distinguishable subgroups.

In addition, our analysis of clinical notes revealed 3 distinct subtypes. Cluster 1 featured terms related to psychiatric manifestations and medications, aligning with findings from previous studies [20,21]. Cluster 2 included terms related to cardiovascular and various motor and sensory issues, supported by previous studies that identified subtypes of CVD [20,21] and aligning with the predominant diagnoses of VCI and LBD within this cluster. Cluster 3 covered a wide array of health conditions, consistent with the higher occurrence of rare ADRD diagnoses, which tend to involve more heterogeneous health conditions. Notably, we observed significant overlap between *ICD* and note clusters, identifying 2 ADRD subtypes of interest that were concordant across the 2 data modalities: the first subtype, “psychiatric manifestations,” and the second subtype, “diabetes with cardiovascular or motor issues.” Thus, our analysis delineated 2 distinct ADRD subtypes with specific diagnostic and symptomatic profiles.

Our study identified sex differences across all clinical note clusters with substantial effects observed in note clusters 1 and 2. For example, note cluster 1 was significantly overrepresented in female participants and had a higher prevalence of AD (PR=1.1). It also overlapped significantly (P<.001) with *ICD* cluster 2, which was enriched for psychiatric and behavioral symptoms (eg, apathy). This aligns with Tang et al [25], who reported stronger psychiatric associations in female patients with AD, including greater links to depression. This pattern may be partially attributed to women’s greater likelihood of seeking mental health care [47,48]. In contrast, note cluster 2 was overrepresented in male participants, with higher prevalence of VCI (PR=1.41) and LBD (PR=1.31), consistent with Tang et al [25], who found vascular dementia was more common in male participants. The higher prevalence of VCI in male participants may be related to a greater burden of hypertension, particularly in early life [49]. In addition, the increased representation of male participants with LBD may reflect potential underdiagnosis in female participants [50,51]. Given the clinical impact of sex disparities in ADRD—particularly in AD and LBD [52]—future studies integrating longitudinal data and clinicopathological evidence will be crucial to disentangling biological influences from health care–seeking behaviors.

Another interesting observation relates to variations in age of onset, a key indicator of disease severity, across the identified subtypes in both clinical notes and *ICD*-based clusters, with notable differences in the *ICD*-derived subtypes. For instance, the early-onset *ICD* cluster 2 was enriched with psychiatric disorders and included diseases known with early-onset,

including FTD [53] and other rare ADRD categories, such as PCA [54]. In contrast, the late-onset *ICD* cluster 3, exhibited a higher prevalence of diverse health conditions, including respiratory issues (eg, cough and shortness of breath), chronic pain, musculoskeletal conditions, such as bilateral low back pain and foot pain, as well as diabetes mellitus. While chronic pain is not typically associated with ADRD, pain could indicate the general aging process [55], and relate to osteoporosis and osteoarthritis, which likely contribute to chronic pain in older adults. Other symptoms, such as foot pain and shortness of breath, may reflect comorbidities of diabetes.

Limitations

Our study has a few limitations. First, there are the challenges associated with using real-world EHR data. Differences in how health care providers document information, stemming from variations in training, personal documentation habits, and clinical judgment, may have contributed to inconsistencies. Furthermore, health care use patterns, such as visit regularity, may influence our clustering results. For example, variations in visit frequency could lead to overrepresentation of certain symptom clusters or skewed associations. Future studies adjusting for health care use patterns may help address this limitation. Second, the inclusion of long-term patient histories in clinical notes—where recent notes may capture both current and past symptoms—could introduce extraneous information, making it difficult to isolate content relevant to the latest diagnosis. This mixture of historical and recent data may have diluted the association between documented ADRD diagnoses and their actual clinical significance, leading to observed trends rather than clear associations. Furthermore, the repetition of relevant language across multiple encounters may have influenced the clustering process, potentially reflecting the frequency of patient visits to the memory clinic, rather than clinical characteristics. Third, our study is constrained by the absence of an independent validation cohort to confirm the identified clusters. While the relative overlap in clusters identified through *ICD* codes and note contents, along with the alignment with findings from previous research, offers some validation, the results could be strengthened by applying the same encoding and clustering techniques to an external validation cohort. To ensure external validity, these results need to be validated at other health care institutions. Fourth, another limitation of this study is that our subtyping characterization only focused on ADRD diagnoses based on etiology, but did not address the stage of disease, which clearly affects the neuropsychological profile. This calls for a focus on the heterogeneity of disease stage in future research. Moreover, there may be sex differences in who receives health care at different stages and ages, adding another layer of complexity to our findings. Finally, our study is limited by the lack of racial diversity in the cohort, with 88.6% of participants being White. Given known racial differences in AD incidence, comorbidities, and health care access [56-59]—and particularly the heightened impact of hypertension on AD risk in some minoritized groups [59,60]—our findings may not fully capture the spectrum of ADRD subtypes in these populations. Future studies with broader representation are necessary to improve the generalizability of our subtyping approach.

Future Directions

In future work, the preprocessing of clinical notes could be enhanced by implementing multiple methods, such as medspaCy [61], with a focus on targeting sections most relevant to diagnoses, such as medical history. To further improve the extraction and analysis of pertinent data, the use of emerging LLMs, such as GPT [39], should be explored. In addition, validating an independent dataset and enriching the patient population would help increase the robustness and reliability of the identified ADRD subtypes. To advance this work, we will use a dual-modality approach that leverages both structured and unstructured data sources, such as medications and imaging. A deep autoencoder that uses multiple modalities simultaneously could offer methodological improvements over our current practice of conducting parallel clustering analyses and relying on heuristic averaging of embeddings. Furthermore, explicitly using the temporal or graph properties of EHRs could yield more informative representations, enhancing unsupervised clustering capabilities, as has been shown in prior approaches in a supervised learning setting [62,63]. Ultimately, our goal is to develop machine learning models capable of predicting these ADRD subtypes from real-word health care systems. Such models may aid in more precise diagnostics, prognostics, and the formulation of targeted treatment strategies.

Acknowledgments

This study was funded by National Institute of Aging P30AG062421 (SD and BTH). The funder played no role in study design, data collection, analysis and interpretation of data, or the writing of this manuscript. The authors acknowledge Yoonchul Shin and Qinglin Gou for annotating the age of onset from clinical notes.

Data Availability

The data used for this study are available from the Mass General Brigham Healthcare System, but restrictions apply to the availability of these data, which were used under permission for this study, and so are not publicly available. Code will be available on GitHub upon publication.

Abstract

Background: Disturbed sleep patterns are common among older adults and may contribute to cognitive and physical declines. However, evidence for the relationship between sleep duration and cognitive frailty, a concept combining physical frailty and cognitive impairment in older adults, is lacking.

Objective: This study aimed to examine the associations of sleep duration and its changes with cognitive frailty.

Methods: We analyzed data from the 2008 - 2018 waves of the Chinese Longitudinal Healthy Longevity Survey. Cognitive frailty was rendered based on the modified Fried frailty phenotype and Mini-Mental State Examination. Sleep duration was categorized as short (<6 h), moderate (6 - 9 h), and long (>9 h). We examined the association of sleep duration with cognitive frailty status at baseline using logistic regressions and with the future incidence of cognitive frailty using Cox proportional hazards models. Restricted cubic splines were used to explore potential nonlinear associations.

Results: Among 11,303 participants, 1298 (11.5%) had cognitive frailty at baseline. Compared to participants who had moderate sleep duration, the odds of having cognitive frailty were higher in those with long sleep duration (odds ratio 1.71, 95% CI 1.48 - 1.97; *P*<.001). A J-shaped association between sleep duration and cognitive frailty was also observed (*P*<.001). Additionally, during a mean follow-up of 6.7 (SD 2.6) years among 5201 participants who were not cognitively frail at baseline, 521 (10%) participants developed cognitive frailty. A higher risk of cognitive frailty was observed in participants with long sleep duration (hazard ratio 1.32, 95% CI 1.07 - 1.62; *P*=.008).

Conclusions: Long sleep duration was associated with cognitive frailly in older Chinese adults. These findings provide insights into the relationship between sleep duration and cognitive frailty, with potential implications for public health policies and clinical practice.

KEYWORDS

aging; frailty; cognition; cohort study; sleep duration; sleep quality; longitudinal study

Introduction

Physical frailty and cognitive impairment are prevalent among older adults and have individually been associated with adverse health outcomes [1,2]. They often coincide with aging and can be bidirectionally linked to each other [3,4], prompting the introduction of the concept of cognitive frailty—the coexistence of both physical frailty and cognitive impairment [5]. The necessity is further justified by the findings that cognitive frailty poses an even greater risk of adverse outcomes compared to the isolated effects of the 2 conditions [6,7]. Identifying factors associated with or contributing to cognitive frailty is important and will provide a better understanding of the underlying mechanisms.

Disturbed sleep patterns, such as an increased number of awakenings, abnormal nighttime sleep duration, and poorer sleep quality, are common among older adults [8]. Numerous epidemiological studies identified sleep disturbances as risk factors for physical frailty and cognitive impairment, such as shorter or longer sleep duration, insomnia, and sleep apnea [9,10]. In addition, recent studies have linked long sleep duration to cognitive frailty, but they are from cross-sectional analyses

[11,12]. A longitudinal study in Mexican older adults reported associations between increasing sleep duration trajectory with greater odds for mild cognitive impairment and frailty separately [13]. Whether sleep patterns are associated with the development of cognitive frailty as a unified concept remains to be elucidated.

To address this knowledge gap, this study aimed to assess the associations of sleep duration with cognitive frailty in a nationally representative, large cohort of older Chinese adults. By focusing on an older Chinese adult population, our findings may offer insights into the relationship between sleep duration and cognitive frailty within this demographic, with potential implications for public health policies and clinical practice.

Methods

Study Design and Participants

We used data from the Chinese Longitudinal Healthy Longevity Survey (CLHLS). As detailed previously, CLHLS is an ongoing, nationwide representative longitudinal cohort study of Chinese adults aged 65 years and older from 23 out of 31 provinces or municipalities or autonomous regions in mainland China [14,15]. The CLHLS started in 1998 with surveys on sociodemographic characteristics, lifestyle, cognitive function, psychological status, and physical function conducted every 2 - 3 years.

In this study, we used data from 4 waves (2008, 2011, 2014, and 2018) of the CLHLS. To maximize statistical power and leverage the large sample size, we first examined cross-sectional associations between sleep duration and sleep quality, with cognitive frailty at baseline (ie, the 2008 wave). For this set of analyses, we included 11,303 participants who had cognition and physical frailty assessments at baseline. We then examined whether baseline sleep duration and sleep quality, as well as change in sleep duration, were associated with the future development of cognitive frailty. For these longitudinal analyses, we excluded 1298 participants who had cognitive frailty at baseline, 4780 participants who had no follow-up cognitive frailty assessment, and 24 participants who had missing value in sleep duration in the 2011 wave. As a result, 5201 participants entered the subsequent longitudinal analysis.

Assessment of Cognitive Frailty

Cognitive frailty was identified as the simultaneous presence of both physical frailty and cognitive impairment [5].

Physical frailty was assessed by a modified Fried frailty phenotype, based on 5 components: shrinking, weakness, low mobility, exhaustion, and inactivity [16,17]. Shrinking was defined as having a BMI of 18.5 kg/m^2 or less. Weakness was determined if participants self-reported that they were unable to lift a bag weighing 5 kg or above. Low mobility was identified if participants self-reported that they were unable to walk 1 km or longer in a row. Exhaustion was identified if participants answered “always,” “often,” or “sometimes” to the question “Do you feel the older you get, the more useless you are?” Inactivity was defined as participants doing the following activities 1 time per week or less: housework, outside activity, garden work, raising domestic animals or pets, playing cards or mah-jongg, and social activity (organized). Participants were considered physically frail when meeting ≥3 of the 5 criteria.

Cognitive impairment was assessed by a validated Chinese version of the Mini-Mental State Examination (C-MMSE) [15,18]. The C-MMSE includes 24 items regarding orientation, memory, attention, calculation, and language, ranging from 0 to 30. Based on a prior study, participants were considered cognitive impairment if the C-MMSE score was ≤22 [15].

Assessment of Sleep Variables

Sleep duration was estimated based on the answers to the question “How many hours do you sleep normally?” Based on their answers, participants were further categorized into short (<6 h), moderate (6 - 9 h), and long (>9 h) sleep durations. This categorization aligned with previous research indicating that both short and long sleep durations are associated with poorer health outcomes [19]. The rate of change in sleep duration was calculated by taking the difference between sleep durations reported in the 2008 and 2011 waves (ie, sleep duration in the 2011 wave minus sleep duration in the 2008 wave) and dividing it by the individual follow-up interval in years. Sleep quality was assessed based on answers to the question “How about the quality of your sleep?” A score of “poor” was assigned if the answer was “so-so,” “bad,” or “very bad,” and a score of “good” was assigned otherwise.

Covariates

We considered the following covariates that have been identified to be associated with physical or cognitive outcomes in previous studies [20,21]: age, sex, education, marital status, residence, economic status, loneliness, smoking status, drinking status, and multimorbidity. Education was categorized as “Not Educated” if the participant had not attended any schools and “With Formal Education” if the participant had attended schools more than 1 year. Marital status was defined as currently married and living with a spouse, and others (eg, separated, divorced, widowed, and never married). Residence was categorized into living in urban (eg, city or town) or rural areas. Economic status was categorized into economic dependence or independence based on their income source. Loneliness was identified if participants answered “always,” “often,” or “sometimes” to the question “Do you feel lonely and isolated?” Smoking status was categorized as “Never smoked,” and “Former or current smoker.” Drinking status was categorized into “Never drank,” and “Former or current drinker.” Multimorbidity was defined from self-reports and categorized as “Yes” if having 2 or more of the following chronic diseases: hypertension, diabetes, heart disease, stroke or cerebrovascular disease, respiratory disease, cancer, and Parkinson disease, or “No” if otherwise.

Statistical Analysis

Listwise deletion was applied to both cross-sectional and longitudinal analyses to handle missing data on covariates. The *t* tests for continuous variables and chi-square tests for categorical variables were used to compare the differences in the baseline characteristics.

Multivariate logistic regression models were performed to assess the associations of sleep duration and sleep quality with

cognitive frailty at baseline (ie, the 2008 wave). We performed 3 models: model A was unadjusted; model B was adjusted for age, sex, and education; model C was further adjusted for marital status, residence, economic status, loneliness, smoking status, drinking status, and multimorbidity.

Cox proportional hazard (PH) models were used to test the associations between sleep duration and sleep quality with incident cognitive frailty during the follow up. Death was treated as a right-censored event at the time of occurrence. The follow-up duration was defined as the time interval in years from baseline to the date of the first occurrence of cognitive frailty, death, or the latest available data, whichever occurred first. We rounded the time to the nearest integer year to account for group-tied events. Similarly, we performed 3 models: model A was unadjusted; model B was adjusted for age, sex, and education; model C was further adjusted for marital status, residence, economic status, loneliness, smoking status, drinking status, and multimorbidity. The PH assumption of the Cox models was assessed using Schoenfeld residuals. No major violations of the PH assumption were detected for exposure variables.

Restricted cubic spline (RCS) curves were plotted to explore the nonlinear cross-sectional and longitudinal associations between sleep duration and cognitive frailty. Additionally, several sensitivity analyses were conducted to verify the robustness of our findings. First, we adjusted for each chronic disease individually and for all chronic diseases simultaneously. Second, we performed stratified analyses by sex and age. Furthermore, we performed similar sets of Cox PH models to investigate the associations of changes in sleep duration and incident cognitive frailty.

All statistical analyses were performed in R (version 4.1.2; R Core Team). Statistical significance was considered at a 2-tailed α level of .05.

Ethical Considerations

The CLHLS was approved by the Duke University Institutional Review Board (Pro00062871) and the Peking University Biomedical Ethics Committee (IRB00001052–13074). All participants provided written informed consent. The data used in this study were deidentified to protect participant privacy and confidentiality. No compensation was provided to participants.

Results

Participant Characteristics

The participant flowchart is presented in Figure 1. Of the 11,303 participants included in the cross-sectional analysis, 6037 (53.4%) participants were female. The mean age at baseline was 84.7 (SD 11.0) years old. Approximately 11.5% (n=1298) of all participants had cognitive frailty at baseline. The numbers of participants who reported short, moderate, or long sleep duration were 1327 (11.7%), 7207 (63.8%), and 2769 (24.5%), respectively. Poor sleep quality was found in 3796 (33.6%) participants. Baseline characteristics stratified by cognitive frailty status at baseline are summarized in Table 1. Additionally, baseline characteristics categorized by sleep duration are presented in Multimedia Appendix 1. Baseline characteristics of 5201 participants included in the longitudinal analysis are summarized in Multimedia Appendix 2.

[a]CF: cognitive frailty.

Association Between Sleep Duration and Cognitive Frailty at Baseline

Compared to participants who had moderate sleep duration, the odds of having cognitive frailty were higher in those who had long sleep duration (odds ratio [OR] 1.71, 95% CI 1.48 - 1.97; *P*<.001) in the initial model adjusted for age, sex, and education Table 2. The association remained statistically significant with a similar OR in the augmented model after further adjustments of marital status, residence, economic status, loneliness, smoking status, drinking status, and multimorbidity (OR 1.69, 95% CI 1.46 - 1.95; *P*<.001). There was no statistically significant

difference in the odds of having cognitive frailty between participants with short and modest sleep durations in the initial model adjusted for age, sex, and education. Compared with those who had a good sleep quality, participants who had a poor sleep quality were at a higher risk for cognitive frailty in both initial and the augmented models with further adjustments (initial model: OR 1.63, 95% CI 1.40 - 1.89; *P*<.001; augmented model: OR 1.41, 95% CI 1.21 - 1.64; *P*<.001; Table 2). In addition, RCS analysis revealed a J-shaped association between sleep duration and cognitive frailty at baseline (*P* for nonlinear<.001; Figure 2).

The results of sensitivity analyses are summarized in Multimedia Appendices 3 and 4. The associations between long sleep duration and baseline cognitive frailty remained consistent when adjusting for each chronic disease individually and when accounting for all chronic diseases simultaneously (Multimedia Appendix 3). For individuals younger than 80 years old, the association of long sleep duration with cognitive frailty became not statistically significant, whereas for individuals older than 80 years old, the association persisted. The association remained significant in sex-stratified models (Multimedia Appendix 4).

Association Between Sleep Duration and Incident Cognitive Frailty During Follow-Up

Over a mean of 6.7 (SD 2.6) years of follow up, 521 (10%) participants out of the 5201 participants developed cognitive frailty. In the initial model adjusted for age, sex, and education, as compared with participants who had moderate sleep duration at baseline, a higher risk of cognitive frailty was observed in participants who had long sleep duration at baseline (hazard ratio [HR] 1.32, 95% CI 1.07 - 1.62; *P*=.008; Table 3). The association persisted after further adjusting for marital status, residence, economic status, loneliness, smoking status, drinking status, and multimorbidity (HR 1.30, 95% CI 1.06 - 1.59; *P*=.01). There was no statistically significant difference in the hazard of incident cognitive frailty between participants with short sleep duration and moderate sleep duration in the initial model. Besides, there was no significant difference in the risk of incident cognitive frailty between participants with good and poor sleep quality. Additionally, RCS analysis showed no significant nonlinear association between sleep duration and cognitive frailty during follow up (*P* for nonlinear=.29; Figure 3).

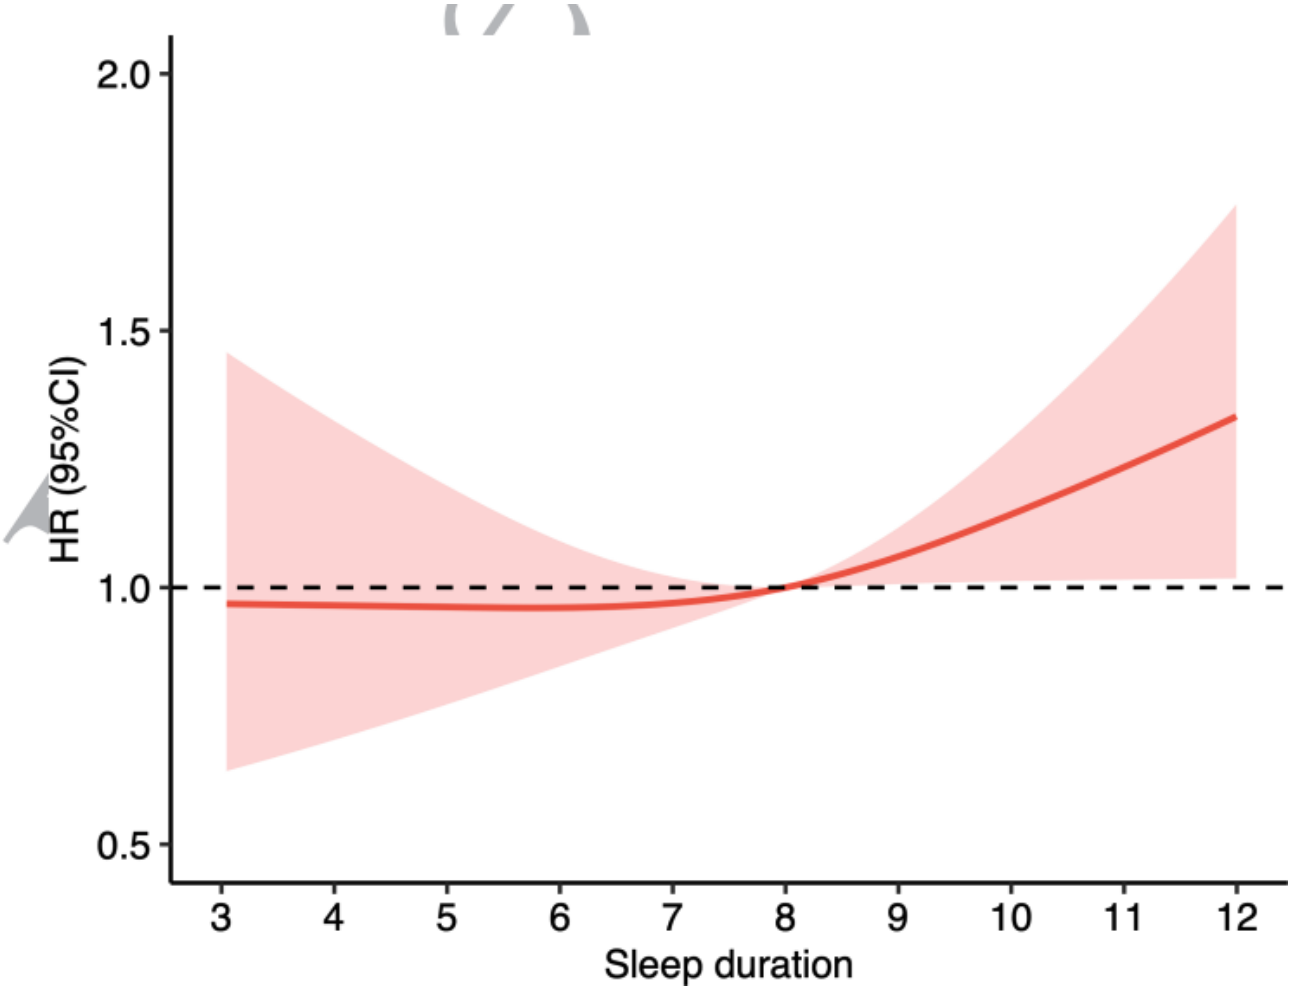
[e]Not applicable.

The results of sensitivity analyses are summarized in Multimedia Appendices 5 and 6. The associations between long sleep duration and baseline cognitive frailty status were consistent when adjusting for each chronic disease individually, or when adjusting for all chronic diseases simultaneously (Multimedia Appendix 5). For individuals younger than 80 years old, the association of long sleep duration with cognitive frailty became not statistically significant, whereas for individuals older than 80 years old, the association persisted. The association was not significant in male participants but remained statistically significant in female participants (Multimedia Appendix 6).

Figure 3. Nonlinear association between sleep duration and cognitive frailty during follow up using restricted cubic spline. The Cox proportional model was used to fit the data, with solid lines representing the estimated HR and shaded areas representing the corresponding 95% CIs. HR: hazard ratio.



Rate of Change in Sleep Duration and Cognitive Frailty

The mean annual rate of change in sleep duration was –0.02 (SD 0.87) hours/year. In the model adjusted for age, sex, education, sleep quality, and sleep duration at baseline, a faster increase in sleep duration per year was associated with a higher risk for cognitive frailty: for 1 hour/year increase in sleep duration, the HR was 1.14 (95% CI 1.03 - 1.27; *P*=.01). The association remained significant after further adjusting for marital status, residence, economic status, loneliness, smoking status, drinking status, and multimorbidity (HR 1.15, 95% CI 1.03 - 1.27; *P*=.01; Multimedia Appendix 7).

Discussion

Principal Findings

In this large community-based prospective study of over 10,000 Chinese older adults, we found that long sleep duration was consistently associated with cognitive frailty status at baseline, as well as an increased risk of cognitive frailty incident during follow up. We also found that a faster annual increase in sleep duration was associated with a higher risk of cognitive frailty during follow up.

The associations of sleep duration with physical frailty or cognitive decline are complex with mixed findings in prior research. A study using data from the National Health and Nutrition Examination Survey demonstrated that prolonged sleep duration (ie, ≥10 h) was associated with physical frailty in older adults, while a prospective study of 309 older Mexican adults showed that participants with either short sleep duration (ie, ≤5 h) or long sleep duration (ie, ≥9 h) had a higher risk of physical frailty [22,23]. Likewise, a Japanese cohort study of 623 older adults reported that long sleepers (>8 h) had a higher risk of cognitive impairment, while a cohort study found that self-reported short sleepers (<7 h) had an increased risk of cognitive decline [24,25]. However, few studies explored the association between sleep duration and cognitive frailty, that is, the coexistence of physical frailty and cognitive impairment. Two recent cross-sectional studies reported an association of long sleep duration with cognitive frailty among community-dwelling older adults and in older adults with heart failure [11,12]. In this study, we confirmed such a cross-sectional association between long sleep duration and cognitive frailty. More intriguingly, we showed consistent evidence from longitudinal analyses that participants with long sleep duration at baseline had an increased risk of developing cognitive frailty in the future. Of note, we did not find a significant association between short sleep duration and cognitive frailty in this study.

We also used the annual rate of change in sleep duration to assess the relationship between sleep duration changes and cognitive frailty. The results showed that a faster annual increase in sleep duration was associated with a higher risk of cognitive frailty, independent of the baseline sleep duration category. Notably, this study accounted for variations in follow-up years by using the annual rate of sleep duration change instead of the absolute change in sleep duration, minimizing classification bias and providing a more accurate representation of the relationship between sleep duration trajectories and cognitive frailty.

The mechanisms underlying the association of sleep duration with incident cognitive frailty remain unclear. However, several potential pathways can be suggested. First, inappropriate sleep duration (either shorter or longer than ideal) has been linked to cardiovascular health [26], which has been reported as a risk factor for both physical frailty and cognitive decline [27,28]. Second, increased sleep duration has also been linked with elevations in C-reactive protein, a marker for systemic inflammation, and interleukin-6, a proinflammatory biomarker [29,30]. Prior studies have shown that even low-level inflammation may pose an increased risk for the development of physical frailty and cognitive impairment [31,32]. Finally, long sleep duration may also be an indicator of or linked to disturbances in circadian control, the internal biological clock that prepares bodily responses to environmental light-dark changes. Circadian disturbances have been previously reported to be associated with both physical frailty and cognitive impairment or decline [33-36].

Several previous studies showed that sleep quality is closely related to impairments in both physical and cognitive domains [37,38]. In addition, 2 recent cross-sectional studies reported that poor sleep quality was associated with cognitive frailty in older Chinese adults living in nursing homes, and among Thai community-dwelling older adults during the COVID-19 restrictions [39,40]. Our observed cross-sectional association between sleep quality and cognitive frailty aligns with these previous findings. However, we did not find evidence of an association between sleep quality and the development of cognitive frailty in this study. It is important to note that the assessment of sleep quality in this study relied on a single question, which may be overly simplistic and may not fully capture the complexity of sleep behaviors. Future studies should use more comprehensive approaches to assess sleep health, considering its multidimensional nature, which includes factors such as duration, timing, efficiency, satisfaction, and alertness [41].

Strengths and Limitations

To the best of our knowledge, this study was the first to assess the association between sleep duration and incident cognitive frailty in a nationally representative sample of older Chinese adults. Strengths of this study include its longitudinal design and a large sample size. This study also has several limitations. First, the sleep duration and sleep quality were from self-reports and may be subjected to recall biases, especially in older adults and individuals with cognitive impairment. Future studies, ideally with an objective sleep monitoring approach (such as combining actigraphy and sleep diary or polysomnography), are warranted. Second, a growing body of studies have linked daytime napping behaviors with physical frailty, cognitive decline, Alzheimer dementia, or cognitive frailty [40,42,43]. Similarly, sleep disorders, such as sleep apnea, have been consistently linked with physical frailty, cognitive impairment, and dementia [10,44]. However, these potential sleep-related influences were not collected in the CLHLS. Future studies may consider incorporating these multidimensional structs when assessing sleep health and its relationships with physical and cognitive outcomes. Finally, the participants in this study were, on average, older than 80 years at baseline. In subgroup analyses, the association between long sleep duration and cognitive frailty was not statistically significant in participants younger than 80 years. This may be due to the limited number of cognitive frailty events in this subgroup, which could have resulted in insufficient statistical power to detect a significant association. Therefore, caution should be taken when translating our findings into younger populations.

Conclusions

In this large cohort study of over 10,000 older Chinese adults, long sleep duration was consistently associated with an increased risk of cognitive frailty, both cross-sectionally and longitudinally. These findings underscore the importance of sleep monitoring in aging populations. Future research using objective sleep assessments and investigating the underlying biological mechanisms is warranted to inform more effective prevention strategies.

Abstract

Background: Frailty is defined as a clinical state of increased vulnerability due to the age-associated decline of an individual's physical function resulting in increased morbidity and mortality when exposed to acute stressors. Early identification and management can reverse individuals with frailty to being robust once more. However, we found no integration of machine learning (ML) tools and frailty screening and surveillance studies in Thailand despite the abundance of evidence of frailty assessment using ML globally and in Asia.

Objective: We propose an approach for early diagnosis of frailty in community-dwelling older individuals in Thailand using an ML model generated from individual characteristics and anthropometric data.

Methods: Datasets including 2692 community-dwelling Thai older adults in Lampang from 2016 and 2017 were used for model development and internal validation. The derived models were externally validated with a dataset of community-dwelling older adults in Chiang Mai from 2021. The ML algorithms implemented in this study include the k-nearest neighbors algorithm, random forest ML algorithms, multilayer perceptron artificial neural network, logistic regression models, gradient boosting classifier, and linear support vector machine classifier.

Results: Logistic regression showed the best overall discrimination performance with a mean area under the receiver operating characteristic curve of 0.81 (95% CI 0.75 - 0.86) in the internal validation dataset and 0.75 (95% CI 0.71 - 0.78) in the external validation dataset. The model was also well-calibrated to the expected probability of the external validation dataset.

Conclusions: Our findings showed that our models have the potential to be utilized as a screening tool using simple, accessible demographic and explainable clinical variables in Thai community-dwelling older persons to identify individuals with frailty who require early intervention to become physically robust.

Introduction

The world population is moving toward an aging society. As health care technology improves, people are expected to live longer and healthier [1]. According to the World Health Organization, the population aged ≥60 years will increase from 1 billion in 2020 to 2.1 billion in 2050 and the number of people aged ≥80 years will reach 426 million in 2050 [2]. Researchers predicted that the proportion of people in Thailand aged ≥60

years would be more than 20% of the population in 2025 and more than 30% in 2031 [3,4].

The prevalence of frailty is high among older adults aged ≥60 years [5]. Global frailty prevalence ranges from approximately 10% to 12% [6-11]. The percentage varies by age, gender, and frailty classification tool. In Thailand, frailty prevalence was 22.1%, which is twice the global frailty prevalence, according to the Thai National Health Examination Survey cohort in 2018. Specifically, Thailand's northern region frailty prevalence was found to be 15% [12,13]. This creates concerns about the increasing aging population in Thailand.

Frailty is defined as a clinical state of increased vulnerability due to the age-associated decline of an individual's body resulting in increased morbidity and mortality when exposed to everyday or acute stressors [14,15]. This clinical syndrome is associated with decreased quality of life [7], slow gait speed [16], more depressive symptoms, higher BMI, reduced cognitive function [17], decreased strength [12], and increased risk of fall, hospital re-admission, and all-cause mortality in the older adult population [13,18-20]. Frailty has become a crucial research topic because this clinical syndrome can be reversed. Studies have shown that early detection and intervention can revert individuals from a frail to a fit state [21-23].

However, incorporating frailty evaluation into clinical practice in a primary care context is challenging due to increased administrative tasks, time limitations, and a lack of diagnostic effectiveness [15,24,25]. In the age of technology, health informatics has become an important role in health care research [26,27]. Several studies have applied information technology to frailty detection in primary care settings using machine learning models and artificial intelligence [28-30]. A study from Canada showcased an efficient frailty identification tool using the XGBoost machine learning model. Features used for the model were medication, medical billing codes, and other primary care clinical data [31]. Another example showed the development of a predictive machine learning model for frailty conditions based on a database of demographic data and clinical characteristics [32]. In China, a study simplified the Frailty Index assessment for older individuals using machine learning techniques and showed that logistic regression was the best performing and most interpretable model, with a mean area under the receiver operating characteristic curve (AUC) of 0.974 in the internal validation dataset [33]. Another study in China also developed and validated models using data from 6997 older adult participants to predict frailty risk, with random forest (RF) and logistic regression (LR) achieving AUC values of 0.77 and 0.76, respectively [34].

Despite the abundance of evidence of conducting frailty assessments using machine learning globally and in Asia, we have found no integration of data science tools and frailty screening and surveillance studies in Thailand. Most studies focused on the risk factors and their association with frailty syndrome but failed to show application in real-world settings [12,13,35,36]. This leads to our research question, "Can machine learning models predict frailty in community-dwelling older adults in Northern Thailand?" Therefore, we propose an approach to frailty detection using a machine learning model in the community-dwelling population from Lampang and Chiang Mai, Thailand, to effectively screen frailty status among Thai community-dwelling older adults and to help decrease clinicians' burden of work.

Methods

Source of Data

Development and Internal Validation Datasets

The datasets were derived from a cross-sectional study carried out in Lampang in 2016 and 2017; it is a northern Thai province with one of the highest aging indexes [37]. This study included older adults aged ≥60 years. Those with dementia (as determined by the Thai Mental State Examination), blindness, deafness, bedridden status, disabilities, or severe acute diseases were excluded.

To represent urban (8 villages), semiurban (8 villages), and rural (8 villages) communities, 24 villages in 3 districts were chosen. The records of the primary care unit were used to compile lists of community-dwelling older adults. The details of the data collection in this study are published elsewhere [36]. A total of 2228 older adults from this study were derived for model development and internal validation.

External Validation Dataset

The datasets used for external validation were derived from a cross-sectional study in Kuamung (suburban), Sankampang, Chiang Mai, Thailand, in 2021. The participants were included and excluded from the study with the same criteria as described in the internal validation datasets. A total of 464 older adults from this study were used for external validation of the derived models.

Predictors

Characteristics and Demographics

Assessments were conducted through a questionnaire at the participant's residence. The questionnaire included questions about sociodemographic information (age, household living arrangement, gender, and education level), self-reported medical diagnoses (such as hypertension, diabetes mellitus, and heart disease), level of physical activity per week, and exhaustion.

Anthropometric Variables

Anthropometric measures included BMI, waist circumference, and calf circumference (CC). A handheld dynamometer (Takei TKK5001) was used to assess handgrip strength. Height and calf circumference were measured with standard tape (Tajima brand, PIT-20BL model), and weight was measured with a calibrated weighing scale (Shaper Disney). The CC was measured over the unclothed area at the maximum diameter on the left leg. The tape was wrapped snugly around the calf and measured to the nearest 0.1 cm. All measurements were administered by 10 qualified field investigators, and the measurements were standardized by the principal investigator.

Outcome Variable

Frailty was evaluated based on Fried's phenotype [38], which includes the following five criteria:

1. Unintentional weight loss: The participant will be asked "In the last ten years, have you lost more than 10 pounds intentionally (not due to diet or exercise)?" If yes, then frail for weight loss criterion. At follow-up, weight loss was calculated as: (weight in previous year – current measured weight)/(weight in previous year)=K. If K≥0.05 and the subject did not report that he/she was trying to lose weight (ie, unintentional weight loss of at least 5% of previous year's body weight), then frail for weight loss=yes.
2. Exhaustion, assessed with self-report using Fried's method of assessment. The participant was first asked to self-assess whether she/he felt exhausted. If yes, she/he would be asked to rate the severity of the exhaustion. Ratings of 2-4 suggested a positive assessment.
3. Physical activity, based on the short version of the Minnesota Leisure time Activity questionnaire, which asked about walking, chores (moderately strenuous), mowing the lawn, raking, gardening, hiking, jogging, biking, exercise cycling, golf, single tennis, doubles tennis, racquetball, and calisthenics. For men, those with <383 kcals of physical activity per week were frail. For women, those with <270 kcals of physical activity per week were frail.
4. Walk time, stratified by gender and height (gender-specific cutoff for medium height).
   - Height ≤173 cm and walk time ≥7 seconds for men.
   - Height >173 cm and walk time ≥6 seconds for men.
   - Height ≤159 cm and walk time ≥7 seconds for women.
   - Height >159 cm and walk time ≥6 seconds for women.
5. Grip strength, stratified by gender and BMI quartiles.
   a. For men:
      - BMI ≤24 and grip strength ≤29 for men
      - BMI 24.1 - 26 and grip strength ≤30
      - BMI 26.1 - 28 and grip strength ≤30
      - BMI >28 and grip strength ≤32
   b. For women:
      - BMI ≤23 and grip strength ≤17
      - BMI 23.1-26 and grip strength ≤17.3
      - BMI 26.1-29 and grip strength ≤18
      - BMI <29 and grip strength ≤21

Older adults with 3 or more phenotypes were considered to have physical frailty, and those who had 1 or 2 phenotypes were classified as prefrailty. According to the study design of the derived datasets, the outcome was concurrently measured with the predictors.

Sample Size Calculation

The sample size for model development was calculated using the *pmsampsize* package via STATA (version 16; StataCorp). A minimum sample size required 16.41 events per predictor, which was 1519 patients with 263 frailty cases based on a maximum candidate predictor of 16, frailty prevalence of 17.29% in the dataset for model development, small overfitting defined as expected shrinkage of predictor effects by 10% or less, a small difference in the developed model's apparent and optimism-adjusted values of 0.15 ($R^2_{Nagelkerke}$), as suggested by Riley et al [39]. For the external validation, the sample size was calculated using the *pmvalsampsize* package via STATA. From the available data of 464 patients with 192 frailty cases, it was able to precisely estimate confidence interval widths of observed/expected statistic of 0.22, calibration slope of 0.60, and concordance statistic of 0.10 [40].

Statistical Analysis Methods and Synthesis of the Results

Data exploration was performed using descriptive statistics to determine the data quantity, quality, and distribution. A frequency and a percentage were used to describe categorical variables. For continuous variables, a mean with SD was used for parametrically distributed data, and a median with an IQR was used for nonparametrically distributed data. The comparison of characteristics between the frail and nonfrail populations was performed using the chi-square test for categorical variables, the independent *t* test for parametric variables, and the rank-sum test for nonparametric variables. The methods for feature selection, model development, and validation are described in the section "Model Development and Validation". Estimates of model discrimination and optimism are reported as the mean AUC with 95% CI across all repetitions of cross-validation for the internal validation and the AUC with 95% CI from 1000 bootstrapping samples for the external validation. To further explain model performance, we also created model calibration plots and calculated secondary metrics of prediction models, including the confusion matrix and specificity, sensitivity, and predictive values.

Missing Data and Imputation

There was only missing data in participants' age in the internal validation dataset (4/2228, 0.18%); therefore, a complete case analysis was performed on the dataset. The external validation dataset contained missing data, including age (2/464, 0.43%), BMI (11/464, 2.37%), waist and calf circumference (3/464, 0.64%), handgrip strength (2/464, 0.43%), and frailty status (4/464, 0.86%). We performed multiple imputations of missing data, except for frailty status (the outcome of interest), using the predictive mean matching imputation with 5 nearest neighbors via the *KNNImputer* from the *Scikit-Learn library 1.1.2*. Four participant records that did not have frailty status were removed (list-wise deletion).

Model Development and Validation

Feature Selection

The classification models were developed using the variables from the derived datasets. The variables for model development were selected using both a data-driven method and domain expertise. For a data-driven selection, a multivariable logistic regression with stepwise backward elimination was performed to determine statistically significant variables (*P* value less than .20). For the *P* value threshold of .20, we used a higher threshold to give priority to clinical reasoning in selecting variables by domain expertise and associated factors from the previous studies, along with statistical significance, which would allow more important variables to be entered into the model.

Rebalancing Data Strategy

We resolved unbalanced classification for the dataset's minority class by using the Synthetic Minority Oversampling Technique (SMOTE) to enhance model decision boundaries via the *imblearn.over_sampling.SMOTE* package [41,42].

Model Development and Internal Validation

The model development and validation were performed using Python (version 3.9; Python Software Foundation). The machine learning algorithms implemented in this study include the k-nearest neighbors (KNN) algorithm, RF machine learning algorithms, multilayer perceptron artificial neural network (MLP), gradient boosting classifier (GBC), linear support vector machine classifier (SVM), and LR models via the *Scikit-Learn library 1.1.2*. The hyperparameters were determined by using a grid search via the *GridSearch CV* package with 10-fold cross-validation on the derived dataset to determine the parameters of each model that led to the best discriminative performance. For 10-fold cross-validation, the derived dataset was divided into 10 folds of data and repeated 10 times to perform model training and testing. For each iteration, 9 folds of data were used to train the model and then it was tested with the remaining fold to ensure that almost all the derived data were used to train and test the models. The discriminative performance of the derived models was assessed by computing a confusion matrix and sensitivity, specificity, and predictive values, as well as AUC with a 95% CI.

The model calibration was evaluated using the calibration plot, which indicated the congruence between the observed proportion of the actual probability of outcome and the mean predicted probability (MPP) from the derived models.

External Validation

The derived models were validated again with the external validation dataset to determine the model optimism and calibration. The discriminative performance and the model optimism were re-evaluated and presented by discriminative performance matrices and a 95% CI of AUC from the 1000 bootstrapping samples, respectively. The model calibration using the external validation dataset was re-evaluated using the calibration plot.

Ethical Considerations

This study complies with the research with exemption category and has been certified by the Research Ethics Committee of the Faculty of Medicine, Chiang Mai University (study code: COM-2565 - 09159, number EXEMPTION 9159/2022). We requested a waiver of informed consent because this study is a retrospective analysis that exclusively utilizes anonymized secondary data from our research database, without collecting any additional information from medical records or other sources. All participants have previously provided informed consent for the primary data collection as described elsewhere [35,36,43]. All personal patient data were anonymized by removing citizen ID numbers, hospital numbers, addresses, and contact information from the dataset. The investigator cannot trace or identify individuals. The study results were reported in accordance with the Transparent Reporting of a multivariable prediction model for Individual Prognosis Or Diagnosis plus Artificial Intelligence (TRIPOD+AI) statement [44].

Results

Baseline Characteristics of Participants in Each Dataset

Baseline characteristics of participants in this study are shown in Table 1. The participants in the internal validation dataset had a mean age of 71.0 years. Most of the participants were male and had finished primary school. Among 2228 old adults, 2160 lived with either their spouse, relative, or children while the others were living alone. The average BMI of the participants was 32.6 (SD 7.4) kg/m^2. The prevalence of hypertension, dyslipidemia, type 2 diabetes mellitus, and heart disease were 45.26%, 19.67%, 16.21%, and 4.31%, respectively. The averages of waist circumference, calf circumference, handgrip strength, and walk time were 83.40 (SD 11.23) cm, 32.40 (SD 4.35) cm, 32.40 (SD 6.68) kg, and 6.42 (SD 2.01) minutes, respectively. Overall, 9.79% of the participants were exhausted and 16.3% had physical activity higher than 150 minutes per week. The prevalence of frailty was 17.3% (n=385).

Table . The characteristics of participants in the development and internal validation datasets and the external validation dataset.

Characteristics	Development and internal validation datasets (Lampang, 2016 - 2017; N=2228)	External validation datasets (Chiang Mai, 2021; N=464)	*P* value
Age (years), mean (SD)	70.96 (7.49)	70.68 (5.58)	.45
Gender, n (%)			
Male	1569 (70.45)	193 (41.59)	<.001
Female	658 (29.55)	271 (58.41)	
Household living arrangement, n (%)			
Living alone	160 (7.18)	42 (9.05)	<.001
Living with spouse	1177 (52.85)	9 (1.94)	
Living with children	823 (36.96)	283 (60.99)	
Living with relatives or others	67 (3.01)	130 (28.02)	
BMI (kg/m^2), mean (SD)	32.64 (7.40)	22.73 (3.89)	.001
Education, n (%)			
No education	192 (8.62)	12 (2.61)	<.001
Primary school	1745 (78.36)	398 (86.52)	
Secondary school or higher	290 (13.02)	50 (10.87)	
Underlying diseases, n (%)			
Hypertension	1008 (45.26)	237 (51.08)	.02
Dyslipidemia	438 (19.67)	79 (17.03)	.19
Type 2 diabetes mellitus	361 (16.21)	78 (16.81)	.75
Heart diseases	96 (4.31)	18 (3.88)	.68
Anthropometric variables, mean (SD)			
Waist circumference (cm)	83.40 (11.23)	81.16 (10.80)	<.001
Calf circumference (cm)	32.40 (4.35)	32.85 (4.55)	.04
Walk time (min), mean (SD)	6.42 (2.01)	8.50 (5.38)	<.001
Exhaustion, n (%)	218 (9.79)	189 (40.74)	<.001
Adequate level of physical activity as defined by the World Health Organization, n (%)	363 (16.30)	104 (22.42)	<.001
Grip strength (kg), mean (SD)	32.40 (6.68)	19.87 (7.29)	<.001
Frailty, n (%)	385 (17.29)	192 (41.74)	<.001

In the external validation dataset, the participants had a mean age of 70.68 years. Most of the participants were male and had finished primary school. Among 464 persons, 422 lived with either their spouse, relative, or children, while the others were living alone. The average BMI of the participants was 22.73 (SD 3.89) kg/m^2. The prevalence of hypertension, dyslipidemia, type 2 diabetes mellitus, and heart disease were 51.08%, 17.03%, 16.81%, and 3.88%, respectively. The averages of waist circumference, calf circumference, grip strength, and walk time were 81.16 (SD 10.80) cm, 32.85 (SD 4.55) cm, 19.87 (SD 7.29) kg, and 8.50 (SD 5.38) minutes, respectively. The prevalence of participants with exhausted state was 40.74%, and 22.42% of the participants participated in physical activity more than 150 minutes per week.

Comparing the variables between the 2 datasets, we found that gender, household living arrangement, BMI, education, waist circumference, walk time, exhaustion, grip strength, and level of physical activity were significantly different.

Model Development

We used a dataset from Lampang (2016 - 2017; N=2228) for model development. The association between candidate predictors and frailty by univariate analysis is reported in Table 2. Feature selection for model development was selected by a backward elimination approach via a multivariable logistic regression and expert judgment. We chose the following features as model predictors: age, gender, status, underlying diseases (hypertension and dyslipidemia), BMI, waist and calf circumference, and level of exhaustion. Finally, the derived data included 385 participants with frailty and 1842 participants

without frailty, and all candidate predictors, as shown in Table 2, were used in model development.

Table . The comparison of participants' characteristics and their associations with frailty in the development and internal validation datasets.

Characteristics	Adjusted odds ratio – full model (95% CI)	*P* value	Adjusted odds ratio – reduced model (95% CI)	*P* value

However, the model appeared to be poor in frailty prediction performance and imbalanced as the classifiers intended to classify only the majority class (accuracy paradox). Therefore, a rebalancing strategy by SMOTE was applied to counter this problem. The oversampling data were generated and rebalanced the minority group in a 1:1 ratio. The details of the final model's hyperparameters using *GridSearch CV* are presented in Table S1 in Multimedia Appendix 1.

Adjusted odds ratios (aORs) of the full model were obtained from a multivariable logistic regression with all features. aORs of the reduced model were obtained from a multivariable logistic regression with stepwise backward elimination (P<.10) and feature selection based on the domain expertise.

Discrimination Performance of Internal Validated Models

We evaluated the model's performance by 10-fold cross-validation. The discrimination performances of the models are presented in Table 3 and Figure 1. The overall discrimination performance was presented by mean AUC 10-fold cross-validation. The KNN model achieved the highest overall performance with a mean AUC of 0.85 (95% CI 0.82 - 0.88), followed by MLP (AUC 0.81, 95% CI 0.72 - 0.89), LR (AUC 0.81, 95% CI 0.75 - 0.86), and SVM (AUC 0.75, 95% CI 0.75 - 0.86), respectively. In addition, the KNN model had the highest sensitivity and specificity (89% and 76%, respectively). RF had the lowest discrimination performance with almost all metrics. Other metrics that were not affected by data rebalancing, like positive predictive value (PPV) and negative predictive value (NPV), were also used to express the performance of the models. The best performances for both

PPV and NPV were found in the KNN model (0.79 and 0.87, respectively).

Table . Discrimination and optimism of internal validated models with 95% CIs.

Models	AUC[a], mean (95% CI)	Predictive values		Sensitivity	Specificity
		Positive	Negative		
LR[b]	0.81 (0.75 - 0.86)	0.74 (0.68 - 0.80)	0.74 (0.69 - 0.78)	0.74 (0.69 - 0.79)	0.73 (0.65 - 0.81)
KNN[c]	0.85 (0.82 - 0.88)	0.79 (0.76 - 0.82)	0.88 (0.86 - 0.90)	0.89 (0.87 - 0.91)	0.76 (0.71 - 0.81)
RF[d]	0.70 (0.60 - 0.79)	0.65 (0.58 - 0.73)	0.70 (0.63 - 0.76)	0.79 (0.74 - 0.83)	0.55 (0.39 - 0.71)
MLP[e]	0.81 (0.72 - 0.89)	0.73 (0.64 - 0.81)	0.75 (0.68 - 0.81)	0.78 (0.71 - 0.84)	0.69 (0.57 - 0.81)
GBC[f]	0.74 (0.72 - 0.89)	0.66 (0.59 - 0.74)	0.70 (0.63 - 0.78)	0.78 (0.73 - 0.83)	0.58 (0.43 - 0.73)
SVM[g]	0.75 (0.75 - 0.86)	0.74 (0.68 - 0.80)	0.73 (0.69 - 0.78)	0.74 (0.69 - 0.79)	0.73 (0.65 - 0.81)

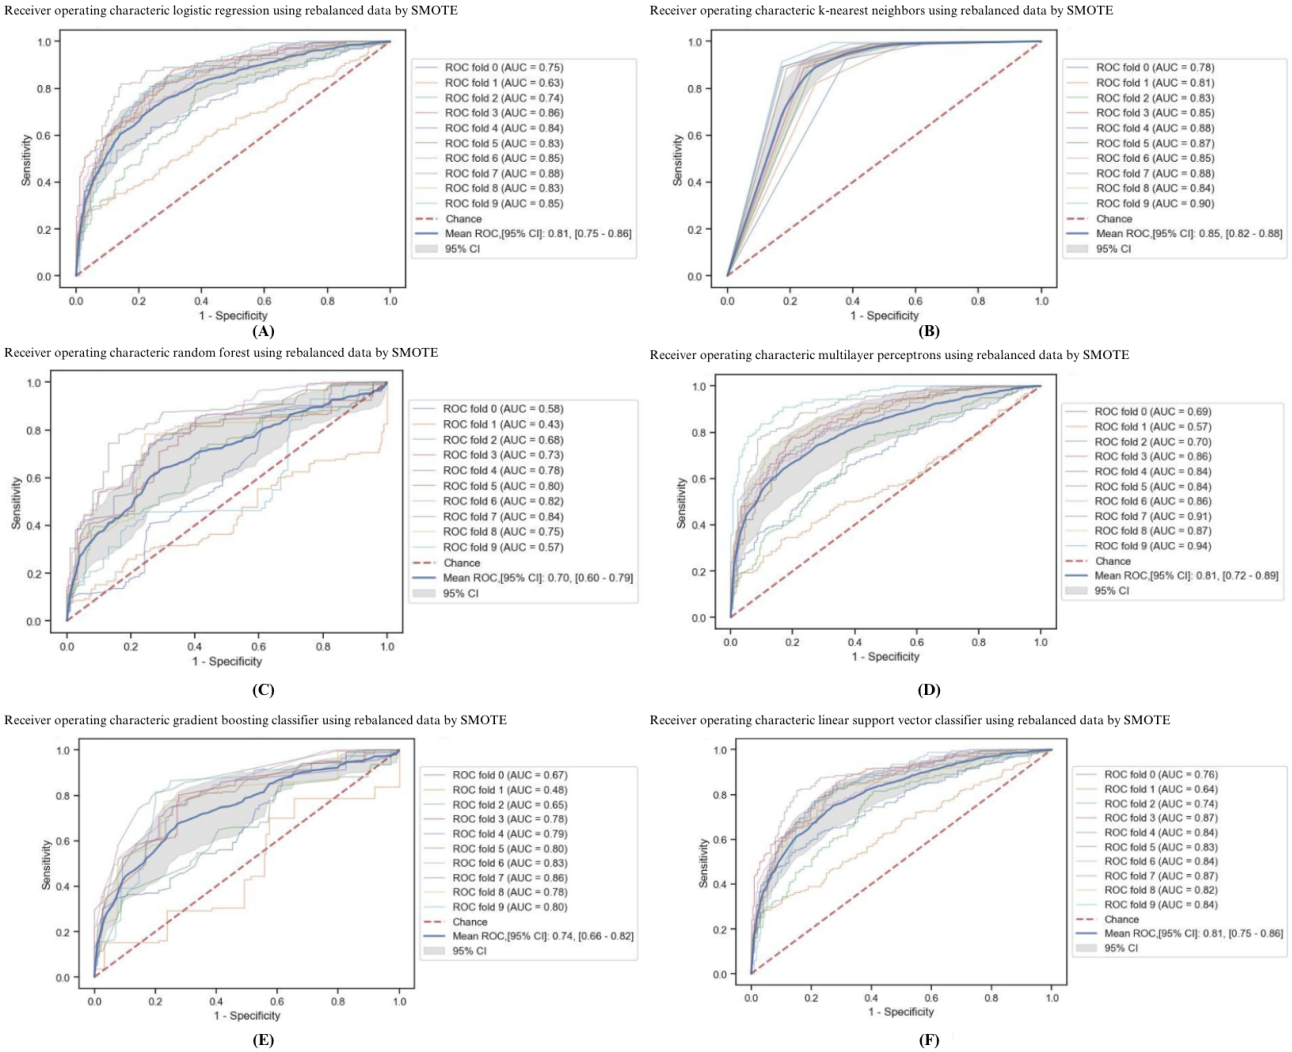
ROC: receiver operating characteristic curve; SMOTE: synthetic minority oversampling technique.



Discrimination Performance of External Validated Models

We validated our trained model with an external validation dataset to evaluate the bias and variance of our trained models. SMOTE was not applied to the dataset since it was already well-balanced between participants with and without frailty. The performance of machine learning models validated by the external validation dataset is shown in Table 4.

Table . Discrimination and optimism of external validated models.

Models and model prediction		True label (frailty/non-frailty)	AUC[a], mean (95% CI)	Predictive values		Sensitivity	Specificity
				Positive	Negative		
Logistic regression							
	Frailty	140/65	0.75 (0.71 - 0.78)	0.68	0.80	0.73	0.76
	Nonfrailty	52/207					
K-nearest neighbors							
	Frailty	41/35	0.54 (0.51 - 0.57)	0.54	0.61	0.21	0.87
	Nonfrailty	151/237					
Random forest							
	Frailty	137/63	0.75 (0.71 - 0.78)	0.69	0.79	0.71	0.77
	Nonfrailty	55/209					
Multilayer perceptron artificial neural network							
	Frailty	98/38	0.68 (0.65 - 0.72)	0.72	0.71	0.51	0.86
	Nonfrailty	94/234					
Gradient boosting classifier							
	Frailty	89/31	0.69 (0.65 - 0.72)	0.74	0.70	0.46	0.89
	Nonfrailty	103/241					
Linear support vector machine classifier							
	Frailty	131/60	0.73 (0.70 - 0.77)	0.69	0.78	0.68	0.78
	Nonfrailty	61/212					

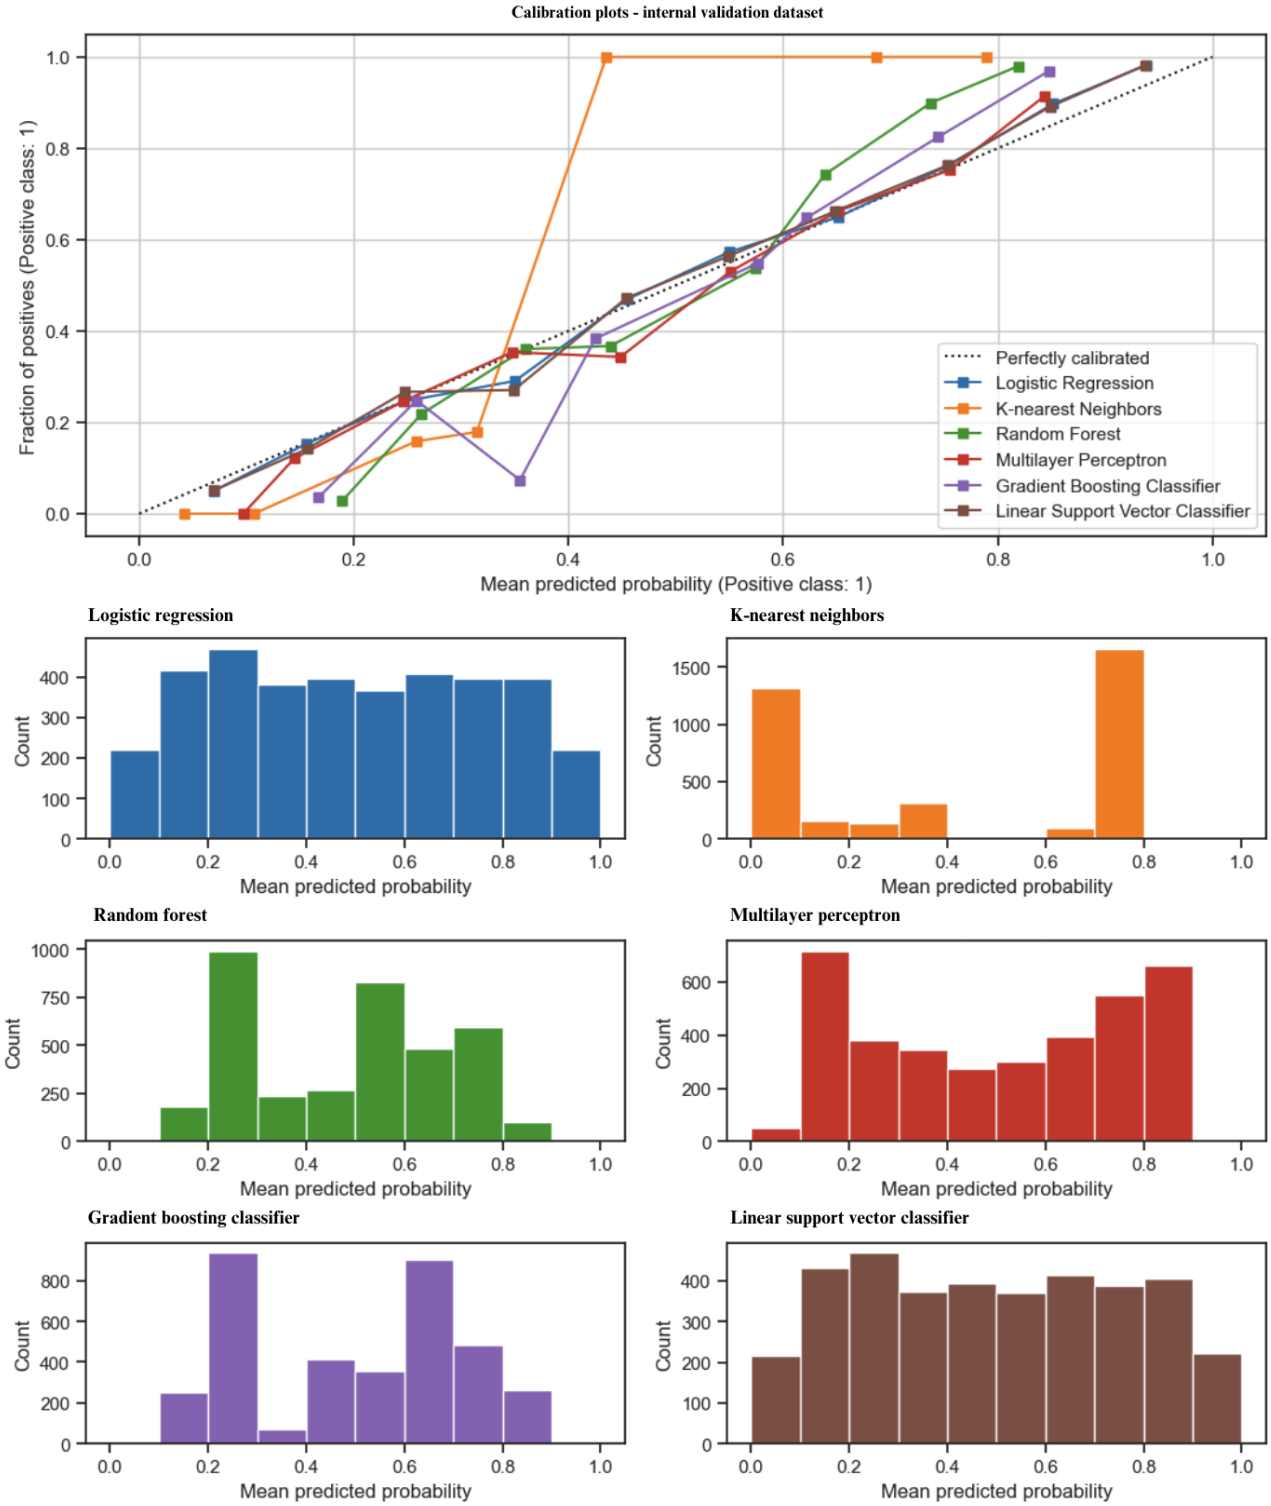
[a]AUC: area under the receiver operating characteristic curve.

The overall discrimination performance was presented by mean AUC and 95% CI via 1000-fold bootstrapping. The LR and RF model achieved the highest overall performance with mean AUC 0.75 (95% CI 0.71 - 0.78), followed by SVM (mean AUC 0.73, 95% CI 0.70 - 0.77), and GBC (mean AUC 0.69, 95% CI 0.65 - 0.72), respectively. The LR model had the highest sensitivity (73%) and the MLP model had the highest specificity (86%). KNN had the lowest discrimination performance with all metrics. Other metrics that were not affected by data rebalancing, like PPV and NPV, were also used to express the performance of the models. The best performance for PPV was found in the GBC model (0.74); for NPV, it was found in the LR model (0.80).

Model Calibration

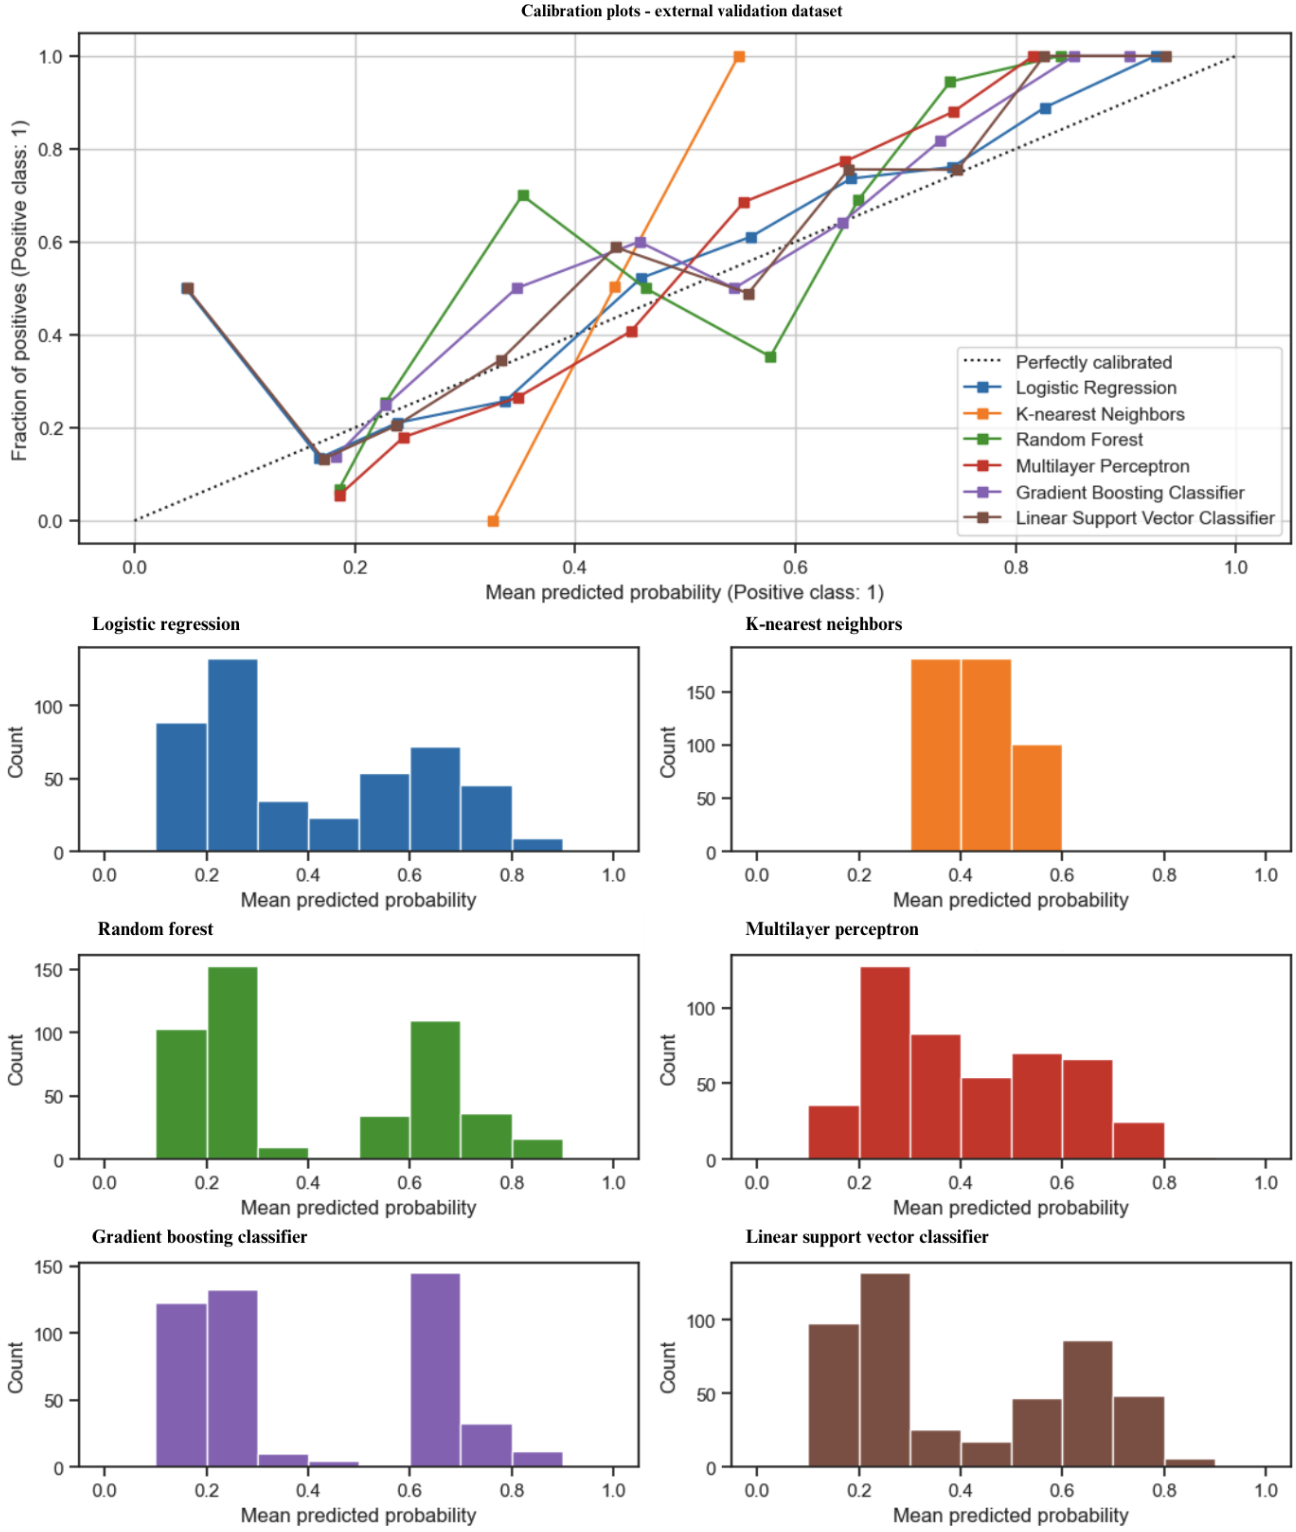
The model calibration was visualized with the calibration plot, which compared the expected probability of frailty, and the mean 10-fold cross-validation predicted the probability of each model. In the internal validation dataset (Figure 2), the LR, SVM, and MLP were well-calibrated with the expected probability of the data. The distribution of predicted probabilities of the models was well-balanced between 0.00 and 1.00. The KNN classifier aligned well with the MPP between 0.00 and 0.40 but it overestimated the high predicted probability. In contrast, the GBC underestimated MPP between 0.20 and 0.40 but aligned well with the rest of the expected probability. These results suggest that LR, SVM, and MLP are the most reliable for balanced predictions, while KNN, GBC, and RF require careful consideration depending on the probability range of interest.

Figure 2. Model calibration of the developed models with internal validation.



In the external validation dataset (Figure 3), the LR, SVM, and MLP were almost perfectly calibrated to the expected probability of the data with a slight overestimation in the 0.40 - 0.80 MPP for MLP and an overestimation in the 0.00 - 0.40 MPP for LR and SVM. These 3 models have a similarly balanced distribution of MPP. RF aligned poorly with an overestimation in the low and high MPP, and it underestimated in the range between 0.40 and 0.70. The GBC aligned well with the calibration plot after 0.60 but overestimated before 0.40. The KNN classifier was poorly calibrated to the plot, giving only MPP in the range of 0.30 - 0.60.

Figure 3. Model calibration of the developed models with external validation.



Discussion

Model Performance

The internal validated models all showed remarkable discrimination performance, with the KNN model having the highest overall discrimination performance. However, the KNN model performed poorly in external validation datasets, indicating overfitting and the inability to generalize its results to other populations. In terms of model optimism, the LR, SVM, and MLP models had better discrimination capabilities, despite a slight decline in the models' performance during external validation. The mean AUCs of these models remained in the range of fair to good performance. When considering all aspects of model performance, the LR model was the most preferable because it provided good discrimination (AUC), an optimal range of predicted probabilities, and good calibration in both the internal and external validation datasets. On the other hand, other models had predicted probabilities that were not extreme enough, resulting in poor to fair calibrations, and they lacked

consistency between the internal and external validation datasets. In comparing the performance and validation aspects of previous frailty prediction models, most studies showed better performance than our best model (LR with a mean AUC of 0.81 in the internal validation set) [45]. The ELSA cohort study (2023) [46] reported the best performance from an RF model with an internal AUC of 0.92. Similarly, Bu et al (2023) [47] presented a multivariate LR model for predicting frailty in diabetic patients that had an AUC of 0.88 in the internal validation set. Additionally, a study on predictive modeling for frailty in older people using various machine learning methods found that artificial neural networks and SVM had the best performance in predicting mortality, with accuracies around 0.78 - 0.79 [32]. Although these studies reported high internal performance metrics, the absence of external validation raises concerns about their generalizability, especially for our focus on the community-dwelling older adult population in general. Our LR showed a mean AUC of 0.75 for the external validation dataset, which dropped slightly from the internal validated results, demonstrating a better edge in the community setting for our focused population. Furthermore, the predictors included in the previously reported model played an important role in prediction performance. Particularly, the utilization of handgrip strength in the study conducted by Bu et al [47] and the assessment of balance and chair stand in the ELSA cohort study [46] could potentially explain the high reported performance in both studies. These predictors either formed part of the frailty phenotype or served as surrogates for physical performance. However, incorporating these predictors into the models necessitated a trade-off between their value added to model performance and the difficulties of model utilization due to the time and skill required for the assessments. In our study, we proposed more parsimonious models using simpler predictions, which still achieved satisfactory performance for frailty screening.

Feature Selection and Findings Explanation

This study's findings suggest that machine learning models can be effective in classifying frailty status among community-dwelling older adults in Northern Thailand using simple predictors including, age, gender, household living arrangement, underlying diseases (hypertension and dyslipidemia), BMI, waist and calf circumference, and level of exhaustion. Age, BMI, waist circumference, and calf circumference are all potent risk factors for frailty in older adults. When the human body deviates from the normal physiologic process of aging, our levels of estrogen and testosterone gradually decline. These hormones play a vital role in maintaining muscle and bone mass, enhancing strength, and promoting optimal nervous system function [48,49]. As a result, the aging process can accelerate the decline of muscle, bone, and the nervous system, transforming an individual from fit to frail. Additionally, the female population is at higher risk of frailty because the normal bone turnover cycle is disrupted by estrogen deficiency during menopause, increasing bone resorption over deposition, and resulting in net bone loss in women [50]. Household living arrangement was also added to model features as we found that there were studies that showed an association of social adversity and support with frailty status [51,52]. Lastly, we selected level of exhaustion as a predictor in our models, as it had the highest crude aOR among all other features, and we found that it is highly feasible and time-efficient to acquire this data in real clinical settings, compared to other Fried's phenotypes, which involve multiple anthropometric and physical performance tests. These predictors also showed a significant contribution to the frailty prediction in the previous studies [46,47]. Most of our features used in the model are easily collectible, which makes it highly feasible and time-efficient to acquire all data in real clinical settings without depending on a high-level professional, making our model highly applicable for early frailty screening.

Limitations

The most important limitation of this study's models is the generalizability of the models. Our internal and external validation datasets were collected from a community-dwelling population in Lampang and Chiang Mai, respectively, which we confidently believe means that our models have high generalizability to the general population in Thailand. From our perspective, we assume that the models could also be implemented in other Asian countries, as studies showed similar frailty prevalence and population characteristics such as anthropometric measurements, age, household living arrangement, and underlying diseases of hypertension and diabetes [53-58].

However, we encourage conducting validation studies for other regions and populations before clinical application as frailty risk factors do vary across countries as well as in regions with different socioeconomic and health care contexts [59-61]. Another limitation of our study is spectrum bias, as our models were only able to distinguish between frail and robust older adults, despite Fried's criteria having 3 stages of frailty: robust, prefrail, and frail [62]. Nonetheless, we do not believe this bias will significantly affect our study's primary objective, which is the early detection of frailty in older adults to effectively prescribe nutrition and exercise interventions.

Implications

Identifying frailty early helps patient gain access to interventions like nutritional support and exercise programs faster, improving outcomes for older adults by preventing frailty progression, reducing falls, hospitalizations, and mortality, and enhancing quality of life [63,64]. We see 2 possibilities for the practical application of our developed and validated models. One option is to develop a web application that serves as a frailty screening tool that could be self-assessed by individuals or be used in outpatient clinic settings to screen patients. This would help health care providers efficiently identify patients with frailty who require closer monitoring or interventions. We have implemented the validated models to run on our web application, which can be accessed at the link in the Data Availability section.

Another option is to incorporate our machine learning models into electronic medical record or health surveillance systems. The machine learning models could be integrated with the electronic medical record system to provide automated frailty probability scores for each patient. This would enable health

care professionals to identify patients who require closer monitoring or interventions and could help optimize treatment plans for the community-dwelling population at risk of frailty. Furthermore, this could help future researchers retrieve and analyze frailty data from the hospital easier, leading to a better understanding of the factors that contribute to frailty and the development of more effective interventions, which also promotes more efficient use of resources within the health care system.

Conclusion

Machine learning models were fairly good at classifying frailty status among Thai community-dwelling older adults using age, gender, household living arrangement, underlying diseases (hypertension and dyslipidemia), BMI, waist and calf circumference, and level of exhaustion as predictors. The LR and RF models demonstrated the best discrimination performance and model calibration in both the internal and external validation datasets.

There are 2 potential practical applications for utilizing the study findings. These include creating a web application for self-screening or individual screening and incorporating machine learning models into electronic medical record or surveillance systems to provide automated frailty probability scores for individual patients. We advocate for further research on model external validation and temporal recalibration to enhance the model's practicality and applicability to the specific context in which it is used.

Abstract

Background: Frailty syndrome in older adults represents a significant public health concern, characterized by a reduction in physiological reserves and an increased susceptibility to stressors. This can result in adverse health outcomes, including falls, hospitalization, disability, and mortality. The early identification and management of frailty are essential for improving quality of life and reducing health care costs. Conventional assessment techniques, including dual-energy X-ray absorptiometry (DXA), bioelectrical impedance analysis (BIA), and muscle ultrasound (US), are efficacious but frequently constrained in primary care settings by financial and accessibility limitations.

Objective: The aim of this study is to analyze the differences in anthropometric characteristics, physical function, nutritional status, cognitive status, and body composition among older adults identified as frail, prefrail, or robust in primary care services using the PowerFrail mobile app. Furthermore, the study assesses the predictive capacity of body composition variables (whole-body phase angle [WBPhA] via BIA, US-measured rectus femoris muscle thickness, and DXA-derived lean mass) in identifying frailty and evaluates their feasibility for implementation in primary care.

Methods: A descriptive cross-sectional study was conducted with 94 older adult participants aged between 70 and 80 years, recruited through the Andalusian Health Service in Spain. Frailty status was classified using the PowerFrail App, which integrates muscle power assessment and provides personalized physical activity recommendations. Body composition was measured using WBPhA (BIA), muscle US, and DXA. Statistical analyses included 1-way ANOVA for group comparisons, logistic regression to investigate associations, and receiver operating characteristic curve analysis to evaluate the predictive accuracy of the body composition measures.

Results: Participants were categorized into frail (n=28), prefrail (n=33), and robust (n=33) groups. All body composition measures exhibited high specificity in detecting frailty, with varying sensitivity. Unadjusted US showed the highest specificity but low sensitivity (10.7%). WBPhA and right leg lean mass (LeanM RL) demonstrated significant predictive capabilities, especially when adjusted for age and sex, with area under the curve values ranging from 0.678 to 0.762. The adjusted LeanM RL model showed a good balance between sensitivity (35.7%) and specificity (93.9%; *P*=.045), indicating its potential as a reliable frailty predictor. These findings are consistent with previous research emphasizing the importance of muscle mass and cellular health in frailty assessment.

Conclusions: Body composition variables, particularly WBPhA, LeanM RL, and US, are effective predictors of frailty in older adults. The PowerFrail mobile app, combined with advanced body composition analysis, offers a practical and noninvasive method

for early frailty detection in primary care settings. Integrating such technological tools can enhance the early identification and management of frailty, thereby improving health outcomes in the aging population.

Introduction

Frailty syndrome in older adults is a multifaceted clinical condition characterized by decreased physiological reserves and increased vulnerability to stressors, which elevates the risk of adverse health outcomes such as falls, hospitalization, disability, and mortality [1,2]. As the global population ages, the prevalence of frailty is projected to rise, posing significant challenges to health care systems worldwide [3]. Early identification and management of frailty are crucial for enhancing quality of life, maintaining functional independence, and reducing health care costs associated with frailty-related complications [4,5].

Primary care facilities are uniquely positioned to play a pivotal role in the early detection and management of frailty due to their accessibility and continuous engagement with the aging population [6]. Implementing effective screening tools within primary care can facilitate timely interventions, thereby mitigating the progression of frailty and its associated adverse outcomes [7]. However, the integration of comprehensive frailty assessments into routine primary care practice remains limited, often due to time constraints, lack of standardized tools, and insufficient training among primary care providers [8].

Body composition variables, particularly those related to muscle mass and tissue quality, are essential in identifying and predicting frailty syndrome [9]. Techniques such as dual-energy X-ray absorptiometry (DXA), bioelectrical impedance analysis (BIA), and muscle ultrasound (US) have been extensively used to assess body composition and muscle status in older adults [10]. The whole-body phase angle (WBPhA), obtained through BIA, serves as an indicator of cellular health and nutritional status, with lower values associated with increased frailty and poorer clinical outcomes [11,12]. Similarly, muscle US offers a noninvasive way to assess muscle thickness and quality, aiding in the detection of sarcopenia and frailty [13]. Although DXA is considered the gold standard for measuring bone and muscle mass, its high cost and limited accessibility in primary care facilities make it necessary to explore alternative assessment methods [14].

In recent years, the advent of mobile health (mHealth) apps has introduced innovative solutions for the assessment and monitoring of complex geriatric syndromes, including frailty. The PowerFrail app represents a pioneering effort in this domain, being the first clinical and scientifically validated app designed to assess muscle power and frailty in older adults in a user-friendly manner [15,16]. This app not only facilitates the screening process but also provides individualized recommendations for improvement and tailored physical activity regimens, thereby supporting personalized intervention strategies. The utilization of validated mobile apps and new trends around artificial intelligence in primary care hold significant promise for enhancing the early detection and management of frailty, offering advantages such as accessibility, ease of use, and the ability to provide real-time feedback and recommendations [17,18].

Moreover, integrating mHealth tools into primary care can bridge gaps in health care delivery by enabling continuous monitoring and follow-up, which are critical for managing chronic conditions and preventing the escalation of frailty [18]. Previous studies have highlighted the effectiveness of mobile apps in improving health outcomes among older adults by facilitating timely interventions and enhancing patient engagement [19]. These findings underscore the potential of mHealth solutions to complement traditional assessment methods, providing a comprehensive approach to frailty management in primary care settings.

From above, the main objective of this study is to analyze the differences in variables related to anthropometric characteristics, physical function, nutritional status, cognitive status, and body composition in phenotypes of frail, prefrail, and robust older adults identified in primary care services. Frailty levels will be classified using the PowerFrail app. Additionally, the second objective is to assess the predictive capacity of body composition variables (US, bioimpedance, and DXA) in identifying older adults with frailty and to evaluate their implementation in primary care services. We used the technological tools WBPhA, US for rectus femoris muscle thickness, and DXA for bone mineral density and lean mass assessment. Our results could demonstrate that these parameters are useful predictors for the identification of frailty, in line with previous findings, thus supporting the potential integration of these tools into primary care practices for the early detection and management of frailty, integrating for the first time mHealth technologies with advanced body composition analysis systems.

Methods

Ethical Considerations

This was a descriptive cross-sectional study that evaluated clinical, physiological, body composition, and psychometric variables in a sample of older adult participants. Recruitment and data collection took place between March and June of 2023. Participants were recruited through advertisements from the public Andalusian Health Service system, Spain. Participants were recruited from primary care centers through referrals by health care professionals. Recruitment was conducted in collaboration with general practitioners, who identified potential

participants meeting the inclusion criteria. The study adhered to the ethical principles of the Declaration of Helsinki for medical research involving human subjects. All participants provided written informed consent. This study was approved by the Costa del Sol Institutional Ethics Committee, under protocol number BON22, on December 23, 2022. All participants provided written informed consent prior to their inclusion in the study. Participants' privacy and confidentiality were ensured throughout the study: all data were anonymized prior to analysis, and identifying information was stored securely and separately from the study data. No identifiable images or information of participants are included in this publication. Participants did not receive compensation for their participation..

Participants

Inclusion criteria for the study were as follows:

- Individuals aged between 70 and 80 years, inclusive.
- Absence or presence of mild cognitive impairment as determined by a Barthel index score [20] greater than 95.
- Sit-to-stand test score [21] between 2.5 and 3.6 for men or between 1.9 and 3 for women.
- Signed informed consent.

Exclusion criteria were the following:

- Individuals younger than 70 years or older than 80 years.
- Individuals with moderate or severe cognitive impairment.
- Sit-to-stand test score [21] less than 2.5 or greater than 3.6 for men or less than 1.9 or greater than 3 for women.
- Individuals living in institutions.
- Individuals with pacemakers or metal prostheses.

Variables and Procedure

The aim of this study was to identify differences in measured parameters to classify individuals into different states of frailty within primary care. To identify different states of frailty, the sit-to-stand test was used, and relative power was calculated using the equations validated by Losa-Reyna et al [16]. Using the cutoff points determined by Losa-Reyna et al [22], participants were classified into 3 groups: frail, prefrail, and robust. This test was performed in the health center's office.

After identifying the study subjects, a detailed evaluation of the remaining variables was carried out in the Functional Testing Laboratory of the Physical Education and Sports Area of the University of Málaga. Participants came to the laboratory fasting (a minimum of 3 hours) and without having done any previous exercise, wearing comfortable and light clothing without metal objects. The tests were carried out between 9:30 AM and 2:00 PM. Once in the laboratory, 2 qualified researchers administered the different tests and assessments; body composition determinations were performed fasting and in the early morning, and the rest of the scheduled evaluations were carried out after breakfast.

Clinical and Demographic Variables

We collected the following clinical and demographic variables:

- Age and sex: Recorded during the initial interview (age in years; sex as male or female).
- Body mass index: Calculated by dividing weight (measured in kilograms using a Digital Scale Extra Large Seca Robusta 813) by height (measured in meters using a stadiometer) squared (m^2).
- Number of medications (drugs): Extracted from the clinical history of the Diraya system (Andalusian Health Service database), with the participants' consent.
- Education level: Recorded during the initial interview.

Body Composition Variables

We collected the following body composition variables:

- Muscle architecture: Muscle thickness and pennation angle of the rectus femoris muscle of the dominant leg were measured using US (Logiq Book XP Ultrasound System and 8L linear transducer). The rectus femoris was examined with the participant in a supine position, with the US operator standing on the ipsilateral side of the participant. The evaluation protocol previously described by Mateos-Angulo et al [23] was used.
- DXA: Lean mass of arms and legs, total lean body mass, skeletal muscle index, and bone mineral density were determined using a Hologic Horizon A DXA scanner (Hologic Inc). Each subject was examined by a certified technician. The distinction between bone and soft tissue, the detection of edges, and regional demarcations were performed using computer algorithms with APEX Corporation Software (version 5.6.0.7). For each scan, patients were asked to remove all materials that could attenuate the X-ray beam, including jewelry. Due to the sensitivity of the soft tissue analysis, the patient should only wear a paper gown for the scan. There should be no pillow on the scan, as the material would affect the soft tissue measurement. The densitometer calibration was checked daily with the standard calibration block supplied by the manufacturer.
- BIA: Total body water, intracellular, extracellular water, and phase angle (WBPhA) variables were determined by multifrequency bioimpedance using the Inbody 770 model. Multifrequency segmental data were obtained that accurately determined total body water, intracellular and extracellular water, impedance (Xc and R), and phase angle (Z) in the 5 body segments (right arm, left arm, trunk, right leg, and left leg).

Cognitive and Nutritional Status

To assess cognitive and nutritional status, the following questionnaires were administered digitally using the Google Forms application.

- Cognitive capacity: Cognitive status was evaluated [24] using the General Practitioner Assessment of Cognition, score 0 to 8, a rapid, reliable, and specific test for the detection of dementia in primary care. This instrument is considered an efficient alternative to others, such as the Mini-Mental State Examination, due to its rapid administration and lack of bias related to gender, education level, or mental health.
- Nutritional status screening: Nutritional status was assessed using the Mini Nutritional Assessment (MNA) [25], score

0 to 14, a widely used scale in the geriatric population. The first part of this test serves as a screening tool to detect the risk of malnutrition, with a cutoff value of 10 points or less. It is a widely used method in older adults and has been validated in different clinical contexts.

Physical Function Evaluation

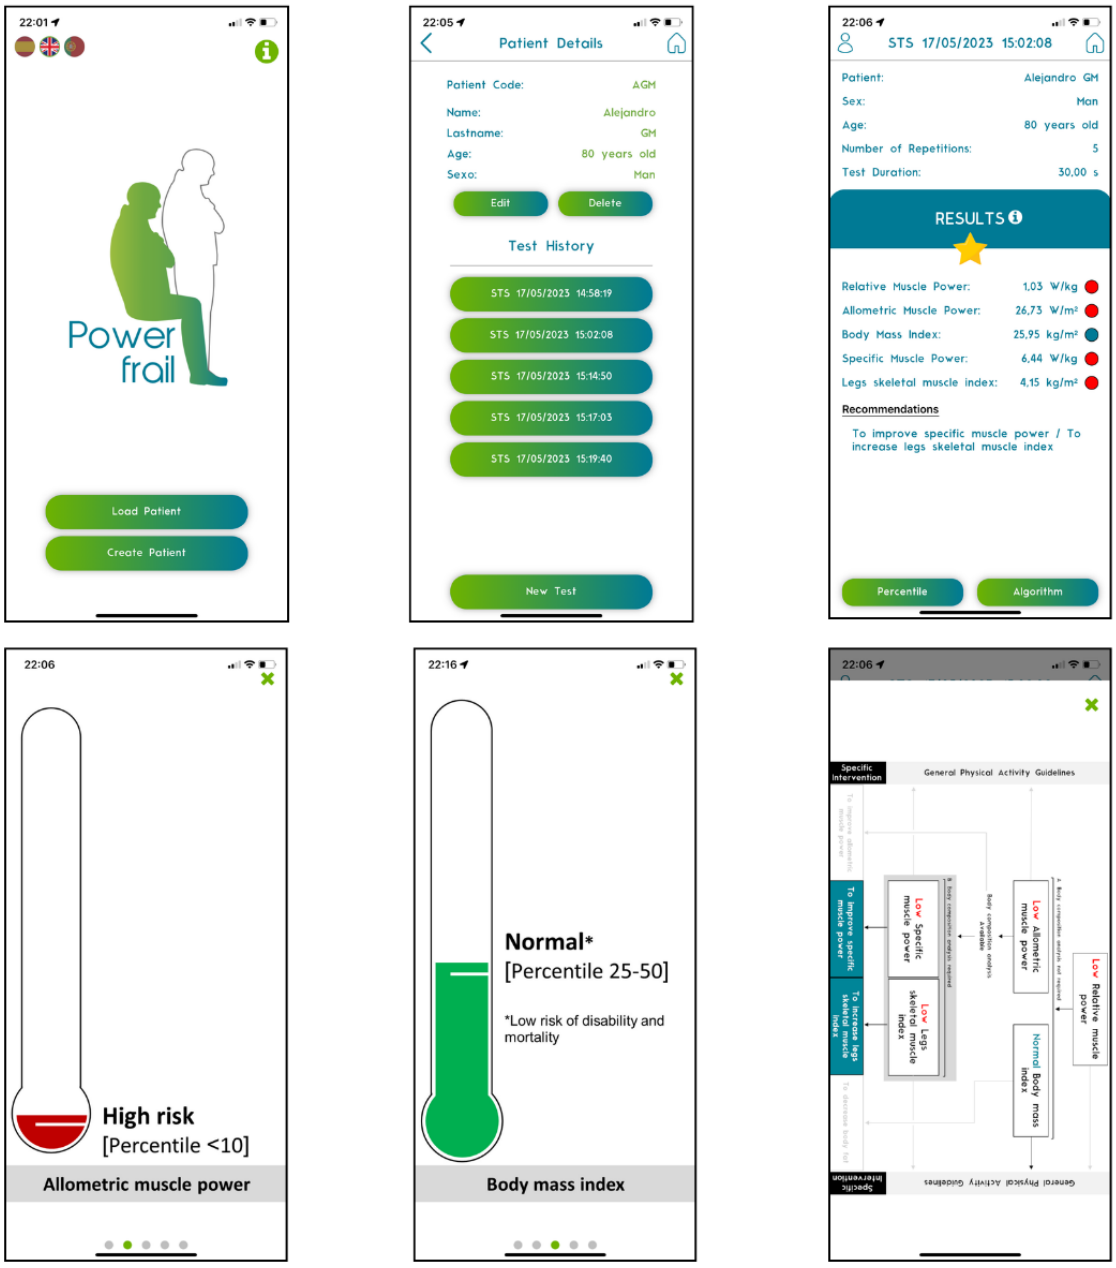
To evaluate the physical function of the participants, the Short Physical Performance Battery (SPPB) was used, score 0 to 12 [26]. This battery includes three tests:

- Walking speed: Measured over a 4-meter distance, expressed in meters per second. Given that gait speed measurement is used as a tool for detecting frailty in older adults from the general population due to its high sensitivity, simplicity, and feasibility, we also used the cutoff points for frailty and prefrailty related to gait speed and sarcopenia in accordance with the consensus document developed by Cruz-Jentoft et al [27]. In this framework, values below 0.6 m/s are identified as frail, between 0.6 and 1 m/s as prefrail, and above 1 m/s as robust [27].
- Static balance: Assessed in 3 different positions.
- Sit-to-stand test: Evaluation of the time it takes for participants to stand up and sit down from a chair 5 times.

In addition to the tests included in the SPPB, two tests were performed:

- Mobile lower limb relative muscle power (RPOW): To measure RPOW, participants performed 5 repetitions of standing up from and sitting down onto a chair with a height of 0.46 m, following the protocol validated by Alcazar et al [15]. The test was performed using the PowerFrail app (Figure 1), developed and validated by Losa-Reyna et al [16], installed on a stable smartphone.
- Handgrip strength: Isometric handgrip strength, expressed in kilograms, was measured using a Takei Physical Fitness Test adjustable dynamometer, following a standardized protocol, as indicated by Roberts et al [28]. Participants performed the test in an erect standing position, with shoulders adducted and arms extended parallel to the body, without touching their torso. Two attempts were made for each extremity, and the maximum value was considered, regardless of hand dominance.

Figure 1. PowerFrail mobile app screenshots.



Sample Size Calculation

The sample size was estimated using an ANOVA model for 3 independent groups (robust, prefrail, and frail). The calculation was performed using the G*Power software. For the sample size calculation, a power of 90% (1–β=.90), a significance level of 5% (α=.05), and an effect size of 0.4 were used. The result was a total sample size of 84 participants. This size was obtained with a noncentrality parameter (λ) of 13.44 and a critical *F* of 3.11, with 2 degrees of freedom in the numerator and 81 in the denominator. To avoid losses in the initial calculation, enough participants were recruited to maintain the robustness of the study. Finally, 94 subjects participated in the study, distributed across 3 groups: robust, prefrail, and frail.

Statistical Analysis

To compare the differences on all variables between robust participants and those with frailty and prefrailty, a 1-way ANOVA was performed on the total sample. Logistic regression analysis was performed to investigate the relationship between body composition and frailty. WBPhA, thickness US, and DXA lean muscle from the lower limbs were entered into the regression model as independent variables, as they were found to have significant differences between the studied groups. Considering that age and sex may influence the relationship between body composition and frailty, these factors were introduced as a confounding variable into an adjusted regression model, treating age as a continuous covariate and sex as a categorical factor. The dependent variable was a binary indicator of frailty, coded as 1 for participants with frailty and 0 for robust participants and those with prefrailty.

To extract values for body composition to identify the presence of prefrailty or frailty, we conducted an analysis using the receiver operating characteristic (ROC) curve. This analysis was applied only to body composition that was significant in the logistic regression analysis. In the ROC analysis, the outcome variable was the presence or absence of frailty. The test variable was the body composition that was significantly associated with frailty. Youden index [29] was calculated with the following formula: Youden index = sensitivity + specificity – 1. The area under the curve (AUC), sensitivity, and specificity were calculated to evaluate the accuracy of the identified predictive models. The AUC could distinguish between nonpredictive (AUC<0.5), less predictive (0.5<AUC<0.7), moderately predictive (0.7<AUC<0.9), and highly predictive (0.9<AUC<1) values, as well as perfect prediction (AUC=1) [30].

Results

The background information of the participants is shown in Table 1. Of the 94 participants in this study, 28 were frail, 33 were prefrail, and 33 had a robust profile. The average age for each frailty category was 76.5, 75.3, and 74.0 years, respectively. The percentages of men and women with frailty and prefrailty were 32% and 52% for men and 68% and 48% for women, respectively. All investigated variables were significantly different among the frailty categories, except BMI, MNA score, skeletal mass index, left arm lean mass, right arm lean mass, and total body lean mass.

Table . Descriptive characteristics of the sample (n=94).

[m]SMI: skeletal muscle index.

The correlation analysis is presented through a heat map in Figures 2-4. Starting with the primary variable identified as a frailty criterion (RPOW), we initially analyzed the behavior of this variable in relation to the other studied variables. Additional correlation analyses were also explored, such as examining the behavior and relationship of handgrip strength. In this regard, we conducted a first analysis on the entire sample (Figure 2), then one each for women (Figure 3) and men (Figure 4). In the entire sample (Figure 1), we found strong positive and negative correlations between the RPOW and all the variables, except MNA score, however, these relationships changed for the women-only and men-only samples. In the complete sample (Figure 2), the results identified stronger correlations between SPPB and RPOW, 5 sit-to-stand time and RPOW, drugs and RPOW, GS4m and RPOW, and handgrip and RPOW. Regarding the analysis of the correlations separately for women and men (Figures 3 and 4), the results were as expected. Specifically, as observed in the cited figures, there were relationships involving body composition variables (BIA, DXA, and US) and expressions of strength, such as lower limb power and, more markedly, handgrip strength. The observed differences in correlations between sexes are consistent with expectations, given the complex biological, hormonal, and social interactions that affect males and females differently during the aging process. It is important to consider these factors when interpreting the results and when designing interventions that address frailty and functional decline in older adults effectively and equitably.

Figure 2. Simple correlation analysis results for the whole sample (n=94). Pearson correlations of all studied variable were carried out on the total sample. 5STS: 5 sit-to-stand time; DRUGS: number of daily medications; GPCOG: General Practitioner Assessment of Cognition score; GS4m: gait speed over 4 meters at a normal pace; HG: handgrip; LeanM LA: left arm lean mass; LeanM LL: left leg lean mass; LeanM RA: right arm lean mass; LeanM RL: right leg lean mass; LeanM TB: total body lean mass; MNA: Mini Nutritional Assessment score; RPOW: relative muscle power; SMI: skeletal muscle index; SPPB: Short Physical Performance Battery score; US: ultrasound on rectus femoris; WALK4m: time to walk 4 meters; WBPhA: whole-body phase angle. *P<.05, **P<.01, ***P<.001.

The logistic regression analyses presented in Table 2 demonstrate the predictive capacity of various diagnostic factors for frailty in older adults. The Nagelkerke R^2 values indicate the proportion of variance in frailty status explained by each model, both before and after adjusting for age and sex. The initial model for US shows that US measurements of the rectus femoris explained 10.1% of the variance in frailty (Nagelkerke R^2=0.101; P=.009). After adjusting for age and sex, the explained variance increases to 20.6% (adjusted Nagelkerke R^2=0.206; P=.002), indicating a stronger association when these factors are considered. WBPhA exhibited a significant association with frailty, explaining 16.4% of the variance in the unadjusted model (Nagelkerke R^2=0.164; P=.001). The adjusted model further enhanced the explained variance to 24.5% (adjusted Nagelkerke R^2=0.245; P<.001), underscoring its robustness as a predictive factor. Both left leg lean mass and right leg lean mass (LeanM RL) were significant predictors of frailty. The unadjusted models explained 12.4% (P=.003) and 16.4% (P<.001) of the variance, respectively. After adjustment, the explained variance increased to 21.5% for the left leg (P=.001) and 24.6% for the right leg (P<.001).

Table . Results of the logistic regression analyses (n=94).

	Nagelkerke R^2	*P* value	Adjusted Nagelkerke R^{2a}	*P* value
Ultrasound on rectus femoris	0.101	.009	0.206	.002
WBPhA[b]	0.164	.001	0.245	<.001
Lean mass, left leg	0.124	.003	0.215	.001
Lean mass, right leg	0.164	<.001	0.246	<.001

[a]Adjusted Nagelkerke R^2 included age as a covariable and sex as a factor.

[b]WBPhA: whole-body phase angle.

The ROC analyses indicated that all evaluated measures demonstrated a high degree of specificity in detecting frailty in older adults. It is notable that unadjusted muscle US demonstrated a high level of specificity, although sensitivity was relatively low. The WBPhA and LeanM RL also exhibited significant predictive capabilities, with AUC and *P* values indicating good discrimination. When adjusting for sex and age, there was a notable improvement in sensitivity, particularly in the case of LeanM RL, which maintained statistical significance (*P*=.045). These findings suggest that the lean mass of the right leg, adjusted for demographic factors, may be a promising indicator for predicting frailty in this population. On the other hand, it is worth noting that the adjusted WBPhA presented the highest Youden index value (0.417), which suggests that it may be the most effective measure in terms of balancing sensitivity and specificity for predicting frailty. Similarly, the adjusted LeanM RL also had a high Youden index (0.296), which establishes it as another promising measure.

Discussion

Principal Findings

This study provides significant evidence on the predictive capacity of body composition variables and their relationship with frailty syndrome in older adults. Technology tools such as BIA, WBPhA, US of the anterior rectus quadriceps muscle thickness, and DXA, were used in this study. The older adult frailty status was calculated using the PowerFrail mobile app [15] (Figure 1). This app is the first scientifically based app that allows the assessment of the muscle power and frailty of older adults in a simple way. Our results showed that these parameters are useful predictors for identifying frailty, in line with previous findings.

This study found several significant correlations between variables related to body composition, physical performance, and cognitive status in female participants, but these were not the same as the values observed in their male counterparts. This may be because women experience more functional limitations than men during the aging process [31]. Women tend to suffer a greater decline in physical function with age, which has been attributed to hormonal changes, particularly the decrease in estrogen levels during menopause [32]. Menopause is associated with changes in body composition characterized by an increase in body fat and a progressive decrease in muscle mass and strength [33]. These alterations can lead to a higher prevalence of sarcopenia and frailty in older women compared to men.

Based on these postmenopausal changes, muscle and fat composition might be more closely related to physical performance in women, which we observed in our correlation results from Figures 2-4. Specifically, the associations between body composition measures (evaluated through BIA, DXA, and US) and expressions of strength, such as lower limb power from the mobile app and handgrip strength, were more pronounced in women. This suggests that changes in muscle quality and quantity may have a greater impact on the physical function of older women.

Although previous research has indicated that muscle quality contributes to physical capacity in older adults, the effect of sex differences on this association has not been thoroughly investigated [34]. Some studies have suggested that muscle quality independently predicts physical function in older men but not in women [35]. However, our findings differ, as we observed significant correlations in women. Unlike previous studies, we included analyses of physical function status, which may explain the different results. The underlying mechanisms of these sex-specific differences still need to be investigated and clarified.

Contributing factors may include differences in muscle structure composition, hormonal influences, and neuromuscular activation patterns between men and women [36]. Additionally, the accuracy and sensitivity of measurement techniques, such as BIA and US, may vary between sexes due to differences in body fat distribution and hydration status [37]. Further research is needed to explore these factors and understand how they influence the relationship between body composition and physical function in older adults.

The connection between body composition and frailty indicators has been the focus of extensive research. However, to our knowledge, no studies have simultaneously compared DXA, BIA, and US, specifically for the identification of frailty syndrome in a primary care setting. Our study addresses this gap by evaluating the predictive capacities of these 3 modalities, offering a comprehensive analysis that can inform clinical practice regarding the most suitable and practical tools for frailty assessment in older adults. Although previous studies have compared two modalities, our inclusion of a third (US) provides a broader perspective on body composition assessment tools available for primary care settings. For instance, research has demonstrated that muscle US is an emerging tool for diagnosing sarcopenia, with studies summarizing its diagnostic accuracy [38]. Additionally, studies have evaluated the reliability and

validity of sarcopenia diagnosis using BIA compared with the gold standard, DXA, assessing the predictive accuracy of BIA for diagnosis [39,40]. However, these studies did not include US in their comparisons. Rossini-Venturini et al [41] highlighted that the anthropometric prediction equations developed in their study provide a reliable, practical, and low-cost instrument to assess the components that change the most during the aging process, corroborating our findings. This perspective emphasizes the significance of considering diverse elements of body composition in the evaluation of health among older adults. Although some studies have recognized muscle mass, assessed via DXA or BIA, as a critical element in forecasting frailty [42,43], our analysis demonstrated that lower extremity lean mass (left left lean mass and LeanM RL) did reveal a direct relationship in the models. The present results are in line with findings that indicate muscle mass reduction alone does not suffice to predict frailty without factoring in physical performance [44]. In fact, physical performance, which can be measured through functional tests such as gait speed or grip strength, is vital for evaluating frailty status among older adults [45].

There has been a growing acknowledgment in recent literature regarding the significance of assessing both the quantity and quality of muscle. Xu et al [46] demonstrated that body composition, encompassing both muscle mass and quality, is significantly associated with frailty in older adult inpatients. The current literature suggests that it is not enough to analyze the quantity of muscle mass in absolute terms; quality is equally important. Quality can be assessed through methods such as US and BIA, which provide insights into muscle integrity and performance in terms of its functional capacity. In this context, analyzing muscle quality through US could effectively complement DXA, which has traditionally been considered the gold standard in the assessment of body composition. Although DXA provides valuable information on lean mass and fat mass, it does not provide details on muscle distribution and quality, critical for understanding frailty in older adults [47].

Moreover, our findings indicated that muscle strength and gait speed are important indicators of frailty, corroborating the work of Tsukasaki et al [48], who found a strong association between muscle strength, gait speed, and cross-sectional muscle area determined by midthigh computed tomography. These findings reinforce the idea that comprehensive evaluations of muscle function should be integrated into frailty assessments. Therefore, muscle composition emerges as a potential public health assessment by enabling the clinical quantification of muscle mass and an estimation of physical function in the older adult population [49].

Our findings demonstrated that all measures exhibited high specificity but varying sensitivity in detecting frailty (Table 3). Our ROC analysis showed moderate predictive ability for WBPhA, US thickness, and lean mass of legs from DXA, with an AUC between 0.678 and 0.749. This aligns with the results from previous studies [50,51], which emphasized that models combining body composition measurements with physical performance tests can improve the predictive ability of frailty. Unadjusted US showed perfect specificity but low sensitivity (10.7%), indicating it is highly effective at correctly identifying nonfrail individuals but less capable of detecting those who are frail. This aligns with previous studies suggesting that muscle US, while precise in measuring muscle thickness, may have limitations in sensitivity due to operator dependency and variability [52].

Table . Results of receiver operating characteristic analysis (n=94)

	Sensitivity	Specificity	Youden index[a]	AUC[b]	*P* value
US[c]	0.107	1.000	0.107	0.678	.02
US (adjusted)[d]	0.321	0.939	0.260	0.732	.24
WBPhA[e]	0.240	0.952	0.192	0.704	.003
WBPhA (adjusted)[d]	0.480	0.937	0.417	0.762	.09
LeanM LL[f]	0.107	0.985	0.092	0.683	.009
LeanM LL (adjusted)[d]	0.250	0.924	0.174	0.741	.17
LeanM RL[g]	0.286	0.939	0.225	0.703	.003
LeanM RL (adjusted)[d]	0.357	0.939	0.296	0.749	.045

[a]Youden index = sensitivity + specificity – 1.

[b]AUC: area under the curve.

[c]US: ultrasound on rectus femoris.

[d]Model adjusted by sex and age.

[e]WBPhA: whole-body phase angle.

[f]LeanM LL: left leg lean mass.

[g]LeanM RL: right leg lean mass.

Adjusting the US measure for age and sex increased sensitivity to 32.1% but reduced specificity to 93.9%, and the adjusted model did not reach statistical significance (*P*=.24). This suggests that while adjustments improve sensitivity, they may

not be sufficient to make US a standalone diagnostic tool for frailty in primary care settings. The WBPhA showed an unadjusted sensitivity of 24% and specificity of 95.2%, with an AUC of 0.704 (*P*=.003). After adjusting for age and sex, sensitivity improved to 48%, specificity slightly decreased to 93.7%, and AUC increased to 0.762, although the *P* value was nonsignificant (*P*=.09). These results suggest that WBPhA, particularly when adjusted for sex and age factors, has potential as a screening tool for frailty. Previous research has shown that lower phase angle values are associated with decreased muscle function, poor nutritional status, and higher frailty risk [12,53]. The noninvasive nature and ease of use of BIA make WBPhA a practical option for primary care, although standardization of measurement protocols is necessary.

LeanM RL emerged as a significant predictor when adjusted for age and sex (*P*=.045), with sensitivity and specificity of 35.7% and 93.9%, respectively, and an AUC of 0.749. This indicates that the adjusted LeanM RL model had a good balance between sensitivity and specificity and may be valuable in predicting frailty. The importance of lower limb muscle mass in frailty assessment is well-documented. For instance, [54] reported that decreased appendicular lean mass is associated with physical disability and increased risk of adverse outcomes in older adults. However, the use of DXA in primary care is limited due to cost, accessibility, and exposure to low-dose radiation.

In comparison, the unadjusted left leg lean mass showed similar specificity (98.5%) but low sensitivity (10.7%), and the adjusted model did not achieve statistical significance. This suggests that while lean mass measurements are informative, the right leg may provide more predictive value than the left in this context, possibly due to dominance or functional differences, although further research is needed to confirm this observation. Overall, our results indicated that LeanM RL, adjusted for age and sex, may be the most effective measure among those studied for predicting frailty. This is significant because identifying reliable, accessible markers for frailty is crucial for early intervention. Given the limitations of DXA in primary care, exploring alternative methods to estimate lean mass, such as predictive equations or portable devices, could enhance feasibility. The high specificity observed across all measures suggests they are effective in ruling out frailty in individuals without frailty. However, the variable sensitivity underscores the need for multicomponent assessment tools. The Comprehensive Geriatric Assessment remains the gold standard for frailty evaluation but is resource-intensive [55]. Incorporating measures like WBPhA and simplified lean mass assessments could enhance screening efficiency in primary care.

Limitations, Clinical Implications, and Future Directions

Limitations of the study include the sample size and homogeneity in some variables, such as BMI and arm lean mass (left arm and right arm), which could have affected the accuracy of the predictive results. Heterogeneity in these measurements has been reported in previous research [56], suggesting that variability in body composition could influence frailty prediction. There is potential for the integration of advanced body composition analysis tools and mobile technology into primary care services for the early identification and management of frailty syndrome in older adults. Methods such as WBPhA, US of the rectus femoris muscle, and DXA analysis proved to be effective predictors of frailty, offering high specificity in detection. The implementation of the PowerFrail mobile app enables rapid and personalized assessments, optimizing preventive interventions. These tools not only improve the accuracy of clinical evaluations but also reduce costs associated with frailty-related complications, promoting healthier aging and alleviating the burden on public health care systems. In addition, while this study incorporated a range of assessment tools, it is essential for future research to concentrate on validating these measures in larger and more diverse cohorts to ensure their wider applicability. The cross-sectional design of this study further restricts the ability to infer causal relationships between body composition variables and frailty. Longitudinal investigations could provide valuable information on how variations in body composition affect the progression of frailty over time. Understanding these dynamics could facilitate developing more effective and personalized interventions for the older adult population. Finally, future studies should explore the integration of these mHealth technologies with advanced body composition analysis systems to optimize early detection and management of frailty.

Conclusions

The findings of this study reinforce the utility of various body composition evaluations, such as WBPhA, LeanM RL measured by DXA, and quadriceps thickness assessed by US, as effective indicators for predicting frailty in older adults, aligning with previous research. However, our results highlight the necessity of not relying exclusively on muscle mass as a predictor of frailty. It is essential to incorporate assessments of muscle function and physical performance into clinical evaluations to enhance the accuracy of identifying individuals susceptible to frailty. The combination of tools such as WBPhA, bioimpedance, and US, along with the PowerFrail app, could provide a more complete and accurate assessment of the health status of older adults, allowing effective preventive interventions to be implemented in primary care services.

Abstract

Background: Sarcopenia (loss of muscle mass and strength) increases adverse outcomes risk and contributes to cognitive decline in older adults. Accurate methods to quantify muscle mass and predict adverse outcomes, particularly in older persons with dementia, are still lacking.

Objective: This study's main objective was to assess the feasibility of using deep learning techniques for segmentation and quantification of musculoskeletal tissues in magnetic resonance imaging (MRI) scans of the head in patients with neurocognitive disorders. This study aimed to pave the way for using automated techniques for opportunistic detection of sarcopenia in patients with neurocognitive disorder.

Methods: In a cross-sectional analysis of 53 participants, we used 7 U-Net-like deep learning models to segment 5 different tissues in head MRI images and used the Dice similarity coefficient and average symmetric surface distance as main assessment techniques to compare results. We also analyzed the relationship between BMI and muscle and fat volumes.

Results: Our framework accurately quantified masseter and subcutaneous fat on the left and right sides of the head and tongue muscle (mean Dice similarity coefficient 92.4%). A significant correlation exists between the area and volume of tongue muscle, left masseter muscle, and BMI.

Conclusions: Our study demonstrates the successful application of a deep learning model to quantify muscle volumes in head MRI in patients with neurocognitive disorders. This is a promising first step toward clinically applicable artificial intelligence and deep learning methods for estimating masseter and tongue muscle and predicting adverse outcomes in this population.

Introduction

Age-related muscle wasting and neurodegeneration, clinically presented as sarcopenia and dementia, respectively, are the major drivers of frailty, falls, and disability in older adults worldwide [1]. Sarcopenia is characterized by loss of muscle mass, strength, and function in older adults. Aging is the leading risk factor, but conditions such as chronic diseases, inflammation, sedentarism, and malnutrition promote sarcopenia onset and progression [2]. Sarcopenia has a 10% overall prevalence globally in older persons, 29% in the community, 14%-33% in long-term care settings, and up to 50% in the very old (>80) [3,4]. Despite being a common and relevant health-related condition, it is unseen and underdiagnosed,

particularly in older persons with cognitive disorders. To diagnose sarcopenia, measurement of muscle mass, muscle performance, and strength is necessary [2]. Estimating muscle performance and strength is accessible and cheap with traditional methods, such as gait speed and grip strength, respectively [5]. However, techniques such as dual X-ray absorptiometry or body magnetic resonance imaging (MRI) are necessary to accurately assess lean or muscle mass. These methods can increase costs and time and are impractical in settings such as dementia clinics [6].

Dementia patients are highly affected by sarcopenia, with a prevalence of around 60% - 70% [7,8]. People living with neurodegenerative diseases are more prone to experience difficulties due to malnutrition, being sedentary, and falling; therefore, having sarcopenia increases the risk of adverse outcomes. Sarcopenia is not only a risk factor for adverse outcomes for those with dementia but also promotes cognitive loss in healthy older adults [9]. Therefore, diagnosing sarcopenia in people with neurodegenerative diseases is relevant and necessary.

Head MRI is a widely used diagnostic method for assessing dementia and Alzheimer disease (AD), as it offers intricate representations of the brain's anatomy and physiology. In clinical practice, MRI is often combined with other imaging techniques and cognitive assessments to support the diagnosis of these conditions. The utilization of MRI has seen an upward trend in recent times, as it has become an instrumental tool for the early detection and tracking of the evolution of dementia and AD. According to estimates, 60% - 80% of patients diagnosed with dementia or AD undergo MRI as part of their diagnostic evaluation [6].

Mastication and deglutition muscles such as the masseter and tongue are visible in brain MRI scans [10,11]. These muscles can reflect not only age-associated general muscle decline but also systemic processes due to highly complex interactions with the immune system and the inflammatory response, the nervous system, and the crossroads of several components of the frailty syndrome [12,13]. Indeed, in a previous publication, we have reported that manually segmented masseter predicts mortality and clinical short-term and long-term outcomes in several contexts [14]. Moreover, head muscles such as the tongue and masseter could be cost-effective alternatives to estimate muscle mass in dementia and other common conditions such as head cancer, stroke, or cranioencephalic trauma [14,15]. However, manual and semi-automatic techniques are labor-intensive and time-consuming, making the image processing task for large studies difficult, expensive, and, most importantly, impractical to apply in a clinical setting. Therefore, in the present study, we aimed to use MRI scans of the head opportunistically to develop an automated deep learning method to evaluate sarcopenia.

Methods

Population and Data Source

The "Dementia Study of Western Norway" (DemVest) is a long-term study between 2005 and 2013, with ongoing follow-up assessments. Participants were referred from dementia clinics in Hordaland and Rogaland and were insured by the same national insurance scheme. The study's methodology is described elsewhere [15]. Those with moderate or severe dementia, delirium, past bipolar or psychotic conditions, terminal illness, or newly diagnosed somatic diseases impacting cognition, function, or participation were excluded.

For this study, subjects with dementia with Lewy bodies (DLB) or mild AD who had baseline MRI scans were included. Out of 111 participants (85 AD and 26 DLB), 33 AD and 20 DLB participants with MRI images for brain and muscle measurement were selected based on the quality of the images and clear delineation of the regions of interest. The diagnosis of dementia was made in accordance with the Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition (DSM-IV) criteria, and patients were classified as AD or DLB [16]. A mini-mental state examination score of ≥20 or a clinical dementia rating global score of 1 was chosen as the definition for mild dementia. The diagnosis was based on inclusion but could be modified with clinical evolution, consensus, and autopsy [15]. Participants were evaluated through structured assessments, and medical records were used to gather complete medical history and comorbidity data. In total, 56 participants had pathological diagnoses with 80% accuracy compared to clinical criteria, which reflects a reliable initial clinical diagnosis [17].

Ethical Considerations

This study was approved by the regional ethics committee (approval code: 2010/633) and the Norwegian authorities for the collection of medical data. All data were handled and kept following national data privacy protocols. All participants signed an informed consent form before inclusion in the study.

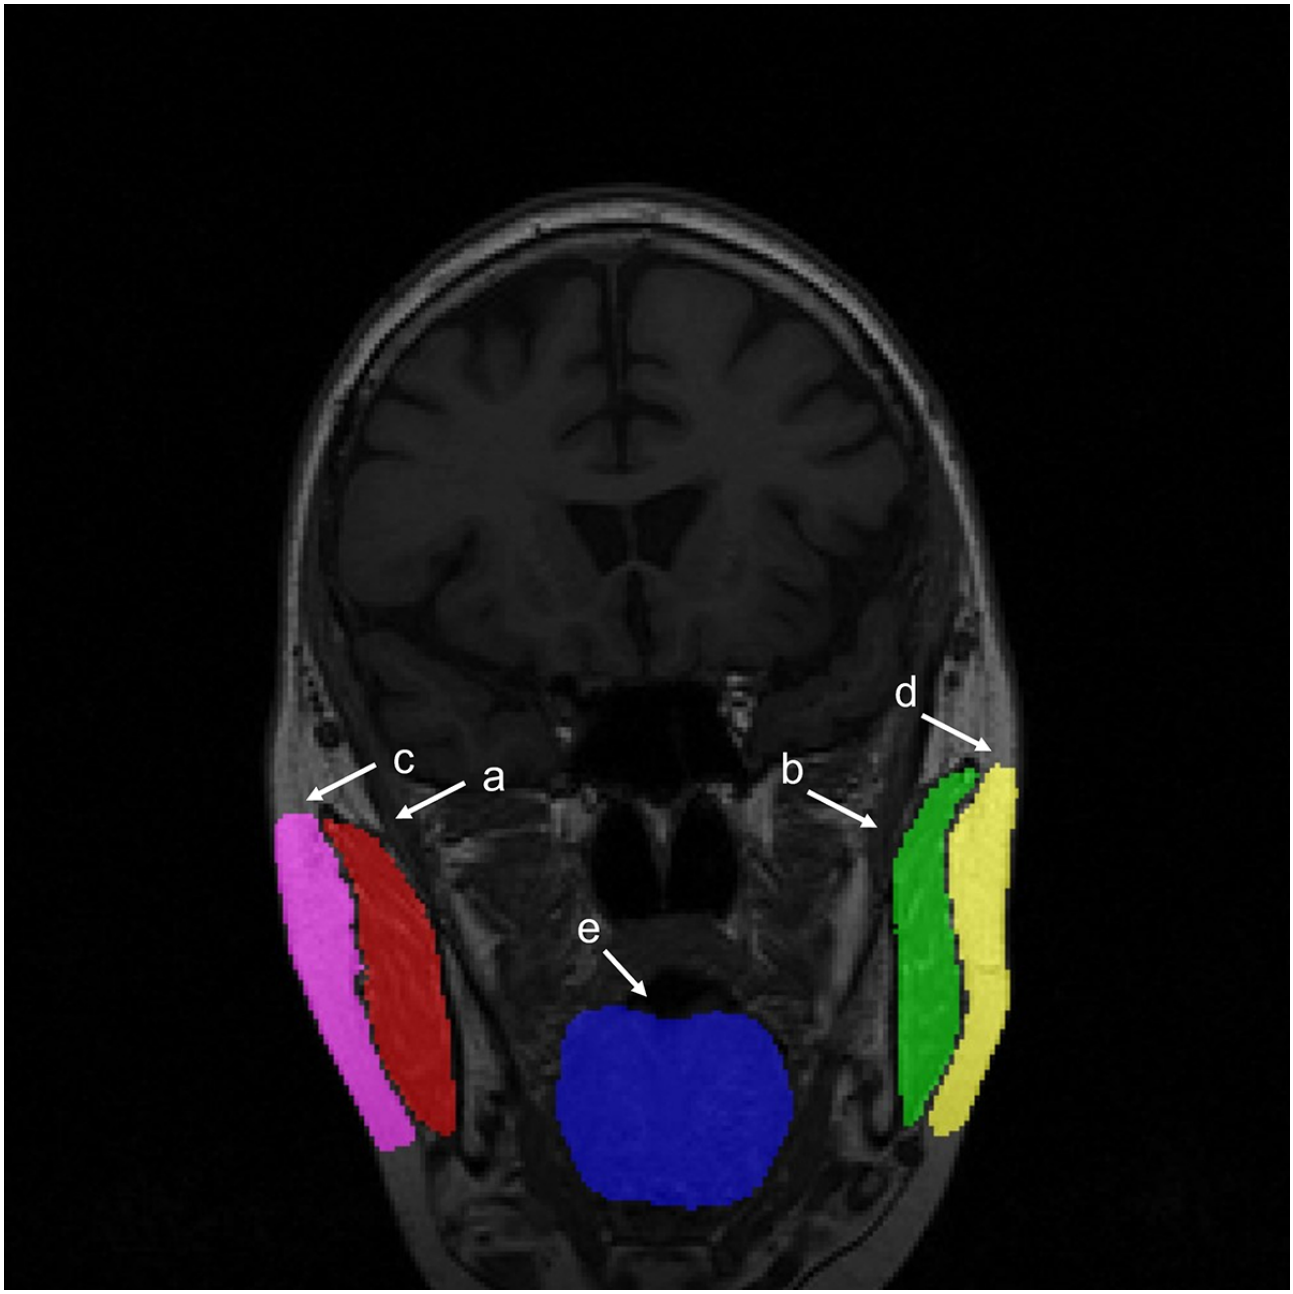
Imaging

All images were acquired at baseline. A 1.5-T Philips Intera-scanner was used to obtain MRI images. The acquisition protocol for 3D T1-weighted sequence was as follows: flip angle of 30°, repetition time/echo time of 10.0/4.6 ms, number of excitations of 2, 2-mm slice thickness with 1-mm spacing between the slices (1-mm slices with no gap), matrix of 256×256 pixels, and field of view of 26 cm. Those with movement artifacts and inadequate image quality were removed from the data using visual quality checks. A standardized preprocessing method for harmonizing multiple collections of MRIs was applied, which consisted of movement correction and intensity normalization following previously validated techniques [15].

Ground Truth Image Segmentation

Ground truth (GT) images were segmented using interactive pixel techniques made available by SliceOmatic software (TomoVision) following a manual method previously reported [18]. The size of the masseter muscle was used as a reference for the selection criteria of the slices. In total, 5 slices were selected from the ones with both right and left masseter muscles at their largest. For each slice, 5 tissues were segmented: left and right masseter muscles, left and right subcutaneous fat, and tongue muscle (Figure 1). The masseter muscle on each side was used as a reference to segment subcutaneous fat.

Figure 1. Example of segmented tissues overlaid on the original MRI. (**A**) Right masseter muscle, (**B**) left masseter muscle, (**C**) right subcutaneous fat, (**D**) left subcutaneous fat, and (**E**) tongue muscle.



Network Architecture

We studied and compared 6 different U-Net-like architectures. The original U-Net architecture [19] was first designed to segment medical images, and many other researchers have tried to improve its performance by integrating additional techniques into its architecture [20]. U-Net consists of a contracting path (encoder) and an expansive path (decoder) with skip connections between these 2 paths. The network learns features from the provided image and the mask at increasingly higher spatial scales by gradually down-sampling to lower resolutions through the encoding path. The expansive path then gradually increases the resolution of the output from the encoding path to the original image size, resulting in a probability map as an output, indicating the chance of each pixel belonging to a specific tissue. One important feature of U-Net is its skip connections, which concatenate feature maps from the encoding path to the corresponding block in the expansive path, making it possible to maintain small details crucial in medical image segmentation.

We have included 5 variants of U-Net in this study, including Attention U-Net, Dense U-Net, Residual U-Net, Inception U-Net, and U-Net++. Attention U-Net is desirable since it allows the model to focus on specific objects and ignore unnecessary areas [21]. In Dense U-Net, the traditional U-Net blocks are replaced with a dense block, enabling the model to segment objects with greater distinction. This feature is important in medical practice since tissues are often very close and sometimes overlap [22]. Residual U-Net architecture tries to tackle the vanishing gradient issue, a common problem in designing deep neural networks [23]. In most cases, the same organ's size can vary between patients, which can cause limitations on the segmentation capability of the model. By using filters with

different sizes, Inception U-Net attempts to overcome this problem [24]. Lastly, U-Net++ aids the classic U-Net model to more accurately segment images by providing semantic information from a dense network of skip connections as an intermediary grid between the encoding and decoding paths [25]. We also included a Wide U-Net architecture to eliminate the effect of increased trainable parameters. This model has the same architecture as U-Net but with more feature maps per layer (30, 60, 120, 240, and 480) compared to the original U-Net (16, 32, 64, 128, and 256). Hence, it will serve as a control to compare the models with larger numbers of trainable parameters with the base U-Net (Table 1).

Table . Number of trainable parameters for each model.

Model	Trainable parameters
U-Net	2,164,390
Attention U-Net	2,233,270
U-Net++	2,555,702
Inception U-Net	5,529,526
Residual U-Net	6,877,110
Dense U-Net	7,666,320
Wide U-Net	7,596,306

Training Procedure

All models were trained with the mini-batch stochastic gradient descent algorithm using the Adam optimizer. A batch size of 8 was selected. The learning rate was 0.0001. The training was done for 200 epochs. The values of hyperparameters were empirically tuned for best performance. Categorical cross-entropy (CSE) was selected as the loss function for this study [26]. The CSE loss function minimizes the distance between 2 distributions (the predicted labels and the GT labels). CSE is one of the most popular loss functions for image segmentation and has shown excellent performance in muscle segmentation [27,28]. All experiments were implemented with open-source software: Python (version 3.7.13), TensorFlow (version 2.8.2), and Keras (version 2.8.0).

Model Evaluation

The results of the experiments were evaluated using 2 main measures: Dice similarity coefficient (DSC) and average symmetric surface distance (ASSD). The DSC represents the agreement between the GT labels and predicted labels that models generate:

$$DSC_{P,G} = 2(P \cap G)(P+G)$$

where $\cap$ is the intersection and P and G are the 2 labels. DSC ranges between 0 and 1, where 0 indicates no agreement and 1 indicates perfect agreement. In our study, DSC is presented as a percentage.

The ASSD measures the average distance from pixels on the boundary of predicted labels to corresponding pixels on the boundary of the GT labels:

where BP and BG are the boundaries of predicted labels and corresponding reference labels, respectively. d(v,B) is the shortest Euclidean distance between voxel v and boundary B. An ASSD of 0 indicates a perfect match between predicted and reference labels. The ASSD was measured in mm.

We used k-fold cross-validation in evaluating the models. This technique splits the data set into k subsets (folds). The deep learning models are trained on all but one of the subsets (k–1), and then the models are evaluated on the subset that was not used for training. This process is repeated k times, and the average of the results is reported. We used k=10.

Additional metrics, including Jaccard coefficient, precision, recall, sensitivity, specificity, and F_1-score, are presented in Multimedia Appendix 1. The results are shown as mean and standard deviation and median and interquartile range across k-fold (k=10) cross-validation.

Statistical Methods

We explored the association between the BMI and the muscle and fat areas and volumes in the MRI images using individual linear regression models adjusted by sex and age. No adjustments for multiple testing were made. All assumptions were checked. All *P*-values were evaluated at a 5% level. The analysis and graphs were carried out using R (version 4.2.2).

Results

Segmentation

DSC and ASSD were used to quantitatively analyze the segmentation results (Figure 2 and Table 2). The Dense U-Net model has a higher average DSC and lower ASSD than other models. In contrast, Attention U-Net has the lowest average DSC score compared to other models. This result is confirmed by the higher ASSD for Attention U-Net for all tissues. Other models have shown almost similar results for all areas. Additional metrics have been presented in Multimedia Appendix 1. The results from these metrics confirm the findings of the study mentioned in this section; hence, they were omitted from the main manuscript.

Figure 2. Box plot of k-fold (k=10) cross-validation results for attention U-Net, dense U-Net, inception U-Net, residual U-Net, U-Net, U-Net++, and wide U-Net. Top: DSC in percentage. Bottom: ASSD in mm.

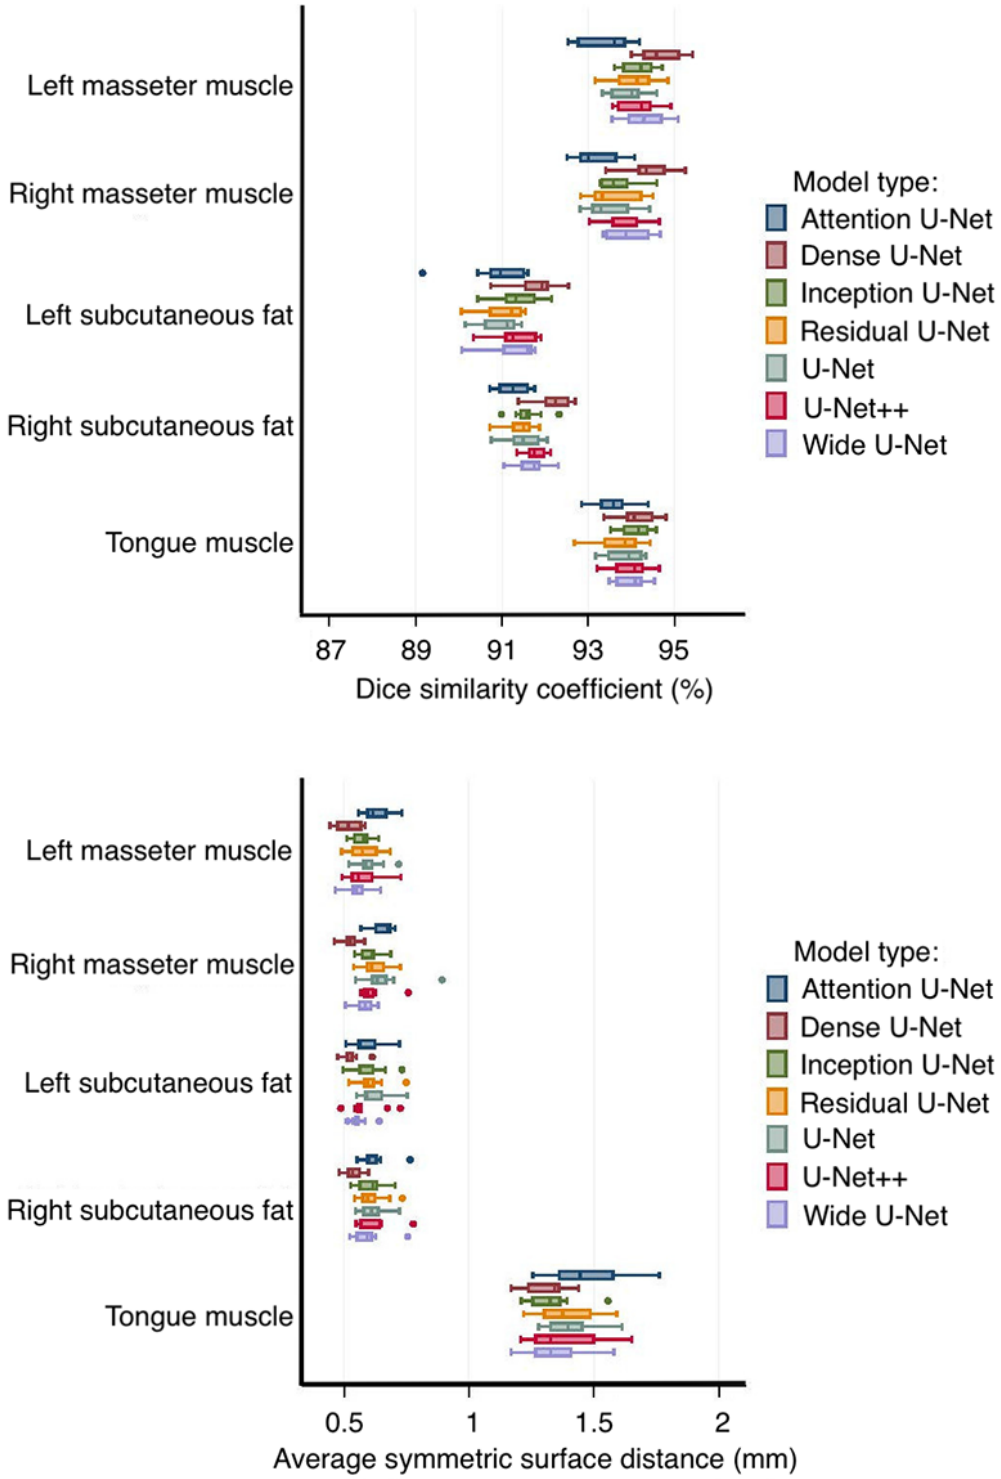


Table . Mean DSC and ASSD for test and validation results for k-fold (k=10) cross-validation. Standard deviation for the measurements in this table is presented in Multimedia Appendix 1.

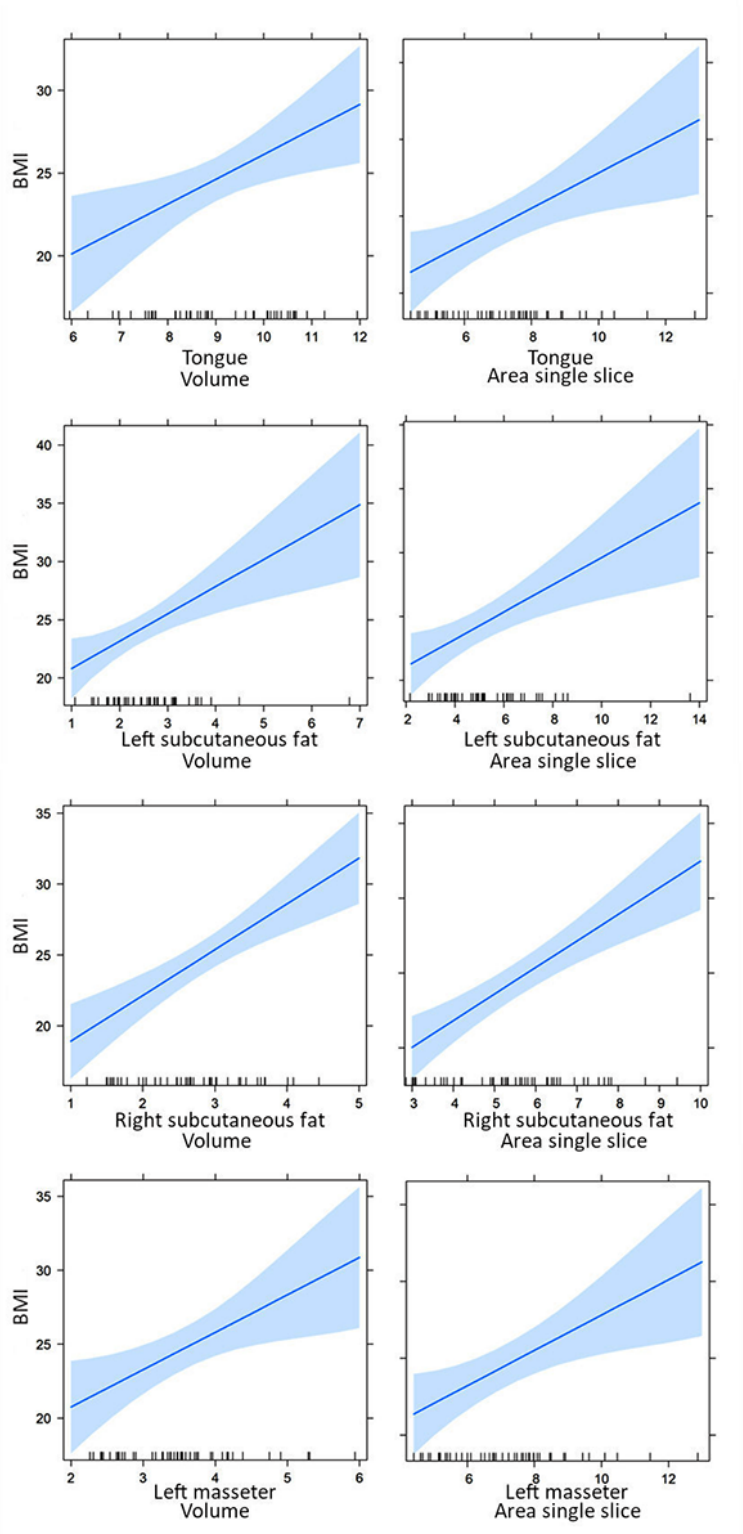
[g]ASSD: average symmetric surface distance.

Clinical Validation

To prove the clinical validity of the measurements, we evaluated the association between the segmented muscles and subcutaneous fat and BMI. We found a significant positive association between tongue muscle, left masseter muscle, and left and right subcutaneous fat and BMI (Figure 3). The area of a single slice as well as the volume of 5 slices per patient was calculated for this experiment. The results were adjusted by age and sex with $P<.05$ (Multimedia Appendix 2).

Figure 3. Individual linear regression repressing the relationship between quantitative results (area of a single slice and volume of 5 slices) from the Dense U-Net model and BMI.



Discussion

In this study, we evaluated the performance of six deep learning models for segmentation of the masseter muscles, subcutaneous fat, and tongue muscle in MRI images of the head. Several variations of the U-Net architecture were trained and tested using k-fold cross-validation. The use of deep neural networks for segmenting musculoskeletal tissues in patients with AD and LBD is a novel experimental contribution to the deep learning-based segmentation literature as well as the clinical literature.

Our study demonstrated that the Dense U-Net model performed superiorly to the other models in all evaluated regions by achieving an overall DSC of 93.43% and ASSD of 0.68 mm on the test data. The remaining models demonstrated comparable outcomes, except the Attention U-Net, which achieved slightly

less accurate results in all regions with an overall DSC of 92.46% and ASSD of 0.79 mm on the test data. Notably, despite having a comparable number of trainable parameters, the Dense U-Net model demonstrated a higher DSC and lower ASSD than the Wide U-Net model. The Dense U-Net model achieves superior performance with a similar number of parameters, suggesting that its architectural efficiency, rather than parameter quantity alone, drives this improvement.

The validation set produced similar results to the training set, indicating that the trained models did not suffer from overfitting. Although we applied data augmentation to the training data set (results not shown), it did not significantly improve the accuracy of the segmentation models.

Furthermore, we observed a significant correlation between the results and BMI, a well-established measure of nutrition and body composition. This underscores the validity and clinical relevance of this method. If these localized muscle measurements correlate with BMI, it suggests that they may reflect broader nutritional and body composition states.

Sarcopenia is a relatively newly recognized condition for which neuromuscular degeneration, central nervous system alpha motor unit loss, and fat infiltration into muscle are the most distinctive proven and observed pathogenic features, leading to loss of muscle mass and strength and predisposing to physical frailty [2]. We have proposed that non-invasive assessment of intermuscular adipose tissue and muscle mass by image analysis could constitute a viable method to diagnose sarcopenia and predict its associated outcomes, the clinical impact of which is also under study by our group [29].

The validity and clinical implications of measuring the masseter muscle have been shown in previous studies [30,31]. In recent work by our group, we compared the diagnostic capacity for sarcopenia between the gold-standard dual X-ray absorptiometry and our measurements of head muscles. The results showed that both methods had equivalent accuracy [32]. In older adults with glioblastoma, a decreased masseter diameter on preoperative imaging was associated with shorter overall survival and 90-day mortality after surgical resection [33]. In addition, low masseter muscle was significantly associated with worse overall survival in patients aged 65 years or older, diagnosed with squamous cell carcinoma of the head and neck and treated with curative intent [34]. Another study evaluated post-operative results after carotid endarterectomy; low masseter mass was associated with a prolonged hospital stay and recurrent stroke within 5 years [35]. In another study, preoperative masseter mass was a predictor of postoperative pneumonia in patients with esophageal cancer [36]. Additionally, other studies have shown that the masseter muscle can be used as a nutritional biomarker. The masseter muscle, analyzed via computed tomography (CT) anthropometry, showed a statistically significant association with systemic nutritional biomarkers [37]. On the other hand, the tongue has shown to be a good marker of prognosis, as tongue strength has shown to be helpful in diagnosing sarcopenia [38]. Previous studies from our group also report that tongue muscle volume is correlated with malnutrition and even brain structures in patients with dementia [18,29].

Therefore, the approach we present in this paper can be opportunistically used to quantify muscle volumes and investigate the implications of having low muscle mass in the masseter or the tongue in people with brain, head, and neck diseases. Thus, it is an important first step toward developing a more efficient method to estimate masseter and tongue muscle with a better capacity to be implemented in clinical practice. Manual and semi-automatic techniques have been employed in several studies for masseter muscle segmentation in MRI [39]. A recent study used shape determination to segment the masseter muscle in MRI images [40]. In this approach, a manual contour for 8 slices must be defined by the user, and the model then determines the shape for the remaining scans, reducing the time and labor required for segmentation. However, this technique still requires manual segmentation, which can be time-consuming and prone to user error compared to our approach.

Model-based techniques have also been explored for the segmentation of the mastication muscle [41,42]. Although these techniques have shown high accuracy (>90%), there must be a distinct boundary between the masseter muscle and surrounding tissues to ensure accuracy. This distinct boundary refers to visible differences in intensity, texture, or anatomical structure on imaging, which enable the models to accurately separate the muscle from adjacent tissues, such as fat or bone.

Machine and deep learning approaches have been widely used to segment muscles in various body parts. CT scans and cone beam CT scans have primarily been investigated for measuring the head organs, including masseter muscle using these techniques [43-45]. In a previous study, a basic U-Net model was applied to segment the masseter muscle in head CT scans to investigate hemifacial microsomia [46]. The mean DSC reported in that study was 79.4% for the experimental group and 82.4% for the group with mandible deformities, which are lower compared to the results obtained in our study. In a study using CT scan of the head for segmentation of masticatory muscles, deep learning techniques were superior to atlas-based techniques, achieving a mean DSC of 83% [47]. To the best of our knowledge, the techniques considered in our study have not yet been used to segment musculoskeletal tissues in MRI images of the head.

Our study had some limitations. The Attention U-Net model demonstrated the lowest DSC values and the highest ASSD values among the evaluated models, indicating suboptimal segmentation accuracy across tissues. This underperformance may be attributed to the Attention mechanism's inability to effectively focus on the target tissue, leading to dispersed attention, particularly in smaller structures or regions with indistinct boundaries. To address this limitation, future work could involve refining the Attention mechanism to enhance its specificity and focus on regions of interest. Alternatively, exploring models that prioritize multi-scale feature extraction and detail preservation may provide improved segmentation performance, particularly for small or complex anatomical regions.

The DemVest study had some limitations that may have impacted the results. Selection bias might have been present if

patients with more complex health conditions were included, as primary care referrals were used. The study was not specifically designed for the paper's purpose, which could limit the data analysis and interaction control. For example, the absence of a healthy control group prevents us from determining whether the observed muscle volume characteristics are specific to individuals with AD or neurocognitive disorders, or if they represent normal variations associated with aging. However, the primary objective of this study was to demonstrate the feasibility and accuracy of our deep learning model in quantifying muscle volumes using head MRI, rather than to establish definitive differences between diseased and healthy populations. In addition, the sample size is relatively small, and there is a risk that our results may not generalize to larger populations. Additionally, the MRI scans were obtained from a single center using a single MRI machine, which may affect the model's generalizability. Longitudinal analyses were not conducted because imaging was only performed at baseline, in line with the initial primary objectives of the DemVest study and the resources allocated for image acquisition.

These limitations should be considered when interpreting this study's results and addressed in future studies seeking broader application of the proposed approach. Whether masseter and tongue volumes in these muscles correlate with lean body mass and inflammaging and could be predictors of neurocognitive conditions and their associated outcomes remains unknown.

On the other hand, this study has several strengths, including well-characterized data, detailed and exhaustive diagnosis to correctly identify people with dementia, and an automated quality control and analysis pipeline. Additionally, the results fill a gap in the literature and provide insights into a possible method to efficiently diagnose sarcopenia in context when a head MRI is already available.

In summary, to our knowledge, this is the first study that validates deep learning methods that could be easily implemented in clinical practice to measure masseter and tongue muscle volumes with a solid potential to become biomarkers with strong predictive value for adverse outcomes in older persons with dementia. Since imaging is widely used in memory clinics worldwide, this opportunistic approach to image analyses could become standard practice in those settings. However, further large longitudinal studies are still required.

Acknowledgments

We want to thank the participants, researchers, and technical staff that made the DemVest study possible, as well as the staff and facilities provided by (SESAM) Centre for age-related medicine at Stavanger, Norway. This work was supported by the Norwegian government, through hospital owner Helse Vest (Western Norway Regional Health Authority) number 911973. It is also funded by the National Institute for Health Research (NIHR) Biomedical Research Centre at South London and Maudsley NHS Foundation Trust, King's College London, and the Australian Institute for Musculoskeletal Science (AIMSS). Mahdi Imani is supported by an Australian Government Research Training Program (TRP) Scholarship.

Abstract

Background: Artificial intelligence (AI) is increasingly being applied in various health care services due to its enhanced efficiency and accuracy. As the population ages, AI-based health technologies could be a potent tool in older adults' health care to address growing, complex, and challenging health needs. This study aimed to investigate perspectives on and acceptability of the use of AI-led health technologies among older adults and the potential challenges that they face in adopting them. The findings from this inquiry could inform the designing of more acceptable and user-friendly AI-based health technologies.

Objective: The objectives of the study were (1) to investigate the attitudes and perceptions of older adults toward the use of AI-based health technologies; (2) to identify potential facilitators, barriers, and challenges influencing older adults' preferences toward AI-based health technologies; and (3) to inform strategies that can promote and facilitate the use of AI-based health technologies among older adults.

Methods: This study adopted a qualitative descriptive design. A total of 27 community-dwelling older adults were recruited from a local community center. Three sessions of semistructured interviews were conducted, each lasting 1 hour. The sessions covered five key areas: (1) general impressions of AI-based health technologies; (2) previous experiences with AI-based health technologies; (3) perceptions and attitudes toward AI-based health technologies; (4) anticipated difficulties in using AI-based health technologies and underlying reasons; and (5) willingness, preferences, and motivations for accepting AI-based health technologies. Thematic analysis was applied for data analysis. The Theoretical Domains Framework and the Capability, Opportunity, Motivation, and Behavior (COM-B) model behavior change wheel were integrated into the analysis. Identified theoretical domains were mapped directly to the COM-B model to determine corresponding strategies for enhancing the acceptability of AI-based health technologies among older adults.

Results: The analysis identified 9 of the 14 Theoretical Domains Framework domains—knowledge, skills, social influences, environmental context and resources, beliefs about capabilities, beliefs about consequences, intentions, goals, and emotion. These domains were mapped to 6 components of the COM-B model. While most participants acknowledged the potential benefits of AI-based health technologies, they emphasized the irreplaceable role of human expertise and interaction. Participants expressed concerns about the usability of AI technologies, highlighting the need for user-friendly and tailored AI solutions. Privacy concerns and the importance of robust security measures were also emphasized as critical factors affecting their willingness to adopt AI-based health technologies.

Conclusions: Integrating AI as a supportive tool alongside health care providers, rather than regarding it as a replacement, was highlighted as a key strategy for promoting acceptance. Government support and clear guidelines are needed to promote ethical AI implementation in health care. These measures can improve health outcomes in the older adult population by encouraging the adoption of AI-driven health technologies.

Introduction

Background

Artificial intelligence (AI) refers to a computerized system that is capable of executing a wide range of tasks that typically involve human intelligence—ranging from physical tasks, cognitive functions, and problem-solving to decision-making—and can be performed without explicit instructions from humans [1]. AI can be classified into 4 main subsets—machine learning, natural language processing (NLP), physical robots, and robotic process automation. The field of AI is rapidly advancing, and AI technologies have been widely applied in different aspects of health care services, including diagnostic assistance, health screening, and imaging interpretations [2]. It has been described as a "second set of eyes" for medical practitioners [3]. Furthermore, over the past decade, the application of AI systems has increasingly centered on empowering patients to actively manage their health and boost their participation in the shared decision-making process, giving rise to diverse AI-driven products such as robots, smart assistants, virtual or augmented reality, wearable devices, and mobile apps [4]. Particularly notable is the emergence of AI-powered chatbot services, which permit patients to seek medical advice and receive triage for their conditions in a prompt and cost-effective manner [5]. With the debut of ChatGPT by OpenAI in November 2022 and the popularity it has gained, it is envisioned that AI-based conversational large language models with NLP abilities could conceivably revolutionize health care practice and education, contributing to substantial transformative shifts [6,7].

The world is currently encountering a significant expansion in the aging population, with the number of people aged 60 years or above anticipated to rise to 1.4 billion by 2030 and 2.1 billion by 2050 [8]. Conventional older adult health care has relied heavily on in-person monitoring; however, the further intensification of the shortage of health care workers could in the long run present a global challenge to the sustainability of delivering quality medical care [9]. In recent years, digital technologies, such as smart older adult health care products, which involve the deep integration of AI, have been used in older adult health care sectors [10]. Evidence has shown that AI-based technologies can play a constructive role in improving the physical and psychological well-being, quality of life, and independent living of older adults [11]. However, there is a great digital divide between the older and younger generations, with the former being the age group that is the least likely to have access to computers and the internet, due to physical obstacles such as physical disabilities and to psychological factors such as a lack confidence in using technology as well as ethical concerns [12,13].

While AI-based health technologies have rapidly evolved, and some studies have comprehensively discussed the advantages of applying them in the field of geriatrics, insufficient academic attention has been paid to acquiring a clear understanding of the attitudes, perceptions, and experiences of seniors toward these technologies [10]. This gap may implicitly influence the acceptance of, and motivation to use, these technologies in the future. In addition, while studies have primarily focused on the perceptions of medical practitioners and patients regarding AI health technologies, the perspectives of older adults—a key user group—have received limited attention [14-16]. For instance, although some research has explored older adults' views on general AI-powered technologies, their relevance to AI health technologies remains uncertain [17]. Concerns about accuracy, reliability, and trust in AI tools compared with in-person medical advice further underscore the need for targeted investigation. This study addresses this gap by exploring older adults' perceptions of and acceptability toward AI-based health technologies, with a specific focus on practical strategies to enhance adoption. By identifying barriers, facilitators, and preferences, the findings have clear clinical implications, offering actionable insights for health care providers, policy makers, and AI developers. These insights can inform the design of tailored, user-friendly AI tools and guide their ethical implementation in health care, ultimately improving older adults' health outcomes.

Theoretical Framework

The interview guide for this study was developed using the Theoretical Domains Framework (TDF) and the Capability, Opportunity, Motivation, and Behavior (COM-B) model behavior change wheel to comprehensively explore factors influencing the acceptability of AI-based health technologies among older adults. The TDF consists of 14 domains that integrate behavioral determinants derived from over 30 psychological theories [18]. To ensure comprehensive coverage of these domains, the interview guide focused on five key areas: (1) general impressions of AI, (2) previous experiences with AI-based technologies, (3) perceptions and attitudes toward AI-based health technologies, (4) expected difficulties and underlying reasons, and (5) willingness. These focus areas were aligned with the study objectives and systematically mapped to the relevant TDF domains, as summarized in Table 1. This approach ensured that all 14 domains were addressed, either directly or indirectly, during the interviews.

Table . The interview questions guided by the Theoretical Domains Framework (TDF).

Focus area	Aligned TDF domains	Example question
General impressions of AI[a]	Knowledge, emotion, and optimism	"What comes to mind when you think about artificial intelligence and its role in health technologies?"
Previous experiences with AI-based technologies	Memory, attention, and decision processes; knowledge; and skills	"Have you used any AI-based technologies before? Can you describe your experience?"
Perceptions and attitudes toward AI-based health technologies	Social or professional role and identity; beliefs about capabilities; beliefs about consequences; emotion; and optimism	"What are your thoughts about using AI-based technologies for managing your health?"
Expected difficulties and underlying reasons	Environmental context and resources; skills; social influences; behavioral regulation; and memory, attention, and decision processes	"What challenges do you think you might face when using AI-based health technologies? Why do you think these occur?"
Willingness	Intentions; goals; beliefs about capabilities; and reinforcement	"Would you be willing to use AI-based health technologies? Why or why not?"

[a]AI: artificial intelligence.

To further enhance the applicability of findings, the identified TDF domains were mapped to the COM-B behavior change wheel (Table 2). The COM-B model summarizes 6 sources of behavior—social or physical opportunity, automatic or reflective motivation, and physical or psychological capability. This model provided a practical framework for identifying specific behavior change factors and strategies to improve the acceptance and adoption of AI-based health technologies among older adults [19].

Table . Capability, Opportunity, Motivation, and Behavior (COM-B) model components and its relation to Theoretical Domains Framework (TDF) domains.

COM-B components		TDF domains
Capability		
	Psychological capability	• Knowledge • Skills • Memory, attention, and decision processes
	Physical capability	• Behavioral regulation • Skills
Opportunity		
	Social opportunity	• Social influences
	Physical opportunity	• Environmental context and resources
Motivation		
	Reflective motivation	• Social or professional role and identity • Beliefs about capabilities • Optimism • Beliefs about consequences • Intentions • Goals
	Automatic motivation	• Social or professional role and identity • Optimism • Reinforcement • Emotion

The interview guide included open-ended questions designed to elicit rich, detailed responses.

This structured mapping ensured that the interview guide covered all 14 TDF domains comprehensively, while tailoring the questions to elicit insights into factors influencing the acceptability of AI-based health technologies among older adults. While alternative models, such as the technology acceptance model and the unified theory of acceptance and use of technology are commonly used in technology adoption studies, these models primarily focus on individual perceptions, such as perceived usefulness and ease of use (technology acceptance model) or performance expectancy and effort expectancy (unified theory of acceptance and use of technology).

These constructs, while valuable, may not fully capture the complex interplay of factors influencing older adults' adoption of AI technologies.

The systematic alignment between the interview guide and the TDF framework facilitated the identification of theoretical mediators and behavioral determinants. This mapping subsequently informed the integration of the findings with the COM-B behavior change wheel, allowing for the development of tailored strategies to promote the use of AI-based health technologies in this population.

Objectives

The objectives of the study were (1) to investigate the attitudes and perceptions of older adults toward the use of AI-based health technologies; (2) to identify potential facilitators, barriers, and challenges influencing older adults' preferences toward AI-based health technologies; and (3) to inform strategies that can promote and facilitate the use of AI-based health technologies among older adults.

Methods

Study Design

A qualitative descriptive design was adopted for this study [20]. This approach helps in the effort to uncover and understand the experiences, attitudes, and perceptions of people, making it appropriate for this study. The findings from a qualitative descriptive study are able to inform strategies that promote and facilitate the use of AI-based health technologies, which makes it particularly useful for this research. To explore perceptions on and acceptability of the use of AI-based technologies in health maintenance among older adults, and to provide insights into their subjective views, in-depth semistructured interviews guided by an interview guide were conducted.

Participants and Recruitment

Community-dwelling older adults aged 60 years or above were recruited from a local community center using a convenience sampling method. Eligible participants included those with or without previous exposure to AI tools who were willing to participate and share their experiences. Exclusion criteria included underlying physical, psychological, or neurodevelopmental problems that impaired interaction, mental instability, cognitive impairments such as traumatic brain injury, substance abuse, dementia, severe psychiatric disorders, intellectual disability, or being bedridden.

Sampling and Sample Size

Convenience sampling approach was employed, guided by the principle of data saturation. The target sample size was 25 participants, which is commonly regarded as sufficient for qualitative descriptive studies to achieve thematic depth and richness [21]. Ultimately, 27 older adults were recruited, providing adequate data to explore the study's focus areas.

Data Collection

Data collection involved 3 sessions of semistructured interviews with each participant, each lasting 1 hour. To minimize ambiguity, AI was classified into 4 categories: machine learning, NLP, physical robots, and robotic process automation. Interviews covered five focus areas: (1) general impressions of AI; (2) previous experiences with AI-based technologies; (3) perceptions and attitudes toward AI-based health technologies; (4) anticipated difficulties in using AI-based health technologies and their underlying reasons; and (5) willingness, preferences, and motivations in accepting AI-based health technologies.

In the first focus area, examples of AI tools were not initially provided to elicit spontaneous responses. However, recognizing that participants might not be fully aware of everyday interactions with AI, the second focus area included real-life examples to clarify potential misconceptions. Examples of machine learning technologies included fitness tracking devices, such as Google Fitbit and Apple Watch, which monitor physical activity and provide insights into health trends. For NLP, the interviewer referenced virtual assistants like Siri (Apple Inc) and Alexa (Amazon Inc), as well as health care chatbots that answer patient inquiries. Computer vision was illustrated with examples of AI systems that analyze medical images, such as detecting abnormalities in x-rays or CT scans. This approach enabled a nuanced exploration of participants' experiences with general AI technologies versus their attitudes toward AI for health purposes. The data were securely stored in Cloud storage, accessible only to the research team.

Data Analysis

Thematic analysis was used in this study [22]. The interview recordings were first translated into English, transcribed, read, and reread to gain a sense of the participants' experiences. Initial ideas were noted down. Next, the data were coded to extract key insights from the transcript. The codes were reviewed in a weekly discussion with the supervisor to obtain agreement on the interpretations. The underlying subthemes that emerged from the codes were identified and the subthemes were further clustered into themes. The themes, subthemes, and representative quotes were used to present the findings. Data were mapped to TDF to identify underlying theoretical mediators that influenced the perceptions and acceptability to the older adults of the use of AI-based health technologies. Once these theoretical domains were identified, they were mapped to components of the COM-B behavior change wheel that matched theoretical mediators with corresponding key strategies.

Ethical Considerations

The study protocol and procedures were approved by the Ethical Committee of the Hong Kong Polytechnic University (approval HSEARS20230810006) on August 29, 2023, and adhered to the ethical standards of the Declaration of Helsinki. Before starting the study, all participants provided informed consent during a face-to-face interview with the researcher. All the participants were fully informed about the nature and purpose of the study. They were guaranteed the right to withdraw from the study at any time without adverse consequences. The collected data were encrypted and stored in a password-protected database. Although the researchers did not foresee any significant risks associated with the proposed study, the researchers recognized that older adults might experience discomfort or fatigue from sitting through the interviews. To address this, the researchers ensured that participants were given

scheduled breaks throughout the interview. In addition, participants were encouraged to request breaks as needed to ensure that they were comfortable during the entire interview process. Participants who completed the interviews received an HK $100 (US $12.80) supermarket gift voucher to compensate for transportation costs.

Results

Participant Characteristics

The study included 27 participants, with 18 females (66.7%) and 9 males (33.3%). The mean age was 69.44 (SD 6.7) years. Most participants were married (19/27, 70.4%) and had a high school education (14/27, 51.9%). A majority lived with family (19/27, 70.4%) and rated their health as good (14/27, 58.3%). In addition, 66.7% (18/27) reported having chronic diseases. Regarding technology, 51.9% (14/27) felt somewhat comfortable using smartphones or tablets, and 59.3% (16/27) were somewhat familiar with tech products. Over 80% (23/27, 85.2%) of participants had heard of AI health technology, though their familiarity was limited. AI product usage varied, with approximately half of the participants reporting they used AI products often or occasionally, while the other half reported they used them seldom or were unfamiliar with them. Most participants (21/27, 77.8%) believed AI was to some extent helpful in health management, and 66.7% (18/27) had a positive overall impression of AI. Further details about the characteristics of the participants are provided in Table 3.

Table . Participant characteristics.

Characteristic		Total (N=27)
Gender, n (%)		
	Men	9 (33.3)
	Women	18 (66.7)
Age (y)		
	Mean (SD)	69.44 (6.17)
	Median (IQR)	70 (66-74)
Marital status, n (%)		
	Single	1 (3.7)
	Married	19 (70.4)
	Divorced	1 (3.7)
	Widowed	6 (22.2)
Education level, n (%)		
	Primary school and below	4 (14.8)
	Junior high school	7 (25.9)
	High school	14 (51.9)
	College or university	2 (7.4)
	Postgraduate degree	0 (0)
Living status, n (%)		
	Live with family	19 (70.4)
	Live alone	7 (25.9)
	Did not complete	1 (3.7)
Self-rated health status, n (%)		
	Poor	1 (3.7)
	Fair	12 (44.4)
	Good	14 (58.3)
Any chronic diseases, n (%)		
	Yes	18 (66.7)
	No	9 (33.3)
Comfort level with using smartphone or tablet, n (%)		
	Very comfortable	10 (37.0)
	Somewhat comfortable	14 (51.9)
	Not very comfortable	2 (7.4)
	Completely uncomfortable	0 (0)
	Did not complete	1 (3.7)
Familiarity with technology products, n (%)		
	Very familiar	0 (0)
	Somewhat familiar	16 (59.3)
	Not very familiar	8 (29.6)
	Completely unfamiliar	2 (7.4)
	Did not complete	1 (3.7)
Have heard of AI [a] health technology, n (%)		
	Yes, very familiar	0 (0)

Characteristic		Total (N=27)
	Yes, somewhat familiar	11 (40.7)
	Yes, not very familiar	12 (44.4)
	No, completely unfamiliar	3 (11.1)
	Did not complete	1 (3.7)
Frequency of AI product usage, n (%)		
	Often used	6 (22.2)
	Occasionally used	6 (22.2)
	Seldom used	5 (18.5)
	Never used	7 (25.9)
	Did not complete	3 (11.1)
Attitude toward AI's helpfulness in health management, n (%)		
	Very helpful	2 (7.4)
	To some extent helpful	21 (77.8)
	Not helpful	0 (0)
	Uncertain	2 (7.4)
	Did not complete	2 (7.4)
Overall impression about AI technology, n (%)		
	Positive	18 (66.7)
	Neutral	6 (22.2)
	Negative	0 (0)
	Uncertain	1 (3.7)
	Did not complete	2 (7.4)

[a]AI: artificial intelligence.

Objective 1: Investigate Older Adults' Attitudes and Perceptions Related to the Use of AI-Based Health Technologies

General Impressions of AI-Based Health Technologies

Most participants had positive views of AI-based health technologies, recognizing their potential to improve health outcomes by enhancing health monitoring, providing personalized recommendations, and assisting in decision-making. However, there was also limited awareness and understanding of specific AI-based health technologies, with some participants confusing them with general technologies such as smartphones. In addition, concerns were raised about fraud and scams associated with AI-based health technologies.

Attitudes and Perceptions Toward AI-Based Health Technologies

Privacy and data security were recurring themes in participants' discussions of AI-based health technologies. Many participants expressed concerns about the potential misuse of personal data and highlighted the importance of robust security measures. These concerns were particularly pronounced among participants with limited experience using technology or those influenced by media reports of data breaches. However, a subset of participants viewed privacy as a societal issue rather than a specific risk associated with AI-based technologies. For instance, one participant remarked:

> *Yes, it's acceptable.…Uh, what privacy do you have? There is no privacy in the whole world. Everyone's mobile phone is being monitored.* [Participant 3]

Another noted:

> *Not to mention privacy nowadays, from where we sit now there is completely no privacy…even if you listen to this song now, then this song will automatically appear (on your phone). When you are viewing clothes, then you will see the clothes later on (on your phone).* [Participant 5]

These contrasting perspectives highlight the varying levels of concern about privacy among older adults and underscore the need for transparent communication about data security in the development and deployment of AI-based health technologies.

Trustworthiness and Accuracy

Trust in AI-based health technologies varied among participants, influenced by previous experiences, information sources, and perceptions of accuracy. While some acknowledged the utility of AI in self-monitoring, others expressed reservations about its accuracy and trustworthiness, stressing the irreplaceable value of human judgment and expertise in health care.

Objective 2: Identify Potential Facilitators, Barriers, and Challenges That Influence Older Adults' Preferences Toward AI-Based Health Technologies

Technological Barriers

Participants identified multiple technological challenges that hindered their ability to use AI-based health technologies effectively. These challenges included operational difficulties, limited digital literacy, and lack of access to required resources, such as hardware or stable internet connectivity. These barriers were particularly evident among participants with physical or cognitive impairments due to age-related degeneration.

For instance, 1 participant described how physical limitations affected their interaction with technology:

> *I have degeneration, too. I could remember a lot of things before. But now I can't. My body movements are slow now, so it's difficult for me to use AI-based health technologies.* [Participant 3]

Another significant barrier was self-perceived incompetence in using digital tools, often leading to frustration or feelings of inadequacy:

> *"I feel like I am stupid after learning something...."* [Participant 7]

In addition, resource-related challenges, such as a lack of access to necessary hardware (eg, smartphones) and stable internet connections, were raised, further limiting participants' ability to engage with AI technologies.

Emotional and Psychological Barriers

Emotional and psychological factors emerged as significant barriers to the adoption of AI-based health technologies. These included fear of technology, skepticism regarding its reliability, and concerns about losing human connection in health care interactions. The prevalence of scams and fraudulent activities in the digital age further compounded participants' fears, making them hesitant to trust digital tools.

For example, 1 participant expressed a deep apprehension about interacting with technology:

> *I don't feel comfortable with these technologies because they seem complicated, and I worry about making mistakes.* [Participant 6]

Concerns about scams were also prevalent, with another participant noting:

> *Nowadays, you hear so much about fraud. It makes me scared to trust anything online, even if it looks helpful.* [Participant 4]

These findings illustrate that emotional and psychological barriers are not only about individual fears but also reflect broader societal concerns regarding trust and safety in the digital world.

Perceived Usefulness and Relevance

Participants perceived AI-based health technologies as useful, particularly those that addressed specific health needs such as the monitoring of blood pressure, blood sugar, and cholesterol. They also appreciated technologies that could assist with health monitoring, reminders, and personalized care.

> *I hope that these three things could be more mature, help to reduce blood pressure, blood sugar, or blood cholesterol, whatever. At least I know whether my blood sugar is good or not; if it is not good, I will eat something and exercise to increase my physical capacity.* [Participant 3]

> *Yeah, like an alarm. As a reminder to alert you. Well, high blood pressure, high blood sugar, high cholesterol level, those we get when are older. If AI can help with these three things, it is definitely good.* [Participant 2]

Acknowledgment by Authorities

The endorsement of AI-based health technologies by official authorities or regulatory bodies significantly facilitated their acceptance and adoption. Participants felt more confident and trusting when these technologies were validated by reputable sources, such as health care agencies or government bodies.

> *If it is something organized by the Hospital Authority or the government, it will be more trustworthy. Because sometimes, if it is made by pharmaceutical companies, it may not necessarily be that clear.* [Participant 2]

> *Well, if you talk about it being official, like the doctors and government, I will assume that this AI is reliable, you will basically feel at ease.* [Participant 1]

> *I have to see if the AI comes from a large or a small company. For example, Hong Kong Polytechnic University, Baptist University — they are more reliable then.* [Participant 4]

Objective 3: Inform Strategies That Promote and Facilitate the Use of AI-Based Health Technologies Among Older Adults

Integration of Human Expertise

While recognizing the potential benefits of AI, participants emphasized the need for AI technologies to complement rather than replace human expertise in health care. They suggested that AI could be useful as an auxiliary tool for making preliminary medical suggestions, but that the final decision-making should involve consultations with a human being.

> *I just ask the AI, but I can ignore its answers or I will think about it again. It is just a reference and I won't believe it completely. Well, when you see a doctor, you won't just see one doctor, you will see many many right?...AI is just the first contact point.* [Participant 2]

User-Friendly Design

To enhance the acceptability of AI-based health technologies, it is crucial to develop solutions that are user-friendly and tailored to the specific needs of older adults. A user-friendly design should include simplified and intuitive interfaces that

minimize cognitive load, with features such as large, high-contrast text and icons for better visibility and ease of use. Voice command functionality can further improve accessibility for users with limited dexterity or vision impairments. In addition, providing step-by-step tutorials, user manuals in multiple formats (eg, videos and print), and accessible customer support can address challenges related to digital literacy. These features collectively ensure that the technology is not only easy to use but also aligns with the physical and cognitive capabilities of older adults, thereby fostering greater adoption and satisfaction.

Addressing Privacy and Security Concerns

Given the concerns around privacy and data security, the development of AI-based health technologies should include robust security measures to protect the personal information of users. Addressing these concerns is essential to building trust and encouraging adoption among older adults.

Government and Regulatory Support

Participants highlighted the importance of government and regulatory support in promoting the ethical implementation of AI in health care. Clear guidelines and endorsements from authoritative bodies can foster trust and enhance the acceptability of AI-based health technologies among older adults.

Table 4 provides a detailed description of how the identified barriers and facilitators toward the use of AI-based health technologies were mapped to the TDF domains and corresponding COM-B components. These mappings were derived from participants' responses during the interviews. The barriers and facilitators were categorized based on their alignment with the TDF domains and subsequently mapped to the COM-B components to identify actionable strategies for behavior change.

Table . Identified Theoretical Domains Framework (TDF) domains and Capability, Opportunity, Motivation, and Behavior (COM-B) components related to the adoption of artificial intelligence (AI)–based health technologies.

Barrier or facilitator	COM-B components	TDF domains	Illustrative participant quote
Barrier: limited technological skills	Capability	Knowledge and skills	"I find it difficult to use these technologies because my body movements are slow, and I don't know how to start." [P3]
Facilitator: perceived usefulness and relevance	Motivation	Beliefs about consequences, intentions, and goals	"If AI can help monitor my blood pressure or remind me, it would be very helpful." [P2]
Barrier: lack of official recognition or endorsement	Opportunity	Social influences	"If it's recognized by the government or hospitals, I would trust it more." [P1]
Facilitator: confidence in trustworthiness and accuracy	Motivation	Beliefs about capabilities	"If the results are accurate, I can rely on it for some guidance." [P4]
Barrier: privacy and data security concerns	Motivation	Emotion	"I worry about my personal information being stolen if I use this technology." [P5]
Facilitator: AI as an auxiliary tool for initial suggestions	Motivation	Beliefs about consequences and intentions	"I can use AI for some advice, but I still prefer to consult a doctor for the final decision." [P2]

Discussion

Principal Findings

The aim of the study was to provide insights into the perceptions and acceptability of AI-based health technologies among older adults, using the TDF and the COM-B behavior change wheel as theoretical frameworks. These frameworks were instrumental in identifying key behavioral determinants and mapping them to actionable strategies for enhancing AI adoption. In total, 9 of the 14 TDF domains (knowledge, skills, social influences, environmental context and resources, beliefs about capabilities, beliefs about consequences, intentions, goals, and emotion) were identified and mapped to 6 COM-B components (psychological capability, physical capability, social opportunity, physical opportunity, reflective motivation, and automatic motivation). By applying these frameworks, the study provided a structured approach to understanding the factors influencing older adults' behavior toward AI adoption. The responses of the participants shed light on various aspects of the adoption and utilization of AI-based health technologies among older adults. First, the participants expressed a range of attitudes and perceptions toward AI-based health technologies, including curiosity, skepticism, and enthusiasm toward the use of AI in the management and maintenance of health. These perceptions align with the TDF domains of knowledge and beliefs about consequences, which underscore the need to enhance understanding of AI and clearly communicate its benefits to older adults. The interviews provided a deeper understanding of the factors influencing these attitudes and the potential benefits and concerns associated with AI adoption in the context of the participants' health. They shared their perceptions of AI technologies, addressing aspects such as reliability, trustworthiness, and their perception of the impacts on health care outcomes. These insights informed the reflective motivation component of the COM-B framework, highlighting the

importance of fostering trust and reliability in AI-based technologies to enhance adoption.

In addition, the study revealed an interesting finding regarding older adults' preferences for using AI in asking for advice and self-health maintenance. Contrary to expectations, participants expressed a higher level of trust and reliability in real persons, particularly physicians, when making decisions about pharmacological interventions such as changing drug dosages. Participants believed that AI could play a valuable role in providing information and acting as a reference tool for self-health maintenance. However, they expressed reservations about relying solely on AI for decisions related to medication management. This finding is linked to the TDF domain of social influences and the social opportunity component of the COM-B framework, as participants emphasized the irreplaceable role of human expertise and interpersonal trust in health care decision-making. They viewed AI as a useful source of information but considered the expertise and experience of physicians and other health care professionals to be more reliable and crucial in making decisions regarding medical interventions and treatment. The emotion domain of TDF also played a role, as participants' skepticism and emotional barriers highlighted the importance of addressing concerns through education and reassurance. The findings were also in line with a mixed methods study indicating that the lack of empathy and a professional human approach made AI chatbots less acceptable to some users [15]. This insight has significant implications for the development of AI-based health technologies. It might indicate that older adults desire a collaborative approach that combines the benefits of AI with the guidance and expertise of real-person health care providers [23-25]. Developers could focus on creating AI systems that could provide accurate and evidence-based information, acting as a reference tool to support older adults' self-health maintenance efforts. In this context, AI could assist older adults in accessing reliable and up-to-date information about medications, potential side effects, and alternative treatment options. AI-based systems could also offer personalized recommendations for lifestyle modifications, nonpharmacological interventions, and self-care strategies that align with the preferences and needs of older adults.

While privacy and confidentiality are often considered to be potential concerns when using AI in health care, surprisingly, many expressed a relaxed and relatively pessimistic attitude toward privacy. One of the reasons for this was that the perceived benefits outweighed the concerns. Most expressed the view that the potential benefits of AI-based health technologies have overshadowed any concerns about privacy or confidentiality. They may have viewed the potential improvement in their health outcomes or access to personalized care as more significant than the potential risks to their privacy. Another underlying reason may be that the participants may have had other concerns that they considered more important than privacy and confidentiality in the context of AI-based health technologies. For example, they may have been more focused on the usability, effectiveness, or reliability of the technology. Regardless, the absence of expressed concerns does not necessarily indicate the lack of importance of privacy and confidentiality. Rather, it highlights the need for researchers and developers to proactively address these concerns and ensure that robust privacy and security measures are in place when designing and implementing AI-based health technologies. It is crucial for future research and development efforts to emphasize the importance of privacy and confidentiality in AI-based health technologies, which involves implementing strong data protection measures, obtaining informed consent from users, and transparently communicating how their data will be used and safeguarded.

To enhance older adults' acceptance of AI-based health technologies, strategies should focus on improving technological skills through tailored training programs, securing official recognition and endorsement from health care authorities, addressing concerns over privacy and data security with robust protocols, emphasizing the trustworthiness and accuracy of AI tools, positioning AI as auxiliary aids for medical suggestions, highlighting the usefulness and relevance of AI applications, and providing emotional support to mitigate psychological barriers. These strategies are directly informed by the COM-B framework, targeting capability, opportunity, and motivation as the key drivers of behavior change. By implementing these targeted strategies, older adults might be encouraged to embrace AI technologies, leading to improved health care outcomes and increased engagement with innovative health care solutions. Meanwhile, government endorsements could also contribute to the establishment of guidelines, standards, and regulations that ensure the ethical use of AI in health care, addressing concerns related to privacy, data security, and quality assurance.

Limitations

The limitations of this study were the sample size and representativeness of participants. While we recognize that this sample size may not fully capture the diversity of the population, the study aimed to offer initial, in-depth insights into older adults' perceptions of AI-based health technologies. Future studies could address subgroup comparisons by incorporating stratified sampling to examine variations across different demographic or socioeconomic groups. In addition, while quantitative comparisons were not a focus of this study, future research could include mixed method approaches to statistically assess participant perceptions and examine their relationships with demographic and contextual factors by using validated survey tools. Last but not the least, many participants had limited before knowledge or experience with AI-driven health technologies. Some participants conflated AI technologies with general digital tools, such as mobile apps, due to a lack of familiarity with the distinction. To address this, the interviewer provided concise explanations and real-life examples of AI subsets, including machine learning, NLP, computer vision, and expert systems. While this approach helped participants better understand the discussion, their responses were still shaped by their interpretations and familiarity with technology. Consequently, the findings reflect older adults' perceptions and acceptance of health technologies they associate with AI, rather than definitive perspectives on AI-driven health technologies.

Conclusion

While the majority of participants recognized the potential advantages of AI-based health technologies, they underscored

the indispensable role of human expertise and interaction. Vital strategies for improving acceptability include crafting user-friendly and customized AI solutions, addressing privacy concerns, ensuring robust security measures, and integrating AI as a complementary tool alongside health care providers. Government backing and guidelines can play a pivotal role in advancing ethical AI integration in health care, fostering trust, and enhancing personalized care for older adults, ultimately leading to improved health outcomes in this population.

Abstract

Background: Depression, characterized by persistent sadness and loss of interest in daily activities, greatly reduces quality of life. Early detection is vital for effective treatment and intervention. While many studies use wearable devices to classify depression based on physical activity, these often rely on intrusive methods. Additionally, most depression classification studies involve large participant groups and use single-stage classifiers without explainability.

Objective: This study aims to assess the feasibility of classifying depression using nonintrusive Wi-Fi–based motion sensor data using a novel machine learning model on a limited number of participants. We also conduct an explainability analysis to interpret the model's predictions and identify key features associated with depression classification.

Methods: In this study, we recruited adults aged 65 years and older through web-based and in-person methods, supported by a McGill University health care facility directory. Participants provided consent, and we collected 6 months of activity and sleep data via nonintrusive Wi-Fi–based sensors, along with Edmonton Frailty Scale and Geriatric Depression Scale data. For depression classification, we proposed a HOPE (Home-Based Older Adults' Depression Prediction) machine learning model with feature selection, dimensionality reduction, and classification stages, evaluating various model combinations using accuracy, sensitivity, precision, and F_1-score. Shapely addictive explanations and local interpretable model-agnostic explanations were used to explain the model's predictions.

Results: A total of 6 participants were enrolled in this study; however, 2 participants withdrew later due to internet connectivity issues. Among the 4 remaining participants, 3 participants were classified as not having depression, while 1 participant was identified as having depression. The most accurate classification model, which combined sequential forward selection for feature selection, principal component analysis for dimensionality reduction, and a decision tree for classification, achieved an accuracy of 87.5%, sensitivity of 90%, and precision of 88.3%, effectively distinguishing individuals with and those without depression. The explainability analysis revealed that the most influential features in depression classification, in order of importance, were

"average sleep duration," "total number of sleep interruptions," "percentage of nights with sleep interruptions," "average duration of sleep interruptions," and "Edmonton Frailty Scale."

Conclusions: The findings from this preliminary study demonstrate the feasibility of using Wi-Fi–based motion sensors for depression classification and highlight the effectiveness of our proposed HOPE machine learning model, even with a small sample size. These results suggest the potential for further research with a larger cohort for more comprehensive validation. Additionally, the nonintrusive data collection method and model architecture proposed in this study offer promising applications in remote health monitoring, particularly for older adults who may face challenges in using wearable devices. Furthermore, the importance of sleep patterns identified in our explainability analysis aligns with findings from previous research, emphasizing the need for more in-depth studies on the role of sleep in mental health, as suggested in the explainable machine learning study.

KEYWORDS

depression; classification; machine learning; artificial intelligence; older adults

Introduction

Depression is a prevalent mental health disorder characterized by emotional dysregulation, leading to persistent sadness, loss of interest, and anhedonia [1-3]. The rising incidence of depression among older adults has become a significant public health issue [4-6]. Early detection of depression and corresponding intervention are vital for improving mental health outcomes and reducing the overall burden on individuals and health care systems [7-9]. Traditional methods for assessing depression include various approaches that typically require in-person evaluations, specialized training in comprehensive geriatric assessments, and reliance on clinical judgment and questionnaires, which can be challenging and resource-intensive [10-12]. These methods require older adults to visit clinical settings frequently, increasing strain on health care facilities and reducing data collection opportunities. Additionally, many older adults prefer to remain in their homes and be remotely monitored in that environment, highlighting the need for remote care solutions in this demographic [13,14].

Physical activity and mobility are among the important factors in evaluating depression, with strong correlations established between these parameters and depression assessments [1,15]. The advent of the Internet of Things has enabled continuous and remote monitoring of physical activity. Several studies have used statistical methods to analyze the relationship between physical activity, as measured by wearable devices, and depression [16-21]. As the field of artificial intelligence (AI) advances, machine learning models have emerged as promising tools for depression classification using physical activity data [22]. For instance, Adamczyk and Malawski [23] used data from wearable actigraph watches in 3 classification models: logistic regression (LR), support vector machine (SVM), and random forest (RF) comparing automatic and manual feature engineering for depression classification. Bai et al [24] used phone use, sleep data, and step counts from 334 participants, using 2 feature selection methods (L1-based feature selection) and 6 machine learning models (decision tree [DT], k-nearest neighbors, naive Bayes, LR, SVM, and RF) for mood classification. Chikersal et al [25] analyzed data from smartphones and fitness trackers of 138 college students to identify those experiencing depressive symptoms, using nested randomized LR for feature selection and AdaBoost with gradient boosting classifier. Dai et al [26] used heart rate, energy expenditure, sleep, and other activity data from wearable Fitbit devices for depression remission detection in 106 participants within 2 intervention and control groups, using a multitask learning algorithm comprising 2 dense layers with shared parameters. Similarly, Griffiths et al [27] classified depression using activity and sleep data from Fitbit devices of 24 participants through an RF model. Espino-Salinas et al [28] used wrist-worn accelerometers to measure physical activity in 55 participants, applying a 2D-convolutional neural network (CNN) and a deep neural network for depression classification. Jakobsen et al [29] used RF, deep neural network, and CNN algorithms for depression classification with wrist-worn actigraph data from 55 participants. Jung et al [30] used gait accelerometry data and a bidirectional long short-term memory network–based classifier to assess depression in 45 older adults. Other studies have also explored the use of wearable device data combined with various classification methods, such as 1D-CNN [31], deep convolutional neuro-fuzzy [32], Ensemble models [33], and extreme gradient boosting [34].

These recent studies highlight the integration of wearable devices with machine learning algorithms as a promising approach for continuous, remote, home-based monitoring and early detection of depression. However, wearable device-based approaches face challenges due to their intrusive nature [35]. Participants are required to wear sensors or devices, which may lead to issues with compliance, comfort, and data accuracy, especially over extended periods [36], particularly among older adults [37]. These challenges can result in inaccurate data collection [38]. Nonwearable methods, such as remote monitoring through ambient sensors, offer potential solutions to these issues [37,39,40]. These approaches can alleviate concerns related to device adherence and physical discomfort, providing a more seamless integration into daily life. Additionally, our literature review indicates that most studies on depression classification use a relatively large number of participants and primarily use single-stage classifiers. Many studies also focus on detailed aspects of physical activity data (eg, body displacement, acceleration) using intrusive wearable sensors, which, while effective, present challenges related to user comfort and compliance. This reliance on wearable technology underscores the need for exploring alternative, less intrusive methods.

Recently, Wi-Fi–based sensing in smart homes has emerged as an alternative method for detecting and monitoring contextual human activity and movement [41]. Wi-Fi–based technologies are increasingly adopted due to their existing infrastructure in homes and minimal additional setup costs [42]. These technologies use signal metrics such as received signal strength indicator (RSSI) and channel state information (CSI) to analyze Wi-Fi signal characteristics, offering human activity identification compared to invasive wearable sensors, image analysis, or video-based systems [43]. Leveraging Wi-Fi–based activity data with machine learning presents a viable approach for different diseases, specifically depression classification, which is the focus of this study.

Technological and AI-based methods for depression classification predominantly rely on wearable sensors and are often conducted on large participant groups and typically use statistical techniques or single-stage machine learning classifiers. Furthermore, these approaches often overlook the explainability analysis of the models, which causes a lack of understanding of the underlying decision-making processes and the contribution of individual features to the model's predictions. To address these challenges, this feasibility study introduces a novel 3-stage machine learning model that incorporates feature selection, dimensionality reduction, and classification for depression classification. This model is specifically designed for a limited number of participants using low cost, easily installable Wi-Fi data, which provides continuous insights into human indoor activities. In addition to creating a model that functions effectively with small sample sizes, this study integrates explainable AI techniques to enhance the interpretability of the model's predictions. This approach ensures that the insights derived from the model are transparent and comprehensible, providing clarity on how specific features contribute to the classification outcomes. Figure 1 illustrates a schematic overview of our proposed framework.

Methods

Data Acquisition

We begin by outlining the data acquisition process for the participants, followed by an in-depth explanation of our proposed HOPE model.

Study Cohort

Our recruitment approach used both digital and in-person strategies. Digital outreach was conducted through email campaigns, social media platforms, and digital posters. Prospective participants were provided with detailed information about the study, and those who expressed interest received a consent form. A member of the research team then coordinated

the setup of the monitoring equipment. Participants were compensated for their time and involvement with an e-gift card.

Participants in this study were required to be aged 65 years or older, capable of communicating in English or French, and have access to an internet connection at home. Exclusion criteria were as follows: (1) individuals with mental or physical conditions that would impede their ability to participate in the study and its 6-month follow-up, such as gait or balance disorders, active mental health issues, or the use of mobility aids such as canes; and (2) individuals with current substance use disorder, including alcohol or drugs, due to their potential impact on physical mobility. However, individuals with a history of substance use disorder who were no longer consuming were considered eligible.

Experimental Protocol

This study used a nonintrusive Wi-Fi–based motion sensor system to facilitate remote monitoring of human activity. Initially, we collected demographic information (ie, age and gender) from the participants. Subsequently, Wi-Fi data were acquired through our remote monitoring technology [44]. This device, installed at the network access point, detects Wi-Fi signals in environments conducive to passive sensing, including private residences and public spaces where Wi-Fi is prevalent [45]. In such indoor settings, Wi-Fi signals exhibit stability in the absence of individuals but fluctuate significantly with the presence and movement of people [45]. These signal variations correspond to distinct patterns associated with human movements and activities, thus providing valuable data for activity monitoring [46]. The collected data were subsequently transferred to secure cloud storage via an internet connection. Our team has developed advanced signal processing and AI-based algorithms to process raw Wi-Fi RSSI and CSI measurements. These algorithms standardize signal variations and translate RSSI and CSI fluctuations into a detailed set of contextual information related to human activity [45]. This information encompasses daily activity duration, bedtime, wake-up time, total sleep duration, and sleep interruption information. In addition to using Wi-Fi–based activity data, frailty and depression statuses were also assessed using validated assessment tools. The Edmonton Frailty Scale (EFS), which measures multiple dimensions of frailty [47-49], and the 15-item Geriatric Depression Scale (GDS) [50] were administered at the end of the experiment.

Analytical Framework

The methodical steps of our proposed model are detailed in the following subsections. During the development, implementation, and reporting, we adhered to the Minimum Information About Clinical Artificial Intelligence Modeling (MI-CLAIM) guidelines [51], following best practices designed to promote transparency and reproducibility of our AI model.

Data Preparation and Feature Extraction

To prepare the contextual human activity data as input for depression classification, obtained from our Wi-Fi signal analysis software, we designed a preprocessing stage. This process involves handling missing values and outliers to ensure the integrity of the data [52,53]. To enhance analytical depth and improve model performance, we implemented feature engineering on contextual human activity data. This process involves extracting a variety of new features, such as the mean and SD of bedtime and wake-up times, mean and SD of sleep duration (in hours), total count and mean of sleep interruptions, total duration and mean duration of sleep interruptions (in hours), longest continuous sleep duration (in hours), percentage of nights with sleep disturbances, and metrics related to daily activity, including the mean and SD of total daily activity and hourly activity durations, as well as peak activity hour. These derived features, combined with EFS data, were incorporated into our 3-stage machine learning classification model. The depression status, determined using the GDS, was used to label the samples for classification purposes.

HOPE Model Development

The proposed HOPE Model was designed for depression classification in older adults using nonintrusive Wi-Fi–based motion sensor data. Due to the limited number of participants, it is necessary to provide an efficient pipeline for preprocessing, feature extraction, and classification. The limited number of participants and high dimensionality of features required a tailored multistage machine learning pipeline to maximize classification accuracy. Furthermore, ensuring that our depression classification model is explainable to clinicians is important, as highlighted in our previous works [54,55]. To address this, we incorporated explainable machine learning techniques such as Shapley additive explanations (SHAP) and local interpretable model-agnostic explanations (LIME). To achieve these goals, our proposed HOPE model was structured into 3 stages of machine learning architecture: feature selection, dimensionality reduction, and classification followed by post hoc explainability analysis using SHAP and LIME. Each stage plays a critical role in refining the data and ensuring that the final classification is both accurate and interpretable. Table 1 provides details on the various techniques used and evaluated at each stage.

[n]SVM: support vector machine.
[o]RFE: recursive feature elimination.
[p]RF: random forest.
[q]GBM: gradient boosting machine.

Feature selection is performed to reduce the dimensionality of the dataset by identifying the most relevant features for depression classification, enhancing both the speed and accuracy of the classification model [79]. The reduced subset of features serves as input for the subsequent dimensionality reduction stage. The validity of the chosen selected features is investigated using correlation analysis in the Results section. Dimensionality reduction techniques are applied to further refine the feature set compared to the initial feature selection stage [80] and to minimize overfitting. The dimensionally reduced features from the second stage were then processed in the third stage, which focused on classification. In this stage, the classification model processes the features derived from the earlier stages to categorize samples into 2 target classes: "participants with depression" and "participants without depression." The classification algorithm leverages the patterns identified in the features, such as sleep duration and interruptions, to make predictions. The classification task involved assigning a probability score to each sample, determining the likelihood of belonging to either class based on the relationships in the feature set. A decision boundary was then established to assign the final class label for each sample. The classification process was systematically evaluated to ensure robustness and reliability, focusing on separating the 2 groups effectively even with the small dataset. The machine learning classification pipeline was designed to minimize the risk of overfitting by using techniques such as feature selection and dimensionality reduction, ensuring that the most informative and relevant features were used for prediction. To conclude, we used explainable AI techniques to interpret the model's predictions, focusing on identifying the most influential features and their impact on classification outcomes.

Following the training and evaluation of all potential combinations for each stage, the architecture using sequential forward selection (SFS) for feature selection, principal component analysis (PCA) for dimensionality reduction, and DT for classification emerged as the most effective configuration. This SFS-PCA-DT framework (Figure 1)

demonstrated superior performance compared to other combinations.

Our proposed model is supported by different considerations. The SFS algorithm incrementally selects features to improve classification performance and is particularly suited for datasets with a smaller number of participants [81]. Unlike filter methods, SFS acts as a wrapper technique that pairs with a machine learning classification algorithm, providing greater stability in performance [81]. The method starts with no selected features and progressively adds them based on their ability to enhance cross-validation outcomes. In the second stage, PCA serves as a highly effective tool for reducing the dimensionality of data in an unsupervised manner [82]. It converts the initial set of features into a reduced number of uncorrelated components, maintaining the bulk of the data's variance. This reduction is important for preventing overfitting, especially with limited sample sizes. As a classification algorithm, DT algorithm, known for its strength in binary classification tasks, effectively uses the streamlined feature set generated in earlier stages. It models data by learning simple decision rules inferred from the input features, creating a tree-like structure. Each internal node in the tree represents a decision based on a feature, each branch represents an outcome of the decision, and each leaf node represents a class label [83]. The integration of SFS, PCA, and DT results in an efficient model that aligns with established methodologies and theoretical principles in the field. In this study, comprising only 4 participants, the training and validation procedure were carefully designed to minimize overfitting and to achieve reliable model generalization. To this end, we used a 4-fold cross-validation strategy. Each fold consisted of 3 participants for training and 1 participant for testing, ensuring that every participant contributed to both training and testing in separate iterations. This approach was repeated 10 times with different random seeds to account for variations in the training process, further enhancing the robustness of the performance metrics. During the training phase, a range of hyperparameter optimization techniques, including random search [84], Bayesian optimization [85], and Hyperband [86] was performed for each component of the 3-stage pipeline. For example, the DT classifier's maximum depth, minimum sample split, and criterion parameters are tuned using Bayesian optimization within predefined search spaces. Similarly, for PCA, the optimal number of components is optimized to maximize variance retention while preventing overfitting. The SFS algorithm was guided by internal cross-validation within the training set to identify the most predictive subset of features.

Evaluation Metrics

To validate the effectiveness of our depression classification method, we used 4 evaluation metrics: accuracy [87], sensitivity [87], precision [87], and F_1-score. Accuracy provides a comprehensive measure of the model's overall performance. Sensitivity helps ensure that the model accurately identifies as many true cases of depression as possible, minimizing the risk of missing individuals who actually have the condition [88]. To further validate the stability of the model, we present the training and test accuracies against the hyperparameter variations, demonstrating the model convergence.

Ethical Considerations

The study received approval from McGill University's Institutional Ethics Committee (A06-B18-21A), allowing data collection and analysis for this project. Written informed consent was collected from all participants prior to their involvement in the study. All collected data were anonymized immediately after collection, with no personally identifiable information retained to ensure participant confidentiality. Participants received a $20 e-gift card as compensation for their time. At every stage of the research, we adhered to the ethical principles outlined in the Declaration of Helsinki [89] and the Tri-Council Policy Statement [90].

Results

Clinical Study Insights

Six community-dwelling older adults residing in Montreal, Canada, were recruited for this study between May 2022 and September 2022. However, 2 participants withdrew due to internet connectivity issues, resulting in the use of data from the remaining 4 participants for the analysis. The EFS results indicated that 2 participants exhibited moderate frailty (scores ranging from 6 to 11), while the other 2 participants were classified as nonfrail (scores of 5 or below). GDS results suggested that 1 participant had depressive symptoms (score=10), while the other 3 participants did not (score range=0-4).

Some of the participants' demographic and clinical characteristics are detailed in Table 2. Over a 6-month period, the activities of each participant were continuously monitored at 15-minute intervals using Wi-Fi motion sensors. Following the identification of potential input features derived from Wi-Fi signals and questionnaire data, we designed and developed a 3-stage architecture as outlined in the methodology section. To support future research and ensure the reproducibility of our findings, the code for our model is openly accessible on our lab's GitHub repository [91].

Table 2. Demographic and clinical characteristics of the participants of this study.

	Participant without depression (n=3)	Participant with depression (n=1)
Sex (female/male), n/n	1/2	1/0
Age (years), mean (SD)	67.05 (3.70)	65.50 (0.00)
Edmonton frailty scale, mean (SD)	3.34 (3.21)	7.00 (0.00)
Geriatric depression scale, mean (SD)	4.00 (1.00)	10.00 (0.00)

We assessed a total of 240 model configurations, which resulted from the combination of 5 feature selection methods, 4 dimensionality reduction techniques, and 12 classifiers. Each configuration was trained 10 times to account for variations in performance metrics, ensuring the robustness of our findings. To mitigate the overfitting risk, we used k-fold cross-validation [92]. We experimented with different initial feature sets to optimize model performance, and among the various hyperparameter tuning methods, Bayesian optimization consistently yielded superior results.

Model Performance and Validation

This section presents the outcomes of our classification model evaluation. Table 3 summarizes the top-performing configurations among the 240 model variations that we tested. The SFS-PCA-DT model, which integrates SFS, PCA, and DT, emerged as the leading performer across multiple metrics. Its relatively high accuracy indicates the model's ability to distinguish between individuals with and without depression. The model's high sensitivity ensures that individuals with depression are correctly identified. This is critical in clinical settings, where depression, particularly among older adults, often goes unrecognized despite its severe impact on cognitive function [93-96], quality of life [97,98], and mortality risk [99,100]. Ensuring high sensitivity reduces the likelihood of missed diagnoses, which is important for timely and effective treatment. However, the relatively high standard deviation in both accuracy and sensitivity suggests that the model's performance may vary, indicating occasional instances of less reliable predictions.

Table 3. Average classification performance of the top 5 architectures.

Model	Accuracy (%)	Sensitivity (%)	Precision (%)	F_1-score (%)
SFS[a] – PCA[b] – DT[c]	87.50 (12.50)	90.00 (20.00)	88.34 (18.34)	86.00 (14.74)
SFS + FA[d] + DT	85.00 (16.58)	83.34 (25.82)	90.00 (20.00)	81.67 (18.93)
SFS + PCA + LR[e]	82.50 (19.53)	85.00 (22.91)	83.34 (25.82)	80.00 (20.82)
SFS + PCA + SVM[f]	82.50 (19.53)	90.00 (20.00)	75.00 (22.42)	80.00 (20.82)
MI[g] + PCA + LR	80.00 (10.00)	85.00 (22.91)	78.34 (22.42)	76.00 (13.06)

[a]SFS: sequential forward selection.

[b]PCA: principal component analysis.

[c]DT: decision tree.

[d]FA: factor analysis.

[e]LR: logistic regression.

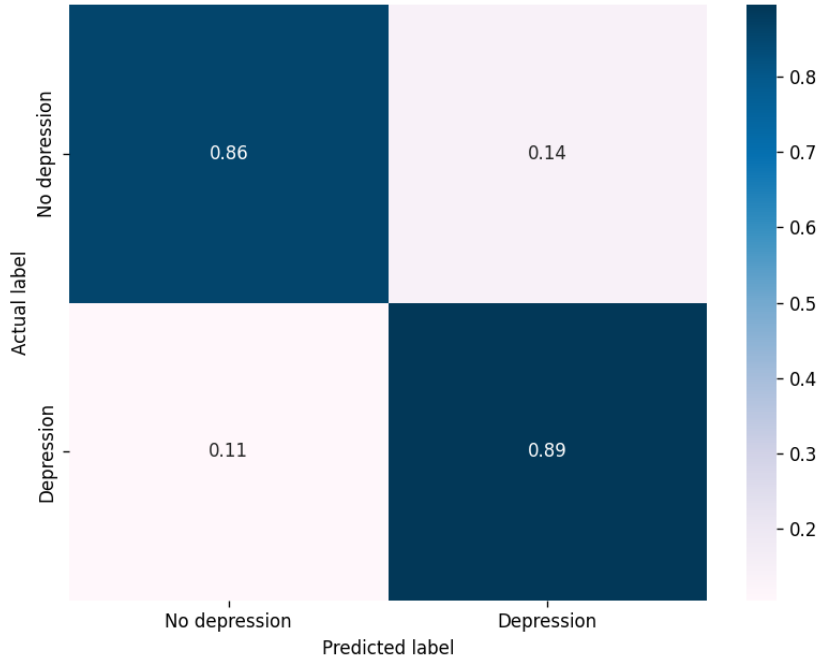
[f]SVM: support vector machine.

[g]MI: mutual information.

Table 3 illustrates that SFS is frequently featured among the highest-performing models, including the top model with 87.50% accuracy, and 3 other strong contenders. Mutual information also proves effective, appearing in 1 model with 80.00% accuracy, indicating that both SFS and mutual information are potent feature selection techniques for depression classification with limited samples. PCA seems to be the preferred method for dimensionality reduction, being used in 4 of the top 5 models. Among classifiers, DT stands out, featuring in the top 2 models with 87.50% and 85.00% accuracy. Other classifiers, such as LR and SVM, also perform well, each appearing in models with an accuracy exceeding 80%. The results highlight interesting tradeoffs, such as the SFS + PCA + SVM model, which, while slightly lower in accuracy (82.50%), maintains a high sensitivity (90.00%). This supports the practice of evaluating models using multiple metrics, especially in situations where the application involves clinical diagnoses, where accurately identifying true positives is crucial.

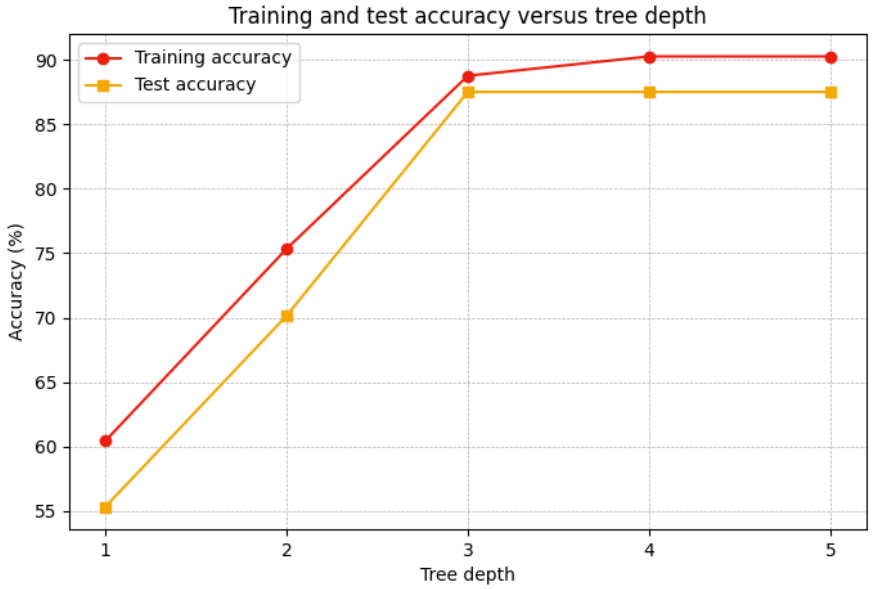
Figure 2 displays the averaged confusion matrix for the top-performing SFS – PCA – DT model used to classify depression status. Due to the constraint of having only 4 samples, we used a 4-fold cross-validation strategy, with each fold being tested 10 times to ensure a thorough evaluation. The model showed promising results, accurately classifying 86% of individuals without depression as not having depression and 89% of individuals with depression as having depression. The average false positive rate, where individuals without depression were incorrectly classified as having it, was 14%, while the average false negative rate, where individuals with depression were incorrectly classified as not having it, was 11%.

Figure 2. Confusion matrix for the top-performing model (SFS – PCA – DT). DT: decision tree; PCA: principal component analysis; SFS: sequential forward selection.



To validate the convergence of the proposed algorithm, we analyzed the relationship between tree depth and accuracy on both the training and test datasets. Figure 3 demonstrates the training and test accuracy of the best performing model (SFS – PCA – DT) as a function of tree depth. The training accuracy increases consistently with tree depth, stabilizing at its maximum, reflecting that the model can fully capture the training data as depth increases. The test accuracy improves initially with increasing tree depth but stabilizes beyond a depth of 3. These observations confirm that the proposed algorithm achieves convergence in terms of performance tradeoffs between model complexity and generalization.

Figure 3. Training and test accuracy as a function of tree depth, demonstrating convergence of our proposed model.

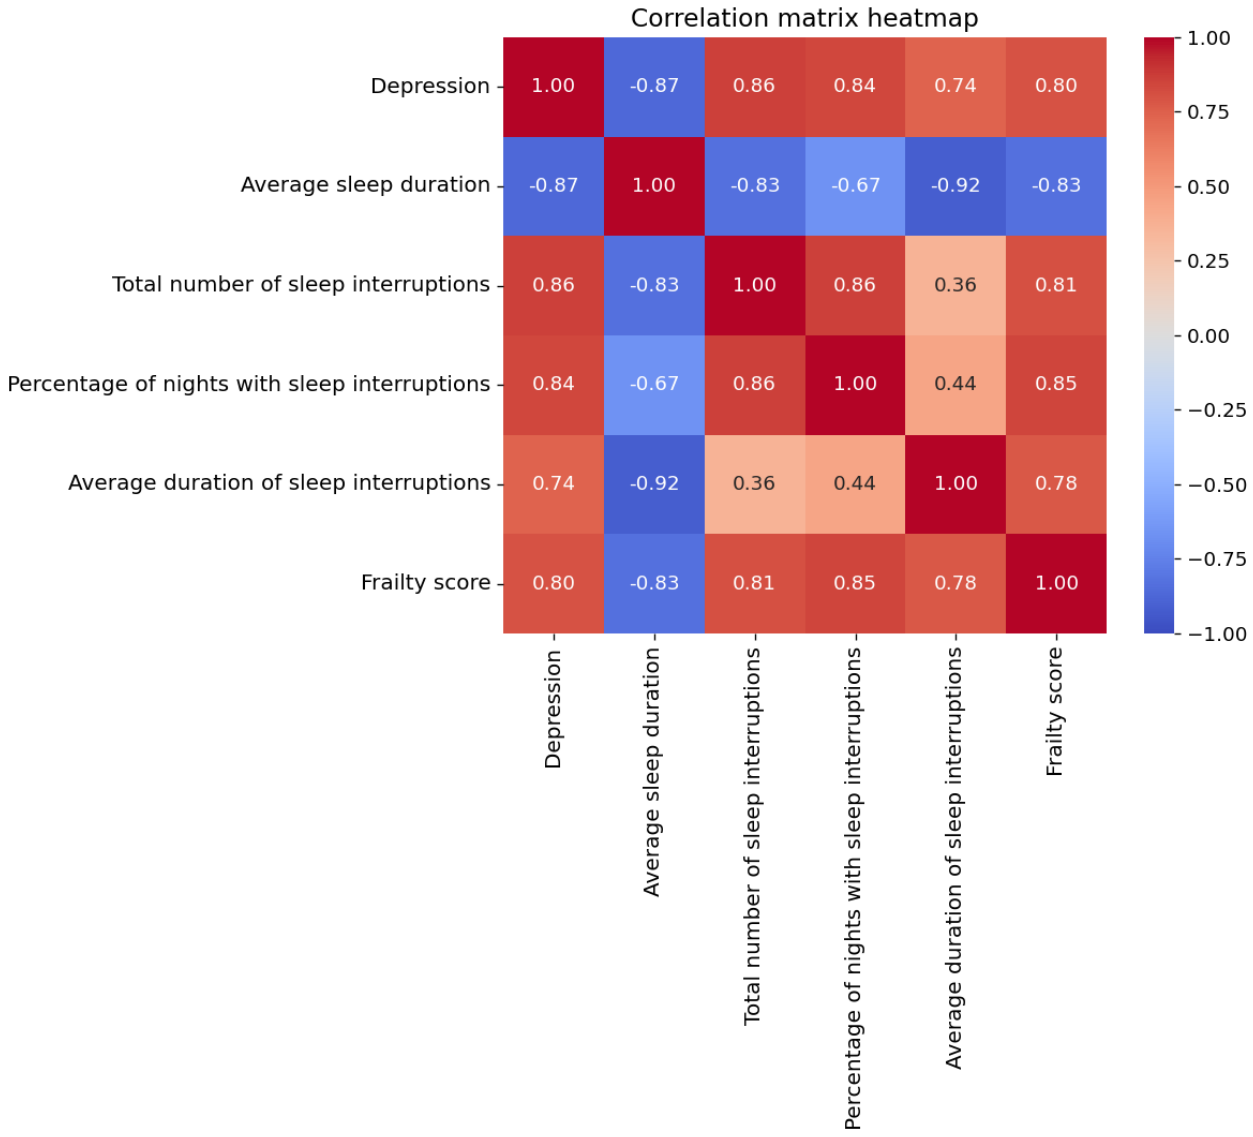


Feature Selection and Analysis

In our 3-stage classification model, we implement a combination of feature selection and dimensionality reduction techniques to improve the efficacy of our machine learning approach [80]. The features selected by SFS included “average sleep duration,” “total number of sleep interruptions,” “percentage of nights with sleep interruptions,” “average duration of sleep interruptions,” and “EFS.” Correlation analysis of these features revealed notable associations with depression status. Such analysis helps identify how variations in these features might be related to changes in depression, providing valuable insights for clinicians and researchers to develop more effective diagnostic tools and treatments.

Figure 4 illustrates a strong negative correlation between depression and average sleep duration. Conversely, depression was positively correlated with the total number of sleep interruptions, percentage of nights with sleep interruptions, average duration of sleep interruptions, and EFS. Blue cells indicate negative correlation values, while red cells represent positive correlations. Darker colors signify stronger correlations. The high correlation values highlight the significance of these factors in understanding and potentially classifying older adults with depression, aligning with findings from previous studies [101-105]. For example, Vallance et al [106] demonstrated that engaging in daily activities can alleviate the adverse effects of depression among older adults. Furthermore, several studies have highlighted a connection between depression and frailty [107,108]. Vaughan et al [109] showed that the prevalence of both depression and frailty among individuals aged 55 years and older exceeds 10%. These findings confirm the association between depression and the features incorporated in our model.

Figure 4. Correlation matrix heatmap between depression and selected features by sequential forward selection.



Comparative Analysis With Baseline Models

In this section, we evaluate the performance of our proposed 3-stage architecture for depression classification, which leverages Wi-Fi–based contextual human activity data, against baseline models previously outlined in the introduction. Although direct comparisons are inherently difficult due to differences in data acquisition methods (wearable devices), feature sets, and sample sizes, this analysis serves to contextualize the effectiveness of our approach for our case study with a limited number of participants.

For the baseline models, we selected the most current classification architectures used in the literature for depression classification. To ensure a fair comparison, each baseline model was trained and tested using the same feature set applied in our experiment. The resulting performance metrics for each baseline model are presented in Table 4. Despite the challenges associated with our smaller sample size, the comparison offers valuable insights into the relative efficacy of our method.

Table 4. Average performance across different baseline machine learning models.

Model architecture	Accuracy (%)	Sensitivity (%)	Precision (%)	F_1-score (%)
RF[a] [23,27]	12.50	5.00	5.00	N/A[b]
SVM[c] [23]	15.00	10.00	10.00	N/A
LR[d] [23]	22.50	15.00	13.34	N/A
XGBoost [34]	25.00	10.00	10.00	N/A
L1-based feature selection + DT[e] [24]	32.50	35.00	18.34	N/A
L1-based feature selection + RF [24]	22.50	15.00	13.34	N/A
L1-based feature selection + kNN[f] [24]	22.50	15.00	13.34	N/A
L1-based feature selection + NB[g] [24]	30.00	25.00	15.00	N/A
L1-based feature selection + LR [24]	37.50	45.00	25.00	N/A
L1-based feature selection + SVM [24]	25.00	10.00	10.00	N/A
Randomized LR + AdaBoost [25]	55.00	73.33	55.00	N/A
HOPE model[h]	87.50	90.00	88.34	86.00

[a]RF: random forest.

[c]SVM: support vector machine.

[d]LR: logistic regression.

[e]DT: decision tree.

[f]kNN: k-nearest neighbor.

[g]NB: naive Bayes.

[h]Best performed proposed model.

As shown in Table 4, traditional single-stage machine learning classifiers such as RF, LR, and SVM demonstrate relatively lower performance, with accuracy ranging from 12.50% to 22.50%. Among these, LR achieves relatively higher accuracy. XGBoost exhibits better performance than the traditional models. Incorporating feature selection techniques further improves the performance of these models. Specifically, combining L1-based feature selection with various classifiers results in modest performance gains, while the randomized LR combined with AdaBoost achieves a significant improvement, reaching 55.00% accuracy and 73.33% sensitivity. Our proposed 3-stage architectures significantly surpass all other baseline models across all metrics. While most baseline models struggle with sensitivity and precision, often scoring below 15%, our best proposed model demonstrates substantial enhancements in these metrics with 90.00% sensitivity and 88.34% precision, indicating a superior capability to correctly identify positive cases and reduce false positives.

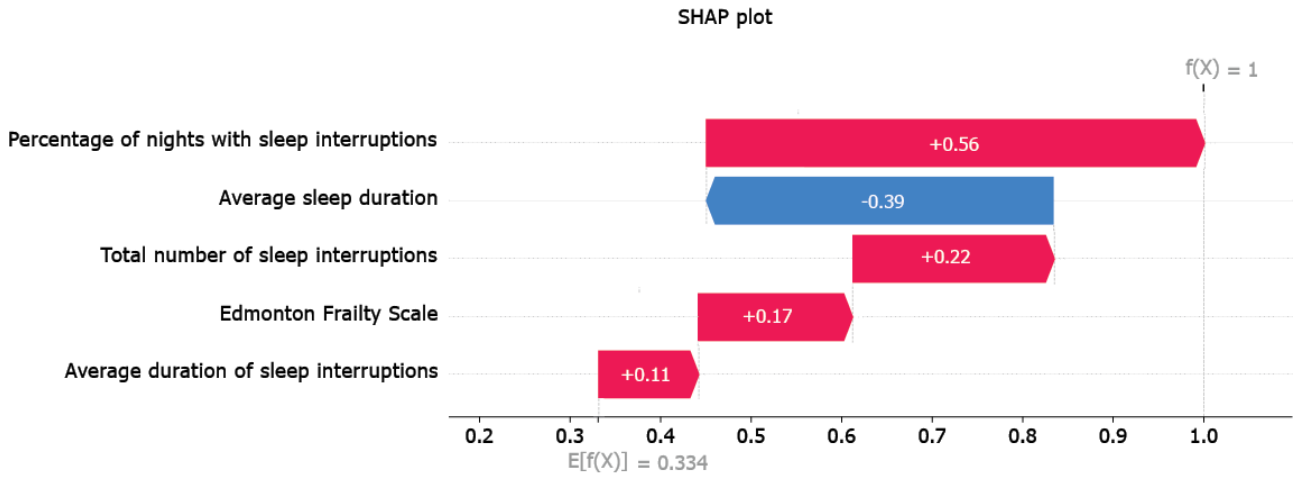
Model Explainability

To enhance our understanding of the decision-making processes within our proposed model, we used SHAP [50] and LIME [54] for model interpretability analysis. These model-agnostic methods can be applied across various machine learning models, providing valuable insights into our model's predictive behavior. By integrating these interpretability techniques, we aim to improve the transparency and potential clinical relevance of our depression classification framework. These methods help us identify which features most significantly influence the model's predictions, particularly in the context of depression classification.

SHAP Analysis

The SHAP waterfall plot (Figure 5) illustrates the relative importance of features for depression classification, with red and blue colors representing positive and negative contributions, respectively. Among the features, "the percentage of nights with sleep interruptions" is the most impactful, positively correlating with depression risk, indicating that frequent sleep disturbances are a strong predictor of depression. Conversely, the average sleep duration exhibits a substantial negative impact on depression prediction, suggesting that longer sleep durations are associated with a reduced likelihood of depression. Sleep-related variables continue to play a pivotal role in the model's predictions; both the total number of sleep interruptions and the average duration of these interruptions contribute positively to depression risk, further underscoring the importance of uninterrupted sleep in depression diagnosis. Although the frailty scale is included in the model, its influence is relatively minor compared to sleep-related features.

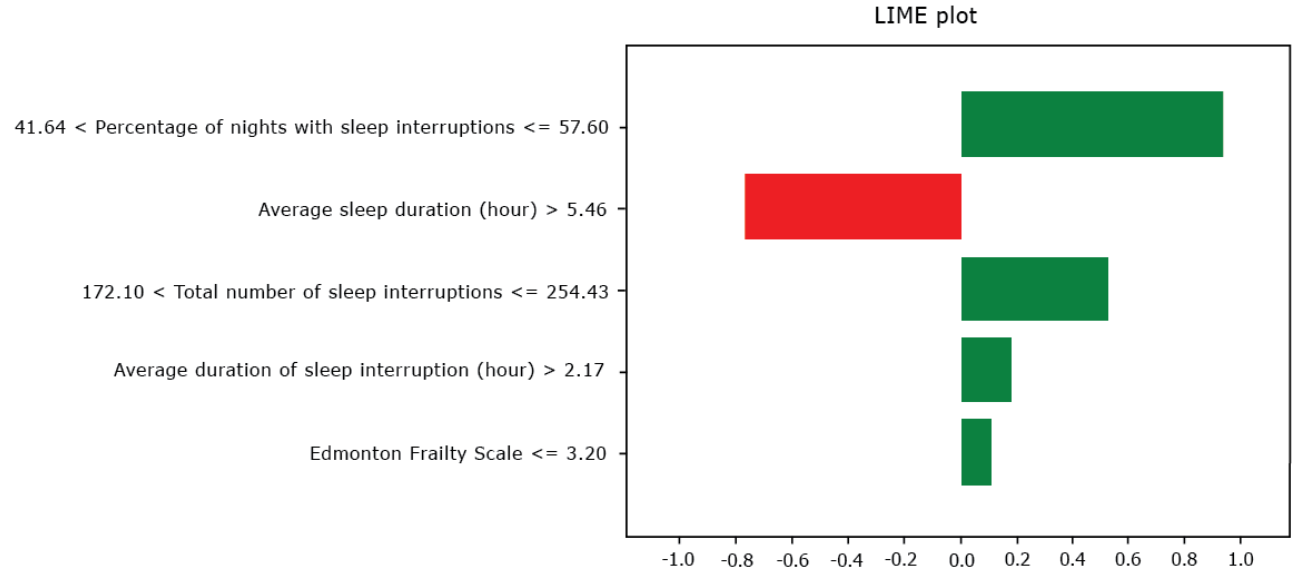
Figure 5. SHAP analysis. SHAP: Shapley additive explanations.



LIME Analysis

The LIME plot (Figure 6) provides a complementary view of feature importance, with green and red colors indicating positive and negative influences, respectively. Consistent with the SHAP results, LIME identifies "the percentage of nights with sleep interruptions" as the most critical feature in the classification of depression of our proposed model. Similarly, the average sleep duration is shown to have a significant negative impact on depression classification, in line with SHAP findings. The total number of sleep interruptions also ranks highly with a positive influence on depression risk, again aligning with SHAP results. A notable difference between the 2 methods is the relatively lower impact of the frailty scale in the LIME analysis, which requires further investigations.

Figure 6. LIME analysis. LIME: local interpretable model-agnostic explanations.



Discussion

Our research uses Wi-Fi–based motion sensors to extract daily activities, which are then used in our proposed machine learning method for depression classification.

Our study findings confirm the feasibility of using Wi-Fi–based motion sensors for depression classification among older adults. Our proposed HOPE (Home-Based Older Adults' Depression Prediction) model achieved an accuracy of 87.5%, sensitivity of 90%, and precision of 88.3%. The most influential features identified were sleep-related metrics, such as average sleep duration and sleep interruptions, highlighting the importance of sleep patterns in depression classification. These findings suggest that Wi-Fi–based monitoring offers a nonintrusive and effective alternative to conventional wearable technologies for depression assessment. These conventional methods, while effective, often present challenges in terms of participant compliance, particularly among older adults, due to their burdensome and sometimes uncomfortable nature. In contrast, our Wi-Fi–based approach is nonintrusive and allows for continuous monitoring without requiring participants to wear or interact with any devices. This can significantly enhance participant compliance and the integrity of the data collected over extended periods. Compared to other nonintrusive monitoring technologies, such as camera-based methods, our Wi-Fi–based approach has distinct advantages. Wi-Fi infrastructure is prevalent in most homes and does not pose

privacy risks, making it a cost-effective and scalable solution for continuous health monitoring. Furthermore, unlike previous studies that rely on microlevel body displacement and accelerometer data, our study emphasizes macrolevel physical activity features like sleep patterns and overall activity levels shift is crucial as it highlights the potential of using broader, more easily obtainable metrics to assess depression status. Our findings demonstrate that these macrolevel features are not only feasible but also effective measures for depression classification, broadening the scope of nonintrusive monitoring technologies in mental health research. The next steps can be extracting more detailed types of human activity using nonintrusive Wi-Fi data and expanding more on using this type of data acquisition for depression classification.

Additionally, our proposed model demonstrates relatively high performance compared to other classification models presented in existing depression classification studies, even with a limited sample size. Many studies using physical activity data from wearable devices often benefit from larger datasets and frequently use single-stage classifiers or deep neural networks. These models generally show strong performance with abundant data; however, their effectiveness diminishes when applied to smaller datasets, such as the one in this feasibility study. To address the limitations imposed by our smaller sample size, we designed a 3-stage machine learning classification architecture, which combines feature selection, dimensionality reduction, and classification into a multistep process. This approach allows for the extraction of the most relevant features while minimizing noise, thereby improving classification performance. Despite the small sample size, our model consistently outperformed conventional single-stage classifiers, highlighting the strength of both the machine learning architecture and the selected human activity features—particularly sleep patterns and activity levels—used for depression classification. This also underscores the adaptability of our model to different data scales, making it a more versatile option for future research where data availability might be limited. While this model shows promising results, however, caution is needed in interpreting these results. Future work should aim to enhance its robustness and generalizability by expanding the dataset. Collecting Wi-Fi–based physical activity data from a larger and more diverse sample would not only improve the model's statistical power but also allow for a more comprehensive evaluation of its performance across different population groups, such as varying age ranges and health conditions. This would be particularly valuable in developing a scalable solution for real-world applications. Additionally, the integration of advanced machine learning techniques, such as deep neural networks or hybrid models combining traditional classifiers with deep learning components, could further enhance classification accuracy.

Our study is distinctive not only in its methodological approach but also in its emphasis on model explainability, a crucial aspect often overlooked in prior research on depression classification. Explainability is essential in health care applications, where understanding the factors driving a model's decision is critical for clinical adoption and trust. By using SHAP and LIME, we were able to dissect the decision-making process of our model and pinpoint the most influential features for classifying depression. Both explainability analyses converge on the identification of sleep interruption features as key predictors in the depression classification of our proposed model. Among these, the "percentage of nights with sleep interruptions," "average sleep duration," and "total number of sleep interruptions" emerged as the primary driving factors. These findings align with existing literature that highlights the strong correlation between sleep disturbances and depression. However, our approach goes a step further by quantifying the impact of these features on the classification outcomes, providing a more nuanced understanding of their role. These findings suggest that future tools for depression assessment may benefit from a stronger focus on sleep quality and patterns and further investigations are required in this regard.

The integration of sensors and AI is transforming health care, yet the application of these technologies in depression classification remains underdeveloped and lacks extensive investigation. This study aimed to create an automated machine learning system for the continuous, remote monitoring and assessment of daily physical activity among older adults in a home setting, with the goal of distinguishing between individuals with and without depression.

In summary, although there were some challenges, our results suggest that using Wi-Fi–based data to capture contextual human activities is a promising and efficient method for classifying depression. The model we developed, leveraging data from Wi-Fi motion sensors, showed strong potential in accurately identifying early signs of depression and paving the way for more advanced and accessible mental health monitoring technologies among community dwelling older adults..

Abstract

Background: Parkinson disease (PD) is a progressive neurodegenerative disorder that affects motor coordination, leading to gait abnormalities. Early detection of PD is crucial for effective management and treatment. Traditional diagnostic methods often require invasive procedures or are performed when the disease has significantly progressed. Therefore, there is a need for noninvasive techniques that can identify early motor symptoms, particularly those related to gait.

Objective: The study aimed to develop a noninvasive approach for the early detection of PD by analyzing model-based gait features. The primary focus is on identifying subtle gait abnormalities associated with PD using kinematic characteristics.

Methods: Data were collected through controlled video recordings of participants performing the timed up and go (TUG) assessment, with particular emphasis on the turning phase. The kinematic features analyzed include shoulder distance, step length, stride length, knee and hip angles, leg and arm symmetry, and trunk angles. These features were processed using advanced filtering techniques and analyzed through machine learning methods to distinguish between normal and PD-affected gait patterns.

Results: The analysis of kinematic features during the turning phase of the TUG assessment revealed that individuals with PD exhibited subtle gait abnormalities, such as freezing of gait, reduced step length, and asymmetrical movements. The model-based features proved effective in differentiating between normal and PD-affected gait, demonstrating the potential of this approach in early detection.

Conclusions: This study presents a promising noninvasive method for the early detection of PD by analyzing specific gait features during the turning phase of the TUG assessment. The findings suggest that this approach could serve as a sensitive and accurate tool for diagnosing and monitoring PD, potentially leading to earlier intervention and improved patient outcomes.

Introduction

Background

Parkinson disease (PD) is a common neurological disease that affects millions of individuals worldwide. This disorder gradually impairs a person's ability to move their body, resulting in a variety of crippling symptoms, including tremors, stiff muscles, and sluggish motions. To effectively manage PD and provide timely measures, accurate and early diagnosis is essential.

Traditionally, clinical evaluations conducted by medical professionals, which can be arbitrary and inconsistent, have

been used to diagnose PD. In distant or underdeveloped areas, access to specialized PD care may be restricted, delaying diagnosis and therapy. The prevalence of PD is predicted to rise as the world's population ages, placing additional demand on health care resources and highlighting the need for easily available and effective diagnostic methods.

In this regard, current technology has shown promise in addressing the difficulties associated with PD diagnosis, especially in the areas of machine learning and deep learning. The limits of conventional clinical procedures can be overcome with the promise of early and objective identification provided by machine learning techniques.

This study investigated the use of machine learning for PD identification with a focus on gait characteristics. The goal was to develop a simple and noninvasive method for screening PD symptoms early through analyzing gait patterns.

In this study, kinematic features during the turning phase of the timed up and go (TUG) assessment were extracted and analyzed. Gait variabilities occurring during body turning are more easily identified, as turning involves complex motor coordination and balance adjustments, making it a challenging movement. This increased complexity can accentuate subtle abnormalities in gait patterns that might not be as apparent during straight walking. Turning is particularly difficult for individuals with PD, as it requires precise control and stability, often revealing difficulties such as freezing of gait (FoG), reduced step length, and asymmetrical movements. Therefore, analyzing the turning phase allows for a more sensitive and accurate detection of PD symptoms, providing a reliable indicator of whether a participant exhibits PD-related gait abnormalities. This focus enhances the effectiveness of the diagnostic tool, which contributes to the facilitation of early and accurate identification of PD.

Conventional Methods

Challa et al [1] proposed an advanced predictive model for PD by using machine learning algorithms, such as multilayer perceptron, boosted logistic regression, random forest, and BayesNet. Their investigation applied the Parkinson Progression Markers Initiative dataset, an extensive dataset containing data from patients with PD and healthy participants. The experimental results showcased remarkable performance improvements over existing methods, boasting accuracy rates of 96.09% for training and 95.45% for testing in the multilayer perceptron algorithm, 96.5854% for training and 96.02% for testing in the BayesNet algorithm, 95.45% for training and 94.87% for testing in the random forest algorithm, and the highest accuracy achieved by the boosted logistic regression algorithm with 97.159% for training and 96.97% for testing. The area under the curve (AUC) of the receiver operating characteristic curve reached an impressive 98.9% for the boosted logistic regression algorithm, emphasizing its robust predictive capabilities. This research represents a significant stride in health care, providing a reliable model for early PD prediction, crucial for timely diagnosis and intervention in addressing this global public health challenge.

In 2019, Polat [2] investigated the recognition of FoG cases in individuals with PD, using a logistic regression classifier trained and tested on a dataset comprising 16 samples. The study meticulously assessed the classifier's performance using a comprehensive set of 10 performance measures, such as accuracy, miss rate, false discovery rate, false positive rate, false omission rate, sensitivity, specificity, precision, and negative predictive value. Impressively, the logistic regression classifier exhibited a noteworthy accuracy of 81.3% in accurately classifying FoG cases. The research further compared the performance of linear regression with 4 alternative models: linear support vector machine (SVM), quadratic SVM, cubic SVM, and k-nearest neighbors (KNN), revealing that the proposed logistic regression model surpassed its counterparts with the highest accuracy of 81.3% in classifying FoG datasets for individuals with PD. This outcome underscores the superior performance of the logistic regression model in the context of FoG classification.

Vidya and Sasikumar [3] conducted a comprehensive study on the application of multiclass SVM in using gait analysis to identify and grade the severity of PD. The researchers used a publicly accessible dataset containing Vertical Ground Reaction Force Sensors and implemented kinematic analysis to extract spatiotemporal features crucial for the diagnostic process. Their suggested framework included a multiregression strategy to normalize gait time series data and a correlation-based feature selection method. A total of 4 distinct SVM kernel functions such as linear, Gaussian, quadratic, and cubic were rigorously evaluated across 3 different walking tests to gauge their performance. Impressively, the quadratic SVM classifier emerged as the most effective, achieving an outstanding average accuracy of 98.65%. This result surpassed existing state-of-the-art methods, showcasing the robustness and efficacy of the proposed SVM-based approach for PD diagnosis and severity rating.

Moreover, Fang [4] performed a study focusing on predicting PD through the application of machine learning techniques. The research extensively compared the accuracy and recall of 3 distinct algorithms: KNN, random forest, and naive Bayesian. Addressing the inherent limitations of equal weighting in traditional KNN, the study introduced an entropy weight method to enhance KNN's performance, specifically mitigating equal-weighting issues. In addition, the research delved into a voice-based Unified Parkinson Disease Rating Scale (UPDRS) prediction scheme, leveraging algorithms to effectively predict UPDRS scores from voice data of patients with PD. Notably, the study used the University of California Irvine dataset, showcasing that the refined KNN algorithm surpassed its traditional counterpart, achieving a notable accuracy rate increase from 91.8% to 93.8%. This research contributes significantly to the advancement of PD prediction methodologies, particularly emphasizing the pivotal role of improved weighting mechanisms in enhancing algorithmic accuracy.

In addition, Gundala et al [5] conducted a comprehensive study using the random forest algorithm for the recognition of PD using the spiral handwritten dataset. The machine learning technique, widely recognized for its efficacy in processing handwritten designs, was applied by partitioning the dataset into subgroups on the basis of features and constructing decision

trees for each feature. The dataset, sourced from the Kaggle website, provided the foundation for training the random forest model. Notably, the algorithm's strength lies in its ability to combine outputs from multiple decision trees through majority voting, resulting in a remarkable accuracy rate of 91%. The study emphasizes the robustness of the random forest algorithm in accurately identifying PD on the basis of the features extracted from handwritten drawings. The results underscore the algorithm's effectiveness in leveraging the diversity of decision trees for enhanced predictive accuracy in the context of PD diagnosis.

Moreover, Govindu and Palwe [6] analyzed Multidimensional Voice Program audio data collected from both patients with PD and healthy individuals. Among the machine learning models evaluated, the random forest classifier emerged as the most effective, achieving a detection accuracy of 91.83% and a sensitivity of 0.95. This model outperformed other techniques, such as SVM, KNN and logistic regression, which were also assessed for their classification capabilities. The superior performance of the random forest classifier highlights its robustness and reliability for detecting PD in its early stages, demonstrating the promise of machine learning in enhancing diagnostic accuracy.

Deep Learning Methods

Pereira et al [7] proposed an innovative method for early identification of PD using a convolutional neural network (CNN) trained on handwritten dynamics data obtained by a smart pen. The CNN effectively learned relevant features from the signals generated during individual exams, enabling discrimination between individuals with and without PD on the basis of these learned features. Experimental results showcased the superiority of the CNN over raw data, with the ImageNet architecture, using 128 times 128 images and a 75% training dataset split, yielding the best overall accuracy of 83.77%. Despite these promising results, the study acknowledged challenges in achieving consistent recognition rates over control individuals, emphasizing the need for further refinement in the proposed approach.

Later, Grover et al [8] introduced a deep learning methodology using a deep neural network (DNN) constructed with TensorFlow and Keras, containing 3 hidden layers with 10, 20, and 10 neurons each and an input layer with 16 units, concluding with an output layer representing the classes *severe* and *nonsevere*. The DNN was trained on the Parkinson telemonitoring voice dataset from the University of California Irvine machine learning repository, comprising biomedical voice measurements from 42 participants. The experiments focused on predicting the severity of PD based on total UPDRS and motor UPDRS scores. The DNN exhibited substantial accuracy improvements over previous research, achieving a classification accuracy of 94.4422% for total UPDRS and 83.367% for motor UPDRS on the training dataset. While test dataset results were comparatively lower, with 62.7335% accuracy for total UPDRS and 81.6667% for motor UPDRS, the proposed DNN classifier showcased enhanced performance compared to previous studies, emphasizing its potential for accurate severity prediction in PD.

Aal et al [9] conducted an optimized approach for early PD detection, using speech features extracted from 2 datasets, dataset 1 and dataset 2, containing recordings from both healthy individuals and patients with PD. Using Mel-frequency cepstral coefficients and delta Mel-frequency cepstral coefficients, the authors proposed a deep learning model combining a recurrent neural network (RNN) with a long short-term memory (LSTM) layer. Comparative evaluation of alternative ML techniques, including SVM, KNN and RNN with stochastic gradient descent, revealed superior performance of the proposed RNN-LSTM model, optimized with the adaptive moment estimation optimizer. The model exhibited remarkable testing accuracy rates of 95.8% on dataset 1 and 90.24% on DS2, accompanied by high recall, precision, and F_1-score on both datasets. Aal et al [9] further demonstrated the model's superiority over existing methods for PD detection, solidifying its potential as an effective tool for early diagnosis.

Apart from that, Ouhmida et al [10] delved into the early recognition of voice-based PD through the application of CNN and artificial neural network (ANN). Using 2 distinct datasets, the study showcased the superior accuracy of CNN over ANN in their experiments. Dataset 1 encompassed 195 voice recordings from 31 individuals, while dataset 2 featured 240 recordings from 80 participants, with a balanced distribution of 40 patients with PD and 40 healthy individuals. The deep learning models, specifically CNN and ANN, underwent training and testing on both datasets, revealing CNN's accuracy rates of 93.10% and 88.89% for datasets 1 and 2, respectively. In contrast, the ANN model achieved slightly lower accuracies, with 82.76% for dataset 1 and 72.22% for dataset 2. Ouhmida et al [10] also highlighted the intricate layers comprising each model, with the ANN model featuring 2 hidden layers and the CNN model incorporating convolution, normalization, activation, softmax, and classification layers. The paper expressed an intent to extend the research by exploring additional deep learning methods and implementing a hybrid system integrating diverse techniques and datasets.

Biswas et al [11] proposed an approach for the early recognition of PD by proposing 2 distinct deep learning models tailored for hand-drawn graphics. The first model, a 2D CNN, processed preprocessed images of spirals, circles, and meanders as input, achieving notable accuracies of 83.6% on circles, 61.5% on spirals, and 67.8% on meanders. Another model, an innovative LSTM model, operated on timeline-series signals and demonstrated an overall accuracy of 0.78. Leveraging the NewHandPD dataset for training and testing, the authors conducted 4 comprehensive experiments, presenting the results. The study posited that early PD detection through these advanced models could potentially enhance treatment outcomes and elevate the overall quality of life for affected individuals.

Apart from that, Khaskhoussy and Ayed [12] evaluate the effectiveness of SVM CNN for classifying data obtained from speech tasks. Total 2 types of input data were analyzed: the raw speech signal values and i-vector features of dimensions 100, 200, and 300. The classification performance was assessed using 5 evaluation metrics: accuracy, precision, recall or sensitivity, specificity, and F_1-score. For a test dataset of 28 participants,

the approach achieved outstanding results, including 100% accuracy, a precision of 0.99, a recall of 0.98, a specificity of 0.96, and an F_1-score of 0.98. A table summarizing the state-of-the-art methods is presented in Table 1.

Table 1. A summary of the state-of-the-art methods.

Study	Methods	Input type	Dataset	Performance
Challa et al [1]	MLP[a], BayesNet, RF[b], and boosted logistic regression	Nonmotor symptoms	PPMI[c] dataset	Best overall accuracy: 96.97%
Polat [2]	Logistic regression	FoG[d]	FoG dataset (Parkinson disease)	81.3%
Vidya and Sasikumar [3]	SVM[e]	Gait features	Gait analysis dataset	98.65%
Fang [4]	KNN[f]	Voice records	UCI[g] dataset	93.8%
Gundala et al [5]	RF	Handwritten drawings	Kaggle handwritten drawings dataset	91%
Pereira et al [7]	CNN[h]	Handwritten dynamics	Public dataset of handwritten dynamics extracted by a smart pen	Best overall accuracy: 83.77%
Grover et al [8]	DNN[i]	Voice dataset	Parkinson telemonitoring voice dataset	Total UPDRS[j]: train 94.44%, test 62.73% and motor UPDRS: train 83.37%, test 81.67%
Aal et al [9]	RNN[k]-LSTM[l]	Speech features	Dataset 1 and dataset 1[2]	Dataset 1: 95.8% and dataset 12: 90.24%
Ouhmida et al [10]	CNN ANN[m]	Voice	Dataset 1, dataset 2	Dataset 1: 93.10% and dataset 2: 88.89%
Biswas et al [11]	LSTM	Hand drawings	NewHandPD	78.7%

Methods

Overview

The study used a methodical approach that started with data collection from young adults, older adults, and patients with PD, followed by obtaining consent, particularly from those diagnosed with the disease. The TUG assessment was a key part of the data collection process. Video enhancements and preprocessing were performed to enhance the quality of the videos. After that, the key points on the human body were obtained using a human pose estimation technique. Next, features such as shoulder distance, step and stride lengths, cadence, and speed were extracted to analyze the gait patterns. The Butterworth filter was applied to refine the data, and peaks were identified to calculate steps and turning durations. Finally, SVM [2] was used to distinguish between the different groups based on the extracted features, aiming to improve the prediction and analysis of PD symptoms.

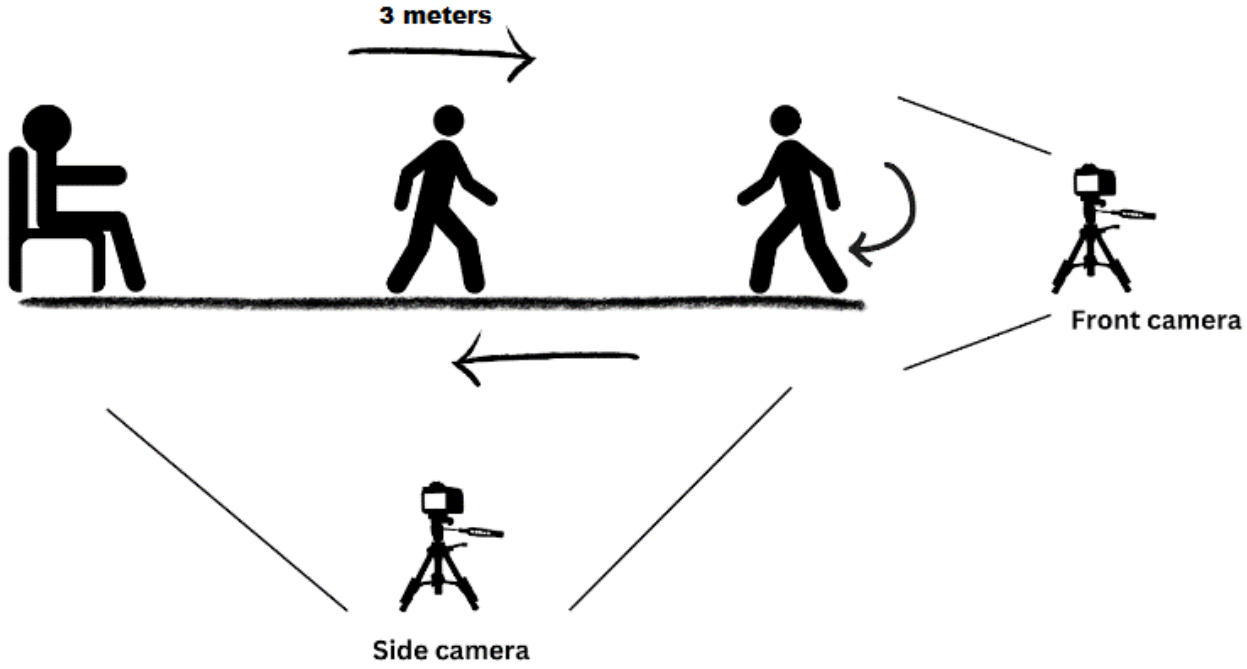
Dataset

The self-collected dataset comprised video recordings of 28 individuals performing the TUG assessment, a standard test used to evaluate mobility and balance. The dataset comprised 3 distinct cohorts: young adults aged between 21 and 33 years, older individuals aged >60 years, and older individuals diagnosed with PD. Consents were obtained from the participants before data collection. The videos captured various gait patterns, providing a comprehensive set of data for analyzing kinematic features, such as step length, stride length, and joint angles. This dataset allowed for controlled conditions and detailed annotations, ensuring high-quality data for feature extraction and analysis.

TUG Assessment

Figure 1 shows a TUG workflow, outlining the sequential steps involved in the activity. The process began with the individual seated at the designated starting point. Upon initiating the recording, the participant stood up and proceeded to walk a distance of 3 meters in a typical manner. Upon reaching the 3-meter mark, the individual executed a turn, walking back to the starting point, where they concluded the TUG process by returning to a seated position. This comprehensive description encapsulated the entire TUG procedure, providing a clear understanding of the task's progression. To enhance data capture, 2 phones were used, one on the front and the other on the side.

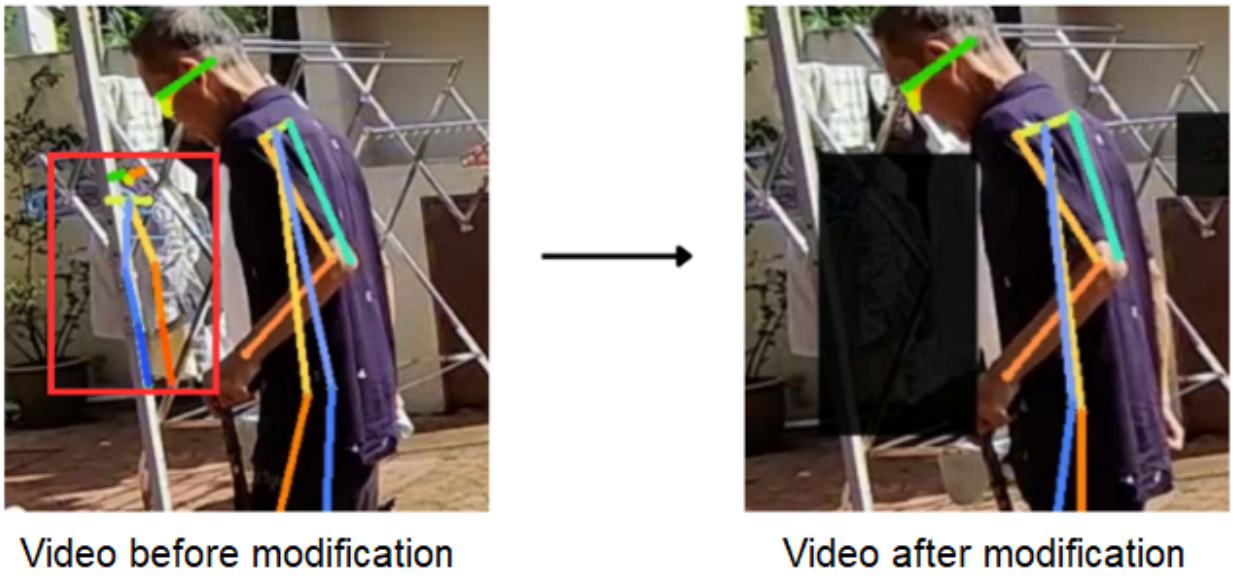
Figure 1. Timed up and go (TUG) assessment shooting site configuration plan.



Video Enhancement

The presence of background clutter in the original video introduces noise, which significantly affects the accuracy of letter pose extraction. Applying human pose estimation technique directly to unprocessed video may result in inaccurate keypoint coordinates, affecting the reliability of analysis results. To alleviate this problem, a preprocessing step was crucial. Specifically, the video was subjected to a customized processing method in which a black block was used to mask certain areas susceptible to noise. This strategic approach ensured that no noise interferes with the subsequent process, resulting in more precise and reliable coordination extraction. Figure 2 shows an example of enhancement performed on the video images.

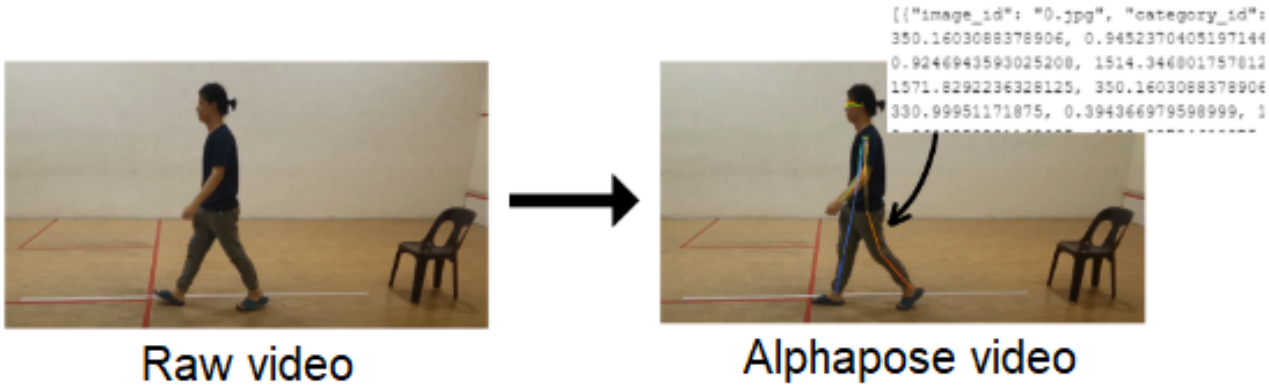
Figure 2. Video enhancement.



Human Pose Estimation

In this study, AlphaPose was used to identify 17 key points from the human body, each corresponding to a specific anatomical location. The process yielded a JSON file containing coefficients for 17 key points. It is important to note that the JSON file, at this stage, has not undergone data processing. The raw file was populated with various elements, including image_id, category_id, key points, and scores within each set. The image_id represented the frame of the video, while the category_id served to identify the object (set as 1 for a person). The key points section contains coordinates for body part locations and corresponding detection confidence, formatted as x1, y1, c1, x2, y2, c2, and so forth, with "c" denoting the confidence score (Figure 3).

Figure 3. Gait analysis using AlphaPose.



Data Extraction

In the data preprocessing phase, the first step involved loading the JSON file and carefully filtering key points and image IDs. In addition, confidence scores were eliminated. The next focus was to mark the 17 identified body key points, including nose, left eye (LEye), right eye (REye), left ear (LEar), right ear (REar), left shoulder (LShoulder), right shoulder (RShoulder), left elbow (LElbow), right elbow (RElbow), left wrist (LWrist), right wrist (RWrist), left hip (LHip), right hip (RHip), left knee (LKnee), right knee (Rknee), left ankle (LAnkle), and right ankle (RAnkle). Next, according to the specific video file name, key point coordinates for each image ID (frame) were marked, ranging from Nose_x and Nose_y to RAnkle_x and RAnkle_y.

The results from the data preprocessing stage boasted a comprehensive structure, encompassing 36 columns that capture key information. Each column was curated to provide a detailed representation of the dataset. Starting with the file_name, which specified the associated video file, and the image_id indicating the frame or image ID corresponding to each set of key points, the subsequent 34 columns focus on the x and y coordinates of 17 distinct body key points.

Frame Segmentation

Frame segmentation is a process to assign a time interval to each frame in the video which helps to determine the occurrence of a turning event. The total duration of the video is divided by the total number of frames (rows). This calculation yields the time interval per frame, assuming a constant frame rate throughout the video. With this interval calculated, a new column named "time_duration" is added to the DataFrame. Each row in the "time_duration" column is populated with the cumulative time, calculated as the frame's index in the DataFrame multiplied by the time interval. This method provided a time stamp for each frame, which is essential for synchronizing the data with the video and analyzing the timing of the detected body turning events. The pseudocode presented in Figure 4 describes the step-by-step procedure for frame segmentation.

Figure 4. Pseudocode describing the step-by-step procedure for frame segmentation.

Algorithm 1: Pseudocode for Frame Segmentation

Data: *df*
Result: *turning_events*

```
function frame_segmentation(DataFrame df)
  for each row in df:
    shoulder_distance = sqrt((RShoulder_x − LShoulder_x)^2 + (RShoulder_y − LShoulder_y)^2)
    set df[shoulder_distance] to shoulder_distance
  end for

  for each row in df:
    if df[shoulder_distance] > threshold then
      set df[turning_event] to TRUE
    else
    set df[turning_event] to FALSE
  end if
 end for

 Return turning_events
End function

# Main Process
DataFrame df = Load data into a DataFrame
Float distance_threshold = Set the distance threshold

DataFrame turning_events = detect_turning_events(df)

Integer total_rows = Length of DataFrame df  # Total number of rows
Float total_duration_seconds = Set the total duration of the video in seconds

Float time_interval = total_duration_seconds / total_rows

For each row in DataFrame turning_events:
   Calculate time_duration = index_of_row * time_interval
   Add time_duration to DataFrame turning_events
```

Noise Filtering

The Butterworth filter was used as the noise filtering tool in this study. The Butterworth filter is a type of signal processing filter that plays a pivotal role in enhancing the clarity of movement coordinate data extracted from videos. By applying the Butterworth filter to the raw coordinates, high-frequency noise is effectively attenuated, resulting in a smoother trajectory on the graph. This smoothed representation provides a clearer visualization of the participant's movements, reducing interference from irrelevant fluctuations.

Combined with the Butterworth filter, a peak detection algorithm was used to identify important points on the graph. These peaks correspond to key events in motion, such as steps taken by the participant. The peak identification process helped in extracting basic features such as the number of steps throughout the video. This kind of feature extraction is particularly valuable for specific PD aspects of analysis and quantification. The Butterworth filter is expressed using equation 1:

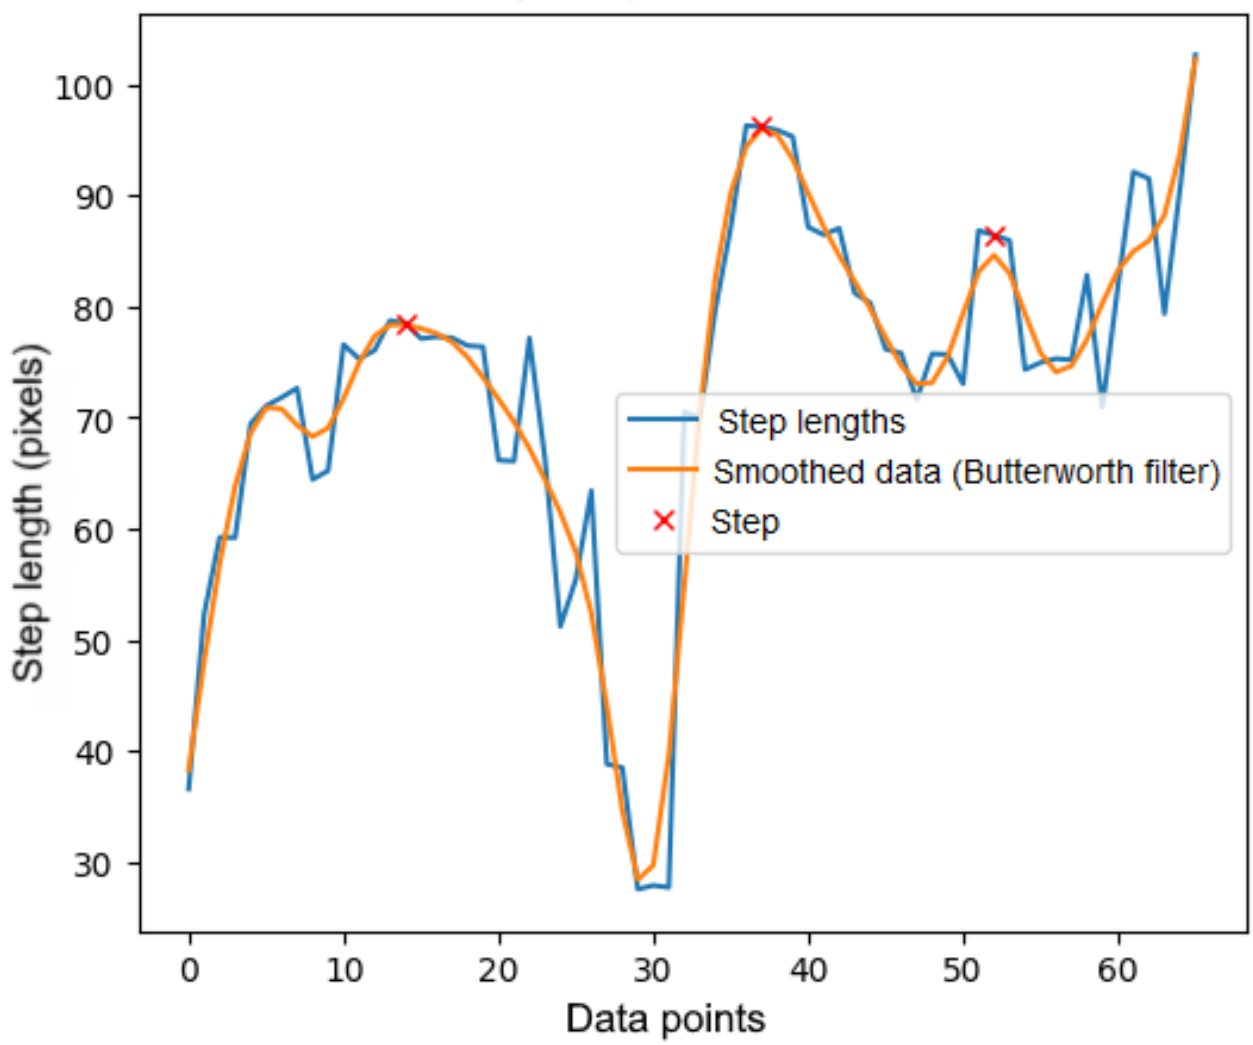
where $y(t)$ is the filtered signal; $x(t)$ is the input signal; fc is the cutoff frequency; f is the frequency of the signal; and n is the order of the filter.

In this study, an order of 4 was used for the Butterworth filters because it provides a smooth yet sufficiently steep roll-off in the transition band. While higher-order filters provide sharper roll-offs, they also require more computational resources. Therefore, a fourth-order filter appeared to be a reasonable compromise, being computationally efficient while providing adequate filtering. On the other hand, the peak detection equation is given by equation 2:

where $y(t)$ is the filtered signal; T is the set of all time points in the signal $y(t)$; t_i represents the time point where a peak occurs; and *height* is the threshold height for peak detection.

Only peaks that have an amplitude greater than or equal to the threshold, h, are detected and included in the output. In this study, the value for the height parameter was set to 100. An example of the graph for noise filtering with peaks is illustrated in Figure 5. This example demonstrates that the application of the Butterworth filter smooths the signal and yields an accurate step count during body turning.

Figure 5. An example of a graph processed with a Butterworth filter, showing peaks.



PD Recognition Using Model-Based Features

Certain gait features can help identify abnormalities or changes in walking patterns, which are particularly useful for diagnosing and monitoring conditions such as PD. By focusing on the body turning period, we aimed to capture the most challenging part of the gait cycle, where gait variabilities for PD are more easily observed. Turning involves complex motor coordination and balance adjustments, making it a difficult movement. This complexity can accentuate subtle abnormalities in gait patterns that might not be as apparent during straight walking. Therefore, analyzing gait features during turns provides a more sensitive and accurate assessment of PD-related gait abnormalities, enhancing the effectiveness of early diagnosis and monitoring. The gait features used in this study are summarized in Table 2.

Table 2. Gait analysis feature definitions and formulas.

Feature	Definition	Formula
Shoulder distance	Average horizontal distance between the left and right shoulders	mean(Shoulder_Distance($LShoulder_x$,$LShoulder_y$,$RShoulder_x$,$LShoulder_y$))
Step length	Average distance between the left ankle and right ankle	mean(Step_Length($LAnkle_x$,$LAnkle_y$,$RAnkle_x$,$RAnkle_y$))
Stride length	Average distance covered in 1 full stride, which consists of 2 steps (1 by each foot)	mean(Stride_Length($RAnkle_x$,$RAnkle_y$))
Angle of both knees	Degrees at the knee joint by considering the vectors formed by the knee to hip and knee to ankle points	Θ_{Knee}(Hip_x,Hip_y,$Knee_x$,$Knee_y$,$Ankle_x$,$Ankle_y$)
Angle of both hips	Degrees at the hip joint by considering the vectors formed by the hip to knee and hip to shoulder midpoint	Θ_{Hip} ($Shoulder_{mid}$,$Shoulder_{midy}$, Hip_x. Hip_y, $Knee_x$, $Knee_y$)
Symmetrical leg	Degrees for each ankle by considering the vectors formed by the knee to hip midpoint and knee midpoint to hip midpoint	Θ_{Leg}($Knee_{mid}$,$Knee_{midy}$, Hip_{mid} . Hip_{midy}, $Knee_x$, $Knee_y$)
Symmetrical arm	Degrees for each arm by considering the vectors formed by the arm to shoulder midpoint and arm midpoint to shoulder midpoint	Θ_{Arm}($Shoulder_{mid}$,$Shoulder_{midy}$, $Elbow_{mid}$. $Elbow_{midy}$)
Trunk Angle 1 (vertical)	Degrees by considering the vertical reference vector and the vector from the hip midpoint to the nose	Θ_{Trunk1}(Hip_{mid} ,Hip_{midy}, $Nose_x$. $Nose_y$)
Trunk angle 2 (horizontal)	Degrees by considering the vector from the hip midpoint to the shoulder midpoint and a horizontal reference vector	Θ_{Trunk2}($Shoulder_{mid}$,$Shoulder_{midy}$, Hip_{mid} ,Hip_{midy})
Shank angle	Degrees at the hip joint by considering the vectors formed by the left ankle to knee midpoint and right ankle to knee midpoint	Θ_{Shank}($Ankle_x$,$Ankle_y$,$Shoulder_{mid}$,$Shoulder_{midy}$)

Body Turning Duration Calculation

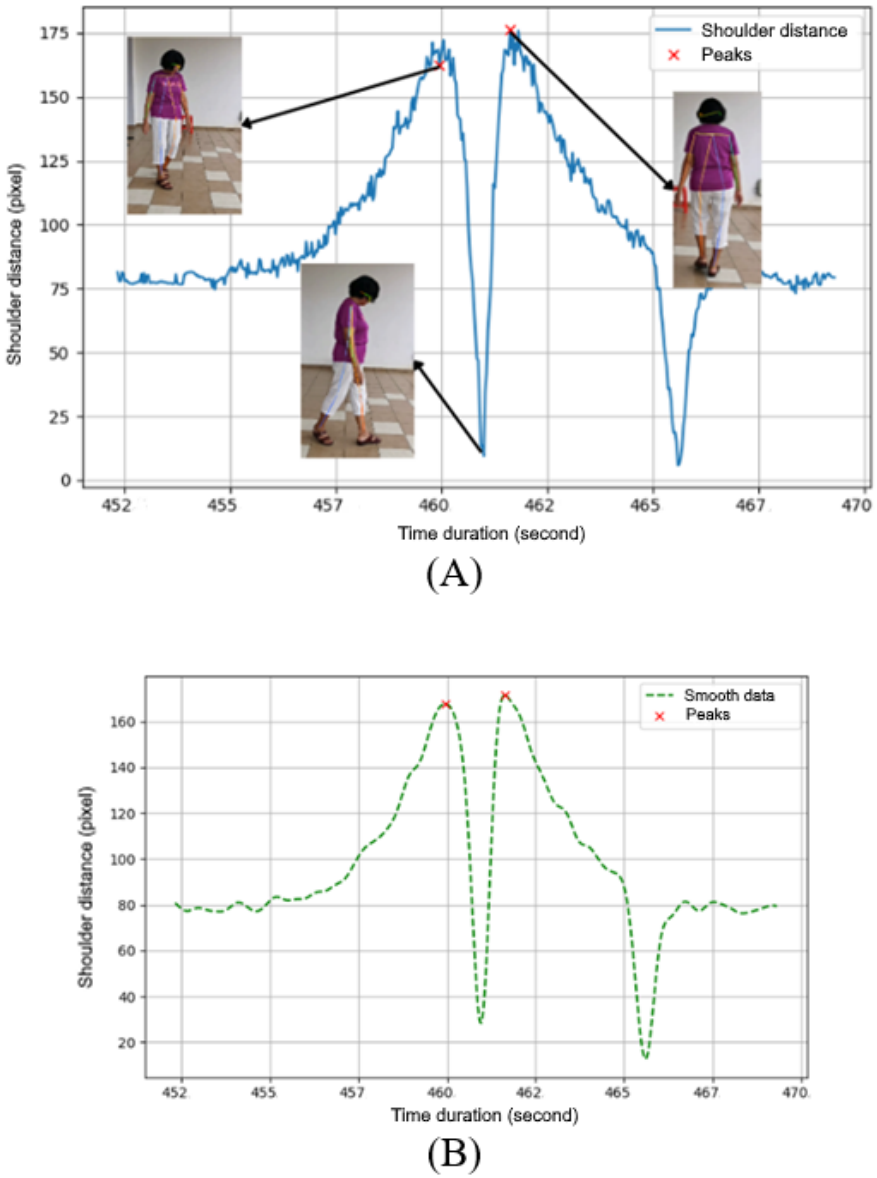
Figure 6 presents 2 graphs related to the analysis of shoulder distance during a body turn. The left graph (Figure 6A) displays the original, unprocessed data, illustrating the raw measurements of shoulder distance over time. The fluctuations observed may correspond to the natural movement variations during a turn. In contrast, the right graph (Figure 6B) exhibits data that have been smoothed using a Butterworth filter, a technique that mitigates short-term fluctuations and reveals the underlying pattern of movement more clearly.

The smoothed data enables effective determination of the peaks of the signal, which identifies the significant turning points. These peaks are highlighted by the red "X" marks in the figure and represent moments where the shoulder distance reaches its maximum, indicating a complete turn or a change in direction. By focusing on the 2 highest peaks, the graph underscores the most substantial turning events, thereby minimizing the potential for misinterpreting minor variations as significant movements.

In the context of shoulder distance, *LShoulder* and *RShoulder* would correspond to the left and right shoulders, with their respective *x* and *y* coordinates. The shoulder distance, *Shoulder_Distance*, which is a measure of how far apart the shoulders are, is calculated as follows (equation 3):

The indexes between these 2 peaks are then taken to determine the exact time the turn occurred. The difference between these peak times is calculated to find the duration between consecutive turning points. Let $T_{peak,i}$ be the time of the *i*th peak and *n* is the total number of peaks detected. Equation 4 calculates the total time duration between the first and the last peak by adding up the durations between each pair of consecutive peaks,

Figure 6. Shoulder distance analysis with peak detection: (A) graph before smoothing and (B) graph after smoothing.



Ethical Considerations

Ethical approval was granted by the Research Ethics Committee Multimedia University (approval number EA0422022). Informed consent was obtained from all the participants. A statement about this is given in the Methods section. Identifiable features of research participants are not visible in the manuscript. No compensation was provided to the participants.

Results

Overview

This section presents the experiment results and discussion for the gait features extracted from the self-collected dataset, focusing on the effectiveness of these features in distinguishing between normal and PD-affected gait patterns using a SVM classifier.

For the experiments, principal component analysis was applied to reduce the dimension of the dataset. The number of components for principal component analysis was set to 8, corresponding to the number of participants with PD. This step helps in capturing the most significant features while reducing computational complexity.

The dataset was additionally divided into a 70:30 ratio. This indicates that the model was trained using 70% of the data, with the remaining 30% set aside for testing and performance evaluation. By splitting the data this way, a significant portion of the data were used to train the model while maintaining enough for a thorough assessment. In total, 10 trials of the experiments were performed, and the average results were recorded.

Participant Details

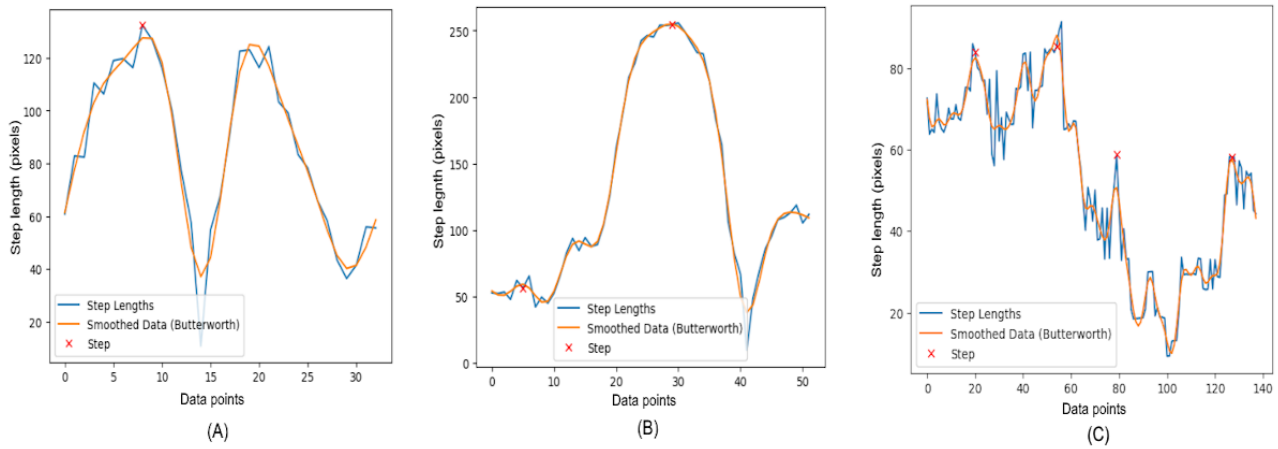
There were 3 groups of participants in the self-collected dataset, namely, patients with PD, older adults, and adolescents. A significant portion of the participants (8/28, 29%) were diagnosed with PD, while the remaining participants were healthy (20/28, 71%). Most of the participants were Chinese (24/28, 85%), with a smaller representation of Indian (3/28, 11%) and Malay (1/28, 4%) individuals. There was a higher

proportion of male participants (21/28, 75%) compared to female participants (7/28, 25%). Finally, most participants fell within the age range of 60 to 69 years (14/28, 50%), followed by the age range of 20 to 29 years (9/28, 32%), and smaller proportions in other age ranges. These results collectively illustrate the diversity and focus of the study population.

Total Steps During Body Turning

Figure 7 presents 3-line graphs that correspond to the step lengths for different demographic groups: younger individuals, older individuals, and individuals with PD. The step lengths are measured during a turning sequence.

Figure 7. A comparative step analysis by step length between different groups: (A) younger individuals, (B) older individuals, and (C) individuals with Parkinson disease.



The graph of younger individuals (Figure 7A) demonstrates a more variable stepping pattern with pronounced peaks, suggesting agility and a higher range of motion (ROM) during turns. The steps are uneven in length, but the peaks return to baseline quickly, indicating swift changes in direction and a potentially more dynamic gait.

In contrast, the graph of older individuals (Figure 7B) has fewer, more rounded peaks, indicative of a more cautious or steady turning strategy. The step lengths are generally more uniform, with smoother transitions between steps. This could reflect a more deliberate and potentially less stable gait, as is often seen with aging.

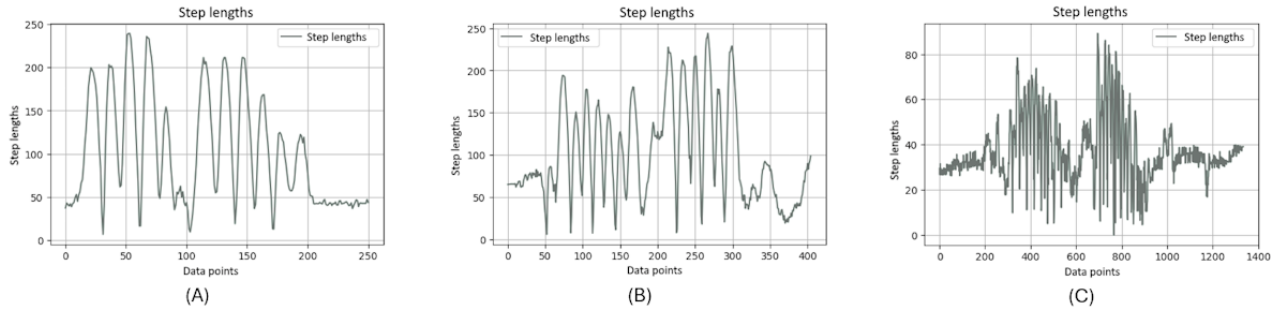
The graph of individuals with PD (Figure 7C) demonstrates a significantly different pattern, with smaller step lengths and a higher frequency of steps, which may point to the short, shuffling steps often associated with PD. The peaks are less pronounced and more erratic, highlighting the challenges individuals with PD may face in maintaining a regular stepping pattern.

Step Length

Step length refers to the distance between the left and right ankle for each step. It is determined by the coordinates of the left ankle ($LAnkle_x$, $LAnkle_y$) and the right ankle ($RAnkle_x$, $RAnkle_y$) at a particular instance in time. The formula to calculate step length is provided in equation 5. This formula gives the straight-line distance between 2 points in a 2D space, such as a video frame or a motion capture system's coordinate plane.

In Figure 8, the graphs illustrate the differences in gait patterns across 3 demographic groups during a TUG test. Each graph plots the variation in step lengths, which reflect the distance between the left and right ankle during individual steps.

Figure 8. A comparative step length analysis between different groups: (A) younger individuals, (B) older individuals, and (C) individuals with Parkinson disease.



The graph of younger individuals (Figure 8A) is characterized by high peaks and deep valleys, indicating significant variability in step lengths. This could suggest a dynamic and robust gait, with the ability to take both long and short steps, perhaps adjusting speed or direction more frequently.

In contrast, the graph of older individuals (Figure 8B) shows a moderate level of variability with somewhat rounded peaks.

The reduced height of the peaks compared to the young group suggests shorter steps on average, which may be a sign of a more cautious approach to movement, possibly due to decreased mobility or balance concerns that come with age.

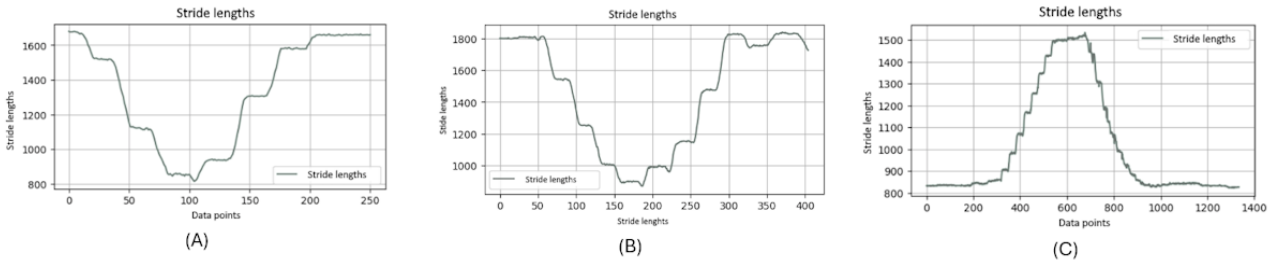
The graph of individuals with PD (Figure 8C) differs markedly from the other 2. It has a much higher frequency of smaller fluctuations, and the overall range of step lengths is noticeably lower. This pattern indicates the short, shuffling steps that are often observed in individuals with PD, reflecting the challenges they face with gait initiation and continuation.

Stride Length

Stride length is typically defined as the distance covered in one full stride, consisting of 2 steps (one by each foot). The equation to calculate the stride length for each frame is presented in equation 6. It calculates the stride length as the Euclidean distance from a point (possibly the origin) to the coordinates of the right ankle for each frame.

Figure 9 shows the stride length of the right ankle throughout a single TUG video. The graph exhibits the dynamic nature of stride lengths, with the vertical axis representing the stride length and the horizontal axis corresponding to data points that likely represent sequential frames of the video.

Figure 9. A comparative stride length analysis between different groups: (A) younger individuals, (B) older individuals, and (C) individuals with Parkinson disease.



It is noteworthy that this graph clearly distinguishes between 2 types of motion: the rising and falling edges indicate the leg in motion, not in contact with the ground, and the flat regions signify the stance phase where the leg is stationary on the floor, awaiting the next step. The consistency in the flat regions indicates moments when the leg is at rest between strides.

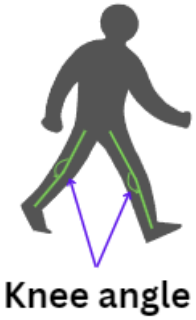
It is evident that the graphs of younger and older individuals (Figures 9A and 9B) display similar frequencies in stride patterns, whereas the graph of the individuals with PD (Figure 9C) significantly diverges. It illustrates a strikingly different frequency in stride lengths, standing out from the more consistent rhythmic patterns observed in the younger- and older-individual groups.

Moreover, from these charts, it is obvious that when younger and older people complete a stride, their feet leave the ground to a greater extent, because a normal stride will take a relatively large range. On the contrary, when patients with PD complete a stride, their feet leave the ground to a relatively smaller extent. The amplitude of the ground is relatively short, which can be considered a symptom of PD.

Angle of Both Knees

Analyzing the positions of the hip, knee, and ankle for each leg to determine the angles at both knees can assist in recognizing PD (Figure 10).

Figure 10. An illustration of the knee angle position.

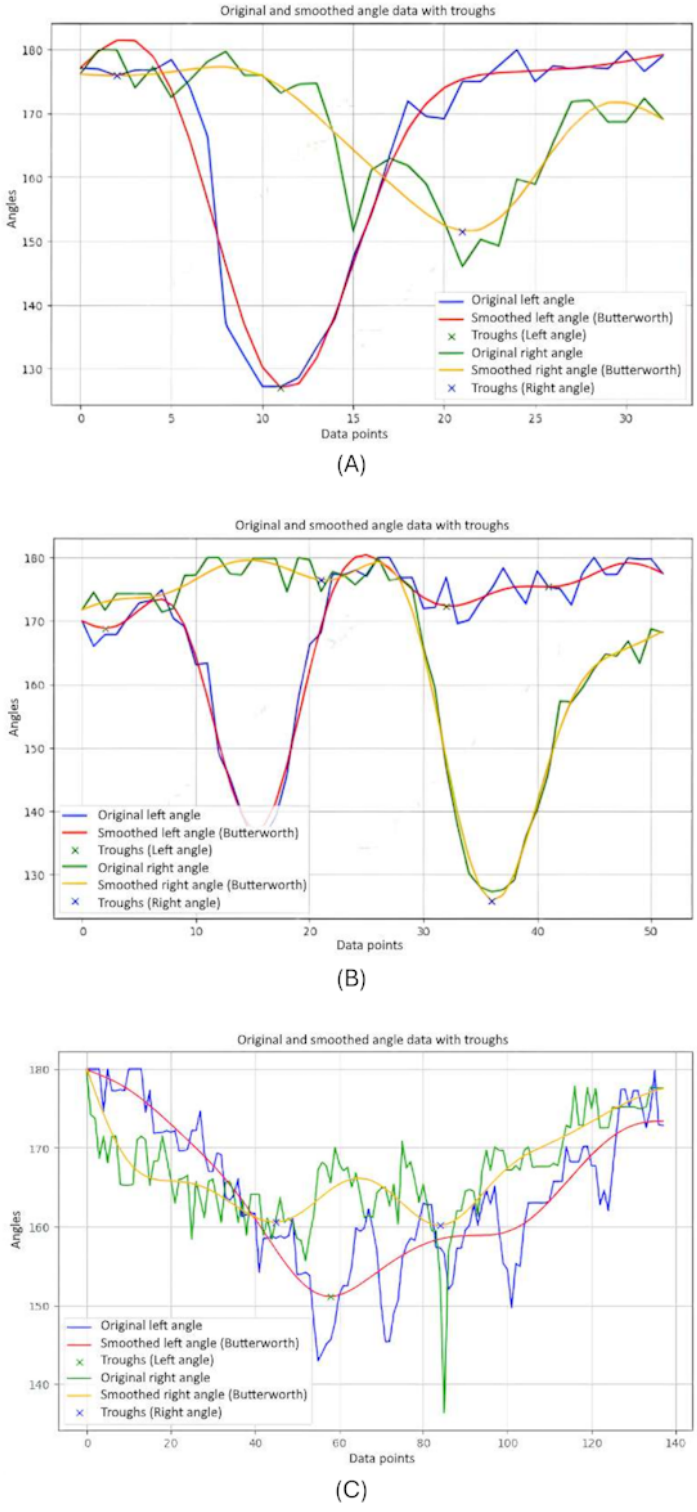


The knee angles provide crucial insights into the degree of bending or extension at the knee joints, which are essential for understanding gait patterns. PD often affects movement and posture, leading to distinctive gait abnormalities. By quantifying these knee angles, the calculation helps in detecting and assessing these gait characteristics, aiding in the identification and monitoring of PD symptoms.

Given the knee, hip, and ankle joint positions, the knee angle and the Θ_{knee} can be computed as follows (equation 7):

Figure 11 presents 3-line graphs comparing the knee joint angles of the 3 groups: younger individuals, older individuals, and individuals with PD. The graph of the younger individuals group (Figure 11A) illustrates smooth and regular oscillations in knee joint angles for both the left and right legs. As they turn their body, the angles show significant flexion and extension, reflecting the youthful ability to execute the turn in a single, fluid step. The peaks and troughs are well-defined, indicating robust and agile movements typical of healthy, young individuals. This pattern highlights their efficient and coordinated gait.

Figure 11. A comparative analysis of the knee angle between different groups: (A) younger individuals, (B) older individuals, and (C) individuals with Parkinson disease.



In the older-individual group graph (Figure 11B), the knee joint angles are more subdued, with 2 distinct curves for each turn. This indicates that older individuals take 2 steps to complete the body turn, reflecting a more cautious and segmented approach. The movement patterns are slower and less dynamic compared to the younger individual group, with a reduced ROM.

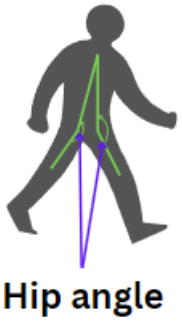
The graph for the group of individuals with PD (Figure 11C) shows highly irregular and erratic knee joint angles. The curves exhibit frequent sharp peaks and drops, indicating inconsistent and disrupted movement as individuals with PD attempt to turn their bodies. These fluctuations reflect the challenges faced by patients with PD, including tremors, rigidity, and difficulty maintaining smooth and coordinated movements. The graph captures their struggle to control knee flexion and extension, leading to a more disordered and interrupted gait pattern during the turning motion.

These graphs highlight clear differences in turning movements: young individuals exhibit fluid, single step turns; older individuals use a careful 2-step approach; and patients with PD show irregular, disrupted turning patterns.

Angle of Both Hips

The ROM angle while turning the body is used to determine the angle of both hips (Figure 12). The positions of the hip, knee, and shoulder are used to find the angle formed at the hip joint. This measurement is crucial for assessing how the hip moves during turns, providing insights into the flexibility and coordination of the lower body. Understanding the hip ROM is especially valuable for identifying movement patterns in different populations, such as detecting mobility issues or assessing gait in individuals with PD.

Figure 12. An illustration of the hip angle position.



The hip angle is calculated as follows (equation 8):

The graphs showing the cosine of the hip angle are shown in Figure 12. The figure shows 3-line graphs comparing hip angles during body turns for the 3 groups. Each graph represents the hip angles for both the left and right sides, with lines depicting both the original and smoothed data.

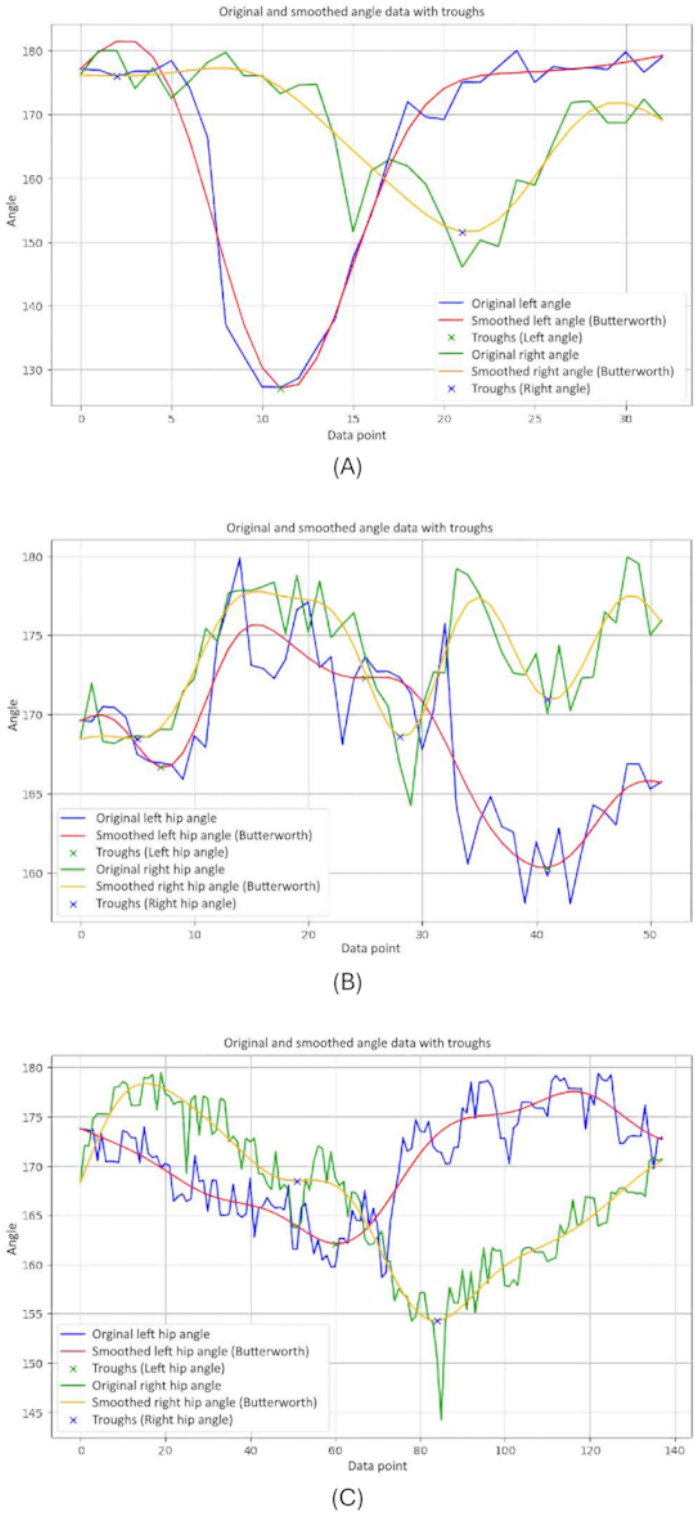
The graph of the younger individuals group (Figure 12A) indicates relatively stable and moderate fluctuations in hip angles during body turns. Both hips show consistent movement with shallow peaks and troughs, reflecting balanced and controlled motion. Younger individuals maintain a steady range of hip angles, suggesting efficient and coordinated hip movement when turning.

In the older-individual group graph (Figure 12B), the hip angles display more pronounced and variable fluctuations compared to the young group. The curves reveal that older individuals experience larger and more variable hip movements during turns. This increased variability suggests that older people adjust their hip movements significantly to maintain balance and stability, resulting in less smooth and more fluctuating hip angles.

The group of individuals with PD (Figure 12C) shows significant irregularity and instability in hip angles. The curves exhibit erratic and sharp changes, highlighting the difficulty individuals with PD face in maintaining consistent hip movement during turns. The frequent and abrupt fluctuations in hip angles are characteristic of the disease, where symptoms such as rigidity and tremors disrupt smooth and coordinated movements.

Figure 13 illustrates clear differences in hip angle dynamics during turns among the 3 groups. Younger individuals (Figure 13A) have controlled and consistent hip movements, older individuals (Figure 13B) show more variability and larger fluctuations in hip angles, and those with PD (Figure 13C) experience erratic and unstable hip movements. These patterns reflect how age and neurological conditions affect the coordination and efficiency of hip movement during body turns.

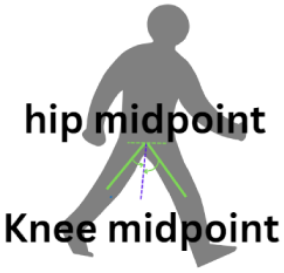
Figure 13. A comparative analysis of the hip angle between different groups: (A) younger individuals, (B) older individuals, and (C) individuals with Parkinson disease.



Leg Symmetry

The symmetry of leg movements is calculated using the angles at the knee joints (Figure 14). The goal was to measure and evaluate the balance and symmetry in the leg movements, which is crucial for understanding gait and stability, especially during turning motions. This information is particularly useful for analyzing the movement patterns in different populations, such as detecting gait irregularities in individuals with conditions such as PD.

Figure 14. An illustration of the symmetrical leg position.



The leg angle is computed as follows (equations 9-11):

Next, the angles of the left and right legs are compared:

The leg symmetry is then assessed as:

Figure 15 displays 3-line graphs comparing the leg symmetry during body turns for the 3 participant groups. Each graph plots the symmetrical leg movements, showing the original and smoothed angles of the left and right legs as they turn.

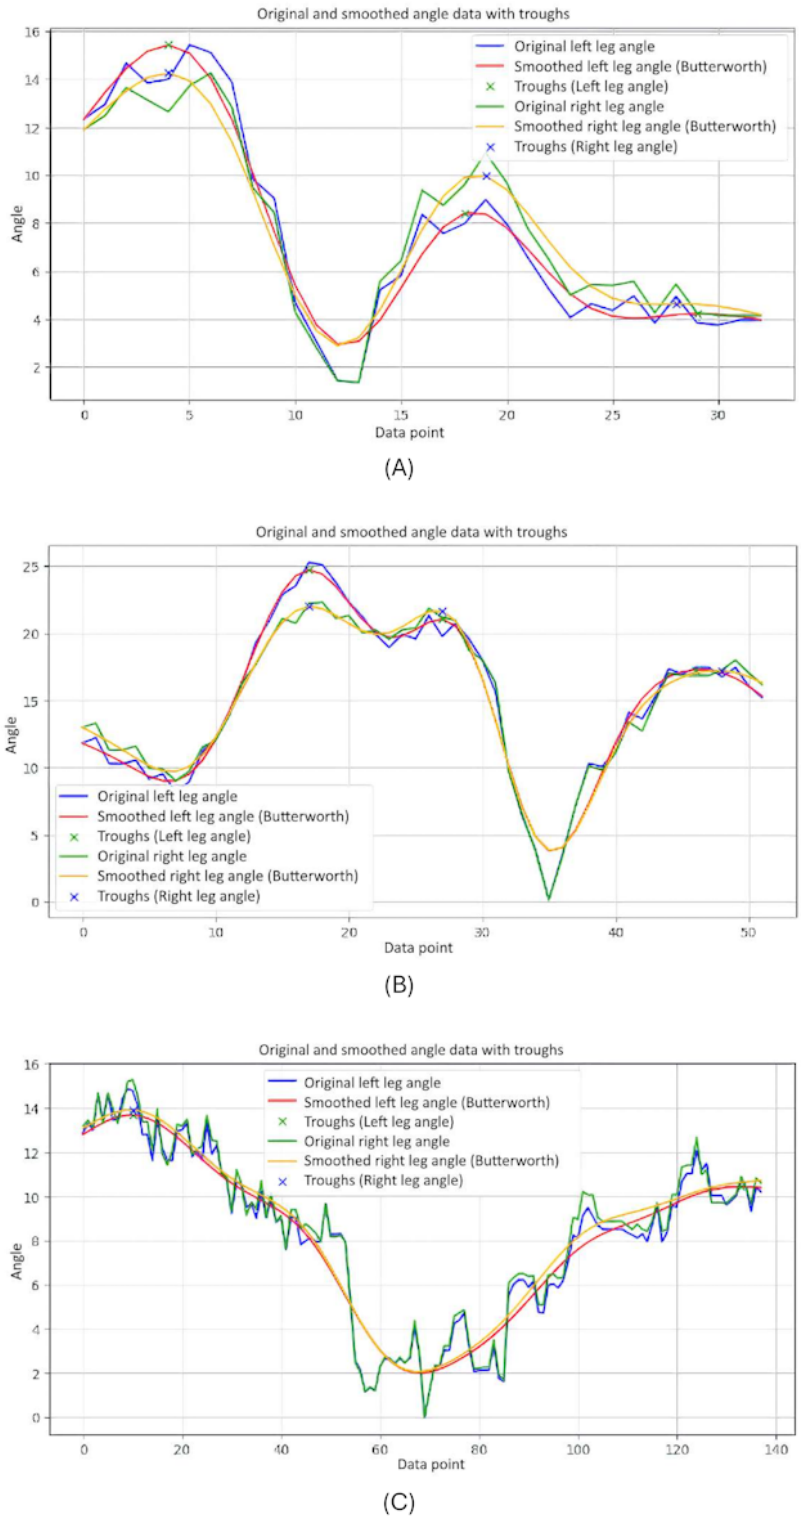
The graph of the younger-individual group (Figure 15A) shows closely aligned curves for the left and right leg angles, indicating high symmetry in their leg movements during turns. Both legs exhibit similar patterns with minimal deviation between them. This close alignment reflects the balanced and coordinated movements typical of young, healthy individuals, suggesting that they maintain a consistent and symmetrical gait.

The older-individual group graph (Figure 15B) reveals more noticeable fluctuations between the left and right leg angles. While the overall patterns still follow a similar trajectory.

On the other hand, the graph of individuals with PD (Figure 15C) shows significant irregularities and less alignment between the left and right leg angles. The curves are erratic and display frequent sharp deviations, reflecting low symmetry in their leg movements. This lack of alignment is characteristic of PD, where symptoms such as tremors and rigidity cause disrupted and uncoordinated movements.

This comparison highlights how age, neurological conditions, and health status impact the ability to maintain balanced and symmetrical gait during turning motions.

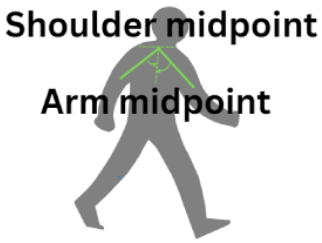
Figure 15. A comparative analysis of the symmetrical leg between different groups: (A) younger individuals, (B) older individuals, and (C) individuals with Parkinson disease.



Arm Symmetry

The symmetry of arm movements was analyzed using the angles at the elbows to the shoulders (Figure 16). The purpose was to measure how balanced and coordinated the arm movements are, especially during activities such as turning the body. This assessment was important for understanding the ROM and the symmetry in arm movements, which can provide insights into overall body coordination and detect possible imbalances or movement disorders.

Figure 16. An illustration of the symmetrical arm position.



The calculation for arm symmetry was similar to that of finding the symmetry in legs (equation 12):

Figure 17 presents 3-line graphs comparing the arm symmetry during body movements for 3 groups. Each graph plots the angles of the left and right arms over time, showing both the original and smoothed data.

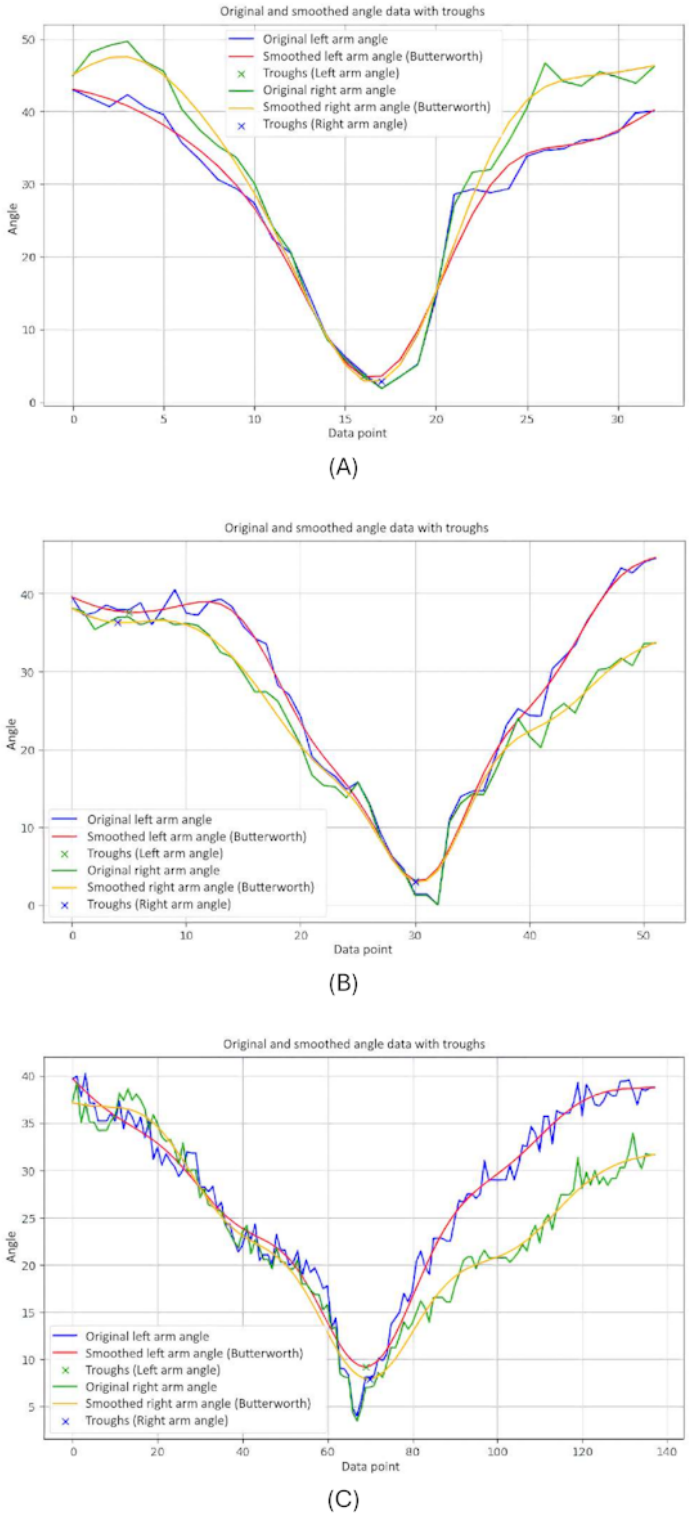
The graph of the younger-individual group (Figure 17A) displays closely aligned curves for the left and right arm angles. Both arms move in a highly synchronized manner, with minimal differences between the left and right angles throughout the motion.

The older-individual group graph (Figure 17B) shows a slightly more varied pattern compared with the young group. While the overall movements of the left and right arms remain relatively synchronized, there are noticeable differences in the magnitude and timing of the angles.

The graph of individuals with PD (Figure 17C) exhibits significant irregularities and discrepancies between the left and right arm angles. The curves are erratic and often diverge sharply, indicating substantial asymmetry in arm movements.

We observed that younger individuals demonstrate highly synchronized and symmetrical arm movements, older individuals show moderate symmetry with some variability, and those with PD experience significant asymmetry and irregularity in their arm movements. These patterns underscore how age and neurological conditions impact the coordination and balance of arm movements during body turns.

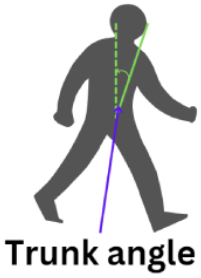
Figure 17. A comparative analysis of the symmetrical arms between different groups: (A) younger individuals, (B) older individuals, and (C) individuals with Parkinson disease.



Trunk Angle 1 (Vertical)

The relative positions of the hips and nose are used to calculate the trunk angle (Figure 18). The trunk angle helps to understand how much the upper body tilts or bends relative to the lower body, especially during activities such as turning. This angle helps in assessing posture and balance, providing insights into the coordination and alignment of the trunk with the hips during movement. It is particularly useful in evaluating movement patterns and detecting postural deviations in various populations, including those with movement disorders such as PD.

Figure 18. An illustration of the trunk angle 1 vertical position.



The calculation of the trunk angle 1 is given as follows (equation 13):

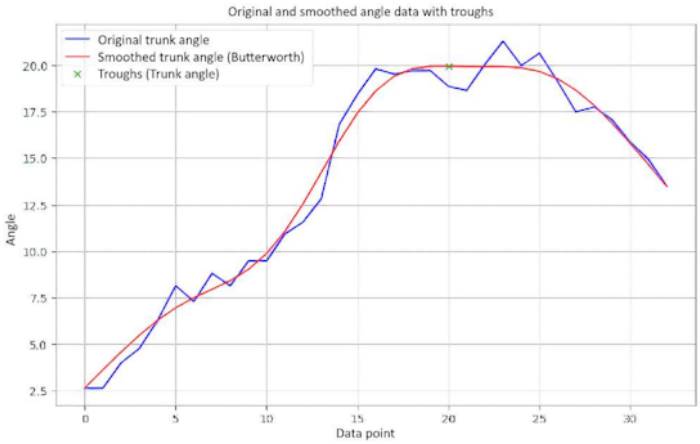
Figure 19 displays 3 graphs comparing trunk angles relative to the vertical axis for 3 groups. Each graph shows the trunk angle over a series of data points during body movements, with both original and smoothed data represented. The trunk angle is used to observe the severity of hunchback, providing insights into the degree of forward bending or curvature of the upper body.

The graph of the younger-individual group (Figure 19A) exhibits a consistent and smooth progression of trunk angles. The trunk angle gradually increases and decreases within a narrow range, reflecting a well-coordinated and balanced posture with minimal forward bending. Younger individuals maintain a steady alignment with minimal deviations, indicating a lack of significant hunchback severity.

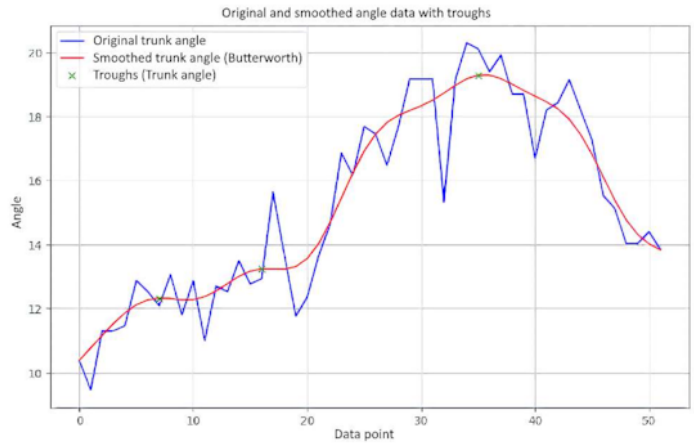
The older-individual group graph (Figure 19B) shows more variability in trunk angles compared to the young group. The curves display noticeable fluctuations and less consistency, with several abrupt changes in angle. These variations suggest that older individuals experience more difficulty in maintaining a stable trunk posture, leading to less smooth and more erratic movements. The increased trunk angles and variability may indicate a greater tendency toward forward bending, suggesting a moderate severity of hunchback as they struggle to maintain an upright posture.

The graph of individuals with PD (Figure 19C) reveals significant irregularities and instability in trunk angles. The curves are highly erratic, with frequent sharp changes and a wide range of deviations from the vertical alignment. These abrupt shifts indicate substantial difficulties in maintaining consistent trunk posture. Individuals with PD struggle with controlling their trunk movements, leading to frequent tilting and misalignment relative to the vertical axis. The pronounced forward bending and high variability in trunk angles reflect severe hunchback, characteristic of the disease's impact on posture and movement control.

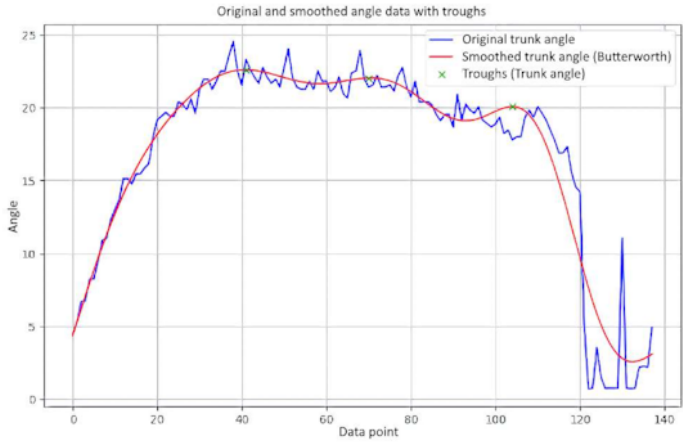
Figure 19. A comparative analysis of the trunk angle 1 between different groups: (A) younger individuals, (B) older individuals, and (C) individuals with Parkinson disease.



(A)



(B)

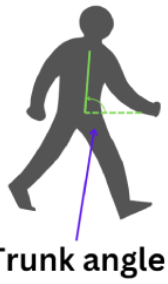


(C)

Trunk Angle 2 (Horizontal)

Trunk angle 2 analyzes the positions of the shoulders and hips (Figure 20). This angle is crucial for understanding the alignment of the trunk relative to the lower body, particularly during movements such as turning. By evaluating the trunk angle, we can assess the severity of hunchback or forward bending, which provides valuable insights into posture and stability.

Figure 20. An illustration of the trunk angle 2 horizontal position.



The calculation for trunk angle 2 is similar to that for trunk angle 1. The only difference is that as trunk angle 2 is horizontal, the default value must be set at the *x* coordinate instead of the keypoint. The formula to calculate trunk angle 2 is given as follows (equation 14):

Figure 21 shows graphs comparing trunk angles relative to the horizontal axis for 3 groups. These angles help assess the severity of forward bending or misalignment.

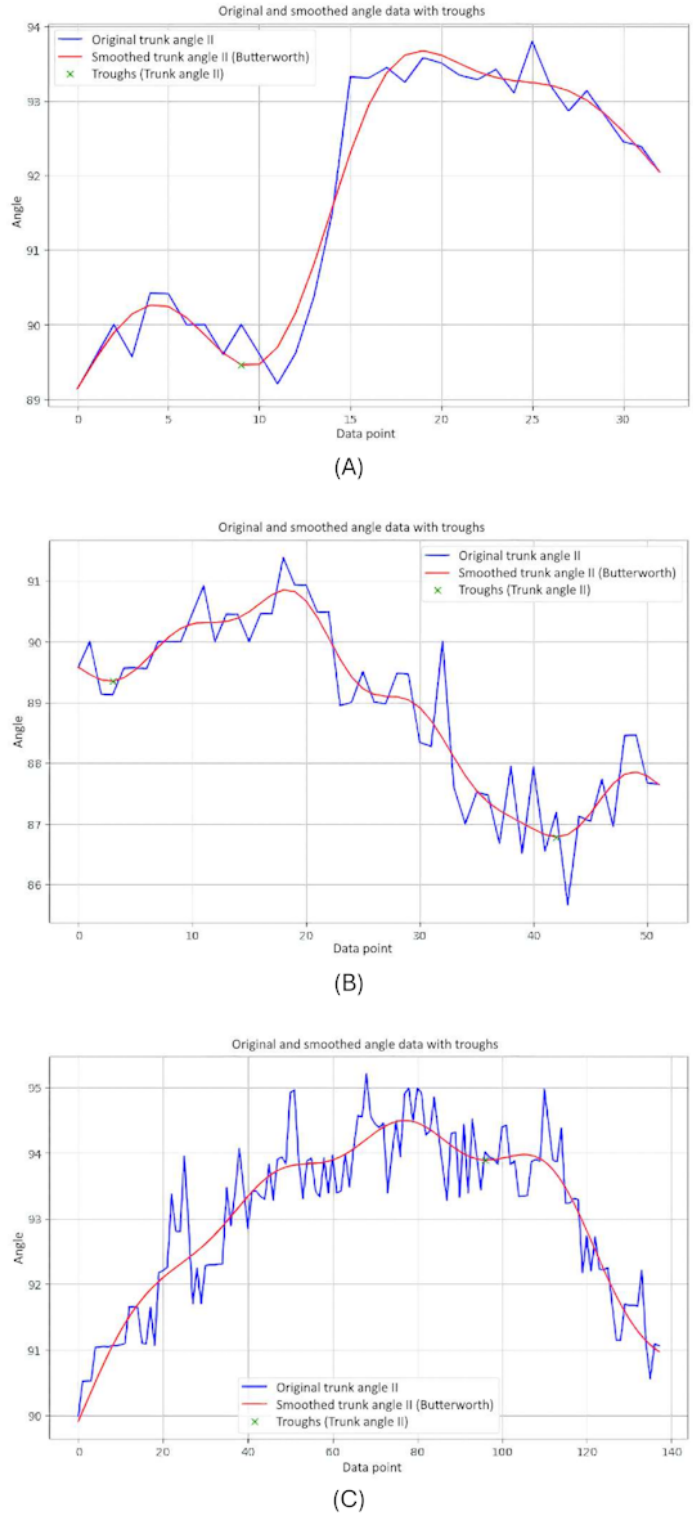
The graph of the younger-individual group (Figure 21A) exhibits stable and controlled trunk angles with minimal deviations, indicating well-balanced posture and low severity of hunchback.

The graph of the older individuals' group (Figure 21B) showed more variability and sudden changes in trunk angle, reflecting moderate forward lean and greater difficulty maintaining stable horizontal alignment, indicating moderate kyphosis severity.

The graph of the individuals with PD (Figure 21C) shows significant instability and frequent sharp changes in trunk angles, indicating severe difficulties in maintaining consistent trunk posture and severe hunchback severity due to the disease's impact on movement control.

Overall, younger individuals maintain a low severity of hunchback, older individuals exhibit moderate severity, and those with PD show severe hunchback, reflecting their challenges in maintaining horizontal alignment.

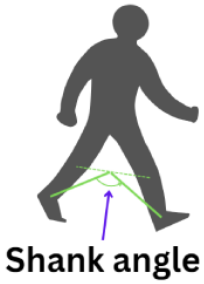
Figure 21. A comparative analysis of the trunk angle 2 horizontal between different groups: (A) younger individuals, (B) older individuals, and (C) individuals with Parkinson disease.



Shank Angle

The shank angle computes the positions of the knees and ankles (Figure 22). This angle is useful to understand the alignment and movement of the lower leg, especially during activities such as turning. By evaluating the shank angle, we can assess the coordination and stability of the lower leg movements, providing valuable insights into gait patterns and detecting any abnormalities in movement, which is particularly useful for analyzing conditions such as PD.

Figure 22. An illustration of the shank angle position.



The formula to calculate shank angle is provided in equation 15:

Figure 23 presents the graphs comparing shank angles during body movements for 3 groups. Each graph shows the shank angle over a series of data points, with both original and smoothed data represented.

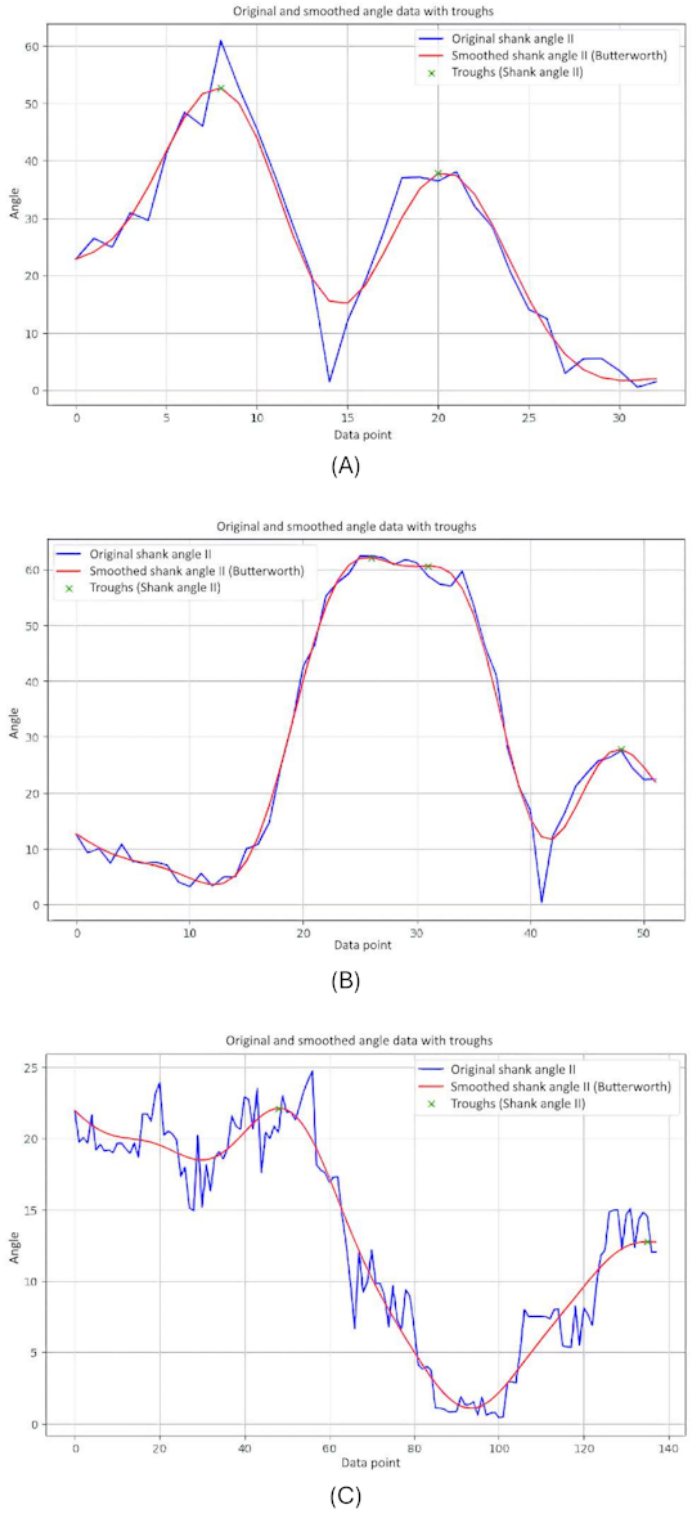
The graph of the younger-individual group (Figure 23A) demonstrates relatively stable and consistent shank angles. Both the original and smoothed curves align closely, indicating smooth and coordinated movements. The angles show moderate fluctuations within a narrow range, reflecting balanced and controlled lower leg movements typical of healthy young individuals.

The older-individual group graph (Figure 23B) shows shank angles that are stable and consistent, such as the younger individuals group. Both the original and smoothed curves align closely, indicating smooth and coordinated lower leg movements. The angles show moderate fluctuations within a narrow range, reflecting balanced and controlled movements. This suggests that older individuals perform nicely, maintaining stable shank angles comparable to the younger individuals group.

The graph of individuals with PD (Figure 23C) reveals significant irregularities and instability in shank angles. The curves are highly erratic, with frequent sharp changes and a wide range of deviations. These abrupt shifts indicate substantial difficulties in maintaining consistent lower leg movements. Individuals with PD struggle with controlling their shank angles, leading to frequent misalignment and instability. This pattern is characteristic of the disease, where symptoms such as rigidity and tremors disrupt smooth and coordinated movements.

Figure 23 highlights the differences in shank angle behavior among the 3 groups. Younger and older individuals exhibit stable and coordinated shank movements with minimal variability, indicating balanced and controlled lower leg movements. In contrast, those with PD display significant instability and erratic shank movements, underscoring the impact of the condition on lower leg control and stability.

Figure 23. A comparative analysis of the shank angle between different groups: (A) younger individuals, (B) older individuals, and (C) individuals with Parkinson disease.



Classification Report

A comprehensive evaluation of the SVM model is provided by the classification report for the test set, as shown in Table 3. The report includes the overall accuracy of the model, as well as each class's recall, precision, and F_1-score. Although the training accuracy was 0.95, the test accuracy was 0.89, indicating that the model fit the training data well with minimal overfitting. The classification report shows that class 0 (normal class) had high precision and recall, while class 1 (PD class) has lower recall. This disparity in recall may be due to the smaller sample size of class 1.

Table 3. Classification report for distinguishing normal and PD[a] classes using gait features (test accuracy: 0.89 and train accuracy: 0.95).

Classes or metrics	Precision	Recall	F_1-score	Support
0 (normal)	0.88	1.00	0.93	7.00
1 (PD)	1.00	0.50	0.67	2.00
Accuracy	—[b]	—	0.89	9.00
Macroaverage	0.94	0.75	0.80	9.00
Weighted average	0.90	0.89	0.87	9.00

[a]PD: Parkinson disease.

[b]Not available.

AUC and Loss Curve

Figure 24 provides specifics regarding the model's capacity to distinguish between the 2 classes. Moderate discrimination capability is indicated by the test set's AUC of 0.6429. An indicator of how well the model performs across various training data subsets is provided by the cross-validation scores. With a mean cross-validation score of 0.9, the model's cross-validation scores are (0.75, 1.00, 1.00, 0.75, 1.00). This shows that the model continues to work well when the data are folded in different ways.

Figure 24. The receiver operating characteristic (ROC) curve.

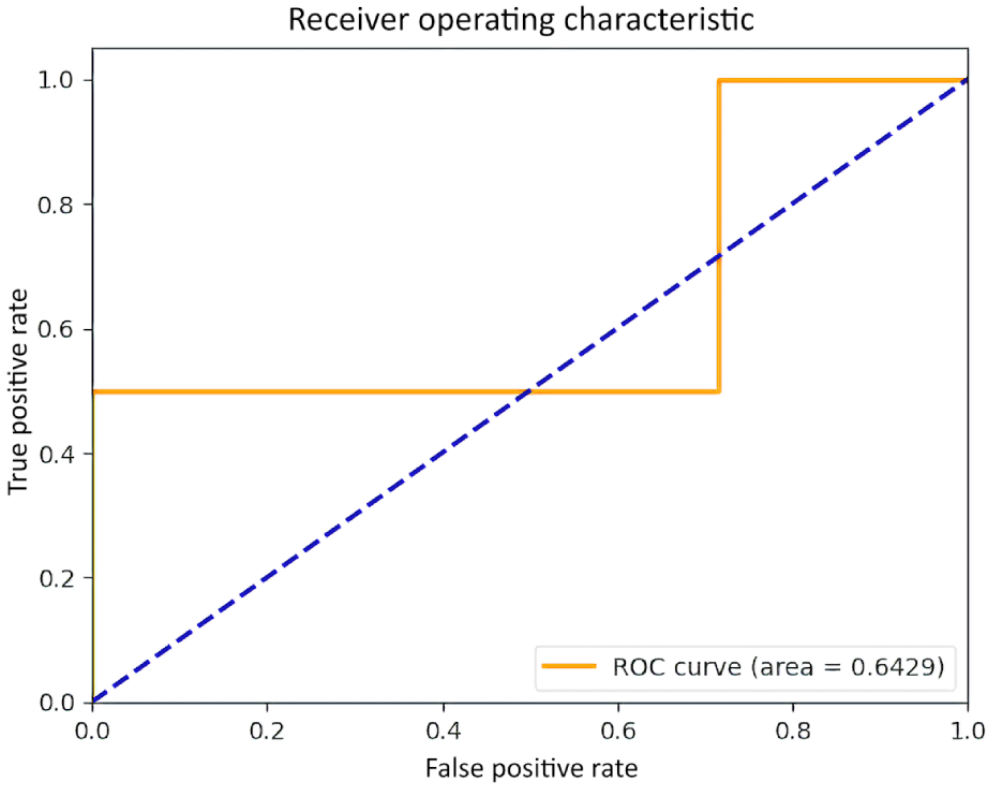


Figure 25 shows the training and validation loss curve, illustrating the log loss for both training and validation sets across various folds of cross-validation. The blue curve indicates the training loss, which stays relatively stable with minor fluctuations. In contrast, the red curve, representing the validation loss, exhibits significant fluctuations, peaking notably at fold 3. This implies that while the model fits the training data well, it experiences considerable variability in performance on unseen data, suggesting possible overfitting or sensitivity to specific data subsets. The difference between the training and validation loss also underscores the model's difficulty in generalizing from the training set to the validation set, highlighting the need for potential adjustments in model complexity or training strategy to achieve more consistent performance.

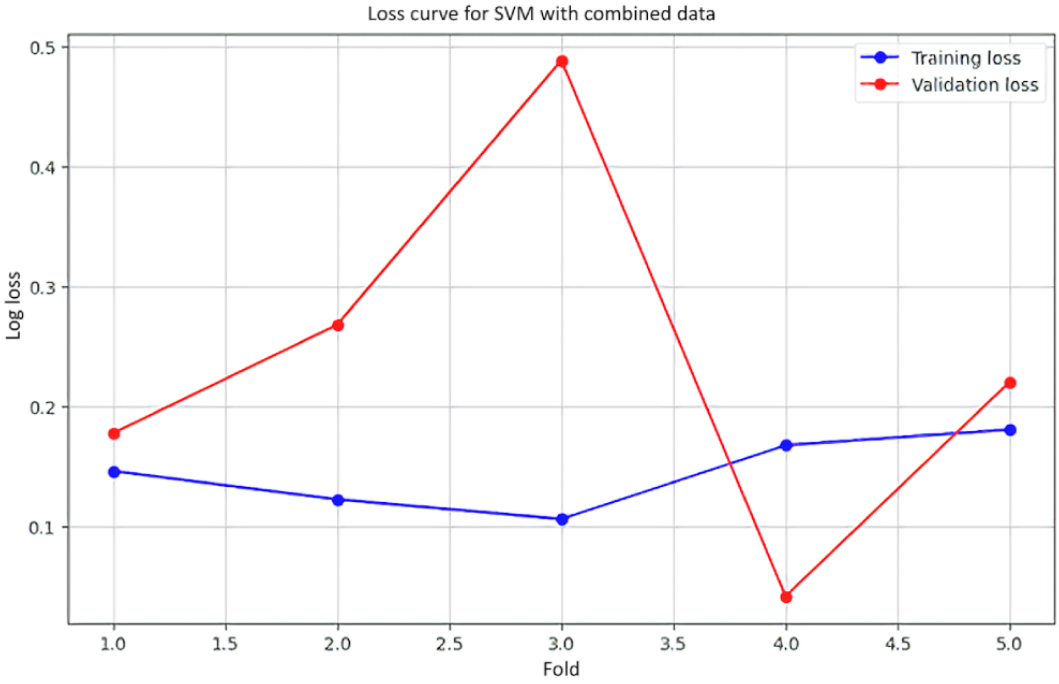
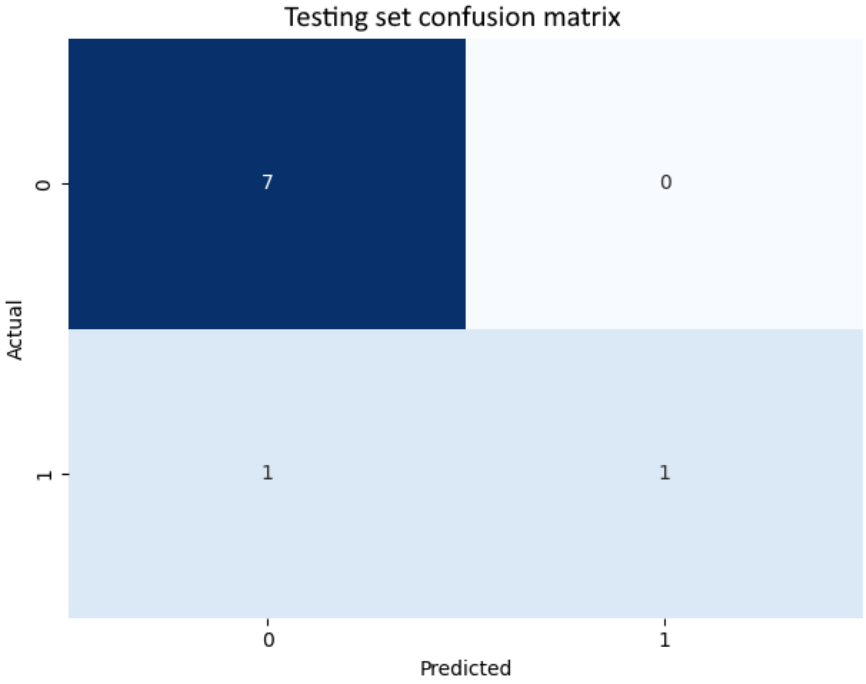
Figure 25. The training and validation loss curve for support vector machine (SVM) with combined data.



Confusion Matrix

The confusion matrix depicted in Figure 26 provides a thorough analysis of the predictions of the model on the test set. It reveals that while the model correctly predicted 7 out of 7 occurrences of class 0 (non-PD), it incorrectly classified 1 out of 2 instances of class 1 (PD). This suggests that although the model is highly accurate in predicting class 0, it faces challenges with class 1, likely due to class imbalance in the dataset.

Figure 26. The testing set confusion matrix for model-based features.



Discussion

This study presents a noninvasive approach for early detection of PD through the analysis of model-based gait features. Using kinematic characteristics, such as shoulder distance, step length, stride length, knee and hip angles, leg and arm symmetry, and trunk angles, we aimed to identify subtle gait abnormalities associated with PD. Data were collected through controlled video recordings of the TUG assessment, and the extracted features were processed using advanced filtering techniques and analyzed using SVM classifier.

The results demonstrate that the model-based features were highly effective in distinguishing between normal and PD-affected gait patterns, achieving high accuracy, precision, recall, and F_1-score. These findings support the potential of model-based gait analysis as a noninvasive, accessible tool for early diagnosis and monitoring of PD. The study also highlights the importance of addressing class imbalance and refining the feature extraction process to further enhance the performance of the classifier.

Future research should focus on validating these findings with larger datasets, exploring other machine learning models, and integrating additional features to improve the robustness and accuracy of PD detection systems. This approach could significantly benefit clinical settings, providing a reliable, noninvasive method for early diagnosis and improved patient outcomes.

Abstract

Background: Polypharmacy, the concurrent use of multiple medications, is prevalent among older adults and associated with increased risks for adverse drug events including falls. Deprescribing, the systematic process of discontinuing potentially inappropriate medications, aims to mitigate these risks. However, the practical application of deprescribing criteria in emergency settings remains limited due to time constraints and criteria complexity.

Objective: This study aims to evaluate the performance of a large language model (LLM)–based pipeline in identifying deprescribing opportunities for older emergency department (ED) patients with polypharmacy, using 3 different sets of criteria: Beers, Screening Tool of Older People's Prescriptions, and Geriatric Emergency Medication Safety Recommendations. The study further evaluates LLM confidence calibration and its ability to improve recommendation performance.

Methods: We conducted a retrospective cohort study of older adults presenting to an ED in a large academic medical center in the Northeast United States from January 2022 to March 2022. A random sample of 100 patients (712 total oral medications) was selected for detailed analysis. The LLM pipeline consisted of two steps: (1) filtering high-yield deprescribing criteria based on patients' medication lists, and (2) applying these criteria using both structured and unstructured patient data to recommend deprescribing. Model performance was assessed by comparing model recommendations to those of trained medical students, with discrepancies adjudicated by board-certified ED physicians. Selective prediction, a method that allows a model to abstain from low-confidence predictions to improve overall reliability, was applied to assess the model's confidence and decision-making thresholds.

Results: The LLM was significantly more effective in identifying deprescribing criteria (positive predictive value: 0.83; negative predictive value: 0.93; McNemar test for paired proportions: χ^2_1=5.985; *P*=.02) relative to medical students, but showed limitations in making specific deprescribing recommendations (positive predictive value=0.47; negative predictive value=0.93). Adjudication revealed that while the model excelled at identifying when there was a deprescribing criterion related to one of the patient's medications, it often struggled with determining whether that criterion applied to the specific case due to complex inclusion and exclusion criteria (54.5% of errors) and ambiguous clinical contexts (eg, missing information; 39.3% of errors). Selective prediction only marginally improved LLM performance due to poorly calibrated confidence estimates.

Conclusions: This study highlights the potential of LLMs to support deprescribing decisions in the ED by effectively filtering relevant criteria. However, challenges remain in applying these criteria to complex clinical scenarios, as the LLM demonstrated poor performance on more intricate decision-making tasks, with its reported confidence often failing to align with its actual success in these cases. The findings underscore the need for clearer deprescribing guidelines, improved LLM calibration for real-world use, and better integration of human–artificial intelligence workflows to balance artificial intelligence recommendations with clinician judgment.

Introduction

Polypharmacy, widely defined as the regular use of at least 5 medications, is common in older adults and at-risk populations [1]. In fact, approximately 30% of patients aged 65 years or older have polypharmacy [2], and nearly half of older emergency department (ED) patients are discharged with one or more new medications [3]. Although necessary and beneficial for some patients, polypharmacy can increase the risk of negative consequences for patients, including ED visits, adverse drug events, falls, disability, and inappropriate medication use [1]. While definitions differ, deprescribing is generally defined as a structured process by which potentially inappropriate medications (PIMs) are identified and withdrawn under the supervision of a health care provider. In some definitions, the process is described as evaluating the risk-benefit tradeoff, focusing on situations where the potential or actual harms of a medication outweigh its benefits, considering the patient's individual care goals and quality of life [2,4,5].

Deprescribing tools, such as the Screening Tool of Older People's Prescriptions (STOPP) [6] and Beers criteria [7], have been developed to help providers assess and identify PIMs based on a patient's medication list [7-9]. These explicit assessments are criterion-based with clear standards but are often impractical to implement in time-constrained clinical settings, such as ED, due to the need to evaluate multiple clinical indications and specialist-prescribed medications [10]. Attempts to digitize these criteria into electronic clinical decision support (CDS) have raised difficulties, typically requiring a labor-intensive coding process and unstructured information such as free text from patient records to contextualize certain criteria [11,12].

Large language models (LLMs) have been shown to interpret complex clinical situations and offer recommendations, from differential diagnoses to care management, leading to growing interest in their application in the medical field [13-16]. Moreover, they have been shown to extract medication-related data such as medication name, dosage, and frequency, necessary for the application of deprescribing criteria [17]. Finally, LLMs are excellent in-context learners, requiring very little labeled data to make predictions [18]. This reduces the annotation burden for time-constrained ED physicians while improving the use of unstructured patient records to contextualize patient medication lists. However, the majority of clinical reasoning evaluations on LLMs have been conducted using standardized exams (the United States Medical Licensing Examination) or digital case reports [14,19]. Their ability to perform clinical reasoning and calibrate responses over physician-generated text remains understudied.

Here, we propose to evaluate the performance of an LLM-based data pipeline in recommending deprescribing options for older adult ED patients at discharge based on 2 leading deprescribing criteria, Beers and STOPP. We have also included a recently developed list of criteria, Geriatric Emergency Medication Safety Recommendations (GEMS-Rx), intended to prevent the initiation of inappropriate medications in the acute care setting, as similar deprescribing lists specific to this care environment are not available [3]. Through this work, we hope to evaluate whether an LLM-based CDS system can effectively triage medications eligible for electronic deprescribing in older adults. Successful implementation of such a system would help address gaps in electronic deprescribing by using an LLM to contextualize recommendations within individual patient records and reduce manual development in CDS tools.

Methods

Ethical Considerations

This study was conducted with approval from the Institutional Review Board (IRB) at Yale University, under protocol number 2000035077. The IRB determined that this research qualifies for exemption as it involves secondary analysis of existing electronic health record (EHR) data, with no additional patient contact or data collection. The original data were collected with patient consent, and the current analysis adheres to the conditions of that consent and IRB approval, permitting

secondary analysis without the need for additional consent. All data were de-identified prior to analysis to ensure patient confidentiality. This study complies with ethical standards and guidelines for research involving human subjects.

Patient Cohort

All older adults (aged 65 years and older) with polypharmacy (5 or more active outpatient medications) presenting to an ED in a large academic medical center in the Northeast United States between January 2022 and March 2022 were identified. Due to budgetary constraints and a lack of prior evidence regarding the performance of LLMs in this task to guide a power calculation, we selected a random sample of 100 unique patients for evaluation.

Identification of Consensus-Based High-Yield Criteria

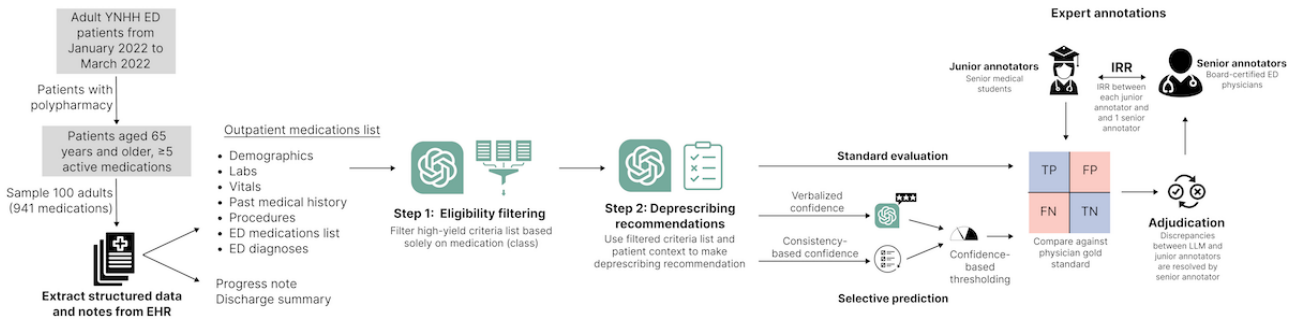
We conducted a consensus-based evaluation to filter three preexisting deprescribing lists (ie, STOPP [6], Beers [7], and GEMS-Rx [3]) into a focused set of high-yield deprescribing criteria for the LLM to use in its recommendations. High-yield criteria were defined as those posing a significant clinical risk to the patient and being identifiable within the electronic health records (EHRs). To identify these criteria, we evaluated 180 recommendations across 2 key dimensions: clinical risk and EHR computability. The consensus panel consisted of 6 board-certified physicians (in Emergency Medicine, Internal Medicine, and Clinical Informatics) and 1 ED pharmacist. Each member of the group individually reviewed each of the criteria and rated them on a 5-point Likert scale. We selected the top 50% of criteria with an average score greater than 3 on both dimensions, calculated across all experts, as high-yield criteria. We further elaborate on this consensus process and the final set of criteria in the Results section.

The need to filter the criteria before proceeding with the study was identified in our preliminary research [20], which revealed that one of the main causes of discrepancies between physicians and LLMs arose from ambiguous inclusion or exclusion conditions in deprescribing criteria. For example, criteria like "Statins for primary cardiovascular prevention in persons aged ≥85 with established frailty with expected life expectancy likely less than 3 years" include elements—such as "established frailty" and "expected life expectancy"—that are challenging to quantify and therefore difficult to implement computationally. The dimensions used to filter criteria were chosen to ensure that an LLM-enabled CDS tool prioritizes meaningful recommendations from high-quality EHR data, enabling accurate, actionable deprescribing recommendations and reduction of alert fatigue. We present the final set of high-yield criteria based on the average results of the consensus study.

Deprescribing Recommendations by GPT-4o

The study was approved under an exemption by the Yale University institutional review board prior to commencement (HIC# 2000035077). All patient-level data were deidentified prior to use with the LLM. We leveraged Microsoft's Azure OpenAI GPT-4o (GPT-4o model version: 2024-08-06 and OpenAI API version: 2024-02-15-preview) to produce deprescribing recommendations through a 2-stage process, as shown in Figure 1. In stage 1, GPT-4o was prompted to filter the full list of high-yield criteria solely based on the patient's medication list, ignoring inclusion or exclusion conditions. In stage 2, GPT-4o was prompted to use its previously filtered criteria list, along with structured (eg, demographics, lab values, vitals, and past medical history) and unstructured (most recent progress note and discharge summary) information, to determine if the patient satisfied any deprescribing criteria and the medication should be recommended for deprescribing. Each medication was evaluated individually to prevent errors from simultaneous processing, such as misattribution of criteria or medication omissions. To ensure optimal performance, we engineered prompts in an iterative fashion [21], using 1 patient at a time from a set of patients (up to 10% of the cohort) not used in the subsequent evaluation. After each evaluation, prompts were adjusted to correct any systematic errors (eg, instances where no relevant criteria in step 1 led to noncriteria-based deprescribing recommendations in step 2) by the LLM. After our third prompt yielded an output without any identifiable errors, we stopped the iterative prompt development process. Consequently, the final 2 patients initially reserved for this purpose were included in the final cohort evaluation (n=92 patients, 626 medications). Aside from the consistency-based method described later, all LLM calls were performed with a fixed temperature (temperature=0; low randomness in generated responses) and seed to ensure reproducibility and deterministic outputs.

Figure 1. Overview of the evaluation pipeline, consisting of a 2-step GPT-4o process, performance comparison with junior annotators (medical students), and final adjudication by senior annotators (board-certified physicians). ED: emergency department; EHR: electronic health record; FN: false negative; FP: false positive; IRR: interrater reliability; TN: true negative; TP: true positive; YNHH: Yale New Haven Hospital.



This 2-stage process was developed to correct errors identified when both stages were accomplished at once. Our initial testing revealed that providing the LLM with the full set of criteria and medications led to simple reasoning errors. The large number

of criteria, combined with the simultaneous processing of the complete patient medication list, resulted in inaccuracies in applying individual criteria to specific medications. Separating the process of criteria filtering and application both reduces confusion due to large input context sizes [22] and ensures that extraneous context does not distract the LLM [23]. The full prompts for step 1 and step 2 are included in Figures S5 and S6 in Multimedia Appendix 1.

Selective Prediction Methods

In addition to evaluating an LLM's ability to make deprescribing recommendations, we assessed whether its confidence estimates were well-calibrated and examined their impact on predictive performance. To do so, we collected GPT-4o's decision confidence for both steps using 2 validated confidence elicitation methods: chain-of-thought verbalized confidence and self-random sampling with average-confidence aggregation, referred to as consistency-based confidence [24]. In verbalized confidence, we asked the LLM to explicitly estimate its confidence for each step following its decision. For the consistency-based approach, we followed the best practices established in prior work [24] by sampling the LLM multiple times (number of samples=5) with high temperature (T=0.8; high randomness in generated responses) and used a majority vote weighted by the confidence of each response to determine the final deprescribing recommendation.

In a human-in-the-loop decision-making system, the LLM's confidence would be used to determine if the model should abstain due to low certainty regarding its own decision. In practice, this case would be considered too difficult for the LLM and forwarded to an expert reviewer. This human-in-the-loop decision-making pipeline is known as selective prediction and has been commonly found to improve performance in non–text-based applications [25,26]. We evaluated both selective prediction methods using risk-coverage curves [27,28], substituting risk for the F_1-score (a measure of the predictive performance of a model balancing precision and recall) to capture the full range of predictive performance. Coverage was also expressed inversely as the deferring fraction, representing the proportion of instances where the LLM abstained from making a decision. We conducted a more in-depth analysis of the method that proved to be more effective.

Comparison and Adjudication With Clinical Experts

In this study, we used a rigorous human review and adjudication process to assess model performance. Two trained senior medical students (M4) classified all medications in the test cohort using a 2-stage pipeline, after first computing interrater reliability (IRR) on an adjudication set of 75 medications from 5 patients. Similar to the LLM pipeline, for each medication, a medical student determined (1) if there exists a relevant high-yield criteria based on the medication list, and (2) whether the medication should be recommended for deprescribing. Discrepancies between the students (junior annotators) and the LLM across both stages were adjudicated by 2 board-certified ED physicians (senior annotators). Similarly to the junior annotators, we measured the IRR between the 2 senior ED physicians, prior to adjudication on the full set of discrepancies. Finally, we classified the errors leading to incorrect recommendations by the LLM, leveraging a prior evaluation framework [29]. We classified each error as 1 of 4 error types: incorrect reading comprehension, incorrect recall of knowledge, incorrect reasoning step, and not enough information, as described in Table 1.

Table 1. Definitions of GPT-4o error types inspired by framework from Lièven et al [29] relevant to deprescribing recommendations.

GPT-4o error types	Definition	Example
Incorrect reading comprehension	Includes misunderstanding of order of text, such as when a medication is dependent on another medication in a specific arrangement. Also includes ignoring information provided in the input text, such as missing a relevant category explicitly stated in the recommendations.	GPT failed to recognize acetaminophen by name from the list of STOPP[a] criteria in a patient at risk for malnutrition or liver disease.
Incorrect recall of knowledge	Includes failure to recognize classes of medications or other medical facts necessary to perform the task.	GPT correctly recognized amlodipine was a calcium channel blocker but failed to recognize it was more broadly an antihypertensive.
Incorrect reasoning step	Faulty reasoning, such as inappropriate assumptions or leads of logic unsupported by the clinical data.	GPT recommended discontinuing warfarin in a patient with a therapeutically elevated INR[b] after assuming that this elevated INR was due to a bleeding disorder.
Not enough information	Inappropriate application of missing data leading to potentially unreliable conclusions, such as assuming abnormality of a missing laboratory study.	GPT recommended discontinuing a QT[c] prolonging antidepressant based on the possibility of QT prolongation without any ECG[d] data or history of abnormal QT interval.

[a]STOPP: Screening Tool of Older People's Prescriptions.

[b]INR: International normalized ratio.

[c]QT: QT interval.

[d]ECG: electrocardiogram.

Data Analysis

We evaluated whether the LLM or the medical student was correct, using a gold standard derived from senior annotator (board-certified ED physicians) adjudication of discrepancies. To compare their proportions of correct responses, we applied the McNemar test, a statistical method commonly used to analyze paired nominal data, such as diagnostic accuracy from different assessments applied to the same cases [30]. All analysis was performed using Python (version 3.9; Python Software Foundation). Statistical testing was carried out using *statsmodels* (version 0.14.4) [31] and all visualizations were generated using *seaborn* (version 0.13.2) [32] and *matplotlib* (version 3.8.2) [33].

Results

Patient Cohort

In total, we identified 10,977 unique patients across 15,161 emergency department encounters from January 2022 to March 2022 meeting our selection criteria, from which 100 patients were randomly selected (Table 2). As our criteria only pertain to oral medication, nonoral medications were subsequently filtered out, resulting in 712 total oral medications across the cohort and a median of 6 oral medications per patient (Figure 2). From our initial study cohort of 100 patients, 10 patients were set aside for both prompt engineering and calculation of IRR between junior annotators. Fewer iterations were needed to refine the prompt than initially anticipated, so the remaining 2 patients were included in the final study cohort. This resulted in a final evaluation cohort of 92 patients, encompassing a total of 626 medications. Based on the mechanism of action, statins were the most common medication class (atorvastatin and rosuvastatin; 6.8% combined), followed by proton pump inhibitors (pantoprazole, esomeprazole, and omeprazole; 4.6% combined). When classified by therapeutic effect, antihypertensive agents were most prevalent (amlodipine, lisinopril, losartan, and valsartan; 10.6% combined).

Table 2. Demographic overview of the 100 patients included in the evaluation (N=100).

Characteristics	Values
Age, mean (SD)	75.8 (7.6)
Sex, n (%)

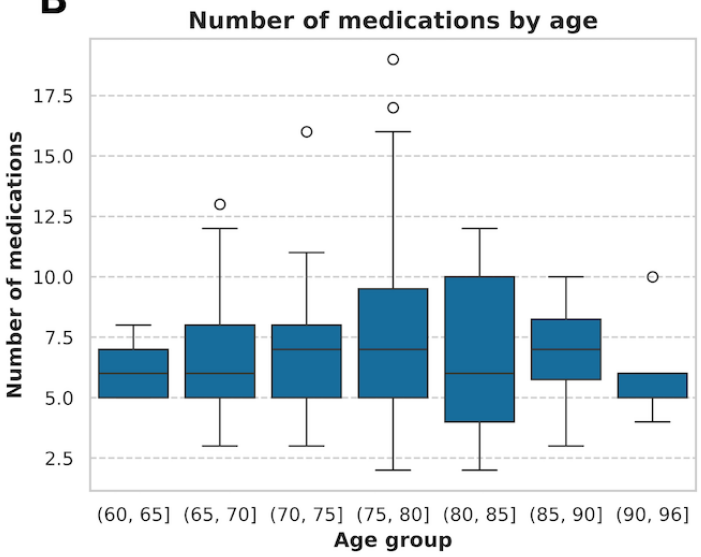
Omeprazole	1.5
Valsartan	1.3

B

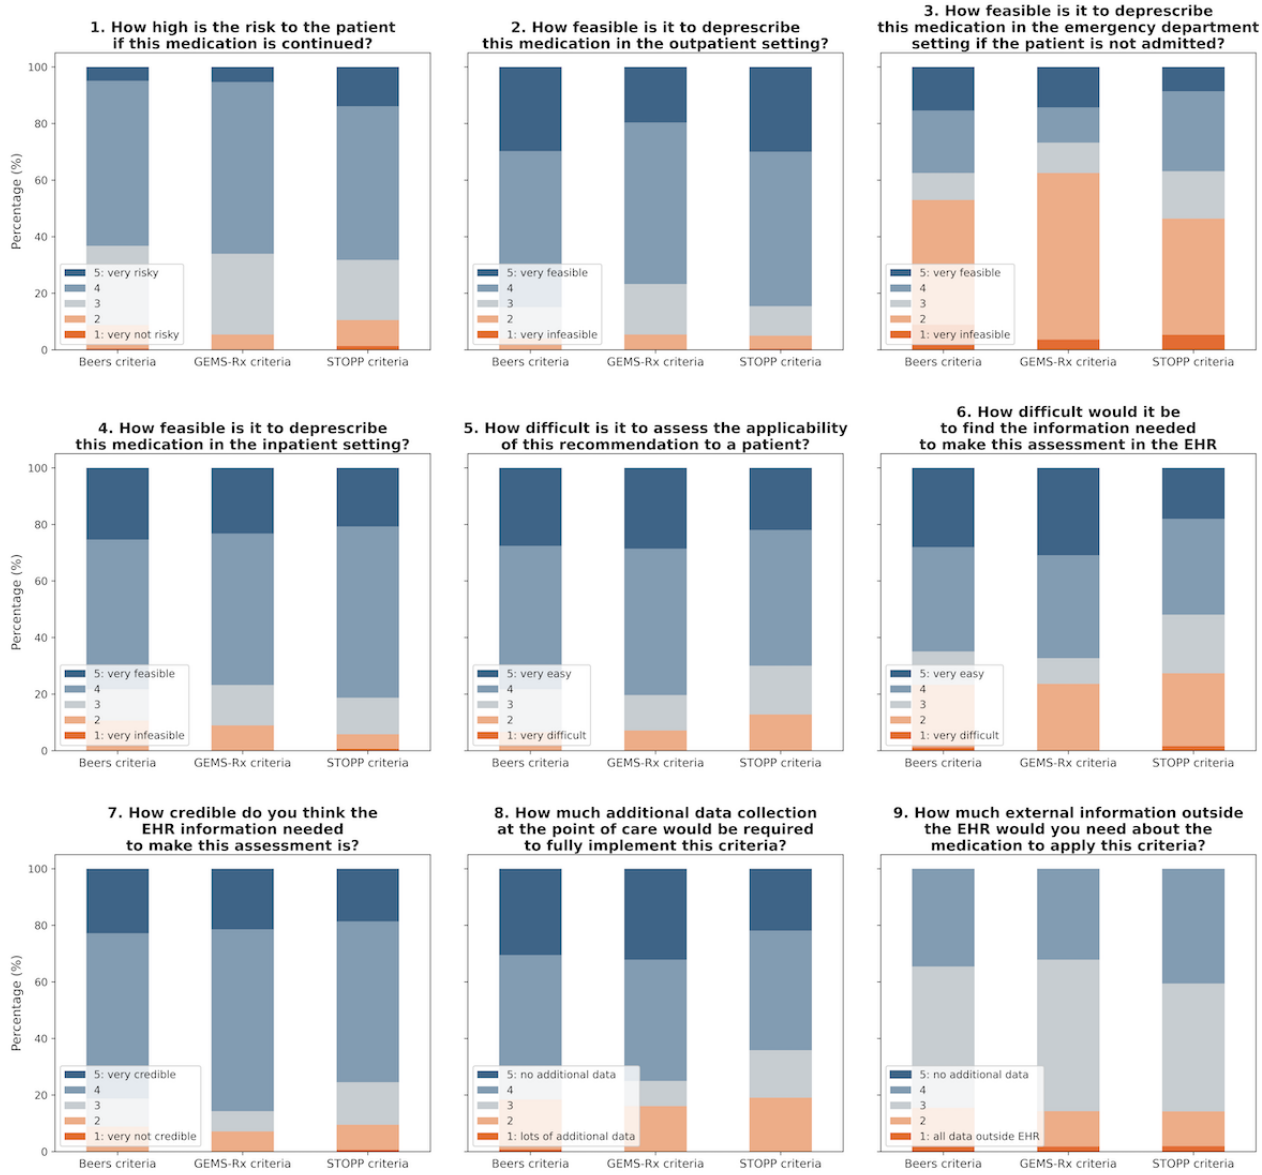


Evaluation of Consensus-Based High-Yield Criteria

To streamline evaluation by the LLM, we filtered criteria using the average scores from an expert consensus panel. All criteria (n=180) were evaluated based on their scores for clinical risk (Q1) and EHR computability (Q2-Q5), as assessed by an expert panel; average scores by deprescribing list are shown in Figure 3. Any criteria scoring less than 3 on both clinical applicability and EHR computability were excluded resulting in 161 criteria. From the remaining set, the top 50% were selected, resulting in 81 high-yield criteria across all 3 deprescribing lists.

On average, STOPP criteria had the lowest clinical risk and EHR computability ratings, while the Beers criteria had the highest, contributing to their respective adoption rates of 45.9% and 62.5% among high-yield criteria. Reduced inclusion of STOPP criteria was primarily attributed to panelists' concerns that the information required was not readily accessible within the EHR and would necessitate additional data at the point of care. We also present the results of feasibility in various clinical settings by criteria list in Figure S1 in Multimedia Appendix 1, showing more likelihood for deprescribing in both outpatient and inpatient contexts, compared to the ED, across all 3 criteria lists. A scatter plot of risk versus EHR computability of high-yield criteria is presented in Figure S2 in Multimedia Appendix 1.

Figure 3. Average distribution of results used to filter high-yield criteria on a 5-point Likert scale from a consensus study by an expert panel (n=7) split by 3 criteria lists: Beers, GEMS-Rx, and STOPP. EHR: electronic health record; GEMS-Rx: Geriatric Emergency Medication Safety Recommendations; STOPP: Screening Tool of Older People's Prescriptions.



Deprescribing Recommendations by GPT-4o

We next evaluated the LLM's deprescribing recommendations by comparing them to those of medical students, resolving any discrepancies through adjudication by board-certified EM physicians. As shown in Figure 4, 315 medications (50.3% of the total) lacked relevant high-yield deprescribing criteria. The LLM effectively identified these cases, achieving an F_1-score of 0.86 (precision=0.83, recall=0.90). Among those medications with relevant criteria, 64 (10.2% of the total) were cases where either GPT-4o or the medical student recommended deprescribing. In this second step, which involved applying relevant criteria to make a recommendation, the LLM performed less effectively, with an F_1-score of 0.58 (precision=0.47, recall=0.76).

For cases where the LLM and the medical students differed, 2 senior annotators (board-certified Emergency Medicine physicians) adjudicated 126 discrepancies after standardizing the codebook and verifying IRR (Cohen *k*: eligibility=0.795, deprescribing=0.745). Notably, the confusion matrix (Figure 4) revealed that a major source of discrepancy was the significantly higher likelihood of the LLM to recommend deprescribing (11.6%) compared to the medical students (1.91%). The confusion matrix describes all possible outcomes when comparing the LLM with the medical students (eg, the medical student recommended deprescribing with eligible criteria and the LLM found no eligible criteria). The adjudication yielded similar results to those observed in comparison with medical students (Figure 5A). Across all discrepancies, GPT-4o was significantly more effective in criteria filtering compared to the medical student (McNemar test for paired proportions [30]: χ^2_1=5.985; *P*=.015). However, in applying relevant criteria, GPT-4o performed worse than the medical students, though the difference was not statistically significant (McNemar test: χ^2_1=1.818; *P*=.178). Adjudication was chosen as the gold standard for resolving discrepancies because preliminary

research showed low IRR among medical students for both steps of the process (Cohen *k*: step 1=0.68, step 2=0.33) across 75 medications.

In cases where GPT-4o was incorrect, error analysis highlighted key patterns across the 2 steps. For criteria filtering, senior annotators observed that errors often stemmed from incorrect reasoning or reading comprehension issues (Figure 5B). Similarly, in making recommendations, the most common error was incorrect reasoning, followed by cases where the LLM lacked sufficient information to make an accurate determination and subsequently made inappropriate assumptions.

Figure 4. Confusion matrix (n=626 medications). The joint confusion matrix across both steps showing alignment and discrepancies between the GPT-4o model and medical students.

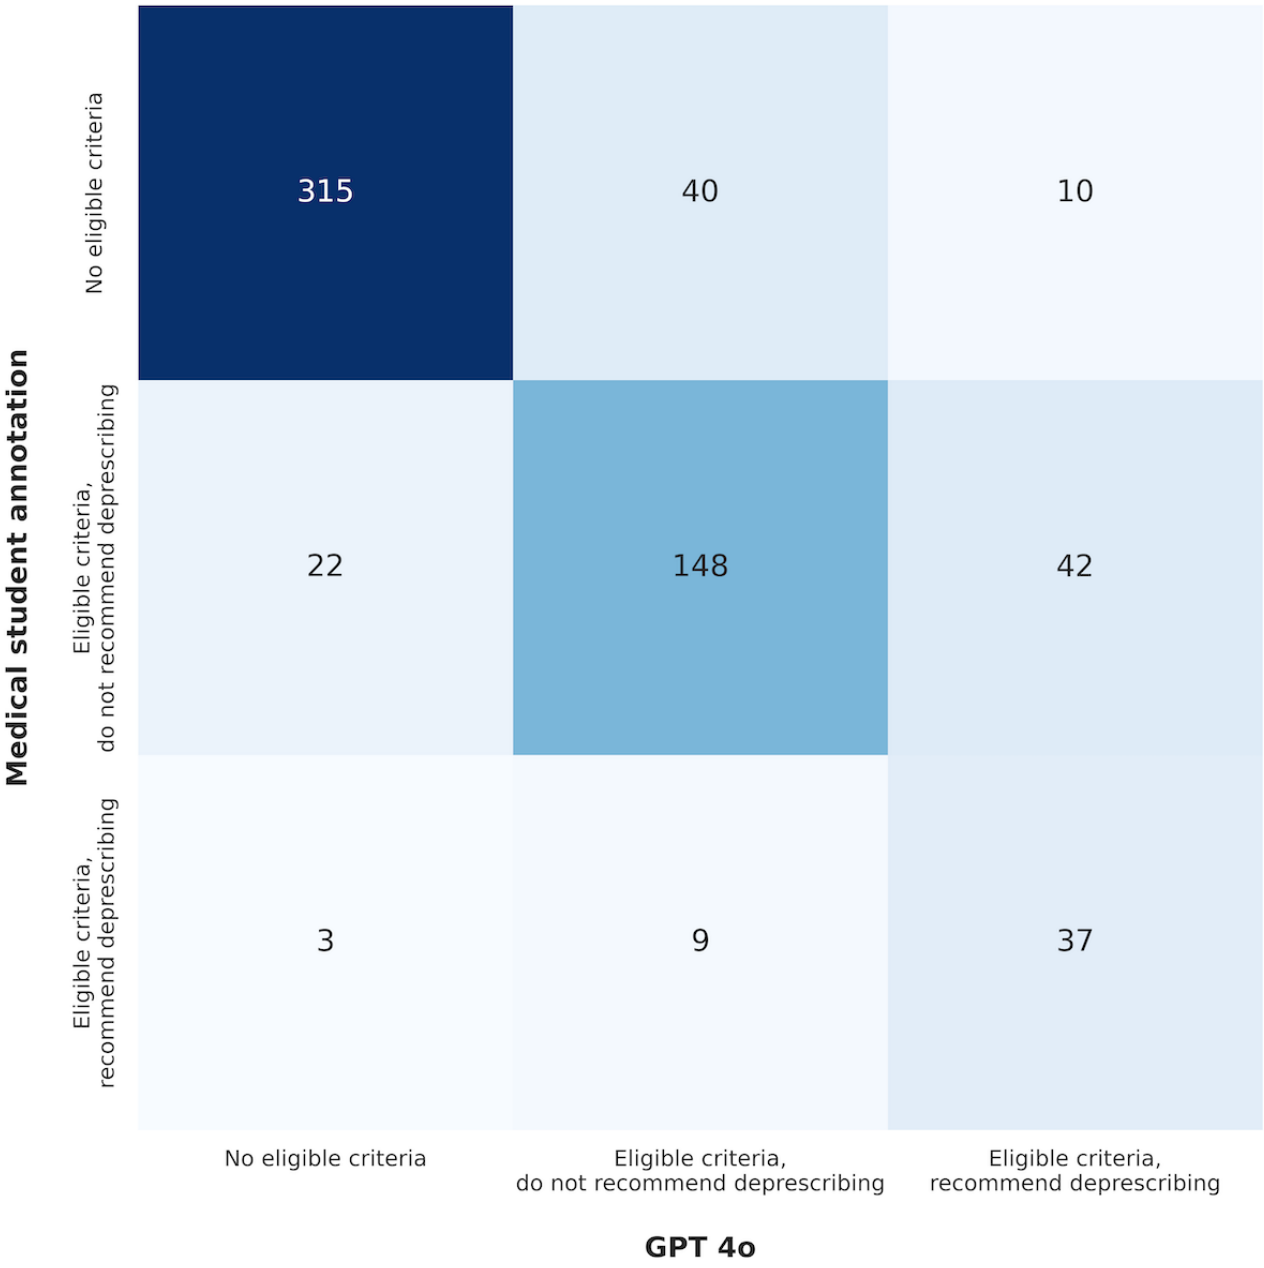


Figure 5. (A) Expert adjudication (n=126). Adjudication by senior clinical expert comparing junior annotators and GPT-4o in both criteria filtering and deprescribing recommendation tasks. (B) GPT-4o error modes. Types of errors by GPT-4o in the adjudication set (n=126) for both criteria filtering and deprescribing recommendation tasks.

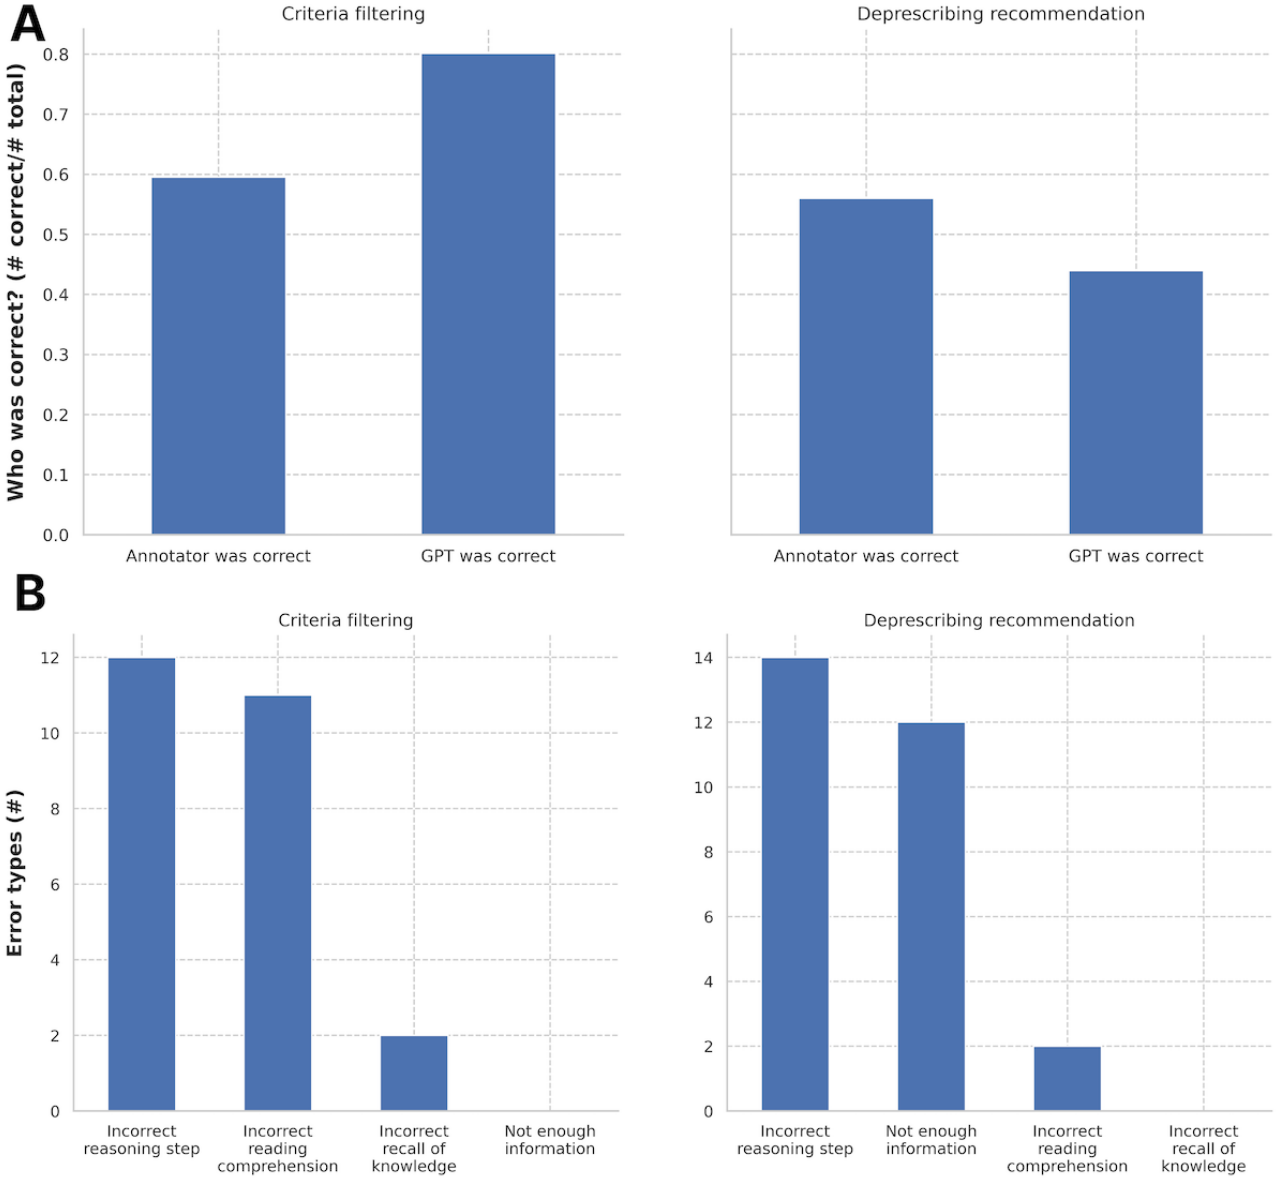
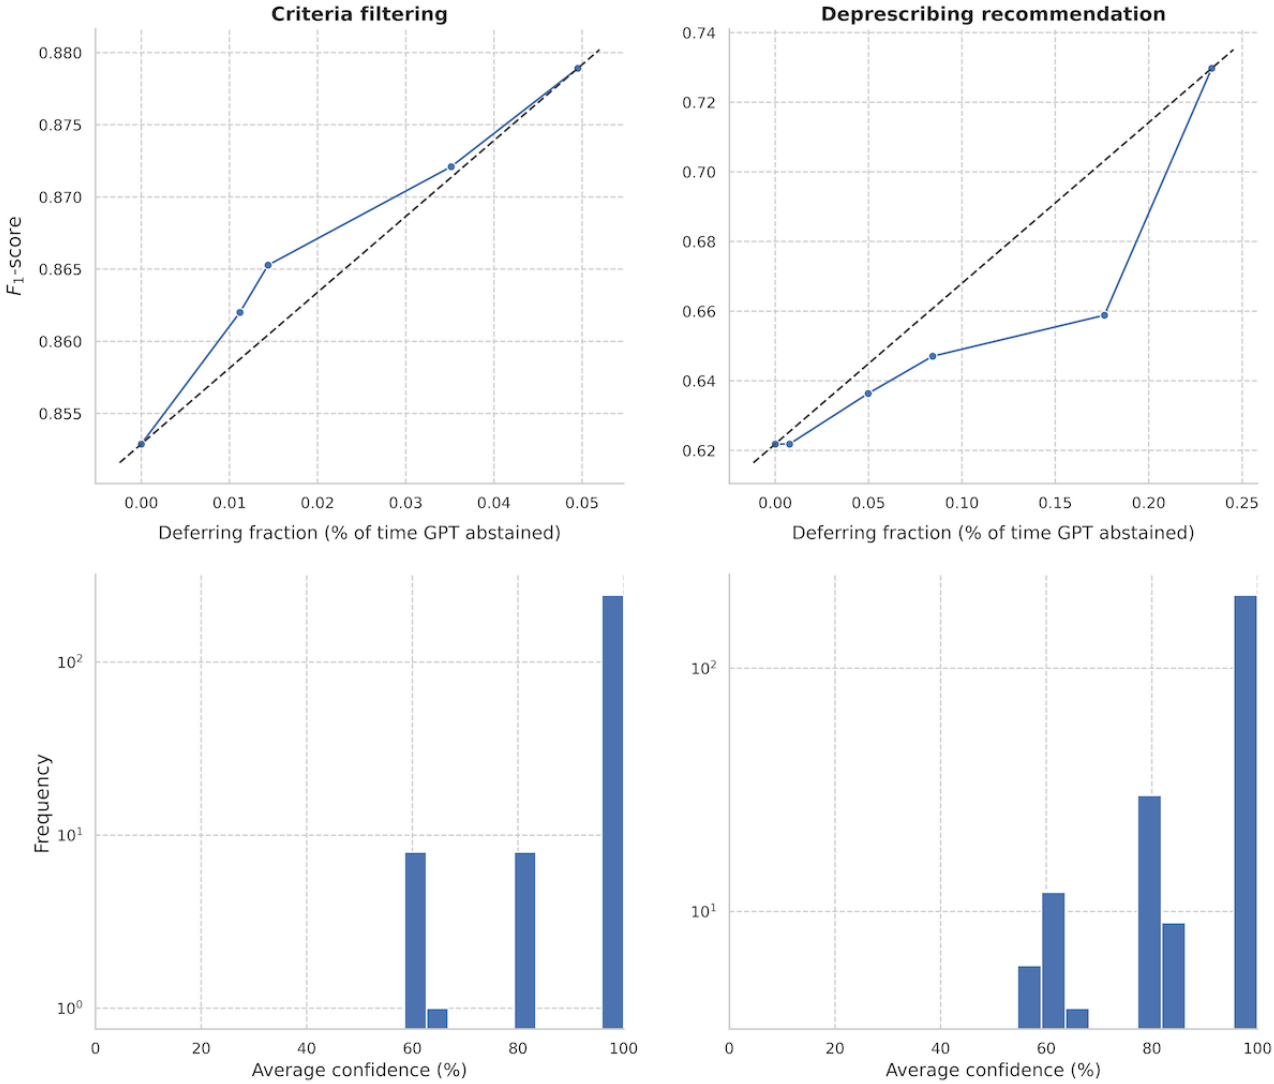


Selective Prediction Methods

Finally, we investigated the impact of incorporating confidence estimates from the LLM to guide selective prediction, allowing the model to abstain from making predictions in cases of low confidence. We compared 2 approaches: verbalized confidence and consistency-based confidence. Verbalized confidence demonstrated a narrower range of F_1-scores overall, with step 1 (eligibility) ranging from 0.860 to 0.863 and step 2 (deprescribing) from 0.58 to 0.69, as shown in Figure S3 in Multimedia Appendix 1. In contrast, consistency-based confidence exhibited broader and higher F_1-score ranges, with step 1 spanning 0.85 to 0.88 and step 2 ranging from 0.62 to 0.73 (Figure 6A). These results suggest that consistency-based confidence provides more flexibility and improved performance compared to verbalized confidence across both steps.

In particular, consistency-based selective prediction demonstrates a positive linear relationship between accuracy in deprescribing recommendations and deferring fractions. However, despite some minor improvements, we find that the LLM is poorly calibrated, as shown in Figure 6B. Despite consistency-based weighting, the confidence distribution is severely left-skewed with the minimum confidence being 58.5% in eligibility filtering and 54.5% in deprescribing recommendations.

Figure 6. Consistency-based selective prediction. (A) Range of F1-scores resulting from the application of consistency-based selective prediction in both steps of the deprescribing pipeline. The dotted line shows ideal performance as a function of deferring fraction. (B) Distribution of confidences for deprescribing recommendations from GPT-4o on a log scale.



Discussion

Principal Findings

In this retrospective cohort study evaluating deprescribing opportunities for PIMs among older adults with polypharmacy in the ED, we found that LLMs effectively identify relevant criteria from verified lists but are less adept at applying these criteria to individual patient cases. GPT-4o's performance was compared to that of medical students in a 2-step pipeline: filtering for criteria-eligible medications and making specific deprescribing recommendations. Adjudication by senior clinicians was used to resolve discrepancies, and selective prediction methods were tested to improve the model's reliability. The results offer insights into both the capabilities and limitations of LLMs in a real-world clinical context, highlighting key areas for improvement in both LLM frameworks and deprescribing guidelines.

Effectiveness of the 2-Step LLM Pipeline

The LLM demonstrated strengths in the initial filtering step, accurately identifying a high proportion of medications that matched deprescribing criteria, thus offering the potential to support clinicians in rapidly screening complex medication lists. In fact, the LLM outperformed medical students by a significant margin (80.1% vs 59.5% correct, McNemar test: P=.02). The adjudication, combined with strong overall performance (maximum F_1-score: 87.8%) using selective prediction methods, suggests that the LLM can effectively minimize the number of criteria requiring final review for deprescribing recommendations. Cases of misclassification were relatively uncommon and primarily related to nonstandard drug class names or overly broad groups, which could be improved with refined deprescribing criteria. However, in the second step—making specific deprescribing recommendations—the LLM encountered considerable difficulty, particularly when dealing with ambiguous criteria, missing information, and nuanced clinical scenarios. For example, thiazide diuretics are recommended for deprescribing in cases of significant hypokalemia, hyponatremia, hypercalcemia, or a history of gout. However, GPT-4o recommended deprescribing without access to current electrolyte values, instead basing its suggestion on a history of chronic kidney disease, a condition associated with

potential electrolyte imbalances but not meeting the relevant inclusion criteria. If implemented in clinical decision support, these inaccuracies might contribute to increased alert fatigue and extend the time required to interpret LLM-generated recommendations, potentially offsetting the intended efficiency gains in identifying deprescribing opportunities.

Our findings on the LLM's performance in identifying medications with relevant deprescribing criteria based on eligibility guidelines align with evidence from clinical trial matching literature [34], where LLMs have shown performance comparable to physicians in applying such criteria to identify eligible patients. One study used a similar "filter-and-apply" pipeline, in which trials were first filtered and then matched to patients, showcasing the effectiveness of this approach [35]. However, despite successes in eligibility filtering, challenges remain when applying complex criteria to specific patient cases. Similar errors to those observed in our work have been reported, such as incorrectly identifying patients who meet partial criteria, or assuming a patient with breast cancer does not have lung cancer simply because it is not explicitly mentioned [36,37]. Overall, while LLMs hold promise for reducing the time burden in determining deprescribing eligibility, their application requires careful consideration, particularly in tasks involving complex clinical reasoning.

Role of Selective Prediction in Clinical Decision-Making

To address the model's limitations in clinical decision-making, we implemented selective prediction methods, which allowed the LLM to "abstain" from making a recommendation in cases of low confidence. Selective prediction marginally improved the LLM's filtering accuracy by enabling it to defer uncertain cases to human reviewers. However, the effectiveness of this approach was limited by the poorly calibrated confidence levels assigned by the LLM to its decisions. Specifically, the LLM displayed a minimum confidence level of 54%, even in cases where its recommendations were incorrect. This indicates a tendency toward overconfidence, particularly in its deprescribing recommendations. While verbalized confidence is known to be overconfident in clinical question answering [38], our results contradict recent work that suggests that consistency-based methods alleviate some of these concerns [39]. This discrepancy underscores the importance of task-specific confidence thresholds and suggests that selective prediction, while useful, is not a one-size-fits-all solution in complex clinical applications.

Improved uncertainty calibration in LLMs could enhance selective prediction methods, optimizing physician-artificial intelligence (AI) workflows in clinical settings. Future applications of a well-calibrated deprescribing CDS tool could flag cases where critical information is missing (eg, antipsychotics at unchanged doses for more than 3 months without a documented medication review). This approach could streamline medication filtering while preserving human oversight, allowing clinicians to focus on complex cases where LLM reliability is limited.

Need for Clearer Deprescribing Guidelines

A notable finding from this study is the need for clearer and more consistent deprescribing guidelines. Ambiguities in criteria definitions, such as those related to medication administration routes and drug classes, present substantial barriers to automation and contribute to discrepancies between human and model interpretations. Additionally, the model often recommended deprescribing medications that, while potentially inappropriate, required specific contextual qualifiers (eg, patient's life expectancy, nutritional status, frailty status) to justify deprescribing—criteria that the LLM misapplied due to lack of explicit context or ambiguous language in the guidelines. It is important to note that current deprescribing criteria were not originally designed for direct implementation in CDS systems, but rather as general recommendations for prescribing physicians. Reorganizing these criteria into a structured, explicit framework tailored for CDS use could reduce ambiguity, improve the model's performance, and support more consistent application in clinical practice. In general, streamlining deprescribing criteria to ensure consistent application across clinical contexts could improve model reliability and help standardize deprescribing practices.

Implications for LLM Use in Clinical Practice and Future Directions

The results of this study underscore the promise of LLMs in enhancing deprescribing workflows by providing rapid filtering of PIMs, which could alleviate some of the burdens on health care providers. However, this work also highlights the limitations of current LLMs in complex, context-sensitive clinical decision-making tasks. The LLM's frequent tendency to overrecommend deprescribing, as compared to medical students, indicates that clear boundaries for medication eligibility and exclusion are critical for reducing false positives in automated recommendations. Cases with the potential for human harm were observed, such as suggesting deprescribing anticoagulation in a patient with recent thromboembolism. Additionally, cases were seen in which the LLM recommended deprescribing without citing a specific criterion. These behaviors suggest that strong guardrails on the LLM are needed to ensure safe, high-quality recommendations. Enhancing guideline specificity, particularly for complex inclusion or exclusion criteria, could reduce both human and model error rates and may foster greater acceptance of AI-assisted deprescribing tools among clinicians. Our findings highlight the potential value of human-AI collaboration frameworks. For example, a human-in-the-loop framework (a model in which humans review difficult cases the LLM cannot resolve) could involve LLMs assisting in the identification of deprescribing opportunities while deferring final recommendations to clinicians [40]. Alternatively, the LLM could focus on the initial filtering of relevant deprescribing criteria for specific medications, leaving the recommendation task entirely to the clinician, thereby leveraging the LLM's strength in mapping medications or medication classes to appropriate criteria efficiently [41]. These approaches not only leverage the model's efficiency in data processing but also mitigate risks associated with erroneous recommendations, particularly in this high-risk clinical context. Future research should focus on refining LLM architectures to better handle the nuances of clinical reasoning and context interpretation, perhaps by incorporating more advanced natural language processing techniques and domain-specific training.

Additionally, efforts to standardize deprescribing guidelines would greatly benefit the development of automated tools in this area, making them more reliable and broadly applicable.

Limitations

This study has several limitations that warrant consideration. First, the retrospective nature of our analysis, relying on historical data from EHRs, may not fully capture the complexity of real-time clinical decision-making in emergency settings. The study's focus on a single large academic medical center limits the generalizability of our findings to other settings with different patient populations, documentation patterns, and health care practices. Second, the selective prediction methods, while providing insights into the LLM's confidence, were not universally effective, particularly in the nuanced task of deprescribing recommendations. The model's performance in these recommendations highlights the challenge of translating structured criteria into actionable clinical decisions, especially when faced with ambiguous inclusion or exclusion conditions. Additionally, the model's reliance on textual prompts and structured EHR data may not fully account for nuanced clinical contexts that influence deprescribing decisions. Third, the small sample size for detailed analysis (100 patients) limits the statistical power and may not reflect broader patterns of medication use and deprescribing needs. Cost may be a barrier to larger sample sizes in the future, as the total application programming interface utilization fees were approximately US $300-$400 over these 100 patients and the cost to both evaluate and implement the system in the real world would scale linearly with the study population. Additionally, the study relied on medical students for initial annotation. While these annotations were reviewed and adjudicated by board-certified physicians, this process may introduce variability, potentially affecting the reliability of their use as a gold standard in selective prediction methods. Our process for selecting these criteria also did not explicitly include any geriatricians, though did include a range of individuals who regularly care for older adults. Finally, the criteria used (STOPP, Beers, and GEMS-Rx) were selected based on their perceived clinical risk and EHR computability, which may not encompass all relevant deprescribing scenarios. The lack of standardized guidelines for implementing deprescribing criteria in LLMs also poses a challenge to consistency and accuracy.

Conclusions

This study demonstrates the potential of LLMs to augment clinical decision support by effectively filtering deprescribing criteria for older adults with polypharmacy in ED. While the LLM showed promise in identifying medications eligible for deprescribing, it faced challenges in making nuanced deprescribing recommendations, underscoring the need for human oversight in AI-driven processes. Future research should prioritize refining the model by addressing ambiguities in deprescribing criteria and integrating broader clinical context, such as longitudinal data from prior progress notes and discharge summaries, to enable the detection of relevant clinical trends. Expanding the dataset and exploring more effective strategies for integrating human judgment with AI capabilities will help overcome limitations in generalizability, helping optimize patient care. The findings underscore the potential of LLMs in AI-enabled automated CDS tools for deprescribing while emphasizing the need to refine deprescribing criteria and establish clearer guidelines to support the integration of AI into clinical practice.

Acknowledgments

VS has received funding from the Yale University-Mayo Clinic Center of Excellence in Regulatory Science and Innovation for this work. MI receives funding through CTSA (grant UL1 TR001863) from the National Center for Advancing Translational Science, a component of the National Institutes of Health. This publication's contents are solely the responsibility of the authors and do not necessarily represent the official views of the National Institutes of Health.

Authors' Contributions

VS, MI, and RAT conceived of the study with help from DSW in the design of its analysis. VS, CD, and LC provided data engineering and analyzed the data. VS prepared figures. DSW, JA, BP, NSK, CXW, AL, and RAT participated in the consensus study. TH, SF, DSW, and MI annotated notes for model training and testing. VS, DSW, LC, and RAT drafted the manuscript, and all authors contributed substantially to its revision. RAT takes responsibility for the paper as a whole.

Conflicts of Interest

RAT receives unrelated support from grants from the National Institutes of Health, Gordon and Betty Moore Foundation, the Federal Drug Administration, the Agency for Healthcare Research & Quality, and Beckman Coulter, Inc as well as options from Vera Health for serving as an advisor. DC is the associate editor for *JMIR Medical Education*.

Abstract

Background: Older adults are the least active in our society and may face additional barriers to taking part in physical activity compared with those experienced by younger people because of factors such as lower digital literacy and negative stereotypes of aging.

Objective: This study aimed to explore how older adults navigate websites that provide access to physical activity opportunities and facilities and make judgments about their suitability.

Methods: Semistructured interviews were embedded within a think-aloud approach. Participants were shown a series of websites and asked to navigate through the websites as if they were going to take up what was on offer, articulating their thoughts and comments out loud as they progressed. Participants viewed up to 4 websites, rotated from a pool of 8, including leisure centers, exercise products, gyms, or community organizations. Additional questions were asked about perceptions of the inclusivity of the websites at the end of the interview. Digital recordings were made and transcribed verbatim, and analyzed using thematic analysis.

Results: Nineteen participants (6 male and 13 female) aged between 65 and 84 years were recruited from southern England; one-third reported having poor digital ability prior to taking part. Three overarching themes relating to the research question were identified as follows: (1) signals of age-inclusivity, (2) limiting beliefs, and (3) confidence in making judgments. Older adults inferred a lot of information about how welcome they would be in physical activity settings from the images and language used on websites. They showed a preference for imagery that was inclusive of age, body shape, and physical ability, not only for those depicting older adults themselves. Some adults reported firm views about the type and intensity of physical activity that is appropriate for older adults, and many expressed a specific dislike of gyms, based on both the (young) age of most users and perceived emphasis towards aesthetic rather than health-related exercise. While most participants could navigate websites successfully, they preferred to visit venues and speak to staff to gain greater confidence that they would feel welcome and that the activities would be at a suitable level.

Conclusions: Websites providing access to physical activity could be more inclusive of older adults by using more diverse imagery, providing clearer descriptions of the activities on offer, along with details of the level of fitness or ability needed to take part, and providing alternatives to web-based booking. Additional societal-level approaches to reducing age-limiting self-stereotyping may also be useful in expanding the opportunities for older adults to access mainstream provisions for physical activity.

KEYWORDS

ageism; inclusivity; digital literacy; older adult; physical activity

Introduction

Older adults are the least active in our society [1], yet they could derive significant benefits from physical activity in terms of preventing and managing chronic disease, promoting strength and function [2], and reducing morbidity [3]. The UK government recommends 150 minutes of moderate-intensity activity per week for older adults, as well as breaking up sedentary periods and including exercise that improves muscle strength, balance, and flexibility [4,5]. Data for 2022 to 2023 from Sport England estimate that around 53% of people older than 65 years achieve this, with 36% achieving less than 30 minutes of activity per week [6]. Activity in later life reduces the risk of disability, the development of noncommunicable diseases, and the decline in functional capacity associated with aging [7]. There may also be benefits to cognitive health [8].

Older adults experience many of the same barriers reported by younger adults to physical activity, including time, cost, and enjoyment, and lack of confidence or fitness [9,10]. Additional barriers that are more commonly seen in older adulthood relate to physical function, such as ill health or disability, safety concerns, and fear of falling [10]. However, there are also indirect barriers that may influence engagement with facilities and activities in older age, including poorer digital literacy, digital exclusion [11], and negative stereotypes around aging [12]. Considering digital literacy, while many older adults do own smartphones or other digital devices, digital acceptability and access decline with age [13]. The physical activity industry mirrors the rest of society in having become more digitized, for example, through moving to web-based bookings, payments, and advertising, and the development of increasingly technical exercise equipment. These changes have an unintended negative impact on access for older adults.

Older adults face several age stereotypes relevant to the physical activity domain, often being portrayed as frail, easily fatigued, and physically inactive [14]. Some of this stereotyping can be observed in how older adults are treated by others, for example, fitness professionals commonly have (and communicate to greater or lesser degrees) low expectations of older adults' capabilities, which in turn discourages older adults from taking part [15]. Providing positive examples of the capabilities of older adults that present a very high level of ability (ie, exceptional fitness) can also be problematic to some older adults who feel they may not be able to match up to expectations, putting them off taking part [16]. Age stereotypes for physical activity are not only held by younger adults, older adults themselves often share these negative perceptions, for example, feeling that their aging body means they are less able to exercise, and that people their age are out of place in physical activity settings, such as gyms and health clubs [17].

The theory of stereotype embodiment sets out one way in which self-stereotyping may develop, proposing that people internalize negative stereotypes throughout their lives, developing negative attitudes toward older adults, which are directed toward themselves as they age [18]. This leads to unconscious effects on behavior, particularly in settings where age stereotypes are primed (eg, depictions of older adults with limited ability), impacting health behaviors [19]. Little research from this perspective has been undertaken specifically in relation to physical activity, and research exploring the impact of age stereotyping on physical activity from other theoretical perspectives has resulted in some conflicting results. For example, in response to age-based stereotype threats (ie, pressure to avoid confirming or exacerbating stereotypes when taking part in an activity; [20]), some studies show poorer performance in physical activities, such as walking speed [21], while others show improved performance, for example in fitness training [22]. Thus, research to provide greater insight into older adults' responses to how they are portrayed during their first approach to physical activity settings is warranted and could help us to understand the variation in effects.

The aim of this study was to explore how websites providing information about physical activity opportunities may influence the barriers or facilitators of physical activity for older adults. Using a "think aloud" approach, our objectives were to (1) explore the social signals older adults identified of inclusivity, fit, or welcome, and (2) capture their views about the digital capability required to find relevant information. Together, this would provide information on how older adults experience web-based gateways to access physical activity opportunities and what information they draw on in assessing whether the activity on offer was suitable for them.

Methods

Ethical Considerations

Ethics approval was granted by the Research Ethics Committee for Health at the University of Bath (EP 20/21 105). All participants provided informed written consent, and any identifying information was anonymized prior to data analysis. Interviews were conducted between January 2022 and August 2023.

Design

This study was situated within a constructivist research paradigm, selecting a "think aloud" approach in order to explore and understand people's subjective experiences and focus on meaning-making in real time [23]. The think aloud approach has shown previous utility in exploring human-computer interactions and decision-making [24] and the usability of websites in health settings [25].

The approach encourages participants to verbalize their thoughts or feelings while navigating web-based resources. In our study, this was embedded within semistructured interviews to ensure interviewees had been asked comparable questions when interpreting the findings, and to allow participants to express their thoughts and experiences at a more general level [26]. The interviews were all conducted in person by slim, White, young women (aged 18 - 23 years); we include this detail as it was commented on by some participants, so it may have influenced some of their responses.

Participants

For this study, we considered adults to be aged 65 years or older, in line with the UK Office for National Statistics [27]. The

inclusion criteria were individuals aged 65 years and older, who can read and speak fluent English, self-assessed as physically able to, and interested in taking part in physical activity. Participants were recruited through advertisements posted in local community centers, on local social media platforms (such as "Nextdoor"), and through the authors' existing networks. We aimed to recruit 20 older adults to provide a range of experiences, focusing on advertising in lower socioeconomic areas. Participants received travel expenses and refreshments but no payment for their time.

Procedure

Volunteers were sent a participant information sheet and consent form and invited to set up a time for their interview; these arrangements were typically made via email, but could be by phone or letter if preferred. Interviews were conducted in public spaces of the participants' choice (to ensure they would feel comfortable) using a laptop provided by the researcher. Participants were asked to nominate a café local to them or could choose to come to the University. At the start of the interview, the researcher talked through the process and obtained written consent. The researcher then presented between 1 and 4 example websites in turn, working through the think aloud process with each until the participant wished to stop or the 1 hour had passed; participants were offered the choice whether to continue at the end of each website viewing. The order in which websites were presented was rotated to ensure that the findings related to a variety of website designs and topics.

Participants were encouraged to provide an honest opinion on the websites, add any thoughts which came to mind [28], and were prompted to reflect on what they were doing as they browsed (eg, "why did you click on that?"; Multimedia Appendix 1 contains the full topic guide). In line with a relaxed think aloud approach, the interviewer only interacted with the participant when asking prompts or in response to a participant's request for help with navigating the websites [28]. At the end of browsing websites, participants were asked to evaluate the content overall. One example of the questions asked for this was "were there any aspects of the websites that made you feel included or excluded?".

The pool of example websites was chosen to reflect different aspects of the physical activity industry following public engagement activity with 7 older adults as part of a related study (ie, what they consider as part of the industry), and discussion with an advisor from a national representative body. Our aims were to include both commercial and noncommercial services, sites that advertise equipment as well as facilities, and ensure we featured a range of activities that are accessible to someone starting out (eg, activities that do not require extensive technical skills, and can be started at low intensity). The research team reviewed the final set to ensure we included variations in website designs (Multimedia Appendix 1 lists the specific websites chosen). Two examples were available from each of the following 5 categories: local authority providers of physical activity services; fitness industry providers (eg, generalist gyms that focused on building strength and endurance); fitness industry product providers (eg, personal fitness equipment and clothing); community organizations that encourage physical activity (eg, walking groups); and UK physical activity campaigns. The order in which the websites were presented was rotated.

After the interview, participants provided information on their demographics, usual physical activity level, and self-rated health.

Data Analysis

Interviews were audio-recorded using a digital voice recorder, transcribed verbatim by VC, and anonymized. Analysis was conducted using a 6-step thematic analysis [29], including familiarization, generating initial codes (including a code book), organizing codes into clusters of shared meaning (themes and subthemes), and refining and naming the themes with the wider research team. Two transcripts were coded by VC and FG to refine the codebook, and the remainder were then coded by VC and the themes were developed iteratively.

Website tracking software was used to generate a recording of participants' progress in order to verify which specific pages participants were looking at as they spoke. This information has been added in square brackets within quotes where appropriate.

Results

Sample

Participants (6 male and 13 female) were aged between 65 and 84 years and based in Southern England. Fourteen (74%) participants had postschool qualifications, and the majority of the participants considered themselves to be healthy (95% scored >7 on a 10-point scale), with moderate fitness (most reported a steady or brisk walking pace) (Table 1).

Around a third of participants considered that they had poor digital ability, but the majority were able to navigate the websites without difficulty, and the challenges experienced most came from using unfamiliar hardware (ie, using the researcher's laptop, rather than a usual PC at home) rather than difficulty using common website functions (scrolling down, search function, clicking through different pages). At the extremes, 2 participants were not confident in navigating websites unaided, so they asked the researcher to do this for them (P11 and P18), while one participant was a website designer prior to retiring (P4).

Three overarching themes relating to the research question were identified as follows: (1) signals of age-inclusivity, reflecting what participants read into the images and language used on websites; (2) limiting beliefs, reflecting how participants related beliefs about their own physical capability, and age stereotypes to website content; and (3) trust, reflecting older adults' reservations about what could be understood from web-based information alone.

Table . Participant characteristics.

	Age group (years)	Gender	Ethnic group	Highest educational attainment	Usual walking pace	Health rating[a]
1	65 - 69	Man	White	Bachelor degree	Steady	8
2	80 - 84	Woman	White	Bachelor degree	Brisk	7
3	75 - 79	Woman	White	Master or postgraduate qualification	Brisk	7
4	65 - 69	Woman	Black or African	GCSE/O level[b]	Slow	3
5	75 - 79	Woman	White	Master or postgraduate qualification	Steady	8
6	70 - 74	Man	White	GCSE/O level	Brisk	8
7	65 - 69	Man	White	Bachelor degree	Steady	7
8	70 - 74	Man	White	Master or postgraduate qualification	Steady	8
9	75 - 79	Man	White	Master or postgraduate qualification	Steady	7
10	65 - 69	Woman	White	Master or postgraduate qualification	Steady	7
11	65 - 69	Woman	White	Bachelor degree	Brisk	8
12	65 - 69	Woman	White	Bachelor degree	Steady	9
13	75 - 79	Woman	White	Master or postgraduate qualification	Slow	10
14	65 - 69	Woman	White	Master or postgraduate qualification	Steady	9
15	65 - 69	Woman	White	No formal qualifications	Slow	8
16	65 - 69	Woman	White	Master or postgraduate qualification	Brisk	8
17	80 - 84	Woman	White	A Level or equivalent	Steady	7
18	75 - 79	Woman	Asian or Asian British	No formal qualifications	Brisk	7
19	65 - 69	Man	Black or African	Master or postgraduate qualification	Slow	8

[a]Self-rated on a scale of 1 - 10 where 1 is very bad health and 10 is excellent health.

[b]GCSE/O level: General Certificate of Secondary Education Ordinary Level.

Theme 1: Signals of Age-Inclusivity

Images

Participants drew on images, language, and the type of physical activity or service offered in judging whether websites were relevant to them. Images were often the first source of information that participants considered ("I noticed almost immediately there was a mix you know, that in photos there were older people" [P9]) and were often taken very literally as an indication of who uses a particular facility. Participants extrapolated from who was depicted as to whether they would be welcome as a participant:

> *This is the gym… oh… group exercise... oh let's see if there's any for old people. [inspects the photograph]. There's a young lady… that's not for me! Absolutely not for me. If they had a photograph of a group with a couple of older people involved in the same group yep, I don't mind being with young people at all, except I wouldn't like to be the only one.* [P2]

> *It's modelled by people, young people without wobbly bits.* [P15]

While seeing older adults depicted was interpreted as a clear indicator that a website was offering something intended for them, most participants used a broader benchmark and judged websites as age-inclusive when they saw images of people of different ages, genders, races, and abilities, as well as people with disabilities. For example, on articulating why certain websites looked age-inclusive, participants stated:

> *[Because] they're all normal people, as in, of an age that I can relate to. So it's not, it's not big punchy*

> *"do this to build your muscle" type thing it's all about… it's all about keeping active and keeping healthy through, through activity, which is good.* [P6]

> *That one is, I think that's very, the seems quite welcoming that, I'd have a look at it, I would if I saw that picture... Because it's a family there, and there's a child there, it is not as though someone's just exercising and looks really fit (laughs). I mean, I'm not saying they don't look fit but I mean it's not a real over-fit.* [P17]

In addition to images, participants responded positively to clear statements that all ages are welcome:

> *Um… they [community rowing club] particularly stress the headline [ages] 13 to 100 so, it definitely was not focused just on the… you know the normally you associate the, I suppose I associate rowing with the boat race, young fit men or women from um from the Universities etc. That's my first reaction so um this seemed quite inclusive in that sense, quite friendly, seems quite informative.* [P9]

Similarly, images of people of all body sizes were considered positive and inclusive, regardless of their age. As such, body size appeared to serve as a proxy for participants believing an activity would be achievable for them:

> *But I mean, but you see that's still good to get people going isn't it because they're all shapes and sizes [in the image] and I'd rather do classes with people like that then just really old people so that's quite nice* [P17]

> *They are… women and they are older women, kind of thing that they are not… slim ones so they really appeal to the likes of me that it can be me, joining them, you see.* [P7]

While wanting to see older adults depicted, participants could be very particular in how old, or how active the older adults were. Some interviewees distanced themselves from websites where older adults were depicted as being too old or inactive:

> *They are very old people and they don't appeal to me at all. I couldn't interact with anybody like that. I mean, okay, they might get satisfaction out of it but nah. It's not me, it's just not me.* [P15]

Very few older adults expressed an interest in exercise sessions that are solely available to older adults, preferring to see indicators of inclusivity to the whole community, with older and larger people depicted as part of this. This may reflect (as suggested by the quote from P15) the degree to which participants have actively embraced an older identity.

Language

In some cases, the language used on websites signaled to participants that these services or facilities were not for them. This was particularly evident in websites relating to gyms and exercise classes, which included new "branded" terms such as classes called "SHRED," "Trax," and "Rush". Participants viewed this terminology as an immediate turn-off, and an indicator that such activities were not for them:

> *It's delving into a sort of more modern language that I don't necessarily understand, but that's probably more my problem than anybody else's!* [P6]

> *Oh… what are glute exercises? Oh… glute, did you know about glute muscles? I didn't.* [P13]

> *Shred (laughing)… see I, well I'm just looking I'm thinking right, so I immediately focused in on classes and I'm not going to go and do a class that says shred because um I just know that that is just, you know, I wouldn't do it.* [P12]

Some participants were explicit in describing the lack of explanation of such classes as discriminatory:

> *I don't think for my particular age group that they are informative enough and I find that they are a bit discriminative and they're… ageist. That's it.* [P15]

Theme 2: Limiting Beliefs

Perceived Physical Capability

Most participants recognized and described a deterioration in their physical ability as they had aged and expressed a desire to avoid injuries by attempting to do too much. While some participants had long-term conditions such as arthritis that limited their activity, for many, this reflected a fear of injury based on the perceived limitations of age alone. This caution influenced their responses to websites based on the type of exercise on offer:

> *With the equipment, I'd end up… tearing something or ending up injuring something of my body. So, I've come to the conclusion that you know, probably it's best not to be going into gyms.* [P4]

This concern was also reflected in participants' desire for more information about the intensity of activities than was provided on most websites. This is often related to expected levels of fitness and capability to start engaging in the exercise on offer, reflecting the fact that although they might have been experienced in some activities (ie, not a beginner), they knew they were much less fit than when they last took part. For example, 2 participants commented on the website of a local walking group that was marketed towards older adults, and depicted older adults in their imagery:

> *It would be helpful if there was a bit more information, to give you… the severity of the walk, is it rough terrain or not. Because obviously as you get older, the flatter the walk the more… probability that you'll actually go onto it…* [P6]

> *Older people do tend to walk a little bit slower so you want to know is this going to take me a couple of hours, or is this going to take all day?* [P6]

> *My concern would be walking out for the first time … I'd be worried about lagging behind and upsetting people who are experienced walkers. If they had a 'break me in walk' and then oh you are broken in a bit now so you can do the next one, and the next one.* [P15]

Similar concerns were offered about fitness classes:

> *It [the website] didn't exclude me, it's just I, my body and everything else that comes with it, makes me feel… a bit worried to try to go and lift weights or do some strenuous thing that I know my body can't take… Do I need to be a certain fitness level before? That's something I need to know.* [P4]

Others expressed concerns about potentially embarrassing themselves in mixed settings or pushing themselves too far. For example, on looking at a strength training class video, one participant commented:

> *If you're not fit I don't think you would ever look [to go] there because you would feel such a fool. You would, you would think I'm a wimp, I couldn't cope with that, so I wouldn't go.* [P17]

Some older adults also expressed concern that younger instructors or trainers would not be able to adapt to what was needed for older adults, and thus that what was demanded of them would be too great. These participants tended to use the age of instructors depicted on websites as a signal of whether a service or facility was appropriate for them:

> *I don't know whether I've just got more respect in general for older people because they've got more experience, maybe that, I just don't quite believe that someone – sorry about this [referring to the young age of the interviewer] – does a three-year course in whatever, fitness, can necessarily have all the information they need to help older people.* [P11]

> *[I'd need] way more support, but who's going to be supporting me, I mean, some squeaky chicky ain't going to come over and say 'Alright, old love let's sort you out!'* [P15]

Preference for older instructors was not a universally held view, and those who had more experience exercising in mixed-age groups provided examples of younger instructors who adapted classes well. They also flagged the need to differentiate people by ability rather than age:

> *My Pilates class is basically for over 50's but they want to stop it too because they say people don't like being defined by their age… so it's like how do you find another way of saying over 55 without patronising somebody?... But at the same time sometimes you don't know what you're looking for. There's some people who are over 65 and they don't need to look at an over 65 sort of over 50s class because they're really fit and they can still do stuff in an ordinary class.* [P12]

Stereotyping

While participants were generally pragmatic and objective in acknowledging age-related changes in physical capability, there was also some evidence of stereotypical thinking. Some of this appeared to relate to self-stereotyping of what types of physical activity older adults should be doing. The example below relates to a comment made while reading through a list of exercise classes at a municipal leisure center.

> *... I'd go for body balance but yoga, no, spin, sounds too fast, those aren't right for old people… If its high intensity, we [older adults] shouldn't be doing things high intensity.* [P2]

However, many of the interview excerpts coded into this theme related to gyms. It was often hard to disentangle participants' pre-existing attitudes towards gyms as a type of business (and their experience of them being predominantly used by young people), from the specific aspects of the website presented ("I'm actually a little bit against gyms anyway, because, it's a modern thing" [P7]). These views typically reflected participants' attitudes towards gyms rather than what was presented on a website, as well as their experience of gyms.

> *I didn't like going in the actual gym bit because it was all people a lot younger than me and they were all trying to outdo each other.* [P15]

> *I see these [gyms] and I only tend to see young people. You know, cool looking sort of young people going into (particular gym), and that doesn't, that doesn't do anything - this website - to disabuse me of that viewpoint. It comes across as a younger, commercial first [place].* [P9]

> *I mean I wouldn't go anywhere near that place [gym]. You know I, not being rude, but I mean cause to me that is just full of… people who are like nearly old enough to be my grandchild so I'm like just wouldn't (laughing), so I wouldn't go in there no.* [P12]

In some cases, the stereotypical thinking reflected assumptions that gyms are a place people go to do image—rather than health—enhancing activity. Often, the negative statements about young people are conflated with assumptions about why people use gyms, given the greater prevalence of young people using them.

> *It's all a bit showy-off-y to me [going to the gym], rather than, I suspect… intended just to get you fit and keep you fit. It's a bit, it's all a bit show-y.* [P7]

> *When I have been into the odd hotel gym there's generally some very, very narcissistic p- you know people there looking at themselves more in the mirror than they are [exercising], you know what I mean, it er, to a younger person you know a, beautiful blonde there or really fit young bloke you know, you know doing whatever I'm thinking, yep, you don't need that.* [P9]

Some participants were less critical of the reasons why people attend gyms, but in believing gyms are for building muscle, and that building muscle is something that only younger people do, they assumed that gyms were not for them. This was reinforced by images of young fit adults lifting weights:

> *When you get over 65, you're more interested probably in er… you're not going to build muscle, you're not going to, you know, attain any major goals. You want to, keep mobile keep flexible, and if there were more things to build upon flexibility, um… that would be more appealing to people of an older age*

group, yes… There doesn't seem to be any of that on this website. [P6]

They [images] all look quite frightening to me, because they all look so much younger and fitter! … I mean look at the, these guys are all pretty stacked, so. I'll never look like that. Not that I ever did! [P6]

Theme 3: Confidence in Making Judgments

Participants preferred websites where information was presented clearly on the first page, where the font was simple, without too many distractions from moving images. The majority considered information about the proximity of facilities ("See, straight away I think what I want to do is find out, where's the nearest one for me?" [P6]), costs, and links to a person they could contact to be of primary importance. They wanted to be able to see this information without needing to click through multiple screens.

I want to know what the membership is and it's giving me "hear from our members." I want to know where it is, how much it is, swimming pay as you go [P15]

So this is, they're not going to give me any information about courses until… until I open the portal and I'm not interested in that. [P5]

Even among those comfortable with using websites and digital tools, many participants expressed a preference to establish some personal contact before committing; they looked for a phone number of someone to talk to, or stated that they would not book via web, but would use the site to gather information and then visit the venue to book. For some, the need to verify information in person reflected a lack of trust in what is presented via web, rather than poor digital literacy.

It's all a marketing ploy, not really giving me the information that I really want. [P15]

I… can't tell, what they would be like from the website… but it's all part of an advertise-advertising their product um so, so yo-you… that's how I would expect it to be I'd expect it to be advertising a product I wouldn't expect to see any truth there [P7]

This hesitancy may also reflect participants' interest in factors that cannot be ascertained from a website, like the atmosphere of the venue or how they are treated by staff.

If I was going to join the gym, I'd go down there and physically look at it. So, um, but only based on having… drawn up a-a-a-a list of 3 say [from their websites]… and that's what I would do and then go and look at them, and see what I thought and judge it on, on um… the people that are um… are um running it so forth, do you get a welcome er a good welcome there, do they seem to know what they're talking about. [P7]

Hesitancy about using websites to make decisions on the appropriateness of physical activity opportunities appeared to differ from general comfort with digital devices or web-based shopping. For example, P7, who would not trust the "truth" of a leisure center website, was comfortable with buying sports equipment via web ("I buy my sports stuff online, or off mates"). Others reported being able to use a device, but not being comfortable with website bookings as a specific function:

Well I'm not very good at websites to be honest, and actually although I'm on it on my iPad with the gym, my son has to book me online all the time. I can't do it, it's sad init? [P18]

Discussion

Principal Findings

This study explored older adults' reactions and views of the age-inclusivity of websites providing access to physical activity opportunities. Together, the themes showed how older adults drew on the imagery and language of websites to inform their decisions, as well as some existing schemas of what types and intensities of activity are appropriate for older adults (ie, implicit ageism). Participants were encouraged by websites depicting people of mixed ages, body shapes, and abilities using their service, and were not looking for services offered purely for older adults. Many older adults judged whether an opportunity was appropriate for them from factors that signaled the intensity and challenge of the physical activity on offer, motivated by a wish to avoid injury or embarrassment, and felt the ability to keep up with others. Information on the level of ability of fitness required to take part was rarely presented directly, which may have caused participants to rely on images and language to make these inferences. Participants showed a greater preference for and trust in websites that provided clear and up-front information on basic considerations such as cost, location, and contact details. Nonetheless, they reported still being reluctant to believe an opportunity was for them without having visited a venue and spoken to staff.

The think aloud approach has been used in previous research to explore how people use and make sense of websites, and what they base their judgments on [28]. For example, users have been shown to use short case examples to understand the relevance of the site by drawing constant comparisons between the examples presented, their own experience [28]. While in this study few websites that we used included case studies (although these were popular where they did), we did observe a similar effect in how participants were extrapolating information from the individuals shown in the images based on their experience and existing attitudes; for example, some participants inferred knowledge about a "typical user's" motivation and fitness level just from a photo. This process was most closely observed in older adults' responses to images of young people, using this information to form judgments that a facility or service was not for them. In part, this reflected participants' explicit narratives of how their capability and motives for physical activity had changed over time, such that they judged what is suitable for young adults would not be suitable for them. While some settings (eg, gyms [30] and surfing [15]) are already considered a young adults' domain by default, our study showed that in other settings too, seeing images predominantly of young adults was used as a heuristic for assessing an activity as irrelevant or inappropriate. This response was diminished when images included mixed age groups, ethnicities, and body shapes alongside young adults.

Past work has described how older adults who take part in physical activity need to navigate the tension between experiencing the benefits of physical activity, noticing their own physical decline, and dealing with social norms about what type of physical activity is acceptable in older age [30]. This tension appeared to be visible in our study, acting as a lens through which participants were evaluating whether the activities that the website was promoting were relevant and welcoming to them. In line with other work [10], we found that older adults' beliefs about their capabilities were a common barrier to physical activity, and evidence of an apparent acceptance of the inevitability of physical decline [17]. Current health messaging, as well as marketing of physical activity facilities and opportunities, may assume that older adults are interested because they believe that there is scope for improvement, so exposing this alternative perspective—that older adults largely do not feel that improvement in strength and fitness is feasible—could be important to inform future approaches.

While participants in this study showed a good ability to navigate websites and good digital literacy, they still exhibited some lack of confidence in applying this. Two participants either asked for help from the Researcher in navigating the websites or reported that they normally ask a younger family member to make web-based bookings or purchases for them. This aligns with previous research demonstrating that even among those with high levels of competency in using websites, older adults may have lower perceptions of their usefulness [31] and acceptability [11]. In this study, this lower perceived usefulness may relate to the fact that information older adults consider crucial was not provided; websites rarely provided explicit statements about welcoming all ages, contact details, clarity about the level of starting fitness required, or information on how demands can be tailored. However, alternatives to web-based booking, whether by phone or in person, will likely remain an important part of providing an age-inclusive offer, to allow older adults to test out the atmosphere of a venue and sample interactions with staff.

Strengths and Limitations

The use of think aloud interviews worked well in this setting by encouraging participants to verbalize their thoughts and experiences while interacting with websites in "real time." It is argued that this often results in more honest accounts of user experience [32]. A limitation of this approach was that participants were navigating websites that they had not chosen for themselves, on a device that was not familiar to them. Participants may have been less distracted by the mechanics of navigating a website if using a familiar device. Our findings may also have been influenced by the specific websites we chose. While we attempted to mitigate this by identifying a range of different websites and rotating these through interviews, providing choice to participants (eg, allowing them to nominate the types of physical activity there were interested in) may have helped to provide a greater test of participants' views on the inclusivity of the website, rather than the type of activity it offered. In particular, it was hard to disentangle participants' comments on the desirability of gyms and the imagery that accompanied them, reported in theme 2, from their preexisting attitudes.

We attempted to recruit a diverse sample by advertising in areas populated by people of lower income and with greater ethnic diversity, and by seeking support from gatekeepers (eg, local Black and minority ethnic support groups for older adults). However, the majority of those willing to take part were White, highly educated, and living in urban areas, which is a limitation of this study. Other studies conducted with older adults report greater challenges with website navigation [25], which we may have found if we had recruited a sample with a more diverse socioeconomic background. Our participants were also relatively healthy; this is less a limitation and more a reflection of our design, as in order to address our research question, we recruited individuals for whom the websites were relevant, that is, those who are capable of engaging in physical activity. However, we may have discovered different barriers had we included more people with limited physical ability. Related to this, the age of our participants spanned around 2 decades from 65 to 84 years, from those still working to those who have been retired for 20 years. People at either end of this age group, as well as those experiencing greater or lesser physical decline or limitations, may have had different perspectives on who the websites depicted and what was offered. Within this small qualitative study, we were not able to tease out these differences.

Implications and Future Directions

The findings of this study suggest that older adults are more likely to consider that services and facilities are relevant and attractive to them when websites depict a diverse set of users, including an explicit statement indicating people of all ages are welcome, and present clear information to users to judge the level of fitness and ability likely to be required to take part. Remaining physically active for longer is key to reducing age-related disability and disease [7] and promoting good cognitive health [8]. In addition, including older adults in intergenerational settings can foster the mental and physical health benefits associated with social inclusion and connection [33,34]. If increased physical activity participation in the growing population of older adults is to be achieved, their needs need to be accommodated affordably within mainstream facilities and services.

A common reason why older adults wanted more information on the likely demands of the physical activity on offer was to reassure them that they would not be pushed too far, feel embarrassed, and that the activity could be adapted safely for someone of their age and level of ability. Classifications referring to the level of experience (beginner, intermediate, etc) may not be meaningful when someone has historical experience but has not taken part in many years, and a lack of explanation alongside activities that have nontraditional names can lead older adults to infer that this is not intended for them. Evidence of venues using older adults as instructors and coaches, and information to confirm that activities can be adapted to be appropriate for all ability levels and ages (where this is the case) would also increase older adults' confidence in trying out physical activity opportunities. While many older adults can navigate websites competently, they expressed a preference for simple information and were put off by too many moving images and the need to click through multiple links to find information.

Conclusions

This study has provided insight into what older adults notice and look for in websites when exploring opportunities to increase their physical activity. It flagged how their pre-existing beliefs and implicit assumptions may influence whether they consider new options for activity, taking into account perceptions of their own capability, social norms, and some stereotypes around age and motivation for physical activity. These existing beliefs may interact with web content to exacerbate or potentially challenge stereotypes, to encourage older adults to feel more welcome to use mainstream facilities and services that support physical activity.

Acknowledgments

We would like to thank Ms Natanya Cassidy and Ms Abigail Russell for their contribution to the interviews, as well as all the participants who gave up their time to take part. EG's time is supported by the National Institute for Health and Care Research Applied Research Collaboration West (NIHR ARC West)

Authors' Contributions

FG, JB, EG, and EB contributed to the conceptualization of the study. VC, EB, and AR were responsible for data collection. VC and FG conducted the analysis. FG and VC drafted the initial version of the manuscript. All authors contributed to further writing, editing, and refinement of the paper.

Conflicts of Interest

None declared.

Abstract

Background: The World Health Organization's (WHO) publication on age-friendly environments (AFEs) imagines future cities to become more age-friendly to harness the latent potential of older adults, especially those who have restricted mobility. AFE has important implications for older adults in maintaining social connections, independence, and successful aging-in-place. However, technology is notably absent in the 8 intersecting domains of AFEs that the WHO imagines improve older adult well-being, and we investigated whether technology should form a ninth domain. While mobility was severely restricted, the COVID-19 pandemic provided an opportunity to test how older adults' perceptions of their AFE changed and what role technology was playing.

Objective: This study examined how life-space mobility (LSM), a concept for assessing patterns of functional mobility over time, and loneliness impacted perceived AFEs and the moderating effect of technology. It also explores whether technology should play a greater role as the ninth domain of the WHO's imagination of the AFE of the future.

Methods: In this cross-sectional quantitative observation study, data from 92 older adults aged 65-89 years were collected in England from March 2020 to June 2021 during the COVID-19 pandemic. The Life-space Questionnaire, Technology Experience Questionnaire, UCLA (University of California, Los Angeles) Loneliness Scale, and age-friendly environment assessment tool were used. Correlation and moderation analyses were used to investigate relationships between variables.

Results: Most participants (86/92, 93%) had not left their immediate town in the previous 4 weeks before the interview. Restricted LSM was positively correlated to the age-friendly environment assessment tool, that is, rising physical isolation was linked to a better perception of AFEs; however, we discovered this result was due to the moderating impact of increased use of technology, and that restricted LSM actually had a negative effect on AFEs. Loneliness was correlated negatively with the perception of AFEs, but technology use was found to moderate the impact of loneliness.

Conclusions: Pandemic-related LSM restrictions impacted perceived AFEs and loneliness negatively, but technology played a moderating role. The findings demonstrate that technology could be considered as a ninth domain in the WHO's assessment of AFEs for older adults and that there is a need for its explicit acknowledgment.

Introduction

Background

Enabling the development of age-friendly environments (AFEs), defined as a physical and social setting that helps people age well and participate in their communities to promote "aging-in-place" for the mental and physical well-being of older adults, has become an increasingly important policy issue. This is in part a response to an aging population dynamic, urbanization, intensification of housing concerns, and community preferences, causing an increase in the deterioration of mental wellness, anxiety, stress, and depression among other disorders [1]. Older adults' perception of AFEs directly affects their quality of life (QOL) and known predictors of depression, including loneliness [2,3]. In urban environments, older adults tend to spend much of their time in their local neighborhoods and are therefore sensitive to change [4,5]. Environmental degradation, such as lack of resources, restricted access to health care, or crime, brings additional challenges.

Previous studies have demonstrated that the perception of AFEs affects the action space of older people, affecting their social participation [6]. It is known to positively moderate the relationship between frailty, mental well-being, and depression, particularly in older adults with poor health, limited mobility, and cognitive decline [1,7,8]. Moreover, a lack of social opportunities can result in loneliness, social isolation, and worsened depression, all of which exacerbate cognitive decline, QOL, and frailty [8-14]. Aboderin et al [15] and Ng et al [16] also noted a reduction in older adults' psychological resilience due to sustained stress and anxiety resulting from crowding, lack of space, and other issues that revolve around a poor age-centered environment. Other research has demonstrated a correlation between loneliness and AFEs [17-21], and identified factors linking the psychological health of economically disadvantaged older adults with their perception of AFE. Rantakokko et al [22] described the impact of person-environment interaction on mental well-being, demonstrating a mechanism by which older adults who experienced loneliness perceived obstacles with their environment. Stafford [23] demonstrated that older age insularity and the accompanying withdrawal from social interaction can result in deteriorating relationships, loneliness, poorer mental health, and a diminished perception of AFEs. If the environment is not conducive to aging-in-place, it causes difficulties in accessing services [24] and an increased risk of physical and mental health care needs [25]. As such, the perception of AFEs must be considered carefully to improve understanding of older adults aging-in-place and mental well-being.

Life-space mobility (LSM) describes the physical environment a person inhabits daily, structured into various zones (called life-space zones), centered on an anchor (eg, bedroom), and expanding outward into the rest of the house, house perimeter, local community, neighborhood, or town [26,27]. This concept corresponds to individuals' functional mobility enabling meaningful participation in community activities. It reflects how older adults move across life-space zones over a given period while incorporating frequency and independence.

According to the United Nations Development Program report "The Sustainable Development Goals and COVID-19" [28], there are unprecedented ongoing burdens on mental health for older adults. Social distancing orders during the COVID-19 pandemic were conceived as advantageous to protect potentially vulnerable populations, such as older adults [29], from disease transmission; however, it has led to long-lasting effects on mental well-being.

Restricted LSM impedes older adults' access to their [30-32] choice of environments and is associated with potential adverse mental health outcomes [27]. In addition, previous research has demonstrated that LSM restrictions reduce participation in out-of-home [33] activities and negatively affect QOL [9,34], which is in turn associated with loneliness [35].

Although pandemics create restricted mobility [36], older adults with knowledge of technology can capitalize on a digitally enabled AFE to avoid loneliness and LSM restrictions that create a strain on mental well-being. It enables older adults to engage in internet-based activities they may have enjoyed in person and gain access to health care, civic services, therapy, counseling [37], and resources that help with mental well-being [38,39]. We therefore expected both variables (LSM and loneliness) to impact AFEs negatively and for technology to moderate their impact.

Feldman and Oberlink [40] pioneered the concept of AFEs, identifying important components such as social engagement, enhancing independence, and optimizing mental functioning and well-being. Age-friendliness is derived from an ecological model of aging, in which a person's mental well-being results from the interaction between their functional and cognitive capacity (competencies) and the environmental characteristics that exert pressure on these competencies (environmental stress) [41].

The age-friendly environment assessment tool (AFEAT) was designed to assess older adults' perception of their environment and focuses on individual-oriented age-friendliness and individual-environment interaction, providing a more holistic picture [11,42,43]. Self-perceived AFEs are associated with improved QOL and mental health regardless of older adult frailty or abilities [8].

Although there is currently no universally accepted definition of an AFE, the World Health Organization (WHO) tentatively defines such communities as those where "policies, services, settings and structures support and enable people to age actively." The WHO [1] publication imagines future cities to become more age-friendly to harness the latent potential of older adults through 8 intersecting domains addressing obstacles to older adults' mental well-being: respect or social inclusion, outdoor spaces and buildings, housing, social participation, transportation, communication and information, civic

participation and employment, and community support and health services. Explicit mention of technology is notably absent.

The WHO framework has been criticized for the exiguous technology element in the domains, prompting a reexamination [44]. Incorporating technology into AFEs in its broadest sense has become an increasingly important area for aging independence and mental well-being [45] in recent years.

Marston and van Hoof [44] discussed the incorporation and use of technology within the AFE assessment agenda, and a recent systematic umbrella review elaborated on the advantages of technology interventions for social connectedness [46]. Their call for the inclusion of digital technology as a domain in AFE evaluations is beginning to resonate.

For example, Pedell et al [47,48] advocated for digital elements to encompass all aspects of environmental age-friendliness, in addition to mental and physical aspects, to realize benefits for older adults. Moreover, Reuter et al [49] acknowledged the WHO's age-friendly city initiative, considering an aging population amid increasing urbanization. However, they determined that such initiatives overlooked technology as a critical component of global digitalization.

Research Objectives

Our study aimed to examine the potentially complex relationship between internal (loneliness) and external (LSM) factors that influence older people's perception of AFEs and to determine whether technology moderates their impact. We aimed to answer a question with an important implication: should technology be included as a ninth domain in the WHO's global age-friendly cities guide in the assessment of AFEs in cities and communities for older adult mental well-being?

We set out to test the following hypotheses:

- Hypothesis (H1): LSM restriction is negatively correlated with perception of AFEs.
- H2: Increased feelings of loneliness are correlated with poor perception of AFEs.
- H3: Technology use moderates the impact of LSM restrictions on the perception of AFEs.
- H4: Technology use moderates the impact of loneliness on the perception of AFEs after considering the LSM restriction effect.

Methods

Study Design

This was a cross-sectional quantitative observational design. This report follows the STROBE (Strengthening Reporting of Observational Studies in Epidemiology) guidelines [50] (STROBE checklist mentioned in Multimedia Appendix 1).

Setting

Participants were recruited from the United Kingdom. Data were collected from January 16, 2020, to June 21, 2021, a period when social distancing mandates were enforced and social engagement outside the home was restricted.

Participants

Eligible participants were required to be living in their own home, be proficient in English, and be 65 years or older. Older people who lived in nursing or care homes or those with cognitive decline or mental health issues were excluded. Volunteers were recruited via advertisements posted in resource centers for older adults, housing associations, third-sector organizations, social activity clubs, local senior groups, direct human interaction, and word-of-mouth recommendations. Volunteers were instructed to either call and leave a voicemail or send an email indicating their willingness to participate; a return call confirmed their eligibility.

G*Power software (Version 3.1; Erdfelder, Faul, and Buchner) was used to calculate the minimum sample size required for the empirical validation of the tested moderation model. Multiple regression was used, with effect size f^2 of 0.15, power of 0.80, and 3 predictors. The recommended sample size was determined to be 87. A total of 110 participants enrolled; however, 18 did not complete all questionnaires and were excluded. The sample achieved included 92 people between the ages of 65 and 92 years (mean age 74.6, SD 7.23 years). All participants identified as either male or female, with more females (55/92, 60%) than males. More than 89% of the participants were White, with less than 11% of minority ethnicities (7 British Asian, 3 British Black). Having collated various demographic information such as age, gender, ethnicity, and education level, we were able to ascertain that participants emanated from diverse sociodemographic backgrounds.

Variables and Measures

All participants filled out a health history questionnaire based on the Scientific Advisory Group for Emergencies (SAGE) Encyclopedia of Communication Research Methods [51].

Loneliness was measured using the 20-item UCLA (University of California, Los Angeles) Loneliness Scale [52], with scores ranging from 20 to 80. Higher scores reflected higher loneliness (Cronbach α=0.88).

Utilization of technology was evaluated using the Technology Experience Questionnaire [53]. The participants were given a list of technologies (communication, computer, daily, health, recreational, and transportation technology) and asked to rate their familiarity with and use of each on a 5-point scale. Scores ranged from 0 to 180, with higher scores indicating greater use and familiarity with technology (Cronbach α=0.84).

The perception of the AFE was assessed by the AFEAT. This is a 10-item measure that uses a 5-point Likert scale, scoring items from (1) strongly disagree to (5) strongly agree and gauging participants' perceptions of their home, their local communities, the resources within the environment, and their appropriateness for meeting their daily needs. The scores ranged from 0 to 50, with higher scores representing a more positive perception of the age-friendliness of the environment (Cronbach α=0.75).

LSM was measured using the Life-Space Questionnaire [26]. Participants were asked yes or no questions about specific places they visited in the last 4 weeks, starting with another room in

their current residence and increasing the distance to a location outside England. The scores ranged from 9 to 18, with higher scores demonstrating greater restriction of LSM (Cronbach α=0.90).

Procedure

Telephone surveys collected information on loneliness, technology use, LSM, and perceptions of AFEs, in addition to basic demographic information (eg, age, education, gender, and ethnicity). Google Analytics was used to collect and tabulate the data. Participants completed the assessments across 14 months.

Statistical Analysis

Analyses were performed using IBM SPSS version 28, using a minimum significance level of 95% probability. There were no missing data, and participants completed all questions. The variables of AFEAT, loneliness, technology use, and LSM were inspected for kurtosis and skewness to assess their distribution deviations from normality via a histogram with simulated overlapping normal curves. Moreover, the homoscedasticity of the residuals was checked using a standardized residual versus a standardized predicted plot. Using the Mahalanobis (P<.001) and Cook distances, we determined whether high leverage points, significant outliers, or highly influential points exist by examining a scatterplot matrix of the dependent and continuous independent variables. A linear regression was performed to check the included variance caused by the data point and if it needed to be removed from the dataset. The criterion for discarding observations was the inability to meet 2 of the distance measures' 3 gauges. However, no outliers were found that would significantly impact the findings, and thus, none were removed. The confirmation of the independence of the observations and the assumption of no autocorrelation in the residuals was checked using the Durbin-Watson d-statistic.

The initial descriptive analyses contained means, frequencies, and SD. Pearson product-moment correlation coefficients (r) were calculated to determine whether associations exist between the variables. The same correlational analysis was used to determine whether the perception of AFE is correlated with LSM during the pandemic (H1) and whether loneliness is correlated with the perception of AFEs (H2).

Hayes' [54] PROCESS macro for SPSS with model 1 was applied to investigate the moderating effects of technology use on the relationship between LSM and AFE (H3) and technology use on the relationship between loneliness and AFEs. If the standardized coefficients of the interaction terms were significant (P<.05) or marginally significant (P<.09), we conducted a simple slope test to examine the interaction effect at different levels to reveal the nature of significant interactions to further explain the moderating effect.

Ethical Considerations

Participants accessed an information sheet either via email or read on the phone and were allowed to ask questions before giving their consent. Before completing the questionnaires, each participant gave informed consent to volunteer without compensation and participate in the study. All participants were fully anonymized.

All participants were informed of their rights to withdraw at any point in the research and informed about anonymity. The ethical procedures were aligned with the guidelines of the British Psychological Society, and the study received ethical approval from the Lancaster University Faculty of Health and Research Ethics Committee (reference number FHMREC19121). Data captured via telephone first confirmed the participant's identity and was recorded in spreadsheets and anonymized thereafter.

Results

Overview

Table 1 shows mean, SD, kurtosis, and skewness values and Shapiro Wilk test results. Kurtosis and skewness values had a relatively small range of ±1; we determined that the normal distribution deviation was insignificant. The distributions of the variables of loneliness, AFE, technology experience, and LSM were close to normal.

Table 1. Descriptive statistics for loneliness, life-space, age-friendly environment assessment tool, and technology experience (N=92).

	Scores					
	Minimum	Maximum	Mean (SD)	Skewness	Kurtosis	Shapiro Wilk test
UCLA[a] loneliness score	21	80	47.49 (17.814)	0.204	−1.630	0.192[b]
Life-space mobility	10	18	13.70 (1.595)	0.515	0.035	0.201[b]
Age-friendliness of environment	0	35	19.51 (9.687)	0.019	−1.399	0.168[b]
Technology experience	48	175	116.87 (40.951)	−0.260	−1.624	0.204[b]

[a]UCLA: University of California, Los Angeles.

[b]P<.001 under moderate.

Participants demonstrated high levels of loneliness, with 44% of older adults demonstrating loneliness scores greater than 50, with scores above 40-50 considered moderate loneliness and scores greater than 50 considered high [55]. LSM scores were high, with more than 93% of the participants scoring >11, showing that they had not been outside their immediate town. Previous prepandemic studies with similar sample sizes and methodology reported almost half that score [26]. The

perceptions of AFEs were mixed, with a mean score of 19.51 (SD 9.69), demonstrating both positive and negative perceptions.

Prepandemic data from Garner and Holland's [8,56] studies provided a mean of 42.2, taken from 132 participants based in England, indicating a more positive perception of AFEs before the pandemic. Most participants scored above 125 (56%) for technology, demonstrating frequent use and familiarity with technology in general [53].

Next, we calculated the Pearson correlation coefficients to establish the relationships between loneliness, technology, LSM, and AFE perception to test H1 and H2. A correlation matrix of the variables was examined and is presented in Table 2.

Table 2. Correlational analysis between variables (N=92).

Variables	UCLA[a] Loneliness Scale	Life-space mobility	Age-friendliness of environment	Technology experience
UCLA Loneliness Scale				
r	1	−0.483[b]	−0.698[b]	−0.631[b]

[b]*P*<.01.

[c]Not applicable.

LSM is Negatively Correlated With the Perception of AFE During the Pandemic (H1)

The correlation between LSM and AFE perception was statistically significant (r=0.461, P<.001) but positively correlated, which was contrary to the hypothesis (Table 2). This meant that higher LSM scores associated with restricted mobility were correlated with a greater positive perception of AFEs. Although this rejected H1, it was a notable result.

Loneliness Is Negatively Correlated to a Perception of AFEs (H2)

The correlation between loneliness and AFE perception was statistically significant (r=−0.698, P<.001) and negatively correlated. This meant that greater loneliness was correlated with more negative perceptions of AFEs, thus confirming H2.

Technology Use Moderates the Impact of LSM Restriction on the Perception of AFEs (H3)

Model 1 was used in the PROCESS 4.0 macro for SPSS to examine the moderation effect proposed in H3 [54], as shown in Figure 1, which shows the moderation role played by technology use in the relationship between LSM and AFE perception.

Here, all continuous variables were converted to z scores for use in the model as suggested by Frazier et al [57] and Hayes [54] (ie, via z scoring, expressed as the deviation from their sample means in SD units). The unconditional interaction of LSM and technology use was insignificant (β=0.1921, t_1=1.963; P=.06; Table 3).

All variables in the model are standardized and brought into the regression equation.

Using the Aiken and West [58] method, a simple slope test was used to analyze the conditional effect of technology use between LSM and AFEs (ie, whether technology use moderates the relationship between LSM and AFEs). As illustrated in Figure 2, when technology experience was high, LSM and AFEs were significantly positively correlated (β simple: mean 1, SD 2.2037, t=3.2216; P=.003), indicating that older adults' perception of their environment was more positive when they used technology more.

In contrast, the relationship between LSM and AFEs was not obvious when the technology experience was low (β simple: mean −1, SD −0.3429, t=−0.3510; P=.73). Thus, there appears to be a positive relationship between LSM restriction and perception of AFEs when technology use was high but not when it was low (explaining the unexpected direction of H1). Furthermore, note the slight downward slope indicating the negative impact of LSM restrictions on the perception of AFEs when technology experience was low. This hints that in the absence of technology use, LSM restrictions had a detrimental impact on the perception of AFEs. This confirms H3 and

explains the initial rejection of the unconditional (overall) moderation impact of technology experience on LSM by a small margin (P=.06).

Technology Use Moderates the Impact of Loneliness on the Perception of AFEs After Considering the Impact of LSM (H4)

Model 1 was used in the PROCESS 4.0 macro for SPSS to examine the moderation effect of technology use on the relationship between loneliness and perception of AFEs, as proposed in H4 [54] and shown in Figure 3, which shows the moderating effect of technology experience on the relationship between loneliness and the perception of AFEs while controlling for LSM.

All continuous variables were converted to *z* scores. As shown in Table 4, the relationship between loneliness and technology experience was significant (β=−0.3829, t_{90}=−5.1518; P<.001), but the impact of LSM when added to the regression model was not significant (β=0.7151, t_{90}=1.665; P=.07), showing that

although technology use had a moderating impact on the relationship between loneliness and AFE perception, the contribution of LSM was not significant on the model once these other variables had been taken into account.

All variables in the model are standardized and brought into the regression equation.

We then used the simple slope test to analyze the conditional effect of technology on the impact of loneliness on the perception of AFEs to further understand the impact. As evidenced in Figure 4, the link between loneliness and AFEs was not as obvious when technology was low (β simple: mean −1, SD −0.0819, t_1=−1.5394; *P*=.13). Conversely, when technology was high, the impact of moderation was apparent more clearly (β simple: mean 1, SD −0.4983, t_{90}=−7.2636; *P*<.001). Thus, we can conclude that technology moderates the impact of loneliness on the perception of AFEs when the technology experience is high, confirming H4.

Discussion

Principal Findings

This study found higher levels of loneliness during the height of the COVID-19 pandemic among the older adult sample compared with the commonly available prepandemic data. For instance, Victor and Bowling [59] reported an average loneliness level of 30%, whereas Hawkley and Cacioppo [60] found the prevalence of loneliness in older adults to be approximately 25%, compared with the 44% found in this study. Numerous studies have found an increase in loneliness during the pandemic [61-63].

Higher loneliness was found to be correlated with a more negative perception of AFE, confirming H2 and in line with what has been theorized by the prevailing literature [18-20,22]. Shortfalls in emotional and social fulfillment have been highlighted as a predictor of loneliness, and the lack of opportunities for older adults to socialize, access important key services, and ability to engage with the community may have worsened perceptions. When older adults perceive that their desired quantity or quality of social engagements is met, they are less likely to experience loneliness and may also have favorable attitudes toward AFEs. Previous research has suggested that this relationship is likely to be complex [19] and bidirectional. AFE perception can be an indicator of a mechanism for aging-in-place, preserving older adults' physical setting of choice, providing a sense of community attachment, and allowing them to engage with a developed social network, with associated familiarity and better mental well-being.

This study found that greater use of technology clearly moderated the relationship between loneliness and the perception of AFEs. It also moderated the LSM-AFE relationship. Furthermore, the ability to use technology successfully to adapt to challenging experiences during lockdown emerged as a potential buffer against the impact of loneliness on AFE perception. Other studies that examined technology use during the pandemic revealed an increase, indicating adaptation to LSM restrictions via alternative pathways [37,64]. An increase in LSM restriction was linked to a positive perception of AFEs, rejecting H1, which at first seemed counterintuitive. However, the moderation effect of technology, such that this relationship existed only when technology use was high, explained the unexpected direction of the relationship. Older adults were overcoming physical restrictions barriers, where the ability to replace previously in-person activities with those online may have impacted perceptions. Other studies that examined AFEs also noted an increase in positive perception of AFEs as the pandemic progressed, but these could also have been linked to the easing of restrictions [56]. Overall, technology use may have improved the negative impacts of loneliness on the perception of AFEs helping with older adult mental health.

In testing H4, we determined that when technology experience was high, it had a moderation effect on the loneliness-AFE relationship. Ng et al [16] attempted to explain the relationship between internet use and loneliness through a moderation-mediation mechanism between internet use, perception of AFE, and loneliness, and depression. Their findings were consistent with those of Park et al [24] and Domènech-Abella et al [65], who confirmed the moderating effect of the internet on the age-friendliness-loneliness-depression mechanism, which may also explain our results. For example, Booth et al [66] discovered a partial mediation effect of feelings of helplessness, social isolation, depression, and distrust between psychological distress and perceived AFE (especially concerning security). Social isolation is a well-established predictor of loneliness and depression, and loneliness has also been linked in the literature. Taken together, these hint at a causal route between loneliness and perception of AFEs. Increased anxiety can lead to increased loneliness and mental health issues, potentially leading to a reduced fit between the older adult and the environment [67,68].

Despite studies highlighting the potential moderating role of technology between loneliness and AFE perception, previous results were always unclear about a direct link between these 3 variables. Our study found a clear moderating role for technology in the relationship between loneliness and AFEs, which is a notable finding.

When using the simple slope test, where technology use was low, we found that LSM negatively affected perceived AFEs when technology use was low. This explained our initial counterintuitive result and supported earlier findings [24]. To substitute or overcome confinement, older adults may have developed alternative routes of access to AFE domains, such as social, civic engagement, and access to services through technology.

Access to the internet may have helped reduce older people's boredom, and there have been examples from recent studies where older adults were able to access informal help networks, reading, or online game groups, as well as participate in community-based activities like attending virtual church gatherings [69,70]. Alternative social and emotional outlets to combat loneliness through access via the internet, to previously in-person services (eg, primary care, counseling) may have contributed to network socialization, allowing older adults to continue feeling like they are a part of their environment and reducing loneliness.

The implications of our study can be applied to situations outside of the pandemic context. Studies have highlighted that older adults prefer to live in their own homes and interact with their local community, where they have developed relationships over time and do so as long as possible [71,72]. A negative perception of AFEs can be viewed as a barometer indicating poor person-environment fit [72], associated with poorer mental health outcomes [25,71]. Therefore, technology could be a solution for those who ordinarily have limited LSM, are at risk for social isolation, and have a negative perception of AFEs.

Our study confirmed the link between LSM, loneliness, and perception of AFEs, as well as the moderating role technology played during the COVID-19 pandemic, advancing the findings of previous studies in this rapidly evolving body of literature. We also strengthened the argument that the WHO's Global Age-Friendly Cities framework would benefit older adults more by including technology use as an additional ninth domain.

Study Limitations

This study had several limitations. For example, the sampling could have been predisposed to participants literate in digital resources and more socially connected. Generally, such participants may have experienced less loneliness [73]. Furthermore, a cross-sectional design cannot establish causality [74]. Although the sample size was small, the statistical power, effect size, precision, type, complexity of analysis, study population variability, and homogeneity overcame this shortcoming. The results are an important contribution to the discourse on the role being played by AFEs in the mental well-being of older adults and the role of technology.

Although it is unlikely that participants will experience the same level of LSM restrictions after the pandemic, this allowed us to examine the studied measures in a normally inaccessible environment. However, we cannot conclude with certainty that the pandemic caused the observations because we did not have a prepandemic assessment for the same participants. Nevertheless, other prepandemic studies supported our hypothesis of mobility restrictions' impact on loneliness.

Conclusion

Despite the limitations, the results suggest that the vulnerability of older adults during the pandemic and their exposure to loneliness and negative perceptions of AFEs increased, and technology played an important role in moderating these influences. Given the advancements in technology, the WHO's 8 domains of AFEs may be obsolete with their narrow implicit recognition of technology. Our study demonstrates the significance of an explicit recognition of technology in the evaluation of AFEs as an integral component of all aspects of older adults' daily lives. Future studies may also wish to look further into the impact of demographics and differences between genders.

Community and mental health service access could be improved by providing online access. Older adults need cheap access to internet infrastructure, and health community centers should provide technology training, attend online meetings, or use mental health applications.

Researchers in the field of loneliness in older adults are encouraged to use our results to inform initiatives to reduce the mental health risks for older adults in vulnerable crises, such as the pandemic and civil insurrections [75,76]. Appropriate consideration of these factors will aid decision makers in developing robust and effective strategies during times of crisis, as well as in assisting an aging population with aging-in-place.

Abstract

Background: With an aging population driven by advances in medical technology, digital literacy has become essential for improving the quality of life of older adults, enhancing access to health information, and promoting healthy lifestyles. Furthermore, the COVID-19 pandemic may have influenced the subjective health perceptions and healthy lifestyle behaviors of older adults. However, there is limited research exploring the relationship between digital literacy, subjective health perceptions, and healthy lifestyle behaviors in Korea.

Objective: This study aimed to investigate digital literacy's impact on Korean older adults' subjective health status and healthy lifestyle behaviors.

Methods: Data of 8664 respondents (aged 65 years and older) from the 2020 National Survey of the Older Koreans were analyzed. Digital literacy was measured based on the use of IT devices (ITDs), difficulty using online information, and inconvenience of ITDs. Statistical analyses, such as the Rao-Scott chi-square test, Wilcoxon rank sum test, and multiple regression analysis, were conducted.

Results: Respondents with above-average ITD use (adjusted odds ratio [aOR] 1.73, 95% CI 1.50 - 1.99) and less difficulty using online information (aOR 1.41, 95% CI 1.24 - 1.61) had higher odds of perceiving themselves as healthy. Conversely, high difficulty using ITDs was associated with lower odds of respondents perceiving themselves as healthy (aOR 0.84, 95% CI 0.82 - 0.87). Furthermore, high ITD use predicted engagement in healthy lifestyle behaviors (aOR 1.51, 95% CI 1.33 - 1.72), whereas high difficulty using ITDs predicted lower odds of engagement (aOR 0.94, 95% CI 0.92 - 0.97). In contrast, there was no difference in the odds of engaging in healthy lifestyle behaviors regardless of difficulty using online information (aOR 1.03, 95% CI 0.92 - 1.15).

Conclusions: This study underscores the significant association between digital literacy and improved health outcomes among older adults. Promotion of digital literacy and relevant policies is essential to help older adults effectively obtain health information online, thereby improving their quality of life and overall health.

KEYWORDS

digital literacy; healthy lifestyle behaviors; older adults; subjective health status; quality of life

Introduction

Advances in medical technology have increased life expectancy, thereby contributing to the growth of an aging population worldwide [1]. South Korea became an aging society in 2017, and it is predicted to transition to a super-aged society by 2025 [2]. Old age is characterized by a general decline in physical and mental functioning, leading to a range of health issues, including senile and chronic degenerative diseases and impaired daily functioning [3]. Prevention, treatment, and management of diseases are necessary to improve of older adults' health care and quality of life. In addition, health information and proactive responses for health care are important [4]. Particularly, the first generation of Korean "baby boomers" (born between 1955 and 1972), specifically those born in 1955, has been incorporated into the older adult population since 2020. Thus, this is a crucial time for discussion on older adults' health care.

Generally, older adults obtain health information from health care providers, friends and relatives, television, newspapers, radio, and other mass media to maintain their health [5]. However, rapid technological developments have increased the opportunities for acquiring health information and news on the internet, leading to digital literacy's increased importance [6-8]. Digital technology initially spread among young people, men, and highly educated people and is gradually spreading to older adults, women, and less educated people. The aging trend and the rapid development of new media technology suggest that older adults will have to use digital technology more in the future [9]. Digital literacy comprises the ability to understand the information generated on a digital device and implement it accordingly [10]. In an information society, digital literacy's importance is expanding to all areas of life as a key factor in improving quality of life [11,12].

The manner in which older adults perceive their health informs how they relate to society. In addition, their subjective well-being is intimately linked to their perceived health status [13]. Meanwhile, health concerns can be a primary motivation for searching health information online [14]. Specifically, the use of the internet promotes the health of older adults by improving access to health information, encouraging healthy lifestyles, and enhancing social interaction [15]. While older adults recognize the effectiveness and usefulness of using health information through digital media such as the internet for health care, they experience challenges when actually attempting to obtain health information online [16,17]. According to a 2022 report on the digital divide, vulnerable groups such as people with disabilities, low-income individuals, farmers, and older adults have markedly lower digital use capabilities, with the latter experiencing the highest level of information vulnerability [18].

The growing importance of digital literacy for older adults has prompted a variety of studies. However, most Korean research is survey-based or restricted to specific geographic regions or disease populations, focusing primarily on health knowledge, mental health aspects such as depression and self-efficacy, or quality of life [19-22]. While subjective health perceptions and healthy lifestyle behaviors of older adults may have been influenced by COVID-19 pandemic, these studies were conducted before the pandemic [23-25]. Furthermore, the rapid progress of aging and the advancement of IT, along with gaps in the acquisition of information, unchecked spread of health information, and dissemination of unverified information, have created growing concerns among the older adult population vis-à-vis the lack of reliable information [26-28].

This study seeks to examine 2 key hypotheses: (1) older adults with higher levels of digital literacy are more likely to perceive themselves as healthy and (2) higher levels of digital literacy among older adults are associated with a greater likelihood of engaging in health-promoting behaviors. Using a nationally representative sample, we aim to investigate the association between different aspects of digital literacy and older adults' subjective health status and healthy lifestyle behaviors.

Methods

Data Source and Study Population

This cross-sectional study used data from the 2020 National Survey of the Older Koreans (NSOK), conducted by the Ministry of Health and Welfare and the Korea Institute for Health and Social Affairs (KIHASA). The NSOK is a survey conducted every 3 years since 2008, in accordance with Article 5 of the Welfare of Senior Citizens Act. It systematically collects data from more than 10,000 older adults aged 65 years and older who are living in ordinary residences across 17 cities and provinces nationwide. Trained surveyors carry out the survey in 969 districts selected based on regional representation. They survey all households with older residents, considering factors such as area of residence, age, gender, education, and marital status [29]. This survey aimed to identify the living conditions, characteristics, and needs of older adults to develop welfare policies to improve their quality of life. In addition, it sought to develop policies in response to Korea's aging society by examining changes in the characteristics of older adults through the accumulation of time-series data [29].

NSOK calculates weights in 3 steps: using design weights, nonresponse-adjusted weights, and poststratification weights. First, the design weights are directly derived from the sampling design, using a 2-stage cluster sampling method. This method involves probability proportional to size (PPS) sampling, where sample areas are selected based on the number of households in each area, followed by the selection of households within each sampled area. Nonresponse adjustment is conducted by upweighting responding households using the reciprocal of the response rate. Final weights are calculated by applying a raking ratio method, and respondent weights, adjusted for design and nonresponse weights, are poststratified to match the distribution of older adults in the population, thereby enhancing the accuracy of estimates. The 2020 NSOK used data from the 2019 Census, the most recent available at the time of survey completion, to calculate final weights by applying population data for older adults by gender, age group (65 - 74 years or 75 years and older), and household size (1-person household, 2+ persons) across the 17 metropolitan areas [21].

The study excluded 1256 of the 10,097 respondents who answered "don't know" or "not applicable" to the digital literacy survey. In addition, if the respondent has a physical or mental illness, the cohabitant or a close representative of the study subject responds on their behalf. In this case, only the objective information of the older adults was surveyed, and the main focus of this study was not surveyed [28]. Therefore, the results were generalized to older Koreans by excluding the 177 respondents who responded on behalf of their cohabitant. These exclusions ensured the objectivity of the health indicator responses, as the survey focused on the subjective judgment of the original respondents [29]. Finally, the study included 8664 participants.

Ethical Considerations

The Institutional Review Board (IRB) of the Yonsei Medical Center approved a consent exemption for this study (No. 4-2023-0361). The 2020 Elderly Survey used in this study was anonymized by the data provider, KIHASA, and the tools and processes used in the survey were approved by the IRB of KIHASA (No. 2020 - 36).

Measurements

Subjective Health Status and Healthy Lifestyle Behaviors

The dependent variables of this study included subjective health status and healthy lifestyle behaviors. Subjective health status has been widely used in various studies as a valid proxy for actual health status, given its reliable predictive value for health outcomes [30-32]. It was categorized into good (very healthy and healthy) and poor (fair, poor, and very poor). Healthy lifestyle behaviors were defined as smoking cessation, decreased alcohol consumption, and exercise [33]. Smoking cessation was defined as having quit smoking, decreased alcohol consumption was defined as not drinking at all in the previous year or drinking less than twice a week, and exercise was defined as answering "yes" to the question, "Do you usually exercise for at least 10 minutes on a consistent basis?"

Digital Literacy

This study's main variable was digital literacy, which was divided into 3 subcategories. It was scored based on the degree of use of IT devices (ITDs), difficulty using information provided online, and inconvenience of ITD usage.

For the item on the degree of ITD usage, 1 point was assigned to each of the activities in Textbox 1, which involved using a PC, mobile phone, or tablet. The sample was divided into 2 groups according to the respondent's score, namely above average (3 points or more) and below average (3 points or less).

For the item on the difficulty of using information provided online, the degree of difficulty in using information or services required for daily life via the internet was categorized into "difficult" and "not difficult." The inconvenience of ITD usage was assessed considering tasks such as making online reservations, conducting purchases using machines such as kiosks and automated teller machines, and shopping at stores that only accept cards. For each task, the level of inconvenience was scored on a scale from 0 ("not at all inconvenient") to 2 ("inconvenient"). Finally, the overall level of inconvenience of using ITDs was rated on a scale from 0 ("not at all inconvenient") to 8 ("inconvenient"). A Cronbach α of 0.88 was identified for ITD usage, and 0.80 for inconvenience of using ITDs.

Textbox 1. Activities that involved using a PC, mobile phone, or tablet.

- Receiving messages.
- Sending messages.
- Searching for and viewing information.
- Taking photos and videos.
- Listening to music.
- Playing games.
- Watching videos.
- Using social media.
- Using e-commerce platforms.
- Using online financial transactions.
- Searching for and installing applications.
- Other activities.

Covariates

The covariates included sociodemographic characteristics and health-related factors. Sociodemographic characteristics included gender, age, residence, educational level, household types, and household income. Age was classified into five 5-year intervals (65 - 69, 70 - 74, 75 - 79, 80 - 84, and ≥85 years old). Residence was classified into "rural (eup/myeon)" and "urban (dong)." Educational status was classified into "elementary school or less," "middle and high school," and "university and above." Household type was classified into "single," "married couple," and "cohabitant (nonspouse)." Household income encompassed all household members' earned, business, property, and transfer incomes. This comprised the annualized gross household income for the most recent year (July 1, 2019, to

June 30, 2020), converted to a monthly basis and divided into quartiles.

Health-related factors included the number of chronic diseases respondents had. Chronic diseases included conditions that lasted for more than 3 months and had been diagnosed by a doctor. These were categorized as "none," "1‐2 chronic diseases," and "3 or more chronic diseases," encompassing 32 conditions.

Statistical Analysis

A frequency analysis was conducted to identify the participants' general characteristics. The Rao-Scott chi-square test and Wilcoxon rank sum test were conducted to evaluate and compare these characteristics. Multiple logistic regression analysis examined the associations of digital literacy with subjective health status and healthy lifestyle behaviors. In addition, a subgroup analysis was conducted to determine whether gender led to differences in the association of digital literacy with subjective health status and healthy lifestyle behaviors. All analyses were conducted using SAS software (version 9.4; SAS Institute), while statistical significance was set to $P<.05$. All analyses were weighted by NSOK to account for differences in survey completion rates across NSOK's survey regions.

Results

The participants' demographic and socioeconomic characteristics are summarized in Table 1. Of the 8664 study participants, all weighted by region, 55.9% (4649) had above-average scores in ITD usage, while 72.3% (6264) found it difficult to use information available online. The level of inconvenience of ITD usage was 4.2 out of 8.

Participants were mostly female (n=5077, 55.7%), aged 65‐69 years (n=3282, 35.8%), urban residents (n=6256, 76.1%), educated up to middle and high school (n=4571, 54.4%), married (n=4502, 59.7%), in household income level 4 (n=2169, 29.1%), and had 1‐2 chronic diseases (n=4936, 56.6%).

Table . Distribution of demographic and socioeconomic characteristics.

3 or more	2195 (26.5)	513 (25)	1682 (75)		1055 (51.1)	1140 (48.9)	

[a]Weighted percentage.

[b]Rao-Scott chi-squared probability for comparison between (1) healthy and nonhealthy groups, and (2) groups engaging in healthy lifestyle behaviors and those not engaging in healthy lifestyle behaviors.

[c]ITD: IT device.

Of participants with above-average ITD usage, 64.8% (n=3038) perceived themselves as healthy and 51.8% (n=2329) engaged in healthy lifestyle behaviors. Of participants who reported difficulty using online information, 45.6% (n=2898) perceived themselves as healthy and 46.1% (n=2773) engaged in healthy lifestyle behaviors. Participants who perceived themselves to be healthy exhibited an ITD inconvenience score of 3.7 and those who engaged in healthy lifestyle behaviors exhibited a score of 4.1.

The association of digital literacy with subjective health status and healthy lifestyle behaviors is shown in Table 2. Compared with participants with below-average ITD usage, the odds of participants with above-average ITD usage were 1.73-times more likely to perceive themselves as healthy (adjusted odds ratio [aOR] 1.73, 95% CI 1.50 - 1.99, *P*<.001) and 1.51-times more likely to engage in healthy lifestyle behaviors (aOR 1.51, 95% CI 1.33 - 1.72, *P*<.001). Participants who did not find it difficult to use information available online had 1.41-times (aOR 1.41, 95% CI 1.24 - 1.61, *P*<.001) higher odds of perceiving themselves as healthy, compared with those who found it difficult. Higher ITD difficulty scores were also associated with 0.84-times lower odds of respondents perceiving themselves as healthy (aOR 0.84, 95% CI 0.82 - 0.87, *P*<.001) and 0.94-times lower odds of engaging in healthy lifestyle behaviors (aOR 0.94, 95% CI 0.92 - 0.97, *P*<.001).

Table . Digital literacy and its association with subjective health status and healthy lifestyle behaviors.

Variable	Perceived as healthy		Engaging in healthy lifestyle behaviors	
	aOR[a,b] (95% CI)	*P* value	aOR[a] (95% CI)	*P* value
Degree of ITD[c] usage				
Below average	Ref.[d]	—[e]	Ref.	—
Above average	1.73 (1.50-1.99)	<.001	1.51 (1.33-1.72)	<.001
Using information provided online				
Difficult	Ref.	—	Ref.	—
Nondifficult	1.41 (1.24-1.61)	<.001	1.03 (0.92-1.16)	.59
Inconvenience of ITD usage (score)	0.84 (0.82-0.87)	<.001	0.94 (0.92-0.97)	<.001

[a]Adjusted for covariates including gender, age, residence, educational status, household type, household income, and number of chronic diseases.

[b]aOR: adjusted odds ratio.

[c]ITD: IT device.

[d]Ref.: reference.

[e]Not applicable.

The association of digital literacy with subjective health status and healthy lifestyle behaviors by gender is shown in Tables 3 and 4. Both men and women with a higher than average degree of ITD usage were more likely to perceive themselves as healthy than those with an average or lower degree of ITD usage, and women in particular were nearly twice as likely (male aOR 1.64, 95% CI 1.34 - 1.99, *P*<.001; female aOR 1.91, 95% CI 1.60 - 2.27, *P*<.001). Similarly, people who did not experience any difficulties in using information provided online were more likely to perceive themselves as healthy than those who did experience difficulties, but this was more likely to be the case for men (male aOR 1.60, 95% CI 1.32 - 1.94, *P*<.001; female aOR 1.27, 95% CI 1.06 - 1.51, *P*=.01). Women with a higher degree of ITD usage were 1.54 times more likely to engage in healthy lifestyle behaviors than women with a lower degree of ITD usage, and this was slightly higher than for men (male aOR 1.47, 95% CI 1.20 - 1.81 *P*<.001; female aOR 1.54, 95% CI 1.30 - 1.82, *P*<.001). The less comfortable they were with using ITD, the less likely they were to perceive themselves as healthy (male aOR 0.84, 95% CI 0.80 - 0.88, *P*<.001; female aOR 0.85, 95% CI 0.81 - 0.88, *P*<.001) and to practice healthy lifestyles (male aOR 0.95, 95% CI 0.90 - 0.99, *P*=.02; female aOR 0.94, 95% CI 0.90 - 0.97, *P*<.001), with similar results for men and women.

Discussion

Principal Findings and Comparison With Previous Work

This study examined the association between older people's digital literacy and their subjective health status and healthy lifestyle behaviors. Research has shown that older people with a high level of digital literacy, those who actively use information devices, and those who have easy access to online information are more likely to feel healthy and maintain healthy lifestyle behaviors. Conversely, those who experience difficulty accessing information online and are uncomfortable using information devices are less likely to engage in healthy lifestyle behaviors.

This study's findings are consistent with those of previous studies showing that both the use and amount of information affect subjective health status. In addition, whether older people own digital devices, how often they use them, and the extent of their internet activity are likely to affect their digital literacy and health [34-36]. According to a study in the United States, searching for and mastering relevant medical knowledge on the internet is beneficial for older adults with high blood pressure and heart disease, improving their health care and reducing disease rates [37]. In addition, using the internet could improve the health of older individuals by increasing their ability to exercise; for example, internet intervention programs helped them select exercise activities in the areas of endurance, flexibility, strengthening, and balance enhancement, which helped older adults increase their exercise frequency, thereby improving their physical health [38,39]. In China, older people with a high frequency of digital device usage experience a positive impact on their lifestyle, including improvements in diet, sleep, and exercise [15,40].

Empowering older people with a wide range of digital skills, from simple computer use to usage of social networks, emails, and online meetings, could enrich their lives, enhance their cognitive capabilities, and make them more productive and efficient members of society [41]. This could significantly contribute to the improvement of their perceived health status [42]. People who understand health information available online can use it effectively in their daily life to acquire valuable insights regarding their illnesses, increase their involvement as patient in the treatment process, and positively assess their subjective health status [43]. The internet provides a wealth of information, creating and increasing thematic content, especially for groups intimately associated with older adults, which helps maintain intergenerational relationships and promotes connected social capital [44]. With this social capital, older adults with a high level of digital literacy could fulfill their desire for belonging and love, which in turn could enable them to evaluate their health more positively [45].

However, unlike previous studies, this study found no difference in healthy lifestyle behaviors between those with and without difficulty using online information. Older people with high digital literacy have easier access to health information and use it effectively to positively impact their health care. Furthermore, they regularly access the internet for health information [27,35]. A previous study reported that adults aged 50 - 60 years who are not in good health access the internet for health care purposes because they want to be actively involved in health care decisions [46]. A few older individuals use emails and social networking sites to promote cancer screening to colleagues [47]. Online mediation, such as effectively managing hemoglobin A_{1c} levels in patients with diabetes through social networking site–based interventions, improved knowledge about the disease and had a positive impact on health behaviors [48,49].

Also in South Korea, Min [50] reported that the use of internet information decreased with age, regardless of physical and environmental accessibility, but this measure of use was comparable with this study's degree of ITD usage. Previous

studies have also highlighted the positive effects of online health information seeking psychological and physical domains, such as increased self-efficacy and improved health behaviors [51,52]. However, these studies were conducted before the COVID-19 pandemic, leaving a gap in understanding health behaviors during and after the pandemic.

The 2020 NSOK survey was conducted during the COVID-19 pandemic—a period marked by reduced outings among older adults due to social distancing policies and concerns about weakened immune systems. This context likely contributed to an overall decline in healthy lifestyle behaviors, particularly exercise, regardless of difficulties in using online information [23-25]. The reliance of Korean older adults on interpersonal sources for health information is deeply rooted in cultural values such as Confucianism and collectivism [53,54]. For health-related information, older adults in South Korea often rely on various sources, including health care professionals, mass media, local health centers, and family members. Particularly, adult children act as intermediaries in accessing and interpreting digital health information. In addition, a strong cultural trust in health care professionals reinforces a preference for direct consultations rather than independent online searches [55-57]. These sources play an important role in supporting health behaviors, even without the use of the internet, and help create an environment where information remains accessible despite low levels of online information use. In addition, older adults may have relied on household members or health center staff to mediate and explain online information, rather than accessing it directly [58-60]. This indirect approach could have resulted in an underestimation of the actual challenges older adults face when navigating online information.

Limitations

The present study had a few limitations. First, this is a part-sectional study. As we measured the variables at the time of the survey, we could only derive meaning in relation to the association between older adults' digital literacy and the causal relationship between their subjective health status and health practices. Second, as life expectancy increases, it is possible to divide the older adult population aged 85 years or older into different age groups. However, the NSOK is limited to detailed age-specific analysis. Nevertheless, this study used the latest data from national units, which ensured the representation of South Korea's older adults. In this study, digital literacy was divided into specific categories such as the degree of ITD usage, the difficulty of accessing online information, and the inconvenience of ITDs. This highlights the importance of linking older people's digital literacy to their subjective health status and health practices.

Conclusions

This study expands the existing knowledge on the subject by using a national-scale survey of South Korea's older adult population. To improve the subjective health and health practices of older adults, digital literacy education and related policies must be promoted. Furthermore, it is important to provide information education, so that older individuals can identify the required information, even among commercial and vague content. Health care and public institutions should provide information, booking systems, guidance, and other services to help older adults make use of these resources. We hope that this study will serve to improve older adults' quality of life and contribute to their health and welfare.

Data Availability

The data can be accessed from the Ministry of Health and Welfare and the Korea Institute for Health and Social Affairs (KIHASA) homepage. However, restrictions apply to data availability. The data were used with permission for the current study and, therefore, are not publicly available. The data are available from the corresponding author upon reasonable request and with prior permission from the KIHASA. Applications to use the National Survey of the Older Koreans (NSOK) data will be reviewed by the inquiry committee of research support, and once approved, raw data will be provided to the applicant for a fee.

Authors' Contributions

SYL was involved in study conception, statistical design, and manuscript drafting. YK and BK were involved in study conception, statistical design, data analysis, and manuscript drafting. SGL and SYJ oversaw the manuscript's development and helped revise it. THK was involved in study conception, statistical design, manuscript development, and manuscript revision. All the authors critically revised the manuscript for important intellectual content and approved its final version.
