Results: In total, 12 studies from the original review were retained, with 17 new peer-reviewed studies added, yielding a total of 29 studies in addition to 30 documents identified in the gray literature search. Barriers included limited digital literacy and physical and cognitive challenges (capability); infrastructural deficits and usability challenges (opportunity); and privacy concerns, mistrust, and high satisfaction with existing care (motivation). Facilitators included tailored training and accessible design (capability), health care provider endorsement and hybrid care models (opportunity), and recognition of digital health benefits (motivation). Health care providers emerged as both facilitators and barriers, positively influencing adoption when engaged and trained but hindering it when lacking confidence or involvement. Comparative analysis of rural and urban contexts was limited by inconsistent reporting of equity-relevant variables. However, gray literature suggested that rural users face additional infrastructural challenges but express higher satisfaction with local care, potentially reducing motivation for digital uptake. Gender differences were observed in 5% (3/59) of the peer-reviewed studies and gray literature sources, with older women showing lower adoption and differing outcome priorities. Co-design enhanced adoption, especially when involving not just older adults but also health care providers and community stakeholders.

Conclusions: Digital health adoption among older adults is shaped by capability, opportunity, and motivation factors. Effective and equitable digital health strategies must address infrastructural and literacy barriers, engage health care providers through training and co-design, and ensure multistakeholder involvement. This review highlights that greater attention to standardized reporting of demographic variables, especially gender and rurality, is essential in digital health research to support inclusive implementation.

older adults; chronic disease; digital health; technology adoption; rural health; co-design

Introduction

Background

The global population aged ≥60 years is projected to double between 2015 and 2050, placing increasing pressure on health care systems [1,2]. Population aging is widely recognized as one of the most pressing challenges facing health and social care worldwide [3]. Chronic disease is the leading cause of death worldwide, posing a major public health burden [4]. Ischemic heart disease, stroke, and chronic obstructive pulmonary disease (COPD) are among the top causes of mortality alongside Alzheimer disease, lung cancer, diabetes, chronic kidney disease, and cirrhosis [5]. These conditions typically require ongoing long-term management and monitoring, such as blood glucose tracking for diabetes and blood pressure tracking for cardiovascular disease. Multimorbidity (more than one chronic disease) is rising sharply, with an estimated two-thirds of adults aged ≥65 years expected to live with multiple chronic conditions by 2035 [6,7]. Rural and remote areas are disproportionately affected, where health systems often face additional challenges due to dispersed populations and resource constraints [8,9].

To address these pressures, innovative strategies are needed to enhance chronic disease management, particularly in settings where health care access is limited. Digital health technologies (DHTs), including telemedicine, mobile apps, remote monitoring devices, and electronic health records, offer promising tools to support health care delivery, improve health outcomes, and enhance system efficiency [10,11]. The global uptake of digital health accelerated during the COVID-19 pandemic, when remote monitoring and web-based consultations became critical [12-14]. When implemented effectively, digital health solutions have the potential to reduce clinician workload [15]; improve patient safety and care quality [16]; and decrease the need for in-person visits, which is an especially valuable benefit in rural areas, where patients often travel long distances to access health care [17]. Despite these potential benefits, there is evidence suggesting that older adults and those in rural areas are less likely to engage with DHTs compared to their urban counterparts [18-20]. Paradoxically, while these groups stand to benefit the most, they often remain digitally excluded.

The importance of digital health is underscored by the World Health Organization (WHO) *Global Strategy on Digital Health 2020-2025*, which promotes digital solutions to enhance health system resilience and equity [11]. Similarly, the regional digital health action plan for the WHO European Region 2023 to 2030 highlights the need to build digital capacity across the public and health care workforce [21]. These priorities have stimulated research into barriers to and facilitators of digital health adoption, with recurring themes such as infrastructural challenges, digital literacy gaps, and the critical role of health care providers in supporting uptake [22].

Although a growing body of literature explores digital health adoption, most studies focus on general populations or specific diseases, with limited attention to older adults with chronic conditions, a group at heightened risk of digital exclusion. For example, individuals aged ≥65 years are 18 times more likely never to have used a health app compared to those aged 18 to 24 years [23]. Despite increasing internet use during the pandemic, 34% of adults aged ≥75 years remain offline, and 13% of those aged ≥65 years do not own a mobile phone [24]. According to a report by Age UK, limited digital skills remain a significant barrier, with an estimated 4.7 million people aged ≥65 years in the United Kingdom lacking the basic digital skills required to use the internet effectively. In addition, the report found that 49% of people aged ≥50 years find it difficult to access their general practitioners (GPs) due to challenges with digital or telephone triage systems. These barriers contribute to feelings of frustration, disempowerment, and disengagement among older adults [25]. It is important to note that older adults are a diverse group whose digital engagement is shaped by the intersection of multiple factors, such as age, gender, socioeconomic status, educational level, place of residence, and health status, which can combine to create unique patterns of digital inclusion or exclusion. Understanding the common barriers to and facilitators of digital health adoption in this population is critical to inform more inclusive digital health strategies. To support this focus on equity, the PROGRESS-Plus (place of residence; race, ethnicity, culture, and language; occupation; gender and sex; religion; education; socioeconomic status; and social capital–plus) framework was selected to guide both the rationale for this review and the structured extraction of equity-related variables during analysis. PROGRESS-Plus is an equity-oriented framework that also considers the *Plus* domains of age, disability, and other contextual factors. This framework is increasingly used in systematic reviews to assess whether and how health interventions account for social determinants of health, ensuring that findings support equitable access and outcomes across diverse populations [26].

Gender is one such factor, with studies suggesting that older women, particularly those in low-income settings, are less likely to adopt DHTs than men due to lower digital confidence, greater privacy concerns, and different expectations regarding the purpose of DHTs [27-29]. These differences underscore the importance of including gender in evaluations of digital health access. Recent reviews have highlighted persistent inequities in digital health adoption; for example, a scoping review of the

XSL•FO
RenderX

WHO European Region found that digital health interventions were more often adopted by White, English-speaking, urban, and economically advantaged individuals, with limited evidence on underserved groups such as rural populations or ethnic minority groups [30]. Similarly, a review of digital health use during the COVID-19 pandemic found that rapid implementation sometimes exacerbated disparities, particularly among those with limited access to devices or low digital literacy [31]. These findings underscore the importance of applying equity frameworks such as PROGRESS-Plus when evaluating digital health uptake.

Previous Work

A previous scoping review that investigated barriers to and facilitators of older adults using eHealth identified common barriers such as lack of self-efficacy, insufficient knowledge and support, concerns over functionality, and lack of clear information about the benefits of digital health [32]. However, few reviews have focused specifically on older adults with chronic diseases, with the notable exception of a systematic review by Bertolazzi et al [33], which explored the barriers and facilitators influencing adoption of DHTs by older adults with chronic diseases. The review identified 5 domains influencing adoption: demographic and socioeconomic factors, health-related factors, dispositional attitudes, technology-related barriers, and social influences. The key facilitators were perceived usefulness, early introduction of technology, social support, and user-friendly design. Barriers included digital literacy, technical issues, a preference for existing ways of managing health, and lack of support.

Goal of This Study

This review significantly extended the work by Bertolazzi et al [33] in both scope and depth to capture a rapidly evolving digital health landscape. While the original review included studies up to April 2022, it missed a critical wave of literature emerging during and after the COVID-19 pandemic, a period marked by a surge in the deployment and evaluation of DHTs [34,35]. By identifying studies published between April 2022 and September 2024, this review broadened the evidence base to reflect more recent trends, challenges, and innovations in digital health adoption among older adults with chronic diseases.

In addition to updating the time frame, this review addresses key limitations of the earlier work by incorporating gray literature, an important yet often overlooked source in fast-moving fields such as digital health. Government reports, policy briefs, and non-peer-reviewed evaluations provide timely, real-world insights. This is particularly relevant to equity, as published literature on digital health often underrepresents older adults [36] and specifically older adults in rural communities [37]. As Landerdahl Stridsberg et al [38] note, “Gray literature is particularly relevant for digital health and HWT… Systematic reviews… should consider including gray literature based on a systematic approach.” This approach is consistent with PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) 2020 guidance [39], which recognises gray literature as a valid evidence source in systematic reviews where eligibility criteria are applied consistently and search processes are transparent.

This review also deepened the analysis by examining previously underexplored dimensions. While the original review noted the value of involving older adults in design, it did not assess the use or impact of co-design approaches. We addressed this by extracting data on co-design and its influence on adoption. Similarly, rurality, a key determinant of access and equity in digital health, was not systematically analyzed. Where reported, we extracted rural-urban comparisons to better understand how context shapes adoption. Equity-related reporting itself also varied widely in the previous review. To address this, we applied the PROGRESS-Plus framework to assess how studies accounted for equity-relevant factors such as gender, geography, and socioeconomic status, dimensions that are essential for informing inclusive digital health strategies.

Finally, we applied a theoretical lens absent from the original work. Using the capability, opportunity, and motivation–behavior (COM-B) model [40], we categorized barriers and facilitators to provide a more structured, behaviorally informed interpretation of the evidence. This theoretical grounding enhances the potential for actionable insights to inform intervention design and policy. This review is an update of the review by Bertolazzi et al [33] and applied the same inclusion criteria, with the search extended from April 2022 to September 2024. Limitations identified in the original review informed the scope and methods of this update, including the addition of gray literature and attention to rurality, co-design, and equity considerations.

Objectives

This review aimed to provide a more comprehensive understanding of the factors that influence digital health uptake among older adults with chronic diseases. The review was guided by the following questions:

1. What are the main factors hindering the adoption of DHTs by older adults with chronic diseases?
2. What are the main factors facilitating the adoption of these technologies?
3. How do these barriers and facilitators vary across equity-relevant factors such as place of residence (urban or rural) and gender?
4. In what ways does co-design support the adoption of DHTs for chronic disease management?

Methods

Protocol and Registration

This review followed a prespecified protocol, which was registered with PROSPERO (CRD42024586893).

Overview

This study is an updated systematic review that synthesizes research results on the barriers to and facilitators of the uptake of DHTs by older adults with chronic diseases following the PRISMA guidelines (see the PRISMA checklist in Multimedia Appendix 1) [39]. To address specific limitations identified in the original review, the update expanded the search to include gray literature, increased attention to rural contexts, and incorporated additional data extractions on co-design processes.

XSL•FO
RenderX

The full search strategies from Bertolazzi et al [33] were available and retained for reference. All studies included in the original review were rescreened using the same inclusion criteria as this update, with only eligible studies retained. In accordance with the PRISMA 2020 guidance for updated reviews [39], we searched only from April 2022 to September 2024 as the previous review had already conducted a comprehensive search from 2012 to April 2022.

Information Sources and Search Strategy

Four electronic databases were searched: PsycArticles, Scopus, Web of Science, and PubMed. Searches were conducted for publications dated April 2022 to September 2024 using a Boolean strategy combining keywords and MeSH (Medical Subject Headings) based on the population, intervention, comparison, and outcome framework [41] (Textbox 1; see Multimedia Appendix 2 for the search strategy). The date restriction was intentional as the period from 2012 to April 2022 had already been searched in the original review and rerunning it risked unnecessary duplication without yielding additional eligible studies.

Textbox 1. Search terms using the population, intervention, comparison, and outcome mnemonic.

Population

"elderly" OR "older adult" OR "ageing people"

Phenomena of interest

"technology" OR "gerontechnology"

Context

"chronic disease" OR "chronic illness" OR "long-term conditions" OR "chronic conditions"

Eligibility Criteria

The eligibility criteria used in the original review for the study selection process are presented in Textbox 2 [33].

The inclusion and exclusion criteria used in this review match those in Textbox 2 with the following amendment: studies were included if they were published between April 2022 and September 2024. Although the database searches only included empirical studies, the gray literature search included nonempirical publications. In line with the original review by Bertolazzi et al [33], *chronic disease* was defined as in their review: "health problems that are long lasting, generally progressive, and require ongoing management over a period of years or decades." This definition includes but is not limited to cardiovascular diseases (eg, hypertension and heart failure), respiratory diseases (eg, COPD and asthma), diabetes and other endocrine disorders, neurological conditions (eg, dementia and Parkinson disease), chronic kidney disease, and cancer (where ongoing management is required). For inclusion in this review, study participants had to be older adults (aged ≥60 years) with one or more diagnosed chronic diseases as defined previously.

Textbox 2. Inclusion and exclusion criteria used in the original review.

Inclusion criteria

- Population: participants aged ≥60 years and diagnosed with one or more chronic diseases
- Phenomenon of interest: focus on barriers to or facilitators of the adoption of digital health technologies for chronic disease management and technology targeting older adults
- Context: empirical studies (qualitative, quantitative, or mixed methods) and published in English between 2012 and 2022

Exclusion criteria

- Population: mixed-age samples (including those aged <60 years)
- Phenomenon of interest: studies evaluating a general health care service without focus on the specific enabling digital tools
- Context: nonempirical publications (eg, reviews, editorials, dissertations, conference abstracts, or narrative-only studies)

Searching for Gray Literature Studies

A targeted gray literature search was conducted between August 2024 and January 2025. This focused on identifying white papers, policy documents, and guidelines related to digital health implementation in rural settings for older adults with chronic conditions. To reflect developments since the publication of the WHO "Global strategy on digital health 2020-2025" [11], only documents published from August 2021 onward were included. The gray literature search included manual searches of international government websites and research organizations and targeted searches for dissertations and conference proceedings. A total of 30 gray literature documents were included. These were not formally quality appraised or counted among the included studies but were used to contextualize findings, particularly for rural settings.

XSL•FO
RenderX

Study Selection

Records were initially screened by title and abstract followed by full-text assessment for eligibility. Two reviewers independently screened titles and abstracts and then full texts for eligibility, with discrepancies resolved through consensus or a third reviewer. Duplicates were removed before screening. All studies from the original review were rescreened in full against the inclusion criteria for this update. Only those meeting the criteria were retained for synthesis alongside newly identified studies from the extended search period.

Data Extraction

Data were extracted using a data extraction tool within Covidence (Veritas Health Innovation) by 2 independent reviewers. Extracted data included (1) barriers to and facilitators of digital health adoption (outcomes); (2) age, gender, chronic conditions, urban or rural residence, and other equity variables relevant to the PROGRESS-Plus framework (participant characteristics); (3) type of DHTs (eg, telemedicine, mobile app, or wearable), setting, and whether co-design was reported (intervention characteristics); and (4) study design (qualitative, quantitative, or mixed methods), country, sample size, and publication year (study characteristics).

Where data were unclear or missing, this was noted in the extraction tables, and no assumptions were made.

Theoretical Framework for Data Interpretation and Equity Considerations

This review applied the COM-B framework [40] to interpret and map research findings on the barriers and facilitators influencing older adults with chronic diseases in their use of digital technology for self-management. As noted in the Introduction section, the PROGRESS-Plus framework was also applied to identify equity-relevant factors reported across the studies in line with Cochrane recommendations [26]. This approach enabled both behavioral and equity-focused interpretations of the findings.

Quality Assessment

The methodological quality of the included studies was assessed using the Mixed Methods Appraisal Tool (MMAT) [42]. Two reviewers independently conducted the quality assessment, with discrepancies resolved through discussion or consultation with a third reviewer.

Synthesis Methods

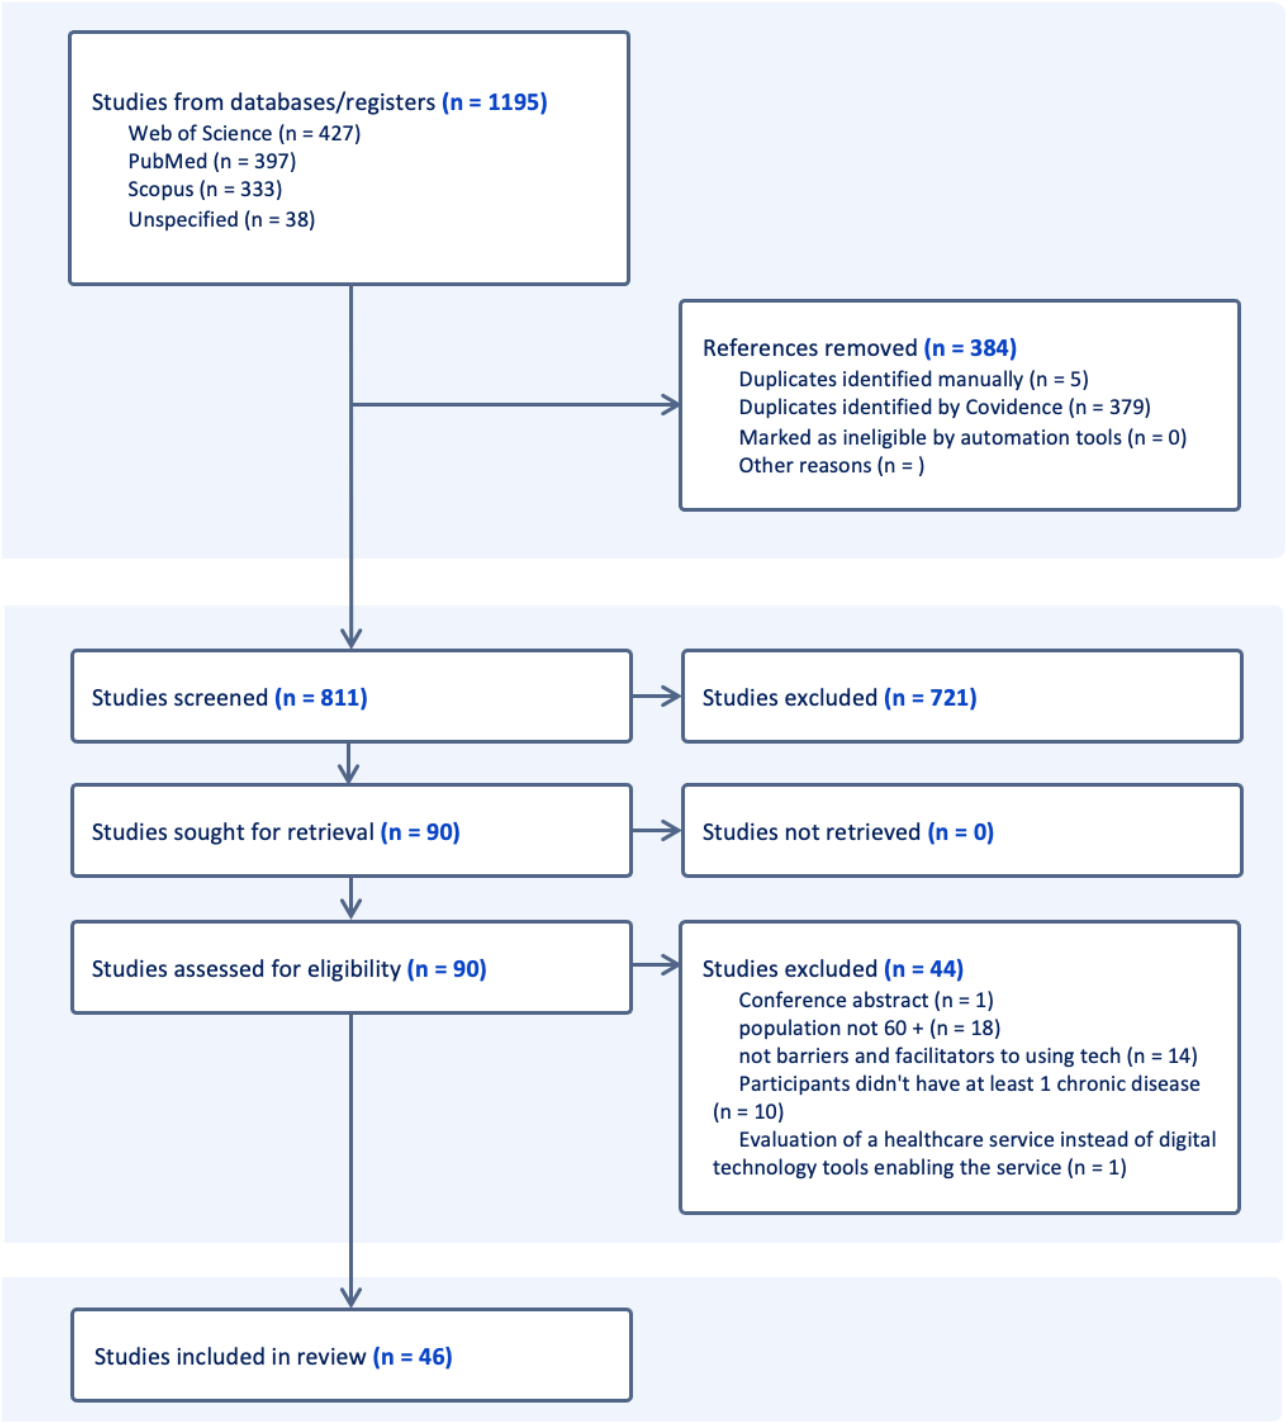
Due to heterogeneity in study designs, interventions, and reporting formats, a narrative synthesis was conducted. Extracted data were manually tabulated using Covidence and Microsoft Excel, and thematic analysis was applied to synthesize findings within the COM-B framework.

1. Eligibility for synthesis: all the included studies were eligible for narrative synthesis and were grouped by study design and type of digital health intervention.
2. Exploring heterogeneity: heterogeneity was explored narratively, with attention to differences across rural versus urban populations, intervention types, and study contexts.
3. Sensitivity analyses: no sensitivity analyses were conducted as no meta-analysis was performed and no pooled effect estimates were produced.
4. Risk-of-bias assessment: no formal assessment of publication bias was conducted as no meta-analysis was performed.
5. Certainty assessment: the certainty of evidence was not formally graded (eg, using the Grading of Recommendations Assessment, Development, and Evaluation) as the synthesis focused on qualitative and mixed methods findings.

Gray literature was presented separately from peer-reviewed studies to maintain transparency as these sources were not subject to the same methodological quality appraisal. This separation allows readers to interpret peer-reviewed evidence independently while still considering the contextual value of gray literature, which is integrated into the Discussion section.

Results

The findings presented in this section are from the updated review and include both newly identified studies and eligible studies retained from the original review following rescreening against the inclusion criteria. A brief comparison with the original review is provided in the Discussion section.



Identification of Studies

A total of 1963 records were retrieved across databases. After removing duplicates, of the 1963 records, 811 (41.31%) were screened. Two authors independently screened titles and abstracts followed by full-text assessment against the eligibility criteria, with discrepancies discussed with a third reviewer. As shown in the PRISMA flowchart (Figure 1), 46 studies were initially included, comprising 17 (37%) new studies published between April 2022 and September 2024. During the data extraction process, eligibility issues in several studies included in the previous review by Bertolazzi et al [33] were identified. Specifically, 59% (17/29) of the studies previously included did not meet the stated inclusion criteria upon re-evaluation and, therefore, were excluded from this review. This explains the difference between the 46 studies initially shown in the PRISMA diagram and the 29 peer-reviewed studies included in the final synthesis. Exclusion was based on one or more of the following factors: inclusion of mixed-age samples that did not isolate findings for adults aged ≥60 years, digital technologies not specifically targeting older adults, or the papers not including barriers to or facilitators of the adoption of DHTs for chronic disease management.

The 12 studies that did meet the criteria were retained and included alongside 17 newly identified studies. As a result, this updated review comprised a total of 29 peer-reviewed studies. Full details on the excluded studies and the reasons for their exclusion are provided in Multimedia Appendix 3 [43-60]. The PRISMA diagram reflects the peer-reviewed studies only. Gray literature was identified and screened separately, with results reported in a dedicated section of this manuscript.

XSL•FO
RenderX

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flowchart.

Characteristics of the Included Studies

A summary of study characteristics is provided in Multimedia Appendix 4 [61-89].

Among the 29 included studies, study designs comprised 1 (3%) randomized controlled trial [61] and 5 (17%) mixed methods studies [62-66]. Most studies were qualitative—38% (11/29) were interview-based studies [67-77], and 10% (3/29) used focus groups [78-80]. In total, 31% (9/29) of the studies used quantitative designs, including questionnaires and surveys [81-89].

The type of technologies used for managing chronic diseases varied widely, including wearable devices [67,72,74,77,89], mobile apps [61,68,70,73,85], digital health platforms [62,64,69,79], patient portals [80], telemonitoring [63,66,75], telemedicine [71,81,83], telehealth [76,87], information and communications technology services [78,84,86], assistive robots [65], and active video games [74].

XSL•FO
RenderX

Regarding the type and number of chronic diseases addressed, most studies (17/29, 59%) focused on multiple conditions [61-64,66,68,72,75,78,80-82,84,85,87-89]. A total of 24% (7/29) of the studies examined a single, specific chronic condition—cognitive impairment [65], COPD [67,70,74,76], or heart failure [73,77].

Barriers and Facilitators (COM-B Framework)

After summarizing the study characteristics, the barriers and facilitators were grouped under the COM-B domains: capability, opportunity, and motivation (see the list of barriers and facilitators in Multimedia Appendix 5 [61-118]).

Capability

Limited digital literacy [71,77,83-85,89] and lower educational attainment [74,76,85,86] were the most common barriers. Other barriers included unfamiliarity with smartphones [78] or the internet [69]; low health literacy [79]; early difficulties with the technology [75,77,79]; being acutely unwell at the time of installation [75]; and age-related visual, manual dexterity, or memory challenges [62,66,67,75,76,83].

Facilitators in this domain included the provision of clear instructions, structured training sessions, and technical support [63,64,68,70,71,75,77,79,80,82,85,87], as well as pretraining initiatives aimed at building users' technical skills before engaging with the technology [79]. Technology that was simple and easy to use [63,65,72,82] and early integration of the technology into care routines [65] further supported engagement.

Opportunity

Key barriers within the opportunity domain were primarily structural and contextual. This included limited access to digital devices [72,85], high technology costs [63,77-79], poor internet connectivity and technical issues [62,75,82,87], lack of goal personalization [68], single-condition focus [82], reduced social interaction [76,78], and reliance on family for support [69,70].

Practical and emotional support from family, friends, and caregivers promoted uptake [63,67,68,70,71,75,79,80,87], with involvement from adult children identified as particularly influential [67,76]. Co-design was reported in 24% (7/29) of the included studies [62-64,68,79,82,85], and person-centered approaches to co-design were specifically highlighted as facilitators in 29% (2/7) of these studies [82,85]. Related findings specific to health care providers are presented in the Health Care Providers section.

Motivation

Many older adults reported apprehension about using DHTs, often driven by concerns about data privacy [67,70,76] and mistrust of digital systems [85]. Emotional responses such as fear, anxiety, and embarrassment were commonly reported when navigating unfamiliar technologies [67,77,80,85] alongside a fear of making mistakes [79]. For some, the technology acted as a distressing reminder of illness or the possibility of recurrence [72,75,79], and negative emotions were triggered when health goals were not achieved or when data readings indicated concerning results [68,79]. Others viewed digital tools as an added burden [64], questioning their reliability [64,67,75,76] or doubting their value or benefit to health [68,69,73]. Feelings of ambivalence [76], fears of losing autonomy [78,79], and a general lack of interest in technology [85] further reduced motivation. In some cases, social perceptions also played a role, with concerns that using digital health tools might make individuals appear older or more dependent [78].

Key motivational facilitators included understanding the health benefits of the technology, gaining insights into condition management, setting goals, and feeling empowered to take an active role in care [63,64,67-69,72-74,76,81]. For some, the technology provided reassurance and a sense of safety, particularly when it enabled ongoing remote monitoring by health care professionals [66,75,78]. Positive experiences with the technology, including successful use [76] and receiving personalized feedback [79], further strengthened motivation to engage. Related findings specific to health care providers are presented in the Health Care Providers section.

Health Care Providers

This section aligns with the COM-B framework, with subthemes mapping primarily to the opportunity and motivation domains. It is presented separately due to the prominence and frequency of health care provider influences across the included studies.

Opportunity

In some instances, health care providers themselves acted as barriers, particularly when they appeared disinterested or lacked time to engage with patient-generated data [64,73,78]. Uptake was also less likely if the technology had not been recommended by a trusted health care professional [72]. Conversely, endorsement or active encouragement from trusted clinicians increased engagement [63,75-77,79,118]. Digital services that strengthened continuity of care or improved communication with clinicians were more likely to be accepted [64,69,70,80].

Motivation

Concerns that digital technologies might reduce or replace personal interaction with health care providers were common, especially among older adults who valued in-person care [71,72,75]. The perception that remote consultations were inferior to face-to-face interactions further contributed to reluctance [70]. However, clinician engagement with patient-generated data was also reported to enhance patient motivation [68,74], and collaborative involvement in care planning fostered a sense of empowerment [63]. Trust in health care providers remained a critical motivational driver for digital health uptake [71].

Rural and Urban Differences

A total of 14% (4/29) of the included studies reported on whether the study took place in a rural or urban area [66,72,75,88], and 75% (3/4) of these studies took place in rural areas. These studies identified the following: unreliable technology use in rural areas due to poor internet connectivity [75], no significant differences in telenursing needs between rural and urban participants regarding desired service features [88], and the fact that combining personalized telemonitoring with a case manager familiar with patients allowed for timely

XSL•FO
RenderX

responses to alerts without overburdening GPs or specialists [66].

Gray Literature: Rural-Specific Barriers and Facilitators

Gray literature findings are presented separately here for transparency but are synthesized with peer-reviewed evidence in the Discussion section. Additional barriers and facilitators specific to rural contexts were identified in the gray literature that were not reported in the included peer-reviewed studies.

Capability

Barriers to capability included the absence of locally delivered and culturally tailored training programs [90-95]. Among health care professionals, a lack of dedicated training, ongoing support, and clear guidance on telehealth use contributed to slower adoption and reduced confidence [93,94,97]. As previously discussed, limited digital literacy among older adults emerged as a key barrier in the peer-reviewed studies, and this was reinforced by the gray literature sources [90,94,95,98-109]. In addition, health care professionals' unfamiliarity with digital health tools and previous negative experiences further hindered engagement [96,97,107].

Facilitators included the provision of targeted local training and culturally relevant support materials tailored to rural communities [90,93,101]. These approaches were reported to enhance digital readiness and build confidence among both patients and clinicians [93].

Opportunity

Poor internet connectivity and fragmented infrastructure were consistently highlighted [90,91,96-102,106,107,109,111-113]. Additional challenges included limited promotion and awareness of available digital tools [102,113,114] alongside workforce constraints such as staff shortages, outdated or nonintegrated equipment, and inadequate resourcing [90,100,108,109,113].

Facilitators included investment in infrastructure, financial and logistical implementation support, and the use of low-technology or hybrid models such as telephone-based care to mitigate digital exclusion [100,115]. Involvement of trusted link workers, digital champions, community navigators, and clinicians was reported to support uptake and reduce burden on GPs [66,92,96,97].

Co-Design

Several sources also identified co-design as a facilitator to ensure that digital tools were relevant and usable in rural contexts. This included participatory approaches that involved older adults, families, caregivers, and community stakeholders to support adoption [90,97,104,107,110,114-117]. Barriers included the absence of participatory design [98], limited consideration of older adults' cognitive and physical needs [106,110], and insufficient community involvement during development [115]. Several sources noted that the lack of family or community input contributed to resistance or reduced the relevance of DHTs [110,115,116].

Motivation

Gray literature identified several motivational barriers affecting digital health uptake in rural areas. These included mistrust of digital platforms [90,95,99,108,110], fear that technology would replace human interaction [101], and a preference for face-to-face care [101-103,114]. Cultural values such as self-sufficiency [118], feelings of underrepresentation in national policy [106], and mistrust of the government [110] were also reported. A lack of face-to-face contact with health care professionals was associated with reduced trust and satisfaction [108]. Culture and trust were described as influencing comfort and willingness to engage with digital tools [110]. In addition, one source reported a positive association between GP availability and satisfaction with local health care, suggesting that perceptions of adequate in-person care provision may reduce motivation to adopt digital alternatives [116].

Equity and PROGRESS-Plus Findings

The PROGRESS-Plus analysis highlighted inconsistent reporting of equity-relevant factors. Characteristics such as race and ethnicity, socioeconomic status, and occupation were often underreported. Only 14% (4/29) of the studies provided data on place of residence (urban vs rural), and none offered a clear operational definition of rurality, limiting comparative analysis.

In total, 93% (27/29) of the studies reported on gender; however, only 11% (3/27) of these studies provided any comparative insights and identified gender as a factor influencing digital health adoption. Men were reported to have a stronger preference for staying up-to-date with technology [67], showed a preference for autonomy-enhancing services [78], and were less likely than women to report technology unreadiness [81]. Gray literature further highlighted that older women, particularly in low-income settings, were less likely to engage with DHTs [90,91,95,111].

This lack of data limited our ability to compare subgroups on many PROGRESS-Plus factors. Multimedia Appendix 6 [61-89] provides a list of these factors. These findings are consistent with broader evidence that reports that digital health adoption tends to favor younger, urban, and socioeconomically advantaged populations, whereas rural and minority groups remain underrepresented [31,32]. This highlights the need for more systematic equity-focused reporting in digital health research.

Quality Assessment

The MMAT was used to assess the methodological quality of all the included peer-reviewed studies. No studies were excluded based on quality in line with guidance for mixed methods systematic reviews [26]. Qualitative studies generally achieved high MMAT scores (4 to 5 stars), with strengths including clearly defined questions, appropriate data collection, and detailed analysis. Only 2/14, (14%) [67,76] explicitly reported reflexivity with the remaining studies (12/14, 86%) [68-75,77-80] focusing on other strategies to enhance rigour, limiting transparency about researcher influence. Quantitative studies were of moderate to high quality (3 to 4 stars), typically showing appropriate methods and outcome measures. However, several had methodological limitations with 3/9 (33%) [83,84,89] employing unclear or convenience sampling approaches, 3/9 (33%) [82,83,88] failing to report or partially reported response rates and 6/9 (67%) [42,82-85,89] relying at

XSL•FO
RenderX

least partially on unvalidated self-report measures. Mixed methods studies were generally of good quality. All 5/5 (100%) [62-66] integrated qualitative and quantitative strands effectively. The majority (4/5, 80%) [62-65] clearly justified their mixed methods design, and 1/5 (20%) [66] did not provide a rationale for combining methods. The full MMAT ratings for each study are provided in Multimedia Appendix 7 [61-89].

Discussion

Principal Findings

This systematic review synthesized evidence on the barriers to and facilitators of digital health adoption among older adults with chronic diseases using the COM-B model and PROGRESS-Plus framework. The main barriers to adoption were limited digital literacy and confidence (capability); poor internet access, high costs, and lack of integrated technical support (opportunity); and fears regarding privacy, mistrust, and satisfaction with existing services (motivation). Facilitators included user-friendly design and training (capability), trusted health care provider endorsement and hybrid care models (opportunity), and perceived benefits of digital health and positive user experiences (motivation).

Regarding rural and urban differences, a key insight from this review is the paradox that, although rural patients are physically distant from health care services and stand to benefit from digital health, they often report high satisfaction and trust in their existing local care. This may act as a motivational barrier, reducing perceived need to adopt digital tools. The gray literature identified a strong preference for face-to-face care [101-103,114]. This may be partly explained by the fact that rural regions often have better GP-to-patient ratios than urban areas, and strong patient-provider relationships may reinforce satisfaction with in-person care [116].

Gray literature sources identified additional challenges specific to rural settings. These included limited digital familiarity among health care professionals [96,107]; insufficient training and ongoing support [93,94]; and structural barriers such as workforce shortages, outdated equipment, and resource constraints [90,100,108,109,113]. One proposed solution to mitigate these issues is the introduction of case managers or community link workers who can engage older adults directly and help reduce the burden on overstretched health care providers [66,92,96,97].

This review also highlights gender as an underexplored factor not addressed in the original review [34]. Evidence from the gray literature indicated that older women, particularly in low-income settings, were less likely to engage with DHTs than men [90,91,95,111]. In addition, peer-reviewed studies suggested that men and women may differ in their preferences for how digital health services are delivered [67,78]. These findings underscore the importance of routinely reporting gender and other equity-related variables to prevent the design of one-size-fits-all digital health solutions. It is also important to acknowledge that sex and gender are frequently used interchangeably in the literature, including studies applying frameworks such as PROGRESS-Plus. This can potentially obscure important distinctions between biological sex and socially constructed gender roles and how they shape health behavior and digital access.

Regarding co-design, while the original review [33] acknowledged the value of involving older adults in design, this review extended that understanding by showing that involving health care providers and other stakeholders (eg, caregivers, local organizations, and community gatekeepers) in co-design processes is also essential in encouraging uptake [90,98,105,109,110,112,116,117,119]. This broader approach ensures that digital tools are not only user-friendly for patients but also practical for providers and sustainable within health care systems.

Limitations

Limitations include inconsistent reporting of equity-relevant variables across peer-reviewed studies. Because many primary studies did not report key demographic details, our ability to analyze subgroup differences was constrained. The exclusion of non–English-language studies is also a potential limitation.

Studies reporting successful adoption might be more likely to be published, potentially biasing the literature; however, our inclusion of gray literature helped mitigate this to some extent. Although considerable care was taken in conducting the gray literature search, the manual systematic search may have led to the omission of some relevant documents. The variability in how gray literature is indexed and the lack of consistent search tools make comprehensive retrieval challenging despite targeted efforts. Nonetheless, by synthesizing multiple data sources and using established frameworks, we believe that the findings identified are reliable and relevant.

Comparison With Previous Work

Our findings align with those of the original review [33] on general barriers such as digital literacy gaps, infrastructural barriers, and motivational challenges as key hurdles for older adults adopting digital health. This review added new insights on gender differences, rural satisfaction paradoxes, the dual role of health care providers, and the expanded role of multistakeholder co-design, broadening the evidence base.

Future Research Directions

This review highlights the need for future studies to improve demographic reporting, particularly regarding characteristics such as rurality and gender, which are associated with digital exclusion. To improve the clarity of such research, future studies should report sex and gender as separate variables in line with the Sex and Gender Equity Research Guidelines [120]. Applying frameworks such as the COM-B and PROGRESS-Plus during the design and reporting could improve consistency and enable a more meaningful interpretation of barriers to and facilitators of DHT engagement. In addition, there is a need to adopt an intersectional approach that recognizes how multiple factors such as age, gender, and rurality shape individual experiences. This is essential for understanding who is most at risk of digital exclusion and for designing interventions that address the complex and intersecting inequalities facing older adults. Finally, the development and application of equity indicators

XSL•FO
RenderX

for digital health interventions would ensure that equity considerations are systematically embedded in both research and implementation.

Conclusions

This review confirms that digital health adoption among older adults with chronic diseases is shaped by a complex mix of capability, opportunity, and motivation factors. While digital health offers potential to improve access and outcomes, high satisfaction with existing care (especially in rural areas) and provider-related barriers highlight the need for targeted strategies. Embedding multistakeholder co-design and paying close attention to equity considerations such as gender and rurality in reporting and design are likely to be critical to developing digital health solutions that are inclusive, effective, and sustainable.

Abstract

Symptoms such as loss of pleasure, agitation, and sadness are subjective experiences that contribute significantly to caregiver burden and health care costs in Alzheimer disease and related dementias (AD/ADRD). However, traditional self-report measures of subjective experiences are limited in AD/ADRD due to cognitive impairments and awareness. Passive sensing, which collects data without active participant input, has emerged as a promising approach to quantify aspects of subjective experiences. Smartphones, wearables, and in-home sensors can quantify mobility, physiology, speech, and social interaction markers of constructs relevant to AD/ADRD. Available research indicates potential but is largely at the proof-of-concept stage. In this Commentary, we discuss several roadblocks to future translation of passive sensing in measuring subjective experiences in AD/ADRD, including technical implementation, data harmonization, validation, ethical and privacy principles. Addressing these challenges could lead to transformative applications to care for AD/ADRD, enabling precise monitoring of behavioral symptoms and related treatment targets, ultimately improving quality of life for persons with AD/ADRD and their caregivers.

(JMIR Aging 2025;8:e71920) doi:10.2196/71920

KEYWORDS

Alzheimer's disease; measurement; passive sensing; subjective experience; mobile assessment

Introduction

Subjective quality of life is a primary concern of persons living with Alzheimer disease and Alzheimer disease-related dementias (AD/ADRD) and their caregivers. Subjective experiences, or an individual's internal and personal perception of events, emotions, or sensations, include important outcomes in AD/ADRD such as well-being, affect, pain, and loneliness. Additional subjective experiences, like loss of pleasure, agitation, and sadness, are among the behavioral symptoms of dementia that lead to the greatest caregiver burden and health care costs. Reliable and valid measurement approaches are thus critical to quantifying these subjective experiences as outcomes in treatment studies. AD/ADRD produce substantial roadblocks to the measurement of subjective experiences, such as cultural differences in how symptoms are expressed, variability in caregiver interpretation of the experiences of patients, or practical usability challenges associated with sensors in older adults. Self-report measures of subjective experiences can make substantial demands for cognitive abilities impaired in AD/ADRD (memory, verbal fluency, comprehension) and can be biased by cultural milieu, social situation, and memories and schemas of the subjective experience in question. In recent years, technological approaches to gathering data about subjective experiences have been developed, implemented, and tested. Passive sensing can be used to gather data proximal to a variety of experiences that would be difficult or impossible to gather without self-report. Moreover, a promise of passive sensors and related devices is their capacity to gather continuous information that could be used to understand within-person dynamics of subjective experiences, and ultimately better personalize interventions to unique timings and contexts. While there is much enthusiasm about the potential for such tools to support subjective measurement, there remain a number of challenges (and opportunities for innovation) to generate translatable and useful passive measurement tools in AD/ADRD. We briefly summarize some of these challenges and provide accompanying suggestions for future innovators in this area.

Passive Sensing Methods

Passive sensing occurs when data are acquired by a device without intentional input from the respondent. Sensing typically uses a variety of devices that can be broadly grouped into three clusters: a) smartphones, b) wearables, and c) in-home sensing devices [1,2]. Common smartphone sensor data streams evaluated in studies of subjective experiences include GPS, accelerometers, Bluetooth, and WiFi data streams. These tools can enable quantification of movement and nearby cell phones, eye movements and facial expressions, and ambient noise and speech features [3]. In addition to sensors, smartphones produce metadata such as calls, texts, app use, and other device interaction data [4]. Also available on mobile devices are more granular device interaction data that has been used to infer

XSL•FO
RenderX

cognitive and emotional processes, such as keyboard analytics like errors or typing speed [5]. Wearable sensors like smartwatches and rings produce data on mobility as well as other physiological parameters, such as heart rate variability, sleep patterns, galvanic skin response, temperature, or respiration rate. In-home sensors have a variety of form factors to include ones that are intended to be "invisible" and interactive ones like robots [6]. In-home sensors include infrared or pressure sensors designed to monitor mobility patterns or other interactions within physical spaces. Audio sensors have been used to gather socially-relevant data such as the quantification of linguistic or acoustic speech markers [7]. Video data includes collection from 3D cameras that can be used to generate facial or skeletal models that quantify deviations from normative trajectories [8]. Increasingly, researchers have attempted to integrate multiple sensor streams via computational approaches [9], and create feedback systems for caregivers leveraging passive sensing data [10]. As consumer-grade devices accumulate greater processing power and more novel and powerful sensors are created, it is easy to see why passive sensing research has burgeoned in recent years.

Challenges in Validating Passive Sensing of Subjective Experiences in ADRD

A first principle in considering and reporting on sensor-based subjective experience research is that subjective experiences are inferred rather than measured directly, as is the case with self-report (see [11] for an excellent summary). Therefore, terminology used in reports should be consistent with the notion that passive sensing is a proxy for but not a direct measure of the construct of interest. This does not mean that sensors cannot be useful for research on subjective constructs. A related point is that the current "gold standard" for validation of passive sensing measures of subjective experience is self-report, which is not free of biases or the impact of cognitive impairments in AD/ADRD. Patients may not recall recent experiences or fully comprehend language and questions. For example, global well-being (*what is your overall well-being?*) can diverge from aggregated immediate experience (*what is your well-being right now?*) measured via ecological momentary assessment (see [12]). It also should not be forgotten that self-report measures can be adapted to people with cognitive impairment or language production difficulties (eg, with visual analog scales [13]), and recent work indicates that active smartphone-based assessments and ecological momentary assessment are feasible and valid in older adults with mild cognitive impairment [14]. Finally, caregiver reports and clinician ratings of patient subjective experiences can also be used as "gold standards" to validate passive sensing measures, but these measures place an added burden on caregivers and providers and are not free of biases or the impact of the observer's capacity to infer patient experiences.

Central to validation of passive sensing measures in AD/ADRD research is this question: What if "gold standard" subjective experience measurement (eg, a questionnaire) is difficult or impossible to obtain due to the effects of cognitive impairment? As Kourtis et al [15] point out that in late-life depression and Alzheimer's disease, multiple passive sensors show promise in detecting multiple subjective experiences, like mood, loneliness, suicide risk, agitation, daily life functioning, and dementia onset and progress, but work is only beginning with these measures. For example, Au-Yeung et al [16] evaluated a home-based mobility sensor in adults with a dementia diagnosis, and documented mobility patterns in an effort to examine within-person dynamics of agitation and apathy. A pilot study by Galambos et al [17] tested an early dementia detection model in older adults, with home-based sensors detecting changes in the amount of time spent in the bedroom, in the living room, and mealtime activities that have congruence with health assessments. Other passive sensing methods use infrared sensors to assess time spent in the house versus out of the house [18] as well as the speed of ambulation through the house [19], which have correlated with cognitive function changes. Another study [20] found that wireless home-based sensors captured differences in activities of daily living patterns between dementia and healthy individuals. Smartphone-based Bluetooth detection of nearby cell phones, actigraphy, and GPS data have been used for predicting loneliness in college students [21] and between Bluetooth features and depression [3], but this work is only beginning in AD/ADRD.

As several reviews of the literature of sensor-based systems of subjective experiences have concluded [1,22] the great majority of research studies to date have been at the "proof of concept" phase. Few studies have been replicated, and few technologies have been evaluated in samples designed for rigorous validation. For research on passive sensing to advance the replicability of sensing, it could be useful to adapt systematic and coordinated methods being used to improve self-report. An enormous amount of effort has gone into developing researcher toolkits like PROMIS (Patient-Reported Outcomes Measurement Information System) and NeuroQoL (Quality of Life in Neurological Disorders) [23]. These National Institutes of Health–sponsored projects spearheaded development of common measures of subjective constructs by rigorous item development, reliability and replicability testing in diverse samples so as to mitigate bias, and application of advanced psychometric techniques toward item selection, short-form development to maximize scalability, along with establishment of convergent and divergent validity specifically in people with diminished cognitive ability (eg, use of visual analog scales). Perhaps some processes involved in these coordinated efforts could serve as models to enhance the utility of passive sensing.

Key roadblocks to creating such a uniform approach to enhancing the replicability of passive sensor data are the intricacies of feature extraction and computational processing of data streams. To move passive sensing toward a more standardized and sharable method, there are open science solutions to enhance transparency, including platforms to harmonize data standards, for example, the Collaborative Aging Research using Technology Initiative (CART) [24]. Repositories for research protocols and other collaborative approaches, such as checklists [25], are available to support best practices in data collection, processing, and validation. Application of Findable, Accessible, Interoperable, and Reusable (FAIR) [26] principles to data collection processes would enable the needed comparison

XSL•FO
RenderX

of the impact of different devices and software versions on outputs. These initiatives should support greater aggregation of results across studies to address fundamental questions about sensing relevant subjective experiences that persist: Which sensor or combination of sensors is most accurate and reliable in sensing aspects of which subjective experiences? How long and at what data density is required to obtain valid results? Which sensors offer the greatest balance of practicality in implementation, unobtrusiveness, cost and data processing demands, and validity and reliability? What are the best practices specific to people with ADRD and their caregivers in maximizing adherence?

While the coming years will undoubtedly bring a plurality of new, more-sensitive sensors, and new approaches to measuring aspects of subjective experience applicable to ADRD, it is essential that this research accompany robust consideration of the principles of the Belmont report in respect to respect for persons, beneficence, and justice. For the same reasons that self-report is hampered, so is informed consent in ADRD. Tools to simplify informed consent and assess and improve decisional capacity are available [24,27], but the technical and privacy considerations surrounding passive sensing (eg, comprehension) can present marked challenges even for people without cognitive impairment. Resources such as guidelines to identify best practices in obtaining proxy or individual informed consent and granular choices surrounding the type of data collected could maximize respect for the individual in the informed consent setting [28]. The industry has a major role in this, including the deployment of health research infrastructure and gatekeeping functions to ensure privacy standards are met and maintained during the research, alongside software updates.

Another piece of the puzzle is engagement in the community in regard to the setting of the sensor and also the results of the research. Few sensors or devices used in the collection of data in sensor studies were designed with older adults in mind. For example, wearable sensors may not be calibrated to age-associated factors such as the thinning of skin, and conclusions from those sensors may be erroneous [29]. Given that caregivers are often essential partners in the deployment and sustainment of data collection, their unique needs and challenges need to be considered [30]. Therefore, part of the researcher's task is to partner with older adults, caregivers, and other stakeholders through user-centered design before deployment [31]. As part of this process, researchers should query participants' desires for the return of information on sensing data, including at the individual level [32]. Community-engaged research approaches may be one way to expand diversity of inclusion in sensor-based research, which will be essential to understand biases that may be present.

Conclusion

Paradoxically, these many challenges to passive sensing in AD/ADRD stem from the very same reasons why such approaches offer promise, pressing unmet needs. The behavioral symptoms of dementia, including agitation or loss of pleasure, are among the single largest drivers of caregiver distress and institutionalization. Making the case for passive sensing in behavioral symptoms even more compelling are the potential risks, costs, and harms of current treatments for behavioral symptoms (eg, side effects, institutionalization). There are emerging systems that infer these subjective symptoms by use of passive sensing alongside contemporaneous dynamic data from potential contributors to the onset and sustainment of these symptoms that could be targets for intervention. Clinical translation opportunities could include more precise monitoring of change in subjective experiences that are targeted by interventions (eg, pharmacologic or nonpharmacologic treatments targeting loss of pleasure). Given the continuous nature of passive sensing, idiographic approaches are possible, wherein personalized interventions could be developed through user-centered design [33] in a just-in-time fashion based on data garnered from the individual. We note that similar to more active digital health solutions, validation is only one step and clinical implementation accompanies many additional challenges (eg, cost, urgent responses, provider burden) [34]. Thus, coordinated efforts at addressing roadblocks to the translation of passive sensing of subjective experience in ADRD could lead to transformative approaches that address critical unmet needs.

Abstract

As the aged care sector undergoes digital transformation, greater attention is needed to development of digital health capability in its workforce. There are many gaps in our understanding of the current and future impacts of technology on those who perform paid and unpaid aged care work. Research is needed to understand how to make optimal use of both digital resources and human resources for better aged care. In this Viewpoint, we reflect on a workshop held during an international conference that identified shared concepts and concerns to shape further research into workforce capability. Digital technologies and digital data can increase quality of care in a system that operates through partnerships among service providers, service users, and community members. To realize this potential, digital health learning and development are needed in the aged care workforce. As digital dimensions of aged care services expand, the sector needs clearer direction to implement approaches to workforce learning and development. These must be appropriate to support the safe and ethical performance of care work and to increase the satisfaction of those who care and those for whom they care.

Why Focus on a Digitally Capable Aged Care Workforce?

The aged care sector is in the spotlight around the world due to the increasing health and well-being needs of aging populations. Examples are the Australian Royal Commission into Aged Care Quality and Safety [1], Japan's Social Welfare for the Elderly Act [2], and Germany's national report examining the human rights of older persons in long-term care [3]. Comparisons of aged care systems internationally focus on a variety of issues [4,5].

In such reports, the aged care workforce emerges as an essential factor. One part of this workforce is paid, structured, and regulated (eg, registered nurses) and formally counted in the health and care workforce. Another part of this workforce is informal—often unpaid and not structured or regulated (eg, relatives as unpaid caregivers) but contributing in incalculable ways [6]. Both parts operate under conditions that can be inequitable, inefficient, uncertain, and unsatisfactory. The overall situation of the aged care workforce demands widespread improvements in recruitment and retention, practice standards, skill levels, recognition, and reward [7].

Digital maturity in aged care service provider organizations lags behind mainstream health care services; there are differences between the two also in terms of information needs, technologies of interest, and administration. The medico-legal record for aged care services works differently from hospitals and primary care services, making data and information standardization problematic [8]. Robotics, sensors, and virtual reality have been

XSL•FO
RenderX

explored for over a decade in many countries for their potential to augment human care-giving, but with little opportunity for uptake due to cost and complexity [9]. Telehealth has been shown to have a promising place in aged care, especially since the COVID-19 pandemic, but funding and service supply remain problematic [10]. Nevertheless, digital transformation of the aged care sector is underway [11,12].

Despite this, digital skills of any kind rarely appear in aged care job descriptions or training programs. Further, national workforce strategies related to digital health capability scarcely address the digital skill shortages in the aged care sector. On one hand, there is hope that the sector will find the "right" staff for digitally enabled aged care and find ways to assure them of technology's quality and trustworthiness [13,14]. On the other hand, there is uneasiness that roles and responsibilities may become invisible, peripheral, or "care-adjacent" in the process of moving to technological efficiency and sustainability [15,16]. In short, the introduction of technology has still-unknown implications for the evolution of work in the aged care sector, with possible effects ranging from displacing workers to supporting productivity in current roles or to elevating responsibilities and recognition. However, much of the research to date into aged carers' digital experiences and expectations has had a short-term focus on technology implementations rather than consequences and outcomes [17,18].

Working with technology in particular ways can support specific well-being factors, including positive emotions, self-awareness, mindfulness, empathy, and compassion—so-called positive computing [19]—and there are reports that this approach can benefit aged care organizations and their workers [20]. But there is no guarantee that this will happen without a deliberate workforce strategy. This raises questions about how to proceed, which shape the aims of further research: How can digital transformation of the aged care sector be optimized through greater investment in the digital knowledge, skills, attributes, and attitudes of its workforce? How can such investment in turn improve working conditions and job satisfaction in the aged care workforce?

The authors explored these questions during a workshop that we facilitated at the July 2023 MedInfo conference in Sydney, Australia. There we presented our view that workforce research and development is needed to achieve optimal outcomes for workers in order to achieve these for service users as the aged care sector moves toward digital maturity. The ensuing discussions with workshop delegates contributed to refining the viewpoint we outline here.

What Knowledge and Skill Building Is Required for Digital Aged Care Work?

Digital aged care work is likely to deliver the greatest benefits when needs for fundamental, complementary digital knowledge and skills are met in both paid and unpaid workers. Table 1 summarizes and juxtaposes the capabilities that we propose.

Table 1. Digital capabilities needed in the aged care workforce.

For paid work	For unpaid work
Knowing about developments in the digital environment in which health and care operate	Knowing about the existence of digital systems and tools, and the ways they can support care users and workers
Knowing how to adopt digital tools to help with care coordination and monitoring	Knowing how to use tools to support care closer to home and enhance care provision
Knowing the importance for care quality of collecting and interpreting digital data collected during episodes of care	Knowing how to navigate a complex aged care system across multiple digital platforms
Ability with general digital proficiency and literacy, including information security	Ability with general digital proficiency and literacy
Ability to evaluate online information critically	Ability to access and interpret information from multiple online sources
Ability to consider usability and empathy when using digital tools with patients and clients	Ability to learn to engage with technology and be comfortable with technology
Ability to interpret biometric data and help the patient or client to understand it	Ability to be connected and share health data between care consumers and providers
Ability to judge when technology is not needed as well as when it is	Ability to access and use technology to overcome isolation

There are parallel aspects of capability, with different levels of sophistication, in the needs of paid and unpaid workers. Accordingly, paid workers must be cognizant of not only their own capabilities, but also the capabilities of the unpaid workers with whom they partner. Aside from the digital capabilities of direct consumers of aged care services, paid workers must consider and collaborate with the capabilities of volunteer carers among family, friends and community members. Thus, to build the digitally capable human resources that will support healthy and dignified aging for all, the sector certainly must increase levels of digital literacy in the paid workforce; digital literacy being defined as the ability to use technology to communicate, retrieve, and evaluate information to make decisions [21]. However, the sector also must increase levels of active engagement in digital citizenship among both paid and unpaid workers; in the concept of digital citizenship, people are increasingly expected to use a range of technologies to access services of all kinds and to participate on all levels in society [22].

Various approaches are possible to support digital knowledge building and skill building for the paid workforce. There seem to be gaps and requirements in terms of both formally accredited

XSL•FO
RenderX

training programs and less formal continuing professional development, as well as for both workplace-based learning and workplace-independent learning. The diverse and differentiated methods needed to uplift the digital capabilities of the unpaid workforce are an even broader challenge. Strategy and culture will have to change in the aged care sector to create an environment that encourages and supports all those who do the work to embrace learning and development for positive uses of technology. Among service providers, technology suppliers, industry and community associations, and government agencies, it is not yet clear where roles and responsibilities should sit for planning, implementing, and evaluating the changes that are needed to create and support a digitally capable aged care workforce.

Although these themes are similar to those arising in the mainstream health care workforce in some respects, they also recognize that the aged care ecosystem is distinctive and heterogeneous in terms of the array of partnerships among service providers, service users, and community members [23]. It may be useful to build a more detailed understanding of the digital capability gaps and needs in this sector by overlaying two other system-level concepts onto the idea of the aged care ecosystem—care ecosystems and workforce ecosystems. A care ecosystem is defined as an approach to configuring paid and unpaid workers, ambient assistive technologies, and digital data sharing as work-arounds for intractable workforce shortages in care, particularly in situations that do not call for advanced or intensive clinical services [24,25]. A workforce ecosystem is characterized by employees and contractors working interdependently with automated processes to achieve the goals of an organization and their personal goals; it is considered a guiding concept for the challenges of human resources management as artificial intelligence changes industries and societies [26,27]. A whole-system approach that acknowledges these concepts could provide a coherent framework to plan, implement, and evaluate the range of complementary measures that are needed for digitally enabled aged care work.

Conclusions and Next Steps

Digital technologies and digital data have the potential to improve many aspects of the experiences of the people who receive aged care and the people who provide it. The context in which we seek to develop the digital capabilities of the aged care workforce is challenging. There are strong sustainability pressures on service providers. Public policies, strategies, and sentiments favor innovative, distributed care. Social and technological services and solutions are not joined up. Workers across the sector are stretched thin, whether they are highly trained professionals (eg, registered nurses), minimally trained caregivers (eg, health and personal care assistants), or informal caregivers (eg families, friends, and neighbours).

Understanding how to build digital capability in this workforce is complex and multifaceted, with many unknowns. Inclusion is one: What learning and development methods are most efficient and effective to enable digital skills across the entirety of this workforce? Empowerment is another: How can aged care workers be enabled to advocate for and implement digital improvements that bring positive changes to care? Expertise is another: What career opportunities and leadership roles are appropriate to motivate digital aged care specialists and sustain their attention to workforce development?

Next steps for the work in this field include reviewing the literature to distill evidence from reports of small-scale efforts, workforce research, and development that engages real-world settings and stakeholders, as well as trials of scalable learning and professional and community development programs. To progress this research requires new collaborations among aged care workers, service provider organizations, aged care technology vendors, and digital health workforce researchers. We can improve the current standing of digital skills in the aged care workforce only if we first clarify what the workforce needs from education providers, employers, technology suppliers, and policy makers to enable and motivate them to use existing and emerging technologies safely and wisely. This work will provide important information to design learning and development that enhances digital capability, and it will establish expectations that allow us to evaluate changes in workforce status and performance as an integral part of the digital transformation of aged care.

Acknowledgments

We are grateful to the convenors of the MedInfo 2023 conference for the opportunity to conduct our workshop and to the delegates who attended and engaged in discussion. The 3 authors prepared the workshop together. To set up the workshop discussion, each author presented on a viewpoint of the topic, followed by KB-H and KD cochairing the discussion. All 3 authors contributed to writing and editing this Viewpoint and signed off the paper as ready for submission.

Abstract

Digital twins—dynamic and real-time simulations of systems or environments—represent a paradigm shift in emergency medicine. We explore their applications across prehospital care, in-hospital management, and recovery. By integrating real-time data, wearable technology, and predictive analytics, digital twins hold the promise of optimizing resource allocation, advancing precision medicine, and tailoring rehabilitation strategies. Moreover, we discuss the challenges associated with their implementation, including data resolution, biological heterogeneity, and ethical considerations, emphasizing the need for actionable frameworks that balance innovation with data governance and public trust.

emergency care; digital twin; prehospital emergency care; in-hospital emergency care; recovery

Introduction

The concept of digital twins—dynamic, real-time simulations of processes, systems, or environments—has garnered increasing attention across various domains, from urban planning to medical monitoring [1]. Unlike predictive analytics and artificial intelligence (AI)–driven simulations, digital twins construct dynamic mirror models of physical entities through real-time data synchronization and simulation technologies, emphasizing virtual to physical mapping and closed-loop feedback to support full lifecycle management. In contrast, predictive analytics focus on trend forecasting based on historical data, whereas AI-driven simulations concentrate on multiscenario modeling of complex systems. The advantages of digital twins lie in their real-time capabilities, dynamic optimization, and potential for cross-system collaboration, enabling a closed-loop process from monitoring to decision-making, significantly enhancing efficiency and precision [2]. Emergency care, characterized by its demand for timeliness, precision, and adaptability, provides an ideal testing ground for this transformative technology. By bridging prehospital care, in-hospital management, and recovery, digital twins promise to reshape emergency medical systems for the future (Figure 1). Textbox 1 provides an explanation of the application of digital twins in prehospital first aid, in-hospital first aid, and rehabilitation.

Textbox 1. The application of digital twins in prehospital first aid, in-hospital first aid, and rehabilitation.

Prehospital emergency care

- Optimized resource allocation: simulation of real-time first-aid scenarios to assess urban emergency needs and spatial distribution of resources, allowing for evidence-based planning and improved efficiency in resource use
- Reduced response time: minimization of procedural delays through real-time data sharing, enabling seamless communication and critical data updates across emergency personnel and systems
- Real-time patient monitoring: leveraging of wearable devices and sensors to create dynamic health profiles, facilitating immediate assessments and predictions of patient conditions (eg, vital signs such as heart rate and blood pressure)
- Risk stratification: aggregation and analysis of patient data to provide superior accuracy in predicting acute events (eg, cardiac arrests), outperforming traditional clinical risk assessments
- Enhanced training: use of simulation-based training environments to strengthen emergency response protocols, improve decision-making, and foster team coordination under high-pressure conditions

In-hospital emergency care

- Advanced imaging analysis: integration of multidimensional data to overcome sample limitations in medical imaging, enabling the development of robust diagnostic models
- Precision medicine: combination of genomic, environmental, and lifestyle data for tailored risk assessments and personalized treatment plans, empowering informed clinical decision-making
- Human digital models: use of digital replicas of anatomical structures to plan surgeries and minimize risks during procedures by simulating operations beforehand
- Digital twin–enabled decision-making: facilitation of real-time analysis and expert-guided interventions (eg, cardiopulmonary resuscitation and drug administration) via remote systems, reducing disparities in emergency care accessibility
- Predictive disease monitoring: use of Internet of Things devices and wearables to continuously monitor patient status, identifying early signs of complications and supporting timely interventions
- Streamlined resource coordination: ensuring efficient resource distribution and effective communication among health care teams through unified, up-to-date patient data sharing

Recovery

- Continuous monitoring: use of sensors and wearable devices to track recovery progress and dynamically adjust treatment plans to optimize outcomes
- Telerehabilitation management: enabling remote monitoring of patients through digital twins, providing clinicians with tools to assess and adjust rehabilitation remotely, particularly for mobility-impaired individuals
- Patient self-management: sharing digital twin insights with patients to encourage active participation in health management through lifestyle modifications and adherence to care plans
- Disease progression monitoring systems: integration of real-time monitoring data to predict the risk of disease exacerbations or complications, thereby intervening in time and triggering early warnings, allowing physicians to adjust treatment during critical windows and improve outcomes.

Prehospital Emergency Care

Current prehospital emergency care systems often struggle with suboptimal resource allocation due to their reliance on simplified decision-making models that fail to account for the complex, dynamic nature of urban environments [3]. Digital twins address these limitations by unifying diverse data streams into a single, adaptable model that enables real-time optimization of emergency resource allocation. These models incorporate multiple layers of data, from historical emergency call patterns to real-time traffic conditions, enabling more nuanced and effective resource deployment decisions.

Digital twins prove particularly valuable in prehospital emergency care, where time-sensitive decisions directly impact patient outcomes. By incorporating high-resolution information about building layouts, land use, population density, and traffic patterns, digital twins create actionable urban simulations that allow emergency response teams to plan and execute their operations with unprecedented efficiency. The integration of these various data sources enables more sophisticated approaches to emergency resource management than previously possible with traditional systems.

This transformation in emergency care delivery demonstrates the broader potential of digital twin technology to revolutionize urban health care systems through data-driven, predictive approaches to resource management. Moreover, wearables in ambulances provide dynamic health profiles, supporting real-time monitoring and accurate risk stratification for acute events. Simulation-based training environments can help improve emergency team readiness and coordination under high-pressure conditions.

XSL•FO
RenderX

In-Hospital Emergency Care

In hospitals, digital twins are redefining precision medicine by integrating diverse data sources to enable robust diagnostics, personalized treatments, and streamlined workflows [4]. By synthesizing real-time patient data with historical health records and predictive algorithms, digital twins facilitate more accurate disease modeling, enhancing clinical decision-making and tailoring interventions to individual patient profiles. This data-driven approach supports the early detection of complications, optimization of treatment pathways, and improvement of patient outcomes.

Preoperative simulations represent a critical application of digital twins in surgical care. By creating highly accurate digital replicas of patient anatomy, clinicians can simulate surgical procedures, anticipate potential challenges, and refine techniques before making the first incision. These virtual rehearsals significantly reduce surgical risks, improve procedural efficiency, and enhance patient safety. Complementing this, predictive monitoring through Internet of Things (IoT) devices enables the continuous assessment of patient vital signs, offering early warnings of complications such as sepsis or cardiac arrest. These alerts allow medical teams to respond swiftly, averting adverse outcomes and saving lives.

An emerging and transformative application is the development of medical device twins (MDTs), which provide virtual counterparts for critical hospital equipment, including ventilators, defibrillators, infusion pumps, and imaging devices. MDTs are created through digital twin technology and are consistent with the actual medical device in terms of function, performance, and status. They can be updated in real time to reflect the actual operation of the medical device. These digital twins continuously monitor device performance, tracking metrics such as wear and tear, calibration accuracy, and operational efficiency. By identifying potential failures before they occur, MDTs facilitate proactive maintenance, reducing downtime and ensuring the reliability of life-saving equipment during critical emergencies.

Beyond maintenance, MDTs contribute to resource optimization. By analyzing use patterns and forecasting demand surges, these systems can dynamically allocate equipment to areas of highest need, such as during mass casualty incidents or seasonal patient influxes. This predictive capability not only prevents bottlenecks in care delivery but also enhances hospital operational efficiency, ensuring that critical resources are always available when and where they are needed.

Recovery

In recovery, digital twins play a transformative role by enabling personalized and adaptive rehabilitation processes. These advanced systems integrate comprehensive patient data, including clinical records, biometric parameters, and lifestyle information, to develop dynamic treatment plans tailored to individual needs. Wearable devices continuously monitor patient progress in real time, providing crucial data to adjust therapies dynamically, ensuring that interventions remain effective and responsive to changes in a patient's condition [5,6]. This real-time feedback loop facilitates precision rehabilitation, minimizing setbacks and promoting steady recovery trajectories.

Telerehabilitation further amplifies these benefits by offering remote monitoring and therapy-adjustment capabilities. Patients can receive professional guidance and care modification without frequent in-person visits, reducing logistical burdens and enhancing access to rehabilitation services. Moreover, digital twins empower patients by offering insights into their recovery progress, encouraging active engagement in health management and fostering adherence to prescribed care plans.

A significant breakthrough in the recovery phase is disease relapse prediction and early warning, a feature that underscores the predictive power of digital twins. By leveraging longitudinal patient data and advanced predictive analytics, digital twin systems can detect subtle patterns indicative of potential disease recurrence. These insights enable the generation of real-time alerts for health care providers, prompting timely interventions that can mitigate complications and prevent hospital readmissions. For instance, changes in respiratory patterns or biomarkers could signal the early stages of a relapse, allowing for preemptive adjustments in treatment strategies.

Digital Twins in Real-World Applications

Currently, the application of digital twins in emergency care remains in its early developmental stages, with significant room for growth, yet they have already demonstrated potential in real-world scenarios. For instance, Pfizer and IBM's collaborative Project BlueSky focuses on developing remote patient monitoring systems that use wearable devices and environmental sensors to track disease symptoms in real time, capture dynamic data, and automatically identify abnormalities for timely intervention [7]. Similarly, Digital Orthopaedics and Dassault Systèmes jointly created a clinical decision support system capable of generating patient-specific computational models to reduce trial-and-error risks and achieve precision treatment [7]. During public health crises like COVID-19, digital twins have proven effective in enhancing emergency response capabilities by simulating real-time data collection and vaccination processes to identify optimal resource allocation strategies and refine contingency planning. These examples underscore the transformative role of digital twin technology in advancing emergency care efficiency and resilience [8].

In the cases mentioned above, digital twins have demonstrated significant advantages over current public health systems. Digital public health enables optimized resource allocation, reduces waste, and enhances emergency response efficiency, and it allows real-time monitoring of patient anomalies to accelerate emergency interventions. Centered on data-driven and intelligent capabilities, these advancements markedly improve the efficiency of resource allocation, response speed, and decision-making precision in emergency care.

In summary, digital twins represent a reliable tool in the era of digital intelligence, becoming increasingly feasible in the current data-rich context. The emergency response system serves as an excellent testing ground for digital twin applications, offering

XSL•FO
RenderX

significant potential across areas such as emergency resource planning, patient monitoring, and rehabilitation. However, the implementation of digital twins in the emergency domain is not a task to be completed overnight. It necessitates advancements in complementary fields, including urban modeling, wearable technology, and the IoT, to fully realize its potential. Despite their promise, the application of digital twins in emergency care faces substantial challenges. Currently, many medical digital twins remain confined to visualization, providing static representations rather than actionable tools for decision-making. For full realization, these systems must evolve beyond visualization to actionable frameworks. A second critical hurdle is data quality and resolution. Biological heterogeneity significantly influences disease progression and treatment outcomes, requiring vast, high-resolution datasets to build robust, accurate models. Lastly, ethical, privacy, and security concerns pose significant barriers to the adoption of digital twins in health care [9]. The integration of sensitive patient data with urban-level modeling raises important questions about data governance, requiring careful consideration to balance innovation with public trust. To address the aforementioned challenges, it is necessary to systematically overcome existing bottlenecks through technological optimization, privacy protection, ethical governance, and multiparty collaboration. On the privacy and security front, full lifecycle data protection must be strengthened by leveraging differential privacy and blockchain technology to anonymize sensitive information and enable traceable storage while implementing dynamic access controls to restrict unnecessary data access. Ethically and legally, clear boundaries and transparent guidelines for technology use must be established. Additionally, collaboration among governments, medical institutions, and technology companies is needed to develop unified technical standards and security evaluation systems alongside public education to build societal trust and ensure patient consent and data authorization. Only through parallel advancements in technology, regulatory frameworks, ethical constraints, and social collaboration can the safe implementation and sustainable development of digital twin technology in emergency scenarios be achieved.

Abstract

Background: The development and introduction of an artificial intelligence (AI)–based clinical decision support system (CDSS) in surgical departments as part of the "Supporting Surgery with Geriatric Co-management and AI" project addresses the challenges of an increasingly aging population. The system enables digital comanagement of older patients by providing evidence-based evaluations of their health status, along with corresponding medical recommendations, with the aim of improving their perioperative care.

Objective: The use of an AI-based CDSS in patient care raises ethical challenges. Gathering the opinions, expectations, and concerns of older adults (as potential patients) regarding the CDSS enables the identification of ethical opportunities, concerns, and limitations associated with implementing such a system in hospitals.

Methods: We conducted 5 focus groups with participants aged 65 years or older. The transcripts were evaluated using qualitative content analysis and ethically analyzed. Categories were inductively generated, followed by a thematic classification of participants' statements. We found that technical understanding did not influence the older adults' opinions.

Results: Ethical opportunities and concerns were identified. On the one hand, diagnosis and treatment could be accelerated, the patient-AI-physician interaction could enhance medical treatment, and the coordination of hospital processes could be improved. On the other hand, the quality of the CDSS depends on an adequate data foundation and robust cybersecurity. Potential risks included habituation effects, loss of a second medical opinion, and illness severity influencing patients' attitude toward medical recommendations. The risk of overdiagnosis and overtreatment was discussed controversially, and treatment options could be influenced by interests and finances. Additional concerns included challenges with time savings, potential declines in medical skills, and effects on the length of hospital stay.

Conclusions: To address the ethical challenges, we recommend allocating sufficient time for use of the CDSS and emphasizing individualized review of the CDSS results. Furthermore, we suggest limiting private financial sponsorship.

Introduction

Background

The global population is aging. A combination of increasing life expectancy [1] and enduring demographic shifts [2] has led to an increase in people aged 65 years or older [3]. Older patients face an increased risk of losing physical function and independence during hospitalization [4]. Comanagement of older patients, defined as a process of joint decision-making between surgical staff and a geriatrician, can improve outcomes such as mortality, length of hospital stay, and perioperative complications [5,6]. The rising prevalence of age-related conditions, including cognitive impairment and multimorbidity [7,8], further increases the demand for individualized, patient-centered treatment and resource-intensive medical care at a time when resources are already limited [2]. In parallel, the medical application of artificial intelligence (AI) is expanding, with the potential to enhance personalized medicine, patient care, prediction, and diagnostics while improving accuracy and efficiency and enabling earlier intervention [9].

A systematic review found the use of clinical decision support systems (CDSSs) to be effective with regard to both process- and patient-related outcomes [10].

The research project "Supporting Surgery with Geriatric Comanagement and AI" addresses the growing challenges in the health care system by developing and introducing an AI-based CDSS for perioperative care of older patients and subsequent care planning [11]. This system automatically processes and analyzes patient data to provide an evidence-based evaluation of the individual's health condition and corresponding medical recommendations. The CDSS aims to improve patient care and support medical professionals in surgical wards. However, the introduction of the CDSS also raises ethical challenges [12].

The benefits of medical AI systems are offset by concerns regarding accountability and transparency, biases in training data that may compromise safety, inequities in access, and data security risks [9]. Considering that older adults represent a patient group considered vulnerable and requiring particular protection, addressing AI-related ethical challenges to safeguard patient integrity is of major importance.

The application of large language models in hospitals as a means of improving patient care has been scientifically analyzed across various medical fields and purposes. However, to the best of our knowledge, an ethical evaluation of their use within a CDSS, particularly in perioperative care of older patients and incorporating the perspectives of potential patients, remains lacking.

Objectives

To explore the opinions, expectations, and concerns of potential older patients regarding the development and introduction of an AI-based CDSS in surgical wards caring for older patients, we conducted focus groups with older adults. We sought to (1) examine how the level of technical understanding influences their views and (2) identify the ethical opportunities, concerns, and limitations associated with implementing such a system in hospitals.

Methods

Ethical Considerations

Ethical approval was waived by the ethics committee of Ulm University, because no information on personal data, health-related data, or data on sexuality of the interviewees was collected (May 16, 2024). To ensure informed consent, all participants were sent a digital copy of the consent form before the discussion and were verbally briefed on the focus group procedures. The information covered data handling, privacy protection, voluntary participation, and the right to opt out, as well as details about the project and its funding. All participants provided written informed consent to participate, and no financial incentives were offered.

Overview

Conducting focus groups enabled us to explore the opinions, expectations, and concerns of older adults. This method allows participants to freely express their views, stimulate ideas through interaction, and provide a wide range of perspectives within each group [13,14].

Participant selection followed a deductive sampling approach. The inclusion criteria were age 65 years or older and sufficient German language skills to participate in a group discussion. Given that focus groups rely on oral conversation, we ensured that all participants met the language requirements through 3 steps. First, participants had to understand the written invitation and respond appropriately. Second, we conducted telephone conversations with participants to answer questions and schedule participation before each focus group. Third and last, before starting each focus group discussion, we verified German speaking and comprehension skills through brief conversational exchanges with all participants.

With the support of a gatekeeper, invitation letters were distributed through mailing lists targeting older adults interested in education, posted on an academic website, and further disseminated via snowball sampling. Participants were assigned to focus groups using a stratified randomization approach. First, interested individuals were divided into groups by gender. Next, an equal number of participants from each group were randomly selected and assigned to 3 different focus groups with unevaluated, mixed levels of technical understanding.

Individuals who had not yet been assigned to a group were asked to complete questionnaires assessing technical knowledge. The questionnaires were scored using a points system, and on the basis of these scores, participants were divided into 2 focus groups: one with higher technical understanding and one with lower technical understanding.

In total, 5 focus groups were conducted with 30 participants from the city of Ulm in southern Germany and surrounding areas in June and July 2024. The sessions were held face-to-face. The conversation, including technical explanations of all AI-related aspects, was held in simple language and at a slower speaking rate to accommodate age-related limitations and varying levels of technical knowledge among the participants.

The discussion guide was semistructured to allow flexible adaptation to the dynamics of each group and was organized into 5 thematic categories: general opportunities, risks and resources, accuracy and trust, data processing, patient-physician relationship, and limitations.

The discussions were recorded, transcribed, and anonymized. The quotations included in this study have been translated from German into English.

The transcripts were first analyzed using qualitative content analysis [15], followed by thematic analysis [16], while taking into account 6 analytic factors specific to focus groups [13]. Categories and subcategories were identified inductively, followed by a deductive analysis structured according to the questionnaire. Participant statements were coded and assigned to the established categories. First, 3 focus groups with mixed levels of technical understanding and the 2 groups with lower and higher technical understanding were analyzed separately, considering the 6 analytic factors [13], and then compared. As no major differences were detected between the groups with lower and higher technical understanding, all focus groups were subsequently combined for comparison and analysis.

Ethical Principles Considered in the Analysis

After this analysis, the categories and findings were reviewed by researchers with technical expertise in medicine, medical ethics, and communication and were ethically analyzed using the principle-based approach proposed by Beauchamp and Childress [17]. This biomedical approach is widely applied as a key method for reasoning about and analyzing ethical challenges in medicine. The ethical principles considered in the analysis reflect core medical values and comprise autonomy, beneficence, nonmaleficence, and justice. The principle of autonomy refers to decision-making based on the patient's individual preferences. Beneficence emphasizes maximizing patient benefit while balancing risks against potential benefits, and nonmaleficence aims to prevent harm to the patient. The principle of justice, also referred to as social justice, addresses the equitable and appropriate distribution of resources [17].

Results

Throughout the focus groups, older adults expressed their opinions, expectations, and concerns on an AI-based CDSS, which were organized into five categories: (1) data use, (2) patient-AI-physician interaction, (3) patient care, (4) resources, and (5) framework.

Data Use

Participants emphasized that the quality of the CDSS, including its technical functionality, depends on an adequate data foundation, while recognizing the patient as an uncertain data source. They pointed out the risk of blindly trusting memory-based information provided by older patients who might forget, cheat, or unintentionally provide inaccurate information in a hospital environment perceived as unusual or stressful.

Most discussants highlighted the importance of protecting health-related patient data and were critical of current data management practices. While participants stressed that data protection measures would be required, they anticipated that security gaps would likely persist:

> *[The data security] is full of holes [...] sometimes. […] Much is impeded but the reality is sometimes bitterly different.* [Participant]

Data manipulation and hacking attacks were classified as high risk. The discussants emphasized concerns about targeted data alteration and about physicians unknowingly referring to the falsified data if such manipulation remained undetected.

In addition, concerns were raised about data access by third parties. Most participants highlighted the risk of data misuse, while a few pointed out that the level of concern would depend on the individual's age and extent of misuse.

Patient-AI-Physician Interaction

The discussants noted that older patients' interactions with, and perspectives of, AI and the physician were influenced by individual personality traits. Three traits emerged from the discussions: (1) passive and trusting, (2) proactive, and (3) skeptical and experience-led (Table 1) .

Table . Representation of personality traits as influencing factors in the interactions and perspectives of older adults.

	Passive and trusting	Proactive	Skeptical and experience-led
Trust in physicians using AI[a]-based system	Complete trust in physician and health care system. Trust promotes acceptance of the use of any medical device.	Precondition: explanation of the system and involvement of the patient.	None: based on AI error rates and prior experiences of misdiagnosis.
Decision about using AI-based system	No involvement	Full involvement: right to demand use of AI-based system	Involvement: right to reject use of AI-based system
Participation (factor: cognitive capability)	None	Active participation of patient: entering their own data into the system	Gaining insights into visualizations as a basis for a discussion with the physician
Explainability of AI-based suggestions	Unnecessary	Highly important	Limitation: AI is not explainable (explainability is questionable when AI explains its own system)
Patient rights	Right not to know	Access right to the CDSS[b] to add missing data	Reviewing AI-based results

[a]AI: artificial intelligence.

[b]CDSS: clinical decision support system.

The relationship between the physician and the AI was expected to evolve into mutual supervision: the AI would oversee the physician's knowledge, while the physician would monitor the AI's accuracy.

The severity of illness was identified as an impact factor, with increasing severity making patients more receptive to treatment suggestions. In particular, in cases of severe illness, patients tended to place greater trust in potentially effective treatment options and to question the physician if their treatment suggestion seemed less effective:

> *If I suffer from a severe illness and AI says, "If this and that, it will turn out well." And my physician says "Um." Whom do I trust in this case?* [Participant]

According to participants, a habituation effect of the CDSS would develop. In the long term, patients would either trust the AI more than the physician or not notice its use. At the same

XSL•FO
RenderX

time, regular use of the CDSS would lead physicians to accept AI-based results as a given, place blind trust in the system, and thereby risk misdiagnosis.

While several discussants described the AI as providing a second opinion alongside the physician's assessment, others characterized the AI and physician together as forming a single first medical opinion. In this context, participants noted the risk that the option of obtaining a true second opinion could be lost if different physicians using the same CDSS arrived at similar conclusions.

Patient Care

Diagnosis and therapy provision were expected to accelerate, and the identification of rare and complex diseases was expected to become easier.

A few participants believed that the CDSS could help prevent overdiagnosis. However, others expressed concerns about the risk of overdiagnosis and overtreatment, which could lead to the prescription of more medication and prophylaxis programs, thereby increasing patients' sense of illness.

The discussants also emphasized the risk of treatment suggestions being influenced by calculations of cost of the lifetime gained, the patient's financial status and age, or third-party interests. The participants called for shared decision-making that accounts for the patient's preferences, individual circumstances, and stage of life:

> *The limitation is that the final decision is not made by the AI but by the human.* [Participant]

Resources

According to the discussants, language barriers could be reduced by providing medical professionals with guidance on patient-friendly communication and by offering staff from abroad information either in a widely spoken international language or in their native language.

Some discussants anticipated time savings through the reduction of complexity. However, others noted that such savings might depend on blind trust in the AI and reduced patient-physician communication.

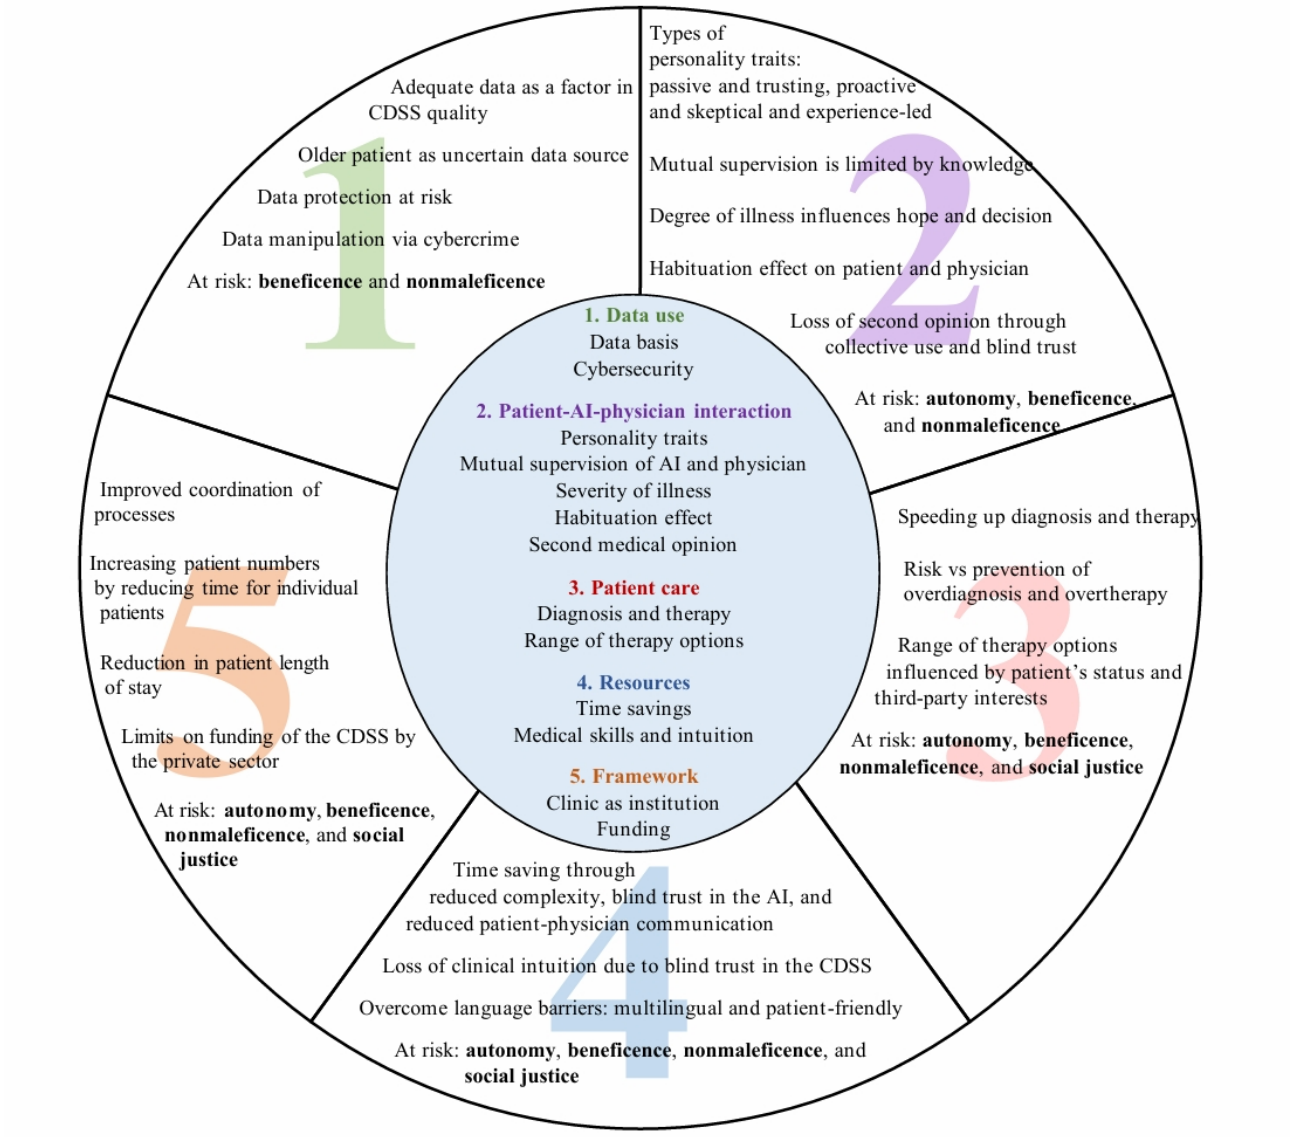
Numerous participants also expressed concern about the potential loss of clinical intuition as a hallmark of good physicians and the inability to work without technical support:

> *I would have the concern that they push AI with the reason "I save employees, we save salaries, because we can just combine less qualified persons with the technology." I think that only works well with good physicians.* [Participant]

Framework

The hospital as an institution was expected to benefit from the CDSS through reduced patient length of stay and improved coordination of processes. However, discussants expressed concerns about a potential increase in patient numbers and a reduction in the time allocated for individual treatment. Furthermore, stress, lack of time, and convenience could lead physicians to blindly trust the CDSS:

> *The downside would perhaps be a transit operation. Each patient has five minutes, has only certain things to tell, to want and you press onto the computer and that is it.* [Participant]



Most of the participants insisted that the AI-based system should not be financed by the private sector, as a precaution during its implementation. This would help prevent profit-oriented influences on the CDSS in the sensitive field of older patient care.

Discussion

Ethical opportunities, concerns, and limitations of an AI-based CDSS, as identified by older adults, are discussed with reference to the 4 principles proposed by Beauchamp and Childress [17]: autonomy, beneficence, nonmaleficence, and social justice (Figure 1).

XSL•FO
RenderX

Figure 1. Representation of ethical challenges raised by older adults regarding the introduction of an artificial intelligence (AI)–based clinical decision support system (CDSS) in older patient care.

Data Use

Participants described CDSS quality as dependent on an adequate data foundation and viewed the older patient as an uncertain data source. The completeness and accuracy of data were identified as the most relevant factors influencing system quality [18]. Low data quality, including insufficient or missing medical information, carries the risk of biased models being developed, which may lead to adverse results from the AI-based system [19]. However, self-reported data from older patients are considered less reliable [20], as they tend to forget or inaccurately recall information in hospital settings [20]. This uncertainty in the underlying data reduces system performance and quality, increasing the risk of incorrect medical suggestions and treatment. Consequently, patient harm from inappropriate treatment or diminished quality of medical care would jeopardize the principle of nonmaleficence.

Discussants expressed concern about cybersecurity. Cyberattacks are an increasing risk in the health care system [21]. Data that are altered, stolen, or manipulated [21] may go undetected [22] and could compromise CDSS recommendations. Medical decision-making based on false data puts patients at risk of receiving incorrect or inadequate treatment, thereby jeopardizing the principle of beneficence. In addition, the misuse of patients' personal data, violations of privacy, and the implementation of incorrect treatment resulting from altered data further threaten the principle of nonmaleficence.

Patient-AI-Physician Interaction

The personality traits of (1) passive and trusting, (2) proactive, and (3) skeptical and experience-led were identified as factors influencing older adults' perspectives. Personality traits shape individual preferences [23], affect older patients' perceptions of the CDSS [24], and influence expectations of the device.

The relationship between physician and AI was expected to develop into mutual supervision. Complementing each other's knowledge and detecting incorrect evaluations [25] through mutual supervision could prevent incorrect treatment and simultaneously improve medical care. This relationship could arise from physicians supervising the AI by interpreting its

XSL•FO
RenderX

results, while the AI minimizes the human errors of the physician [26]. The benefits that older patients experience from improvements in their medical care would support the principle of beneficence, whereas preventing patients from receiving incorrect medical treatment by minimizing human errors would strengthen the principle of nonmaleficence. However, mutual supervision remains imbalanced, given that the detection of AI-based errors is limited by the physician's knowledge [27] and the lack of explainability of black-box systems [28]. In such cases, rather than mutual supervision, a paternalistic relationship could develop between the AI and the physician [28].

Furthermore, illness severity was described as an impact factor. Life-threatening diseases tend to increase patients' hope for potential cures and create uncertainty when trusting a physician's less effective treatment options. Transparent communication of AI-based results is therefore necessary to enable patients to make autonomous, informed decisions and to demonstrate the range of available treatment options. However, physicians do not necessarily want to communicate AI-based results transparently to their patients; they would rather withhold information [29]. Withholding medical information hinders shared decision-making [29] and undermines a trustful patient-physician relationship. Uncertainty in trust may cause patients to experience worry and avoid decision-making [30]; it may also reduce their ability to make rational treatment choices. Consequently, the consideration of patients' individual preferences in medical decision-making, influenced by the severity of their illness, could be restricted, compromising the principle of autonomy.

Participants anticipated the development of a habituation effect. After becoming familiar with the application, patients might come to trust the AI more than the physician. Such distrust of the physician could lead patients to become skeptical of medical recommendations [31], thereby reinforcing uncertainty. Medical decision-making based on uncertainty and a general mistrust of physicians' recommendations undermines patients' independent decision-making, thereby jeopardizing the principle of autonomy. In addition, a general mistrust of medical recommendations could lead patients to decline beneficial treatment options, thus compromising the principle of beneficence. Physicians using the device regularly were also assumed to develop blind trust in the CDSS. Previous research has shown that habituation can lead users to take advantage of systems that permit unquestioned acceptance of suggestions, despite the high risks involved [32]. Blindly following CDSS suggestions that may not be accurate carries the risks of misdiagnosis and incorrect treatment, thereby jeopardizing the principle of nonmaleficence.

The discussants highlighted the risk of losing access to a genuine second medical opinion when different physicians using the same system reach similar conclusions. In this context, the combination of device and physician was described as a single first medical opinion. While a CDSS is designed to support physicians by providing a second medical evaluation, patients retain the option of consulting another physician for a second medical opinion [33]. However, if physicians collectively place blind trust in the CDSS and if similar systems generating similar results are used across hospitals, patients risk being deprived of a second medical opinion. Such circumstances would undermine patients' independent consideration of medical options and preference-based decision-making, thereby conflicting with the principle of autonomy.

Patient Care

The discussants emphasized that the CDSS would speed up diagnosis, particularly in rare and complex diseases, as well as facilitate the provision of treatment. The medical use of AI enables rapid analysis of patient data, leading to a reduction in the time required for diagnosis [34]. Early diagnosis in older patients provides a basis for timely initiation of treatment, lowering the risk of impairment and secondary complications [35]. As a result, overall medical care would improve. Prompt diagnosis may also enhance the healing process of older patients, thereby supporting the principle of beneficence. Furthermore, the prevention and decreased risk of medical complications through timely treatment provision aligns with the principle of nonmaleficence.

Several participants expressed concern that the CDSS could contribute to overdiagnosis and overtreatment, causing patients to feel increasingly ill, while others suggested that it could prevent these problems. Previous studies with AI-based screening devices have shown that AI can accurately detect cell changes that are not necessarily pathological but nevertheless result in overtreatment [36]. Overdiagnosis exposes patients to unnecessary medical treatments and the associated risk of harmful side effects [37], thereby conflicting with the principle of nonmaleficence. Overdiagnosis can also heighten patients' perception of illness, and when combined with treatment that offers no medical benefit, it further undermines the principle of beneficence. In addition, the preventable use of already limited resources fosters an imbalanced distribution of medical resources, conflicting with the principle of social justice. Conversely, if the CDSS helps prevent overdiagnosis and overtreatment, it could improve the provision of essential treatment, supporting the principle of beneficence. Preventing insufficient treatment in older patients and the resulting consequences would also reinforce the principle of nonmaleficence.

Participants expressed major concerns about treatment options being influenced by financial considerations and third-party interests. Security gaps and unauthorized access to data or algorithms could enable alterations to the AI-based system [38], thereby influencing CDSS outcomes. Restricting treatment options to serve profit-oriented interests of third parties could result in less effective treatment options for older patients. Such restrictions reduce older patients' capacity for informed decision-making and jeopardize the principle of autonomy. Limiting treatment options on the basis of third-party or financial interests carries the risk of excluding effective treatments, conflicting with the principle of beneficence. Moreover, narrowing treatment options in ways that compromise patient outcomes would undermine the principle of nonmaleficence.

Resources

Participants expected time savings through reduced complexity, blind trust in the CDSS, and avoidance of extensive

XSL•FO
RenderX

patient-physician communication. However, given the limited accuracy of a CDSS [39], physicians must review the AI-generated results individually to reduce the risk of incorrect treatment. Understanding the individual preferences and concerns of older patients requires time-intensive conversation [40] and is fundamental for decision-making. A lack of communication regarding the patient's preferences could lead to medical decision-making that does not sufficiently take these preferences into account, thereby jeopardizing the principle of autonomy. Relying blindly on the CDSS without examining the results for false implications could harm patient outcomes and compromise the principle of nonmaleficence. Together, blind trust in the CDSS and reduced patient-physician communication could undermine patient-centered medical care and treatment and, in turn, jeopardize the principle of beneficence.

The discussants expected the CDSS to help medical staff overcome language barriers. Effective communication between patients and medical professionals is necessary to identify individual concerns and to build trust [41]. Language barriers may cause patients to avoid follow-up appointments [42], leading to undetected postoperative complications. Poor medical care and worse outcomes resulting from communication difficulties [43] could be prevented by reducing language-related barriers. A multilingual, patient-centered use of the AI-based CDSS could therefore improve patient care and support the principle of beneficence. Improved communication about side effects, treatment risks, and patient concerns could support the principle of nonmaleficence. In addition, language support for medical staff from abroad can save time and human resources while laying the foundation for equitable medical treatment regardless of the language skills of patients or staff, thereby strengthening the principle of social justice.

Medical professionals who regularly use the CDSS were expected to lose clinical intuition and develop a dependency on technical support. Some researchers suggest that the CDSS could enhance medical skills by allowing physicians to learn from its results [44]. However, blind trust in the system may instead reduce medical skills and foster dependency [44]. As a result, the accuracy of medical treatment and thus the protection of patient integrity could become dependent on technology, jeopardizing the principle of beneficence. Moreover, the ability of physicians to verify suggested results and prevent incorrect treatment might no longer be ensured, thereby compromising the principle of nonmaleficence.

Framework

According to participants, hospitals would benefit from the CDSS through better coordination of processes, shorter patient stays, and reduced time spent on individual patient care, thereby enabling treatment of more patients. The shortest possible perioperative stay is financially the most profitable [45]. Minimizing length of stay while increasing patient volume enhances hospital revenue and saves resources. In addition, a higher number of patients could receive treatment, supporting the principle of social justice. However, a balance must be maintained between the needs of individual patients and those of the broader population. Older patients with multiple comorbidities, in particular, face a higher risk of mortality after premature discharge [46]. Profit-driven discharge of patients before medical necessity increases the risk of delayed complication detection and increased mortality in older patients, thereby jeopardizing the principle of nonmaleficence. Delayed treatment of postoperative complications could further expose patients to more severe consequences and subsequently compromise the principle of beneficence.

The discussants were emphatic about the need to restrict private-sector funding of the CDSS to prevent profit-oriented influence. As the algorithms and underlying data of a CDSS are adjustable [38], treatment options could be altered to favor sponsors. This would restrict the consideration of patients' individual preferences in medical decision-making and thereby jeopardize the principle of autonomy. Limiting treatment options for financial gain could also result in withholding effective treatments, undermining the principle of beneficence. Moreover, biased treatment suggestions could expose patients to incorrect medical care, compromising the principle of nonmaleficence.

Conclusions

This research indicates that older adults anticipate both opportunities and ethical challenges in data use, the patient-AI-physician interaction, patient care, resources, and framework when an AI-based CDSS is introduced in older patient care.

To address the ethical concerns raised by the limited number of potential patients in this qualitative research, we recommend allowing sufficient time for use of the CDSS to account for individual patient concerns and preferences. Furthermore, individualized review of AI-generated suggestions and avoidance of private sponsorship are recommended to reduce the risk of less effective medical treatments.

This research is limited by the fact that the participants lived in southern Germany and were privileged in having access to the internet and an academic network. Given the qualitative design, their subjective opinions do not represent average experiences and cannot be generalized to the global older population.

To further analyze the concerns of older adults, consideration of gender and differentiation by age ranges (eg, 65-74, 75-84, and ≥85 years) is recommended. On the basis of our small sample of participants from a single region in Germany, we recommend continuing the research with larger samples involving transregional and transnational participants to examine the scope and generalizability of our findings.

Abstract

Background: Neuroimaging is crucial in the diagnosis of Alzheimer disease (AD). In recent years, artificial intelligence (AI)–based neuroimaging technology has rapidly developed, providing new methods for accurate diagnosis of AD, but its performance differences still need to be systematically evaluated.

Objective: This study aims to conduct a systematic review and meta-analysis comparing the diagnostic performance of AI-assisted fluorine-18 fluorodeoxyglucose positron emission tomography (^{18}F-FDG PET) and structural magnetic resonance imaging (sMRI) for AD.

Methods: Databases including Web of Science, PubMed, and Embase were searched from inception to January 2025 to identify original studies that developed or validated AI models for AD diagnosis using ^{18}F-FDG PET or sMRI. Methodological quality was assessed using the TRIPOD-AI (Transparent Reporting of a Multivariable Prediction Model for Individual Prognosis or Diagnosis–Artificial Intelligence) checklist. A bivariate mixed-effects model was employed to calculate pooled sensitivity, specificity, and summary receiver operating characteristic curve area (SROC-AUC).

Results: A total of 38 studies were included, with 28 moderate-to-high-quality studies analyzed. Pooled SROC-AUC values were 0.94 (95% CI 0.92 - 0.96) for sMRI and 0.96 (95% CI 0.94 - 0.98) for ^{18}F-FDG PET, demonstrating statistically significant intermodal differences (P=.02). Subgroup analyses revealed that for machine learning, pooled SROC-AUCs were 0.89 (95% CI 0.86 - 0.92) for sMRI and 0.95 (95% CI 0.92 - 0.96) for ^{18}F-FDG PET, while for deep learning, these values were 0.96 (95% CI 0.94 - 0.97) and 0.97 (95% CI 0.96 - 0.99), respectively. Meta-regression identified heterogeneity arising from study quality stratification, algorithm types, and validation strategies.

Conclusions: Both AI-assisted ^{18}F-FDG PET and sMRI exhibit high diagnostic accuracy in AD, with ^{18}F-FDG PET demonstrating superior overall diagnostic performance compared to sMRI.

Introduction

Alzheimer disease (AD) is a progressive neurodegenerative disorder characterized by insidious onset, cognitive decline, and memory impairment. In the United States, approximately 6.7 million adults aged ≥65 years are affected by AD, while China faces an even greater burden, with over 13 million cases [1,2]. The prolonged disease course and high comorbidity rates

XSL•FO
RenderX

have established AD as one of the most fatal and economically burdensome conditions of the 21st century [3-5]. Accurate diagnosis of AD is critical for therapeutic decision-making and prognostic evaluation, particularly in the context of global population aging and increasing demands for precise patient stratification in clinical trials [6,7].

Neuroimaging modalities, including fluorine-18 fluorodeoxyglucose positron emission tomography (^{18}F-FDG PET) and structural magnetic resonance imaging (sMRI), have become cornerstone technologies in AD diagnostic frameworks (eg, National Institute on Aging-Alzheimer's Association criteria) because of their noninvasive nature and quantitative capabilities [8-10]. Recent advancements in artificial intelligence (AI) have revolutionized medical image analysis: machine learning (ML) enables data-driven predictive modeling beyond traditional rule-based programming, while deep learning (DL), an advanced ML paradigm, employs multilayer neural networks to extract high-level features from complex datasets, demonstrating transformative potential in neuroimaging [11-14]. Despite extensive research on AI-assisted sMRI or ^{18}F-FDG PET for AD diagnosis, two critical challenges hinder evaluation of model generalizability: (1) substantial heterogeneity in algorithm designs and validation frameworks, and (2) significant variability in the quality of individual studies [15]. Furthermore, no high-quality meta-analysis has comprehensively compared the diagnostic performance of these two imaging modalities.

This systematic review and meta-analysis addresses three critical objectives: (1) quantitative evaluation of diagnostic accuracy metrics for AI-assisted ^{18}F-FDG PET and sMRI based on moderate-to-high-quality evidence; (2) direct comparison of diagnostic performance between modalities; and (3) investigation of confounding factors, including study quality (moderate-to-high vs low), algorithm types (ML vs DL), and validation strategies (internal vs external), through meta-regression. The findings are anticipated to inform evidence-based optimization of AD diagnostic pathways.

Methods

Overview

This study adhered to the PRISMA-DTA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses of Diagnostic Test Accuracy) guidelines and was prospectively registered on PROSPERO (ID: CRD42023449927) to ensure transparency and minimize reporting bias [16,17]. Two reviewers independently conducted all stages of the review process, including title and abstract screening, full-text evaluation, data extraction, adherence assessment to reporting guidelines, and risk-of-bias evaluation. Discrepancies were resolved through group consensus.

Literature Search Strategy

Two investigators (TLZ and BW) systematically searched PubMed, Web of Science, and Embase from inception to January 2025 using a combination of Medical Subject Headings (MeSH) terms and free-text keywords. Additional searches were performed on clinical trial registries and OpenGrey to identify unpublished clinical trials and gray literature. Search terms encompassed four domains: (1) disease terminology (Alzheimer disease, AD, Alzheimer Syndrome); (2) imaging modalities (^{18}F-FDG PET, sMRI); (3) AI methodologies (ML, DL); and (4) diagnostic metrics (sensitivity, specificity, summary receiver operating characteristic curve area [SROC-AUC]). Reference lists of included studies were manually screened to identify additional relevant publications. The specific search strategies are provided in Table S1 in Multimedia Appendix 1.

Literature Inclusion and Exclusion Criteria

The inclusion criteria were as follows: (1) human studies developing or validating AI models using ^{18}F-FDG PET or sMRI to differentiate AD from normal controls; (2) AD diagnosis based on National Institute on Aging-Alzheimer's Association or International Working Group for New Research Criteria for Alzheimer’s Disease criteria; (3) availability of diagnostic performance metrics (eg, true positives, false positives, true negatives, false negatives) or explicit reporting of sensitivity and specificity; and (4) full-text availability in English. The exclusion criteria were as follows: (1) case reports, reviews, letters, or conference abstracts; (2) studies lacking sufficient diagnostic performance data; and (3) duplicate publications reporting on the same cohort without novel analyses.

Literature Screening and Data Extraction

Two reviewers (TZ and BW) independently performed title and abstract and full-text screening, followed by cross-verification to ensure accuracy. Two additional investigators (RM and XH) extracted data using predefined forms, including study characteristics (first author, publication year), model specifications (algorithm type, validation strategies), and diagnostic performance metrics (2×2 contingency tables, sensitivity, specificity). Extracted data were cross-checked for completeness and precision.

Quality Assessment of Included Studies

The methodological quality of included studies was evaluated using an adapted TRIPOD-AI (Transparent Reporting of a Multivariable Prediction Model for Individual Prognosis or Diagnosis–Artificial Intelligence) checklist (Table S2 in Multimedia Appendix 1) by two independent reviewers (RM and XH) [18]. The instrument assessed four domains: (1) data quality (sample diversity, adequacy, preprocessing standardization), (2) model development (feature extraction rationale, algorithm selection, hyperparameter optimization), (3) validation methods (cross-validation rigor, external validation), and (4) clinical applicability (interpretability, net clinical benefit). Each of the nine items was scored 0‐2 (0=unsatisfied; 1=partially satisfied; 2=fully satisfied), with total scores categorized as high quality (≥16), moderate quality (10-15), or low quality (≤9). Disagreements were resolved through discussion.

Data Analysis

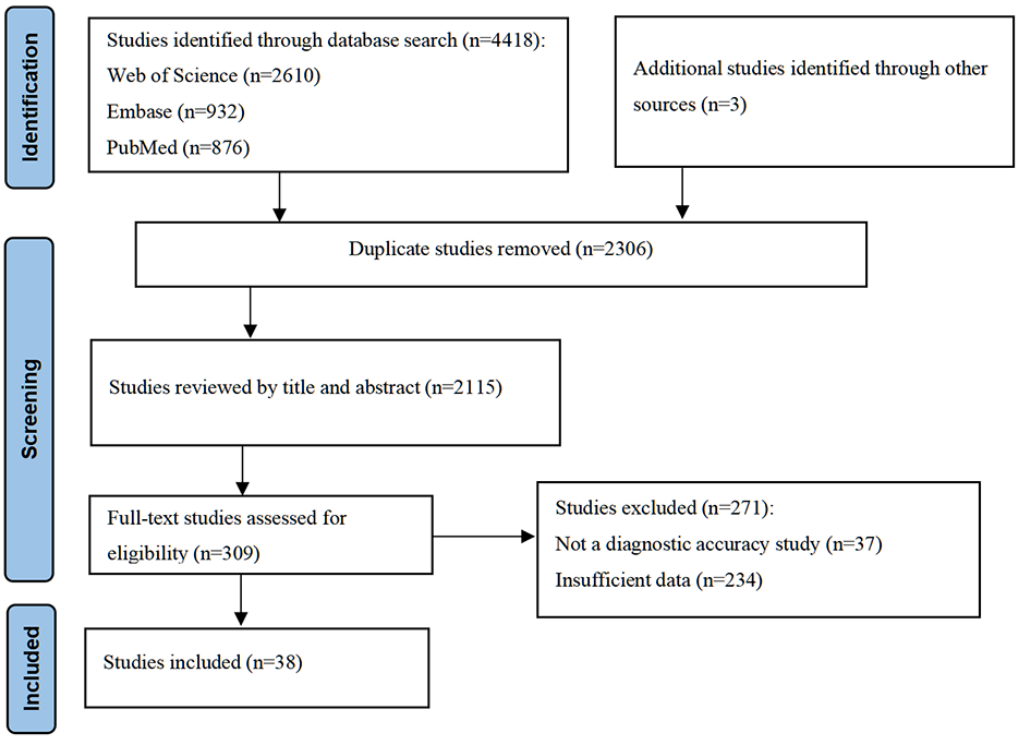
Diagnostic performance metrics were calculated using a bivariate mixed-effects model. SROC-AUC served as the primary outcome due to its threshold independence. Diagnostic

XSL•FO
RenderX

accuracy was classified per National Institutes of Health criteria as high (AUC≥0.90), moderate (0.70 - 0.89), or low (AUC<0.70) [19].

Heterogeneity Assessment and Publication Bias Evaluation

Heterogeneity was quantified using Cochran *Q* test (significance defined at the .05 level) and I^2 statistics (25%: low; 50%: moderate; 75%: high heterogeneity) [20]. Threshold effects were assessed using Spearman correlation between logit-transformed sensitivity and 1–specificity. Sensitivity analyses evaluated outlier influence by iteratively excluding individual studies. Univariable meta-regression analyses were conducted to assess the influence of potential confounding factors, including study quality (moderate to high vs low quality), algorithm type (ML vs DL), and validation strategy (internal vs external validation). Statistical significance of modifiers of the pooled effect size was defined at the .05 level after adjustment via the Holm-Bonferroni method. Publication bias was assessed via funnel plot asymmetry and Egger test, with significance defined at the .05 level. All analyses were conducted in Stata 16.0 using the MIDAS commands.



As this study focused on diagnostic accuracy, we employed the bivariate random-effects model via the MIDAS command in Stata to jointly synthesize sensitivity and specificity. This approach accounts for both within- and between-study variability, as well as the inherent correlation between sensitivity and specificity. In such models, conventional heterogeneity measures like I^2, although still reported for completeness, may not fully capture the joint variability of test performance measures. Therefore, to better understand heterogeneity, we additionally performed meta-regression and calculated joint likelihood ratio tests to explore potential effect modifiers. These methods align with recommended practices in diagnostic test accuracy meta-analyses [21,22].

Results

Literature Screening Process and Results

Initial searches identified 876 PubMed records (n=89 involving ^{18}F-FDG PET; n=787 sMRI), 932 Embase records (n=111 ^{18}F-FDG PET; n=821 sMRI), and 2610 Web of Science records (n=230 ^{18}F-FDG PET; n=2380 sMRI), supplemented by 3 additional studies. After deduplication in EndNote 20, 2 reviewers independently screened titles and abstracts using the Population, Intervention, Comparison, Outcome, Study Design (PICOS) criteria, followed by full-text evaluation against predefined inclusion/exclusion criteria. This rigorous process yielded 38 studies for systematic review and meta-analysis [23-60]. The literature screening process and results are shown in Figure 1.

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analysis) flow diagram.

Characteristics of Included Studies

Table 1 and Table S3 in Multimedia Appendix 1 detail the characteristics of the included studies. Imaging modalities comprised sMRI (n=15, 39%), ^{18}F-FDG PET (n=15, 39%), and combined sMRI/^{18}F-FDG PET (n=8, 22%). Data sources predominantly relied on open-access databases (n=29, 76%), with 28 (97%) from the Alzheimer's Disease Neuroimaging Initiative database and 1 (3%) from the Open Access Series of Imaging Studies database. Four studies (11%) used institutional data, while 5 (13%) combined Alzheimer's Disease Neuroimaging Initiative database with local datasets. Algorithmically, 26 studies (68%) employed ML, predominantly support vector machines (17/26, 65%), whereas 12 (32%)

XSL•FO
RenderX

utilized DL, primarily convolutional neural networks (9/12, 75%). Internal validation was implemented in 33 studies (87%), with 10-fold cross-validation in 16 (48%); only 5 studies (13%) incorporated external validation.

Quality Assessment Results of Included Studies

Nine (24%) studies were high quality, characterized by adequate sample sizes, rigorous validation (eg, multicenter external validation), and standardized reporting. Moderate-quality studies (n=19, 50%) met basic methodological standards (eg, cross-validation) but had limitations such as single-center data or insufficient clinical correlation analyses. Ten (26%) studies were low quality due to small sample sizes (<100 cases) and inadequate validation strategies, compromising external validity. The results of quality assessments for each study are detailed in Table S4 in Multimedia Appendix 1.

Data Analysis Results

Overall Diagnostic Performance

Analysis of 29 sMRI-related contingency tables demonstrated a pooled sensitivity of 88% (95% CI 86%-89%), a specificity of 92% (95% CI 90%-93%), and an SROC-AUC of 0.94 (95% CI 0.92-0.96). Subgroup analyses stratified by algorithm type revealed that ML (19 tables) achieved a sensitivity of 86% (95% CI 85%-88%), a specificity of 91% (95% CI 88%-93%), and an SROC-AUC of 0.88 (95% CI 0.85-0.90), while DL (10 tables) showed improved performance with a sensitivity of 88% (95% CI 86%-91%), a specificity of 92% (95% CI 90%-94%), and an SROC-AUC of 0.96 (95% CI 0.94-0.97). Stratification by study quality indicated that moderate-to-high-quality studies (24 tables) yielded a sensitivity of 87% (95% CI 85%-89%), a specificity of 91% (95% CI 89%-93%), and an SROC-AUC of 0.94 (95% CI 0.92-0.96), whereas low-quality studies (5 tables) reported elevated metrics with a sensitivity of 91% (95% CI 87%-94%), a specificity of 95% (95% CI 92%-97%), and an SROC-AUC of 0.98 (95% CI 0.96-0.99). Validation strategy–based analysis showed that internal validation (25 tables) achieved a sensitivity of 88% (95% CI 86%-90%), a specificity of 92% (95% CI 90%-94%), and an SROC-AUC of 0.95 (95% CI 0.92-0.96), while external validation (4 tables) demonstrated marginally lower performance with a sensitivity of 85% (95% CI 81%-89%), a specificity of 91% (95% CI 85%-94%), and an SROC-AUC of 0.93 (95% CI 0.90-0.95).

For ^{18}F-FDG PET (27 tables), pooled estimates demonstrated a sensitivity of 90% (95% CI 88%-92%), a specificity of 93% (95% CI 91%-94%), and an SROC-AUC of 0.96 (95% CI 0.94-0.98). Subgroup analyses stratified by algorithm type revealed that ML (15 tables) achieved a sensitivity of 89% (95% CI 86%-90%), a specificity of 91% (95% CI 88%-93%), and an SROC-AUC of 0.94 (95% CI 0.91-0.96), while DL (12 tables) exhibited superior performance with a sensitivity of 91% (95% CI 89%-93%), a specificity of 94% (95% CI 93%-96%), and an SROC-AUC of 0.98 (95% CI 0.96-0.99). Moderate-to-high-quality studies (21 tables) demonstrated a sensitivity of 90% (95% CI 88%-92%), a specificity of 93% (95% CI 91%-94%), and an SROC-AUC of 0.96 (95% CI

XSL•FO
RenderX

0.94-0.98), whereas low-quality studies (6 tables) showed comparable metrics with a sensitivity of 91% (95% CI 86%-94%), a specificity of 93% (95% CI 87%-96%), and an SROC-AUC of 0.96 (95% CI 0.94-0.98). Internal validation (24 tables) yielded a sensitivity of 90% (95% CI 89%-92%), a specificity of 93% (95% CI 91%-94%), and an SROC-AUC of 0.96 (95% CI 0.94%-0.97%), while external validation data (3 tables) were insufficient for SROC-AUC calculation but reported a sensitivity of 87% (95% CI 81%-93%) and a specificity of 95% (95% CI 91%-97%). The data analysis results are shown in Table 2.

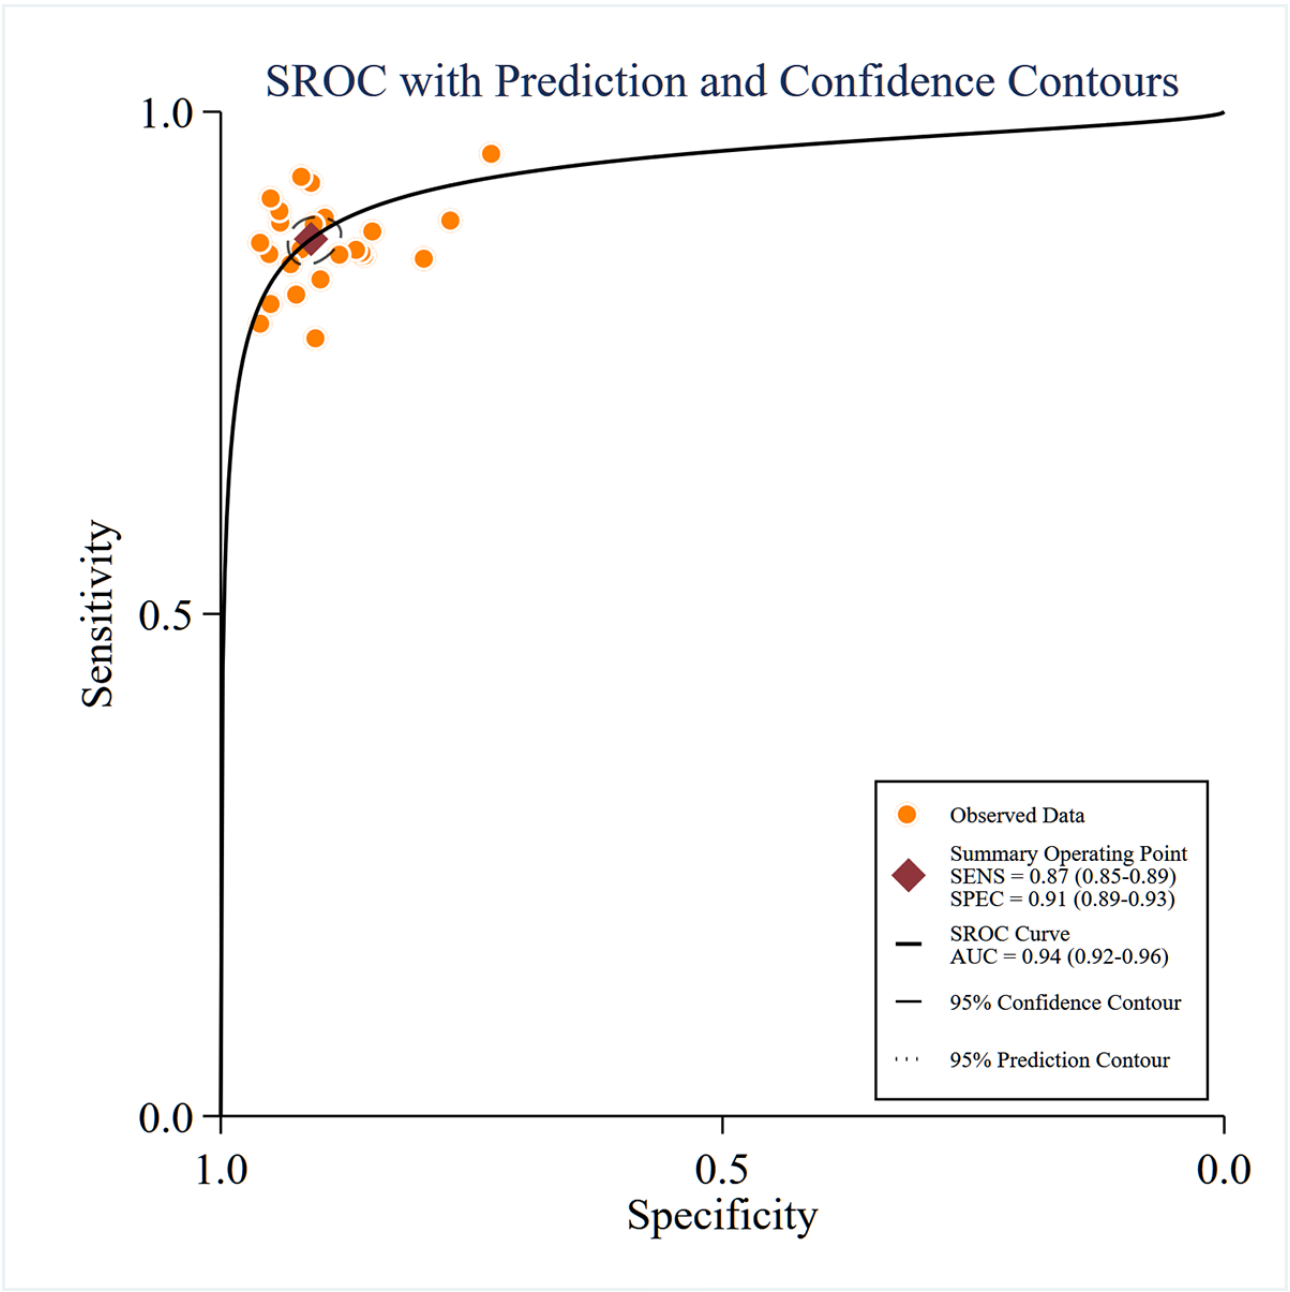
Moderate-to-High-Quality Study Subgroup Analysis

For sMRI, pooled sensitivity, specificity, and SROC-AUC were 87% (95% CI 85% - 89%), 91% (95% CI 89% - 93%), and 0.94 (95% CI 0.92 - 0.96), respectively (see Figures 2 and 3). Stratification by algorithm type indicated that ML models achieved 86% (95% CI 84% - 88%) sensitivity, 89% (95% CI 86% - 92%) specificity, and an SROC-AUC of 0.89 (95% CI 0.86 - 0.92), while DL models demonstrated 88% (95% CI 86% - 91%) sensitivity, 92% (95% CI 90% - 94%) specificity, and an SROC-AUC of 0.96 (95% CI 0.94 - 0.97).



For ^{18}F-FDG PET, pooled sensitivity, specificity, and SROC-AUC were 90% (95% CI 88% - 92%), 93% (95% CI 91% - 94%), and 0.96 (95% CI 0.94 - 0.98), respectively (see Figures 4 and 5). Subgroup analyses revealed ML models achieved 89% (95% CI 86 - 91%) sensitivity, 91% (95% CI 87% - 93%) specificity, and an SROC-AUC of 0.95 (95% CI 0.92 - 0.96), whereas DL models outperformed with 91% (95% CI 89% - 93%) sensitivity, 94% (95% CI 93% - 96%) specificity, and SROC-AUC 0.97 (95% CI 0.96 - 0.99). The data analysis results are also shown in Table 3.

Exploration of Statistical Heterogeneity Sources

Full Study Cohort

For sMRI contingency tables, sensitivity exhibited moderate heterogeneity (I^2=55.32%), while specificity showed high heterogeneity (I^2=74.08%). Threshold effect testing revealed no significant threshold effect (r=−0.101, P=.60). Subgroup analyses identified study quality stratification (P=.02) as a source of heterogeneity, with moderate-to-high-quality studies demonstrating lower sensitivity (87% vs 91%) and specificity (91% vs 95%) compared to low-quality studies. Algorithm type (P=.40) and validation strategy (P=.33) were not significant contributors.

For ^{18}F-FDG PET analyses, sensitivity and specificity displayed moderate (I^2=42.04%) and high heterogeneity (I^2=61.49%), respectively, with no threshold effect (r=−0.087, P=.67). Algorithm type (P=.01) significantly influenced heterogeneity, as ML models demonstrated lower sensitivity (89% vs 91%) and specificity (91% vs 94%) than DL. Study quality (P=.96) and validation strategy (P=.26) showed no significant impact. The data analysis results are also shown in Table 2.

Moderate-to-High-Quality Study Subgroups

For sMRI-based models, ML implementations demonstrated minimal sensitivity heterogeneity (I^2=3.72%) but high specificity heterogeneity (I^2=75.58%). Exclusion of studies using traditional ensemble algorithms (random forest, boosting) reduced specificity heterogeneity to moderate (I^2=45.47%), revealing that ensemble methods achieved higher sensitivity (89% vs 87%) but significantly lower specificity (79% vs 93%) compared to nonensemble ML models (P<.001). In contrast, DL-based sMRI models exhibited high heterogeneity for both sensitivity (I^2=76.56%) and specificity (I^2=76.53%). Removing external validation data mitigated heterogeneity to moderate (I^2=54.36%) and low levels (I^2=38.60%), respectively, with external validation studies showing significantly reduced sensitivity (85% vs 90%) and specificity (91% vs 93%) compared to internal validation (P<.001).

For ^{18}F-FDG PET-based models, ML implementations showed low sensitivity heterogeneity (I^2=16.51%) and moderate specificity heterogeneity (I^2=53.95%). DL models exhibited moderate sensitivity heterogeneity (I^2=54.59%) and low specificity heterogeneity (I^2=36.23%). The data analysis results also are shown in Table 3 and Table S5 in Multimedia Appendix 1.

Publication Bias Test

Funnel plot analysis of the full study cohort revealed no significant publication bias for sMRI (P=.69), whereas the ^{18}F-FDG PET subgroup exhibited significant bias (P<.001). In the moderate-to-high-quality cohort, both sMRI (P=.03) and ^{18}F-FDG PET (P=.01) demonstrated publication bias. However, subgroup analyses showed no significant bias for sMRI+ML (P=.06), sMRI+DL (P=.89), ^{18}F-FDG PET+ML (P=.08), or ^{18}F-FDG PET+DL (P=.28).

Discussion

Principal Findings

This meta-analysis confirms that AI-enhanced sMRI and ^{18}F-FDG PET achieve high diagnostic accuracy for AD, with pooled SROC-AUCs of 0.94 and 0.96, respectively, outperforming conventional visual assessments [61,62]. ^{18}F-FDG PET demonstrated superior overall performance (P=.02), likely attributable to its sensitivity to AD-specific metabolic abnormalities. Notably, ML amplified PET's diagnostic advantage (SROC-AUC: 0.95 vs 0.89), while DL narrowed the gap (SROC-AUC: 0.97 vs 0.96), highlighting DL's capacity to extract complex metabolic features and mitigate structural imaging limitations [63].

Subgroup analyses identified three key determinants of heterogeneity and performance variation. First, methodological quality significantly influenced sMRI models: moderate-to-high-quality studies reported lower sensitivity (87% vs 91%) and specificity (91% vs 95%) compared to low-quality studies (P=.02), suggesting inflated performance in the latter due to small sample sizes, single-center data, or nonstandardized preprocessing. Adherence to TRIPOD-AI guidelines and transparent reporting of preprocessing workflows are critical for future studies [18]. Second, algorithm type drove technical divergence in PET models: DL outperformed ML (sensitivity: 91% vs 89%; specificity: 94% vs 91%; P=.01) through end-to-end feature learning. However, ML's interpretability better aligns with clinical demands for transparency, whereas DL's reliance on large annotated datasets and computing resources limits its deployment in resource-constrained regions [64]. Third, validation strategies exposed generalizability limitations: external validation of sMRI+DL models showed reduced sensitivity (85% vs 90%) and specificity (91% vs 93%) compared to internal validation (P<.001).

The reduced diagnostic accuracy observed in externally validated models may stem from (1) data distribution shift—differences in feature distributions, class balance, and temporal trends between training and external datasets; (2) overfitting—models may have overfitted to training-specific noise or spurious patterns, limiting generalization; and (3) implementation and annotation inconsistencies—variations in data preprocessing, feature scaling, and labeling protocols across datasets [65].

Future Directions and Study Limitations

This study has two methodological constraints: potential selection bias from English-only inclusion and possible overestimation by prioritizing optimal contingency tables. Future research should focus on enhancing evidence robustness through multinational, multiethnic cohorts; improving transparency via open-source preprocessing codes, findable, accessible, interoperable, and reusable-compliant data sharing, and independent validation; and balancing performance and interpretability via explainable DL frameworks to meet clinical ethical standards [66].

We also acknowledge the risk of publication bias, as studies with positive results are more likely to be published, particularly in AI-related research where rapid progress and selective reporting may skew the literature. Additionally, language and geographic biases may exist since only English-language articles were included and most studies originated from a limited number of regions (eg, China, the United States, and Europe). This may limit the generalizability of our findings to underrepresented regions.

Despite ^{18}F-FDG PET's higher accuracy, its radiation exposure and cost hinder widespread screening [67]. Conversely, sMRI's cost-effectiveness and noninvasiveness position it as a first-line screening tool, with PET reserved for confirmatory testing in complex cases—a tiered diagnostic strategy. The 2023 Responsible AI for Social and Ethical Healthcare consensus implementation priorities, including transparent cost-benefit frameworks cross-modal standardization, and dynamic performance monitoring [68].

Comparison With Existing Reviews

Although previous reviews have explored the diagnostic accuracy of AI in AD, studies involving meta-analyses remain scarce [69-71]. Conducting such meta-analyses faces significant challenges, particularly due to substantial methodological heterogeneity across studies. This heterogeneity manifests in multiple dimensions, including variations in neuroimaging modalities, disparities in model validation strategies, and differences in algorithm types—all of which influence AD diagnostic performance and complicate the synthesis of evidence.

Borchert et al [70] conducted a comprehensive systematic review of 255 neuroimaging studies utilizing AI for dementia diagnosis and prognosis. Their findings demonstrated that discriminative models, particularly DL approaches, outperformed algorithmic classifiers in distinguishing AD patients from healthy controls. However, they emphasized critical methodological limitations, with conclusions primarily relying on qualitative synthesis rather than quantitative evidence.

In a systematic review and meta-analysis by Sun et al [71], the diagnostic accuracy of DL models based on ^{18}F-FDG PET for AD was investigated. While the study reported excellent diagnostic performance, notable heterogeneity was observed during meta-analysis, raising concerns about the reliability of the findings. Furthermore, the study focused exclusively on DL, overlooking the widespread application of traditional ML methods in current clinical research for AD diagnostic modeling.

In contrast, our meta-analysis incorporates a broader range of studies, rigorously controls methodological heterogeneity through stringent quality assessment and detailed subgroup analyses, and systematically evaluates the diagnostic accuracy of both ML and DL in AD. By emphasizing methodological rigor and the importance of external validation in AI-assisted neuroimaging for AD diagnosis, this study addresses critical gaps in the existing literature.

Although our subgroup comparisons between ML and DL models provide a useful overview of broad methodological trends, it must be noted that algorithm complexity, training data size, and model optimization procedures vary considerably

XSL•FO
RenderX

within each group. The observed performance differences may, therefore, reflect not only model class but also differences in dataset size, feature representation, and implementation quality. Future studies should aim to compare individual algorithms under standardized conditions.

Conclusions

In conclusion, AI can effectively support the diagnosis of AD using sMRI and ^{18}F-FDG PET imaging. Among these approaches, combining PET imaging with DL techniques yields the highest diagnostic accuracy. These findings suggest that a future direction lies in integrating precision neuroimaging with AI tools. To bring such systems into routine clinical use—helping doctors detect AD earlier, personalize treatment, and improve patient outcomes—future studies should focus on repeated validation with high-quality clinical datasets and the development of standardized implementation protocols.

Abstract

Background: In long-term care (LTC) for older adults, data on client, employee, and organization levels are collected in various ways, covering quality of care, life, and work. There is, however, a lack of understanding of how to introduce data-informed care in LTC and thus create value from data.

Objective: This study aims to investigate the experiences and perceptions of various stakeholders in LTC regarding data and data-informed care.

Methods: A qualitative study using the World Café cocreation technique was conducted with a diverse group of LTC stakeholders. Four questions were addressed: (1) What thoughts do you have when you hear the term “data” in relation to LTC? (2) What purposes do data have (in the future) in LTC? (3) What knowledge and skills are needed to enable data-informed care? (4) How can data contribute to and improve multidisciplinary learning? Stakeholders’ notes and the plenary summary were analyzed using conventional content analysis.

Results: Stakeholders included nurses, members of client councils, data specialists, researchers, and managers (N=20; mean age 50, SD 13 years). Five themes were identified: (1) despite uncertainty, the benefits of using data outweigh the associated risks; (2) the lack of accessibility and uniformity hinders integrating data-informed care; (3) human resources and finance departments pioneer data usage; however, potential lies in clinical decision-making; (4) data-informed care demands individual, collective, and organizational prerequisites; and (5) multidisciplinary collaboration enriches collective knowledge regarding data.

Conclusions: Introducing data-informed care requires enhancing data literacy of health care professionals, establishing clear communication about the role of data within the organization, and introducing new job positions, such as data scientists. Data-informed care was considered a multidisciplinary approach in which data have a supportive role to enhance collective understanding and are considered crucial for improving quality of care.

KEYWORDS

long-term care; data; cocreation; data-informed; quality of care

Introduction

Data are crucial for making the right decisions in health care systems [1]. Information systems and electronic health records (EHRs) improve data management, offering potential benefits, such as enhancing the quality of care and increasing the knowledge levels of health care professionals [2,3]. For example, in clinical decisions, prompt data entry allows for timely access to information and better decision-making [4,5]. Additional examples include the facilitation of information-sharing, which enables collaborative approaches to decision-making [6,7].

In long-term care (LTC) for older adults, vast amounts of data are consistently collected on client, employee, and organizational levels [8,9]. Data can be collected in various ways, such as conversations, questionnaires, and the use of technologies like sensors or wearables. These data can, for example, provide new insights regarding quality of care, support the early detection of diseases, and enhance decision-making [10,11]. Despite the potential of data, integrating data into daily care practice is challenging due to uncertainties about interoperability regarding different data sources (ie, EHRs) and how to use this data for clinical decision-making [12-14]. In addition, health care professionals are often ambivalent about data and the use of information technology [15,16].

Clients in LTC often have complex and multifaceted needs that require, besides clinical data, additional considerations, such

XSL•FO
RenderX

as personal preferences [17,18]. Consequently, challenges arise in decision-making processes due to the context, available data, and characteristics of the decision-makers, such as experience and skills [19]. Previous research has argued that delivering care to individuals with complex care needs should be of high value, team-based, and data-informed [20,21]. Therefore, the informative role of data to support several processes, including decision-making and care delivery, is gaining increased attention in LTC [22-24]. While data-driven methods prioritize decisions based solely on information, data-informed care balances quantitative data with valuable insights from previous experiences and qualitative input from clients, relatives, and health care professionals [25,26]. As data-informed care has not yet been implemented in LTC, however, this may indicate that LTC clients are not receiving the most appropriate care [27].

To date, there is a lack of understanding of how data-informed care can be introduced in LTC settings. For example, the literature regarding the implications of data-informed care for different stakeholders (eg, caregivers, managers, nurses, and data specialists) is scarce [28,29]. Moreover, it remains uncertain which specific requirements are necessary and how LTC organizations and their stakeholders view the role of data in LTC [30]. Therefore, this study aims to investigate the experiences and perceptions of various stakeholders in LTC settings regarding data and data-informed care practices. The findings in this study provide insights into the status quo of data usage and highlight topics to transform toward data-informed care practices in LTC.

Methods

Design

This qualitative study used the cocreation method "The World Café," which allows an open conversation with a variety of stakeholders [31]. This creative method establishes informal discussions in small groups about central questions [32]. The chosen methodology aligns well with the exploratory aims of this study, making it a suitable approach for gaining initial insights [33]. In 3 constructive rounds, collaborative knowledge was created with the stakeholders and evaluated in a plenary session in which the findings were summarized and presented to the group for reflection and feedback [31].

Participants

This study was embedded within the interdisciplinary core group "Data Science of the Limburg Living Lab in Aging and Long-Term Care" (in Dutch: Academische Werkplaats Ouderenzorg Limburg [AWO-L]) [34]. This formal multidisciplinary network consists of a collaboration among Maastricht University, 9 large LTC organizations, and 3 educational institutions (secondary, vocational, bachelor's, or master's level). Together, the Limburg Living Lab delivers care to more than 50,000 clients daily with the support of 27,000 employees. The mission of the network is to conduct scientific research to contribute to the improvement of the quality of life for older adults and their relatives, quality of care, and quality of work for individuals active in LTC [34].

For this study, all organizations within the AWO-L Living Lab were approached and invited to participate based on purposive sampling. This study aimed to include a diverse group of stakeholders. In total, 3 LTC organizations and 2 educational institutes were registered. The principal investigator provided an informative presentation on location. Interested individuals were invited via an email in which the objectives of the study and practical information about the World Café sessions were provided, including the date, location, and time. For those who were interested in participating, a link was included in the email to register. Stakeholders were not required to have prior knowledge of data or data-informed care but were expected to be familiar with the LTC context—either through direct care provision for older adults or through involvement in research or education related to this setting. At the start of the World Café session, a presentation was delivered to introduce the concept of data-informed care. This allowed stakeholders to develop a common interpretation before engaging in group discussions.

Data Collection

Data collection took place in January 2024 using the seven design principles for conducting a World Café session: (1) set the context, (2) create a hospitable environment, (3) explore questions that matter, (4) encourage everyone's contribution, (5) connect diverse perspectives, (6) listen together for patterns and insights, and (7) share collective discoveries [35].

Starting the cocreation session, the stakeholders were welcomed with an introductory presentation to review the objectives of the World Café as well as an introduction into the concept of data-informed care. Time was allocated for questions from the stakeholders regarding the information provided by email or during the presentation. Thereafter, stakeholders received an informed consent form that detailed important aspects of the session. This included the type of information that was collected (ie, photos during the session, audio recordings of the plenary summary, and written answers given by the stakeholders), and how this information would be analyzed, processed, and stored. After signing the informed consent, the stakeholders were given a small toolkit containing Post-its, a notepad, markers, and pencils to provide written answers during the World Café session.

The World Café session was hosted in a public venue that simulated a restaurant's layout, with 4 round tables, as well as snacks and beverages. The World Café method is described as being conducted in a café-style layout of tables, which encourages enthusiasm, contribution, and participation [31,36]. Hence, the World Café facilitates an open conversation with a variety of stakeholders on several topics. The stakeholders were placed into 4 heterogeneous groups based on their profession and organization. Each group gathered at 1 table, and the group's composition remained unchanged during the cocreation session. In total, 4 tables (and thus 4 groups) were established [35]. All tables were hosted by a "moderator": a member of the research team with experience in qualitative data collection and in-depth knowledge about the research topic.

For each table, 1 central question and prompts were formulated during 3 meetings prior to the World Café with the research

XSL•FO
RenderX

team, based on their relevance to the aim of this study (Table 1) [37]. All moderators participated in a preparatory meeting prior to the World Café to collaboratively discuss the questions and prompts aligned with the study's aim. Moderators also received additional information on the session's structure, along with a written manual detailing the prompts assigned to each table. The prompts, which were subquestions regarding the central questions, were used to guide and enhance dialog to acquire a collective understanding.

Table . Central question per table.

Central questions	Examples prompts
T1 - What thoughts do you have when you hear the word "data" in relation to LTC[a]?	• Why do we collect data in LTC? • What information does a health care professional need to provide care? • What objection do you have to using data in the care process?
T2 - What purposes will data have (in the future) in LTC?	• Could data support improve the quality of care? • Why should a health care professional consider data usage in their work? • What role has data regarding decision-making?
T3 - What knowledge and skills are needed to enable data-informed care?	• How can data enhance care practices? • What competencies are required regarding data-informed care? • What systems or other resources does the health care professional need here?
T4 - How can data contribute to and improve multidisciplinary learning?'	• What is multidisciplinary working, and what role has learning and improving played in this? • How can multidisciplinary learning support care practices? • What challenges should be considered when integrating data into multidisciplinary learning?

[a]LTC: long-term care.

Each group discussed the corresponding central question for 30 minutes. In the first round, the stakeholders introduced themselves within their group. As the composition of the groups remained unchanged, introducing oneself once was sufficient [35]. After the moderators stated the central question, stakeholders started brainstorming individually and wrote their ideas down on Post-its before starting the conversation, ensuring that all stakeholders' perspectives were included [38]. Afterward, the dialog between the stakeholders started, and new ideas and answers were formulated on Post-its. The collaborative nature of the World Café methodology aligns with key principles of participatory research by fostering inclusive discussion and meaningful stakeholder engagement. In particular, it facilitates coconstruction, a higher level of participation as defined in adaptations of the participation ladder, where stakeholders actively contribute to shaping insights rather than functioning merely as data sources [39].

In the second and third rounds, the groups shifted to new tables. The moderators started by summarizing the insights of the previous rounds to the new group via the Post-its from the latter group. This allowed stakeholders to link with the previous group and build upon their work to discover new insights regarding the central question [40]. The moderators then stated the central question and let the stakeholders brainstorm individually again before starting the conversation. By expanding on each other's thoughts, the World Café sessions allowed "cross-pollination," meaning that sharing and interchanging information and thoughts enriches the group's capabilities and connects diverse perspectives, resulting in collective knowledge [31]. To conclude the 3 rounds, the 4 moderators provided a plenary summary of the overall findings from their tables. Additional comments or feedback shared during the plenary reporting of each table's insights were incorporated into the results. All stakeholders present during the world-café session were given the opportunity to share their opinion or provide comments based on the plenary reporting, in case something was missing or misinterpreted.

Data Analysis

The informed consent acquired additional information from each stakeholder, namely their age, gender, the name of their organization, their job title, and their years of work experience in their current profession, as described in the "Results" section. Descriptive analysis was performed to provide insights into the demographics of the stakeholders (eg, mean age, SDs, and range).

The notes on the Post-its and the written text on the sheet from the tables, as well as the audio record of the plenary summary, were transcribed verbatim [41]. The transcripts (ie, notes per table and the plenary summary) were subsequently uploaded to the qualitative analysis software MAXQDA (VERBI Software GmbH [42]). The first author familiarized himself with the data by reading all transcripts multiple times, which facilitated an in-depth understanding of the data [43]. Conventional content analysis was conducted to describe the experiences and perceptions of stakeholders' daily work with data in LTC [44,45]. Conventional content analysis avoids predetermined categories and inductively processes the data. Therefore, categories or themes, along with their names, emerge from the data when using a systematic approach [46,47]. This study

XSL•FO
RenderX

conducted the conventional content analysis by following up with systematic coding [46].

The first author conducted the coding process by performing a line-by-line analysis that identified meaningful units of information [48]. These text segments were "open coded" with overarching labels describing the condensed meaning. The descriptive labels of the open-coded segments were summarized by grouping similar codes to identify clusters of codes. By integrating the codes into clusters, overarching categories were formulated [49]. Establishing overarching categories by specifying subcategories is often referred to as axial coding [50]. This process was evaluated by all coauthors. The content and interpretation of the themes were discussed with the whole research team [51]. The translation process was checked for content and context independently within the research team, based on the central questions, used prompts, original notes written by the stakeholders, and translations conducted by the first author.

Ethical Considerations

The study protocol was approved by the ethics committee of Maastricht University (approval number: Faculty of Health, Medicine, and Life Sciences - FHML-REC/2024/055). All information about the aim of this study was communicated to the stakeholders in advance by email. Informed consent was provided, and participation was strictly voluntary. Withdrawal from the study was allowed at any moment for any or no reason. To guarantee the anonymity of the stakeholders, no names or organizations were documented.

Results

Overview

The descriptive characteristics of the stakeholders are reported in Table 2. In total, 20 stakeholders participated with a mean age of 50 (SD 13) years. The stakeholders had, on average, 16 (SD 9) years of working experience, and 55% (11/20) were female. This study included 7 different professions from LTC organizations and educational institutions.

Table . Descriptive characteristics of stakeholders (N=20).

Characteristics	Value
Age (years), mean (SD; range)	50 (13; 33-79)
Work experience (years), mean (SD; range)	16 (9; 3-40)
Sex (female), n (%)	11 (55)
Profession, n (%)	
Health care professionals[a]	6 (30)
Business Intelligence specialists[b]	3 (15)
Members client council	3 (15)
Education[c]	4 (20)
Managers	4 (20)

[a] health care professionals included 4 nurses, 1 specialist in involuntary treatment, and 1 specialist in client well-being.

[b]Business Intelligence specialists included 2 Business Intelligence architects and 1 specialist in data storage and exchange.

[c]Education included 2 teachers and 2 researchers.

Five themes were identified during the World Café session [52]: (1) despite uncertainty, the benefits of using data outweigh the associated risks; (2) the lack of accessibility and uniformity hinders integrating data-informed care; (3) human resources and finance departments pioneer data usage, yet potential lies in clinical decision-making; (4) data-informed care demands individual, collective, and organizational prerequisites; and (5) multidisciplinary collaboration enriches collective knowledge regarding data. The 5 themes, including their underlying axial codes and some examples of direct quotations in stakeholders' notes, are reported in Table 3.

XSL•FO
RenderX

Table . Overview of themes, axial codes, and stakeholders' notes.

Themes and axial codes	Stakeholders' notes (direct quotations)
Despite uncertainty, the benefits of using data outweigh the associated risks	
Knowledge about data	Data is just a word–data is not used (yet)–there is a lot of data in LTC.
Negative feelings	Data collection should not become the aim–fear of the unknown–risk that data steers a professional too much.
Current applications	AI in practice–eHealth (data that is not necessarily added or used by humans)–going from retrospective to real-time insights, to prospective improvements.
Ethical dilemmas	Uncertainty about reliability of data-Ethical dilemmas about data usage.
Data's potential for care	Data usage of quality of care–data supports tailored care to the client–identifying group selections.
The lack of accessibility and uniformity hinders integrating data-informed care	
Indicating variety of data	Demographical information – Clinical Measurements – kinds of data, including audio, video, qualitative and quantitative.
Uniformity in systems	Standardizing definitions in the systems—System often requires jargon, should switch to layman's' language—database structure is crucial for enhancing uniformity.
Simplification	Translating data to present understandable information for clients, informal caregivers and public–professionals will be supported if data becomes more comprehensive and easy to use–simplifying data improves multidisciplinary learning and improving.
Interoperability	Sharing data and associated solutions to increase data usage–LTC can continuously improve by connecting data between systems–Link external sources and strive for open data.
Electronic health record	Double checks in EHR–Data could support medication registration–Compliance cannot be tracked with data yet.
Information gain	Systems should be unambiguously and easy to use–Making data both findable and usable–With LTC, agreements are needed for accessibility and governance of data.
Accessibility	Creating overview of aging population (in region)–Matching eHealth and specific client(characteristics)–Insight into data of future clients.
Centralizing storage	Working towards one platform and format for different disciplines-Centralizing information–Reducing workload or pressure as data entry and retrieval are in one place.
HR and finance departments pioneer data usage, yet the potential lies in clinical decision-making	
Organizational opportunities	Determination of long-term vision, supported by financial numbers–Organize care differently (more care with less resources–Data can be used positively or negatively to finance care.
Data collection and analysis techniques	Collecting information on different levels, to gain insights what is important and for who–classifying systematic problem analysis–Identifying the different instruments for data collection will result in less administration costs.
Predictions	Data can support in findings patterns and trends–Estimating lifestyle and preferences of clients–Predicting care intensity.
Data-informed care demands individual, collective, and organizational prerequisites	
Education, training, and support	Education to understand the goal of data and information–Support needed for individuals with less digital literacy–Education or train employees systematically.
Teamwork and collective skills	Communicational skills within a team–Dare to innovate-mentality needed in a team–Every team should include an attention raiser or data specialist.
Individual contribution toward data-informed working	Feeling the urge to do own contribution independently or together with informal caregiver)–Taking control and responsibility–Understanding that data should support and not influence.

XSL•FO
RenderX

Themes and axial codes	Stakeholders' notes (direct quotations)
Requirements for learning and improving	Multidisciplinary collaboration with different layers (care, cure, management, IT)–Organizational or team objective should be formulated and communicated more clearly with everyone–Define responsibilities and roles.
Multidisciplinary collaboration enriches collective knowledge regarding data	
Central role for data	Data supports individuals in multidisciplinary approaches with shared and offering new ideas–Adhering to Evidence Based Practice working principles–Enhance dialogue and understanding between different professions.
Collaborative and shared decision-making	Integrating multiple sources and professions allows for better consideration and substantiation–Appropriately implementing SDM result in more, better dialogue with clients–making decisions as a team.
Striving for overarching goals	Teams should mitigate working with limited perspectives from other professions–by working multidisciplinary, the shared objective should be accepted by all–Crucial advantage is "multi-perspectivity" on the one subject.
Collective knowledge	Leaning-by-doing enhances individual digital literacy levels–Gaining knowledge about digital systems, finding information and using that information – Collective understanding acquired by individual contributions.

Despite Uncertainty, the Benefits of Using Data Outweigh the Associated Risks

When asking stakeholders what data means to them, the majority reported recognizing the presence of "data" in their organizations. They mentioned, however, that it is hard to describe data specifically. In addition, they expressed that data are not part of their daily tasks. As stakeholders discussed their role in collecting data, such as demographic information about their clients, they also indicated being aware of different types of data present in LTC (eg, images, audio, and quantitative).

> *Well, initially it was about numbers. Then you have to think of other things that we collect, for example data on wounds or falls or pain and stories in file - stories that employees write down in the files about clients.*

> *Information about personnel files but also sensor technology were added – this data was not collected by humans, but collected in a different way, such as video, audio.*

As the stakeholders considered data usage beneficial, they proposed that LTC should start shifting on the organizational level to increase the use of data. Stakeholders mentioned that such transitions should be done not only to enhance data usage but also to allow the evaluation of how decision-making is integrated in the organization. They emphasized the benefit of data use for the quality of care and discussed that LTC organizations should go from retrospective improvements to real-time insights and even to prospective improvements in the future. Several solutions were mentioned by the stakeholders to support such data transitions, for example, artificial intelligence. However, stakeholders noted that the use of data in practice entails both advantages and disadvantages due to underlying uncertainties, including ethical considerations and client privacy concerns.

> *First, we need to make sure that shared decision-making really happens. If that is not the case, how do you want to add the data part to introduce data-informed decision-making? Than we should think about the process, before adding data into it. Especially about how we want to offer it to that group.* [Client, relatives, and healthcare provider]

> *Implementation of data into solutions that can mimic ChatGPT in which insights from different disciplines can be linked together. Artificial intelligence may support care processes but could also bring more improvements over time. Everybody in the group [client, relatives, and healthcare provider] could experience then an added value.*

While summarizing the variety of data sources, stakeholders mentioned the negative aspects of using data. For example, a few stakeholders mentioned applications that could automatically collect (real-time) data (eg, sensors) but discussed their concern about the reliability of the data. Moreover, stakeholders indicated that using data for data-informed care includes the risk that health care professionals will be influenced too much by the data without assessing or recognizing their quality.

> *Again, not too critical, but critical enough to evaluate the data to see what do the data say, is it correct and does that match my gut feeling? Is that also how I see the client?*

The majority of the stakeholders indicated that using data could support gaining more insights into their clients. They wished for a supportive role for data to oversee their clients, including underlying data that might help them provide care. In addition, care processes on both an individual level (delivery-receiving care) and an organizational level (arranging and organizing care) can experience the benefits of using data, according to the stakeholders. They mentioned that data in LTC help deliver more personalized care and improve quality of care in the organization.

> *Because we want to improve the quality of care, we want to be able to get care tailored to the client by*

XSL•FO
RenderX

providing personalized care. Therefore, we will get a better picture of: OK, we now have this client in a group or subgroup with related data, for example, in a nursing home.

The Lack of Accessibility and Uniformity Hinders Integrating Data-Informed Care

A few stakeholders indicated that work processes were established for data entry and retrieval in their systems. Most stakeholders, however, mentioned that the systems in place did not complement their work processes and therefore negatively influenced their daily work. For example, stakeholders mentioned that they noticed differences in data entry between colleagues, mainly due to missing definitions or badly defined processes.

It is relevant to ensure uniformity by entering data in the same way in an organization. One person puts a "V" for woman (in Dutch: vrouw), and another tries the whole word "woman" or another enters an "f" for "female" in English.

Another example is weighing our clients. Do we need to weigh our clients with or without clothes: there's already a difference there.

The dialog of the stakeholders shifted to the shortcomings in the digital systems. They mentioned that data systems often require jargon, as decided by the developers. Stakeholders wished to switch to a more "layman's language" approach, as this would support professionals in translating information to make it more comprehensible to their clients, informal caregivers, and even the public.

The fact is that we are looking for clarity and uniformity, but at the same time you must be able to report in your own jargon. So ideally, we also use systems or even technology that can translate the jargon to everyone's needs.

Stakeholders noted that simplifying data presentation was only part of the solution. They also experienced a degree of ambiguity regarding the systems, with the main concern being the lack of central storage. Many recognized that entering data into different systems (eg, EHRs and personal files) increased their administrative burden. Centralizing information on 1 platform in a consistent format could, according to the stakeholders, reduce their workload and enhance data accessibility.

We would have a lot of new possibilities with developments in the organizations, such as gathering all information at one place–as this would allow you to plan much better, control better what has been said, and monitor more.

When it comes to potential, you can also think that more data together has a signaling function. Monitors, signals, help you to say at the right moments: Yes, now, we have to be careful [regarding the situation of this client] and we have to take action now.

Supposing that the uniformity and accessibility were deemed sufficient, stakeholders mentioned that connecting with other systems would be desirable. Stakeholders indicated that most of their clients were admitted from various organizations, such as hospitals or rehabilitation centers. As these organizations might use different systems, the connections needed to retrieve clients' data (eg, background and history) are often missing.

But in specific terms, this is the most important thing we find with this client, this is the most important data that comes with it. Also between other domains, such as primary care, general practitioners, and hospitals, everyone does things in their own way, and that does not connect well with each other.

For instance, this is how it works in practice now: You go to the dentist with a cavity, and afterwards you are being referred to a dental surgeon. You will hear probably that they should take another X-ray, because they cannot get the picture taken at the dentist practice, so twice the cost, twice the time, which becomes your concern.

Human Resources and Finance Departments Pioneer Data Usage, Yet Potential Lies in Clinical Decision-Making

Stakeholders noted that data are collected at all levels of LTC (eg, the client, department, and organization levels), each using different instruments and having various goals. They mentioned that, although data are not used for clinical decision-making, departments, such as human resources (HR) and finance, are already integrating data insights (eg, resource allocation and bed occupancy per department). Stakeholders observed, however, that data usage in LTC primarily focuses on HR and finance. These departments are supporting the organizations, and insights from these departments are crucial for determining the organization's long-term vision, sometimes supported by financial numbers. They pointed out that, by using systematic approaches (eg, problem analysis and running reports), these departments could be an example for other departments to show how information should be presented to a wider audience.

There are also different levels that you have to think about: you have the individual, but you can also learn from each other in the department, and you can learn from each other within the organization.

Data usage can be very effective and works for many people. You can show the performance of your staff, and you will consider more the allocation of resources, which is good for the sustainability of healthcare in the future.

For example, making an order, how to finance things, a lot can be automated based on data if we can properly see what data we already have.

Regarding data-collection and -analysis techniques, stakeholders mentioned the importance of gathering information at different levels to understand what is important and for whom. For example, stakeholders mentioned that working in a systematic order and using a limited number of different instruments for data collection could be used to reduce costs—both the financial cost and the burden experienced by health care providers.

XSL•FO
RenderX

> *We often see that we want to reduce the administrative tasks for an employee–which of course may lead to lower costs for the organization as a whole.*
>
> *Electronic health records of the person is a system in which a part of the wishes and needs is often missing and is not actually discussed when we look at how we can provide care for this person. Therefore, sometimes preparations in analyzing data could actually accelerate [the care] process.*

Stakeholders also discussed the predictive capabilities of data, noting that it can help find patterns and trends, estimate clients' lifestyles and preferences, and predict care intensities. They acknowledged that the data collected and analyzed could support care processes.

> *For example, if there is a client with behavioral issues, you hope to match them with a care professionals with the necessary expertise–and in a later stadium, you even want to predict to development of the behavioral issues among clients. Data servers than as a signaling function, where it monitors with you together and alerts you at the right moment.*

Data-Informed Care Demands Individual, Collective, and Organizational Prerequisites

To realize the benefits of using data for decision-making in LTC, stakeholders indicated that several transformations should be considered. First, stakeholders noted a need for training or education to understand data and its potential on an employee level. They indicated that the purpose of data collection is often unclear, as they experienced collecting data as a routine process. Stakeholders mentioned that the lack of clarity in work processes was leading to the underuse of data to provide tailored care or engage clients in dialog—both crucial for decision-making. Stakeholders mentioned that support would be needed for employees with less digital literacy.

> *Data literacy, learning the language, digital skills, are more often expected as basis for professionals, but it should not be considered as a basis [set of skills] and we should understand that some professionals really need support in this. Thinking about a digital coach.*
>
> *We also mentioned that such things should be included more in education. For future healthcare professionals, certain aspects will change, as the professionals we train now are definitely different from those we trained twenty years ago.*
>
> *To analyze data in groups, and perhaps, we should do this also during the education, to see whether we can let people get familiar with data earlier, learning what data are and what can be done with them.*

In addition, stakeholders mentioned the urgency of better top-down communication. According to them, management should clearly formulate objectives to improve data usage and clarify processes for data-informed care. Most stakeholders noted that collaboration across different layers and professions was required. Stakeholders also discussed the need for better-defined responsibilities and roles, as stakeholders described data-informed decision-making as a collaborative approach that includes multiple perspectives and experiences. Clear role definitions enhance clarity and focus on organizational objectives. Stakeholders suggested introducing roles, such as attention-raisers and data specialists, to maintain focus and improve data usage and understanding. The importance of these new roles within the LTC organizations lies in their specific skill sets, which contribute to both the team level (ie, fulfilling the collective need to understand and work with data) and the organizational level by facilitating and promoting the adoption of data-informed care. These roles allow for combining domain-specific knowledge with ICT (information and communication technology) and data expertise, enabling the bridging of the gap toward practical care applications.

> *If you are not clear about what your vision is as an organization, if you are not clear on what you want to focus on, how can a healthcare professional incorporate data into his or her work?*
>
> *Very important is the communication, collaboration and also a bit of trust.*
>
> *The question is if it is clear to everyone if we discuss a topic in a group setting? If some people say, that is not clear to me and then you immediately notice that everything that has been discussed may be correct, but that there are a number of concepts that were not communicated the right way.*

Stakeholders also noted the importance of teamwork and collective skills, including communication and a "dare to innovate" mentality. For individual contributions to data-informed work, stakeholders mentioned expecting pressure to contribute to group gatherings, including taking control and responsibility. First, stakeholders stressed the need for collaboration across various layers within an organization (ie, health care professionals, managers, and IT specialists).

> *It also requires a bit of openness, a bit of innovative capacity–especially from a diverse group of professionals. Suppose we all want to do something with data-informed working. Who could possibly do that? In fact, everyone should be aware of the importance of this, and we should work together with all layers.*

Second, clear communication of the organization's objects is important. It should be clear what vision the organization has about data usage.

> *You will also need a kind of outcome measure, a result and that addresses the needs of the client, this is our main objective. This should be formulated and communicated in a clear manner.*

Finally, responsibilities and roles should be better defined, as should the tasks of each individual.

> *You have to determine who is responsible for what, and what are we going to do–in which data can support to determine who is responsible for what. So*

XSL•FO
RenderX

you interact with the group get to say to everyone: yes, you had to do that, and you had to do that.

Multidisciplinary Collaboration Enriches Collective Knowledge Regarding Data

Stakeholders indicated that data-informed care needs a multidisciplinary approach in which data usage supports collaboration. Multidisciplinary collaboration involves health care professionals from LTC organizations and emphasizes the participation of clients and relatives. They mentioned that, by integrating data, experiences, and knowledge, new ideas could be generated. It was highlighted that acquiring general knowledge on data during multidisciplinary collaborations becomes more relevant when different professions gather. Moreover, they expected a collective understanding of data and client relevance. In addition, stakeholders mentioned that data should have a central role in a multidisciplinary approach or should even be a starting point.

> *Together, we mainly look at what the needs and wishes of the person are. What information do the relatives of a client already have? How can we achieve this in a combined intervention, a collaboration within our organization? That should be realized.*
>
> *We have to look more for common ground, where we can find each other, and see what we are doing the same, instead of just looking for the differences. We could go a lot further that way, towards a dream scenario–if this could be done with including data to improve multidisciplinary learning.*

Some stakeholders even mentioned that making decisions as a team allowed for comprehensive substantiation, promoting evidence-based practice and justification for care decisions. Stakeholders also noted that team decisions should not mitigate professional perspectives but rather take advantage of the diverse perspectives that occur in such collaborations.

> *When receiving the correct information to translate into data from which you have to choose again: which data are essential? Then you check this [information] multidisciplinary, in dialogue–before and during making a decision.*
>
> *As long as you have a shared goal and everybody is open to exchange [their] insights you can work together. And there are many stakeholders that all play a role to contribute and share their piece of knowledge.*

Stakeholders emphasized that multidisciplinary collaborations could improve individual competencies for all those involved (ie, professionals, clients, and informal caregivers). They noted that it was difficult to specify how and which competencies would be affected but that data perform a supportive role that enriches knowledge and experience—as data could simplify complex information by summarizing or illustrating it graphically. As for clients, some stakeholders mentioned that multidisciplinary approaches may result in better dialogs during consults and improved quality of care when data are available as a central component. Therefore, employees require suitable competencies to introduce data during dialogs with clients.

> *Not sure of how exactly that [specific set of competencies] would look like, but it will of course help a lot in the whole process to work with data and enhancing multidisciplinary collaborations.*
>
> *Therefore, we need the right match between good employees, good competencies and a specific client to work with. Then we could have more time to discuss what everybody in the group [staff, informal caregiver, and client] wants.*

Discussion

Principal Findings

This study aimed to provide insights into the experiences and perceptions of stakeholders from different LTC organizations (eg, health care professionals, client representatives, data and ICT specialists) regarding data and data-informed care. The findings indicate that these stakeholders are aware of the importance of data in LTC organizations but do not yet use data to their full potential. Stakeholders recognized its benefits, particularly in personalizing and improving care quality, and identified diverse types of data, such as quantitative data from wearables and qualitative data from EHRs or video materials. While engaging with data was not perceived as a regular part of their day-to-day professional lives, several stakeholders did recognize their role in collecting and using data (eg, health care professionals documenting information in EHRs and using these data when caring for clients). Data were primarily used for operational purposes, such as HR and finance departments. However, the integration of data into care decision-making remains limited. Stakeholders highlighted key conditions for improving data-informed care, including enhanced data literacy, clearer communication from leadership, and better-defined roles, responsibilities, and work processes. These conditions span different organizational levels—from individual competencies to system-wide coordination and support.

The findings align with previous literature, which emphasizes that health care professionals recognize the potential of data to enhance personalization and care quality, yet remain concerned about data accuracy and adequacy [53]. While data holds the potential to support a collective understanding of clients' needs and preferences, data is not yet systematically applied in everyday practice. Studies mentioned various factors that contribute to increased data use, such as clearly defined work processes [54], roles [55], and responsibilities [56,57]. In line with this, the uptake of data-informed care requires improvements in data literacy, clearer organizational communication, and clarifying data definitions [54-57]. Especially, data literacy plays a foundational role in enabling data-informed practices. It encompasses a set of competencies related to data interpretation, quality improvement, and communication within a multidisciplinary context [58,59]. Research indicates that several personal competencies may be crucial for adopting data-informed practices, such as problem-solving, reasoning, or critical thinking [60]. Understanding different levels of data literacy across professions

XSL•FO
RenderX

enables tailored training programs, such as eLearnings and digital coaches with job-specific cases, to support self-paced learning and improve adoption [23,61-63]. Furthermore, data-informed care is considered a multidisciplinary approach that creates new insights by integrating data, experiences, and knowledge from different disciplines [64,65]. Introducing new roles (eg, data scientist) might enhance data usage, as they require knowledge and skills to leverage data and generate predictions to uncover new insight related to care provision [56]. Especially when care needs are complex, the demand for the skills that support multidisciplinary approaches is growing, as they are often associated with an improved perceived quality of care [66-68]. In health care, research indicates that health care professionals in multidisciplinary teams continue to face challenges in using ICT systems and, consequently, data [28,69].

To date, there are multiple initiatives within LTC to contribute to data-informed care. For example, Business Intelligence (BI) solutions—consisting of systems and activities to process data into information—are often present in these organizations [70-72]. Such BI solutions allow LTC organizations to develop a platform to centralize data from different systems (eg, HR systems, EHRs, and supply chain systems) as they help streamline data entry and retrieval [73]. However, they have yet to be used to support data-informed care for clients. In this study, all participating organizations employed at least 1 BI specialist who supports management by providing data summarized in reports or dashboards. The use, however, is still mainly focused on support for the HR department, while its potential indicates a broader potential in LTC for clinical relevance and quality of care.

To our knowledge, this study is the first to provide an overview of the experiences and perceptions of a diverse group of stakeholders in LTC regarding the use of data. By conducting a World Café session, collective knowledge about data and data-informed care was collected. As all stakeholders had different backgrounds and years of working experience, multiple perspectives were included in this study [51]. To ensure the trustworthiness (ie, credibility and reliability) of this study, multiple actions were deployed. First, data-source triangulation was apparent, as stakeholders from three different LTC organizations and 2 educational institutes participated [74,75]. Second, to enhance trustworthiness in qualitative research, this study provided a detailed overview of the procedures in the data collection and analysis while having a constant dialog within the research team about the codes [76]. Third, to strengthen the confirmability, the main results of the World Café session were summarized and shared in a plenary, as a member check [76]. However, the results of this study should be viewed in light of some possible limitations. First, the authors adopted a reflexive and practice-informed position throughout the study, acknowledging their active role in shaping the research design, data collection, and interpretation of findings. Given the close collaboration with LTC organizations and the participatory nature of the research, the potential for bias was recognized. One factor might be confirmation bias, where researchers—consciously or unconsciously—may have interpreted the data in ways that align with their expectations or prior experiences within the LTC setting [77]. To mitigate this, multiple strategies were used, including triangulation of data sources and iterative coding with multiple researchers. These measures were intended to enhance the credibility of the findings while remaining sensitive to the context in which the research was embedded. Moreover, the plenary session with all stakeholders also served as a validation mechanism to enhance the credibility and interpretability of the findings and supports clarification of ambiguity. Second, the stakeholders who participated in this study might be more interested in data-informed care than the average stakeholder of LTC organizations [78]. Therefore, it might imply that the current result may not be applicable to all stakeholders in the LTC domain. Finally, to realize an impact within the participating organizations to transform toward data-informed care, more stakeholders should have been participating. It supports the dissemination of information and insights while simultaneously considering more experiences and perceptions.

This study identified several challenges that hinder integrating data into daily LTC practices. Addressing these challenges should be a key focus of future research. When prioritizing the adoption of data-informed care in LTC organizations, gaining insights into the status quo of their own data use might be the first step. For example, by conducting a data maturity assessment, several domains (eg, IT architecture, strategic management, data quality, and employee skills) can be evaluated regarding data usage and data-informed working and support for the transformation toward data-informed practices [79]. Gaining insight into these prerequisites for data-informed care within organizations might enhance the support for the development of strategies to embed data-informed care with primary processes. To realize the potential of data-informed care, LTC organizations must prioritize system interoperability, data quality, and a shared understanding of the data's purpose. Policies should support digital literacy at all levels and promote clear roles, responsibilities, and outcome-oriented data strategies. Building on recent national initiatives in the Netherlands, the Artificial Intelligence Navigator for LTC is well-positioned to integrate these insights for broader dissemination. Moreover, there is also a need to promote standardization and alignment of data entry processes across LTC organizations nationally. Variations in terminology, documentation practices, and digital systems currently limit the usability and reliability of data. Establishing uniform data entry guidelines and encouraging centralized, accessible information systems could reduce administrative burden, improve data quality, and prepare for real-time monitoring and personalized care planning nationwide.

Conclusion

Stakeholders in LTC recognize data as essential for personalized care; however, challenges like low standardization and fragmented systems hinder the transitions toward data-informed care. Enhancing data literacy, fostering organizational clarity, and implementing roles, such as data scientists, were considered necessities. Seen as a multidisciplinary approach, data-informed care aims to support collective understanding and inform decision-making, ultimately enriching quality of care by integrating diverse perspectives.

Abstract

Background: The global cancer burden is rapidly increasing, with 20 million new cases estimated in 2022. The world population aged ≥65 years is also increasing, projected to reach 15.9% by 2050, making cancer control for older patients urgent. Surgical resection is important for cancer treatment; however, predicting postoperative disability and mortality in older patients is crucial for surgical decision-making, considering the quality of life and care burden. Currently, no model directly predicts postoperative functional disability in this population.

Objective: We aimed to develop and validate machine-learning models to predict postoperative functional disability (≥5-point decrease in the Barthel Index) or in-hospital death in patients with cancer aged ≥ 65 years.

Methods: This retrospective cohort study included patients aged ≥65 years who underwent surgery for major cancers (lung, stomach, colorectal, liver, pancreatic, breast, or prostate cancer) between April 2016 and March 2023 in 70 Japanese hospitals across 6 regional groups. One group was randomly selected for external validation, while the remaining 5 groups were randomly divided into training (70%) and internal validation (30%) sets. Predictor variables were selected from 37 routinely available preoperative factors through electronic medical records (age, sex, income, comorbidities, laboratory values, and vital signs) using crude odds ratios (P<.1) and the least absolute shrinkage and selection operator method. We developed 6 machine-learning models, including category boosting (CatBoost), extreme gradient boosting (XGBoost), logistic regression, neural networks, random forest, and support vector machine. Model predictive performance was evaluated using the area under the receiver operating characteristic curve (AUC) with 95% CI. We used the Shapley additive explanations (SHAP) method to evaluate contribution to the predictive performance for each predictor variable.

Results: This study included 33,355 patients in the training, 14,294 in the internal validation, and 6711 in the external validation sets. In the training set, 1406/33,355 (4.2%) patients experienced worse discharge. A total of 24 predictor variables were selected for the final models. CatBoost and XGBoost achieved the largest AUCs among the 6 models: 0.81 (95% CI 0.80-0.82) and 0.81 (95% CI 0.80-0.82), respectively. In the top 15 influential factors based on the mean absolute SHAP value, both models shared the same 14 factors such as dementia, age ≥85 years, and gastrointestinal cancer. The CatBoost model showed the largest AUCs in both internal (0.77, 95% CI 0.75-0.79) and external validation (0.72, 95% CI 0.68-0.75).

Conclusions: The CatBoost model demonstrated good performance in predicting postoperative outcomes for older patients with cancer using routinely available preoperative factors. The robustness of these findings was supported by the identical top influential factors between the CatBoost and XGBoost models. This model could support surgical decision-making while considering postoperative quality of life and care burden, with potential for implementation through electronic health records.

KEYWORDS

older patients with cancer; postoperative outcomes; functional disability; machine learning; decision-making

Introduction

The global cancer burden is rapidly increasing, with an estimated 20 million new cases and 9.7 million deaths in 2022 [1]. In Japan, the lifetime risk of being diagnosed with cancer is approximately 65.5% and 51.2% for men and women, respectively [2].

XSL•FO
RenderX

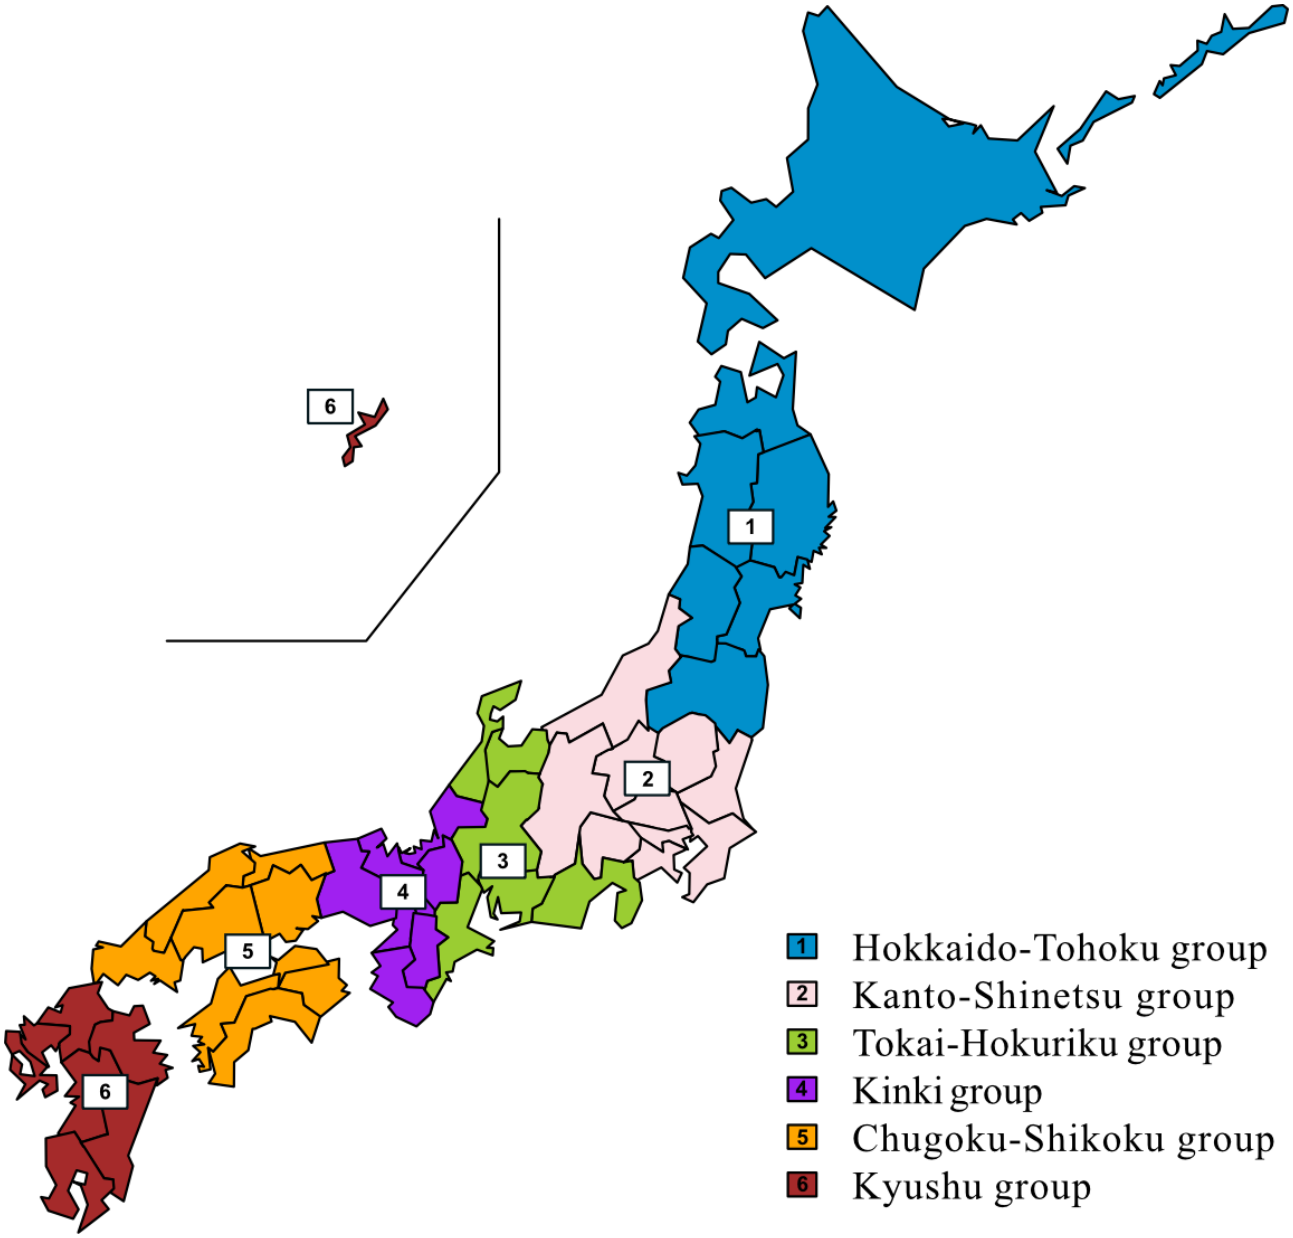
In addition, the global population is aging rapidly, with the proportion of those aged ≥65 years expected to increase from 9.1% in 2019 to 15.9% by 2050 [3]. Japan faces the most advanced stage of this demographic shift, with the population of older adults expected to increase from 28.8% in 2020 to 37.7% by 2050 [4]. Thus, cancer control for older patients has become an urgent issue worldwide, including in Japan.

Older patients with cancer often face challenges such as frailty [5], comorbidities [6-8], and socioeconomic status [6], which affect treatment outcomes and quality of life (QOL). Surgical resection is a key treatment, which requires careful consideration in older patients with cancer due to concerns about postoperative functional disability and its impact on long-term outcomes [9]. Some factors may influence surgical outcomes in older patients, including age [9], anemia [10], BMI [11,12], dementia [6,7], frailty [5], low household income [6], malnutrition [13], and smoking [14].

Considering the postoperative QOL and care burden on patients' families and society, it is important to predict not only postoperative mortality but also functional disability [15]. Hospital-associated disability, defined as functional disability following acute hospitalization, is recognized as a crucial outcome in older patients with significant impact on health care costs and long-term prognosis [16,17]. Some models can predict postoperative mortality [5,13]; however, few have addressed functional disability. A model after lower-extremity surgery [6] could predict the risk of in-hospital mortality and discharge to a nursing home, which is a surrogate for functional disability, in patients admitted from home. Currently, no model can directly predict functional disability after cancer surgery.

Therefore, this study aimed to develop a machine learning–based model for predicting postoperative functional disability and in-hospital mortality in patients with cancer aged ≥65 years using data from 70 hospitals across Japan. This approach will enable patients and their families to make informed decisions about undergoing cancer surgery, considering their postoperative QOL and care burden.

Methods



Study Design and Data Source

We conducted a retrospective cohort study to develop machine-learning models for predicting postoperative functional disability and in-hospital mortality in older patients with cancer. This study used data between April 2016 and March 2023 from 70 Japanese hospitals within the National Hospital Organization (NHO) database across 6 regional groups: Hokkaido-Tohoku group, Kanto-Shinetsu group, Tokai-Hokuriku group, Kinki group, Chugoku-Shikoku group, and Kyushu group (Figure 1) [18].

The NHO maintains 2 databases: (1) an administrative claims database based on the Diagnosis Procedure Combination–based Per-Diem Payment System [19] and a clinical information database based on the standardized structured medical record information exchange [20]. The administrative claims database contains patient information, such as age, sex, cost, comorbidities, complications, diagnosis, medical procedures, and medications. The clinical information database includes medical charts, laboratory data, and vital signs on a daily basis.

XSL•FO
RenderX

Figure 1. A total of 6 National Hospital Organization regional groups across Japan.

Participants

The study included patients aged ≥65 years who were admitted to NHO hospitals between April 2016 and March 2023 and underwent surgery for major cancers, including lung, stomach, colorectal, liver, pancreatic, breast, and prostate cancers. These cancer sites were selected because of their high incidence [2] and mortality rates [21] in Japanese and global cancer statistics [1]. The surgical procedures included both scopic and open surgeries under general anesthesia.

We excluded patients who had missing Barthel Index data at admission or discharge, were first included in the database at admission (no medical history available), underwent surgery more than 1 week after admission, or had the Barthel Index of 0 at admission. These exclusion criteria were applied because: (1) patients missing Barthel Index data could not be evaluated for outcome, (2) most of the predictor variables were missing if patients had no medical history, (3) we eliminated the effect of hospitalization on physical function from admission to surgery, and (4) the Barthel Index change from admission to discharge was an outcome variable, but patients with a minimum score of 0 at admission cannot show further decline [22].

Outcome Variables

The primary outcome was worse discharge, defined as either in-hospital death or postoperative functional disability. Postoperative functional disability was characterized as hospital-associated disability [16] (≥5-point decrease in the Barthel Index between admission and discharge) [17]. The Barthel Index consists of 10 items, including transfer, bathing, and stair climbing, used to evaluate activities of daily living on a scale of 0 - 100, with lower scores indicating a decline in physical function.

The secondary outcomes were health care costs and postoperative length of stay (LOS) in patients predicted to be at high risk and low risk for worse discharge. The optimal cut-off point for high-risk or low-risk classification was

XSL•FO
RenderX

determined using the Youden index [23] on the receiver operating characteristic (ROC) curve.

Predictor Variables

We identified the following 37 potential predictors of worse discharge based on previous studies: age (65 - 74, 75 - 84, and ≥85 years) [9], sex [24], underweight (BMI <18.5 kg/m^2) [12] and obesity (BMI ≥30 kg/m^2) [11], route of admission (home or nonhome), emergency admission, an estimated household income in the lowest tertile based on post-code (low income) [6], smoking (Brinkman Index ≥200) [14], functional dependence (Barthel Index ≤60) [22], surgical factors (open surgery, scopic surgery, and combined general and epidural anesthesia), the presence of gastrointestinal cancer (colorectal, liver, pancreas, and stomach), the cancer staging (0–II or III–IV) [25], the presence of recurrent cancer, Charlson Comorbidity Index (CCI) ≥3 [26,27], Hospital Frailty Risk Score (HFRS) ≥5 [28], comorbidities common in older patients (cerebrovascular disease, chronic pulmonary disease, congestive heart failure, dementia [8], diabetes, liver disease, myocardial infarction, peptic ulcer disease, peripheral vascular disease, and renal disease), medical history about cancer within 8 weeks before surgery that allowed the evaluation of preoperative chemotherapy [29] and radiotherapy [30] (chemotherapy, radiation, and surgery), vital signs (body temperature ≥38°C [31], systolic blood pressure >180 mm Hg [32]), and laboratory test values (albumin <3.5 g/dL [13], total bilirubin ≥2.0 mg/dL [33], creatinine ≥ 2.0 mg/dL [33], platelet <10^5/μL [33], and hemoglobin <11 g/dL [10]).

These predictors were measured as follows: age, sex, BMI, route of admission, emergency admission, income, cancer staging evaluated using the Tumor Nodes Metastasis (TNM) classification system [34], the presence of recurrent cancer, Brinkman Index, and Barthel Index were assessed at admission. Surgical factors were assessed during the surgery. The type of cancer was determined during the surgery using the *International Statistical Classification of Diseases and Related Health Problems, 10th Revision* (*ICD-10*) coding system [35]. Comorbidities were identified from *ICD-10* codes within 8 weeks before surgery (Table S1 in Multimedia Appendix 1). Notably, dementia was determined if it was either identified from *ICD-10* codes within 8 weeks before surgery or documented in the clinical summary at admission, as Japanese hospitals are required to include the dementia status of inpatients aged ≥65 years at admission [8]. Vital signs were measured closest to surgery after admission, and laboratory values were obtained using those measured closest to surgery within 8 weeks before surgery.

Statistical Analysis

We randomly selected one of the 6 NHO regional groups for the external validation set [36], while hospital data from the remaining 5 groups were randomly divided into the training (70%) and the internal validation (30%) sets [37]. The missing predictor variables were imputed using the "missRanger" [38], which is a random forest–based algorithm [39], assuming that the data are missing at random.

To summarize patient characteristics, continuous variables were expressed as mean (SD) or median (IQR), depending on the distribution of variables. The Wilcoxon rank-sum test or the Welch test was used to assess between-group differences. Categorical variables were expressed as proportions and compared using the χ^2 test.

In the training set, a double penalty was implemented by eliminating unnecessary variables to create a more practical model for clinical use [40]. The first penalty involved selecting predictor candidates with a crude odds ratio (OR) at P<.1 [41]. The second penalty to further narrow down the predictor candidates used the least absolute shrinkage and selection operator (Lasso) method, which allowed for the selection of clinically relevant variables with consistent relationships [36,42].

The selected factors were incorporated into 6 machine learning models: category boosting (CatBoost) [36,43], extreme gradient boosting (XGBoost) [36,42], logistic regression, neural networks [44], random forest [36], and support vector machine (SVM) [36]. Model performance was evaluated using the area under the ROC curve (AUC) with 95% CIs). Similarly, we calculated the accuracy, sensitivity, specificity, F_1-score, and the area under the precision-recall curve (PRAUC) to assess the performance of the models [36,37]. The precision-recall curve of the models was also shown.

We used the synthetic minority oversampling and random undersampling techniques to avoid overfitting owing to the imbalance between the positive and negative events [45]. The minority class was oversampled at 50%, 100%, and 200% of its original size, followed by random undersampling of the majority class to achieve equal numbers between classes. The models were trained using 10-fold cross-validation with grid search for hyperparameter optimization. Of these sampling ratios and hyperparameter combinations, those yielding the largest AUC were selected. We ranked the predictor variable using the Shapley additive explanations (SHAP) method [46] to assess the contribution of the predictors to the models. Moreover, considering higher cancer stages are associated with poorer postoperative outcomes [25], a multiple logistic regression was conducted to evaluate the interaction between cancer staging and other predictor variables using OR (95% CI). We examined interactions between cancer stage III–IV and the top 5 features based on the mean absolute SHAP value.

We analyzed the AUC difference between the models using the DeLong method [47], which was based on the model with the largest AUC in both internal and external validation. Sensitivity analyses were used to assess the impact of missing data and assessing 2 outcomes simultaneously (death or functional disability) on the models. For missing values, a complete case analysis was performed to confirm the robustness of the results obtained from the imputed data set. We also evaluated the AUC of the models when the models predicted only death in all patients or functional disability in patients with survival discharge. We conducted subgroup analyses by LOS, cancer type (breast, colorectal, liver, lung, pancreas, prostate, or stomach), and cancer staging (stage 0–I, II, III, or IV). For the LOS analysis, we calculated the 75th percentile of LOS for each cancer type separately and divided patients into LOS for each

XSL•FO
RenderX

cancer type <75th percentile (short-stay) and LOS ≥75th percentile (long-stay) groups [48].

For the analysis of secondary outcomes, we compared LOS and health care costs between patients at high and low risk based on the model with the highest AUC in both internal and external validation. Health care costs were assessed across various categories, including total, medical consultation, medication, medical procedure, surgical procedure, laboratory tests, hospital stay, and others. The currency conversion rate was 150 JPY to US $1.

All hypothesis tests had a 2-sided significance level of .05. All statistical analyses were performed using R version 4.3.1 (R Foundation for Statistical Computing) .

Ethical Considerations

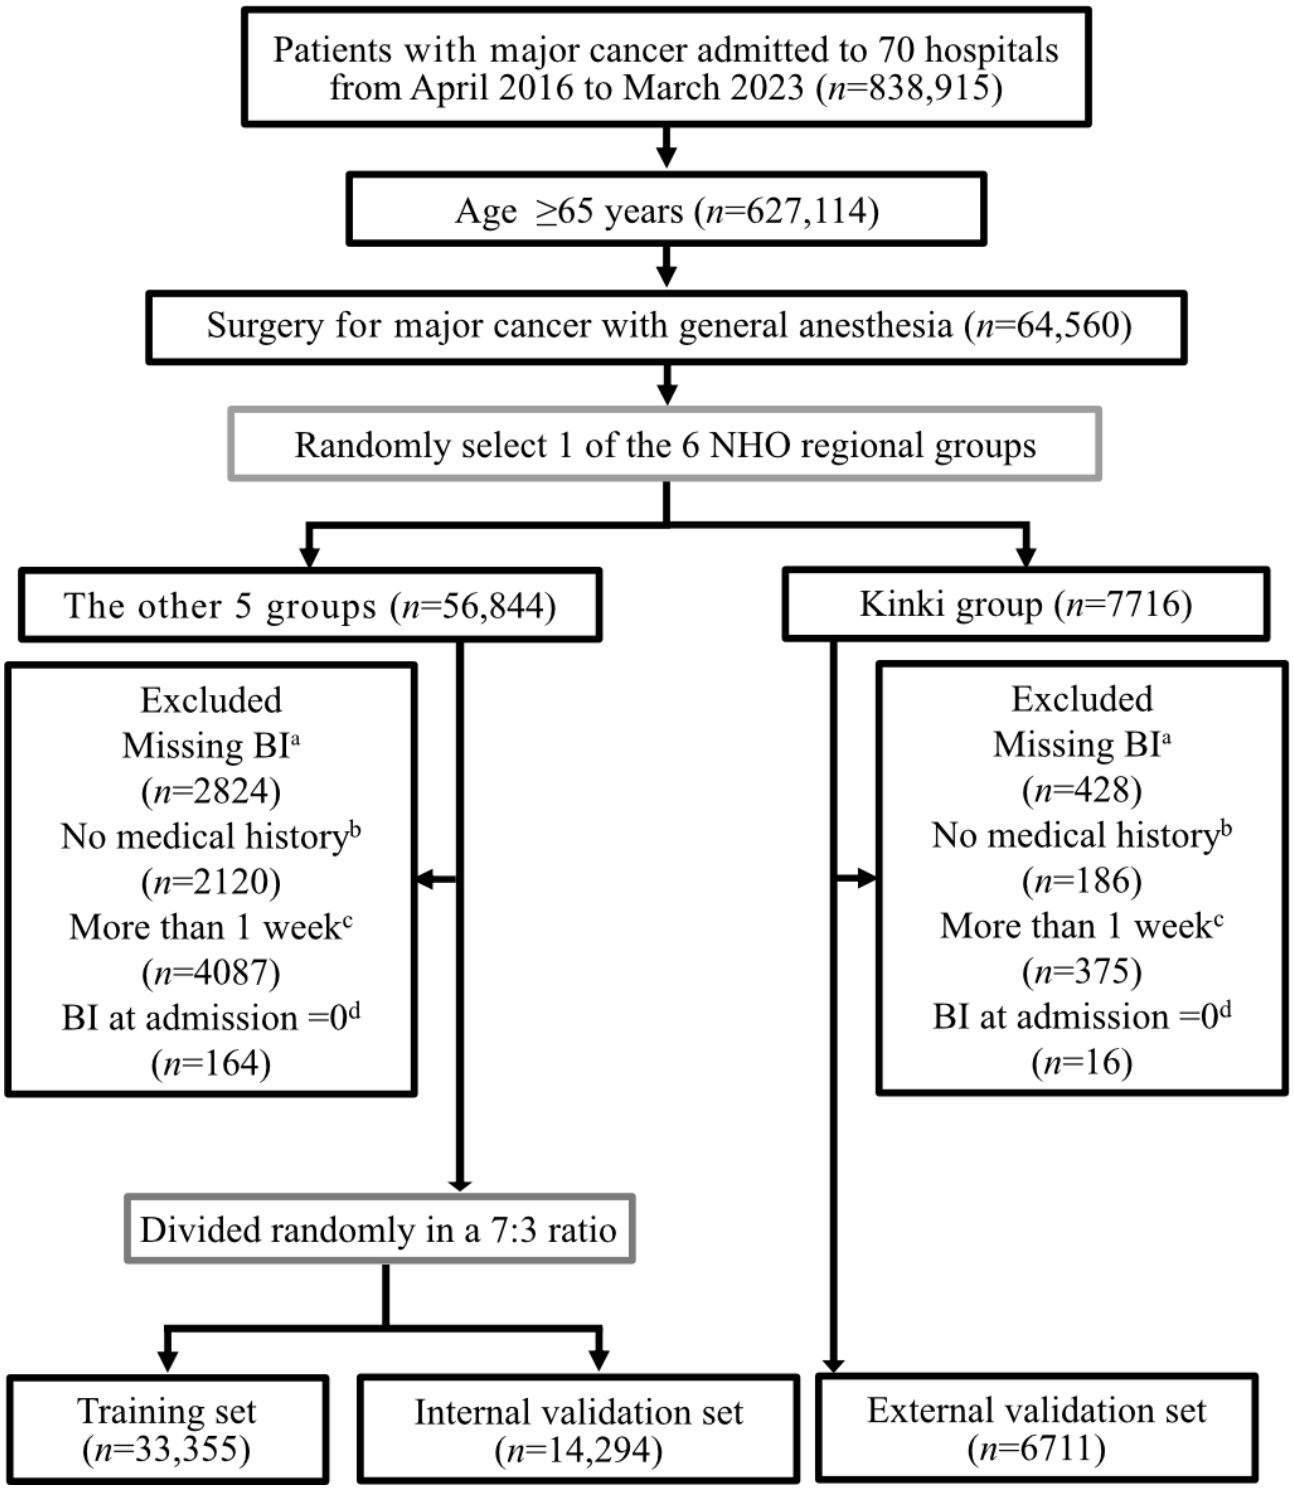
Our study was approved by the Institutional Review Board of Showa University (approval number 2023 - 129-A). Individual consent was not required because this was an opt-out study. This study conforms to the principles outlined in the Transparent Reporting of a multivariable prediction model for Individual Prognosis or Diagnosis (TRIPOD) statement.

Results

In total, 54,360 patients from 70 hospitals were included in this study (Figure 2): 6711 in the external validation set from Kinki group, 33,355 in the training set, and 14,294 in the internal validation set from the remaining 5 regional groups. In the training set, 1406/33,355 (4.2%) patients experienced worse discharge (Table 1). These patients were older (24.5% [344/1406] vs 5.8% [1864/31,949] for age ≥85 years), more likely to be admitted from nonhome (8.1% [114/1406] vs 0.9% [281/31,949]), and had higher prevalence of dementia (28.7% [403/1406] vs 5.6% [1783/31,949]), gastrointestinal cancer (64.3% [904/1406] vs 41.7% [13,326/31,949]), and advanced cancer stage (32.6% [458/1406] vs 24.2% [7716/31,9] for stage III–IV).

In the training set, we selected 31 predictor variables for worse discharge using crude OR (Table S2 in Multimedia Appendix 1). Further selection using the Lasso method resulted in 24 factors: age (75 - 84 y and ≥85 y), male sex, BMI <18.5 kg/m^2, nonhome admission, emergency admission, low income, Barthel Index at admission ≤60, open surgery, gastrointestinal cancer, cancer stage III–IV, HFRS ≥5, cerebrovascular disease, congestive heart failure, dementia, diabetes, liver disease, myocardial infarction, medical history of chemotherapy, systolic blood pressure ≥180 mm Hg, albumin<3.5 g/dL, creatinine ≥ 2.0 mg/dL, platelet <10^5/μL, and hemoglobin <11 g/dL. All 6 models were developed using these 24 variables.

Furthermore, the AUCs were 0.81 (95% CI 0.80 - 0.82) for CatBoost, 0.81 (95% CI 0.80 - 0.82) for XGBoost, 0.79 (95% CI 0.78 - 0.80) for random forest, 0.79 (95% CI 0.78 - 0.80) for neural networks, 0.78 (95% CI 0.77 - 0.80) for SVM, and 0.78 (95% CI 0.77 - 0.80) for logistic regression (Figure 3). CatBoost and XGBoost were the 2 models with AUC ≥0.80 and showed similar values with relatively high accuracy (0.76), sensitivity (0.72), specificity (0.76), F_1-score (0.20), and area under the precision-recall curve (PRAUC) (0.22). The performance metrics and precision-recall curves for all models are shown in Table S3 and Figure S1 in Multimedia Appendix 1, respectively. In the top 15 influential factors based on the mean absolute SHAP value, the CatBoost and XGBoost models had the same combination for the 14 features: dementia, age ≥85 years, age 74 - 85 years, gastrointestinal cancer, albumin <3.5 g/dL, open surgery, male sex, hemoglobin <11 g/dL, low income, nonhome admission, Barthel Index at admission ≤60, BMI <18.5 kg/m^2, diabetes, and stage III–IV (Figure 4). There were no significant interactions between stage III–IV and the top 5 influential features that both models shared (Table S4) in Multimedia Appendix 1.



For both the internal and external validation set, the CatBoost model had the largest AUCs among the 6 machine- learning models: 0.77 (95% CI 0.75 - 0.79) and 0.72 (95% CI 0.68 - 0.75), respectively (Figure 5). In sensitivity analysis, all 6 models maintained comparable performance to the main analysis (Table S5 in Multimedia Appendix 1). The CatBoost model achieved relatively high AUCs and showed consistent performance in complete cases (0.78, 95% CI 0.76 - 0.80; 0.72, 0.68 - 0.76), death only (0.77, 0.71 - 0.82; 0.73, 0.65 - 0.81), and functional disability only (0.77, 0.75 - 0.79; 0.71, 0.68 - 0.75) for internal and external validation, respectively.

In subgroup analyses, the models maintained consistent performance for LOS and cancer staging (Table S5 in Multimedia Appendix 1). However, the performance varied based on cancer types: the CatBoost model achieved a larger AUC in patients with stomach cancer (internal: 0.80, 95% CI 0.76 - 0.84; external: 0.81, 95% CI 0.69 - 0.92) but a smaller AUC in patients with prostate cancer (0.53, 95% CI 0.40 - 0.66; 0.46, 95% CI 0.28 - 0.63) than the main analysis.

Based on the CatBoost model, patients at high risk had significantly longer LOS (internal: median 13, IQR 9 - 19 d vs median 9, IQR 7 - 13 d; external: median 13, IQR 10 - 19 d vs median 10.0, IQR 7.0 - 14.0 d) and higher total health care costs (internal: median US $11,048, IQR US $9191 - 13,106 d vs median US $10,092, IQR US $7894 - 11,893; external: median 11,069, IQR US $9401 - 13,499 vs median US $10,371, IQR US $8820 - 11,936) than patients at low risk (all P<.01). However, the high-risk group had slightly lower surgical procedure costs than the low-risk group in internal validation and was comparable to the low-risk group in external validation (Table 2).

[a]Functional disability" means a decrease in the Barthel Index by ≥5 points at discharge compared with admission.

[b]LOS: length of stay.

Discussion

Principal Findings

In this study, we developed and validated machine-learning models to predict postoperative functional disability and mortality in older patients with cancer. Our CatBoost model achieved good performance using routinely available preoperative factors from electronic health records, indicating the potential for clinical implementation. Although ethical training for hospital staff is essential to prevent unauthorized disclosure of prediction results, implementing this model within closed electronic health record systems could provide protection for patient privacy.

The previous model for lower-extremity surgery had an AUC of 0.72 in external validation [6], similar to our model; however, our model directly predicted functional disability using the Barthel Index rather than using nursing home discharge as a surrogate. The model performance remained consistent across sensitivity analyses for death and functional disability separately, and complete cases, indicating the robustness of our findings. Notably, the model demonstrated higher predictive performance in patients with stomach or colorectal cancer than the other cancers, making it especially valuable for surgical decision-making in these patients.

The CatBoost model identified patients at high risk who had longer LOS and higher health care costs; however, surgical procedure costs were comparable between patients at high and low risk. These findings suggested that the increased cost was based on the varying postoperative course. Our model can support decision-making for older patients with cancer and their families regarding cancer surgery by providing insights into potential postoperative QOL and care burden. Moreover, if patients at high risk choose to undergo cancer surgery, our model may enable health care providers to implement targeted interventions such as intensive postoperative rehabilitation. Early identification of patients at high risk, such as those aged ≥85 years with dementia, can help health care providers prepare support systems, including caregiver education, social work consultation for home health support, and coordination with multidisciplinary teams [15]. This proactive approach may help reduce caregiver burden and improve outcomes for both patients and their families.

Of the 6 machine-learning models, the CatBoost and XGBoost models, with AUC ≥0.80, had the same combination of 14 features in the top 15 influential factors. These factors include established risk factors for poor postoperative outcomes in older patients as identified in previous studies: dementia [7], older age [9] (≥85 y and 75 - 84 y), male sex [24], anemia [10] (hemoglobin <11 g/dL), low income [6], underweight [12] (BMI <18.5 kg/m²), diabetes [49], and cancer staging [25]. In addition,

XSL•FO
RenderX

several factors serve as proxies for known risk factors. For frailty [5], the factors include (1) open surgery, which generally results in a more pronounced postoperative functional disability compared with scopic surgeries; (2) nonhome admission, likely indicating that patients are too frail to live independently; and (3) Barthel Index ≤60 at admission, indicating severe dependence [22]. For malnutrition [13], the proxies are (1) albumin <3.5 g/dL, a marker of malnutrition, and (2) gastrointestinal cancer, which often involves a long time to restart food intake after surgery, increasing the risk of malnutrition compared with other cancer types. The consistency between the 2 models in identifying these factors further validates their importance in predicting postoperative outcomes. Although chemotherapy and creatinine ≥2.0 mg/dL were not common in both models, these factors, identified as influential factors in previous studies [33,50], might also be included as predictor variables in future models. Moreover, our models included several factors associated with social vulnerability, such as age ≥85 years, dementia, and low income. Without ensuring model transparency to health care providers, our model could unconsciously contribute to reduced surgical care access for vulnerable populations. Therefore, when implementing our model in clinical practice, health care providers should consider these model characteristics to ensure fair allocation of health care resources [51].

Limitations

Our study has some limitations. First, we only validated all models using Japanese data. While our CatBoost model showed moderate accuracy (AUC: 0.7 - 0.9) [52] in both internal and external validation, the AUC in the external validation was lower than that in the internal validation as observed in a previous study [6]. Further studies using data from other countries and ethnic groups are necessary to evaluate model robustness, including potential bias and overfitting [51], and confirm their applicability to different health care systems. However, our study used data from 70 hospitals across Japan, which may enhance generalizability within the country. In addition, considering the global trend of population aging, our models may prove valuable for other countries in the future, particularly when these countries reach levels of demographic aging similar to Japan's current situation.

Second, we did not have information on predictor variables such as marital status [6] because of the retrospective nature of the study. Despite this limitation, our models had good predictive performance in the validation sets. While our analysis showed no significant interactions between stage III–IV cancer and the top features, future studies incorporating additional variables may evaluate such interactions to enhance the predictive performance of models.

Finally, the long-term prognosis of patients classified as high-risk by our models remains unclear. Further research is required to determine the extent of functional recovery and mortality in these patients. At a minimum, postoperative functional disability in patients at high risk indicates an increased immediate post-discharge burden on family caregivers and health care resources.

Conclusions

Our CatBoost model achieved good performance for predicting postoperative functional disability and mortality in older patients with cancer. This model could support surgical decision-making for patients and families while guiding targeted interventions by health care providers. This model, which is based on routinely available preoperative factors, has the potential for implementation in clinical settings through electronic health records.

Acknowledgments

We thank Masato Koizumi of the Information Technology Department in the National Hospital Organization Headquarters for his advice on data handling. This research was partially funded by the Daiwa Securities Foundation, JSPS KAKENHI (grant number 23K19882), and Pfizer Health Research Foundation.

Data Availability

The datasets generated or analyzed during this study are not publicly available due to being sensitive personal information. The analytic code is available from the corresponding author on request.

Abstract

Background: Alzheimer disease and related dementias (ADRD) exhibit prominent heterogeneity. Identifying clinically meaningful ADRD subtypes is essential for tailoring treatments to specific patient phenotypes.

Objective: We aimed to use unsupervised learning techniques on electronic health records (EHRs) from memory clinic patients to identify ADRD subtypes.

Methods: We used pretrained embeddings of non-ADRD diagnosis codes (*International Classification of Diseases, Ninth Revision*) and large language model (LLM)–derived embeddings of clinical notes from patient EHRs. Hierarchical clustering of these embeddings was used to identify ADRD subtypes. Clusters were characterized regarding their demographic and clinical features.

Results: We analyzed a cohort of 3454 patients with ADRD from a memory clinic at Massachusetts General Hospital, each with a specialist diagnosis. Clustering pretrained embeddings of the non-ADRD diagnosis codes in patient EHRs revealed the following 3 patient subtypes: one with skin conditions, another with psychiatric disorders and an earlier age of onset, and a third with diabetes complications. Similarly, using LLM-derived embeddings of clinical notes, we identified 3 subtypes of patients as follows: one with psychiatric manifestations and higher prevalence of female participants (prevalence ratio: 1.59), another with cardiovascular and motor problems and higher prevalence of male participants (prevalence ratio: 1.75), and a third one with geriatric health disorders. Notably, we observed significant overlap between clusters from both data modalities (χ^2_4=89.4; P<.001).

Conclusions: By integrating *International Classification of Diseases, Ninth Revision* codes and LLM-derived embeddings, our analysis delineated 2 distinct ADRD subtypes with sex-specific comorbid and clinical presentations, offering insights for potential precision medicine approaches.

Introduction

Background

Alzheimer disease (AD) is a neurodegenerative condition which affects more than 55 million people globally [1], and it is the seventh leading cause of death in the United States [2]. Despite its substantial public health burden, AD remains poorly understood, with limited treatment options available. AD and related dementias (ADRD) is an umbrella term that refers to multiple dementing illnesses, including AD, frontotemporal dementia (FTD), Lewy body dementia (LBD), and vascular dementia. AD is the most prevalent, accounting for around 60% to 80% of all dementia [2]. While these diseases have distinct clinical and neuropathological criteria, there is substantial overlap in both clinical presentation and autopsy findings at the individual patient level. For example, AD is clinically characterized by an amnestic-predominant dementia and neuropathologically defined by the build-up of amyloid beta (Aβ) plaques and neurofibrillary tangles formed by hyperphosphorylated tau protein [3]; however, these lesions are frequently accompanied by cerebrovascular disease (CVD) [4] or Lewy body pathology [5], which can influence clinical presentation. Likewise, LBD is defined by Lewy bodies but is also associated with plaques and tangles [6], which may accelerate the rate of cognitive decline [7]. This clinical and neuropathological heterogeneity limits our ability to target disease-modifying drugs to each specific neuropathological lesion. The so-called *amyloid hypothesis* has prevailed as the leading explanation of AD disease etiology, where it is held that Aβ toxicity leads to tau hyperphosphorylation, synaptic dysfunction, and neurodegeneration [8]. However, treatments targeting this hypothesis only show limited efficacy, which may stem in part from the clinical and neuropathological comorbidities [9], highlighting the need for a tailored approach to identify potential subtypes of disease and develop more effective targeted treatments.

Previous approaches to AD subtyping have focused on RNA expression, as well as brain imaging and cognitive assessments. Neff et al [10] identified 5 molecular subtypes of AD using RNA-sequencing signatures, characterized by different dysregulated pathways related to tau-mediated neurodegeneration, Aβ neuroinflammation, synaptic signaling, immune activity, mitochondria organization, and myelination. The Subtype and Stage Inference algorithm, applied to magnetic resonance imaging and positron emission tomography imaging data, identified distinct AD trajectories based on the rate and sequence of brain atrophy [11] and tau deposition [12]. Cognitive subtypes have also been identified based on memory, visuospatial and linguistic capabilities, and executive function [13-15]. These studies were limited to research cohorts with specific selection criteria, and it is unclear whether these subtypes can be extended to larger samples.

In contrast, real-world data, such as, electronic health records (EHRs), provide readily accessible large observational datasets and have been used for clustering AD or ADRD subtypes [16]. Unsupervised learning approaches on EHR datasets have revealed latent structure in conditions, such as autism [17,18] and Parkinson disease [19]. For AD subtyping, EHR-based approaches have used the *International Classification of Diseases* (*ICD*) or similar diagnostic codes, showing varying success depending on the methodology and population. Xu et al [20] used hierarchical clustering on EHR data from patients with AD, identifying subtypes related to CVD, mental illness, age of onset, and sensory problems. Alexander et al [21] found the following 5 patient subtypes: mental health, nontypical AD, typical AD, CVD, and men with cancer. They later identified a consistent subtype with early-onset AD, predominantly female participants, with a faster rate of progression using various machine learning methods [22]. Landi et al [23] used unsupervised deep learning to encode EHRs with temporal information, identifying early-onset AD, later-onset AD with mild comorbidities, and typical-onset AD with moderate symptoms. He et al [24] applied spectral clustering to EHRs of patients with AD, discerning 4 subtypes with significant demographic, mortality, and medication use differences. Tang et al [25] analyzed comorbidity patterns in EHRs of patients with AD, revealing sex-dependent variations. In another study, Tang et al [26] used EHRs with knowledge networks to predict AD onset and identify sex-specific genetic markers. These studies collectively highlight the varied methodologies and results in EHR-based research, emphasizing the complexity and potential of these approaches for a deeper understanding of AD.

However, none of these prior studies leveraged the richer representation of EHR data by embedding full sequences of clinical text. Transformers have emerged as state-of-the-art architecture for language modeling and are broadly characterized by the concept of attention [27]. Attention, named for its similarity to cognitive attention, enables the sharing of contextual information among word representations without directly encoding their sequence. The transformer used in this work is a version of the Bidirectional Encoder Representations from Transformers (BERT) architecture [28]. This architecture consists of an encoder which can be fine-tuned on downstream applications and domains. Specifically, we use Clinical BERT [29], which is pretrained on a large corpus of clinical notes from the critical care database Medical Information Mart for Intensive Care (MIMIC) [30].

Objectives

In this work, we used both pretrained embeddings of *ICD-9* code diagnostic data and transformer-derived embeddings of clinical notes. This dual approach addresses the limitations of previous studies by incorporating structured *ICD* codes, which allow us to study subtypes of patients with similar *ICD* codes (non-ADRD diagnosis in charts), and unstructured clinical notes, which capture detailed clinical history and manifestations provided by specialists. By combining these 2 modalities, we aimed to enhance the clustering of patient ADRD subtypes.

Methods

Cohort Selection Process

Patients were selected from the Massachusetts General Hospital (MGH) EHR database. The selection criteria included patients who had at least 2 MGH memory clinic visits (either an in-person office visit or a video telemedicine visit) from August

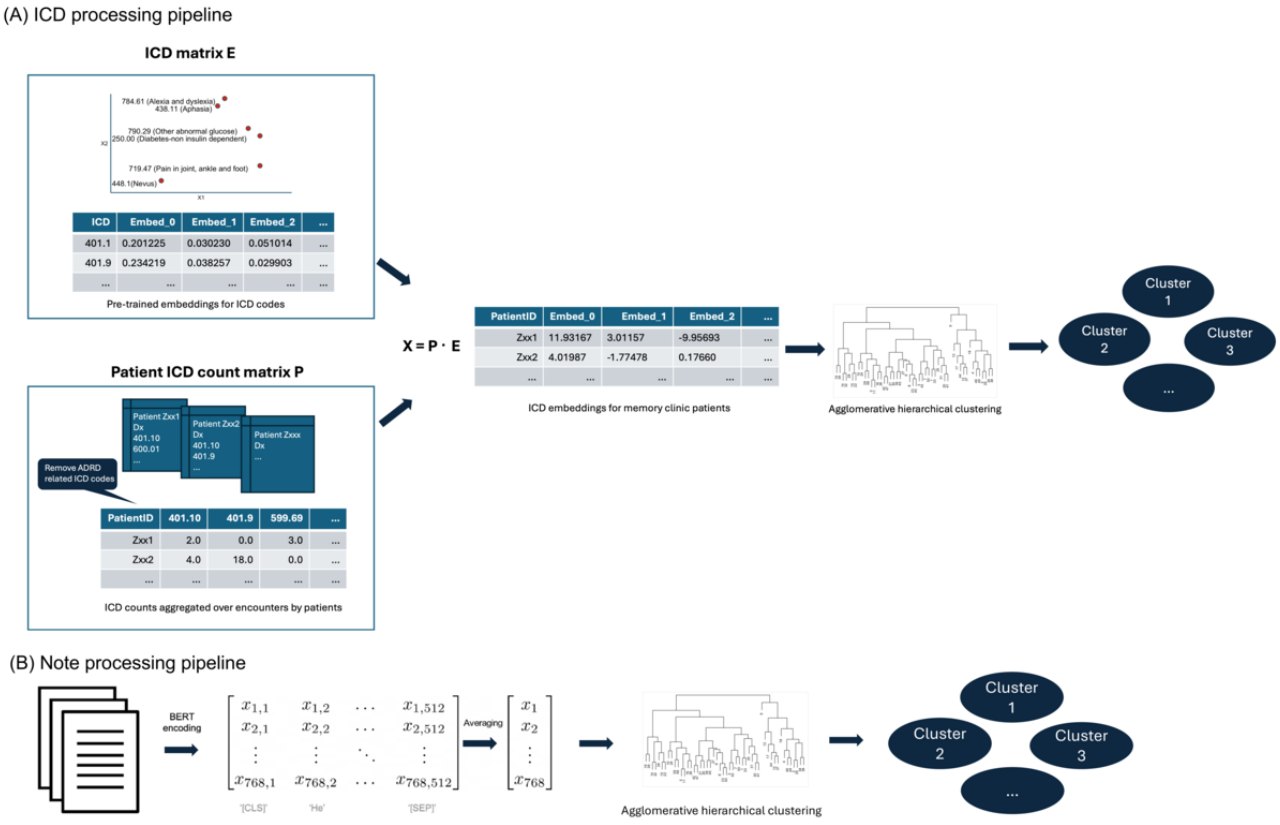
XSL•FO
RenderX

2015 to June 2022, were aged >50 years at their first visit, and had progress notes of substantial length (≥512 characters). These criteria were chosen due to the richness of the notes for the clustering analysis and the high quality of the ADRD diagnosis from specialists. From the identified patient cohort, 2 datasets were extracted as follows: one containing structured diagnostic *ICD* code data from the patients' entire medical history and another consisting of unstructured clinical notes authored by memory clinic specialists, limited to the most recent visit. We chose only the most recent visit note because it typically consolidates the patient's prior history, thereby reducing redundancy and providing a focused, up-to-date clinical snapshot. In addition, the dataset was filtered to exclude patients who did not have ADRD diagnoses (Multimedia Appendix 1), as well as those who lacked non-ADRD *ICD* codes (ie, patients who only had ADRD *ICD* codes were excluded).

Ethical Considerations

This study was approved by the Mass General Brigham Institutional Review Board (protocol 2015P001915), which granted a waiver of informed consent for secondary analysis of electronic health data. No participant compensation was provided. Electronic health data was queried from Epic and securely stored on servers within the Mass General Brigham firewall. Access was restricted to authorized study personnel, in full compliance with institutional privacy and data security policies.

Embedding Methodology



ICD Codes

Before clustering, it was necessary to derive a patient-level representation that encoded information relevant to phenotype in a single vector. While some prior work has relied on one-hot encoding (where categorical data are converted into binary vectors) of clinical data to represent patient phenotype, we leverage existing pretrained embeddings that capture relevant biomedical semantics in their latent representations of clinical concepts. In particular, we use a set of 300-dimensional embeddings for *ICD-9* codes, derived from prior work by Choi et al [31].

For a count-based encoded representation of *m ICD-9* codes across our cohort, $P \in R^{3454 \times m}$, and an embedding matrix, $E \in R^{m \times 300}$, our design matrix for clustering, $X \in R^{3454 \times 300}$, is given by the following matrix multiplication: $X = P \cdot E$.

This matrix multiplication sums the non-ADRD *ICD* embeddings across a patient record, and the resultant embedding is directly affected by the number of times each code appears in a patient's history. ADRD codes were dropped from the matrix *P* to not confound clustering based on structured ADRD phenotype. A schematic depicting the *ICD* representation pipeline is provided in Figure 1A.

XSL•FO
RenderX

Clinical Notes

Clinical notes were encoded using Clinical BERT before clustering. To derive patient-level representations of clinic notes, several preprocessing steps were undertaken. First, unwanted delimiter characters were stripped from patient notes, and notes were chunked into contiguous sections of up to 1024 characters. This resulted in a distribution of token numbers of ~200 to 300 per note following BERT's WordPiece encoding of input sequences. After passing through the transformer encoding, we took the final layer representation averaged over the 12 attention heads, such that each note was represented by a matrix of dimension (768, n), corresponding to each of the n input tokens having a 768-dimensional contextual vector representing it. Following this encoding, the representation was averaged over the token dimension to arrive at a single 768-dimensional vector for the whole note. This was explored using both simple averaging (arithmetic mean) over the token dimension, as well as attention-weighted averaging based on row-wise entropy of the final layer attention matrix. Attention-weighted averaging was used in patient representations due to the resultant lower inertia and increased silhouette score on average. A schematic depicting the note representation pipeline is provided in Figure 1B.

Attention-Weighted Averaging

For a given input sequence of length n, the final layer representation in a transformer model has an associated self-attention matrix, $A \in R^{n \times n}$. For BERT-based models, n is ≤512 due to the constraint on the length of the context window. To provide weights for averaging the embedding, $E \in R^{768 \times n}$, over the token dimension, we compute the row-wise differential entropy of the attention matrix, given in equation (1). Differential entropy is the continuous analog of Shannon entropy, which is usually only defined for discrete random variables [32]. In particular, the method described in Ebrahimi et al [33] is used to approximate the differential entropy, implemented in the Python (Python Software Foundation) library *SciPy version 1.7.3* [34], as the closed-form expression for the attention distribution for a given row $f(x)$ is not known analytically from the values of attention sampled. The differential entropy for a row i is given by

and the corresponding vector $h \in R^{n \times 1}$ corresponds to the entropy across every row. From the row-wise entropy, this vector is softmaxed to obtain the corresponding weights, $w \in R^{n \times 1}$, as follows:

The resultant embedding for a note sequence, $N \in R^{768 \times 1}$, is then given by the matrix multiplication as follows:

and the final patient-level representation is the simple average over all note fragments for a given patient, for their most recent encounter. A visualization of attention matrices with varying row-wise entropy and thus varying weighting per token is provided in Figures S1 and S2 in Multimedia Appendix 2.

Hierarchical Clustering

Clustering analysis was performed on *ICD-9* embeddings and clinical text representations to identify ADRD subtypes. We selected hierarchical agglomerative clustering with Ward linkage due to its ability to capture the hierarchical structure of clinical data, as seen in *ICD-9* codes (eg, metabolic disorders branching into type 1 and type 2 diabetes) and clinical notes (eg, cognitive impairment branching into memory loss and aphasia). Cluster quality was evaluated using elbow plots and silhouette scores, with implementation via *Scikit-learn v1.0.1* [35].

Optimal Transport

To address provider-specific effects in embeddings of clinical notes, we first applied Uniform Manifold Approximation and Projection (UMAP) to reduce the dimensionality of the data and then applied the earth mover distance transport approach using the Python *Optimal Transport* package [36]. *Optimal Transport* provides a mathematical framework to minimize the cost of transforming one distribution into another, which can address the problem of domain adaptation [37]. Domain adaptation involves adjusting data from different sources to make their data distributions more comparable, ensuring that models trained on these data perform well across various settings. In this context, the earth mover distance method was used to align the embeddings from various providers to a standard reference. This alignment ensured that the subsequent clustering analysis was less skewed by provider-related differences, allowing a more accurate interpretation of the underlying phenotypic variation.

Enrichment Analysis: ICD Clusters

ICD clusters were phenotypically characterized by testing for enrichment of *ICD-9* codes within each cluster. For each cluster, a 2×2 contingency table was generated for each *ICD-9* diagnosis code, comparing counts of patients with that code within cluster to counts of patients with that same code in other clusters. A chi-square test for enrichment was performed; the prevalence ratio (PR), calculated as the prevalence of each code in one cluster divided by its prevalence in the rest, was calculated to measure the strength of the association. A Bonferroni correction was applied to the resultant P values to correct for multiple comparisons, and *ICD* codes in each cluster were ranked by corrected P value to characterize the most significant enrichments. All P values in this investigation were two-sided, with a postcorrected α of 0.05 to determine significance. The top-10 significant diagnoses with the highest PR were extracted from each cluster for interpretation. If a cluster lacked significant diagnoses, the top diagnoses with the highest PR among the nonsignificant ones were selected. The enrichment analyses were conducted in Python version 3.8.15.

Topic Modeling: Note Clusters

We used BERTopic [38], using the Python package *BERTopic* v0.16.0, to identify representative topics and key terms within each note cluster. Embeddings obtained through optimal transport were directly used for clustering and topic assignment, bypassing the need for additional embedding and dimensionality

XSL•FO
RenderX

reduction steps. Before conducting cluster-based term frequency–inverse document frequency (TF-IDF) for topic assignment, the clinical text was preprocessed using a vectorizer to remove stop words and exclude common terms that appeared too frequently across most notes. Furthermore, to fine-tune and enhance the word representation of topics, we applied the KeyBERTInspired model, which extracts keywords by leveraging embeddings and cosine similarity to find the words with the closest semantic relationship to the note texts, thereby making them more representative of the topics. Following the extraction of representative terms within each cluster, we used GPT-4 (OpenAI) [39], a state-of-the-art large language model (LLM), to enhance interpretability. GPT-4 summarized the representative words provided by BERTopic into coherent themes with greater clinical significance, such as specific medical conditions, treatments, and medications. The PR, calculated as the prevalence of each word in one cluster divided by its prevalence in the rest, was calculated to measure the strength of the semantic relationship. The BERTopic modeling and analyses were conducted in Python version 3.9.6.

ADRD Diagnosis Categorization

The categorization of ADRD diagnoses was conducted using an extensive list of diagnostic names based on disease etiology. This list was meticulously reviewed for each unique diagnosis name recorded for the MGH memory clinic patients in the EHR system. The ADRD diagnoses categories included AD; dementia unspecified; FTD; LBD; vascular cognitive impairment (VCI); and others, such as posterior cortical atrophy (PCA), progressive supranuclear palsy, corticobasal degeneration, and primary progressive aphasia. An expert behavioral neurologist (JRD) provided critical input during this process, helping to develop a comprehensive mapping list that correlates specific diagnosis names with their corresponding ADRD categories. The application of this mapping to the data was performed using R version 4.3.2 (R Foundation for Statistical Computing). The full list of diagnosis names corresponding to ADRD diagnosis categories is provided in Multimedia Appendix 1.

Cluster Characterizations

To assess associations between clusters and sex, as well as ADRD diagnoses, we used the chi-square test. For each cluster, a 2×2 contingency table was generated for each variable, comparing the counts of patients with the characteristic within the cluster to those in other clusters. The PR, defined as the prevalence of a characteristic in one cluster divided by its prevalence in the remaining clusters, was calculated to measure the strength of the association: 1 indicates no difference in prevalence between the 2 groups, >1 indicates higher prevalence in the first group, and <1 indicates lower prevalence in the first group. In addition, to examine variations in the age of onset across clusters, we initially conducted a Kruskal-Wallis Rank Sum Test using the *stats* package from R. η^2 (calculated by subtracting the number of groups from the Kruskal-Wallis H statistic plus one, and then dividing this result by the total number of observations minus the number of groups) based on the H statistic was reported as the effect size: values closer to 0 indicate a smaller effect and values closer to 1 indicate a larger effect. Following significant findings, further post hoc analyses using the Dunn test were performed to delineate differences between groups. The *P* values were adjusted for multiple comparisons using the Benjamini-Hochberg method to control the false discovery rate (FDR). Age-of-onset data were rigorously annotated by human experts reviewing clinical notes; where notes did not specify an exact age of onset, the age at the first clinical visit within the memory clinic was used as an approximation. Finally, we conducted a chi-square test between *ICD* clusters and note clusters to test whether patient cluster assignment was consistent across note and *ICD* representations. If the contingency table was larger than 2×2, Cramér V (calculated as the square root of the chi-square statistic divided by the product of the sample size and the minimum dimension minus one) was reported as the effect size: 0 indicates no association and 1 indicates a strong association. Standardized residuals (standardized differences between the observed count and the expected count) were reported for each cell: values close to 0 indicate the observed count is close to the expected count, positive values indicate the observed count is higher than expected, and negative values indicate the observed count is lower than expected. All statistical analyses were conducted in R version 4.3.2.

Results

Study Population

Our final study population consisted of 3454 patients from the MGH tertiary care memory clinic with clinical notes and *ICD* codes in the EHR system. The average age of onset for patients was 72.1 (SD 9.5) years, with 1678 (48.58%) being female. The majority were White (n=3059, 88.56%), followed by Asian (n=90, 2.61%), Black or African American (n=77, 2.23%), American Indian or Alaska Native (n=4, 0.12%), and Native Hawaiian or Other Pacific Islander (n=1, 0.03%). In addition, 103 (2.98%) identified as belonging to other races, and race data were not available for 120 (3.47%) patients. Regarding ethnicity, 3020 (87.43%) identified as non-Hispanic, 106 (3.07%) as Hispanic, and ethnicity data were not available for 328 (9.5%) patients. AD was the most prevalent diagnosis, affecting 1317 (38.13%) patients, followed by dementia unspecified, which accounted for 1101 (31.88%) patients. Each encounter recorded only one diagnosis name, and only the most recent encounter was used. The patient selection details are illustrated in Figure 2. The demographic and ADRD diagnosis breakdowns are provided in Table 1 and ADRD categorization details are provided in Multimedia Appendix 1.

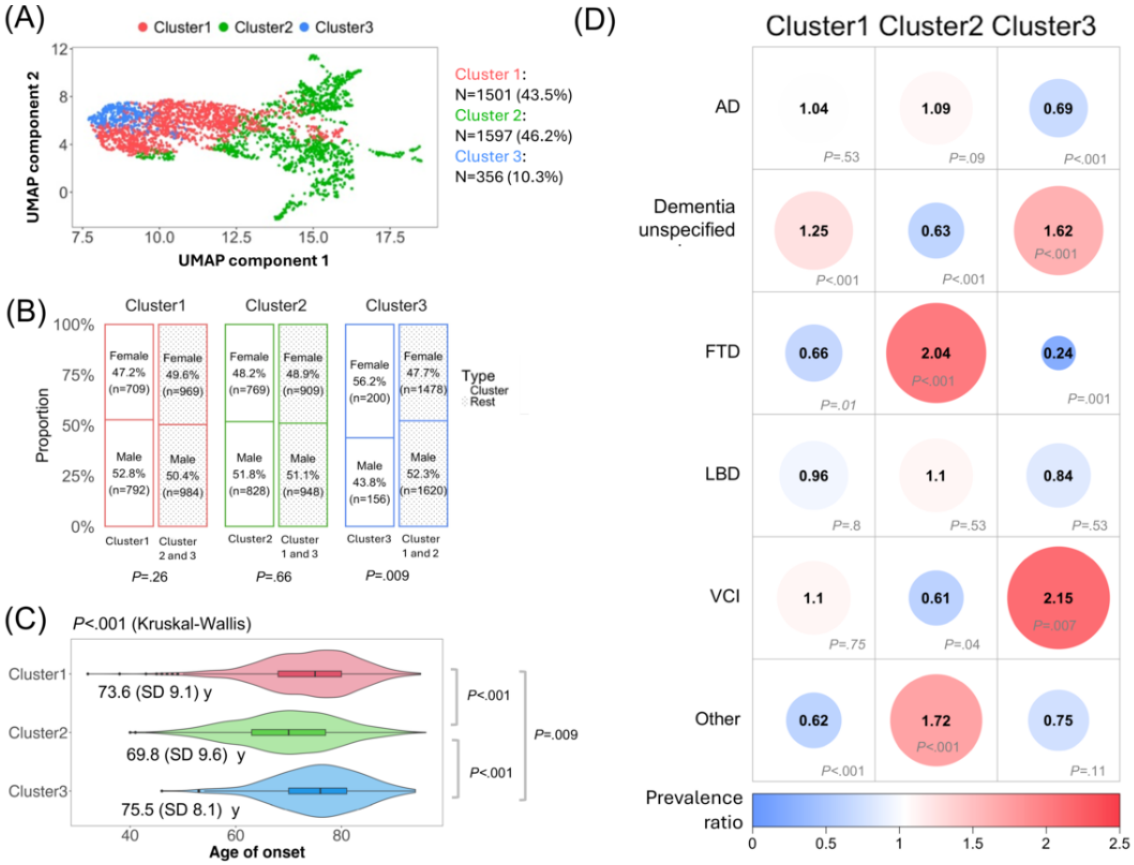
ICD Clustering



To investigate the clinical heterogeneity within ADRD, we clustered the embeddings of non-ADRD *ICD* codes assigned to this tertiary care sample from the MGH ADRD cohort. We hypothesized that this approach would reveal distinct clinical subtypes based on clinical comorbidities, which were associated with demographics (ie, age of onset and sex). The hierarchical agglomerative clustering method revealed 3 distinct clusters in the embeddings of non-ADRD *ICD* codes, as determined by the silhouette score. Figure 3A depicts a heatmap of enriched *ICD* codes across each cluster, and a 2D UMAP projection of these *ICD* code embeddings, colored by cluster, is displayed in Figure 4A. The distribution of patients across the clusters was as follows: cluster 1 included 1501 (43.46%) patients, cluster 2 included 1597 (46.24%) patients, and cluster 3 included 356 (10.31%) patients. Detailed summary statistics for these clusters are presented in Table 2.

Figure 3. Heatmap of enrichment in International Classification of Diseases (ICD) clusters and topics in note clusters. (A) This heatmap displays the enrichment of ICD-9 codes across ICD embedding clusters. Cluster 1 is primarily dominated by skin-related and certain cardiovascular conditions. Cluster 2 is marked by its exclusive and high prevalence ratios (PR) in psychiatric and behavioral conditions. Cluster 3 shows a diverse set of conditions with a significant prevalence of respiratory, pain-related, and complicated diabetic mellitus. (B) This heatmap displays representative words for each note cluster identified through topic modeling. Cluster 1 is primarily dominated by psychiatric manifestations and medications. Cluster 2 highlights cardiovascular, motor, and sensory issues. Cluster 3 covers a variety of symptoms and conditions, including autoimmune issues, behavioral and movement disorders, sleep disturbances, etc. In both (A) and (B), the color intensity of each code or word-cluster pairing reflects the PR (prevalence of code or word in observed group divided by prevalence in other groups) associated with that code or word. Words colored as exclusive were only present in one cluster.

XSL•FO
RenderX

Figure 4. Clustering of International Classification of Diseases (ICD) embeddings and their demographic and diagnostic associations. (A) Uniform Manifold Approximation and Projection (UMAP) visualization of ICD embeddings were characterized by 3 clusters: cluster 1 includes 1501 (43.5%) patients, cluster 2 comprises 1597 (46.2%) patients, and cluster 3 contains 356 (10.3%) patients. (B) Bar plot showing prevalence for sex by cluster, significance based on a chi-square test. Notably, cluster 3 has a significantly higher proportion of female participants compared to male participants (P_{FDR}=.009). (C) Violin plot illustrating the distribution of age of onset across clusters. Each violin plot shows the kernel density estimate of the data, with the center line representing the median age of onset. Box plot elements are overlaid, where the box limits indicate the upper and lower quartiles, and the whiskers extend to 1.5 times the IQR. Individual points are hidden for clarity. Significant differences are observed, with cluster 2 showing the earliest average age of onset at 69.8 (SD 9.6) years, and cluster 3 the latest at 75.5 (SD 8.1) years (P<.001). (D) Heatmap showing prevalence ratio for Alzheimer disease and related dementias (ADRD) diagnoses across clusters, significance derived from a chi-squared test. Clinical diagnoses include Alzheimer disease (AD); dementia unspecified; frontotemporal dementia (FTD); Lewy body dementia (LBD); vascular cognitive impairment (VCI); and others such as posterior cortical atrophy (PCA), progressive supranuclear palsy (PSP), corticobasal degeneration (CBD), and primary progressive aphasia (PPA). Significant distribution variations are evident across clusters. The circle size, color, and number indicate the magnitude of the prevalence ratio. Blue indicates underrepresentation while red indicates overrepresentation. *P* values were corrected with false discovery rate adjustments.

We examined differences in non-ADRD *ICD* code frequency across patient *ICD* embedding clusters (Figure 3A). In cluster 1, diagnoses, such as seborrheic keratoses (χ^2_1=243.15; P_{FDR}<.001; PR=3.32), actinic keratosis (χ^2_1=236.53; P_{FDR}<.001; PR=3.91), pure hypercholesterolemia (χ^2_1=199.13; P_{FDR}<.001; PR=2.71), history of basal cell cancer (χ^2_1=196.22; P_{FDR}<.001; PR=4.45), and nevus (χ^2_1=184.53; P_{FDR}<.001; PR=4.23), show notably high PRs. These diagnoses largely fall into skin-related disorders (such as various types of skin cancer and keratoses). Cluster 2 appears to be unique, with top PRs noted only for clinical signs, such as disinhibition behavior (χ^2_1=1.14; P_{FDR}=.99; PR=4.65), alexia (χ^2_1=0.426; P_{FDR}=.99; PR=3.49), and orofacial dyskinesia (χ^2_1=0.017; P_{FDR}=.99; PR=2.33), suggesting behavioral and psychiatric manifestations which are consistent with the FTD enrichment and earlier onset noted above. Notably, although these diagnoses did not reach significance in cluster 2, they were absent in the other clusters. Moreover, many diagnoses in cluster 2 were marked with a lack of PR, indicating a lower relevance of these diagnoses compared to clusters 1 or 3. Cluster 3 exhibited significant increases in diagnoses from a variety of categories, including respiratory issues (eg, cough: χ^2_1=339.47; P_{FDR}<.001; PR=3.77 and shortness of breath: χ^2_1=306.60; P_{FDR}<.001; PR=6.03), chronic pain (χ^2_1=460.55; P_{FDR}<.001; PR=4.80), musculoskeletal problems (eg, bilateral low back pain without sciatica: χ^2_1=456.91; P_{FDR}<.001; PR=4.80 and foot pain: χ^2_1=372.91; P_{FDR}<.001; PR=3.86), and complications of diabetes mellitus. Notably, diabetes mellitus (type 2 with autonomic neuropathy: χ^2_1=322.98; P_{FDR}<.001; PR=11.60 and insulin-dependent diabetes: χ^2_1=308.96; P_{FDR}<.001; PR=11.30) had exceptionally high PRs, suggesting a very strong association with these severe diabetes conditions in cluster 3.

[a]Age of onset was manually annotated by experts viewing clinical notes; for notes without age of onset, we approximated with the age of first encounter.

[b]Dx: diagnosis.

[c]AD: Alzheimer disease.

[d]FTD: frontotemporal dementia.

[e]LBD: Lewy body dementia.

[f]VCI: vascular cognitive impairment.

[g]Includes posterior cortical atrophy, progressive supranuclear palsy, corticobasal degeneration, and primary progressive aphasia.

Furthermore, statistical analyses revealed significant associations between ICD cluster membership, demographic variables, and diagnostic categories. Cluster 3 had an overrepresentation of female participants relative to clusters 1 and 2 (χ^2_1=8.8; P_{FDR}=.009; PR=1.178); however, clusters 1 and 2 showed no significant differences in sex distribution (cluster 1: χ^2_1=1.8; P_{FDR}=.26 and cluster 2: χ^2_1=0.2; P_{FDR}=.66; Figure 4B). In addition, the age of onset varied significantly among the ICD clusters (Kruskal-Wallis χ^2_2=182.6; P_{FDR}<.001, η^2=0.052). Cluster 2, with a mean age of onset of 69.8 (SD 9.6) years, had a significantly earlier age of onset compared with clusters 1 (Z=10.13; P_{FDR}<.001) and 3 (Z=−8.83; P_{FDR}<.001). Moreover, cluster 1 (mean 73.6, SD 9.1 years) had an earlier onset than cluster 3 (mean 75.5, SD 8.1 years; Z=−2.61; P_{FDR}=.009; Figure 4C). Cluster 1 was significantly enriched by dementia unspecified (χ^2_1=20.2; $_{FDR}$<.001; PR=1.252); cluster 2 was significantly enriched by FTD (χ^2_1=23.9; $_{FDR}$<.001; PR=2.039) and other rare ADRDs (χ^2_1=41; $_{FDR}$ <.001; PR=1.724); and cluster 3 was significantly enriched by VCI (χ^2_1=8.6; $_{FDR}$=.007; PR=2.147) and dementia unspecified (χ^2_1=50.2; $_{FDR}$<.001; PR=1.622). In contrast, no cluster was significantly enriched by AD, though AD was significantly underrepresented in cluster 3 (cluster 1: χ^2_1=0.6; $_{FDR}$=.53; cluster 2: χ^2_1=3.5; $_{FDR}$=.09; and cluster 3: χ^2_1=19.4; $_{FDR}$<.001; Figure 4D) or LBD (cluster 1: χ^2_1=0.1; $_{FDR}$=.80; cluster 2: χ^2_1=0.5; $_{FDR}$=.53; and cluster 3: χ^2_1=0.5; $_{FDR}$=.53; Figure 4D). the UMAP projections colored by sex, age of onset, and ADRD diagnoses are available in Figures S3A, S3B, and S3C, respectively, in Multimedia Appendix 2.

Note Clustering

Initially, a provider effect was detected in the UMAP projection of note embeddings from the latest clinical notes of 3454 patients (Figure S4A in Multimedia Appendix 2). To address this, we used an optimal transport method, aligning the embeddings from all providers to the 2D embedding of a selected reference provider (Figure S4B in Multimedia Appendix 2). Following this alignment, hierarchical agglomerative clustering was applied to the adjusted note embeddings, revealing 3 distinct clusters, as determined by the silhouette score. The adjusted UMAP projection, color coded by cluster, is presented in Figure 5A. The patient distribution within these clusters was as follows: cluster 1 included 1280 (37.06%) patients, cluster 2 included 1161 (33.61%) patients, and cluster 3 included 1013 (29.33%) patients. Detailed summary statistics for each cluster are outlined in Table 3.

Figure 5. Clustering of note embeddings and their demographic and Alzheimer disease and related dementias (ADRD) diagnosis associations. (A) Uniform Manifold Approximation and Projection (UMAP) visualization of note embeddings characterized by 3 clusters: cluster 1 includes 1280 (37.1%) patients, cluster 2 includes 1161 (33.6%) patients, and cluster 3 includes 1013 (29.3%) patients. (B) Bar plot showing prevalence for sex by cluster, with significance based on chi-square tests. Notably, cluster 1 and cluster 3 were both enriched by female participants (P<.001) while cluster 2 was enriched by male participants (P<.001). (C) Violin plot illustrating the distribution of age of onset across clusters. Each violin plot shows the kernel density estimate of the data, with the center line representing the median age of onset. Box plot elements are overlaid, where the box limits indicate the upper and lower quartiles, and the whiskers extend to 1.5 times the IQR. Individual points are hidden for clarity. Significant differences are observed, with cluster 2 showing the latest average age of onset at 72.8 (SD 9.2) years, and cluster 1 the earliest at 71.5 (SD 9.3) years (P<.001). (D) Heatmap showing prevalence ratio for ADRD diagnoses across clusters, with significance derived from a chi-square test. Diagnoses include Alzheimer disease (AD); dementia unspecified; frontotemporal dementia (FTD); Lewy body dementia (LBD); vascular cognitive impairment (VCI); and others such as posterior cortical atrophy (PCA), progressive supranuclear palsy (PSP), corticobasal degeneration (CBD), and primary progressive aphasia (PPA). No significant distribution variations are observed across clusters (P>.05). The circle size, color, and number indicate the magnitude of the prevalence ratio. Blue indicates underrepresentation while red indicates overrepresentation. *P* values were corrected with false discovery rate (FDR) adjustments.

[d]FTD: frontotemporal dementia.

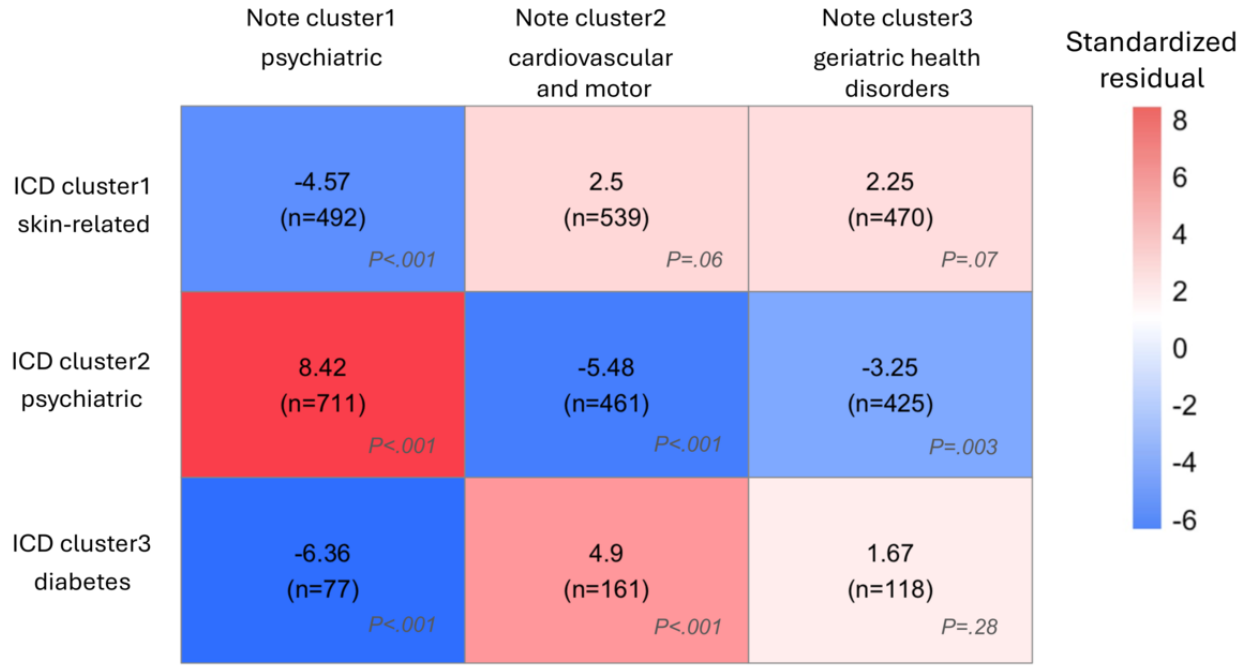
[e]LBD: Lewy body dementia.

[f]VCI: vascular cognitive impairment.

[g]Includes posterior.

We extracted common topics from each note cluster using topic modeling and examined the distribution of ADRD diagnoses across these clusters. In cluster 1, we found more terms related to psychiatric manifestations (eg, compulsive, indifference, and anxiety) and medications (eg, clozaril, trazodone, and sertraline), with a slight but nonsignificant enrichment in AD diagnosis (χ^2_1=4.9; P_{FDR}=.14; PR=1.10). Cluster 2 had more terms related to cardiovascular issues (eg, pacemaker, hypotension, and arrhythmia) and motor and sensory issues (eg, slurring, cochlear, and tremors), with a slight but nonsignificant enrichment in LBD (χ^2_1=4.6; P_{FDR}=.14; PR=1.31) and VCI (χ^2_1=2.5; P_{FDR}=.25; PR=1.41) diagnoses. Cluster 3 encompassed a wide variety of symptoms and conditions common in geriatric populations, including autoimmune (eg, scleroderma and vasculitis), behavioral changes and movement (eg, usual jocular behavior and imbalance, dysphagia), sleep (eg, insomnia), and sensory (eg, diplopia) problems, with a slight but not-significant enrichment in rare ADRD diagnoses (χ^2_1=3; P_{FDR}=.12; PR=1.25). Figure 3B depicts the list of representative words from each cluster and their PR, and Figure S5D in Multimedia Appendix 2 illustrates sentence examples from each cluster.

Furthermore, statistical analyses revealed significant associations of note cluster membership, with demographic variables, but not with ADRD diagnoses. First, both cluster 1 and 3 were significantly enriched by female participants (cluster 1: χ^2_1=178.7; P_{FDR}<.001; PR=1.593 and cluster 3: χ^2_1=12; P_{FDR}<.001; PR=1.14) while cluster 2 was enriched by male participants (χ^2_1=290.5; P_{FDR}<.001; PR=1.749; Figure 5B). In



XSL•FO
RenderX

addition, age of onset varied significantly among the note clusters (Kruskal-Wallis χ^2_2=14.9; P<.001; η^2=0.004), with cluster 2 (mean 72.8, SD 9.2 years) having a significantly later age of onset compared to cluster 1 (Z=−3.82; P_{FDR}<.001) and cluster 3 (Z=2.31; P_{FDR}=.03), while cluster 1 (mean 71.5, SD 9.3 years) and cluster 3 (mean 71.9, SD 9.8 years) did not differ (Z=−1.33; P_{FDR}=.19; Figure 5C). However, no association was observed between note cluster membership and ADRD diagnoses (Cluster 1-AD: χ^2_1=4.9; P_{FDR}=.14; Cluster 1-dementia unspecified: χ^2_1=1.9; P_{FDR}=.32; Cluster 1-FTD: χ^2_1=0.02; P_{FDR}=.99; Cluster 1-LBD: χ^2_1=4.1; P_{FDR}=.15; Cluster 1-other: χ^2_1=0.19; P_{FDR}=.92; Cluster 1-VCI: χ^2_1<0.001, P_{FDR}=.99; Cluster 2-AD: χ^2_1=0.3; P_{FDR}=.89; Cluster 2-dementia unspecified: χ^2_1=0.6; P_{FDR}=.76; Cluster 2-FTD: χ^2_1=0.01; P_{FDR}=.99; Cluster 2-LBD: χ^2_1=4.6; P_{FDR}=.14; Cluster 2-other: χ^2_1=8.3; P_{FDR}=.07; Cluster 2-VCI: χ^2_1=2.5; P_{FDR}=.25; Cluster 3-AD: χ^2_1=3.1; P_{FDR}=.21; Cluster 3-dementia unspecified: χ^2_1=0.4; P_{FDR}=.89; Cluster 3-FTD: χ^2_1<0.001; P_{FDR}=.99; Cluster 3-LBD: χ^2_1<0.001; P_{FDR}=.99; Cluster 3-other: χ^2_1=6.1; P_{FDR}=.12; Cluster 3-VCI: χ^2_1=3; P_{FDR}=.21; Figure 5D). Additional visualizations of the UMAP projections colored by sex, age of onset, and ADRD diagnoses are provided in Figures S5A, S5B, and S5C, respectively, in Multimedia Appendix 2.

Comparison Between ICD Clusters and Note Clusters

Statistical analysis demonstrated significant associations between *ICD* and note clusters (χ^2_4=89.43; P<.001; Cramér V=0.114). Specifically, note cluster 1, characterized by more female participants (PR=1.593) and terms related to psychiatric manifestations and medications, significantly overlapped (standardized residual=8.42; P_{FDR}<.001) with *ICD* cluster 2, which is noted for the earliest onset of disease (mean 69.8, SD 9.6 years) and a higher prevalence of psychiatric disorders and higher proportion of patients with FTD (PR=2.039). In addition, note cluster 2, which had higher proportion of male participants (PR=1.749) and terms related to cardiovascular and motor issues, overlapped significantly (standardized residual=4.90; P_{FDR}<.001) with *ICD* cluster 3, which is marked by the oldest onset of disease (mean 75.5, SD 8.1 years), a higher occurrence of VCI (PR=2.147), and dementia unspecified (PR=1.622) and had high prevalence of diabetes. These findings suggest a meaningful pattern of cluster correspondence across modalities (Figure 6).

Figure 6. Heatmap of the association of International Classification of Diseases (ICD) clusters with note clusters. Heatmap of the association of ICD clusters with note clusters. ICD clusters were significantly associated with note clusters (P<.001). Post hoc analyses revealed that note cluster 1 was positively associated with ICD cluster 2 (standardized residual=8.42, P<.001) and negatively associated with ICD clusters 1 and 3 (cluster 1: standardized residual=−4.57, P<.001; cluster 3: standardized residual=−6.36, P<.001). Furthermore, note cluster 2 was positively associated with ICD cluster 3 (standardized residual=4.9, P<.001) and negatively associated with ICD cluster 2 (standardized residual=−5.48, P<.001). Finally, note cluster 3 was negatively associated with ICD cluster 2 (standardized residual=−3.25, P=.003). Each cell displays standardized residuals (standardized differences between the observed count and the expected count) along with the count of overlapping patients (n). Color bar represents the value of the standardized residual. P values were corrected with false discovery rate adjustments.

Discussion

Principal Findings

This study aimed to characterize the clinical heterogeneity across ADRD by applying representation learning techniques on patient EHRs in a tertiary care clinic. We used pretrained *ICD* code embeddings, a transformer architecture for encoding clinical notes, and unsupervised learning to identify distinct ADRD subtypes. This work represents the first example of clustering patients with ADRD using embeddings derived directly from an LLM, without prior rule-based extraction of relevant medical concepts from the clinical note. The *ICD* codes allowed us to investigate subtypes of patients with similar *ICD* codes (non-ADRD diagnosis in charts), while the clinical notes allowed us to capture clinical history and presentation recorded by memory specialists. Our results demonstrate distinct patterns of disease manifestation with significant overlap between the *ICD* and note clusters. The overlap of clusters between the 2 approaches suggests that the subtypes may reflect common underlying clinical heterogeneity, as distinct subtypes can be identified through different data modalities.

Our choice of hierarchical agglomerative clustering was guided by the hierarchical nature of our data, empirical evidence from prior dementia subtyping studies, and theoretical limitations of alternative algorithms. Alternative methods, such as K-means, Gaussian mixture models [40], and density-based spatial clustering of applications with noise (DBSCAN) [41], face theoretical limitations: K-means assumes spherical clusters that is difficult to satisfy in high-dimensional embeddings; DBSCAN relies on density thresholds that break down in such spaces; and Gaussian mixture models can be unstable with overlapping subtypes. In contrast, hierarchical clustering preserves these nested relationships, resulting in more homogeneous [42] and reproducible [43] clusters.

In our study, we identified 3 clusters from *ICD* embeddings, each characterized by distinct health conditions. Cluster 1 predominantly featured issues related to skin health, with a commonality of dementia unspecified diagnoses and an average age of onset in the early 70s. The association between skin health and dementia in this cluster may be attributed to age, as both conditions become more prevalent with advancing age. This aligns with findings from previous studies, which reported an increase in the prevalence of actinic keratosis [44] and seborrheic keratosis [45], as well as AD [46], with age. Cluster 2 is marked by early-onset, psychiatric and behavioral manifestations; enrichment in FTD and other less common forms of ADRD; and the earliest age of onset among our clusters, typically in the late 60s. This cluster extends the characterization found in previous studies that described a behavioral symptom subtype in patients [20,21] by demonstrating similar characteristics in a broader population of patients with ADRD. Cluster 3 encompasses a broad array of conditions like respiratory issues and severe diabetes, affecting older patients, more female participants than male participants, with a higher incidence of VCI and dementia unspecified, and an age of onset in the mid-70s. Reflecting the AD subtype identified by previous researchers, this group was characterized as being overall older and having more comorbidities [20]. Landi et al [23] further differentiated patients with AD by onset timing, which we also observed but across a more diverse set of ADRD diagnoses. Notably, our *ICD*-based clustering did not reveal clearly separated clusters in the 2D UMAP projections. While UMAP aims to preserve both local and global relationships when reducing high-dimensional data to a lower-dimensional space, some distortions may inevitably occur during dimensionality reduction. Alternatively, the overlapping clusters could reflect the complexity of comorbid conditions in ADRD, which may not form clearly distinguishable subgroups.

In addition, our analysis of clinical notes revealed 3 distinct subtypes. Cluster 1 featured terms related to psychiatric manifestations and medications, aligning with findings from previous studies [20,21]. Cluster 2 included terms related to cardiovascular and various motor and sensory issues, supported by previous studies that identified subtypes of CVD [20,21] and aligning with the predominant diagnoses of VCI and LBD within this cluster. Cluster 3 covered a wide array of health conditions, consistent with the higher occurrence of rare ADRD diagnoses, which tend to involve more heterogeneous health conditions. Notably, we observed significant overlap between *ICD* and note clusters, identifying 2 ADRD subtypes of interest that were concordant across the 2 data modalities: the first subtype, “psychiatric manifestations,” and the second subtype, “diabetes with cardiovascular or motor issues.” Thus, our analysis delineated 2 distinct ADRD subtypes with specific diagnostic and symptomatic profiles.

Our study identified sex differences across all clinical note clusters with substantial effects observed in note clusters 1 and 2. For example, note cluster 1 was significantly overrepresented in female participants and had a higher prevalence of AD (PR=1.1). It also overlapped significantly (P<.001) with *ICD* cluster 2, which was enriched for psychiatric and behavioral symptoms (eg, apathy). This aligns with Tang et al [25], who reported stronger psychiatric associations in female patients with AD, including greater links to depression. This pattern may be partially attributed to women’s greater likelihood of seeking mental health care [47,48]. In contrast, note cluster 2 was overrepresented in male participants, with higher prevalence of VCI (PR=1.41) and LBD (PR=1.31), consistent with Tang et al [25], who found vascular dementia was more common in male participants. The higher prevalence of VCI in male participants may be related to a greater burden of hypertension, particularly in early life [49]. In addition, the increased representation of male participants with LBD may reflect potential underdiagnosis in female participants [50,51]. Given the clinical impact of sex disparities in ADRD—particularly in AD and LBD [52]—future studies integrating longitudinal data and clinicopathological evidence will be crucial to disentangling biological influences from health care–seeking behaviors.

Another interesting observation relates to variations in age of onset, a key indicator of disease severity, across the identified subtypes in both clinical notes and *ICD*-based clusters, with notable differences in the *ICD*-derived subtypes. For instance, the early-onset *ICD* cluster 2 was enriched with psychiatric disorders and included diseases known with early-onset,

XSL•FO
RenderX

including FTD [53] and other rare ADRD categories, such as PCA [54]. In contrast, the late-onset *ICD* cluster 3, exhibited a higher prevalence of diverse health conditions, including respiratory issues (eg, cough and shortness of breath), chronic pain, musculoskeletal conditions, such as bilateral low back pain and foot pain, as well as diabetes mellitus. While chronic pain is not typically associated with ADRD, pain could indicate the general aging process [55], and relate to osteoporosis and osteoarthritis, which likely contribute to chronic pain in older adults. Other symptoms, such as foot pain and shortness of breath, may reflect comorbidities of diabetes.

Limitations

Our study has a few limitations. First, there are the challenges associated with using real-world EHR data. Differences in how health care providers document information, stemming from variations in training, personal documentation habits, and clinical judgment, may have contributed to inconsistencies. Furthermore, health care use patterns, such as visit regularity, may influence our clustering results. For example, variations in visit frequency could lead to overrepresentation of certain symptom clusters or skewed associations. Future studies adjusting for health care use patterns may help address this limitation. Second, the inclusion of long-term patient histories in clinical notes—where recent notes may capture both current and past symptoms—could introduce extraneous information, making it difficult to isolate content relevant to the latest diagnosis. This mixture of historical and recent data may have diluted the association between documented ADRD diagnoses and their actual clinical significance, leading to observed trends rather than clear associations. Furthermore, the repetition of relevant language across multiple encounters may have influenced the clustering process, potentially reflecting the frequency of patient visits to the memory clinic, rather than clinical characteristics. Third, our study is constrained by the absence of an independent validation cohort to confirm the identified clusters. While the relative overlap in clusters identified through *ICD* codes and note contents, along with the alignment with findings from previous research, offers some validation, the results could be strengthened by applying the same encoding and clustering techniques to an external validation cohort. To ensure external validity, these results need to be validated at other health care institutions. Fourth, another limitation of this study is that our subtyping characterization only focused on ADRD diagnoses based on etiology, but did not address the stage of disease, which clearly affects the neuropsychological profile. This calls for a focus on the heterogeneity of disease stage in future research. Moreover, there may be sex differences in who receives health care at different stages and ages, adding another layer of complexity to our findings. Finally, our study is limited by the lack of racial diversity in the cohort, with 88.6% of participants being White. Given known racial differences in AD incidence, comorbidities, and health care access [56-59]—and particularly the heightened impact of hypertension on AD risk in some minoritized groups [59,60]—our findings may not fully capture the spectrum of ADRD subtypes in these populations. Future studies with broader representation are necessary to improve the generalizability of our subtyping approach.

Future Directions

In future work, the preprocessing of clinical notes could be enhanced by implementing multiple methods, such as medspaCy [61], with a focus on targeting sections most relevant to diagnoses, such as medical history. To further improve the extraction and analysis of pertinent data, the use of emerging LLMs, such as GPT [39], should be explored. In addition, validating an independent dataset and enriching the patient population would help increase the robustness and reliability of the identified ADRD subtypes. To advance this work, we will use a dual-modality approach that leverages both structured and unstructured data sources, such as medications and imaging. A deep autoencoder that uses multiple modalities simultaneously could offer methodological improvements over our current practice of conducting parallel clustering analyses and relying on heuristic averaging of embeddings. Furthermore, explicitly using the temporal or graph properties of EHRs could yield more informative representations, enhancing unsupervised clustering capabilities, as has been shown in prior approaches in a supervised learning setting [62,63]. Ultimately, our goal is to develop machine learning models capable of predicting these ADRD subtypes from real-word health care systems. Such models may aid in more precise diagnostics, prognostics, and the formulation of targeted treatment strategies.

Acknowledgments

This study was funded by National Institute of Aging P30AG062421 (SD and BTH). The funder played no role in study design, data collection, analysis and interpretation of data, or the writing of this manuscript. The authors acknowledge Yoonchul Shin and Qinglin Gou for annotating the age of onset from clinical notes.

Data Availability

The data used for this study are available from the Mass General Brigham Healthcare System, but restrictions apply to the availability of these data, which were used under permission for this study, and so are not publicly available. Code will be available on GitHub upon publication.

Authors' Contributions

MW was responsible for conceptualization, formal analysis, investigation, methodology, software, and writing original draft. YC was responsible for data curation, formal analysis, investigation, methodology, software, visualization, writing original draft,

review, and editing. YH was responsible for data curation and analysis, review, and editing. YL was responsible for formal analysis, methodology, and software. CM was responsible for conceptualization, review, and editing. BTH was responsible for review and editing. JRD was responsible for data curation, review, and editing. AS-P was responsible for review and editing. DB was responsible for review and editing. SD was responsible for conceptualization, funding acquisition, investigation, methodology, supervision, review, and editing.

Conflicts of Interest

JRD served on a scientific review board for I-Mab Biopharma. All other authors declare no conflicts of interest.

Multimedia Appendix 1
List of diagnosis names to Alzheimer disease and related dementias diagnosis categories. This document provides a list of diagnosis names from the electronic health records of patients at a memory clinic to various Alzheimer disease and related dementias diagnosis categories.
[PDF File (Adobe PDF File), 613 KB - aging_v8i1e65178_app1.pdf]

Multimedia Appendix 2
Visualizations of model attention and embedding representations. This appendix includes attention heatmaps from the final transformer layer across heads, as well as Uniform Manifold Approximation and Projection projections of International Classification of Diseases code, and clinical note embeddings, characterized by sex, age of onset, Alzheimer disease and related dementia diagnosis, and provider information.

Abbreviations

AD: Alzheimer disease
ADRD: Alzheimer disease and related dementia
Aβ: amyloid beta
BERT: Bidirectional Encoder Representations from Transformers
CVD: cerebrovascular disease
DBSCAN: density-based spatial clustering of applications with noise
EHR: electronic health record
FDR: false discovery rate
FTD: frontotemporal dementia
ICD: International Classification of Diseases
LBD: Lewy body dementia
LLM: large language model
MGH: Massachusetts General Hospital
MIMIC: Medical Information Mart for Intensive Care
PCA: posterior cortical atrophy
PR: prevalence ratio
TF-IDF: term frequency–inverse document frequency
UMAP: Uniform Manifold Approximation and Projection
VCI: vascular cognitive impairment

Abstract

Background: Frailty screening for older adults is of particular importance for those with declining health and social risk factors. However, many existing frailty tools do not offer automated appraisal in clinical settings due to challenges in data collection and the complexity of current approaches. Although routine frailty screening is inconsistently implemented, elements of frailty are captured in the electronic health record (EHR) from hospital admissions data. Thus, further adjustments and adaptations are required to correctly identify frailty.

Objective: This study investigated existing frailty-related EHR data at two hospitals within a single health system to (1) identify key data elements and establish their availability in existing clinical workflows, and (2) use these data elements to reconstruct a validated and widely used frailty index.

Methods: This developmental study included encounters of older adult patients (aged ≥65 years) admitted to medical-surgical units at 2 academic hospitals in North Florida between January 2012 and May 2021. EHR data were used to reconstruct a frailty index modeled after the Risk Analysis Index. Optimal cut points for frailty classification were determined through receiver operating characteristic analysis. Multiple logistic regression models were compared to evaluate predictive performance for hospital mortality, and component importance was assessed by sequentially removing each frailty parameter from the comprehensive model. Age-stratified analyses were performed to evaluate the robustness of classifications across age groups and race/ethnicity. All regression models were estimated to address rare outcome events.

Results: A total of 10,863 hospital patients (45.5% male; mean age 75.4, SD 7.7 years) were included. Using optimal cut points, patients were classified as not frail (40.6%), prefrail (43.5%), or frail (14.9%), with corresponding mortality rates of 0.45%, 0.82%, and 3.24%. After adjustment for confounders, frail patients had significantly higher odds of mortality compared to not frail patients (odds ratio 7.14, 95% CI 4.30 - 11.8; P<.001). Component importance analysis identified shortness of breath (area under the receiver operating characteristic curve reduction: 0.051) and functional status (area under the receiver operating characteristic curve reduction: 0.047) as the strongest predictors. Age-stratified analyses confirmed the classification system's validity, with frail patients aged 65 to 75 years (mortality 3.97%) having higher mortality risk than not frail patients aged ≥86 years (mortality 0.48%).

Conclusions: This study developed and validated a 3-category frailty classification system with strong predictive validity for hospital mortality among older adults. The generated frailty index leverages existing EHR data to capture frailty without increasing provider workload or interfering with workflow. Component importance analysis identified respiratory dysfunction and functional limitations as key predictors. This automated approach to frailty assessment could improve risk stratification, providing critical

XSL•FO
RenderX

information to clinical teams with minimal burden and supporting clinical decision-making for hospitalized older adults. Future study of the overall reliability and validity of these derived frailty scores is warranted.

(JMIR Aging 2025;8:e67888) doi:10.2196/67888

KEYWORDS

frailty; risk assessment; nursing; clinical informatics; geriatrics

Introduction

Frailty, a geriatric syndrome characterized by increased vulnerability to adverse health outcomes, poses a significant challenge in the current health care system [1]. Recent guidelines from both the American Academy of Family Physicians and the International Conference of Frailty and Sarcopenia Research emphasize the importance of widespread screening for adults aged ≥65 years, particularly those with specific health conditions or social risk factors [2]. Routine frailty screening has been used in some preoperative settings [3]; however, it has been sporadic and inconsistently implemented in most acute care settings. Therefore, there is a need to improve and systematize the process of identifying frailty in these clinical settings.

Numerous tools have been developed to assess frailty. Some, such as the frailty phenotype [4], focus on diagnosing frailty, whereas others, such as the Frailty Index [5] and the Risk Analysis Index (RAI) [6,7], aim to identify risk factors for frailty and assess the risk of adverse events such as mortality, disability, or hospital readmissions. However, agreement among different frailty tools is only fair to moderate [8]. Despite the availability of validated tools, their implementation within acute care settings remains limited. This is largely due to challenges related to data collection and the complexity of existing approaches. The key challenge involves the reliance of many existing frailty assessment tools on primary assessments that are time-consuming and may not be feasible in acute care settings, especially with critically ill patients [9]. These tools often require data beyond routine documentation, which can be burdensome for already overworked health care professionals. Any future frailty assessment tool must easily integrate with the routine clinical workflow to facilitate the uptake of the tool by health care professionals.

In the context of modern digitalized collection of health data, frailty assessment in acute care settings can be facilitated by capturing the data that are already routinely collected as part of administrative operations and clinical workflows [10]. For example, in the United States, frailty is captured as a diagnosis under the Centers for Medicare and Medicaid Services. Kim et al [11,12] showed that a Medicare claims-based frailty index predicted disability, mobility impairment, recurrent falls, and number of skilled nursing facility days. Despite support for the validity of a claims-based frailty index, the utility of claims-based tools is limited to retrospective analyses given the delay in data availability. Among older adults in particular, an accurate and reliable way to assess frailty is essential to meet the projected demographic shifts in both the number and proportion of world population that are caused by increased longevity [13] and for the US context, the transition of baby boomers to retirement age [14]. This limitation is particularly problematic in view of the increasing emphasis on precision or personalized medicine and the need for rapid clinical decision-making in real or near real time among hospitalized patients.

Owing to these modern information technology demands and demographic pressures, a novel, digital tool is needed to assess the risk of frailty in hospitalized older adults. Therefore, any future frailty assessment tool must leverage the readily available data from electronic health records (EHRs) that capture patient data for 84% of non–federal acute care hospitals in the United States [15]. EHRs include a wide array of data about a patient and may be sufficient sources of all information that is necessary for a *hands-off* frailty assessment.

This study addresses the limitations of existing frailty assessment tools in acute care by offering a data-driven approach to frailty risk assessment. The long-term goal is to develop a prognostic index for frailty that automates the process of frailty risk assessment based on EHR data collected through routine acute care. The proposed tool is entitled “The Automated Frailty Index Tool” (A-FIT). A-FIT leverages concepts from existing, validated frailty assessment tools and operationalizes these concepts based on expertise from clinical practice. The primary aim of this research was to acquire accuracy and clinical decision support comparable to that of existing frailty index tools while substantially reducing assessment and documentation burdens. The findings will inform the development of a robust and clinically actionable frailty assessment and decision support tool for hospitalized older adults, contributing to the advancement of precision medicine within acute care.

Developing and validating a prediction model for a robust risk assessment tool is a multistep process [16-18]. For an EHR data-driven tool, this may involve substantial workflow assessments and multiple iterations of operationalization and calibration of predictors. This study serves as a critical first step in the development process. The objectives of this study were to investigate existing frailty-related EHR data at 2 hospitals within a single health system to identify key data elements and establish their availability in existing clinical workflows and to use these data elements to reconstruct a validated and widely used frailty index.

Methods

Study Design

This was a development study that used secondary data from a large retrospective observational study of EHR data. The study included encounters of adult patients (aged ≥65 years) admitted to a medical/surgical unit at 1 of 2 academic hospitals in North Florida between January 2012 and May 2021. The larger study

XSL•FO
RenderX

examined iatrogenic conditions among older adults in the acute care setting [19].

Ethical Considerations

This study was conducted under a University of Florida IRB protocol (IRB201900208) designated as exempt under Category 4(iii) for secondary research using identifiable health information. Under this determination, informed consent was waived in accordance with 45 CFR 46.104(d)(4)(iii) and HIPAA provisions for research (45 CFR 164.501 and 164.512[b]). All data were analyzed within a secure, HIPAA-compliant environment, with no direct patient contact and no identifiable information disclosed. Procedures adhered to institutional and national guidelines and the principles of the Declaration of Helsinki. Standard technical and administrative safeguards were in place to protect patient privacy and ensure compliance with institutional and federal data security requirements.

Conceptual Framework

The first step in the development process was informed by the Practice-Based Knowledge Discovery for Comparative Effectiveness Research framework proposed by Lucero and Bakken [20]. The framework, grounded in the Quality Health Outcomes Model [21] and the Knowledge Discovery in Databases [22] process, guides the extraction of actionable insights from electronic clinical data. This framework was chosen for its iterative approach to engaging practice-based experts in informatics research. A practice-based framework was crucial for developing a frailty index that not only demonstrated statistical and computational rigor but also possessed clear clinical utility. To this end, an interdisciplinary team of clinical experts was convened, including nurses, physicians, and physical therapists, as part of an iatrogenic conditions task force established to conduct the large retrospective observational study described earlier.

Analytic Sample

In alignment with existing frailty screening recommendations, the analytic sample for this study included only hospital patients aged ≥65 years. The original dataset consisted of 60,475 inpatients. Patients with missing data for any of the 11 frailty parameters, including patients without any documented assessments of 1 of the 4 ADLs or those for whom living status (independent or dependent) could not be clearly established from the recorded residence (eg,“country clinic,” “unable to assess,” and “homeless”) were excluded. Furthermore, 1 patient was excluded because their documented age was outside the plausible range for age (ie, ≥116 years). This can occur during admissions to the emergency room, for example, in the case of major traumatic injury, where information could not be collected directly from a patient or their family member. The resulting analytical sample consisted of 10,863 patients with complete data for all frailty parameters. Among these patients, 113 (1.04%) experienced in-hospital mortality, which served as the primary outcome for model development and validation.

Frailty Assessment Tool Construction

The second step in the development of the A-FIT involved a collaboration with the clinical expert task force to identify variables that were considered the most clinically meaningful representations of the RAI parameters and were expected to be widely and consistently documented within the medical/surgical setting. Through feedback from the team of clinical experts, important considerations were given to the stated goal that the tool enabled continuous assessment of frailty status across hospital admissions. To that end, 11 RAI frailty parameters were identified by the clinical task force.

For the next phase of development, the RAI was selected for comparison because the tool has an established validity across both surgical and nonsurgical settings. The RAI was developed and validated within the United States Department of Veterans Affairs (VA) health care system by adapting the Minimum Data Set Mortality Risk Index–Revised [23]. The RAI includes 11 assessment variables addressing various demographic, physiological, cognitive, and functional domains. As such, the RAI includes a broader range of factors beyond the 5 criteria of the frailty phenotype [4], but less than the Frailty Index [5], which requires consideration of at least 30 clinical variables. The RAI emphasizes effective distinction between frail and nonfrail patients in terms of increased risk of posttreatment complications and mortality. While the RAI was originally developed as a postoperative frailty assessment tool, it has been adapted and validated in nonoperative settings and across multiple hospitals.

To date, 3 versions of the index have been developed. The Clinical RAI (RAI-C) is a prospective screening tool in the form of a 14-item questionnaire addressing 11 frailty parameters [6]. The 11 frailty parameters are sex, age, cancer, renal failure, heart failure, cognitive decline, unintentional weight loss, poor appetite, shortness of breath at rest, activities of daily living (ADLs), and residence other than independent living. The Administrative RAI is a retrospective version that derives the same 11 frailty parameters from data available in surgical quality data sets [7]. The most recent version, called Risk Analysis Index-International Classification of Diseases (RAI-ICD), extends the application of RAI beyond the surgical population using the *International Classification of Diseases (ICD), Tenth Revision, Clinical Modification*, codes [24]. The RAI tools have numerous strengths, most notably their demonstrated validity and feasibility in assessing frailty in diverse and predominantly nonfrail populations. However, none of them fulfills the proposed criteria of automated assessment, thus requiring further adjustment and adaptation.

Our study extended the application of RAI by developing and validating empirically derived cut points for frailty risk categories. While previous applications of RAI primarily focused on binary classification (frail vs not frail), our approach sought to identify meaningful thresholds for 3 distinct risk categories (ie, not frail, prefrail, and frail) to enhance clinical utility and risk stratification.

Data Operationalization

To operationalize the 11 RAI frailty parameters identified by the clinical task force, the fourth step in the A-FIT development encompassed categorizing the 11 parameters. The first category comprised parameters assessed on admission that are unlikely to change during the hospitalization. The RAI parameters in this category were age, sex, and residence other than

XSL•FO
RenderX

independent living. The second category contained parameters assessed throughout hospitalization, for example, once a day or once a shift. These included shortness of breath and ADLs. Finally, there were parameters that are assessed on admission and may be updated as a patient's condition changes but not with regular frequency. These included unintentional weight loss and poor appetite, which are part of required nursing admission documentation but may not be assessed further unless directly relevant to the principal diagnosis or care plan. Similarly, current active medical diagnoses are documented on admission and only updated at discharge unless additional unexpected clinical problems emerge.

Informed by this practice-based data operationalization, the final step was to reconstruct a frailty assessment based on RAI parameters. Key data sources are listed in Textbox 1. While this study used retrospective data, an emphasis was placed on the use of data points available to clinicians at the point of care. Of the 11 frailty parameters, 7 had such accessible data points. Owing to limitations of available secondary data, the need to use administrative codes (ICD-9 and ICD-10) to represent cancer, heart failure, renal failure, and cognitive decline was necessary during this stage of development. Finally, hospital mortality was determined based on a discharge disposition of 'expired.'

Textbox 1. Automated Frailty Index Tool data operationalization.

Single time point

- Age on admission
- Sex
- Residence other than independent living (intake information)

Several time points

- Shortness of breath (at least one "dyspnea at rest" under Respiratory Pattern in Simple or Complex Assessment Flowsheet)
- Activities of daily living: eating, grooming, toileting, and walking (Activity Measure for Post-Acute Care assessment tool [25,26])

Continuous

- Unintentional weight loss
- Poor appetite (nutrition screening and admission documentation)
- Hospital problems or active diagnoses: cancer, heart failure, renal failure, cognitive decline (identified by *International Classification of Diseases, Ninth Revision*, or *International Classification of Diseases, Tenth Revision*, codes)

Statistical Analysis

Descriptive statistics

Descriptive statistics for each parameter, including frequency distribution (count and percent), central tendency (mean and median), and variability (SD), were generated following construction of the frailty assessment parameters as displayed in Textbox 1. A frailty score for each patient was calculated based on the scoring criteria proposed by Hall et al [6]. Differences between frailty categories were assessed using Kruskal-Wallis tests for continuous variables (age and ADL scores) and χ^2 tests for categorical variables. For significant Kruskal-Wallis results, post hoc pairwise comparisons were performed using Dunn test with Bonferroni correction. For the multicategory race/ethnicity variable, post hoc χ^2 tests were conducted with Bonferroni adjustment to identify specific between-group differences. In addition to statistical significance testing, standardized mean differences (SMDs) were calculated to assess the magnitude of differences between frailty categories, with SMD values >0.1, >0.3, and >0.5 considered to represent small, moderate, and large differences, respectively.

Frailty Classification

To determine optimal cut points for frailty classification, a data-driven approach was used. First, a binary cutpoint was identified using the Youden index (maximizing sensitivity+specificity–1) to distinguish frail from nonfrail patients. Subsequently, established data-driven cut points were established using receiver operating characteristic curve analysis and the Youden index to maximize discrimination. This approach yielded 3 clinically meaningful risk categories: not frail, prefrail, and frail. The robustness of these classifications was evaluated across age groups to ensure the index captured vulnerability beyond chronological age alone.

Model Development and Validation

To validate our frailty index and determine its incremental value beyond basic patient characteristics, several comparative models were constructed. The first model included only potential confounding factors (eg, hospital location, race/ethnicity, and smoking status). The second model added key clinical predictors (eg, age, sex, and functional status) to assess whether our composite frailty index provided additional predictive power beyond these established risk factors. The third and fourth models evaluated our frailty index in both continuous and categorical forms. Finally, a comprehensive model, including all individual frailty components, was constructed to determine whether our composite index adequately captured the predictive information contained in its constituent parts.

Multiple modeling approaches were compared to evaluate the predictive performance of the frailty index. Four models were constructed: (1) a confounders-only model, including hospital

XSL•FO
RenderX

location, race/ethnicity, and smoking status; (2) a key components model adding age, sex, and functional status (ADL) to the confounders; (3) a continuous frailty index model adding the index score to the confounders; and (4) a categorical frailty index model adding the 3-category frailty classification to the confounders. Additionally, these models were compared to a comprehensive model, including all individual frailty components.

Model performance was evaluated using discrimination (AUC) and calibration (Akaike Information Criterion [AIC]). Likelihood ratio tests were used to compare nested models. To assess the contribution of individual components to the frailty index's predictive ability, component importance analysis was conducted by sequentially removing each component and measuring the resulting change in AUC.

Additionally, age-stratified analyses were performed to evaluate the performance of the frailty classification system across different age groups (ie, 65 - 75, 76 - 85, and ≥86 years). For each age stratum, separate logistic regression models were fitted to estimate the odds of mortality associated with frailty categories, adjusting for potential confounders, including hospital location, race/ethnicity, and smoking status. All regression models were estimated using Firth's penalized likelihood approach to address potential issues related to rare events, as in-hospital mortality was an uncommon outcome in our dataset. Analyses were completed using R (version 4.3.1 [25]) with packages, including logistf, pROC, dplyr, tidyr, cutpointr, and dunn.test.

Results

Sample Characteristics

A total of 10,863 hospital patients aged ≥65 years were included. The average age was 75.4 (SD 7.7) years. Of the included participants, 4938 (45.5%) were male. With regard to race/ethnicity, 7724 participants (71.1%) were non-Hispanic White, 2406 participants (22.1%) were non-Hispanic Black, 314 participants (2.9%) were Hispanic, and the remaining 419 participants (3.9%) were other or unknown race/ethnicity. Hospital mortality occurred for 113 patients in the sample (1.04%). The frailty index scores ranged from 24 to 84. The skewness statistic was 0.39 (SE 0.02), indicating mild positive skew. The overall mean frailty score for the sample was 45.3 (SD 8.7).

Development of Frailty Categories

Using a data-driven approach, optimal cut points were identified to classify patients into 3 distinct risk categories. The first cutpoint at a frailty score of 54 was identified using the Youden index to maximize the sum of sensitivity (53.1%) and specificity (82.5%) for mortality prediction. A second cut point at a frailty score of 42 was established to distinguish between low-risk and intermediate-risk patients. On the basis of these thresholds, patients were classified as not frail (RAI <42), prefrail (RAI 42 - 53), and frail (RAI ≥54). The distribution of patients across these categories was as follows: not frail 40.8% (n=4434), prefrail 43.8% (n=4763), and frail 15.3% (n=1666). Hospital mortality rates showed a clear gradient across categories: 0.45% (95% CI 0.28%–0.70%) in not frail, 0.82% (95% CI 0.59%–1.12%) in prefrail, and 3.24% (95% CI 2.49%–4.23%) in frail patients.

Differences Between Frailty Categories

Significant differences were observed across frailty categories for both demographic and clinical characteristics and presented in Table 1. Post hoc pairwise comparisons using Dunn test with Bonferroni correction revealed significant age differences across all 3 frailty categories (all $P<.001$), with progressively higher median ages from not frail to prefrail to frail groups. For ADL scores, frail patients had significantly higher scores (indicating worse function) than both prefrail ($P<.001$) and not frail groups ($P=.046$), but no significant difference was found between not frail and prefrail groups ($P=.12$).

[a]SMD: standardized mean difference.

[b]ADL: activities of daily living.

Analyses of race/ethnicity distribution using χ^2 tests with Bonferroni correction identified a significant difference between non-Hispanic Black and non-Hispanic White patients (*P*=.039). Non-Hispanic Black patients were less likely to be classified as not frail (38.1% vs 41.3%) and more likely to be classified as prefrail (46.7% vs 43.1%) compared to non-Hispanic White patients. The proportion classified as frail was similar across all racial/ethnic groups, ranging from 12.1% among Hispanic patients to 15.5% among non-Hispanic White patients.

Model Performance Comparison

Multiple models were compared to evaluate the predictive performance of our frailty index. A baseline model, including only potential confounders (eg, hospital location, race/ethnicity, and smoking status), showed poor discrimination for hospital mortality (AUC 0.592). A model incorporating key clinical predictors (eg, age, sex, and functional status) performed better (AUC 0.760). The continuous frailty index model demonstrated good discrimination (AUC 0.738), whereas the categorical frailty classification model achieved similar performance (AUC 0.717). A comprehensive model using all individual frailty components demonstrated the highest discrimination (AUC 0.887).

Likelihood ratio tests confirmed that both the continuous frailty index (χ^2_1=100.7; *P*<.001) and the 3-category classification (χ^2_2=75.4; *P*<.001) significantly improved prediction compared to the confounders-only model (Table 2). The AIC values showed a similar pattern, with the all-components model having the lowest AIC (935.47), followed by the continuous frailty index model (1142.02), the categorical model (1169.38), and the confounder-only model (1240.73).

Component Importance Analysis

To identify the key drivers of predictive performance, a component importance analysis was conducted by sequentially removing each frailty parameter from the comprehensive model shown in Figure 1. This analysis revealed that shortness of breath was the strongest predictor (AUC reduction: 0.051 when removed), followed by ADL limitations (AUC reduction: 0.047) and renal failure (AUC reduction: 0.019). Interestingly, age showed minimal independent contribution within this 65+ population (AUC reduction: –0.0005), suggesting that our frailty index captures vulnerability beyond chronological age.

XSL•FO
RenderX

Figure 1. Contribution of each component to model performance. ADL: activities of daily living; AUC: area under receiver operating characteristic curve.

Age-Stratified Analysis

As presented in Table 3, the proportion of patients classified as frail increased with age: 12% in the 65 to 75 years age group, 18% in the 76 to 85 years age group, and 26% in the ≥86 age group. In all age groups, the frail category identified patients at substantially higher risk, with mortality rates 6 to 8 times higher than patients classified as not frail. Notably, a frail patient in the 65 to 75 years age group (mortality 3.97%) had higher mortality risk than a not frail patient in the ≥86 years age group (mortality 0.48%).

Table . Age-stratified odds of mortality controlling for hospital location, race/ethnicity, and smoking status.

	Total (N)	Mortality, n (%)	Adjusted odds ratio	95% CI	*P* value
Age group (years)					
65 - 75					
Not frail	3066	15 (0.49)	*Reference*	—[a]	—
Prefrail	2287	17 (0.74)	1.56	0.78 - 3.13	.208
Frail	706	28 (3.97)	8.50	4.59 - 16.32	<.001
76 - 85					
Not frail	1159	4 (0.35)	*Reference*	—	—

[a]Not applicable.

XSL•FO
RenderX

After adjusting for hospital location, race/ethnicity, and smoking status, age-stratified logistic regression models showed varying strengths of association between frailty categories and mortality. In the 65 to 75 years age group, frail patients had significantly higher odds of mortality compared to not frail patients (odds ratio [OR] 8.50, 95% CI 4.59 - 16.32; *P*<.001), whereas prefrail status showed a positive but nonsignificant association (OR 1.56, 95% CI 0.78 - 3.13; *P*=.208).

In the 76 to 85 years age group, the association remained strong for frail patients (OR 6.42, 95% CI 2.41 - 21.02; *P*<.001), but prefrail status did not reach statistical significance (OR 2.47, 95% CI 0.94 - 8.01; *P*=.069). In the oldest age group (≥86 years), the point estimate for frail status remained elevated (OR 3.99, 95% CI 0.91 - 37.48) but did not reach statistical significance (*P*=.07).

Discussion

Principal Findings

The purpose of this research was to automate risk assessment and early frailty detection by using readily available EHR data, with the long-term goal of improving frailty detection while minimizing the documentation burden on health care providers. Our study not only developed a viable frailty index but also established empirically derived cut points for a 3-category frailty classification system with strong predictive validity for hospital mortality. This work demonstrates that routinely collected EHR data can be leveraged to create a clinically meaningful risk stratification tool for older adult medical/surgical patients.

Frailty Index Performance and Comparison With Previous Work

In this study, the average frailty index score was 45.3, considerably higher than the mean frailty scores reported in the development and validation of the original RAI instruments (11.8 for clinical RAI and 9.6 for RAI-administrative). This difference is largely explained by our focus on adults aged ≥65 years, whereas Hall et al [6] included all adults aged ≥18 years. Our 3-category classification system identified 14.9% of patients as frail (RAI ≥54), 43.5% as prefrail (RAI 42 - 53), and 40.6% as not frail (RAI <42). This distribution aligns with previous literature, suggesting that approximately 10% to 15% of community-dwelling older adults are frail, with a larger proportion in the prefrail category [27,28].

Our model comparison revealed that while individual frailty components provide optimal predictive power (AUC=0.887), the composite frailty index (AUC=0.738) and 3-category classification (AUC=0.717) offer substantial improvement over basic demographic factors alone (AUC=0.592). Interestingly, a simpler model using only age, sex, and functional status achieved slightly better discrimination (AUC=0.760) than our composite index, echoing previous findings about the powerful predictive value of functional status in geriatric populations [29-31]. However, our 3-category frailty classification offers conceptual advantages, clinical interpretability, and standardization that may outweigh the modest reduction in statistical performance.

Component Importance and Novel Insights

Our component importance analysis yielded several notable findings. First, respiratory dysfunction (shortness of breath) emerged as the strongest mortality predictor, with an AUC reduction of 0.051 when removed from the model. This aligns with growing recognition of respiratory parameters as important indicators of acute deterioration in hospitalized patients [32,33]. That shortness of breath was the most significant factor for the development of frailty, which is consistent with other research that revealed among older persons, respiratory impairment and frailty are strongly associated with one another [29,34]. Additionally, there is a substantial increase in vulnerability to adverse health outcomes, such as heart failure or chronic obstructive pulmonary disease, and risk of death when both are present. These conditions contribute to reduced physical activity, muscle weakness, and overall functional decline, thereby accelerating the progression toward frailty. Unfortunately, frailty is often underrepresented in respiratory management guidelines, which may contribute to limited recognition of its comorbidity in respiratory care [35].

Functional status (ADL) was the second most important component (AUC reduction: 0.047), consistent with extensive literature establishing functional measures as robust predictors of outcomes in older adults [36]. Notably, age contributed minimally to prediction beyond these clinical factors, confirming that our index captures frailty as a distinct clinical entity rather than merely reflecting chronological aging. This finding is particularly significant, given that our study focused exclusively on adults aged ≥65 years, suggesting that frailty assessment provides valuable risk stratification even within the older adult population.

Age-Stratified Analysis and Demographic Patterns

Our age-stratified analysis revealed that while the prevalence of frailty increases with age (12% in ages 65 - 75 years, 18% in ages 76 - 85 years, and 26% in ages ≥86 years), the predictive value of frailty categories remains robust across all age strata. The striking finding that frail patients aged 65 to 75 years had higher mortality risk than nonfrail patients aged ≥86 years underscores the clinical importance of frailty assessment beyond simple age-based approaches to risk stratification.

The gradient in ORs across age groups (OR decreasing from 8.50 to 6.42 to 3.99) suggests that while frailty remains an important predictor of mortality across all age groups, its relative impact may diminish somewhat in the oldest old. This pattern aligns with the concept of survival bias, where those who reach advanced age despite being classified as frail may represent a resilient subpopulation [37]. Nevertheless, the consistency of the association pattern across age strata supports the clinical utility of the frailty classification system throughout the geriatric age spectrum.

The declining statistical significance observed in the oldest age group likely reflects limited statistical power rather than absence of effect, as evidenced by the wide CIs. This highlights a common challenge in geriatric research where sample sizes often decrease with advancing age categories.

XSL•FO
RenderX

Our analysis of race/ethnicity distribution revealed significant differences between non-Hispanic Black and non-Hispanic White patients, with Black patients less likely to be classified as not frail (38.1% vs 41.3%) and more likely to be classified as prefrail (46.7% vs 43.1%). This finding adds to the growing body of evidence on health disparities in frailty prevalence [38,39] and highlights the importance of considering social determinants of health in frailty assessment and intervention planning.

The ORs for mortality demonstrate the strong discriminative ability of our classification system; after adjusting for confounders, prefrail patients had 1.8 times higher odds of mortality than not frail patients, whereas frail patients had 7.1 times higher odds. These magnitudes of association are clinically meaningful and comparable to established frailty measures in the literature [4-7].

Technical Implications

This study went beyond validation of an existing tool. Rather than using identical predictors and operational definitions from the original RAI development, the framework was adapted to work with routinely available EHR data, enhancing translatability across sites and settings. Our methodological approach to handling the rare outcome (hospital death) was rigorous, using Firth's penalized likelihood method to address potential bias in logistic regression with rare events.

Our 3-category classification system represents an important methodological advancement over binary approaches. By identifying a prefrail intermediate category, our system provides greater nuance for risk stratification and potentially enables earlier intervention before patients progress to more severe frailty. The use of SMDs in addition to statistical testing helped identify clinically meaningful differences between frailty categories, particularly for functional and respiratory parameters.

Clinical Implications

Frailty is recognized as an important predisposing factor for and predictor of adverse outcomes. Therefore, there is a necessity for frailty screening to identify potentially modifiable vulnerabilities among frail older adults. A practical application includes such procedures as the utilization of prehabilitation and optimized nutrition that have demonstrated beneficial effects on functional outcomes postoperatively [40-45]. This research extends these efforts beyond the surgical arena to also optimize hospitalized medical patients' condition and reduce the incidences of many possible complications that increase morbidity, prolong lengths of stay, and may lead to mortality.

The clinical implications of our findings are substantial. First, our 3-category frailty classification system provides clinicians with a practical framework for risk stratification that can be automatically generated from EHR data without additional documentation burden. Second, the identification of shortness of breath and functional status as the strongest predictors suggests potential targets for intervention and monitoring. Third, our finding that frailty predicts mortality independent of age challenges age-based stereotypes and encourages individualized risk assessment.

Our tool extends frailty assessment beyond the surgical arena to all hospitalized medical/surgical patients, addressing a significant gap in current practice. While much previous research on functional decline due to frailty has focused on surgical outcomes [46-48], our work demonstrates the relevance of frailty assessment across the broader inpatient population. Furthermore, addressing shortness of breath through appropriate medical intervention and pulmonary rehabilitation can potentially mitigate the risk of frailty development in older adults for improved clinical outcomes [49,50].

Frailty is also appreciated as a dynamic condition for older adults, who may experience changes in their frailty status over time. This may occur as either a gradual decline or sudden change in an acute care setting or possibly reversible with rehabilitation. Previous research has shown an association between older age and faster progression of frailty [51]. Additionally, patients who were postsurgery, especially emergency general surgeries, can induce or worsen frailty. Ng et al [52] showed that 33.3% of older patients undergoing emergency surgery experienced an increase in their frailty status 90 days postoperatively. Furthermore, 15.9% of patients were considered with a new frail condition impacting their discharge destination. Our automated approach creates opportunities for continuous monitoring of frailty status across hospital admissions, potentially allowing clinical teams to detect and respond to changes in patient vulnerability during hospitalization.

Strengths and Limitations

This study has several strengths, including the large sample size, rigorous methodological approach, and comprehensive validation of the frailty classification system. The use of data-derived cut points for our 3-category system provides a data-driven foundation for clinical implementation. Our component importance analysis identified key drivers of mortality prediction, offering valuable insights for focused assessment and intervention.

However, limitations must be acknowledged. First, our reliance on secondary data meant that some frailty parameters were derived from administrative codes rather than direct clinical assessment. Second, hospital mortality was a rare event (1.04%), necessitating specialized statistical approaches and potentially limiting statistical power for some analyses. Our use of Firth's penalized likelihood method helped address issues related to rare events, but validation in cohorts with more outcome events would strengthen confidence in our findings.

Additionally, our analytical sample excluded patients whose residential status could not be clearly established, including homeless individuals, potentially introducing selection bias. Future studies should investigate the inclusion of homelessness as an independent risk factor to improve generalizability. The observed differences in frailty distribution between racial/ethnic groups also warrant further investigation into potential disparities in frailty assessment and care.

While our study demonstrated the predictive validity of our frailty classification for in-hospital mortality, longer-term outcomes or other clinically relevant end points, such as

XSL•FO
RenderX

functional decline, discharge disposition, or readmission, were not assessed. Future research should explore these additional outcomes to further validate the clinical utility of our approach and include sequential measures to investigate how frailty changes during acute care so that clinicians can monitor and respond to changes in patient vulnerability during hospitalization.

Conclusions

This paper describes the development and validation of a 3-category frailty classification system based on readily available EHR data that demonstrate strong predictive validity for hospital mortality among older adults. Our approach provides meaningful risk stratification with mortality rates of 0.45%, 0.82%, and 3.24% across not frail, prefrail, and frail categories, respectively. Component importance analysis identified respiratory dysfunction and functional limitations as the strongest predictors, offering potential targets for monitoring and intervention.

This automated approach to frailty assessment could provide critical information to clinical teams with minimal additional documentation burden, potentially improving risk stratification and clinical decision-making for hospitalized older adults. Further research should explore how this frailty classification system performs for additional outcomes and whether implementation in clinical workflows improves patient care and outcomes.

Abstract

Background: Oral health of nursing home residents is generally poor, largely due to age-related conditions that increase their vulnerability and make them more dependent on others for oral care. Poor oral health can significantly impact general health and well-being, highlighting the important role of caregivers in preventing, detecting, and addressing residents' oral health problems in time. The interRAI Suite of instruments, widely used for comprehensive health assessments, offers the opportunity for nondental caregivers to assess oral health as part of general health and well-being and facilitates the integration of oral health in general care planning.

Objective: Based on interRAI data, this study explored the associations between oral health and general health outcomes of nursing home residents in Flanders (Belgium) and the Netherlands.

Methods: This cross-sectional study included baseline interRAI assessments of 2362 Flemish and Dutch residents aged 65 years and older, collected by caregivers (eg, nurses, nurse aids) between October 2020 and February 2024. Validated outcome scales (eg, Activities of Daily Living Hierarchy Scale, Cognitive Performance Scale, and Depression Rating Scale), health conditions such as diabetes and low weight (BMI ≤19), and family support and participation in social activities, included in the interRAI instrument, provided information on residents' general health and well-being. Oral health was defined according to the 9 items of the optimized Oral Health Screener (OHS) for use in the interRAI instruments. Adjusted logistic regression models were used to explore the associations between oral and general health outcomes.

Results: Oral health problems were interconnected, with conditions in one oral structure impacting the health of others. When controlling for confounding variables, dependency on others for personal care and hygiene was significantly associated with poor oral hygiene (odds ratio [OR] 1.7, 95% CI 1.1 - 2.4), chewing difficulties (OR 2.2, 95% CI 1.3 - 3.5), compromised teeth (OR 1.7, 95% CI 1.1 - 2.5), and the need for dental referral (OR 1.8, 95% CI 1.4 - 2.3). Natural dentition and gender had a significant impact on oral health status. Low weight was associated with poor chewing function (OR 2.0, 95% CI 1.1 - 3.6) and dry mouth (OR 1.8, 95% CI 1.0 - 3.2), both associated with oral discomfort or pain (OR 6.8, 95% CI 3.3 - 14.0 and OR 3.5, 95% CI 1.8 - 6.9, respectively). Family support was identified as a facilitator in mitigating oral health problems.

Conclusions: The interRAI instrument, including the OHS, is a valuable tool for monitoring residents' health and identifying areas requiring additional support. The results demonstrated the importance of prioritizing oral health as an integral component of comprehensive care. Recognizing the interconnection between oral health and other health conditions, including indicators of well-being, can guide caregivers and other health care professionals in incorporating preventive and supportive oral care practices into daily care routines, contributing to improved resident health and well-being outcomes.

Introduction

Oral diseases are among the most widespread noncommunicable diseases, affecting nearly half of the population worldwide, with older adults among the most vulnerable persons [1]. Common oral diseases and conditions in older persons include dental caries, periodontitis, tooth loss, and dry mouth [2]. Although most oral diseases are largely preventable with adequate daily care and regular dental checkups, older adults face several challenges, making it difficult to maintain good oral health. These challenges include a reduced ability to self-care due to compromised general health, polypharmacy, difficult accessibility, and inadequate availability of dental care [3,4].

Suboptimal oral health can have major consequences for general health and quality of life and vice versa [5]. Research has shown a bidirectional relationship between periodontitis and systemic diseases such as diabetes and cardiovascular disease [6]. Individuals with cognitive impairment may have difficulty understanding the importance of oral health and maintaining consistent hygiene routines [3,7]. Conversely, tooth loss has been associated with cognitive decline, due to reduced chewing ability [8]. Wearing dentures at night can increase the risk of pneumonia due to accumulated plaque levels [3]. In addition, certain types of medications can reduce saliva production, increasing the risk of oral health problems [9]. Poor oral health can also lower a person's self-esteem, leading to social isolation and depressive symptoms [3,10]. Conversely, depression and other mental health conditions often result in neglected oral hygiene due to a lack of motivation or energy, which worsens oral health [3,10]. Given the complex interactions between oral and general health, it is important to address oral health problems in time to prevent further health deterioration.

Through regular oral health assessments, caregivers can help improve oral health of older adults by enabling prevention, early detection, and timely treatment of oral health problems [11,12]. In this regard, the interRAI Suite of instruments is useful due to its holistic approach and wide range of applications [13].

The interRAI Suite consists of comprehensive web-based assessment instruments for caregivers to collect information in a standardized way from care-dependent persons on key factors including physical and cognitive function, psychosocial factors, clinical situation, social support, and so on. These instruments have been introduced in more than 35 countries and are compatible across different care settings. The interRAI Suite provides reliable and high-quality data to improve continuity of care, promote a person-centered approach, and enhance the ability to assess clinical outcomes. The integration of collaborative action points (CAPs), which are trigger algorithms to identify care needs and the risk of adverse outcomes, facilitates collaborative decision-making and helps prevent health deterioration and improve quality of life. Since the interRAI instrument for use in long-term care facilities (LTCFs) (eg, nursing homes) includes oral health as an integral part of general health and well-being, it has the potential to integrate oral care into general care planning [13,14].

However, research has shown that the oral health section within version 9 of the interRAI instrument is incomplete and has limited validity [15]. Replacing the oral health section in the interRAI LTCF with an optimized oral health section may allow caregivers to more effectively identify oral health problems, while also considering the other non–oral health conditions indicated in the assessments that may serve as risk factors [16].

Therefore, an optimized oral health section, the ohr-interRAI, was developed and recently identified in a systematic review as the most appropriate oral health instrument for nondental caregivers to evaluate older adults' oral health [12,15,17]. Based on a Delphi study with 53 oral health experts from 34 countries, further improvements were made, resulting in the Oral Health Screener (OHS) for use in the interRAI instruments, which takes into account national and cultural differences that may exist regarding oral health, oral care, and oral behavior [18].

The OHS consists of 9 items: chewing function, discomfort or pain in the mouth, dry mouth, hygiene of removable dentures, oral hygiene, teeth, gums, tongue, and palate and inner surface of cheeks and lips. Based on the assessment of these items, the CAP *oral hygiene* and the CAP *referral to a dentist* will be activated when help with daily oral hygiene and a referral to a dentist is needed, respectively. To help caregivers identify oral health problems, photographs, guidelines on the general assessment, items and CAPs, and instruction videos are available [17,18].

Although not yet officially included in the global interRAI Suite of instruments, the OHS is already in use in nursing homes in Flanders (Belgium) and in the Netherlands. Since the interRAI LTCF instrument collects data on oral health and general health, including well-being, from residents, it allows for assessing the associations between these outcomes. This study is the first to explore such associations using the OHS. Given the limited validity of the current oral health section and the widespread use of the interRAI instruments, this study aims to support the implementation of the OHS in the interRAI instruments and to strengthen the interRAI's overarching goals. Understanding the links between oral health and other health problems can facilitate early intervention and comprehensive care planning, thereby improving residents' quality of life. In addition, recognizing these associations contributes to prevention, supporting cost-effective health care, and guides the development of policies and preventive programs targeting oral and general health in older populations.

Methods

Study Design and Inclusion Criteria

This cross-sectional study included interRAI LTCF baseline data from persons aged 65 years and older living in nursing homes in Flanders (Belgium) and in the Netherlands. The data were collected by professional caregivers (nurses, physiotherapists, occupational therapists, etc) using the interRAI LTCF instrument, including the OHS, to assess residents' oral and general health status. This study differs from a previous study by Schoebrechts et al [19], reporting the prevalence of oral health problems identified using the OHS, by including data from a larger number of residents and examining

XSL•FO
RenderX

associations with other health and well-being indicators. All data were collected between October 2020 and February 2024.

Ethical Considerations

This multicenter study was approved by the Belgian Privacy Commission and the Ethics Committee Research UZ/KU Leuven (B3222021000448). All participants or their family members gave informed consent for the use of their data for research purposes. To ensure privacy and confidentiality, all data were pseudonymized and data access was limited to the research team. No compensation was provided for participation.

Outcomes

Oral Health

Using the OHS, the assessment of chewing function, discomfort or pain in the mouth, and dry mouth requires a conversation or observation during meals, while the assessment of *hygiene of removable dentures*, *oral hygiene*, *teeth*, *gums*, *tongue*, and *palate and inner surface of cheeks and lips* requires a visual inspection in the mouth. These items are assessed on a scale that distinguishes between acceptable and unacceptable conditions, with photographs available for the 6 items requiring a visual inspection. In addition, caregivers have the option to indicate whether the assessment is not possible (eg, if persons resist) or not applicable (eg, no dentures). The CAP *oral hygiene* and the CAP *referral to a dentist* are activated when help with daily oral hygiene and a referral to a dentist are needed, respectively.

General Health

General health, including well-being, outcomes in the interRAI instrument were selected based on previous research indicating their relevance to oral health. The interRAI instrument includes internationally validated outcome scales to evaluate a person's clinical status, which are automatically calculated based on a number of individual items [20]. The following scales were included in the analyses. They were dichotomized using validated cutoff values, with higher scores indicating greater severity.

The Activities of Daily Living Hierarchy (ADLH) Scale, ranging from 0 to 6 (cutoff ≥3), refers to the degree of dependence on personal care, based on the items related to personal hygiene, toilet use, locomotion, and eating [21]. The Cognitive Performance Scale (CPS), ranging from 0 to 6 (cutoff ≥3), represents a person's cognitive status, including cognitive skills in daily decision-making, short-term memory, procedural memory, ability to make self-understood, and eating self-performance [22]. The Depression Rating Scale (DRS), ranging from 0 to 14 (cutoff ≥3), represents the presence of depressive symptoms based on several items such as making negative statements, expressions of unrealistic fears, and repetitive health complaints or crying [23]. The Changes in Health, End-Stage Disease, Signs, and Symptoms (CHESS) Scale, ranging from 0 to 5 (cutoff ≥3), demonstrates a person's health instability and is a strong predictor of mortality. The scale is based on several items such as changes in decision-making and activities of daily living status, dyspnea, dehydration, and weight loss [24]. The Communication Scale has a range from 0 to 8 (cutoff ≥4) and is calculated based on residents' ability to make themselves understood and to understand others [25]. The Revised Index of Social Engagement, ranging from 0 to 6 (cutoff ≥3), is calculated from items describing an individual's sense of initiative and social involvement in the nursing home. Unlike the other scales, a higher Revised Index of Social Engagement score indicates a positive outcome [26].

In addition, residents' general health was evaluated based on the presence of the following health diseases recorded in the interRAI instrument: dementia, diabetes mellitus, congestive heart failure, chronic obstructive pulmonary disease (COPD), Parkinson disease, anxiety, bipolar disorder, schizophrenia, and pneumonia. Other health conditions included aspiration, reflux, low weight (BMI ≤19), and polypharmacy (≥10 medications). Information on residents' mood or behavior status and psychosocial well-being was collected by including the interRAI items *resistance to care*, *reduced social interactions*, *strong and supportive relationships with family*, and the CAP *behavior*. This CAP is calculated based on residents' wandering behavior, verbal and physical abusive attitude, socially inappropriate or disruptive behavior, and resistance to care. In addition, information in the interRAI instrument such as *extensive to total dependency for personal hygiene*, *modified mode of nutritional intake* (due to not swallowing all types of food), and *severe vision impairment in adequate light* was included in the analyses as well as the item on having a dental checkup in the last year and information on a physician visit in the last 14 days. All items were dichotomized.

Covariates

The following variables were considered covariates: age (divided into 3 groups: 65 - 75, 76 - 85, and 86+ years), sex (female and male), smoking (smoker and nonsmoker), presence of teeth (based on the *not applicable* response option of item *teeth*), and presence of dentures (based on the *not applicable* response option of item *denture hygiene*).

Missingness Information

Analysis of missing values showed that they were random, which means that the probability of a missing value did not depend on the item itself or on certain characteristics of the assessors [19,27]. Possible causes for incomplete assessments with the interRAI instrument are discussed in detail by Vanneste et al [28].

Data Analyses

Descriptive statistics were used to illustrate the characteristics (eg, demographic information and oral and general health status) of the residents. Categorical variables were summarized as absolute numbers and percentages, and continuous variables were presented as means and accompanying standard deviations.

For bivariate analyses, the oral health items, originally assessed using 3 or 4 response options, were dichotomized considering only the options when an assessment was possible (ie, acceptable or unacceptable condition). Unadjusted logistic regression models were performed to explore associations between the oral health–related and the selected general health–related

XSL•FO
RenderX

variables. These analyses provided a preliminary understanding of the direct associations between the individual variables. Subsequently, multivariable logistic regression models were developed for each oral health item adjusted for oral and general health variables. Each model included a fixed set of explanatory variables (*ADLH/extensive to total dependency for personal hygiene*, *CPS*, *DRS*, *CHESS*, *Communication Scale*, *strong and supportive relationships with family*, and covariates), together with variables identified as significant in the bivariate analyses or supported by previous research. The variables considered as covariates were included in the regression models to control for potential confounding variables. *Denture hygiene*, *oral hygiene*, and *teeth* were excluded as explanatory variables in the models because these variables were assessed only in residents with dentures and natural teeth, respectively. Including these variables would have restricted the models to a limited subgroup of residents without dentures, without natural teeth, or without both. To address collinearity, variables measuring the same construct or part of another item (eg, *extensive to total dependency for personal hygiene* and *ADLH scale*, *resistance to care* and CAP *behavior*, and *presence of teeth* and *teeth*) were excluded from the models. *Extensive to total dependency for personal hygiene* variable was included instead of the ADLH Scale in the models for *denture hygiene*, *oral hygiene*, and CAP *oral hygiene*, as it may provide a better indication of these items' status. The associations between the variables were expressed using odds ratios (ORs) and 95% CIs. All statistical analyses were performed using IBM SPSS Statistics (version 28.0.1.1; IBM) and SAS Enterprise Guide (version 8.1; SAS Institute). A *P* value of <.05 was considered statistically significant.

Results

Baseline Characteristics

The data consisted of 2362 baseline assessments (ie, first assessments of the residents using the interRAI instrument, including the OHS), 789 from 12 Flemish nursing homes and 1573 from 26 Dutch nursing homes. The mean age of the residents was 82.17 (SD 7.53) years and most residents were female (1567/2362, 66.3%). About 8.0% (180/2346) of the residents were daily smokers (Table 1).

Table . Baseline characteristics of the participating nursing home residents.

Characteristics	Value (N=2362)
Age (years), mean (SD)	82.17 (7.53)
Age range (years), n (%)[a]	
65 - 75	633 (26.8)
76 - 85	1121 (47.5)
86+	608 (25.7)
Sex, n (%)[a]	
Female	1567 (66.3)
Male	795 (33.7)
Daily smoker, n (%)[a]	180 (7.7)

[a]Specific outcome per item.

Oral Health

Table 2 shows the distribution of the oral health conditions in the sample. Of the 3 self-reported items, chewing problems (290/2254, 12.9%) were the most reported condition by the nursing home residents. About 10.0% (226/2214) of the residents indicated having a dry mouth, and 4.0% (89/2219) reported discomfort or pain in the mouth. The condition of the teeth could be assessed in 49.8% (1147/2301) of the nursing home residents. This was found to be compromised in 25.6% (294/1147) of these residents. The second most commonly observed oral health problem was poor oral hygiene, identified in 20.6% (313/1519) of the residents with assessable oral hygiene (1519/2297, 66.1%). Hygiene of removable dentures could be assessed in 64.9% (1499/2310) of the participants with dentures and was found to be poor in 9.1% (136/1499). Gum problems were observed in 7.7% (155/2006) of the residents, problems with the tongue were observed in 4.0% (87/2057), and problems with the palate and inner surface of cheeks and lips were also observed in about 4.0% (76/1959) of the residents.

Cannot be assessed	340/340 (100)
Missing oral health data	63/2362 (2.7)

[a]Data included in the model/total available oral health data.

[b]"Cannot be assessed" when the item could not be assessed adequately, for example, due to resistant behavior or cognitive impairment.

Based on the results of the assessments with the OHS, the CAP *oral hygiene* was activated in 16.8% (384/2289), indicating a need for help with daily oral care, and the CAP *referral to a dentist* was triggered in 27.5% (611/2221), indicating a need for dental treatment. In addition, caregivers indicated a dental checkup in the last year in 56.5% (1319/2333) of the nursing home residents.

General Health

Analyses of the outcome scales revealed that the majority of the residents were dependent on others for activities of daily living (1276/2351, 54.3%) and were cognitively impaired (1335/2341, 57.0%). Symptoms of depression were found in 36.7% (862/2346) and poor communication in 24.3% (5272/2351). Based on the CHESS Scale, health instability was present in 5.5% (126/2296) of the nursing home residents. Most residents (1902/2337, 81.4%) showed initiative and social involvement in the nursing home.

About 30.0% (706/2345) of the residents were experiencing dementia, 21.6% (506/2344) were experiencing diabetes, and 27.0% (634/2346) had behavior problems. The use of polypharmacy, indicated by taking 10 or more medications, was noted in 30.7% (721/2345). Strong and supportive relationships with family were reported by 88.2% (2070/2346) of the residents. More information on residents' general health and well-being is shown in Table 3.

[a]Data included in the model/total available oral health data.

[b]CAP: collaborative action point.

[c]OR: odds ratio (significant OR >1: significant contributor; significant OR <1: significant protector).

[d]*P*<.05.

[e]ADLH: activities of daily living hierarchy.

[f]Not included in the model.

[g]*P*<.001.

[h]*P*<.01.

[i]CPS: Cognitive Performance Scale.

[j]DRS: Depression Rating Scale.

[k]CHESS: Changes in Health, End-stage disease, Signs, and Symptoms.

[l]RISE: Revised Index of Social Engagement.

[m]COPD: chronic obstructive pulmonary disease.

The following factors were significantly associated with *chewing problems*, after controlling for confounders: discomfort or pain in the mouth (OR 9.1, 95% CI 4.4 - 18.5), modified mode of nutritional intake (OR 8.8, 95% CI 5.6 - 13.7), gum problems (OR 3.8, 95% CI 1.8 - 8.1), dry mouth (OR 2.8, 95% CI 1.7 - 4.8), aspiration problems (OR 2.4, 95% CI 1.4 - 4.2), ADLH problems (OR 2.2, 95% CI 1.3 - 3.5), and low weight (OR 2.0, 95% CI 1.1 - 3.6). This means that older adults with these conditions were more likely to have chewing difficulties than older adults with no such conditions. In addition, older age (more than 76 years) was also associated with more chewing problems (OR approximately 2.0, 95% CI 1.1 - 3.4) than those aged 65 - 75 years. The presence of teeth (OR 0.7, 95% CI 0.4 - 1.0) contributed to a better chewing function. Having heart failure (OR 0.6, 95% CI 0.4 - 0.9) was associated with fewer chewing problems.

XSL•FO
RenderX

In the adjusted logistic model for *discomfort or pain in the mouth*, chewing function (OR 6.8, 95% CI 3.3 - 14.0) and dry mouth (OR 3.5, 95% CI 1.8 - 6.7) had significant ORs, which means that residents with chewing difficulties and dry mouth had a higher chance of discomfort or pain in the mouth than those with no such conditions. A modified mode of nutritional intake (OR 0.4, 95% CI 0.2 - 1.0) was associated with less discomfort or pain in the mouth.

Chewing difficulties (OR 2.8, 95% CI 1.6 - 4.8) and discomfort or pain in the mouth (OR 3.5, 95% CI 1.8 - 6.9) were also identified as associated factors for a *dry mouth*. In addition, reflux (OR 2.6, 95% CI 1.2 - 5.4), poor conditions of the tongue (OR 2.6, 95% CI 1.2 - 5.5) and palate and inner surface of cheeks and lips (OR 2.5, 95% CI 1.0 - 6.3), aspiration problems (OR 2.3, 95% CI 1.2 - 4.3), health instability derived from the CHESS Scale (OR 2.1, 95% CI 1.0 - 4.2), COPD (OR 2.1, 95% CI 1.3 - 3.4), and low weight (OR 1.8, 95% CI 1.0 - 3.2) contributed to experiencing a dry mouth. Residents taking 10 or more medications (OR 1.5, 95% CI 1.0 - 2.2) were also more likely to have a dry mouth. The presence of teeth (OR 0.7, 95% CI 0.5 - 1.0), cognitive impairment (OR 0.5, 95% CI 0.4 - 0.8), and resisting care (OR 0.5, 95% CI 0.3 - 0.9) showed protective effects, reducing the experience of dry mouth.

Gum (OR 5.3, 95% CI 2.3 - 12.4, and OR 7.5, 95% CI 4.0 - 14.1, respectively) and tongue problems (OR 6.1, 95% CI 2.6 - 13.9, and OR 3.2, 95% CI 1.3 - 8.2, respectively) are both contributing factors to poor *denture hygiene* and poor *oral hygiene*. In the oral hygiene model, residents with discomfort or pain in the mouth (OR 3.2, 95% CI 1.4 - 7.4), resistance to care (OR 1.7, 95% CI 1.1 - 2.7), or extensive to total dependence on personal hygiene (OR 1.7, 95% CI 1.1 - 2.4) were also more likely to have poor oral hygiene. It was found that males were more prone to poor oral hygiene than females (OR 1.6, 95% CI 1.1 - 2.3). Family support (OR 0.6, 95% CI 0.4 - 1.0) and the presence of dentures (OR 0.2, 95% CI 0.2 - 0.3) contributed to acceptable oral hygiene. Despite its lack of significance in the bivariate analyses, pneumonia status was included in the adjusted logistic models for denture hygiene and oral hygiene based on evidence from previous research. However, the models yielded no significant contribution to poor denture or oral hygiene.

The highest ORs in the adjusted logistic model for *teeth* were found for the condition of the gums (OR 7.2, 95% CI 3.9 - 13.3) and tongue (OR 3.3, 95% CI 1.3 - 8.8). This means that older adults presenting gum or tongue problems were more likely to have dental problems than those with no such conditions. Chewing difficulties yielded an OR of 2.2 (95% CI 1.2 - 4.1), indicating an association with poor condition of the teeth. When resistance to care (OR 1.8, 95% CI 1.1 - 3.0) or extensive dependence on personal care (ADLH; OR 1.7, 95% CI 1.1 - 2.5) was reported, the association with dental problems was significant. The same was true for adults aged 76 - 85 years (OR 1.7, 95% CI 1.1 - 2.7) compared with those aged 65 - 75 years. On the contrary, family support (OR 0.5, 95% CI 0.3 - 0.9) and the presence of dentures (OR 0.5, 95% CI 0.3 - 0.7) showed protective effects.

Gum problems were more frequently reported when residents had problems with the tongue (OR 6.0, 95% CI 2.7 - 13.3) or still had teeth (OR 5.2, 95% CI 2.8 - 9.7). In addition to both being associated with dry mouth, discomfort or pain in the mouth (OR 2.9, 95% CI 1.3 - 6.7) and chewing difficulties (OR 2.8, 95% CI 1.5 - 5.4) were also associated with gum problems. Based on evidence from previous research, diabetes and heart failure were included as variables in the adjusted logistic model. However, these conditions were not significantly associated with gum problems.

Gum problems (OR 5.8, 95% CI 2.7 - 12.1) also presented the highest OR in the adjusted logistic model for *tongue* problems, followed by health instability (OR 3.7, 95% CI 1.6 - 8.4). Severe vision impairment in adequate light (OR 3.7, 95% CI 1.3 - 10.7) and diabetes (OR 2.5, 95% CI 1.4 - 4.4) were also identified as contributors to tongue problems. Dry mouth (OR 3.2, 95% CI 1.6 - 6.1, and OR 2.9, 95% CI 1.4 - 5.9, respectively) and discomfort or pain in the mouth (OR 3.1, 95% CI 1.3 - 7.7, and OR 4.8, 95% CI 2.0 - 11.5, respectively) were both associated with tongue problems and *palate and inner surface of cheeks and lips*. In addition, depressive symptoms increased the chance of problems with the palate and inner surface of cheeks and lips (OR 1.9, 95% CI 1.0 - 3.5).

Gum problems (OR 8.1, 95% CI 4.7 - 14.0) were a major contributor to the activation of the CAP *oral hygiene*, as well as tongue problems (OR 3.7, 95% CI 1.9 - 7.1), highlighting the need for improved oral care. Extensive to total dependence on personal hygiene (OR 1.6, 95% CI 1.2 - 2.2) and being male compared with being female (OR 1.5, 95% CI 1.1 - 2.0) also increased the chance of activation of the CAP. The model showed that residents with heart failure (OR 0.7, 95% CI 0.5 - 1.0) were less likely to need help with daily oral care.

The CAP *referral to a dentist* was more likely to be activated when residents had a modified mode of nutritional intake (OR 3.5, 95% CI 2.6 - 4.6) or were dependent on personal care (ADLH; OR 1.8, 95% CI 1.4 - 2.3). Aspiration (OR 1.5, 95% CI 1.0 - 2.2), communication problems (OR 1.4, 95% CI 1.0 - 1.8), and depressive symptoms (OR 1.3, 95% CI 1.0 - 1.6) also increased the chance of referral to a dentist. Family support showed a protective effect in the activation of the CAP (OR 0.7, 95% CI 0.5 - 0.9).

Smoking was included in each adjusted logistic model but did not significantly contribute to the presence of oral health problems. Similarly, pneumonia was included in all models except the one for teeth (not significant in bivariate analysis) but showed no association when adjusted for the other variables. Reflux, COPD, and Parkinson disease were conditions included only in the model for dry mouth, with reflux and COPD showing significant associations with dry mouth, while Parkinson disease did not.

Discussion

Principal Findings

This study examined the associations between oral health and general health outcomes based on interRAI assessments of nursing home residents in Flanders and the Netherlands,

XSL•FO
RenderX

performed by their caregivers. This is the first study to explore these associations using the OHS, the optimized Oral Health Screener for use in the interRAI instruments.

Advancements in prevention, restorative techniques, and dental materials have enabled older adults to retain their natural dentition longer [29]. Despite changing patterns of tooth retention, tooth loss is still prevalent in the older population. Research indicates that most individuals aged 85 years and older in industrialized countries wear removable dentures, with the majority being completely edentulous [29]. In addition, nursing home residents tend to have fewer teeth than those living independently [29]. In this study, at least 42.0% (961/2301) of participating residents had lost all of their natural teeth and at least 65.0% (1499/2310) were wearing removable dentures. This finding aligns with the prevalence of edentulism (40.0% - 60.0%) and the use of removable dentures (40.0% - 85.0%) among nursing home residents in Europe, as reported in a systematic review by Janssens et al [30].

Natural teeth are much more complex and time-consuming to clean than an edentulous mouth with complete dentures [29]. Tooth loss is frequently the result of dental caries and gum inflammation, resulting from poor oral hygiene [31]. This study suggests that the combination of natural teeth and dentures is associated with better oral hygiene and condition of the teeth. However, the exact number of remaining teeth among the residents in this study was unknown. Poor brushing and inadequate cleaning of dentures allow the accumulation of plaque and food debris, increasing the risk of infections in the mouth [32]. The interrelated nature of the oral health problems identified in this study may be consistent with research showing that the microbial environment associated with poor hygiene affects not only teeth and gums but also the entire oral cavity including the tongue, palate, and inner surface of cheeks and lips [33,34]. These areas may be affected by conditions such as ulcers, fungal infections such as candidiasis, or mucosal irritation [32,35]. Wong et al [36] confirmed that poor oral hygiene among residents was probably due to inadequate brushing or cleaning of teeth and dentures, which increases the prevalence of dental problems, periodontal diseases, and other severe complications.

Age-related conditions, such as functional impairment, frailty, and chronic illnesses, reduce residents' ability to self-care and increase their reliance on caregivers for their daily care [3,5,37]. Such dependence on others for personal care was associated with a higher risk of chewing difficulties, poor condition of the teeth, and a higher need for dental referral. The increased retention of natural teeth, along with the growing need for care and support in old age, may explain why significantly more dental problems were observed in adults aged 76 - 85 years than in those a decade younger [29,38]. In addition, extensive to total dependence on personal hygiene was associated with poor oral hygiene and activation of the CAP oral hygiene, consistent with previous research on oral health among older institutionalized residents, identifying high care dependency as a predisposing factor for poor oral hygiene [36]. The association was particularly true for men compared with women and aligns with broader research indicating that women tend to have better oral health behaviors [39]. However, oral care is often neglected when assistance is needed for activities of daily living [29]. Research has shown that caregivers often lack knowledge of oral health, give lower priority to oral care over other care tasks, and consider the mouth as an intimate area of the body [15]. In addition, residents' resistance to care was often associated with oral health problems, as confirmed by this study [15]. Residents may also lack awareness of oral health problems due to health conditions such as cognitive impairment, sensory losses (eg, impaired vision or reduced sense of taste and smell), or the misconception that poor oral health is part of aging [3,37,40,41]. This may explain the association between severe vision impairment in adequate light and more tongue problems.

A higher need for dental referral was found when residents struggled to express themselves or understand others, which is consistent with previous research that suggests that nonverbal individuals may be more vulnerable to oral health problems [42]. Research suggests that older adults often visit the dentist only in the event of certain symptoms, such as pain, rather than regularly for preventive care [36]. As they are unable to communicate discomfort or pain, it can be challenging for caregivers to address these problems on time [42]. This highlights the need for targeted training and support for caregivers to address these challenges and ensure better oral health outcomes for residents [43]. Family support was identified as beneficial for oral health outcomes. Family members can assist with daily oral hygiene, or can ensure or demand consistent care, as well as bridge gaps in communication or resistance [44].

This study showed that the presence of teeth plays an important role in residents' ability to chew all types of food. The scoping review by Lahoud et al [8] demonstrated that tooth loss and musculoskeletal conditions, including frailty and sarcopenia—age-related loss of skeletal muscle mass and function, are the most common factors that negatively affect chewing function. Chewing difficulties are associated with discomfort or pain in the mouth and can negatively affect food selection and nutritional intake, increasing the risk of malnutrition [8]. This study confirmed that the type of food consumed may also contribute to chewing difficulties. Diets that primarily consist of softer foods can lead to a decline in chewing function due to reduced use of the masticatory muscles and teeth. Furthermore, insufficient intake of essential nutrients, such as folic acid and vitamin A, may exacerbate oral health problems, including chewing difficulties [8,45]. Consistent with the systematic review by Fan et al [46], this study identified discomfort or pain in the mouth, dry mouth, and periodontal diseases as contributing to chewing problems, underscoring the importance of maintaining good oral health to support proper chewing. Interestingly, individuals with heart failure experienced fewer chewing difficulties, which could result from lifestyle changes, including dietary adjustments or more frequent medical consultations. However, further research is needed to clarify these associations and explore underlying mechanisms.

Significant associations were found between chewing function, discomfort or pain in the mouth, and dry mouth. Chewing stimulates the salivary glands, enhancing the production of saliva, which facilitates the swallowing of food [47,48]. Lack of saliva can lead to dry mouth, which can cause discomfort or

XSL•FO
RenderX

pain in the mouth and make it difficult to chew food, often necessitating dietary adjustments [47]. The association between the presence of teeth and residents experiencing less dry mouth is consistent with research showing that individuals with natural teeth generally retain a more effective chewing function than those with complete dentures, as dentures alone do not provide the same mechanical stimulation to the salivary glands [49]. Saliva also contributes to the protection of oral mucosa from pathogens [48]. The latter could explain the association between dry mouth and poor condition of the tongue and palate and the inner surface of cheeks and lips. In addition, it is also important to note that in the earlier version of the OHS, the ohr-interRAI, the item Tongue received a negative (poor) score when a dry tongue was observed [17]. Since the adjustment of the item was made in 2023 and the assessments were collected between 2020 and 2024, it is possible that caregivers took this into account when assessing the mouth [18].

Dry mouth is a common side effect of medication, particularly among older adults, who often take multiple medications due to a range of chronic systemic diseases [50]. This may explain the association between health instability and dry mouth, in addition to dehydration—one of the items in the CHESS Scale indicating health instability and a known cause of dry mouth [51]. Reflux and COPD were also associated with dry mouth. Reflux may lead to dry mouth due to acid exposure, which irritates salivary glands, reducing their function [52]. Residents with COPD may experience dry mouth as a side effect of inhaled medications or due to chronic mouth breathing, which exacerbates dryness [53]. However, further research is necessary to clarify the underlying mechanisms. Interestingly, this study suggested that dry mouth is linked to better cognitive function, which may be explained by medications commonly prescribed for dementia that improve cognition while also causing dry mouth as a side effect.

This study yielded significant associations between depressive symptoms and poor conditions of the palate and inner surface of cheeks and lips, as well as an increased need for dental referrals. Antidepressants, commonly prescribed for the management of depression and other mental health problems, are known to increase the likelihood of dry mouth, increasing the prevalence of oral health problems, including mouth sores and cracked lips [50,54]. In addition, the associations may be explained by research indicating that individuals with depressive symptoms often experience a lack of motivation and energy, which may lead to neglect of oral hygiene practices, contributing to poor oral health outcomes [55,56]. Several studies confirm the link between depressive symptoms and poor oral health outcomes among older adults [57-59]. Although depression is not a normal part of aging, older adults—particularly nursing home residents compared with those living independently—are more likely to experience loneliness and social isolation, poor physical health, and restrictions in daily activities, which can increase the risk of depression [60]. Given the high prevalence of depressive symptoms and oral health problems in nursing home residents, timely identification and management of both conditions is important due to their bidirectional relationship [1,60,61].

Despite research showing evidence on the relationship between periodontitis and systemic diseases such as cardiovascular disease and diabetes, these diseases were not significantly linked to gum problems in this study [3]. This discrepancy may be due to methodological factors, such as the sample size, the participants included, or the assessments by the caregivers. Diabetes was, however, associated with tongue problems. Diabetes is common in nursing home residents, with reported prevalence rates ranging from 20.0% to 34.0%, aligning with the prevalence of 21.6% (506/2344) in this study [62]. This condition is well known for its association with oral health problems, including an increased risk of developing oral infections and alterations to the oral mucosa, such as a coated and fissured tongue or aphthous stomatitis [63].

To better understand the results of this study, some key considerations and limitations should be acknowledged. The generalizability of the results to the wider population is limited. All participants resided in nursing homes where a specific software system was used, integrating the OHS into the interRAI instrument. While using the interRAI instrument became mandatory in Flemish nursing homes since June 2023, this was not the case in the Netherlands. The Dutch participating nursing homes, all part of the Omring group, specifically requested to use the interRAI LTCF, including the OHS [64]. It is therefore possible that these homes were particularly motivated to work on improving residents' oral care and oral health, which may have impacted the results, in addition to possible differences in context and health practices between Flanders and the Netherlands. Schoebrechts et al [19] compared the oral health status of older adults living in Flemish and Dutch nursing homes assessed by nondental caregivers using the OHS and found more oral health problems among Flemish than Dutch residents. In addition, they reported some differences in general health status, including a higher level of dependence on others for activities of daily living and personal hygiene, as well as fewer depressive symptoms among Flemish residents compared with their Dutch counterparts [19]. Comparing associations between oral health and general health outcomes among nursing home residents in Flanders and the Netherlands was beyond the scope of this study but could be a subject for future research.

The quality and accuracy of the interRAI assessments also depend on the knowledge and qualifications of the caregivers completing them. Previous research has shown that nondental caregivers often underestimate oral health problems in nursing home residents compared with dental professionals [17]. This underestimation may be due to lack of knowledge, inadequate training, limited experience, or discomfort in addressing oral health [15,17]. In addition, underestimation of oral health problems may be attributed to some assessment criteria. For instance, oral and denture hygiene are assessed based on the extent of plaque accumulation, with the presence of plaque covering more than one-third of a tooth or denture surface. It should be noted that this may be a crude measure for the assessors. Another reason may be due to limitations of the observational assessment, particularly when residents have communication difficulties, cognitive impairment, or resist care.

In this study, the oral health assessments using the OHS were performed for the first time by various caregivers whose training

XSL•FO
RenderX

or education was unknown. Therefore, it can be assumed that oral health problems identified through the assessment may have been severe. This highlights the importance of regular oral health assessments by caregivers to identify oral health problems that may otherwise go unnoticed, as well as the need for adequate training and practice.

Some of the associations that are observed in this study can be deduced from logical connections or previous research. Other associations remain less well explained, as they appear to be nonlogical at first glance or contradict existing studies. Therefore, caution is warranted when interpreting the results. Further research may explore these associations more thoroughly, contributing to a better understanding of the relationship between oral and general health in nursing home populations. Given the mandatory use of the interRAI instrument in nursing homes in Flanders, analyses of larger datasets can also facilitate the determination of the validity of the results and how they sustain over time. However, it should be noted that a large sample size can lead to statistically significant findings that do not necessarily have clinical significance [65]. In addition, it is important to note that the interRAI instrument primarily records the occurrence of conditions. Further research is needed to identify causal factors and inform targeted interventions.

Strengths

Collecting data with the interRAI instrument can be considered as a strength of this study as it is a validated, comprehensive, holistic, and widely used tool for assessing residents' health and well-being. In addition, the integration of the OHS showed significant improvements over its current version, allowing for more accurate identification of oral health problems [66].

Conclusions

This study provided valuable insights into the associations between oral health and general health outcomes, underscoring the importance of a holistic approach that considers oral health as an integral part of general health and well-being. Recognizing these associations can enhance care planning and improve quality of care.

In practical terms, these findings support measures such as integrating regular oral health assessments into care protocols, ensuring timely access to oral health professionals, and providing caregivers with targeted training on oral care and identifying poor oral health. In addition, the results showed the importance of interdisciplinary collaboration to comprehensively address oral health. An integrated approach has the potential to improve both oral and general health outcomes, help reduce the risk of related complications, and ultimately enhance residents' quality of life.

Acknowledgments

The authors would like to thank all residents and caregivers in the participating nursing homes for their valuable contribution to this study. This work was supported by KU Leuven (C24M-20 - 063) and Research Foundation Flanders (FWO TBM T003220N).

Data Availability

The datasets generated and analyzed in this study are not publicly available due to data privacy policies; however, information on the official procedure for requesting the data can be obtained by contacting the corresponding author.

Authors' Contributions

ES contributed to conception and design, data acquisition, analysis and interpretation, and drafting and revising the manuscript. JdAM and JD contributed to conception and design, data interpretation, and substantively revising the manuscript. PAIV, HPJvH, JDL, AD, and DD contributed to conception and design and substantively revising the manuscript. All authors approved the submitted version and agreed to be personally accountable for all aspects of the manuscript.

Conflicts of Interest

None declared.

Abstract

Background: The urban environment is an important determinant of frailty, primarily through factors such as infrastructure that supports physical activity, availability of social and medical support, and access to nutritious food. Given the increasing aging population, understanding the link between urban quality, frailty, and metabolic health is crucial for effective public health and urban planning interventions.

Objective: This study aims to quantify the impact of distinct urban domains (built-environment characteristics, accessibility to essential services, availability of green and recreational spaces, and neighborhood socioeconomic context) on frailty status, nutritional profile, and hematological or biochemical biomarkers in community-dwelling older adults by integrating geospatial analysis.

Methods: A cohort of 251 older adults (aged older than 65 years) was studied. Frailty was assessed using the Frailty Trait Scale 5, and nutritional status was determined using the Controlling Nutritional Status score. Hematological and biochemical parameters were evaluated in a subset of 70 participants by MINDRAY automatic equipment. A spatial analysis of frailty was conducted by incorporating Geographic Information System layers that mapped the distribution of urban facilities, including fruit and vegetable shops, senior centers, pharmacies, emergency health centers, parks and squares, community centers, and exercise facilities. Statistical analyses included *t* tests, Mann-Whitney *U* test, ANOVA, and correlation analyses.

Results: The prevalence of frailty was 17.5%. Frail individuals exhibited significantly higher BMI (mean 31.5, SD 4.4 vs mean 28.5, SD 4.5 kg/m²; *P*=.0001). When comparing the upper (Q4) and lower (Q1) quartiles of urban quality, Q4 participants had higher Frailty Trait Scale 5 scores (mean 15.2, SD 7.4 vs mean 11.8, SD 6.4; *P*=.0334) and lower handgrip strength (mean 19.1, SD 4.4 vs mean 22.8, SD 7.3 kg; *P*=.006). Frail individuals resided significantly closer to emergency health centers (*P*=.0010), family health centers (*P*=.0412), and exercise facilities (*P*=.0322). In addition, bilirubin (Spearman ρ=0.33; *P*=.0049), serum iron (Spearman ρ=0.27; *P*=.0272), transferrin saturation (Spearman ρ=0.24; *P*=.0386), red blood cell count (Spearman ρ=0.26; *P*=.0303), and red blood cell distribution width (Spearman ρ=0.23; *P*=.0462) were positively correlated with urban quality. Frail participants also had higher Controlling Nutritional Status scores (*P*=.0323), which were positively correlated with urban quality (Spearman ρ=0.25; *P*=.0359).

Conclusions: Urban quality was significantly associated with hematological parameters, nutritional status, and frailty. Frail individuals in areas with better urban quality exhibit lower handgrip strength, higher frailty scores, and greater proximity to emergency rooms, community health centers, and exercise facilities. This spatial distribution may reflect higher accessibility to health care and recreational resources among frail participants. Urban planning and public health strategies should focus on creating age-friendly environments to prevent frailty and improve health outcomes.

Introduction

Global demographic changes have indicated an accelerated increase in the aging population, along with a rise in the prevalence of older adults [1]. This demographic transition has prompted the analysis of various key factors associated with the aging process, with frailty being one of the primary foci in geriatric medicine [2]. This multisystemic syndrome is characterized by a decline in physiological reserves and intrinsic capacity, which leads to an increased vulnerability to stressors and a higher risk of adverse outcomes such as falls, hospitalization, disability, and mortality [3,4]. The global prevalence of frailty varies between 12% and 24%, depending on the diagnostic tool used, and it is one of the key factors to prevent and reverse according to the World Health Organization recommendations [5]. The increase in the frailty prevalence among older adults poses significant challenges for health care systems, highlighting the need for comprehensive strategies to address its underlying determinants [2,3,6]. Recent studies have highlighted the significant role of the urban environment in frailty, influencing both its development and improvement, independent of individual factors [7]. The built environment, characterized by access to green spaces, health services, community resources, places for physical activity, diet, and social interactions, plays a key role in frailty [7-9]. This is reflected in various studies indicating that older adults living in areas with lower land-use diversity and more social incivilities may be at risk of developing mobility limitations. In contrast, those residing in urban areas with limited resources and higher pollution levels tend to exhibit higher mortality rates associated with frailty [10,11]. In this context, frailty and mobility limitations have been associated with the neighborhood physical characteristics, including land-use mix diversity, land-use mix access, street connectivity, walking infrastructure, esthetics, crime safety, and social incivilities [11,12]. Due to the relevance of frailty in older adults, the World Health Organization has recognized the need to create age-friendly environments to enhance healthy aging and reduce the risk of frailty [5]. In Latin America, urban inequalities are particularly pronounced, with limited access to critical services and stark disparities in urban quality [13]. Chile exemplifies this context, characterized by rapid urbanization, a pronounced rural-urban divide, and significant socioeconomic heterogeneity. While previous studies have linked environmental factors to frailty in high-income countries [7-9], evidence from Latin America remains limited, particularly concerning the interplay between urban quality, hematological or biochemical markers, and nutritional status in aging populations. Notably, no Chilean study to date has integrated geospatial analysis with clinical biomarkers to examine how specific urban features (eg, proximity to emergency centers or green spaces) correlate with frailty phenotypes. This gap is critical, as Chile's unique urban-rural dynamics and aging demographics may reveal patterns not observed in more developed settings [14]. In this study, we address this gap by combining Geographic Information System (GIS)–based urban metrics with multidimensional frailty assessments (Frailty Trait Scale 5 [FTS-5]), biochemical or hematological profiling, and nutritional status (Controlling Nutritional Status [CONUT] score) in a Chilean cohort, offering novel insights for regional public health strategies. By integrating GIS data with health and sociodemographic variables, we aim to analyze possible spatial clusters of frailty, assess the impact of urban quality, and highlight the potential of urban planning and policy interventions in mitigating frailty risks [8,9,15]. In addition to environmental factors, nutritional and hematological status is a key component associated with frailty. Urban environmental conditions have also been implicated in modulating blood-based health indicators [16,17]. Hematological abnormalities, such as variations in red blood cell (RBC) count and iron status, are linked to frailty, potentially through their effects on muscle function, oxygen transport, and fatigue. Moreover, several biochemical markers reflecting hepatic and renal function have been associated with frailty in older adults [18]. Understanding how urban quality influences these clinical parameters may provide novel perspectives for developing targeted frailty prevention strategies [17]. With this background, the aim of this study was to quantify the impact of distinct urban domains (built-environment characteristics, accessibility to essential services, availability of green and recreational spaces, and neighborhood socioeconomic context) on frailty status, nutritional profile, and hematological or biochemical biomarkers in community-dwelling older adults by integrating geospatial analysis.

Methods

Participants and Study Design

A representative sample of 251 older adults (aged 65 years and older; both men and women) from the older adult population of Talca, Chile (Maule Region), registered with Family Health Centers and community organizations, participated in this cross-sectional study. The inclusion criterion was adults aged 65 years and older. Participants with self-reported or medically documented cancer, Parkinson disease, or vascular accidents were excluded, as well as older individuals unable to walk or speak, and those currently on statin therapy [19]. The sample size calculation was based on an estimated frailty prevalence of 24.6% among older adults, with a 95% confidence level, 80% statistical power, and an anticipated 20% attrition rate. The gender distribution of the sample reflected that of the population aged 65 years and older, according to data from the National Socioeconomic Characterization Survey.

Frailty Diagnosis

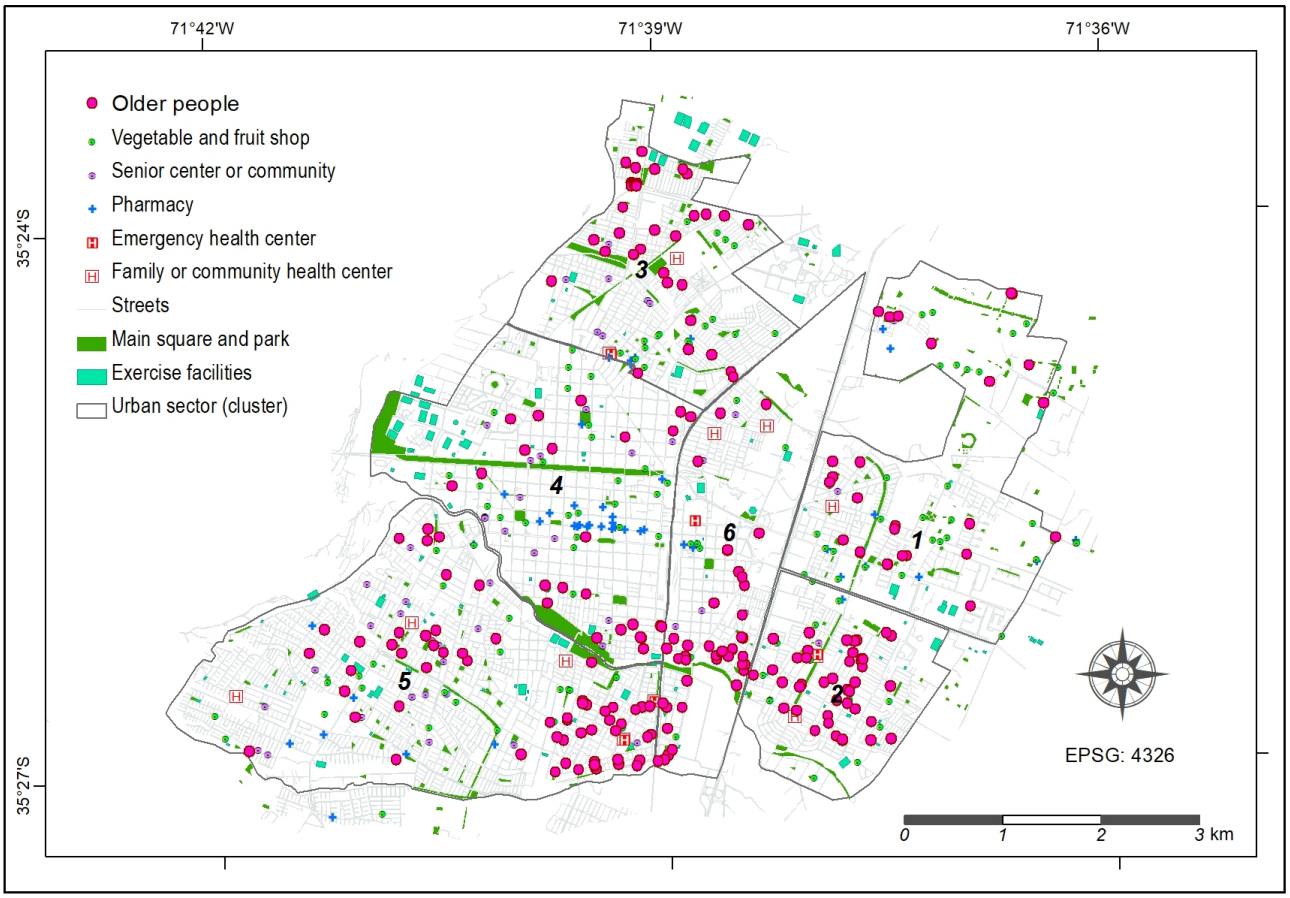
Frailty was measured using the FTS-5, which assesses frailty across 5 key domains: nutrition, physical activity, nervous system, strength, and gait speed. Nutrition was evaluated using BMI [20]. Physical activity was assessed with the Physical Activity Scale for Elderly. Nervous system function was evaluated using the Progressive Romberg Test. Strength was determined by handgrip strength in the dominant hand. Gait speed was measured by time taken to complete a 3-meter walk at a usual pace. Each domain is scored on a scale from 0 to 10 points. Frailty was determined by summing the scores across all 5 domains, resulting in a total range of 0-50 points. A score above 25 was considered indicative of frailty. The FTS-5 Scale has demonstrated high diagnostic accuracy (AUC: 0.81 - 0.85 for frailty incidence) in urban-dwelling older adults, with strong

XSL•FO
RenderX

psychometric properties relative to Fried's phenotype (sensitivity 0.608; specificity 0.823) and the FRAIL Scale (sensitivity 0.642, specificity 0.814). Unlike Fried's criteria, which rely solely on physical characteristics, the FTS-5 incorporates neurophysical and functional dimensions, enhancing its sensitivity in heterogeneous urban populations.

Nutritional Status

Nutritional status was assessed using the CONUT score, a validated tool based on 3 biochemical parameters: serum albumin, total lymphocyte count, and total cholesterol levels [21]. Each parameter is assigned a score based on predefined thresholds, and the sum of these scores provides the overall CONUT score. Higher scores indicate a greater degree of malnutrition, with classifications ranging from normal (0 - 1) to severe malnutrition (≥9).



Hematological and Biochemical Profile

Seventy plasma and serum samples were randomly obtained from cohort participants. Blood samples were collected using ethylenediaminetetraacetic acid (4.5 mL) and without anticoagulant (5 mL) by phlebotomy. The ethylenediaminetetraacetic acid blood sample was used to determine hematological profile (BC-3600 MINDRAY) using automated equipment. The blood sample without anticoagulant was centrifuged at 240 g for 15 minutes to obtain serum, which was used to determine the biochemical profile (BC-300 MINDRAY) using automated equipment. The sample size was calculated using the GRANMO calculator with a 95% confidence level, 80% statistical power, and an expected loss rate of 20%.

Geospatial Database

A georeferenced database was created using GIS technology to represent the physical environment of the study area and the locations of the older adults participating in the study (Figure 1). Each participant was geographically located as a point object based on the residence data provided during the medical evaluation. All data were organized into a point feature layer, accompanied by a corresponding thematic table. The database included relevant factors related to urban physical infrastructure within the city, such as fruit and vegetable shops, senior centers or communities, pharmacies, emergency health centers, main squares and parks, family or community health centers, and exercise facilities. Each component was represented as a GIS layer, either in point or polygon form, at the neighborhood level, using geographical information from OSM (OpenStreetMap), Google Maps, and IDE Chile (Geospatial Infrastructure of Chile).

Figure 1. Locations of each older adult in the study within the city of Talca, alongside the available urban physical facilities.

The city of Talca (Maule Region, Chile) was further divided into 6 main clusters based on sociodemographic characteristics: cluster 1 represents the northeastern sector with a high socioeconomic status (SES), cluster 2 covers the southeastern sector with a low SES, cluster 3 includes the northern sector with a lower-middle socioeconomic class, cluster 4 corresponds to the historic center, cluster 5 encompasses the southern sector with a medium-high socioeconomic level, and cluster 6 refers

XSL•FO
RenderX

to the industrial center area. These clusters were defined using census data and municipal planning criteria, considering variables such as household income, education level, housing density, and land use. Classification was based on expert-informed manual grouping rather than statistical clustering algorithms.

Urban Quality Level

Each GIS layer was analyzed using the Euclidean distance method to assess the proximity of every location within the city to various urban facilities. The resulting distance layers were then classified into 3 zones: close, medium, and distant. Each zone was assigned a score on a scale from 1 to 3, with the closest proximity receiving a score of 3 and the most distant areas a score of 1. The distance ranges and corresponding scores for each urban facility were defined based on the local context, as shown in Table 1. These parameters had been previously applied in the same city [14] and are considered representative of 3 distinct levels of access efforts. The general criterion was that closer proximity to a facility indicated higher urban quality. A raster calculator was used to aggregate all layers into a summary index, with higher numerical values reflecting better urban quality in the corresponding area. The facilities included in this index were vegetable and fruit shops, senior centers or communities, pharmacies, emergency health centers, main squares and parks, family or community health centers, and exercise facilities, as detailed in Table 1. The summary index was computed as a continuous raster surface (50-m resolution) covering the entire urban area. Values were extracted at each participant's georeferenced location using a spatial join. While the index was later analyzed in relation to spatial clusters, its computation was conducted across the full urban extent rather than per cluster. All data management, processing, and analysis were performed using ArcGIS software (version 10; ESRI).

Table . Distance ranges and corresponding values assigned to each urban physical facility.

Facility	Distance ranges, m		
Vegetables and fruits shops	<300	300 - 600	>600
Senior centers or communities	<500	500 - 1000	>1000
Pharmacies	<500	500 - 1000	>1000
Emergency health centers	<1000	1000 - 2000	>2000
Main squares and parks	<200	200 - 400	>400
Family or community health centers	<700	700 - 1400	>1400
Exercise facilities (stadiums and green areas with urban assets designed for physical activity)	<400	400 - 600	>600
	Values		
	3	2	1

Statistical Analysis

Statistical analyses were conducted using GraphPad Prism 9. Continuous variables were expressed as mean (SD) or median with 95% CI. Categorical variables were expressed as percentages with 95% CI. Group differences were assessed using the Chi-square test with Yate's correction for proportions. For differences in means or medians, the *t* test, Mann-Whitney *U* test, or ANOVA was applied, depending on the context. Correlation analysis was performed using Spearman correlation coefficient (ρ). Statistical significance was considered at *P* values of <.0500.

Ethical Considerations

The institutional review board approval for this study was obtained from the Comité de Ética Científica of Universidad de Talca (reference number 06-2021). All procedures adhered to the ethical standards of the Comité de Ética Científica and the World Medical Association's Declaration of Helsinki. All participants provided written informed consent. All data were deidentified; stored on encrypted, password-protected institutional servers with access restricted to authorized personnel; and reported only in aggregate. Geospatial data were coded to administrative units to minimize reidentification. Participants participated voluntarily and received no compensation.

Results

Sociodemographic Characteristics and Spatial Cluster Distribution by Frailty Status

Table 2 shows the sociodemographic characteristics of the study cohort, as well as the geospatial distribution of nonfrail and frail individuals across the spatial clusters (1-6). The cohort consists of 17.5% (44/251) frail older adults and 82.5% (207/251) nonfrail older adults. No significant differences were observed in the prevalence of women between groups (*P*=.642). The frail group had a higher mean age (mean 75.6, SD 7.4 years) than the nonfrail group (mean 73.8, SD 5.2 years); however, this difference was not statistically significant (*P*=.0583). Conversely, the frail group exhibited a significantly higher mean BMI (mean 31.5, SD 4.4 kg/m²) than the nonfrail group (mean 28.5, SD 4.5 kg/m²) (*P*=.0001). Regarding geospatial distribution, no significant differences were observed between the groups.

Cluster 6 (95% CI)	17.4 (12.8 - 23.1)	18.2 (9.5 - 31.9)	.5918

Frailty Characterization According to Quartile Distribution of Summary Index

Figure 2 illustrates the different levels of urban quality based on a cumulative assessment (summatory index) of physical environmental factors considered in this study. These factors primarily encompass essential urban services and infrastructure relevant to the older adult cohort under investigation. Urban quality levels are closely linked to the accessibility of various facilities from each location within the city. In addition, Figure 2 displays the spatial distribution of individual participants, with each one identified by frailty status.

Figure 2. Frailty status of older adults across the summary index within the geospatial clusters defined for the city of Talca.

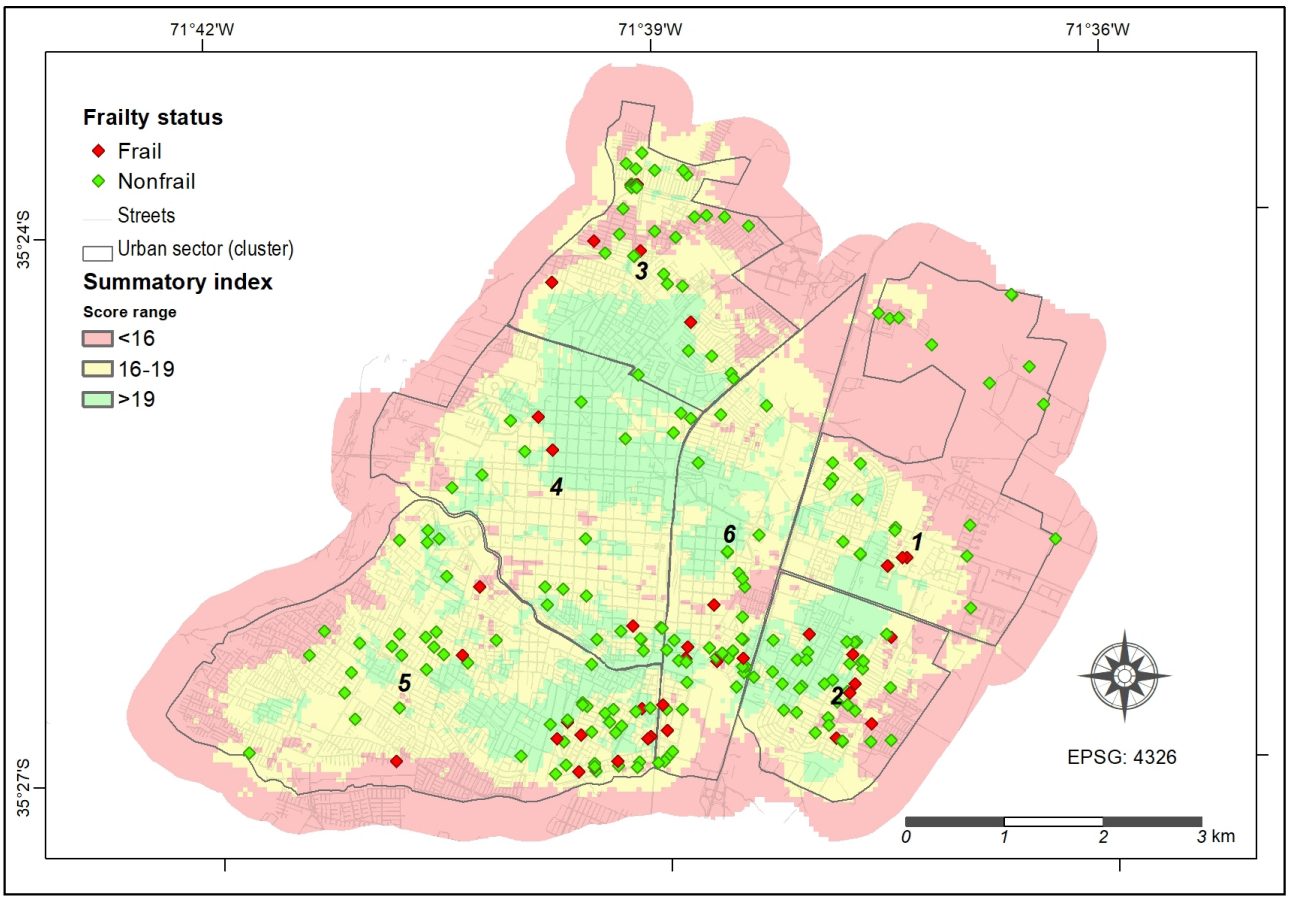

Table 3 shows mean values for frailty prevalence, frailty score, handgrip strength, gait speed, and BMI, grouped by quartiles of the urban quality summary index. While spatial clusters represent areas with homogeneous socioeconomic and urban characteristics (eg, cluster 1 corresponds to a high SES area in the northeast), the quartiles (Q1-Q4) classify areas based solely on their objective accessibility to services, regardless of SES. As shown in Figure 2, for instance, cluster 5 (classified as

XSL•FO
RenderX

medium-high SES) includes both Q1 (poorest access) and Q4 (best access) zones, highlighting that even socioeconomically advantaged areas may contain localized disparities in service provision. As previously described, lower values on the summary index indicate poorer urban quality, while higher values reflect better urban quality. Q1 represents the quartile with the lowest index values (poorest urban quality), and Q4 represents the highest values (best urban quality). No statistically significant differences were observed across quartiles for the analyzed variables concerning frailty prevalence (*P*>.0500). However, when comparing Q4 with Q1, participants in Q4 exhibited a significantly higher FTS-5 score (mean 15.2, SD 7.4 vs mean 11.8, SD 6.4; *P*=.0334) and a significantly lower handgrip strength (mean 19.1, SD 4.4 vs mean 22.8, SD 7.3; *P*=.0059). No significant differences were found between Q4 and Q1 for frailty prevalence, gait speed, or BMI (*P*>.0500).

Table . Frailty prevalence, handgrip strength, gait speed, and BMI according to quartile distribution of summary index.

Frail status	Q1 (12-17)	Q2 (>17 - 19)	Q3 (>19 - 20)	Q4 (>20 - 22)	*P* value
Frail % (95% CI)	15.3 (8.7 - 25.3)	17.8 (11.6 - 26.4)	17.3 (9.4 - 29.7)	23.1 (11.0 - 42.0)	.8462
FTS-5 Scale score, mean (SD)	11.8 (6.4)	13.6 (7.9)	13.7 (8.3)	15.2 (7.4)[a]	.2092
Handgrip strength (kg), mean (SD)	22.8 (7.3)	21.3 (7.3)	22.4 (7.2)	19.1 (4.4)[a]	.2620
Gait speed (m/s), mean (SD)	1.0 (0.3)	0.9 (0.2)	0.9 (0.2)	0.9 (0.2)	.6593
BMI (kg/m^2), mean (SD)	29.3 (4.3)	29.4 (4.1)	29.1 (4.4)	28.5 (4.2)	.7723

[b]FTS-5: Frailty Trait Scale 5.

Relationship Between Frailty and Distances to Urban Facilities and Urban Quality

Figure 3 shows a comparison of average distance to urban facilities by frailty status, as assessed using the FTS-5 clinical tool. No significant differences were observed in the distance between frail and nonfrail groups for key urban areas such as vegetable and fruit shops (Figure 3A), senior centers or communities (Figure 3B), pharmacies (Figure 3C), and main squares and parks (Figure 3E) (*P*>.0500). However, Figure 3A suggests a trend where frail individuals tend to live further from vegetable and fruit shops. In contrast, Figure 3D shows that the frail group is significantly closer to emergency health centers (*P*=.0010). Similarly, the frail group was significantly closer to family or community health centers (Figure 3F) (*P*=.0412) and stadiums and exercise facilities (Figure 3G) (*P*=.0322).

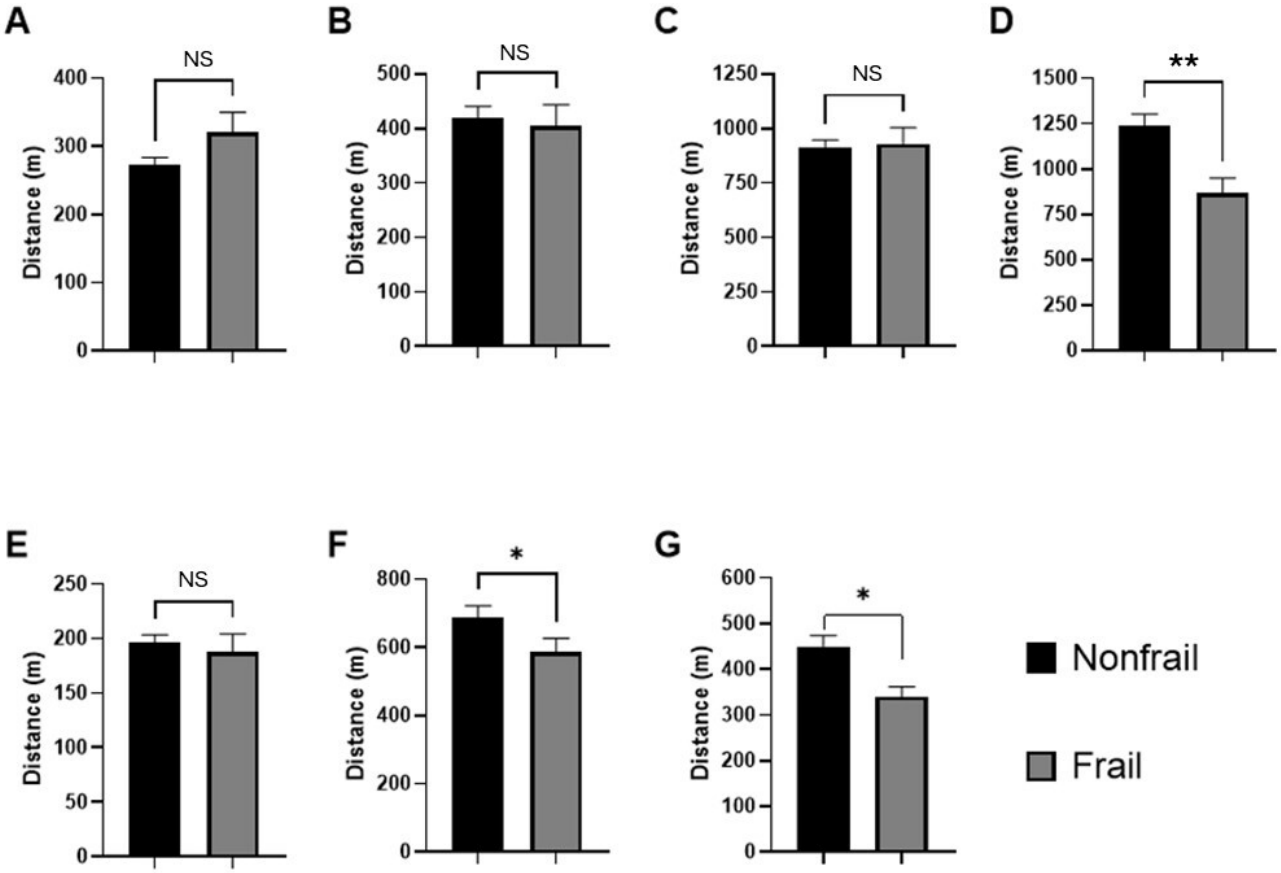
RenderX

Figure 3. Comparison of mean distance for different frailty status diagnosed by Frailty Trait Scale 5 Scale with respect to relevant urban facilities: (A) vegetables and fruits shops, (B) senior centers or communities, (C) pharmacies, (D) emergency health centers, (E) main squares and parks, (F) family or community health centers, and (G) exercise facilities. The data presented are mean (SEM). Statistical analysis was performed using the *t* test or Mann-Whitney *U* test, as appropriate. *P<.0500. **P<.0001. NS: not significant.



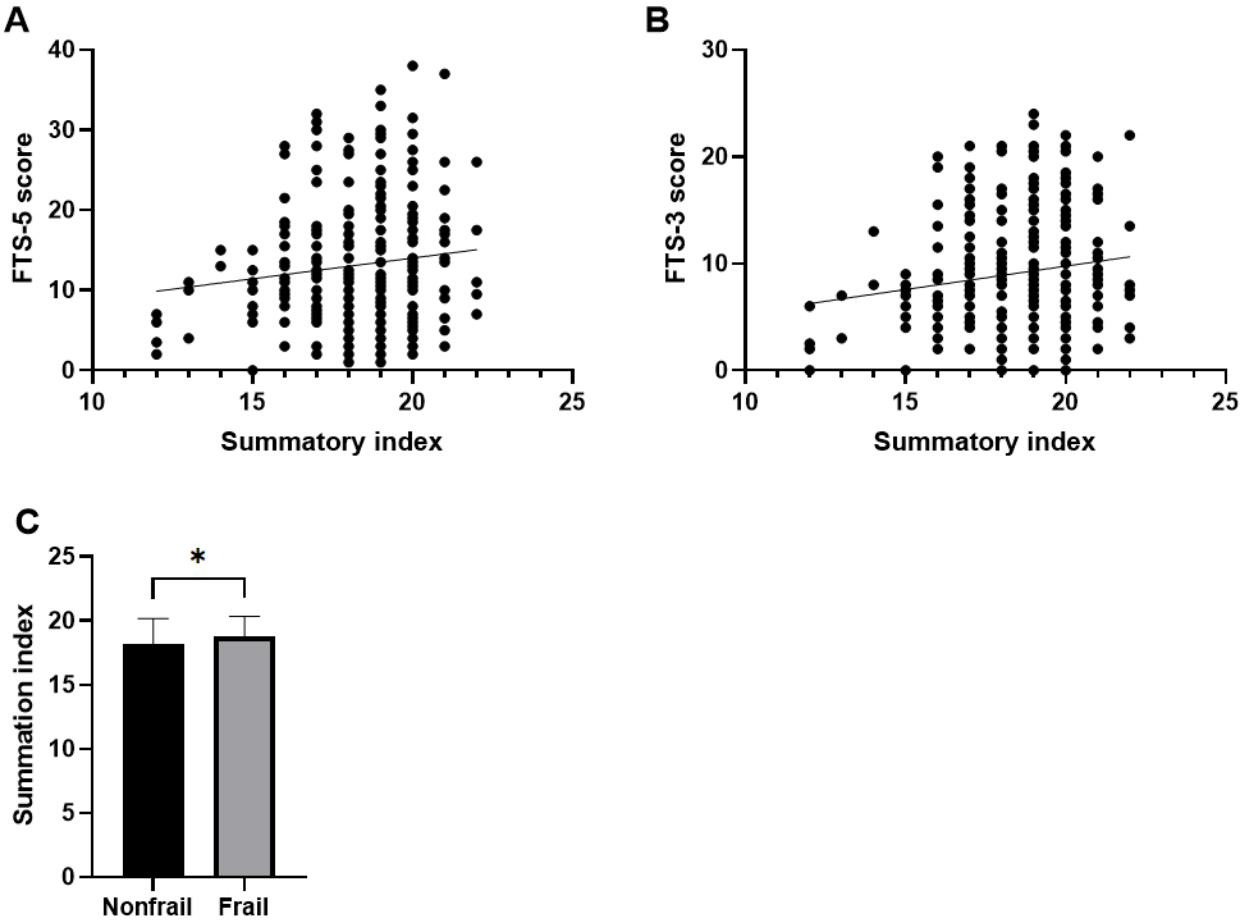


Figure 4 shows the correlation analysis between frailty scores and the summary index and compares this parameter by frailty status. In Figure 4A, the linear regression between the summary index and the FTS-5 score shows a positive correlation, where an increase in the summary index corresponds to a higher FTS-5 score. This correlation is statistically significant, with a Pearson *r* of 0.1319 (*P*=.0368). A similar trend is observed in Figure 4B, which illustrates the correlation between the summary index and the FTS-3 score (a shortened version of FTS-5), showing a Pearson *r* of 0.1562 (*P*=.0132). Figure 4C compares the summary index by frailty status, demonstrating a modest but significant increase in the frail group (*P*=.0310).

Relationship Between Urban Quality and Biochemical and Hematological Parameters

Table 4 shows the results of the correlation analysis between the summary index and the biochemical and hematological parameters of the older adult participants. At the biochemical level, only bilirubin levels showed a significant correlation with the summary index (Spearman ρ=0.3325) (P=.0049). Figure 5A displays the linear regression for this parameter, illustrating a direct relationship where higher summary index values are associated with increased bilirubin levels in older adults. At the hematological level, several parameters showed a significant correlation with the summary index. Serum iron exhibited a positive correlation (Pearson r=0.2720; P=.0272), as illustrated in Figure 5E, where higher summary index values correspond to increased serum iron levels. Similarly, transferrin saturation (Spearman ρ=0.2478; P=.0386), RBC count (Pearson r=0.2629; P=.0303), and red blood cell distribution width (RDW) (Pearson r=0.2391; P=.0462) also displayed positive correlations with the summary index. The linear regression graphs in Figure 5B-E, corresponding to each parameter, respectively, further illustrate this direct relationship, where an increase in the summary index was associated with higher values of these hematological parameters.

Nutritional Status Assessed by CONUT Score According to Frailty Status and Its Correlation With Urban Quality

Figure 6 shows a comparison of the CONUT score by frailty status and its correlation with urban quality, measured through the summary index. In Figure 6A, the frail group shows a significantly higher CONUT score (P=.0323), indicating poorer nutritional status. Meanwhile, Figure 6B displays the linear regression analysis between the CONUT score and the summary index, revealing a significant positive correlation between both variables (Spearman ρ=0.2513; P=.0359).

Discussion

Principal Findings

This study examined the association between urban quality and frailty in older adults by integrating geospatial analysis with nutritional and hematological or biochemical parameters. Key findings revealed that higher urban quality was significantly associated with altered hematological markers (eg, elevated bilirubin, serum iron, and RBC count), poorer nutritional status (as indicated by higher CONUT score), and increased frailty prevalence. Frail individuals living in areas of higher urban quality also exhibited lower handgrip strength, higher frailty scores, and greater proximity to emergency health centers, community centers, and exercise facilities. In summary, older adults residing in neighborhoods with the greatest proximity to services, parks, and health facilities were more frequently classified as frail and exhibited weaker muscle strength, poorer nutritional status, and modest increases in iron-related and erythrocyte markers, while inflammatory and renal-hepatic indicators remained largely unaffected. While these spatial patterns suggest potential links between urban environment and health outcomes in aging populations, the cross-sectional design limits causal inference. Because all exposures and outcomes were assessed at a single point in time, the cross-sectional design precludes establishing temporal precedence; therefore, observed associations cannot be interpreted as causal. Reverse causation is plausible, and residual confounding from unmeasured factors may persist despite statistical adjustment. Several potential sources of bias should also be acknowledged. First, recruiting participants through primary care clinics may overrepresent older adults who are relatively health-seeking, potentially underestimating the true prevalence of frailty (selection bias). Second, minor geocoding errors and reliance on single time-point biomarker measurements may lead to exposure and outcome misclassification. Given these limitations, we emphasize the need for prospective studies to further investigate these associations and clarify their causal pathways.

The results indicate that frailty prevalence in the studied cohort was 17.5% (44/251), which aligns with previous research reporting frailty rates ranging from 12% to 27% in Chilean older adults [19,22]. The higher BMI observed in frail individuals is consistent with studies suggesting that obesity exacerbates physical limitations and inflammation, contributing to frailty [23-25]. Although the frail group had a higher mean age, the difference was not statistically significant. Age is a well-known factor for frailty, with prevalence increasing in advanced age, particularly in individuals aged 80 years and older [26,27]. However, it is important to consider that environmental and lifestyle factors may play a more substantial role than age alone [3]. The lack of significant differences in frailty prevalence across spatial clusters suggests a uniform distribution of risk factors in the evaluated area. This also highlights the need to expand the geospatial analysis to different urban and rural areas to capture the variations in frailty prevalence and associated risk [8].

Consistent with the previous findings, no significant difference in frailty prevalence was observed across quartiles based on the summary index. However, Q4 did show a higher prevalence of frailty than Q1, although this difference did not reach statistical significance, suggesting that a larger sample size may be needed to confirm this trend. In addition, Q4 exhibited a higher FTS-5 score, indicating a greater level of frailty. These findings suggest that frail older adults may be more likely to reside in areas with better urban quality, potentially reflecting adaptive behaviors related to their health status and quality of life [28,29]. For example, improved access to natural environments (an important component of urban quality) has been associated with reduced health inequality linked to income deprivation, indicating that older adults may choose to reside in better quality urban areas to support their health [30]. Likewise, increased greenery in urban neighborhoods has been linked to better physical and mental health, which may encourage frail individuals to settle in or remain within such environments to mitigate health declines [31].

On the other hand, Q4 also showed a significant decrease in handgrip strength, which correlates with a high FTS-5 score and greater frailty prevalence. Reduced handgrip strength is a marker of poorer muscle condition and is associated with increased risk of sarcopenia, chronic diseases, and mortality [32]. These findings suggest that addressing sarcopenia could be a valuable strategy in high-accessibility areas when designing interventions to prevent frailty and promote healthy aging in older adults [33].

This study also found that frail individuals tended to live significantly closer to exercise facilities, community health centers, and emergency medical services, which may reflect adaptive behaviors in response to health care accessibility. While proximity to these facilities suggests that frail older adults may prioritize access to spaces supporting physical activity and social interaction, closeness to emergency and community health centers likely provides critical support for managing both acute and chronic health conditions [31,34]. It is important to note that in this study, exercise facilities were operationally defined as stadiums and green areas equipped with infrastructure for physical activity. This definition represents a limitation when interpreting the associations observed. Moreover, the significant correlation between the summary index and frailty scores reinforces the hypothesis of a close relationship between frailty and urban environment quality. While our findings indicate that frail individuals live nearer to health and recreational facilities, actual use of these resources may be constrained by unmeasured sociodemographic barriers. These may include gender-related mobility limitations (particularly in older women), migration status (eg, language barriers), disability, and digital literacy (eg, limited access to digital health services) [35-37]. Future geospatial studies should incorporate individual-level data on these factors to better assess accessibility gaps in urban aging populations.

Limitations

In addition, some methodological limitations should be noted. The use of a summatory index, while straightforward and consistent with previous local studies [14], may oversimplify the relative importance of each facility type. More complex approaches (eg, weighted indices or principal component

XSL•FO
RenderX

analysis) may offer additional insights in future research. Moreover, spatial autocorrelation and the modifiable areal unit problem were not formally addressed. These are inherent challenges in geospatial analyses and should be explored in future studies using alternative spatial units and subjective environmental assessments. It should also be noted that the spatial clusters used in this study were not constructed based on direct SES indicators. Rather, they were defined using historical, structural, and industrial characteristics of the region. Therefore, any interpretation of these clusters as SES proxies should be made with caution. This limitation highlights the need for future studies to integrate direct SES variables when analyzing spatial health inequalities.

The results support the notion that environmental factors significantly influence the health status of older adults, revealing modest but statistically significant correlation between frailty, urban quality, and select biochemical and hematological parameters. Given the study's cross-sectional design, we emphasize the need for longitudinal research to confirm these associations and further explore causal mechanisms. The observed correlations offer valuable insights into the impact of urban environments on the nutritional status and metabolic health of older populations. Higher urban quality was associated with elevated bilirubin levels, which may reflect better liver function and more effective oxidative stress regulation. However, this correlation is modest and should be interpreted cautiously. Bilirubin, a well-established antioxidant, has been linked to reduced cardiovascular risk and lower systemic inflammation in prior studies [38]. Urban environments with better infrastructure are often associated with healthier lifestyles, including increased physical activity and dietary habits that support liver health [17]. Moreover, the positive correlation between urban quality and serum iron, RBC count, transferrin saturation, and RDW indicates a tentative association with certain hematological parameters [39]. These indicators are essential for evaluating anemia and overall oxygen transport capacity, both of which are critical determinants of functional status and frailty in older adults [18]. Conversely, poor urban quality, characterized by limited access to nutrient-dense food and inadequate health care services, has been linked to higher risks of anemia and micronutrient deficiencies [40]. Our findings are consistent with previous studies suggesting that the built environment influences dietary patterns, which may in turn affect hematological and biochemical health markers [16].

Our results also reveal an association between frailty and higher CONUT scores, underscoring the close interplay between nutritional status and frailty. Malnutrition is a well-established contributor to frailty, and the CONUT score has been validated as a reliable marker of nutritional risk in frail older adults [21,41]. Our findings indicate that frail individuals tend to have poorer nutritional status, which aligns with previous research linking malnutrition to sarcopenia, immune dysfunction, and increased morbidity [19,42,43]. The observed association between elevated CONUT scores and frailty also supports evidence connecting malnutrition to chronic inflammation and sarcopenia, key biological pathways underlying frailty [21,41]. While our study included C-reactive protein as an inflammatory marker (showing no significant correlation with urban quality), future studies should incorporate proinflammatory cytokines such as interleukin-6 and tumor necrosis factor α to more comprehensively assess inflammatory dysregulation [41]. It is important to note that the CONUT score's reliance on serum albumin (a negative acute-phase reactant) may reflect both malnutrition status and subclinical inflammation, complicating its interpretation. The cutoff values used (albumin <3.5 g/dL, lymphocytes <1500/mm^3, and total cholesterol <160 mg/dL) are based on the original CONUT validation [21]; however, their applicability and sensitivity to aging populations warrant further investigation. Interestingly, this positive correlation observed between urban quality and CONUT scores may indicate that better urban infrastructure supports improved nutritional status. Access to fresh food markets and community resources likely promotes better dietary intake, helping to reduce malnutrition and the burden of nutrition-related chronic diseases [44,45]. In contrast, lower urban quality may be associated with food insecurity and limited access to nutrient-dense foods, increasing the risk of frailty through inadequate protein and micronutrient intake [40,46].

It is important to emphasize that these findings highlight the need to address sociourban inequities in age-friendly urban planning. As demonstrated, targeted interventions, such as increasing opportunities for physical activity in low SES areas, can help mitigate health disparities. This suggests that improvements in urban quality should prioritize vulnerable subgroups to reduce frailty gradients across populations [47].

Notably, the paradoxical finding that frailer individuals resided closer to fresh food markets and yet exhibited poorer nutritional status (as indicated by higher CONUT scores) warrants further investigation. Although proximity to food sources is often assumed to enhance dietary intake, various barriers (such as mobility limitations, financial hardships, or lack of social support) may prevent frail older adults from effectively using these resources. This observation is consistent with prior studies indicating that physical access alone does not ensure food security or healthy eating behaviors, particularly among socially and physically vulnerable populations [40,45]. Similarly, the observed proximity of frail individuals to exercise facilities may reflect adaptive strategies to manage functional decline; however, actual engagement in physical activity may be constrained by comorbidities, pain, or reduced mobility [33]. These findings underscore the importance of complementing urban infrastructure with targeted, supportive interventions that bridge the gap between accessibility and actual utilization among frail older adults.

Conclusions

Our research demonstrates that among older adults in Chile, urban quality has a significant impact on their metabolic health, nutritional status, and frailty. Frail individuals residing in areas with higher urban quality exhibited lower handgrip strength and higher frailty scores. In addition, they tended to live closer to emergency rooms, community health centers, and exercise facilities. While this spatial pattern suggests potential accessibility advantages, its relationship with frailty requires further investigation. Moreover, higher CONUT scores in frail individuals and positive correlations between urban quality and

XSL•FO
RenderX

key biochemical or hematological parameters indicate that better urban environments may support healthier metabolic and nutritional profiles. Given the cross-sectional design and localized scope of this study, future research should incorporate longitudinal approaches and larger, more diverse cohorts to confirm these associations and explore the underlying mechanisms. Finally, urban planning strategies promoting age-friendly environments may help mitigate frailty risk; however, longitudinal studies are needed to clarify the roles of selective migration, aging in place, and disparities in urban development in shaping these outcomes.

Abstract

Background: Research on the effects of social and intellectual activities on frailty remains limited, particularly longitudinal studies examining how these activities influence the dynamic progression of frailty over time. We aimed to examine this association in a nationally longitudinal study.

Objective: This study aimed to investigate the relationship between social and intellectual and frailty trajectories in the middle-aged and older Chinese population. Specifically, it sought to identify distinct frailty trajectories and quantify the longitudinal protective effects of social and intellectual activities against adverse frailty progression, while exploring differential impacts across age, sex, and residence subgroups.

Methods: This study used data from the China Health and Retirement Longitudinal Study and group-based trajectory modeling identified frailty trajectories over seven years. Frailty was assessed using a 38-item frailty index. The frequency of social activities and intellectual activity were quantified separately. Multivariate ordinal logistic regression analyzed associations between activity frequencies and trajectory membership.

Results: Three different trajectories of frailty were identified in this study: “low progressive trajectories” (n=7208, 65.8%), “moderate progressive trajectories” (n=3061, 28.5%), and “high progressive trajectories” (n=609, 5.7%). Compared to nonparticipants, frequent social activity participation reduced the likelihood of transitioning to the “moderate progressive” trajectory (odds ratio [OR] 0.84, 95% CI 0.75 - 0.94; *P*=.004). Intellectual activity engagement lowered risks of both “moderate” (OR 0.77, 95% CI 0.63 - 0.94; *P*=.01) and “high progressive” trajectories (OR 0.63, 95% CI 0.40 - 0.99; *P*=.04). Subgroup analyses revealed differential effects by age, sex, and residence.

Conclusions: This study confirms the existence of heterogeneous long-term frailty trajectories among middle-aged and older Chinese adults, social and intellectual activities significantly mitigate frailty progression in Chinese middle-aged and older adults. Regular participation in structured social and intellectual activities can effectively delay frailty development in this population.

frailty; social activity; intellectual activity; trajectory modelling; CHARLS; China Health and Retirement Longitudinal Study

Introduction

Frailty is a complex age-related clinical condition characterized by a decline in physiological capacity across multiple organ systems, leading to increased susceptibility to stressors [1]. As an emerging global health burden, frailty has significant implications for clinical practice and public health [2]. Globally, systematic assessments indicate that the prevalence of frailty among community-dwelling adults aged 65 years and older varies widely, ranging from 4.0% to 59.1% [3]. In a follow-up cohort study involving frail older adults across 28 countries, the incidence of comorbidities associated with frailty was reported to be 43.4 per 1000 person-years [4]. Frailty imposes a substantial burden on national health care utilization and expenditure costs. Given the increasing prevalence and growing harm caused by frailty, identifying it and implementing

XSL•FO
RenderX

interventions to slow its progression is crucial for the healthy [5,6].

As a multifactorial syndrome, frailty is influenced by a range of modifiable risk factors, among which, physical, social, and intellectual activities have garnered significant research interest for their potential protective roles. Numerous studies have confirmed that subjects with low social support or social engagement, measured by social frequency, are more likely to exhibit a rapid increase in frailty trajectory, often validated by professional tools such as the Fried phenotype or frailty indices [7-10]. Similarly, a prospective cohort study suggested that frequent intellectual activities—such as reading, playing games, or other cognitively stimulating pursuits—have been identified as a key modifiable factor for mitigating frailty [11]. While these studies underscore the potential protective role of social and intellectual activities, many focus primarily on frailty status or onset rather than its long-term dynamic progression. Furthermore, the specific correlation between the frequency of these activities and distinct longitudinal frailty trajectories remains underexplored in the context of an aging society, particularly within large national cohorts like CHARLS (China Health and Retirement Longitudinal Study).

In summary, this study aims to evaluate the association between social/intellectual activities and distinct frailty trajectories in middle-aged and older adults. The findings may inform strategies for preventing frailty onset and improving outcomes in individuals with frailty.

Methods

Study Population and Design

The analyses were performed based on the CHARLS. CHARLS is a longitudinal survey of inhabitants in mainland China aged 45 and older that provides information such as socioeconomic position and health status. It covers 17,708 participants from 150 counties of 28 provinces in China [12]. The data on socioeconomic status, lifestyles, medications, health status, and functioning assessments were collected. Details on the study design, sampling procedure, and details of the surveys are available in its report [12].

Our study used four waves of data (2011 - 2018). Participants were restricted to individuals aged ≥45 years who had attended the "health status and function" module at baseline, yielding an initial sample of 17,596. Exclusions comprised 3048 individuals: 497 were aged <45 years, 2436 lacked frailty composite indicator data, and 115 had missing social or intellectual activity data at baseline. During follow-up between 2011 and 2013, 2557 individuals were excluded due to attrition (including death, withdrawal, or loss of contact), while 878 newly eligible individuals were enrolled in 2013. A further 1991 participants were excluded between 2013 and 2018 due to loss to follow-up. A comparison of baseline characteristics between the final analytical cohort and participants lost to follow-up is provided in Multimedia Appendix 1.

Ethical Considerations

Ethical approval for the China Health and Retirement Longitudinal Study (CHARLS) was obtained from the Biomedical Ethics Review Committee of Peking University (Approval Number: IRB00001052-11015). Written informed consent was secured from all participants prior to enrollment. No direct compensation was provided to participants for this survey. For this secondary analysis, we used fully anonymized and deidentified data from CHARLS.

Assessment of Frailty

Frailty was assessed using a frailty index (FI), constructed following a standardized procedure [13]. The detailed method for the calculation of FI was reported in previously published studies [14,15]. Briefly, 38 deficit variables relevant to frailty were selected, including impairments in activities of daily living (ADL) and instrumental activities of daily living (IADL), covering 11 tasks such as personal hygiene, dressing, and financial management. The index also incorporated limitations in physical function (9 items), chronic diseases (9 items), psychological health markers (5 items), and subjective measures (eg, self-rated health).

Each variable was scored dichotomously (0=no deficit, 1=deficit present). The FI score was derived by summing all deficits and dividing by the total number of variables. Frailty was defined as FI ≥ 0.25. Full variable definitions and methodological details are provided in Multimedia Appendix 2.

Assessment of the Frequencies of Social and Intellectual Activities

In the CHARLS survey, participants reported their social and intellectual activities over the preceding month. Social activities, which included four items, were defined as: interacting with friends; attending sports/social clubs; participating in community organizations; and engaging in voluntary or charity work. Intellectual activities, comprising four items, were defined as: playing Ma-jong, playing chess, playing cards, or going to the community club; attending educational courses; investing in stocks; and browsing the internet. Each activity was assigned scores based on the number of participants (Multimedia Appendix 3). The frequency of participants in social activities and intellectual activities was counted separately, categorized into three groups: ≥3 (frequent participation), 1 - 2 (nonregular participation), and 0 (no participation) [11].

Covariates

Based on previous research, several sociodemographic and health-related covariates were included in the study. Sociodemographic covariates comprised age, sex, marital status, location of residence, educational attainment, and retirement status. Health-related covariates included current drinking, current smoking, physical activity levels, and inpatient care. Current drinking and smoking statuses were assessed via self-report using the following questions: "Do you currently smoke?" and "Do you currently drink alcohol?" Marital status was categorized as "married" or "unmarried." Location of residence was classified as "rural" or "urban," and educational attainment was grouped into three categories: "primary school or below," "middle school," and "high school or above." Physical activity levels were categorized based on participation frequency as "inactivity," "low-intensity activities," "moderate activities," or "vigorous activities." Inpatient care was evaluated

XSL•FO
RenderX

by the question: “Have you received inpatient care in the past year?” Retirement status was determined by the question: “Are you currently retired?”

Statistical Analysis

Continuous variables were assessed for normality and are presented as median (25th–75th percentiles) due to their non-normal distribution. Group comparisons were performed using the Kruskal-Wallis test, Pearson’s χ^2 test, Wilcoxon rank-sum test, and Fisher exact test, with false discovery rate correction for multiple comparisons. Categorical variables are summarized as frequencies and percentages, and group differences were assessed using χ^2 tests.

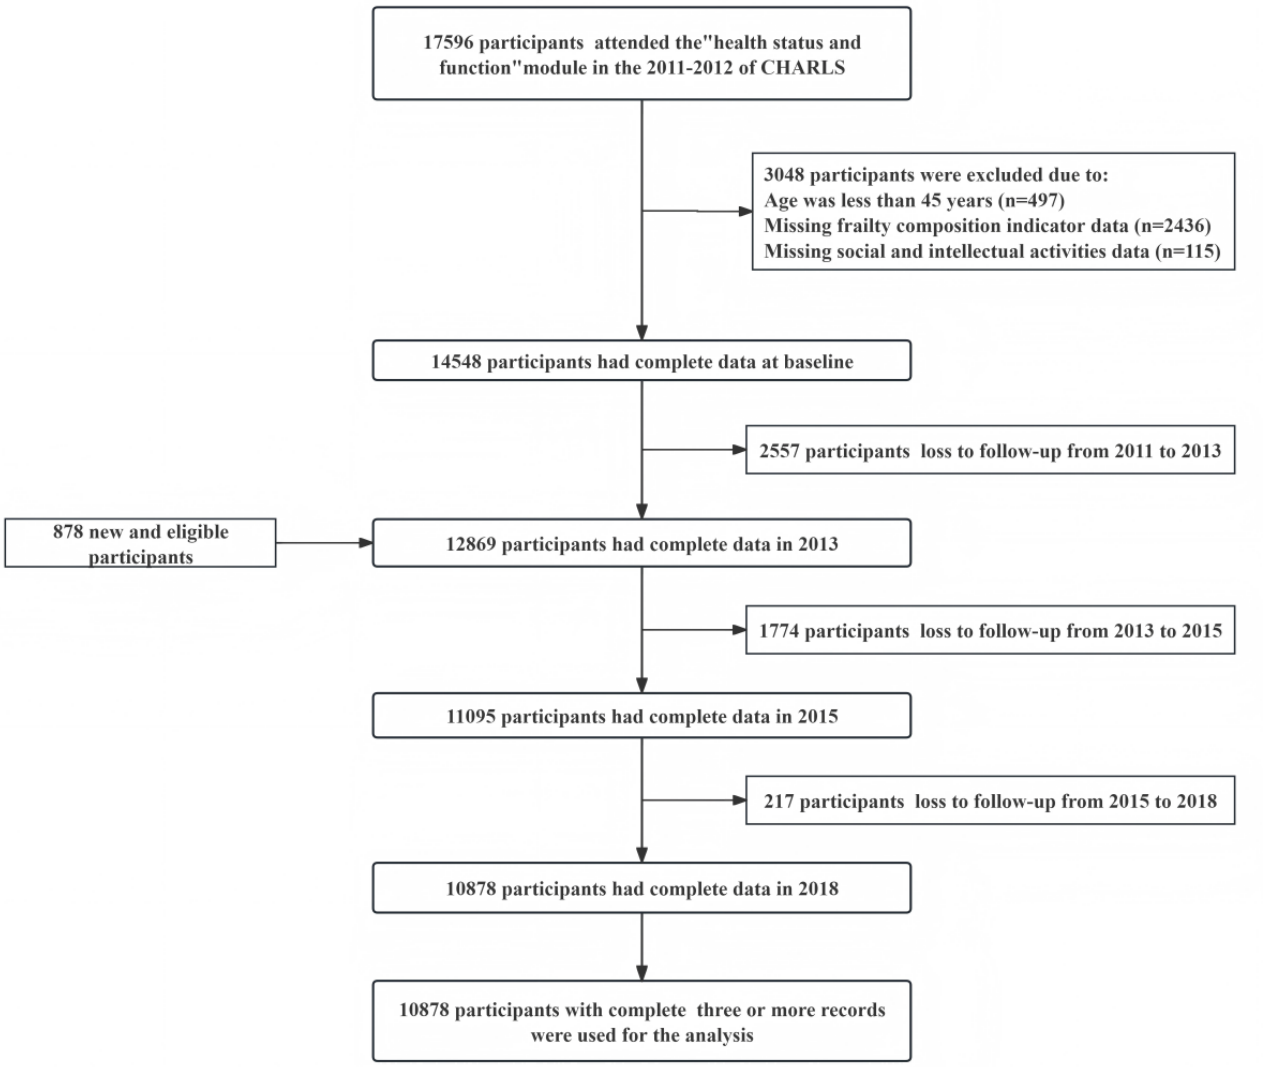
The Group-Based Trajectory Modeling (GBTM) approach was employed to investigate frailty trajectories in middle-aged and older adults. This method applies finite mixture modeling to identify observations with similar temporal developments and assign them to distinct trajectory groups. The optimal trajectory groups were selected based on the following criteria to the greatest extent possible [16]: (1) smaller absolute Bayesian Information Criterion (BIC) values; (2) larger BIC changes; (3) average posterior probability (APP)>0.7; (4) odds of correct classification (OCC) >5; (5) class proportions ≥5%; (6) relative entropy (Ek) is close to 1; (7) parsimony; and (8) interpretability of group patterns.

Subsequently, a multinomial logistic regression model was utilized to estimate the associations between social and intellectual activities and frailty trajectory patterns. Adjusted odds ratios (OR) and corresponding 95% CI are reported.

The multivariable-adjusted model incorporated the following covariates: age at baseline (continuous), sex (male vs female), education (primary school and below, middle school, high school and above), marital status (married vs others), smoking status (yes vs no), alcohol consumption (yes vs no), location of residence (rural vs. city), physical activity levels (inactivity, low-intensity activities, moderate activities, vigorous activities), inpatient care history (yes vs no), and retirement status (yes vs no). The benefits of social and intellectual activities may vary distinctly by subgroup. Sex-based differences in social roles [17], age-related transitions in health status [18], and China’s pronounced rural-urban disparities in infrastructure are all posited as key modifiers of these associations [19]. Thus, stratified analyses were additionally performed in separate models by age groups (<65 y and ≥65 y), sex (male vs female), and location of residence (rural vs city).

Two sensitivity analyses were conducted to assess the robustness of the associations between social/intellectual activities and frailty. First, the 878 newly enrolled participants in 2013 were excluded; second, frailty was stratified into three categories: nonfrailty, prefrailty, and frailty, to investigate its association with social and intellectual activities.

Results



Baseline Characteristics

Of the initial 17,596 participants, a total of 10,878 individuals with three or more complete records comprised the final analytical cohort for trajectory modeling. The detailed flow of participant inclusion and exclusion is presented in Figure 1.

A total of 10,878 participants were included in the study, with 52.0% (n=5655) being female. Among them, 19.7% (n=2143) had a social activities score≥ 3, and 6.1% (n=662) had an intellectual activities score≥ 3. Most participants resided in rural areas, were married, had a primary school education or below, reported physical inactivity, and had retired (P<.001).

Estimated Frailty Trajectories

The trajectories model, consisting of three different trajectories, showed the best fit using the BIC, Akaike Information Criterion, APP, and interpretability in the trajectories analysis (Multimedia Appendix 4). Consequently, the GBTM with three trajectories was selected as the optimal model. Figure 2 illustrates the trajectories labeled as: (1) “low progressive” (n=7208, 65.8%), (2) “moderate progressive” (n=3,061, 28.5%), and (3) “high progressive” (n=609, 5.7%). The frailty function trajectories across the three groups are depicted in Figure 1. The “low progressive” group, comprising the majority of participants (65.8%), exhibited minimal FI values that remained consistently low throughout the observation period. The “moderate progressive” group (28.5%) showed gradual progression toward mild frailty over seven years, while the “high progressive” group (5.7%) displayed rapid FI escalation within approximately four years, followed by a plateau.

Comparative analysis of baseline characteristics across trajectory groups revealed that participants in the “high progressive” group were older, more likely to be female, married, rural residents, former smokers or alcohol consumers, and had higher educational attainment (high school or above). Additionally, this group exhibited higher rates of physical inactivity, hospitalization history, and reduced participation in social and intellectual activities compared to the “low progressive” group. Detailed distribution of baseline covariates and frailty trajectory groups was provided in Table 1.

Baseline Social, Intellectual Activities Scores and Frailty Trajectories

The multinomial regression analysis (Model 2) revealed distinct associations between social/intellectual activity scores and frailty trajectory membership. For social activities, compared to the reference group (score=0): participants with 1 - 2 scores showed no significant reduction in the odds of transitioning to the moderate progressive trajectory or the high progressive trajectory. Participants with ≥3 activity scores exhibited a 16% reduction in the odds of belonging to the moderate progressive trajectory (odds ratio [OR] 0.84; 95% CI 0.75 - 0.94; *P*=.004), while no significant association was observed for the high progressive trajectory.

For intellectual activities, compared to the reference group (score=0): participants with 1 - 2 scores demonstrated an 18% reduction in the odds of entering the moderate progressive trajectory (OR 0.82; 95% CI 0.72 - 0.94; *P*=.005) and a 40% reduction in the odds of transitioning to the high progressive trajectory (OR 0.60; 95% CI 0.43 - 0.83; *P*=.002). Participants with ≥3 activity scores showed even stronger protective effects: a 23% reduction in the odds for the moderate progressive trajectory (OR 0.77; 95% CI 0.63 - 0.94; *P*=.01) and a 37% reduction in the odds for the high progressive trajectory (OR 0.63; 95% CI 0.40 - 0.99; *P*=.04). Detailed results are presented in Table 2.

Table . Multinomial logistic regression analysis for the associations of social and intellectual activities with membership in the frailty trajectories group. Model 1 adjusted for age, sex, current drinking, current smoking; Model 2 plus additional adjustments for married, residence, education, physical activities, inpatient care, and retirement.

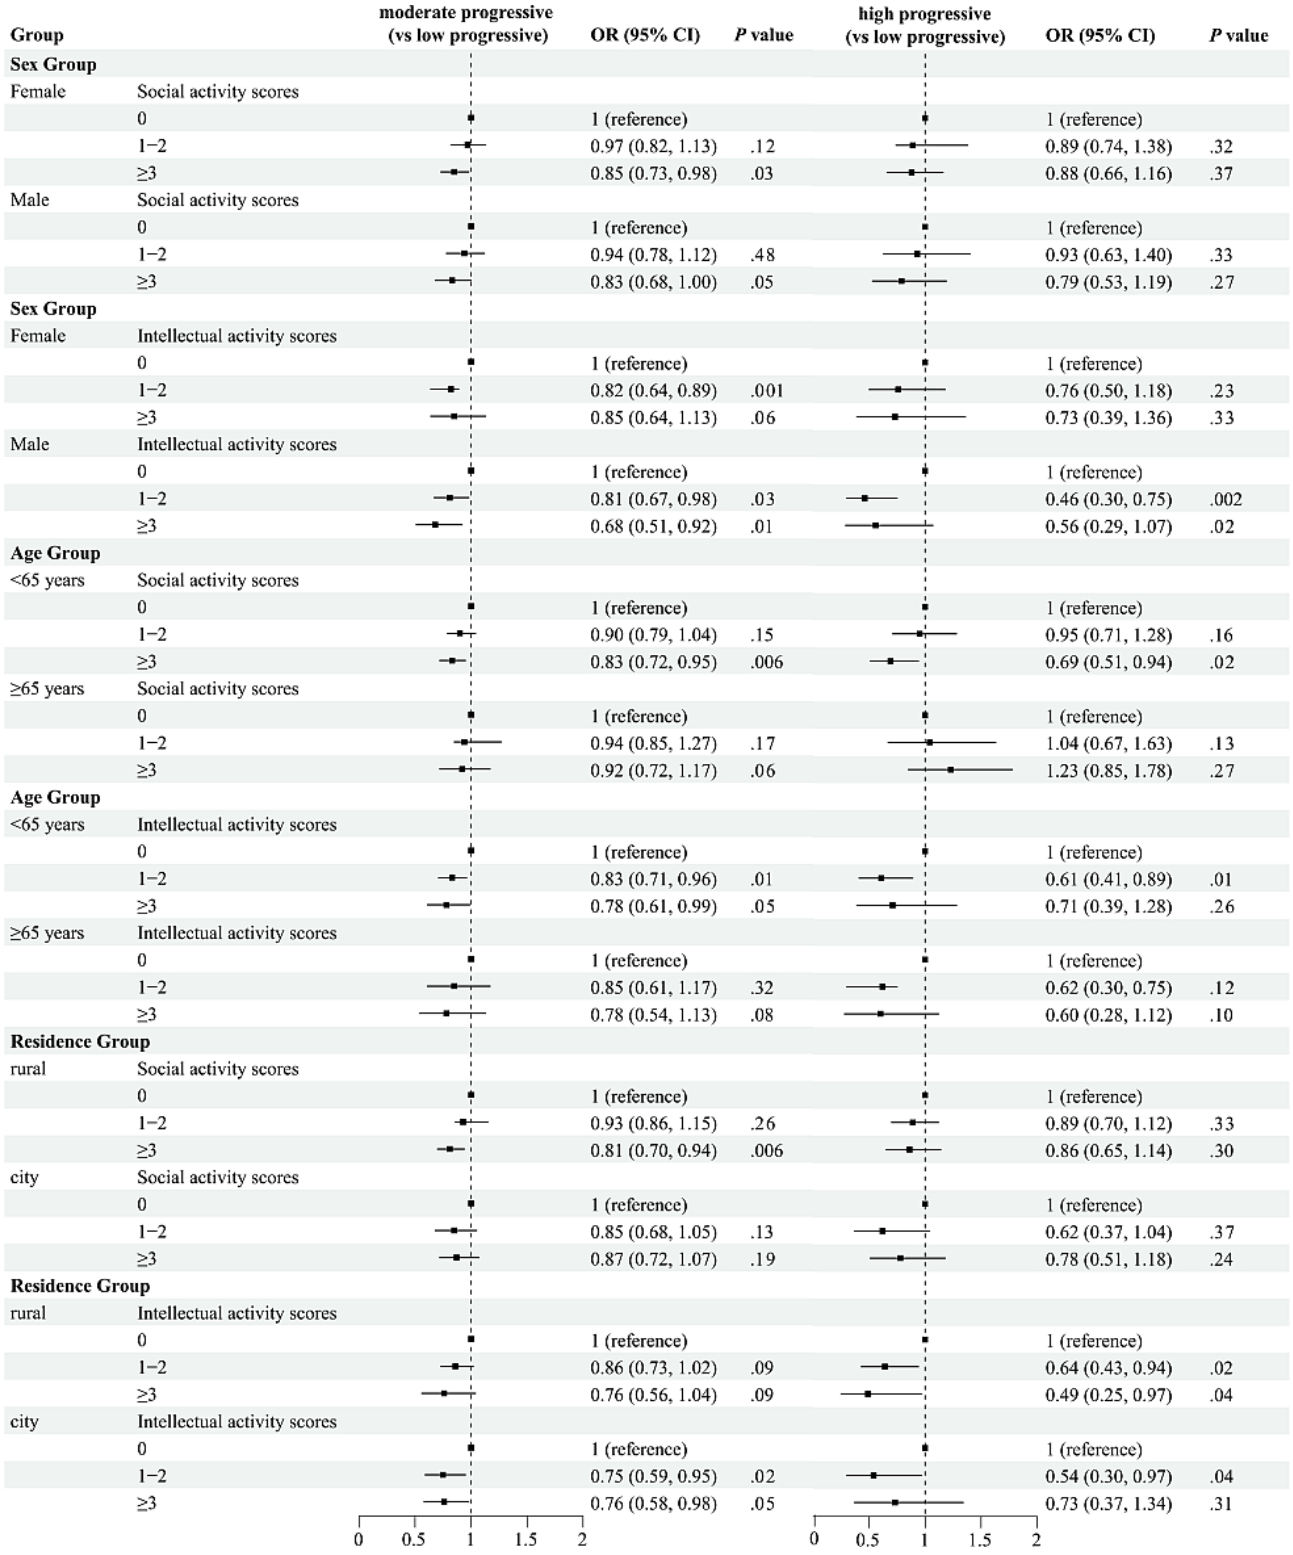
[a]OR: odds ratio.



[b]Not applicable.

Stratified Analysis

The stratified analyses are shown in Figure 3. We found that significant associations between social activities scores and frailty trajectories seem to differ with sex and age. In men, higher social activity scores had a significant effect on the moderate progression of reducing frailty, (OR 0.85; 95% CI 0.73 - 0.98, *P*=.003). For women, intellectual activities demonstrated stronger protective effects against frailty progression. Women engaging in frequent intellectual activities had a 32% lower risk of entering the “moderate progressive” trajectory (OR 0.68; 95% CI 0.51 - 0.92, *P*=.001). At the same time, high levels of social activities have a positive role in preventing frailty in people aged <65 years. Frequent social activity reduced the risk of “moderate progressive” (OR 0.83; 95% CI 0.72 - 0.95, *P*=.05) and “high progressive” (OR 0.69; 95% CI 0.51 - 0.94, *P*=.02) trajectories. In terms of the geographical distribution, rural residents showed stronger associations between social activity and favorable vulnerable trajectories(OR 0.81; 95% CI 0.70 - 0.94, *P*=.006), while urban residents benefited more from structured intellectual engagement(OR 0.76; 95% CI 0.58 - 0.98, *P*=.05).

XSL•FO
RenderX

Figure 3. The association of intellectual activities and social activities, stratified by age group, sex group, and residence group. Odds ratio (OR), 95% CI, and *P* values test the significance of the association within each subgroup. Adjusted for age, sex, current drinking, current smoking, marital status, residence, education, physical activities, inpatient care, and retirement.

Sensitivity Analyses

In the sensitivity analyses, first, to account for potential bias introduced by participant selection, the cohort was reanalyzed after excluding 878 participants enrolled in 2013 (Table S1-S2 in Multimedia Appendix 5). Second, participants were categorized into three frailty states based on the frailty index to examine the association between distinct frailty states and engagement in social and intellectual activities. Across all sensitivity analyses, the results remained consistent, further supporting the robustness of the observed associations (Table S1-S2 in Multimedia Appendix 6).

Discussion

Principal Findings

In this longitudinal study, we identified three distinct frailty trajectories—low progressive, moderate progressive, and high progressive. Our findings demonstrated that frequent participation in social and intellectual activities is associated with a reduced risk of transitioning to adverse frailty trajectories. Unlike prior studies that primarily focused on frailty status or onset, our analysis captures the dynamic progression of frailty, thereby offering a longitudinal perspective on how modifiable psychosocial factors influence frailty development over time. Additionally, this study found that both social and intellectual activities can affect the frailty trajectory of different genders, different age groups, and different regions. These associations remained robust across sensitivity analyses, underscoring the potential protective role of engagement in social and intellectual activities against frailty progression. To our knowledge, this is one of the first studies to simultaneously examine the association of both social and intellectual activity frequencies with longitudinal frailty trajectories, providing a dynamic perspective on frailty progression and its modifiable psychosocial predictors.

Association Between Social Activity and Frailty Trajectories

Consistent with previous studies [20-22], our findings demonstrate that frequent participation in social activity is significantly associated with a reduced likelihood of progression along a moderate frailty trajectory. These associations can be explained by various factors: Firstly, social activity often involves physical exertion, which enhances muscle mass, strength, balance, and cardiopulmonary function [23], thereby directly counteracting established pathways linking skeletal muscle structure and function to frailty. However, whereas previous studies largely examined social support or isolation as static risk factors, our trajectory-based approach reveals how varying levels of social activity dynamically influence frailty progression over time. Previous studies have reported that loneliness and social isolation are established risk factors for frailty [24,25]. Social activity mitigates established risk factors for frailty, such as loneliness and social isolation, by providing emotional support and improving psychological well-being. Evidence also suggests that inflammation may play a regulatory role in the progression of frailty; inflammatory responses can be exacerbated by social isolation [26-29]. Thus, increased social activities could attenuate systemic inflammation and delay frailty progression.

Notably, we observed differential effects across subgroups. Our study found that men may derive greater benefits from social activities in slowing frailty progression, potentially due to their tendency to seek support through social networks to manage stress, whereas women may prioritize educational or cultural activities [17]. Notably, the protective effect was more pronounced in participants younger than 65 years of age in the present study, possibly because the middle-aged population socializes more frequently and is more affected. Additionally, geographic differences were evident. Social activities were particularly effective in reducing frailty among rural residents, possibly due to rural China's social structure and residential distribution, which leads to a strong reliance on kinship networks. These networks provide instrumental help and reduce loneliness through the incorporation of physical labor in agriculture-based social activity.

Association Between Intellectual Activity and Frailty Trajectories

Our findings corroborate earlier observational studies linking intellectual activity to a lower risk of frailty [11], but extend them by demonstrating a longitudinal and dose–response relationship between intellectual engagement and frailty trajectory. However, prior research has not adequately addressed the longitudinal effects of social and intellectual activities on frailty trajectories. Frailty often coexists with cognitive impairment [30]. Lack of intellectual activity increases the risks of cognitive impairment [31], which in turn creates a higher risk of frailty occurrences. In a cross-sectional study, Wang et al [32] found that engaging in intellectual activity in later life was associated with a lower prevalence of frailty, particularly among older adult women. This aligns with our observation in females that intellectual activity exerts a stronger protective effect against frailty progression in females. Furthermore, urban residents benefited more from intellectual activities; this may be due to urban areas with better-developed public infrastructure and information accessibility may facilitate cognitive stimulation through intellectual engagement.

Frailty has evolved from the initial concept to a complex, multidimensional bio-psycho-social syndrome [33]. Compared to previous interventions that have focused on physical activity and nutritional strategies, our findings highlight the importance of integrating social and psychological strategies. Based on the results of our study showing a significant association between participation in social activity and intellectual activity and reduced vulnerability development, this encourages the inclusion of frailty interventions in future social activity and intellectual activity intervention strategies in middle-aged and older adults. Specifically, tailored interventions should be implemented. For men, social activities should be actively promoted to delay the development process of frailty, while women should carry out a variety of learning skills from the perspective of intellectual activities. From the age group, we advocate intervention in the development of the frailty trajectory early in middle age, which can effectively prevent and reduce the development of frailty. In rural areas, enhancing public infrastructure could amplify the benefits of intellectual activities, whereas urban communities should prioritize social activity programs to address isolation risks. Furthermore, if social and intellectual activity are performed simultaneously and combined with physical exercise, it may have a positive impact on maintaining the normal operation of the physiological system, thus delaying the progression of cognitive fragility [34-36].

Strengths and Limitations of This Study

To our knowledge, this is the first study to investigate the relationship between social and intellectual activity and frailty trajectory. The strength of this study is that we used a relatively large nationally representative cohort of Chinese middle-aged and elderly people to evaluate the influence of social activity

XSL•FO
RenderX

and intellectual activity on frailty trajectory, and we found that frequent intellectual activity was associated with a lower frailty trajectory, suggesting that we provide a new direction for the management and prevention of frailty. Furthermore, state-of-the-art statistical models were used to fit frailty development trajectories. This approach helps to identify groups of individuals who have experienced similar levels and patterns over time, and more helps to identify people with similar frailty trajectories, thus rationing the intervention for the population.

However, limitations should be acknowledged. First, despite rigorous adjustment, residual confounding from unmeasured factors cannot be ruled out. Specifically, more granular data on socioeconomic status, nutritional status were not available. These factors may influence both activity participation and frailty risk. Second, self-reported activity frequencies are susceptible to recall bias, though nondifferential misclassification would likely attenuate observed associations. Third, the generalizability of our findings to other ethnic or cultural contexts may be limited. The CHARLS cohort, while nationally representative of middle-aged and older Chinese adults, has distinct sociodemographic characteristics that may differ from populations in Western countries.

Conclusion

This study provides novel evidence that social and intellectual activities are independently associated with favorable frailty trajectories in middle-aged and older adults. The sex- and age-specific effects highlight the need for tailored interventions—promoting social engagement in men and intellectual stimulation in women, particularly in younger populations. Furthermore, future research should investigate whether interventions that simultaneously combine social, intellectual, and physical activity could have synergistic effects in maintaining physiological system integrity and thus delaying frailty progression, building on existing evidence.

Abstract

Background: Baseline sarcopenia has been linked to cognitive decline in older adults; however, the impact of longitudinal changes in sarcopenia status on cognitive trajectories remains unclear.

Objective: This aims to examine the association between 2-year transitions in sarcopenia status and subsequent 5-year cognitive trajectories among middle-aged and older adults in China.

Methods: We analyzed data from 8189 participants (median age 58, IQR y; n=432952.9% female) in the China Health and Retirement Longitudinal Study. Sarcopenia status was determined in 2011 and 2013 according to the 2019 Asian Working Group for Sarcopenia criteria, and participants were classified into 7 transition groups based on status changes. Cognitive function was assessed from 2013 to 2018 using standardized *z* scores for executive function and episodic memory. Linear mixed-effects models were applied to evaluate associations between sarcopenia transitions and cognitive trajectories, adjusting for demographic, lifestyle, and health-related covariates.

Results: Progression from a nonsarcopenic state was associated with greater cognitive decline compared to stable nonsarcopenia (β=–0.016, 95% CI –0.026 to –0.007; *P*<.001), with greater decline observed among those progressing from possible sarcopenia to sarcopenia (β=–0.027, 95% CI –0.054 to –0.001; *P*=.04). In contrast, regression from possible sarcopenia was associated with improved cognitive performance (β=0.028, 95% CI 0.015-0.041; *P*<.001). No significant improvement was observed among individuals regressing from established sarcopenia. Subgroup analyses showed consistent benefits of regression from possible sarcopenia across sex, age, residence, and education groups, except among urban residents (*P*=.05).

Conclusions: Progression in sarcopenia status was independently associated with accelerated cognitive decline, whereas regression from possible sarcopenia predicted cognitive benefit. These findings highlight possible sarcopenia as a clinically actionable and potentially reversible stage and underscore the importance of early identification and intervention to preserve cognitive health in aging populations.

KEYWORDS

aging; cognitive function; China Health and Retirement Longitudinal Study; longitudinal studies; sarcopenia

Introduction

Dementia currently affects more than 50 million people worldwide, and its prevalence is projected to reach 150 million by 2050 as the global population continues to age [1]. The societal and economic consequences are profound, with cumulative costs estimated to exceed US $14.5 trillion between 2020 and 2050 [2,3]. Despite intensive research efforts, current therapeutic options remain limited in effectiveness, reinforcing the urgent need to identify modifiable risk factors that may help delay or prevent cognitive decline [4].

Sarcopenia, a progressive skeletal muscle disorder characterized by decline in muscle mass, strength, and physical performance, is highly prevalent among older adults, affecting approximately 10%-27% of this population globally [5]. In addition to its established associations with frailty, falls, disability, and mortality [6-8], emerging evidence suggests a link between sarcopenia and neurocognitive impairment, including mild cognitive impairment and dementia [9-12]. Importantly, unlike many neurodegenerative conditions, sarcopenia is potentially modifiable through targeted interventions such as resistance exercise, adequate protein intake, and nutritional

XSL•FO
RenderX

supplementation, making it a promising intervention target for preserving cognitive health in aging populations [13-15].

However, most previous studies have focused on sarcopenia assessed at a single time point and have not accounted for its dynamic nature [9-12]. Sarcopenia may progress or regress over time due to changes in lifestyle or health status, and these transitions may differentially influence cognitive aging. Understanding the longitudinal impact of sarcopenia progression or recovery on cognitive trajectories may provide critical insights into optimal timing of interventions.

To address this gap, we analyzed data from the China Health and Retirement Longitudinal Study (CHARLS), a nationally representative cohort of middle-aged and older adults in China. We investigated whether 2-year transitions in sarcopenia status were associated with subsequent 5-year cognitive trajectories. To our knowledge, this is among the first large-scale longitudinal studies to evaluate the cognitive implications of dynamic changes in sarcopenia status, capturing both progression and regression patterns. We hypothesized that progression to possible sarcopenia or sarcopenia would be associated with accelerated cognitive decline, whereas regression from these states would be linked to a slower rate of cognitive deterioration. Additionally, we examined whether these associations differed across subgroups defined by sex, age, and residential status, and educational attainment, as these factors influence sarcopenia risk [16-18] and modify its relationship with cognitive function.

Methods

Study Population

This study used data from the CHARLS, a nationally representative cohort of Chinese adults aged ≥45 years [19]. The CHARLS adopted a multistage, stratified probability sampling strategy, with baseline interviews conducted in 2011 (wave 1) and follow-up assessments in 2013, 2015, and 2018 (waves 2 - 4). Sarcopenia status was evaluated in waves 1 and 2, while cognitive function was assessed from Wave 2 onward. Data from wave 5 (2020) were used only in sensitivity analyses due to the partial use of remote video interviews during the COVID-19 pandemic.

Of the 17,708 participants at baseline, we excluded those <45 years of age, those with missing sarcopenia or cognitive data, and those who reported psychiatric or memory-related disorders. Participants lacking sarcopenia assessments in wave 2 or without any cognitive follow-up data were further excluded [20,21].

Assessment of Sarcopenia

Sarcopenia was defined according to the 2019 criteria of the Asian Working Group for Sarcopenia [22]. Severe sarcopenia was classified as low muscle mass accompanied by both low muscle strength and poor physical performance. Sarcopenia was defined as low muscle mass combined with either low muscle strength or poor physical performance, whereas possible sarcopenia was defined as low muscle strength or reduced physical performance in the absence of low muscle mass.

Appendicular skeletal muscle mass was estimated using an anthropometric prediction equation validated against dual-energy X-ray absorptiometry (DXA), demonstrating high correlation (R^2=0.90) [23,24]. Sex-specific thresholds for low appendicular skeletal muscle mass or height squared were defined as the lowest 20% of the sex-specific distribution: <7.00 and <7.04 kg/m² for men and <5.25 and <5.32 kg/m² for women in waves 1 and 2, respectively [24,25]. Muscle strength was assessed by handgrip strength, measured twice for each hand using a handheld dynamometer; the maximum value was used for analysis. Low muscle strength was defined as <28 kg for men and <18 kg for women. Physical performance was evaluated using the 5-time chair stand test (≥12 s), walking speed (<1.0 m/s), or the Short Physical Performance Battery (≤9 points) [26].

Cognitive Function Assessment

Cognitive function was evaluated using structured face-to-face interviews covering 2 cognitive domains: executive function and episodic memory [27,28]. Executive function was assessed through 3 tasks: orientation to time (0 - 5 points), serial subtraction (0 - 5 points), and figure drawing (0 - 1 point), with a total score ranging from 0 to 11. Episodic memory was measured using immediate and delayed recall of a 10-word list, and the mean number of correctly recalled words across both trials was used as the final score (range: 0 - 10). Global cognitive function was calculated as the sum of executive function and episodic memory scores, yielding a total score from 0 to 21. All cognitive outcomes were standardized to *z* scores using the baseline mean and standard deviation, with higher values indicating better cognitive performance.

Covariates

Covariates were selected a priori based on previous research [29]. Demographic factors included age and sex. Socioeconomic variables encompassed education level (elementary or lower vs secondary or higher), marital status (married or partnered vs other), and place of residence (urban vs rural). Health behaviors included smoking status (ever vs never), alcohol use (ever vs never), and BMI (kg/m²). Chronic conditions included self-reported or medication-confirmed diagnoses of hypertension, diabetes, dyslipidemia, heart disease, and stroke.

Pain and depressive symptoms were also included as covariates due to their known associations with both sarcopenia and cognitive outcomes [30-33]. Pain was assessed dichotomously (yes or no). Depressive symptoms were measured using the 10-item Center for Epidemiological Studies Depression Scale (CES-D-10), a validated instrument in the CHARLS population that is widely used in aging research [34,35]. Scores on the CES-D-10 range from 0 to 30, with higher scores indicating more severe depressive symptoms; continuous CES-D-10 scores were included in all models.

Ethical Considerations

The study protocol of the CHARLS was reviewed and approved by the Biomedical Ethics Review Committee of Peking University (approval No. IRB00001052-11015). All study procedures involving human participants adhered to the ethical standards of Peking University and the Declaration of Helsinki

XSL•FO
RenderX

(1964) and its later amendments. Written informed consent was obtained from all participants prior to data collection. All data used in this secondary analysis were deidentified and publicly available; thus, no additional institutional review was required.

Statistical Analysis

Baseline Characteristics

Participants were categorized into groups based on changes in sarcopenia status from wave 1 to wave 2. Baseline characteristics were summarized using medians and IQRs for continuous variables and frequencies with percentages for categorical variables.

Sarcopenia Transitions and Cognitive Decline

The primary objective of this analysis was to estimate the rate of cognitive decline associated with different transition patterns in sarcopenia status. Linear mixed-effects models (LMMs) with random intercepts and random slopes were used to model individual cognitive trajectories over time. LMMs account for within-person correlation of repeated measures, accommodate participants with unequal numbers of observations, and are robust to unbalanced longitudinal data under the missing-at-random assumption. Cognitive decline was defined as the annual rate of change in standardized cognitive *z* scores over time, as estimated from the time effect in the LMMs. More negative regression coefficients (β) indicated a faster decline in cognitive function. This modeling approach has been widely applied in longitudinal studies of cognitive aging [36-39]. Given the robustness of LMMs to missing outcome data, no imputation procedure was implemented [40,41]. Model estimates were reported as β coefficients with 95% CIs.

Models were built sequentially. Model 1 adjusted for age, age squared (to capture nonlinearity), and sex. Model 2 further adjusted for education, marital status, residence, smoking, alcohol use, BMI, and BMI squared. Model 3 additionally controlled for chronic conditions.

Subgroup Analyses

Subgroup analyses were stratified by sex (male vs female), age group (<65 vs ≥65 y), residence (urban vs rural), and educational level (elementary or lower vs secondary or higher). These analyses were implemented using 3-way interaction terms between sarcopenia transition group, time, and each subgroup variable.

The sarcopenia transition variable included 3 categories to reflect changes in sarcopenia status between 2 survey waves: (1) progression from nonsarcopenia, (2) change in possible sarcopenia (including progression to sarcopenia and regression to nonsarcopenia), and (3) regression from sarcopenia.

Each subgroup variable was entered into the LMMs as a fixed effect together with its interaction terms with group and time. Effect modification was assessed using the overall *P* value for the 3-way interaction. Stratified associations within each subgroup were further reported to illustrate the pattern and magnitude of associations.

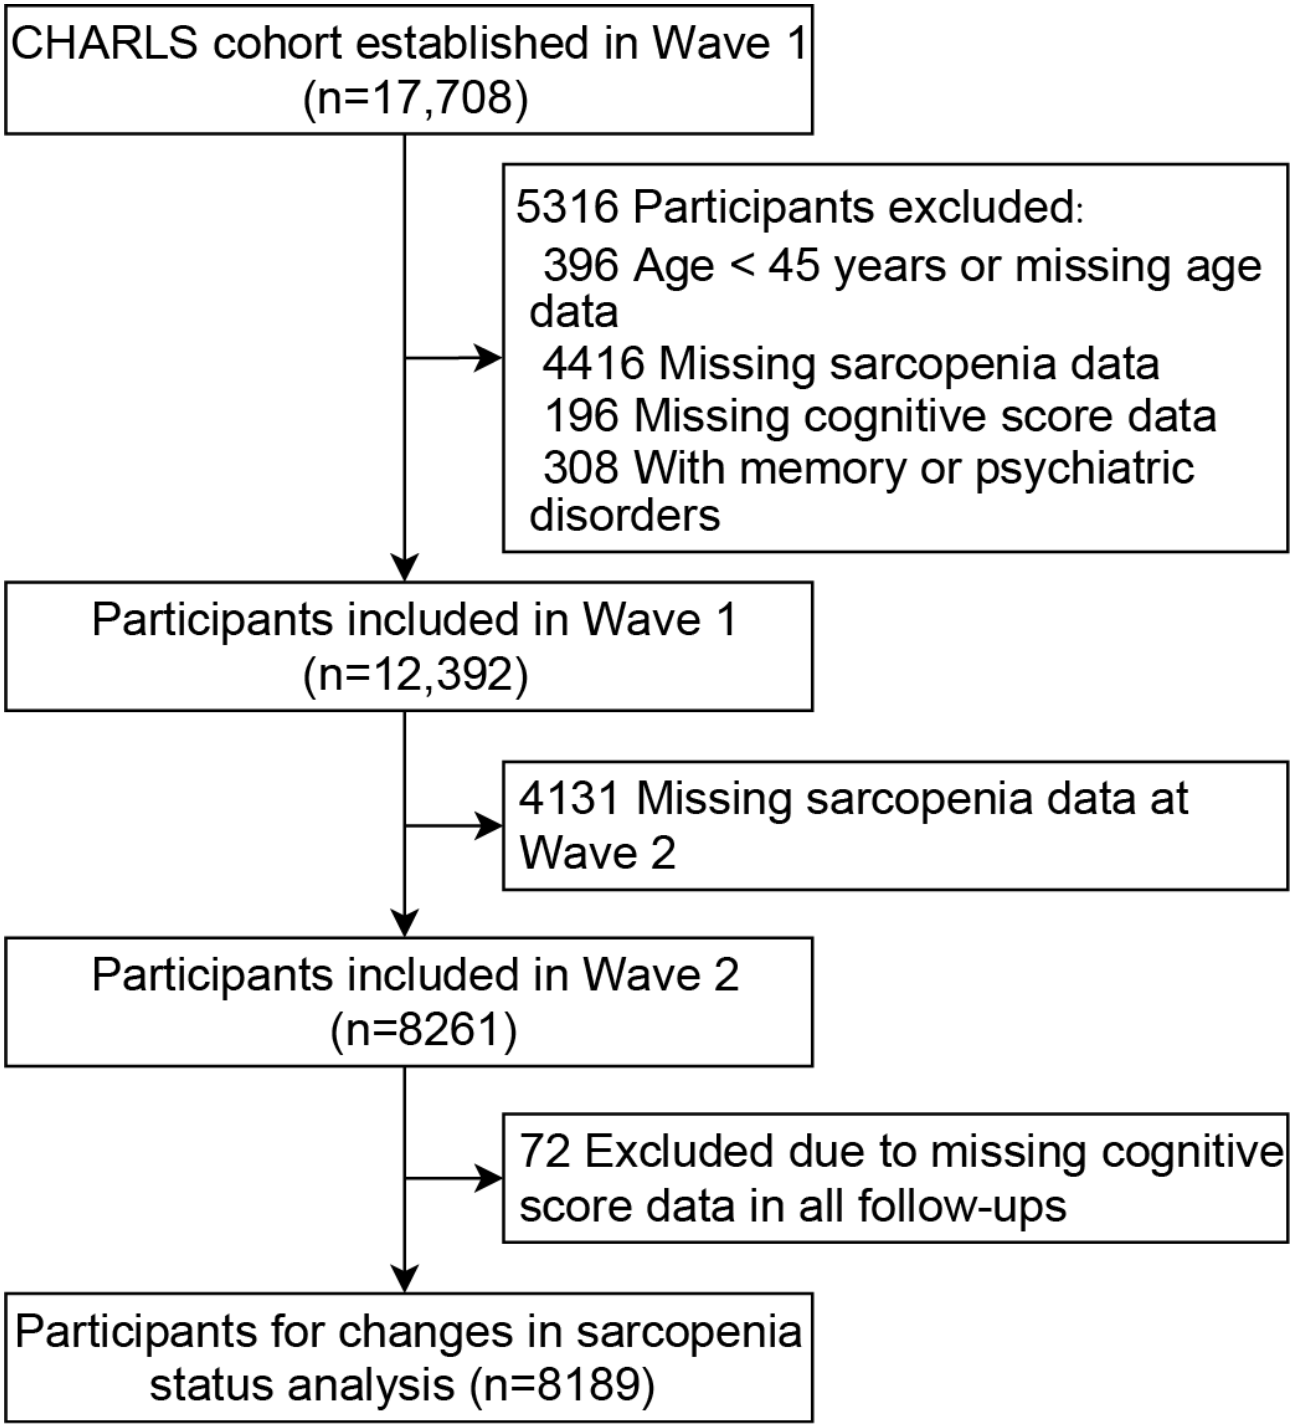
Sensitivity Analyses

Several sensitivity analyses were performed to assess the robustness of the findings. First, memory scores from wave 4 were harmonized using equipercentile equating to address potential inconsistencies arising from differences in test versions [42]. Second, a 9-category classification of sarcopenia transitions was applied to capture finer distinctions in status changes and assess whether more granular classification would yield similar associations with cognitive outcomes. Third, wave 5 cognitive data were included, despite partial implementation of remote video assessments during the COVID-19 pandemic, to incorporate the most recent follow-up and examine the stability of the results.

Additional Analyses

We further examined whether baseline sarcopenia status (wave 1) predicted subsequent cognitive decline during follow-up. In addition, to identify which diagnostic component contributed most to cognitive deterioration, we evaluated the unique and longitudinal effects of each sarcopenia component—low muscle strength, low muscle mass, and low physical performance—within the fully adjusted LMM (Model 3). For each component, we estimated the time × component interaction term, where a significant coefficient indicated that the component was associated with the rate of cognitive decline over time. We also calculated the semi-partial R^2 (part R^2) values and corresponding 95% CIs using 1000 bootstrap resamples, representing the proportion of variance in cognitive decline uniquely explained by each component after accounting for covariates.

All analyses were conducted using the R software (version 4.4.1; R Foundation for Statistical Computing), and part R^2 values were obtained with the *partR2* package (0.9.2). A 2-sided *P* value <.05 was considered statistically significant.



Results

Participant Grouping and Baseline Characteristics

A total of 8189 participants were included in the final analysis after applying the exclusion criteria (median age 58 y; n=4329, 52.9% female; Figure 1). Participants were initially classified into 9 groups based on sarcopenia status transitions between wave 1 and wave 2 (Table 1).

Table . Transition of sarcopenia status across wave 1 and wave 2[a].

Waves 1 and 2	Participants, n (% of total)	Trend of change
Nonsarcopenia (n=4870)		
Nonsarcopenia	3755 (45.9)	Stable
Possible sarcopenia	830 (10.1)	Progression
Sarcopenia	285 (3.5)	Progression
Possible sarcopenia (n=2010)		
Nonsarcopenia	1022 (12.5)	Regression
Possible sarcopenia	839 (10.2)	Stable
Sarcopenia	149 (1.8)	Progression
Sarcopenia (n=1309)		
Nonsarcopenia	161 (2.0)	Regression
Possible sarcopenia	96 (1.2)	Regression
Sarcopenia	1052 (12.8)	Stable

[a]The time interval between wave 1 and wave 2 survey was 2 years in the China Health and Retirement Longitudinal Study (CHARLS).

However, several transition groups—such as progression from nonsarcopenia to sarcopenia—comprised fewer than 3.5% (n=285) of the total sample, resulting in limited statistical power and unstable model estimates. To improve statistical robustness and model stability, transition groups with similar clinical patterns were consolidated. The final analysis included 7 groups: stable nonsarcopenia, progression from nonsarcopenia, stable possible sarcopenia, regression from possible sarcopenia, progression from possible sarcopenia, stable sarcopenia, and regression from sarcopenia. Baseline characteristics across the 7 transition groups are summarized in Table 2.

[a]Missing data were observed for education (n=1), pain (n=4), diabetes (n=10), stroke (n=21), dyslipidemia (n=30), BMI (n=39), heart disease (n=45), and depressive symptoms (n=369).

[b]Depressive symptoms were assessed using the 10-item Center for Epidemiological Studies Depression Scale.

Sarcopenia Transitions and Cognitive Decline

In the fully adjusted model (Model 3), progression from nonsarcopenia was associated with a significantly faster decline in global cognitive function (β=–0.016, 95% CI –0.026 to –0.007; *P*<.001), as was progression from possible sarcopenia (β=–0.027, 95% CI –0.054 to –0.001; *P*=.04), compared with stable trajectories. In contrast, regression from possible sarcopenia was linked to improvement in global cognition (β=0.028, 95% CI 0.01-0.041; *P*<.001). Regression from sarcopenia did not confer a statistically significant cognitive benefit (Table 3).

Table . Associations between transitions in sarcopenia status and global cognitive decline[e].

Groups	Model 1[a]		Model 2[b]		Model 3[c]	
	β[d] (95% CI)	*P* value	β (95% CI)	*P* value	β (95% CI)	*P* value

[a]Model 1 was adjusted for baseline age, age squared, and sex.

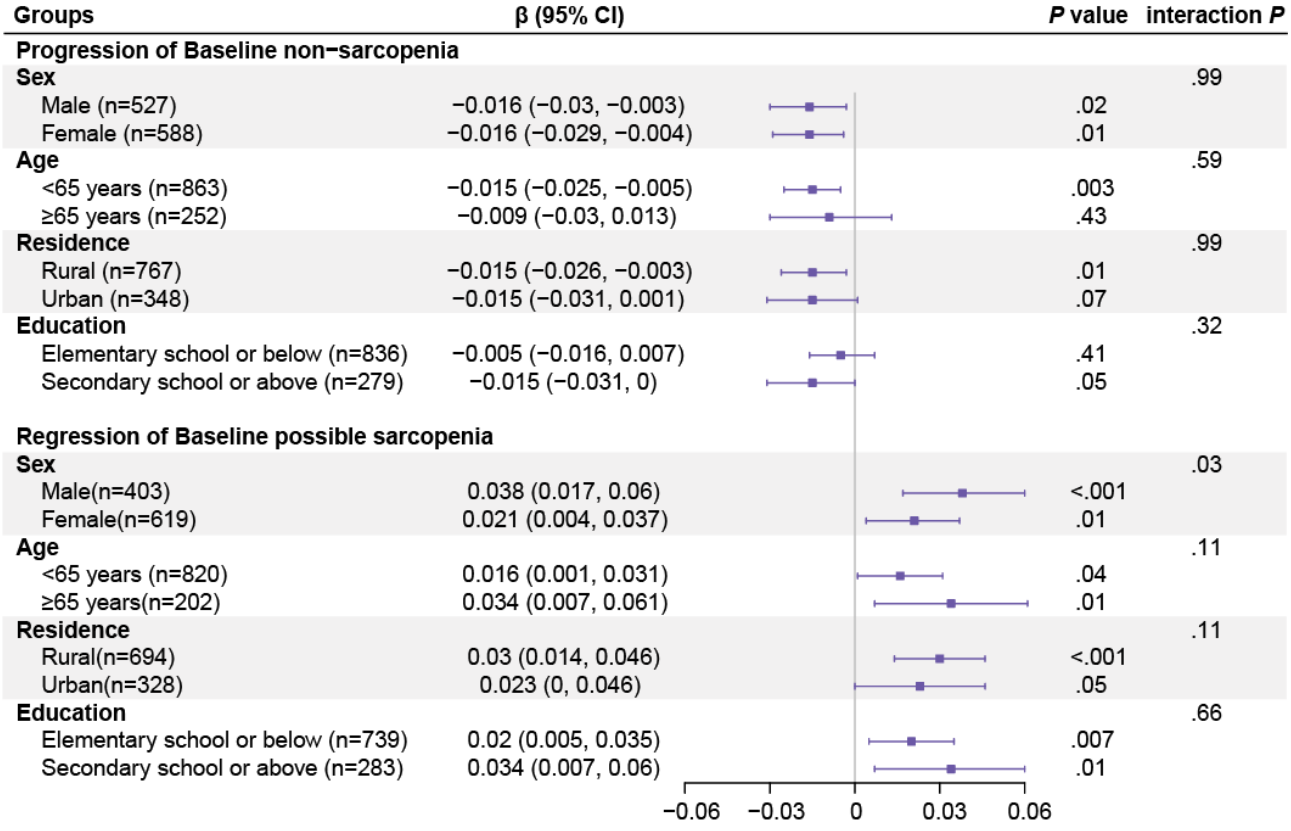
[b]Model 2 further adjusted for educational level, marital status, residence, smoking status, alcohol consumption, BMI, and BMI squared.

[c]Model 3 additionally included dyslipidemia, diabetes, hypertension, cardiovascular disease, stroke, depressive symptoms, and pain.

[d]β: regression coefficient.

[e]Data were analyzed using linear mixed-effects regression models. The β values (95% CI) represent the annual change in cognitive *z* scores (SD/year), relative to the reference group.

Domain-specific analyses yielded results consistent with the findings for global cognition. Progression from nonsarcopenia was associated with declines in executive function (β=–0.009, 95% CI –0.018 to –0.001; *P*=.03) and episodic memory (β=–0.021, 95% CI –0.034 to –0.009; *P*<.001). Regression from possible sarcopenia was associated with improvements in both executive function (β=0.014, 95% CI 0.001-0.026; *P*=.03) and episodic memory (β=0.039, 95% CI 0.022-0.056; *P*<.001). No significant improvements were found among those who regressed from sarcopenia (Tables S1–S2 in Multimedia Appendix 1).



Subgroup Analyses

The results of subgroup analyses for global cognitive function are presented in Figure 2 and Figure S1 in Multimedia Appendix 1. Among participants without sarcopenia at baseline, those who progressed to possible sarcopenia or sarcopenia showed faster declines in cognition compared with those who remained nonsarcopenic. These associations were statistically significant

XSL•FO
RenderX

in both men and women, in adults aged <65 years, and among those living in rural areas. Marginal associations were observed among urban residents (*P*=.07) and participants with secondary school education or higher (*P*=.05). However, no significant effect modification was observed across sex, age, residence, or education (all *P* for interaction >.05).

Figure 2. Subgroup analyses of the association between sarcopenia status transitions and global cognitive decline. Results are presented for 2 key transitions: progression from nonsarcopenia and regression from possible sarcopenia. Associations were estimated using linear mixed-effects models, stratified by sex, age group (<65 vs ≥65 y), residential location (urban vs rural), and educational level. Models were adjusted for baseline age and age squared, sex (except in sex-stratified models), education (except in education-stratified models), marital status, residence (except in residence-stratified models), smoking status, alcohol use, BMI and BMI squared, dyslipidemia, diabetes, hypertension, cardiovascular disease, stroke, depressive symptoms, and pain. Error bars indicate 95% CIs. Because transitions from baseline possible sarcopenia include both progression to sarcopenia and regression to nonsarcopenia, a single omnibus interaction *P* value was calculated across these transitions; therefore, the same interaction *P* value is shown here and in Figure S1 in Multimedia Appendix 1.

Among participants with baseline possible sarcopenia, transitions demonstrated opposite associations with cognition. Regression to nonsarcopenia was consistently associated with slower cognitive decline across all subgroups, with significant associations observed in most subgroups (all *P*<.05), except for a marginal association among urban residents (*P*=.05). Conversely, progression from possible sarcopenia to sarcopenia was associated with faster cognitive decline, and a significant interaction with sex was observed (*P* for interaction=.03). Specifically, in the progression from possible sarcopenia to sarcopenia, cognitive decline was significant among men (β=–0.054, 95% CI –0.094 to –0.014; *P*=.008) but not among women (β=–0.004, 95% CI –0.039 to 0.031; *P*=.81).

Among participants with baseline sarcopenia, regression to possible sarcopenia or nonsarcopenia was not associated with significant cognitive benefit in any subgroup (all *P*>.05). Domain-specific subgroup analyses for executive function and episodic memory are presented in Tables S3-S4 in Multimedia Appendix 1.

Sensitivity Analyses

The findings were generally robust across all sensitivity analyses. When wave 4 memory scores were harmonized using equipercentile equating (Table S5 in Multimedia Appendix 1), the direction of associations remained unchanged; however, among participants who progressed from possible sarcopenia to sarcopenia, effect estimates were attenuated and no longer statistically significant. When analyses were repeated using the original 9-category classification of sarcopenia transitions (Tables S6-S7 in Multimedia Appendix 1), the results were broadly consistent with the primary analysis. The strongest associations were observed among participants progressing from nonsarcopenia to possible sarcopenia (β=–0.018, 95% CI –0.028 to –0.007; *P*<.001) and those regressing from possible sarcopenia to nonsarcopenia (β=0.028, 95% CI 0.015-0.041; *P*<.001). Incorporating wave 5 cognitive data (Table S8 in Multimedia Appendix 1) did not materially alter the associations, and effect estimates were similar in magnitude and direction to those observed in the main models. Overall, across all sensitivity analyses, progression from nonsarcopenia consistently predicted accelerated global cognitive decline, regression from possible

XSL•FO
RenderX

sarcopenia was associated with slower decline, and regression from established sarcopenia did not yield significant cognitive benefit.

Additional Analyses

We evaluated whether baseline sarcopenia status predicted subsequent cognitive decline. The participant selection flowchart is presented in Figure S2 in Multimedia Appendix 2, and baseline characteristics stratified by sarcopenia status are summarized in Table S9 in Multimedia Appendix 1. As shown in Table S10 in Multimedia Appendix 1, baseline sarcopenia was associated with faster decline in global cognition, executive function, and episodic memory.

We further investigated the relative contributions of individual diagnostic components of sarcopenia to cognitive decline. Longitudinal associations for each component are reported in Table S11 in Multimedia Appendix 1. Among the 3 components, low muscle strength was significantly associated with accelerated cognitive decline (β=–0.016, 95% CI –0.027 to –0.004; *P*=.006) and accounted for the largest proportion of explained variance (part R^2=0.002, 95% CI 0.000 - 0.022), as shown in Table S12 in Multimedia Appendix 1. In contrast, low muscle mass was not significantly associated with cognitive decline (β=–0.028; *P*=.23), and low physical performance demonstrated only a marginal association (β=–0.020; *P*=.06).

Discussion

This study used longitudinal data from a nationally representative cohort to examine the association between changes in sarcopenia status and cognitive trajectories among middle-aged and older adults. We found that progression from a nonsarcopenic state was significantly associated with accelerated cognitive decline, whereas regression from possible sarcopenia—but not from established sarcopenia—was linked to better cognitive performance. Importantly, the beneficial association of regression from possible sarcopenia with global cognition was consistently observed across multiple sensitivity and subgroup analyses. These findings highlight the importance of early detection and timely intervention during the possible sarcopenia stage, when the potential to preserve cognitive function and delay neurodegeneration may be greatest.

Previous CHARLS-based studies have reported associations between baseline sarcopenia and subsequent cognitive trajectories [11,35]. Our study extends this evidence by focusing on longitudinal changes in sarcopenia status (progression and regression), rather than baseline sarcopenia alone, using nationally representative data. In our cohort, 31.1% (n=2543) of the participants experienced a change in sarcopenia status over 2 years—15.4% (n=1264) progressed and 15.6% (n=1279) regressed—consistent with prior CHARLS findings [24]. Both progression from nonsarcopenia and progression from possible sarcopenia were consistently associated with steeper declines in global cognition, executive function, and episodic memory. In contrast, regression from possible sarcopenia was associated with improved cognitive outcomes. Notably, regression from established sarcopenia was not associated with meaningful cognitive gains, suggesting a limited therapeutic window once sarcopenia becomes entrenched.

In the subgroup analyses, participants who progressed to possible sarcopenia or sarcopenia exhibited faster cognitive decline than those who maintained a stable nonsarcopenic state. Significant associations were observed in certain subgroups (eg, men, women, individuals aged <65 y, and rural residents), whereas other subgroups showed attenuated or nonsignificant associations. None of the interaction terms for sex, age, residence, or education reached statistical significance. Consistent with guidance from Sun et al [43], the nonsignificant interactions observed in our study do not imply identical effects across subgroups but may reflect small true differences that our sample lacked adequate power to detect. Although the direction of associations between sarcopenia progression and cognitive decline was consistent across demographic strata, subtle population heterogeneity cannot be excluded. These findings underscore the need for larger, adequately powered prospective studies to validate potential subgroup-specific effects.

For instance, in the age-stratified analyses, the association between sarcopenia progression and accelerated cognitive decline was evident among participants aged <65 years but attenuated in those aged ≥65 years, although the interaction effect was not statistically significant. This finding contrasts with prior cross-sectional CHARLS research [44], which reported significant associations between sarcopenia and cognitive function in older adults. Although Du et al [44] examined cross-sectional relationships in participants aged ≥60 years, our longitudinal design captured within-person changes in cognition over time—an approach that better reflects temporal dynamics but is also influenced by attrition and survivorship effects. Selective attrition in longitudinal cohorts often leads to loss of participants with poorer cognitive function or declining health, leaving a more resilient survivor subset with reduced between-person variability [45]. Consequently, those at the greatest risk for cognitive decline may be disproportionately lost to follow-up, attenuating observed effects among older adults. Moreover, unaccounted competing risks such as mortality or severe morbidity may further underestimate associations; Austin and Fine [46] noted that treating participants who experience competing events as censored can bias estimates downward by excluding high-risk individuals. Finally, the smaller sample size in the ≥65-year group likely reduced statistical power and widened confidence intervals. Collectively, these factors likely contributed to the absence of statistically significant associations in older adults despite consistent effect directions across age strata.

Importantly, regression from possible sarcopenia was consistently associated with improved global cognitive function across all subgroups, with significant results (all *P*<.05) except among urban residents, where the association reached marginal significance (*P*=.05). These findings suggest that recovery from possible sarcopenia—representing an intermediate and potentially reversible stage—may provide a critical window for intervention to preserve cognitive health.

Our sensitivity analyses demonstrated that the main findings were robust. Incorporating wave 5 data, which reflect the most

XSL•FO
RenderX

recent cognitive assessments, yielded results nearly identical to the primary analyses, underscoring the stability and reproducibility of our findings. In contrast, when wave 4 memory scores were harmonized using equipercentile equating, associations in the progression from possible sarcopenia to sarcopenia group were attenuated and no longer statistically significant. This attenuation likely reflects the conservative nature of the equating method, which reduces variability across test versions and may compress score distributions, thereby lowering statistical power despite consistent effect directions [42].

Similarly, when the original 9-category classification of sarcopenia transitions was used, the association between progression from nonsarcopenia to sarcopenia and cognitive decline became weaker. This was primarily due to the very small number of participants in this transition group, which reduced statistical power and produced less stable estimates. Moreover, the strong association observed in the nonsarcopenia to possible sarcopenia group is biologically plausible. Possible sarcopenia represents an early transitional stage characterized predominantly by reduced muscle strength, a parameter that has been shown to be a more sensitive indicator of functional decline and adverse health outcomes than muscle mass alone. Consistent with our additional analyses, low muscle strength—but not low muscle mass—was independently associated with faster cognitive decline. These findings align with evidence from population-based cohorts and Mendelian randomization studies showing that handgrip strength is more strongly linked to cognitive performance than muscle mass [47,48]. Therefore, cognitive deterioration may become detectable during the possible sarcopenia stage, before the onset of advanced muscle wasting in established sarcopenia. Across all analyses, however, regression from possible sarcopenia consistently demonstrated cognitive benefits, reinforcing the notion that this transitional stage is particularly amenable to intervention [49].

Several biological mechanisms may explain these associations. The muscle-brain axis has been proposed as a key pathway linking musculoskeletal and cognitive health [50]. Skeletal muscle secretes myokines—signaling molecules that regulate systemic inflammation, metabolic homeostasis, and neuroplasticity [51,52]. Sarcopenia may reduce myokine production and disrupt neuroprotective signaling, whereas reversal through physical activity may restore these pathways [52-54]. In addition, sarcopenia progression is associated with chronic inflammation and oxidative stress—both implicated in cognitive decline and neurodegeneration [55-58]—which may be mitigated through improved muscle function [59,60]. Emerging evidence also suggests a role of gut microbiota dysbiosis in sarcopenia-related neuroinflammation, underscoring the potential importance of the gut-muscle-brain axis [61,62].

These findings have important implications for clinical practice and public health. Routine screening for possible sarcopenia should be incorporated into cognitive risk assessment protocols for aging populations. Such screening is feasible using simple measures—such as grip strength and chair-stand tests—that can be implemented in primary care or community settings without specialized equipment. Early detection may help identify individuals at elevated risk of cognitive decline who could benefit from timely, multidisciplinary interventions. In our cohort, more than half of participants with possible sarcopenia reverted to a nonsarcopenic state (Table 1), reinforcing the reversibility of early-stage functional decline and the importance of timely intervention. Growing evidence from intervention trials suggests that resistance training, alone or combined with nutritional supplementation, can improve muscle function and sarcopenia-related outcomes [13-15], supporting the potential reversibility of early-stage sarcopenia. Future studies should evaluate whether such interventions can also yield sustained cognitive benefits.

This study has several limitations. First, its observational nature precludes causal inference. While associations were consistent across sensitivity analyses, randomized controlled trials are needed to establish causality. Second, sarcopenia was assessed using a validated anthropometric prediction equation rather than dual-energy DXA, the reference standard. Although highly correlated with DXA (R^2=0.90) [23], some misclassification may have occurred. However, the 15% sarcopenia prevalence in our study aligns with previous meta-analyses using DXA or BIA, supporting its validity [5]. Third, modifications to the episodic memory test in 2018 may have introduced measurement inconsistencies; therefore, we applied equipercentile equating to harmonize memory scores across waves. Although this conservative adjustment attenuated associations in the progression from possible sarcopenia to sarcopenia group, the overall direction of effects remained consistent, supporting the robustness of the main findings [42]. Fourth, although physical exercise has been shown to be significantly associated with both cognitive function and sarcopenia [63,64], information on physical activity was missing in 61.0% (n=4995/8189) of participants in our cohort. Therefore, physical exercise was not included as a covariate in our analyses, and residual confounding related to physical activity cannot be excluded. Finally, residual confounding remains possible. Relevant factors such as hearing loss or social isolation—which may influence both sarcopenia and cognitive decline—were not fully captured and should be explored in future research [65].

Progression from a nonsarcopenic state—including progression from possible sarcopenia—is associated with accelerated cognitive decline, whereas regression from possible sarcopenia is linked to cognitive benefit. These findings identify possible sarcopenia as a critical and potentially reversible stage in the trajectory toward sarcopenia and cognitive impairment. They also support incorporating routine screening for possible sarcopenia into cognitive risk assessment protocols for aging populations. Given the simplicity, low cost, and feasibility of screening measures such as grip strength and chair-stand tests, implementation in primary care and community settings is both practical and scalable. Early identification and intervention at the possible sarcopenia stage may offer a key opportunity to preserve cognitive health and delay neurodegenerative processes. Future research should prioritize developing and evaluating targeted, evidence-based strategies to prevent sarcopenia progression and promote cognitive resilience in at-risk populations.

Acknowledgments

We sincerely thank the China Health and Retirement Longitudinal Study (CHARLS) team for making the data available for this study. We also appreciate the efforts of the field staff and the invaluable contributions of the participants. This study was supported by the Zhejiang Provincial Medical and Health Science and Technology Project (grant 2023KY1032) and the Natural Science Foundation of Ningbo (grant 2023J229). The funders had no role in the study design, data collection, analysis, interpretation, or manuscript preparation.

Data Availability

The data used in this study are from the CHARLS, which is available to registered users for academic research purposes. Access to the dataset requires user registration and approval through the CHARLS official website [66].

Authors' Contributions

CL and BL conceived and designed the study. CL, HW, XS, and SH conducted data curation, statistical analysis, and initial interpretation of the findings. CL and HW contributed to the literature review and drafting of the manuscript. LL and BL critically revised the manuscript for important intellectual content and supervised the overall project. All authors contributed to the final version of the article, approved it for submission, and agreed to be accountable for all aspects of the work.

Conflicts of Interest

None declared.

Abstract

Background: Frailty is defined as a clinical state of increased vulnerability due to the age-associated decline of an individual's physical function resulting in increased morbidity and mortality when exposed to acute stressors. Early identification and management can reverse individuals with frailty to being robust once more. However, we found no integration of machine learning (ML) tools and frailty screening and surveillance studies in Thailand despite the abundance of evidence of frailty assessment using ML globally and in Asia.

Objective: We propose an approach for early diagnosis of frailty in community-dwelling older individuals in Thailand using an ML model generated from individual characteristics and anthropometric data.

Methods: Datasets including 2692 community-dwelling Thai older adults in Lampang from 2016 and 2017 were used for model development and internal validation. The derived models were externally validated with a dataset of community-dwelling older adults in Chiang Mai from 2021. The ML algorithms implemented in this study include the k-nearest neighbors algorithm, random forest ML algorithms, multilayer perceptron artificial neural network, logistic regression models, gradient boosting classifier, and linear support vector machine classifier.

Results: Logistic regression showed the best overall discrimination performance with a mean area under the receiver operating characteristic curve of 0.81 (95% CI 0.75 - 0.86) in the internal validation dataset and 0.75 (95% CI 0.71 - 0.78) in the external validation dataset. The model was also well-calibrated to the expected probability of the external validation dataset.

Conclusions: Our findings showed that our models have the potential to be utilized as a screening tool using simple, accessible demographic and explainable clinical variables in Thai community-dwelling older persons to identify individuals with frailty who require early intervention to become physically robust.

Introduction

The world population is moving toward an aging society. As health care technology improves, people are expected to live longer and healthier [1]. According to the World Health Organization, the population aged ≥60 years will increase from 1 billion in 2020 to 2.1 billion in 2050 and the number of people aged ≥80 years will reach 426 million in 2050 [2]. Researchers predicted that the proportion of people in Thailand aged ≥60

XSL•FO
RenderX

years would be more than 20% of the population in 2025 and more than 30% in 2031 [3,4].

The prevalence of frailty is high among older adults aged ≥60 years [5]. Global frailty prevalence ranges from approximately 10% to 12% [6-11]. The percentage varies by age, gender, and frailty classification tool. In Thailand, frailty prevalence was 22.1%, which is twice the global frailty prevalence, according to the Thai National Health Examination Survey cohort in 2018. Specifically, Thailand's northern region frailty prevalence was found to be 15% [12,13]. This creates concerns about the increasing aging population in Thailand.

Frailty is defined as a clinical state of increased vulnerability due to the age-associated decline of an individual's body resulting in increased morbidity and mortality when exposed to everyday or acute stressors [14,15]. This clinical syndrome is associated with decreased quality of life [7], slow gait speed [16], more depressive symptoms, higher BMI, reduced cognitive function [17], decreased strength [12], and increased risk of fall, hospital re-admission, and all-cause mortality in the older adult population [13,18-20]. Frailty has become a crucial research topic because this clinical syndrome can be reversed. Studies have shown that early detection and intervention can revert individuals from a frail to a fit state [21-23].

However, incorporating frailty evaluation into clinical practice in a primary care context is challenging due to increased administrative tasks, time limitations, and a lack of diagnostic effectiveness [15,24,25]. In the age of technology, health informatics has become an important role in health care research [26,27]. Several studies have applied information technology to frailty detection in primary care settings using machine learning models and artificial intelligence [28-30]. A study from Canada showcased an efficient frailty identification tool using the XGBoost machine learning model. Features used for the model were medication, medical billing codes, and other primary care clinical data [31]. Another example showed the development of a predictive machine learning model for frailty conditions based on a database of demographic data and clinical characteristics [32]. In China, a study simplified the Frailty Index assessment for older individuals using machine learning techniques and showed that logistic regression was the best performing and most interpretable model, with a mean area under the receiver operating characteristic curve (AUC) of 0.974 in the internal validation dataset [33]. Another study in China also developed and validated models using data from 6997 older adult participants to predict frailty risk, with random forest (RF) and logistic regression (LR) achieving AUC values of 0.77 and 0.76, respectively [34].

Despite the abundance of evidence of conducting frailty assessments using machine learning globally and in Asia, we have found no integration of data science tools and frailty screening and surveillance studies in Thailand. Most studies focused on the risk factors and their association with frailty syndrome but failed to show application in real-world settings [12,13,35,36]. This leads to our research question, "Can machine learning models predict frailty in community-dwelling older adults in Northern Thailand?" Therefore, we propose an approach to frailty detection using a machine learning model in the community-dwelling population from Lampang and Chiang Mai, Thailand, to effectively screen frailty status among Thai community-dwelling older adults and to help decrease clinicians' burden of work.

Methods

Source of Data

Development and Internal Validation Datasets

The datasets were derived from a cross-sectional study carried out in Lampang in 2016 and 2017; it is a northern Thai province with one of the highest aging indexes [37]. This study included older adults aged ≥60 years. Those with dementia (as determined by the Thai Mental State Examination), blindness, deafness, bedridden status, disabilities, or severe acute diseases were excluded.

To represent urban (8 villages), semiurban (8 villages), and rural (8 villages) communities, 24 villages in 3 districts were chosen. The records of the primary care unit were used to compile lists of community-dwelling older adults. The details of the data collection in this study are published elsewhere [36]. A total of 2228 older adults from this study were derived for model development and internal validation.

External Validation Dataset

The datasets used for external validation were derived from a cross-sectional study in Kuamung (suburban), Sankampang, Chiang Mai, Thailand, in 2021. The participants were included and excluded from the study with the same criteria as described in the internal validation datasets. A total of 464 older adults from this study were used for external validation of the derived models.

Predictors

Characteristics and Demographics

Assessments were conducted through a questionnaire at the participant's residence. The questionnaire included questions about sociodemographic information (age, household living arrangement, gender, and education level), self-reported medical diagnoses (such as hypertension, diabetes mellitus, and heart disease), level of physical activity per week, and exhaustion.

Anthropometric Variables

Anthropometric measures included BMI, waist circumference, and calf circumference (CC). A handheld dynamometer (Takei TKK5001) was used to assess handgrip strength. Height and calf circumference were measured with standard tape (Tajima brand, PIT-20BL model), and weight was measured with a calibrated weighing scale (Shaper Disney). The CC was measured over the unclothed area at the maximum diameter on the left leg. The tape was wrapped snugly around the calf and measured to the nearest 0.1 cm. All measurements were administered by 10 qualified field investigators, and the measurements were standardized by the principal investigator.

Outcome Variable

Frailty was evaluated based on Fried's phenotype [38], which includes the following five criteria:

XSL•FO
RenderX

1. Unintentional weight loss: The participant will be asked "In the last ten years, have you lost more than 10 pounds intentionally (not due to diet or exercise)?" If yes, then frail for weight loss criterion. At follow-up, weight loss was calculated as: (weight in previous year – current measured weight)/(weight in previous year)=K. If K≥0.05 and the subject did not report that he/she was trying to lose weight (ie, unintentional weight loss of at least 5% of previous year's body weight), then frail for weight loss=yes.
2. Exhaustion, assessed with self-report using Fried's method of assessment. The participant was first asked to self-assess whether she/he felt exhausted. If yes, she/he would be asked to rate the severity of the exhaustion. Ratings of 2-4 suggested a positive assessment.
3. Physical activity, based on the short version of the Minnesota Leisure time Activity questionnaire, which asked about walking, chores (moderately strenuous), mowing the lawn, raking, gardening, hiking, jogging, biking, exercise cycling, golf, single tennis, doubles tennis, racquetball, and calisthenics. For men, those with <383 kcals of physical activity per week were frail. For women, those with <270 kcals of physical activity per week were frail.
4. Walk time, stratified by gender and height (gender-specific cutoff for medium height).
    - Height ≤173 cm and walk time ≥7 seconds for men.
    - Height >173 cm and walk time ≥6 seconds for men.
    - Height ≤159 cm and walk time ≥7 seconds for women.
    - Height >159 cm and walk time ≥6 seconds for women.
5. Grip strength, stratified by gender and BMI quartiles.
    a. For men:
        - BMI ≤24 and grip strength ≤29 for men
        - BMI 24.1 - 26 and grip strength ≤30
        - BMI 26.1 - 28 and grip strength ≤30
        - BMI >28 and grip strength ≤32
    b. For women:
        - BMI ≤23 and grip strength ≤17
        - BMI 23.1-26 and grip strength ≤17.3
        - BMI 26.1-29 and grip strength ≤18
        - BMI <29 and grip strength ≤21

Older adults with 3 or more phenotypes were considered to have physical frailty, and those who had 1 or 2 phenotypes were classified as prefrailty. According to the study design of the derived datasets, the outcome was concurrently measured with the predictors.

Sample Size Calculation

The sample size for model development was calculated using the *pmsampsize* package via STATA (version 16; StataCorp). A minimum sample size required 16.41 events per predictor, which was 1519 patients with 263 frailty cases based on a maximum candidate predictor of 16, frailty prevalence of 17.29% in the dataset for model development, small overfitting defined as expected shrinkage of predictor effects by 10% or less, a small difference in the developed model's apparent and optimism-adjusted values of 0.15 ($R^2_{Nagelkerke}$), as suggested by Riley et al [39]. For the external validation, the sample size was calculated using the *pmvalsampsize* package via STATA. From the available data of 464 patients with 192 frailty cases, it was able to precisely estimate confidence interval widths of observed/expected statistic of 0.22, calibration slope of 0.60, and concordance statistic of 0.10 [40].

Statistical Analysis Methods and Synthesis of the Results

Data exploration was performed using descriptive statistics to determine the data quantity, quality, and distribution. A frequency and a percentage were used to describe categorical variables. For continuous variables, a mean with SD was used for parametrically distributed data, and a median with an IQR was used for nonparametrically distributed data. The comparison of characteristics between the frail and nonfrail populations was performed using the chi-square test for categorical variables, the independent *t* test for parametric variables, and the rank-sum test for nonparametric variables. The methods for feature selection, model development, and validation are described in the section "Model Development and Validation". Estimates of model discrimination and optimism are reported as the mean AUC with 95% CI across all repetitions of cross-validation for the internal validation and the AUC with 95% CI from 1000 bootstrapping samples for the external validation. To further explain model performance, we also created model calibration plots and calculated secondary metrics of prediction models, including the confusion matrix and specificity, sensitivity, and predictive values.

Missing Data and Imputation

There was only missing data in participants' age in the internal validation dataset (4/2228, 0.18%); therefore, a complete case analysis was performed on the dataset. The external validation dataset contained missing data, including age (2/464, 0.43%), BMI (11/464, 2.37%), waist and calf circumference (3/464, 0.64%), handgrip strength (2/464, 0.43%), and frailty status (4/464, 0.86%). We performed multiple imputations of missing data, except for frailty status (the outcome of interest), using the predictive mean matching imputation with 5 nearest neighbors via the *KNNImputer* from the *Scikit-Learn library 1.1.2*. Four participant records that did not have frailty status were removed (list-wise deletion).

Model Development and Validation

Feature Selection

The classification models were developed using the variables from the derived datasets. The variables for model development were selected using both a data-driven method and domain expertise. For a data-driven selection, a multivariable logistic regression with stepwise backward elimination was performed to determine statistically significant variables (*P* value less than .20). For the *P* value threshold of .20, we used a higher threshold to give priority to clinical reasoning in selecting variables by domain expertise and associated factors from the previous studies, along with statistical significance, which would allow more important variables to be entered into the model.

XSL•FO
RenderX

Rebalancing Data Strategy

We resolved unbalanced classification for the dataset's minority class by using the Synthetic Minority Oversampling Technique (SMOTE) to enhance model decision boundaries via the *imblearn.over_sampling.SMOTE* package [41,42].

Model Development and Internal Validation

The model development and validation were performed using Python (version 3.9; Python Software Foundation). The machine learning algorithms implemented in this study include the k-nearest neighbors (KNN) algorithm, RF machine learning algorithms, multilayer perceptron artificial neural network (MLP), gradient boosting classifier (GBC), linear support vector machine classifier (SVM), and LR models via the *Scikit-Learn library 1.1.2*. The hyperparameters were determined by using a grid search via the *GridSearch CV* package with 10-fold cross-validation on the derived dataset to determine the parameters of each model that led to the best discriminative performance. For 10-fold cross-validation, the derived dataset was divided into 10 folds of data and repeated 10 times to perform model training and testing. For each iteration, 9 folds of data were used to train the model and then it was tested with the remaining fold to ensure that almost all the derived data were used to train and test the models. The discriminative performance of the derived models was assessed by computing a confusion matrix and sensitivity, specificity, and predictive values, as well as AUC with a 95% CI.

The model calibration was evaluated using the calibration plot, which indicated the congruence between the observed proportion of the actual probability of outcome and the mean predicted probability (MPP) from the derived models.

External Validation

The derived models were validated again with the external validation dataset to determine the model optimism and calibration. The discriminative performance and the model optimism were re-evaluated and presented by discriminative performance matrices and a 95% CI of AUC from the 1000 bootstrapping samples, respectively. The model calibration using the external validation dataset was re-evaluated using the calibration plot.

Ethical Considerations

This study complies with the research with exemption category and has been certified by the Research Ethics Committee of the Faculty of Medicine, Chiang Mai University (study code: COM-2565 - 09159, number EXEMPTION 9159/2022). We requested a waiver of informed consent because this study is a retrospective analysis that exclusively utilizes anonymized secondary data from our research database, without collecting any additional information from medical records or other sources. All participants have previously provided informed consent for the primary data collection as described elsewhere [35,36,43]. All personal patient data were anonymized by removing citizen ID numbers, hospital numbers, addresses, and contact information from the dataset. The investigator cannot trace or identify individuals. The study results were reported in accordance with the Transparent Reporting of a multivariable prediction model for Individual Prognosis Or Diagnosis plus Artificial Intelligence (TRIPOD+AI) statement [44].

Results

Baseline Characteristics of Participants in Each Dataset

Baseline characteristics of participants in this study are shown in Table 1. The participants in the internal validation dataset had a mean age of 71.0 years. Most of the participants were male and had finished primary school. Among 2228 old adults, 2160 lived with either their spouse, relative, or children while the others were living alone. The average BMI of the participants was 32.6 (SD 7.4) kg/m^2. The prevalence of hypertension, dyslipidemia, type 2 diabetes mellitus, and heart disease were 45.26%, 19.67%, 16.21%, and 4.31%, respectively. The averages of waist circumference, calf circumference, handgrip strength, and walk time were 83.40 (SD 11.23) cm, 32.40 (SD 4.35) cm, 32.40 (SD 6.68) kg, and 6.42 (SD 2.01) minutes, respectively. Overall, 9.79% of the participants were exhausted and 16.3% had physical activity higher than 150 minutes per week. The prevalence of frailty was 17.3% (n=385).

Table . The characteristics of participants in the development and internal validation datasets and the external validation dataset.

Characteristics	Development and internal validation datasets (Lampang, 2016 - 2017; N=2228)	External validation datasets (Chiang Mai, 2021; N=464)	*P* value
Age (years), mean (SD)	70.96 (7.49)	70.68 (5.58)	.45
Gender, n (%)			
Male	1569 (70.45)	193 (41.59)	<.001
Female	658 (29.55)	271 (58.41)	
Household living arrangement, n (%)			
Living alone	160 (7.18)	42 (9.05)	<.001
Living with spouse	1177 (52.85)	9 (1.94)	
Living with children	823 (36.96)	283 (60.99)	
Living with relatives or others	67 (3.01)	130 (28.02)	
BMI (kg/m^2), mean (SD)	32.64 (7.40)	22.73 (3.89)	.001
Education, n (%)			
No education	192 (8.62)	12 (2.61)	<.001
Primary school	1745 (78.36)	398 (86.52)	
Secondary school or higher	290 (13.02)	50 (10.87)	
Underlying diseases, n (%)			
Hypertension	1008 (45.26)	237 (51.08)	.02
Dyslipidemia	438 (19.67)	79 (17.03)	.19
Type 2 diabetes mellitus	361 (16.21)	78 (16.81)	.75
Heart diseases	96 (4.31)	18 (3.88)	.68
Anthropometric variables, mean (SD)			
Waist circumference (cm)	83.40 (11.23)	81.16 (10.80)	<.001
Calf circumference (cm)	32.40 (4.35)	32.85 (4.55)	.04
Walk time (min), mean (SD)	6.42 (2.01)	8.50 (5.38)	<.001
Exhaustion, n (%)	218 (9.79)	189 (40.74)	<.001
Adequate level of physical activity as defined by the World Health Organization, n (%)	363 (16.30)	104 (22.42)	<.001
Grip strength (kg), mean (SD)	32.40 (6.68)	19.87 (7.29)	<.001
Frailty, n (%)	385 (17.29)	192 (41.74)	<.001

In the external validation dataset, the participants had a mean age of 70.68 years. Most of the participants were male and had finished primary school. Among 464 persons, 422 lived with either their spouse, relative, or children, while the others were living alone. The average BMI of the participants was 22.73 (SD 3.89) kg/m^2. The prevalence of hypertension, dyslipidemia, type 2 diabetes mellitus, and heart disease were 51.08%, 17.03%, 16.81%, and 3.88%, respectively. The averages of waist circumference, calf circumference, grip strength, and walk time were 81.16 (SD 10.80) cm, 32.85 (SD 4.55) cm, 19.87 (SD 7.29) kg, and 8.50 (SD 5.38) minutes, respectively. The prevalence of participants with exhausted state was 40.74%, and 22.42% of the participants participated in physical activity more than 150 minutes per week.

Comparing the variables between the 2 datasets, we found that gender, household living arrangement, BMI, education, waist circumference, walk time, exhaustion, grip strength, and level of physical activity were significantly different.

Model Development

We used a dataset from Lampang (2016 - 2017; N=2228) for model development. The association between candidate predictors and frailty by univariate analysis is reported in Table 2. Feature selection for model development was selected by a backward elimination approach via a multivariable logistic regression and expert judgment. We chose the following features as model predictors: age, gender, status, underlying diseases (hypertension and dyslipidemia), BMI, waist and calf circumference, and level of exhaustion. Finally, the derived data included 385 participants with frailty and 1842 participants

XSL•FO
RenderX

without frailty, and all candidate predictors, as shown in Table 2, were used in model development.

Table . The comparison of participants' characteristics and their associations with frailty in the development and internal validation datasets.

Characteristics	Adjusted odds ratio – full model (95% CI)	*P* value	Adjusted odds ratio – reduced model (95% CI)	*P* value
Age (years)	1.04 (1.02 - 1.07)	<.001	1.09 (1.06 - 1.11)	<.001
Gender				
Male	Reference		Reference	
Female	1.93 (1.26 - 2.94)	.002	0.90 (0.63-1.27)	.55
Status				
Living alone	Reference			
Living with others	0.92 (0.46 - 1.86)	.82	0.87 (0.45 - 1.68)	.68
BMI (kg/m^2)	0.92 (0.90 - 0.95)	<.001	0.91 (0.88 - 0.93)	<.001
Education				
No education	Reference			
Primary school	1.00 (0.59 - 1.70)	.99		
Secondary school or higher	1.34 (0.65 - 2.77)	.42		
Underlying diseases				
Hypertension	1.47 (1.03 - 2.10)	.03	1.27 (0.92 - 1.75)	.15
Dyslipidemia	1.22 (0.78 - 1.91)	.38	1.45 (0.97 - 2.17)	.07
Type 2 diabetes mellitus	0.84 (0.54 - 1.31)	.44		
Heart disease	1.03 (0.45 - 2.34)	.95		
Anthropometric variables				
Waist circumference (cm)	1.02 (1.00 - 1.04)	.046	1.02 (1.00 - 1.04)	.02
Calf circumference (cm)	1.05 (1.01 - 1.09)	.01	1.04 (1.01 - 1.08)	.02
Walk time (min)	1.89 (1.71 - 2.10)	<.001	1.95 (1.78 - 2.13)	<.001
Exhaustion	20.39 (12.61 - 32.94)	<.001	28.23 (18.22 - 43.73)	<.001
Adequate level of physical activity as defined by the World Health Organization	4.49 (3.06 - 6.59)	<.001		
Grip strength	0.83 (0.79 - 0.85)	<.001		

However, the model appeared to be poor in frailty prediction performance and imbalanced as the classifiers intended to classify only the majority class (accuracy paradox). Therefore, a rebalancing strategy by SMOTE was applied to counter this problem. The oversampling data were generated and rebalanced the minority group in a 1:1 ratio. The details of the final model's hyperparameters using *GridSearch CV* are presented in Table S1 in Multimedia Appendix 1.

Adjusted odds ratios (aORs) of the full model were obtained from a multivariable logistic regression with all features. aORs of the reduced model were obtained from a multivariable logistic regression with stepwise backward elimination (P<.10) and feature selection based on the domain expertise.

Discrimination Performance of Internal Validated Models

We evaluated the model's performance by 10-fold cross-validation. The discrimination performances of the models are presented in Table 3 and Figure 1. The overall discrimination performance was presented by mean AUC 10-fold cross-validation. The KNN model achieved the highest overall performance with a mean AUC of 0.85 (95% CI 0.82 - 0.88), followed by MLP (AUC 0.81, 95% CI 0.72 - 0.89), LR (AUC 0.81, 95% CI 0.75 - 0.86), and SVM (AUC 0.75, 95% CI 0.75 - 0.86), respectively. In addition, the KNN model had the highest sensitivity and specificity (89% and 76%, respectively). RF had the lowest discrimination performance with almost all metrics. Other metrics that were not affected by data rebalancing, like positive predictive value (PPV) and negative predictive value (NPV), were also used to express the performance of the models. The best performances for both

XSL•FO
RenderX

PPV and NPV were found in the KNN model (0.79 and 0.87, respectively).

Table . Discrimination and optimism of internal validated models with 95% CIs.

Models	AUC[a], mean (95% CI)	Predictive values		Sensitivity	Specificity
		Positive	Negative		
LR[b]	0.81 (0.75 - 0.86)	0.74 (0.68 - 0.80)	0.74 (0.69 - 0.78)	0.74 (0.69 - 0.79)	0.73 (0.65 - 0.81)
KNN[c]	0.85 (0.82 - 0.88)	0.79 (0.76 - 0.82)	0.88 (0.86 - 0.90)	0.89 (0.87 - 0.91)	0.76 (0.71 - 0.81)

Discrimination Performance of External Validated Models

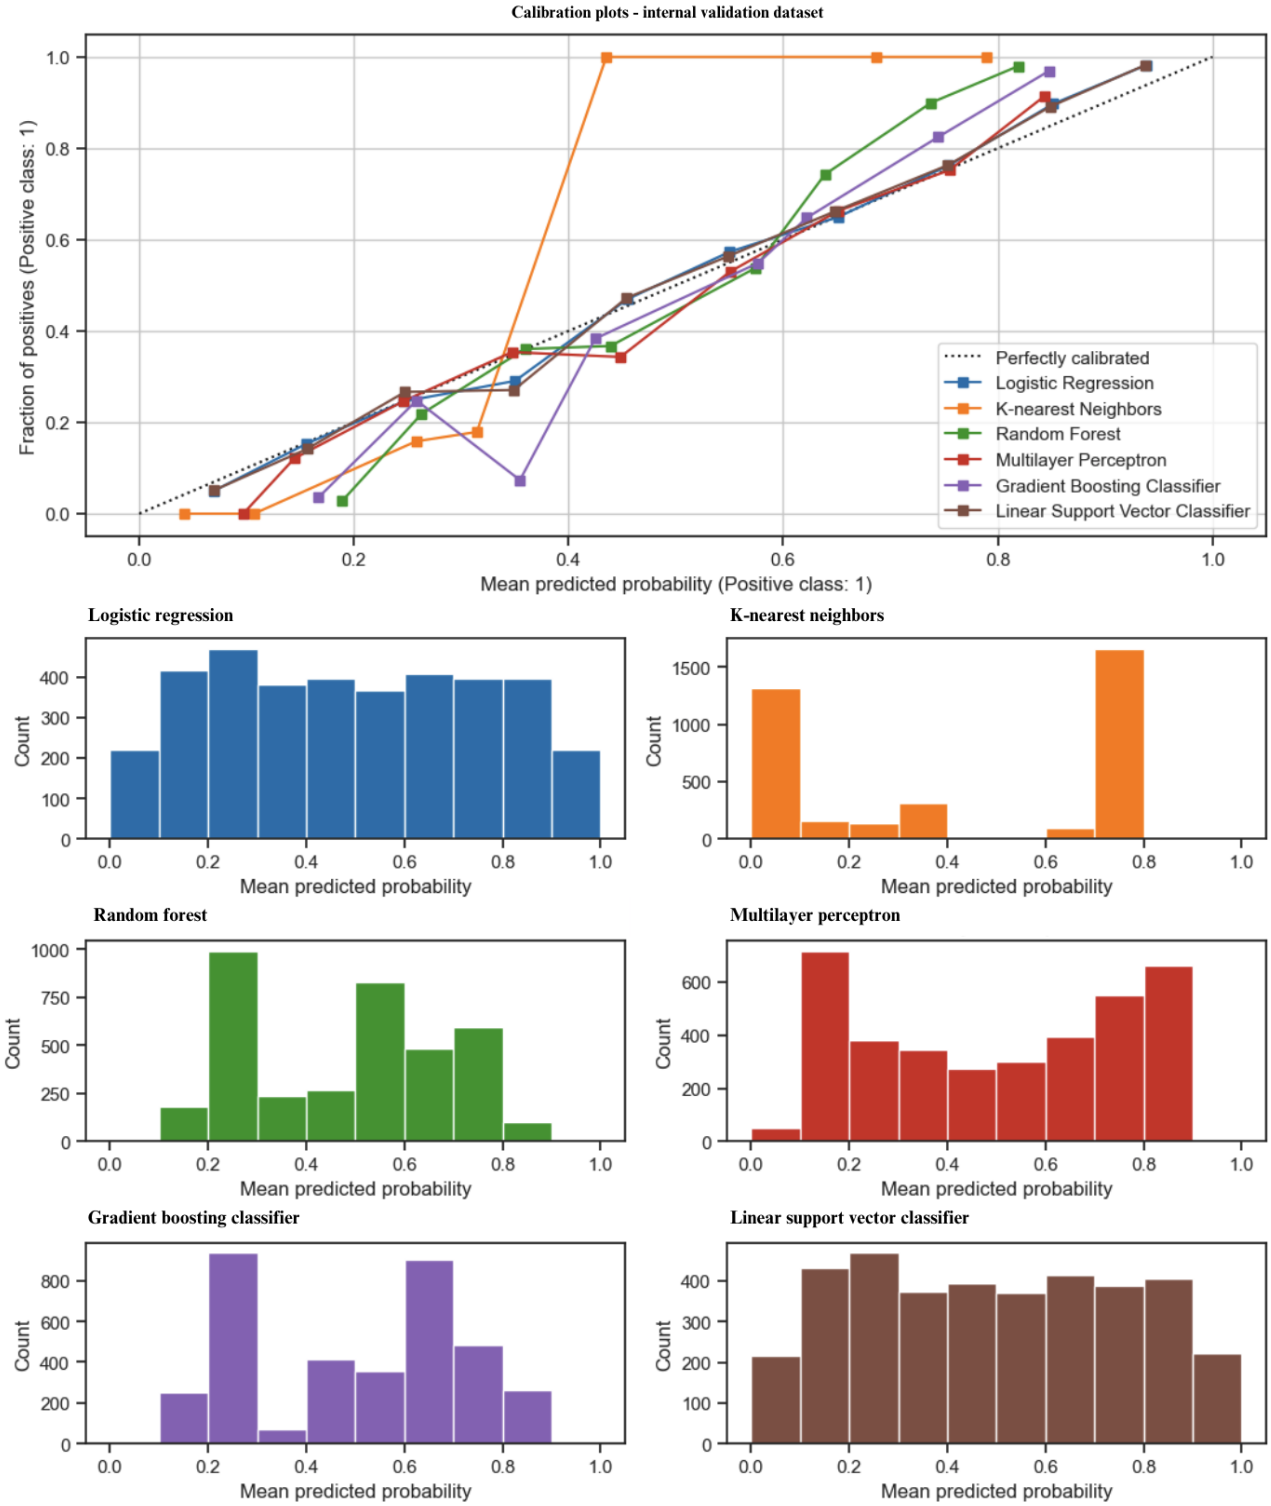
We validated our trained model with an external validation dataset to evaluate the bias and variance of our trained models. SMOTE was not applied to the dataset since it was already well-balanced between participants with and without frailty. The performance of machine learning models validated by the external validation dataset is shown in Table 4.

XSL•FO
RenderX

Table . Discrimination and optimism of external validated models.

Models and model prediction		True label (frailty/non-frailty)	AUC[a], mean (95% CI)	Predictive values		Sensitivity	Specificity
				Positive	Negative		
Logistic regression							
	Frailty	140/65	0.75 (0.71 - 0.78)	0.68	0.80	0.73	0.76
	Nonfrailty	52/207					
K-nearest neighbors							
	Frailty	41/35	0.54 (0.51 - 0.57)	0.54	0.61	0.21	0.87
	Nonfrailty	151/237					
Random forest							
	Frailty	137/63	0.75 (0.71 - 0.78)	0.69	0.79	0.71	0.77
	Nonfrailty	55/209					
Multilayer perceptron artificial neural network							
	Frailty	98/38	0.68 (0.65 - 0.72)	0.72	0.71	0.51	0.86
	Nonfrailty	94/234					
Gradient boosting classifier							
	Frailty	89/31	0.69 (0.65 - 0.72)	0.74	0.70	0.46	0.89
	Nonfrailty	103/241					
Linear support vector machine classifier							
	Frailty	131/60	0.73 (0.70 - 0.77)	0.69	0.78	0.68	0.78
	Nonfrailty	61/212					

[a]AUC: area under the receiver operating characteristic curve.



The overall discrimination performance was presented by mean AUC and 95% CI via 1000-fold bootstrapping. The LR and RF model achieved the highest overall performance with mean AUC 0.75 (95% CI 0.71 - 0.78), followed by SVM (mean AUC 0.73, 95% CI 0.70 - 0.77), and GBC (mean AUC 0.69, 95% CI 0.65 - 0.72), respectively. The LR model had the highest sensitivity (73%) and the MLP model had the highest specificity (86%). KNN had the lowest discrimination performance with all metrics. Other metrics that were not affected by data rebalancing, like PPV and NPV, were also used to express the performance of the models. The best performance for PPV was found in the GBC model (0.74); for NPV, it was found in the LR model (0.80).

Model Calibration

The model calibration was visualized with the calibration plot, which compared the expected probability of frailty, and the mean 10-fold cross-validation predicted the probability of each model. In the internal validation dataset (Figure 2), the LR, SVM, and MLP were well-calibrated with the expected probability of the data. The distribution of predicted probabilities of the models was well-balanced between 0.00 and 1.00. The KNN classifier aligned well with the MPP between 0.00 and 0.40 but it overestimated the high predicted probability. In contrast, the GBC underestimated MPP between 0.20 and 0.40 but aligned well with the rest of the expected probability. These results suggest that LR, SVM, and MLP are the most reliable for balanced predictions, while KNN, GBC, and RF require careful consideration depending on the probability range of interest.

XSL•FO
RenderX

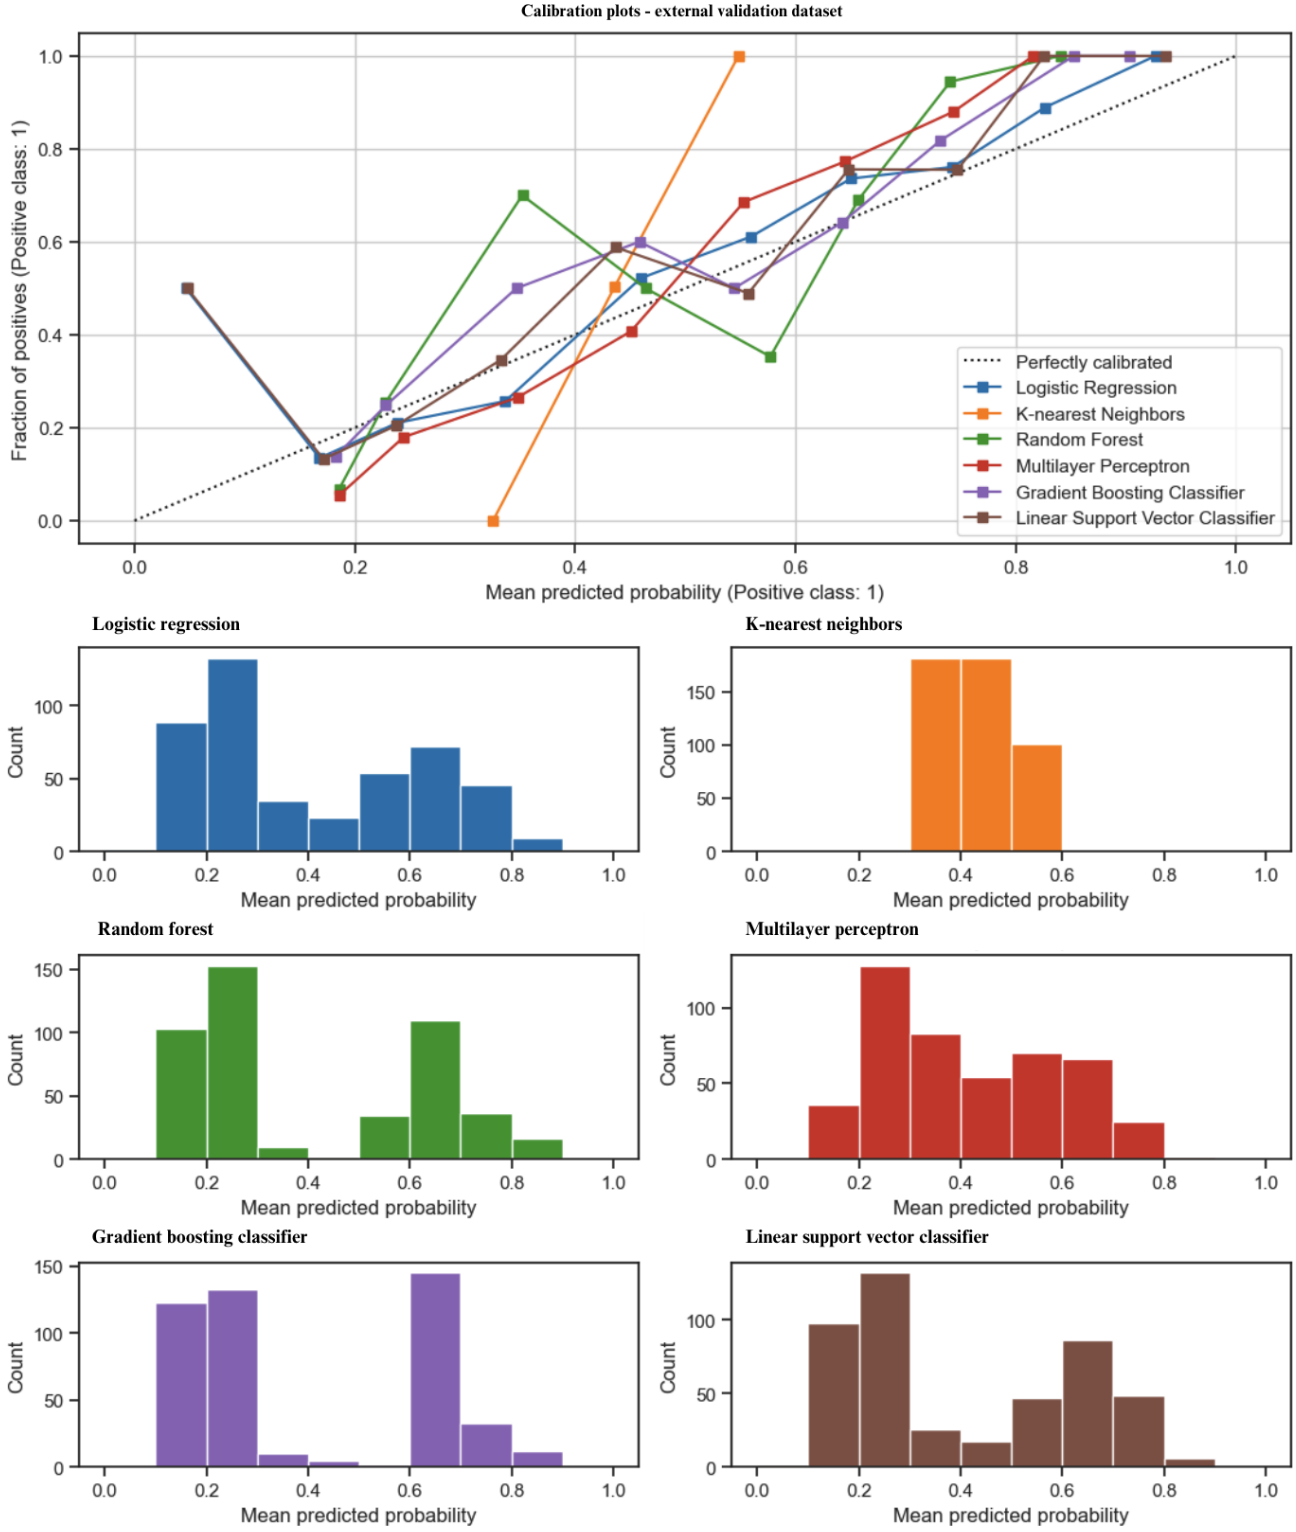


Figure 2. Model calibration of the developed models with internal validation.

In the external validation dataset (Figure 3), the LR, SVM, and MLP were almost perfectly calibrated to the expected probability of the data with a slight overestimation in the 0.40 - 0.80 MPP for MLP and an overestimation in the 0.00 - 0.40 MPP for LR and SVM. These 3 models have a similarly balanced distribution of MPP. RF aligned poorly with an overestimation in the low and high MPP, and it underestimated in the range between 0.40 and 0.70. The GBC aligned well with the calibration plot after 0.60 but overestimated before 0.40. The KNN classifier was poorly calibrated to the plot, giving only MPP in the range of 0.30 - 0.60.

Discussion

Model Performance

The internal validated models all showed remarkable discrimination performance, with the KNN model having the highest overall discrimination performance. However, the KNN model performed poorly in external validation datasets, indicating overfitting and the inability to generalize its results to other populations. In terms of model optimism, the LR, SVM, and MLP models had better discrimination capabilities, despite a slight decline in the models' performance during external validation. The mean AUCs of these models remained in the range of fair to good performance. When considering all aspects of model performance, the LR model was the most preferable because it provided good discrimination (AUC), an optimal range of predicted probabilities, and good calibration in both the internal and external validation datasets. On the other hand, other models had predicted probabilities that were not extreme enough, resulting in poor to fair calibrations, and they lacked

XSL•FO
RenderX

consistency between the internal and external validation datasets. In comparing the performance and validation aspects of previous frailty prediction models, most studies showed better performance than our best model (LR with a mean AUC of 0.81 in the internal validation set) [45]. The ELSA cohort study (2023) [46] reported the best performance from an RF model with an internal AUC of 0.92. Similarly, Bu et al (2023) [47] presented a multivariate LR model for predicting frailty in diabetic patients that had an AUC of 0.88 in the internal validation set. Additionally, a study on predictive modeling for frailty in older people using various machine learning methods found that artificial neural networks and SVM had the best performance in predicting mortality, with accuracies around 0.78 - 0.79 [32]. Although these studies reported high internal performance metrics, the absence of external validation raises concerns about their generalizability, especially for our focus on the community-dwelling older adult population in general. Our LR showed a mean AUC of 0.75 for the external validation dataset, which dropped slightly from the internal validated results, demonstrating a better edge in the community setting for our focused population. Furthermore, the predictors included in the previously reported model played an important role in prediction performance. Particularly, the utilization of handgrip strength in the study conducted by Bu et al [47] and the assessment of balance and chair stand in the ELSA cohort study [46] could potentially explain the high reported performance in both studies. These predictors either formed part of the frailty phenotype or served as surrogates for physical performance. However, incorporating these predictors into the models necessitated a trade-off between their value added to model performance and the difficulties of model utilization due to the time and skill required for the assessments. In our study, we proposed more parsimonious models using simpler predictions, which still achieved satisfactory performance for frailty screening.

Feature Selection and Findings Explanation

This study's findings suggest that machine learning models can be effective in classifying frailty status among community-dwelling older adults in Northern Thailand using simple predictors including, age, gender, household living arrangement, underlying diseases (hypertension and dyslipidemia), BMI, waist and calf circumference, and level of exhaustion. Age, BMI, waist circumference, and calf circumference are all potent risk factors for frailty in older adults. When the human body deviates from the normal physiologic process of aging, our levels of estrogen and testosterone gradually decline. These hormones play a vital role in maintaining muscle and bone mass, enhancing strength, and promoting optimal nervous system function [48,49]. As a result, the aging process can accelerate the decline of muscle, bone, and the nervous system, transforming an individual from fit to frail. Additionally, the female population is at higher risk of frailty because the normal bone turnover cycle is disrupted by estrogen deficiency during menopause, increasing bone resorption over deposition, and resulting in net bone loss in women [50]. Household living arrangement was also added to model features as we found that there were studies that showed an association of social adversity and support with frailty status [51,52]. Lastly, we selected level of exhaustion as a predictor in our models, as it had the highest crude aOR among all other features, and we found that it is highly feasible and time-efficient to acquire this data in real clinical settings, compared to other Fried's phenotypes, which involve multiple anthropometric and physical performance tests. These predictors also showed a significant contribution to the frailty prediction in the previous studies [46,47]. Most of our features used in the model are easily collectible, which makes it highly feasible and time-efficient to acquire all data in real clinical settings without depending on a high-level professional, making our model highly applicable for early frailty screening.

Limitations

The most important limitation of this study's models is the generalizability of the models. Our internal and external validation datasets were collected from a community-dwelling population in Lampang and Chiang Mai, respectively, which we confidently believe means that our models have high generalizability to the general population in Thailand. From our perspective, we assume that the models could also be implemented in other Asian countries, as studies showed similar frailty prevalence and population characteristics such as anthropometric measurements, age, household living arrangement, and underlying diseases of hypertension and diabetes [53-58].

However, we encourage conducting validation studies for other regions and populations before clinical application as frailty risk factors do vary across countries as well as in regions with different socioeconomic and health care contexts [59-61]. Another limitation of our study is spectrum bias, as our models were only able to distinguish between frail and robust older adults, despite Fried's criteria having 3 stages of frailty: robust, prefrail, and frail [62]. Nonetheless, we do not believe this bias will significantly affect our study's primary objective, which is the early detection of frailty in older adults to effectively prescribe nutrition and exercise interventions.

Implications

Identifying frailty early helps patient gain access to interventions like nutritional support and exercise programs faster, improving outcomes for older adults by preventing frailty progression, reducing falls, hospitalizations, and mortality, and enhancing quality of life [63,64]. We see 2 possibilities for the practical application of our developed and validated models. One option is to develop a web application that serves as a frailty screening tool that could be self-assessed by individuals or be used in outpatient clinic settings to screen patients. This would help health care providers efficiently identify patients with frailty who require closer monitoring or interventions. We have implemented the validated models to run on our web application, which can be accessed at the link in the Data Availability section.

Another option is to incorporate our machine learning models into electronic medical record or health surveillance systems. The machine learning models could be integrated with the electronic medical record system to provide automated frailty probability scores for each patient. This would enable health

XSL•FO
RenderX

care professionals to identify patients who require closer monitoring or interventions and could help optimize treatment plans for the community-dwelling population at risk of frailty. Furthermore, this could help future researchers retrieve and analyze frailty data from the hospital easier, leading to a better understanding of the factors that contribute to frailty and the development of more effective interventions, which also promotes more efficient use of resources within the health care system.

Conclusion

Machine learning models were fairly good at classifying frailty status among Thai community-dwelling older adults using age, gender, household living arrangement, underlying diseases (hypertension and dyslipidemia), BMI, waist and calf circumference, and level of exhaustion as predictors. The LR and RF models demonstrated the best discrimination performance and model calibration in both the internal and external validation datasets.

There are 2 potential practical applications for utilizing the study findings. These include creating a web application for self-screening or individual screening and incorporating machine learning models into electronic medical record or surveillance systems to provide automated frailty probability scores for individual patients. We advocate for further research on model external validation and temporal recalibration to enhance the model's practicality and applicability to the specific context in which it is used.

Abstract

Background: Disturbed sleep patterns are common among older adults and may contribute to cognitive and physical declines. However, evidence for the relationship between sleep duration and cognitive frailty, a concept combining physical frailty and cognitive impairment in older adults, is lacking.

Objective: This study aimed to examine the associations of sleep duration and its changes with cognitive frailty.

Methods: We analyzed data from the 2008 - 2018 waves of the Chinese Longitudinal Healthy Longevity Survey. Cognitive frailty was rendered based on the modified Fried frailty phenotype and Mini-Mental State Examination. Sleep duration was categorized as short (<6 h), moderate (6 - 9 h), and long (>9 h). We examined the association of sleep duration with cognitive frailty status at baseline using logistic regressions and with the future incidence of cognitive frailty using Cox proportional hazards models. Restricted cubic splines were used to explore potential nonlinear associations.

Results: Among 11,303 participants, 1298 (11.5%) had cognitive frailty at baseline. Compared to participants who had moderate sleep duration, the odds of having cognitive frailty were higher in those with long sleep duration (odds ratio 1.71, 95% CI 1.48 - 1.97; *P*<.001). A J-shaped association between sleep duration and cognitive frailty was also observed (*P*<.001). Additionally, during a mean follow-up of 6.7 (SD 2.6) years among 5201 participants who were not cognitively frail at baseline, 521 (10%) participants developed cognitive frailty. A higher risk of cognitive frailty was observed in participants with long sleep duration (hazard ratio 1.32, 95% CI 1.07 - 1.62; *P*=.008).

Conclusions: Long sleep duration was associated with cognitive frailly in older Chinese adults. These findings provide insights into the relationship between sleep duration and cognitive frailty, with potential implications for public health policies and clinical practice.

KEYWORDS

aging; frailty; cognition; cohort study; sleep duration; sleep quality; longitudinal study

Introduction

Physical frailty and cognitive impairment are prevalent among older adults and have individually been associated with adverse health outcomes [1,2]. They often coincide with aging and can be bidirectionally linked to each other [3,4], prompting the introduction of the concept of cognitive frailty—the coexistence of both physical frailty and cognitive impairment [5]. The necessity is further justified by the findings that cognitive frailty poses an even greater risk of adverse outcomes compared to the isolated effects of the 2 conditions [6,7]. Identifying factors associated with or contributing to cognitive frailty is important and will provide a better understanding of the underlying mechanisms.

Disturbed sleep patterns, such as an increased number of awakenings, abnormal nighttime sleep duration, and poorer sleep quality, are common among older adults [8]. Numerous epidemiological studies identified sleep disturbances as risk factors for physical frailty and cognitive impairment, such as shorter or longer sleep duration, insomnia, and sleep apnea [9,10]. In addition, recent studies have linked long sleep duration to cognitive frailty, but they are from cross-sectional analyses

XSL•FO
RenderX

[11,12]. A longitudinal study in Mexican older adults reported associations between increasing sleep duration trajectory with greater odds for mild cognitive impairment and frailty separately [13]. Whether sleep patterns are associated with the development of cognitive frailty as a unified concept remains to be elucidated.

To address this knowledge gap, this study aimed to assess the associations of sleep duration with cognitive frailty in a nationally representative, large cohort of older Chinese adults. By focusing on an older Chinese adult population, our findings may offer insights into the relationship between sleep duration and cognitive frailty within this demographic, with potential implications for public health policies and clinical practice.

Methods

Study Design and Participants

We used data from the Chinese Longitudinal Healthy Longevity Survey (CLHLS). As detailed previously, CLHLS is an ongoing, nationwide representative longitudinal cohort study of Chinese adults aged 65 years and older from 23 out of 31 provinces or municipalities or autonomous regions in mainland China [14,15]. The CLHLS started in 1998 with surveys on sociodemographic characteristics, lifestyle, cognitive function, psychological status, and physical function conducted every 2 - 3 years.

In this study, we used data from 4 waves (2008, 2011, 2014, and 2018) of the CLHLS. To maximize statistical power and leverage the large sample size, we first examined cross-sectional associations between sleep duration and sleep quality, with cognitive frailty at baseline (ie, the 2008 wave). For this set of analyses, we included 11,303 participants who had cognition and physical frailty assessments at baseline. We then examined whether baseline sleep duration and sleep quality, as well as change in sleep duration, were associated with the future development of cognitive frailty. For these longitudinal analyses, we excluded 1298 participants who had cognitive frailty at baseline, 4780 participants who had no follow-up cognitive frailty assessment, and 24 participants who had missing value in sleep duration in the 2011 wave. As a result, 5201 participants entered the subsequent longitudinal analysis.

Assessment of Cognitive Frailty

Cognitive frailty was identified as the simultaneous presence of both physical frailty and cognitive impairment [5].

Physical frailty was assessed by a modified Fried frailty phenotype, based on 5 components: shrinking, weakness, low mobility, exhaustion, and inactivity [16,17]. Shrinking was defined as having a BMI of 18.5 kg/m^2 or less. Weakness was determined if participants self-reported that they were unable to lift a bag weighing 5 kg or above. Low mobility was identified if participants self-reported that they were unable to walk 1 km or longer in a row. Exhaustion was identified if participants answered “always,” “often,” or “sometimes” to the question “Do you feel the older you get, the more useless you are?” Inactivity was defined as participants doing the following activities 1 time per week or less: housework, outside activity, garden work, raising domestic animals or pets, playing cards or mah-jongg, and social activity (organized). Participants were considered physically frail when meeting ≥3 of the 5 criteria.

Cognitive impairment was assessed by a validated Chinese version of the Mini-Mental State Examination (C-MMSE) [15,18]. The C-MMSE includes 24 items regarding orientation, memory, attention, calculation, and language, ranging from 0 to 30. Based on a prior study, participants were considered cognitive impairment if the C-MMSE score was ≤22 [15].

Assessment of Sleep Variables

Sleep duration was estimated based on the answers to the question “How many hours do you sleep normally?” Based on their answers, participants were further categorized into short (<6 h), moderate (6 - 9 h), and long (>9 h) sleep durations. This categorization aligned with previous research indicating that both short and long sleep durations are associated with poorer health outcomes [19]. The rate of change in sleep duration was calculated by taking the difference between sleep durations reported in the 2008 and 2011 waves (ie, sleep duration in the 2011 wave minus sleep duration in the 2008 wave) and dividing it by the individual follow-up interval in years. Sleep quality was assessed based on answers to the question “How about the quality of your sleep?” A score of “poor” was assigned if the answer was “so-so,” “bad,” or “very bad,” and a score of “good” was assigned otherwise.

Covariates

We considered the following covariates that have been identified to be associated with physical or cognitive outcomes in previous studies [20,21]: age, sex, education, marital status, residence, economic status, loneliness, smoking status, drinking status, and multimorbidity. Education was categorized as “Not Educated” if the participant had not attended any schools and “With Formal Education” if the participant had attended schools more than 1 year. Marital status was defined as currently married and living with a spouse, and others (eg, separated, divorced, widowed, and never married). Residence was categorized into living in urban (eg, city or town) or rural areas. Economic status was categorized into economic dependence or independence based on their income source. Loneliness was identified if participants answered “always,” “often,” or “sometimes” to the question “Do you feel lonely and isolated?” Smoking status was categorized as “Never smoked,” and “Former or current smoker.” Drinking status was categorized into “Never drank,” and “Former or current drinker.” Multimorbidity was defined from self-reports and categorized as “Yes” if having 2 or more of the following chronic diseases: hypertension, diabetes, heart disease, stroke or cerebrovascular disease, respiratory disease, cancer, and Parkinson disease, or “No” if otherwise.

Statistical Analysis

Listwise deletion was applied to both cross-sectional and longitudinal analyses to handle missing data on covariates. The *t* tests for continuous variables and chi-square tests for categorical variables were used to compare the differences in the baseline characteristics.

Multivariate logistic regression models were performed to assess the associations of sleep duration and sleep quality with

XSL•FO
RenderX

cognitive frailty at baseline (ie, the 2008 wave). We performed 3 models: model A was unadjusted; model B was adjusted for age, sex, and education; model C was further adjusted for marital status, residence, economic status, loneliness, smoking status, drinking status, and multimorbidity.

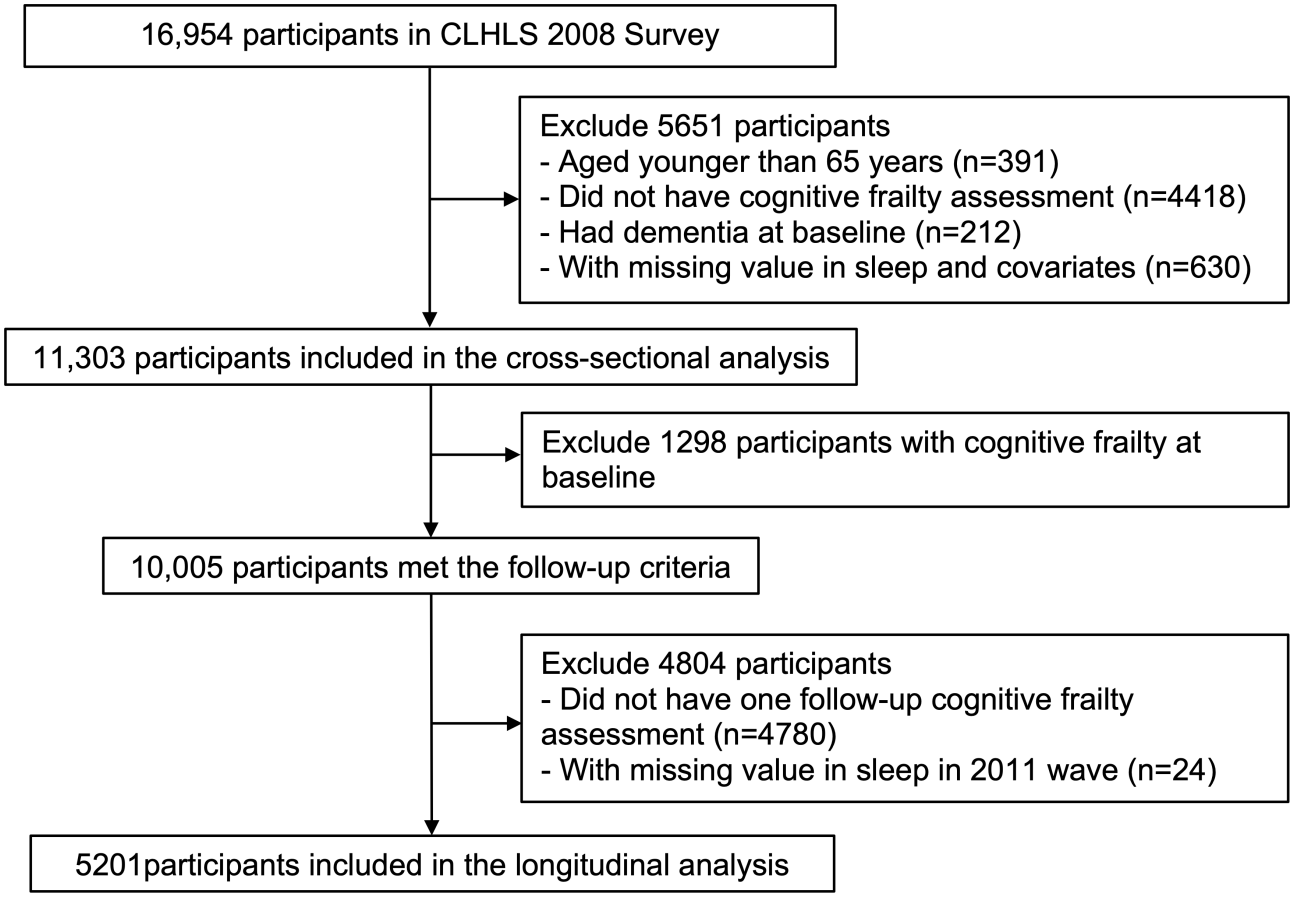
Cox proportional hazard (PH) models were used to test the associations between sleep duration and sleep quality with incident cognitive frailty during the follow up. Death was treated as a right-censored event at the time of occurrence. The follow-up duration was defined as the time interval in years from baseline to the date of the first occurrence of cognitive frailty, death, or the latest available data, whichever occurred first. We rounded the time to the nearest integer year to account for group-tied events. Similarly, we performed 3 models: model A was unadjusted; model B was adjusted for age, sex, and education; model C was further adjusted for marital status, residence, economic status, loneliness, smoking status, drinking status, and multimorbidity. The PH assumption of the Cox models was assessed using Schoenfeld residuals. No major violations of the PH assumption were detected for exposure variables.

Restricted cubic spline (RCS) curves were plotted to explore the nonlinear cross-sectional and longitudinal associations between sleep duration and cognitive frailty. Additionally, several sensitivity analyses were conducted to verify the robustness of our findings. First, we adjusted for each chronic disease individually and for all chronic diseases simultaneously. Second, we performed stratified analyses by sex and age. Furthermore, we performed similar sets of Cox PH models to investigate the associations of changes in sleep duration and incident cognitive frailty.

All statistical analyses were performed in R (version 4.1.2; R Core Team). Statistical significance was considered at a 2-tailed α level of .05.

Ethical Considerations

The CLHLS was approved by the Duke University Institutional Review Board (Pro00062871) and the Peking University Biomedical Ethics Committee (IRB00001052–13074). All participants provided written informed consent. The data used in this study were deidentified to protect participant privacy and confidentiality. No compensation was provided to participants.



Results

Participant Characteristics

The participant flowchart is presented in Figure 1. Of the 11,303 participants included in the cross-sectional analysis, 6037 (53.4%) participants were female. The mean age at baseline was 84.7 (SD 11.0) years old. Approximately 11.5% (n=1298) of all participants had cognitive frailty at baseline. The numbers of participants who reported short, moderate, or long sleep duration were 1327 (11.7%), 7207 (63.8%), and 2769 (24.5%), respectively. Poor sleep quality was found in 3796 (33.6%) participants. Baseline characteristics stratified by cognitive frailty status at baseline are summarized in Table 1. Additionally, baseline characteristics categorized by sleep duration are presented in Multimedia Appendix 1. Baseline characteristics of 5201 participants included in the longitudinal analysis are summarized in Multimedia Appendix 2.

[a]CF: cognitive frailty.

Association Between Sleep Duration and Cognitive Frailty at Baseline

Compared to participants who had moderate sleep duration, the odds of having cognitive frailty were higher in those who had long sleep duration (odds ratio [OR] 1.71, 95% CI 1.48 - 1.97; *P*<.001) in the initial model adjusted for age, sex, and education Table 2. The association remained statistically significant with a similar OR in the augmented model after further adjustments of marital status, residence, economic status, loneliness, smoking status, drinking status, and multimorbidity (OR 1.69, 95% CI 1.46 - 1.95; *P*<.001). There was no statistically significant

XSL•FO
RenderX

difference in the odds of having cognitive frailty between participants with short and modest sleep durations in the initial model adjusted for age, sex, and education. Compared with those who had a good sleep quality, participants who had a poor sleep quality were at a higher risk for cognitive frailty in both initial and the augmented models with further adjustments (initial model: OR 1.63, 95% CI 1.40 - 1.89; *P*<.001; augmented model: OR 1.41, 95% CI 1.21 - 1.64; *P*<.001; Table 2). In addition, RCS analysis revealed a J-shaped association between sleep duration and cognitive frailty at baseline (*P* for nonlinear<.001; Figure 2).

The results of sensitivity analyses are summarized in Multimedia Appendices 3 and 4. The associations between long sleep duration and baseline cognitive frailty remained consistent when adjusting for each chronic disease individually and when accounting for all chronic diseases simultaneously (Multimedia Appendix 3). For individuals younger than 80 years old, the association of long sleep duration with cognitive frailty became not statistically significant, whereas for individuals older than 80 years old, the association persisted. The association remained significant in sex-stratified models (Multimedia Appendix 4).

Association Between Sleep Duration and Incident Cognitive Frailty During Follow-Up

Over a mean of 6.7 (SD 2.6) years of follow up, 521 (10%) participants out of the 5201 participants developed cognitive frailty. In the initial model adjusted for age, sex, and education, as compared with participants who had moderate sleep duration at baseline, a higher risk of cognitive frailty was observed in participants who had long sleep duration at baseline (hazard ratio [HR] 1.32, 95% CI 1.07 - 1.62; *P*=.008; Table 3). The association persisted after further adjusting for marital status, residence, economic status, loneliness, smoking status, drinking status, and multimorbidity (HR 1.30, 95% CI 1.06 - 1.59; *P*=.01). There was no statistically significant difference in the hazard of incident cognitive frailty between participants with short sleep duration and moderate sleep duration in the initial model. Besides, there was no significant difference in the risk of incident cognitive frailty between participants with good and poor sleep quality. Additionally, RCS analysis showed no significant nonlinear association between sleep duration and cognitive frailty during follow up (*P* for nonlinear=.29; Figure 3).

RenderX

Figure 3. Nonlinear association between sleep duration and cognitive frailty during follow up using restricted cubic spline. The Cox proportional model was used to fit the data, with solid lines representing the estimated HR and shaded areas representing the corresponding 95% CIs. HR: hazard ratio.

Rate of Change in Sleep Duration and Cognitive Frailty

The mean annual rate of change in sleep duration was –0.02 (SD 0.87) hours/year. In the model adjusted for age, sex, education, sleep quality, and sleep duration at baseline, a faster increase in sleep duration per year was associated with a higher risk for cognitive frailty: for 1 hour/year increase in sleep duration, the HR was 1.14 (95% CI 1.03 - 1.27; *P*=.01). The association remained significant after further adjusting for marital status, residence, economic status, loneliness, smoking status, drinking status, and multimorbidity (HR 1.15, 95% CI 1.03 - 1.27; *P*=.01; Multimedia Appendix 7).

Discussion

Principal Findings

In this large community-based prospective study of over 10,000 Chinese older adults, we found that long sleep duration was consistently associated with cognitive frailty status at baseline, as well as an increased risk of cognitive frailty incident during follow up. We also found that a faster annual increase in sleep duration was associated with a higher risk of cognitive frailty during follow up.

The associations of sleep duration with physical frailty or cognitive decline are complex with mixed findings in prior research. A study using data from the National Health and Nutrition Examination Survey demonstrated that prolonged sleep duration (ie, ≥10 h) was associated with physical frailty in older adults, while a prospective study of 309 older Mexican adults showed that participants with either short sleep duration (ie, ≤5 h) or long sleep duration (ie, ≥9 h) had a higher risk of physical frailty [22,23]. Likewise, a Japanese cohort study of 623 older adults reported that long sleepers (>8 h) had a higher risk of cognitive impairment, while a cohort study found that self-reported short sleepers (<7 h) had an increased risk of cognitive decline [24,25]. However, few studies explored the association between sleep duration and cognitive frailty, that is, the coexistence of physical frailty and cognitive impairment. Two recent cross-sectional studies reported an association of long sleep duration with cognitive frailty among community-dwelling older adults and in older adults with heart failure [11,12]. In this study, we confirmed such a cross-sectional association between long sleep duration and cognitive frailty. More intriguingly, we showed consistent evidence from longitudinal analyses that participants with long sleep duration at baseline had an increased risk of developing cognitive frailty in the future. Of note, we did not find a significant association between short sleep duration and cognitive frailty in this study.

XSL•FO
RenderX

We also used the annual rate of change in sleep duration to assess the relationship between sleep duration changes and cognitive frailty. The results showed that a faster annual increase in sleep duration was associated with a higher risk of cognitive frailty, independent of the baseline sleep duration category. Notably, this study accounted for variations in follow-up years by using the annual rate of sleep duration change instead of the absolute change in sleep duration, minimizing classification bias and providing a more accurate representation of the relationship between sleep duration trajectories and cognitive frailty.

The mechanisms underlying the association of sleep duration with incident cognitive frailty remain unclear. However, several potential pathways can be suggested. First, inappropriate sleep duration (either shorter or longer than ideal) has been linked to cardiovascular health [26], which has been reported as a risk factor for both physical frailty and cognitive decline [27,28]. Second, increased sleep duration has also been linked with elevations in C-reactive protein, a marker for systemic inflammation, and interleukin-6, a proinflammatory biomarker [29,30]. Prior studies have shown that even low-level inflammation may pose an increased risk for the development of physical frailty and cognitive impairment [31,32]. Finally, long sleep duration may also be an indicator of or linked to disturbances in circadian control, the internal biological clock that prepares bodily responses to environmental light-dark changes. Circadian disturbances have been previously reported to be associated with both physical frailty and cognitive impairment or decline [33-36].

Several previous studies showed that sleep quality is closely related to impairments in both physical and cognitive domains [37,38]. In addition, 2 recent cross-sectional studies reported that poor sleep quality was associated with cognitive frailty in older Chinese adults living in nursing homes, and among Thai community-dwelling older adults during the COVID-19 restrictions [39,40]. Our observed cross-sectional association between sleep quality and cognitive frailty aligns with these previous findings. However, we did not find evidence of an association between sleep quality and the development of cognitive frailty in this study. It is important to note that the assessment of sleep quality in this study relied on a single question, which may be overly simplistic and may not fully capture the complexity of sleep behaviors. Future studies should use more comprehensive approaches to assess sleep health, considering its multidimensional nature, which includes factors such as duration, timing, efficiency, satisfaction, and alertness [41].

Strengths and Limitations

To the best of our knowledge, this study was the first to assess the association between sleep duration and incident cognitive frailty in a nationally representative sample of older Chinese adults. Strengths of this study include its longitudinal design and a large sample size. This study also has several limitations. First, the sleep duration and sleep quality were from self-reports and may be subjected to recall biases, especially in older adults and individuals with cognitive impairment. Future studies, ideally with an objective sleep monitoring approach (such as combining actigraphy and sleep diary or polysomnography), are warranted. Second, a growing body of studies have linked daytime napping behaviors with physical frailty, cognitive decline, Alzheimer dementia, or cognitive frailty [40,42,43]. Similarly, sleep disorders, such as sleep apnea, have been consistently linked with physical frailty, cognitive impairment, and dementia [10,44]. However, these potential sleep-related influences were not collected in the CLHLS. Future studies may consider incorporating these multidimensional structs when assessing sleep health and its relationships with physical and cognitive outcomes. Finally, the participants in this study were, on average, older than 80 years at baseline. In subgroup analyses, the association between long sleep duration and cognitive frailty was not statistically significant in participants younger than 80 years. This may be due to the limited number of cognitive frailty events in this subgroup, which could have resulted in insufficient statistical power to detect a significant association. Therefore, caution should be taken when translating our findings into younger populations.

Conclusions

In this large cohort study of over 10,000 older Chinese adults, long sleep duration was consistently associated with an increased risk of cognitive frailty, both cross-sectionally and longitudinally. These findings underscore the importance of sleep monitoring in aging populations. Future research using objective sleep assessments and investigating the underlying biological mechanisms is warranted to inform more effective prevention strategies.

Abstract

Background: Frailty syndrome in older adults represents a significant public health concern, characterized by a reduction in physiological reserves and an increased susceptibility to stressors. This can result in adverse health outcomes, including falls, hospitalization, disability, and mortality. The early identification and management of frailty are essential for improving quality of life and reducing health care costs. Conventional assessment techniques, including dual-energy X-ray absorptiometry (DXA), bioelectrical impedance analysis (BIA), and muscle ultrasound (US), are efficacious but frequently constrained in primary care settings by financial and accessibility limitations.

Objective: The aim of this study is to analyze the differences in anthropometric characteristics, physical function, nutritional status, cognitive status, and body composition among older adults identified as frail, prefrail, or robust in primary care services using the PowerFrail mobile app. Furthermore, the study assesses the predictive capacity of body composition variables (whole-body phase angle [WBPhA] via BIA, US-measured rectus femoris muscle thickness, and DXA-derived lean mass) in identifying frailty and evaluates their feasibility for implementation in primary care.

Methods: A descriptive cross-sectional study was conducted with 94 older adult participants aged between 70 and 80 years, recruited through the Andalusian Health Service in Spain. Frailty status was classified using the PowerFrail App, which integrates muscle power assessment and provides personalized physical activity recommendations. Body composition was measured using WBPhA (BIA), muscle US, and DXA. Statistical analyses included 1-way ANOVA for group comparisons, logistic regression to investigate associations, and receiver operating characteristic curve analysis to evaluate the predictive accuracy of the body composition measures.

Results: Participants were categorized into frail (n=28), prefrail (n=33), and robust (n=33) groups. All body composition measures exhibited high specificity in detecting frailty, with varying sensitivity. Unadjusted US showed the highest specificity but low sensitivity (10.7%). WBPhA and right leg lean mass (LeanM RL) demonstrated significant predictive capabilities, especially when adjusted for age and sex, with area under the curve values ranging from 0.678 to 0.762. The adjusted LeanM RL model showed a good balance between sensitivity (35.7%) and specificity (93.9%; *P*=.045), indicating its potential as a reliable frailty predictor. These findings are consistent with previous research emphasizing the importance of muscle mass and cellular health in frailty assessment.

Conclusions: Body composition variables, particularly WBPhA, LeanM RL, and US, are effective predictors of frailty in older adults. The PowerFrail mobile app, combined with advanced body composition analysis, offers a practical and noninvasive method

for early frailty detection in primary care settings. Integrating such technological tools can enhance the early identification and management of frailty, thereby improving health outcomes in the aging population.

Introduction

Frailty syndrome in older adults is a multifaceted clinical condition characterized by decreased physiological reserves and increased vulnerability to stressors, which elevates the risk of adverse health outcomes such as falls, hospitalization, disability, and mortality [1,2]. As the global population ages, the prevalence of frailty is projected to rise, posing significant challenges to health care systems worldwide [3]. Early identification and management of frailty are crucial for enhancing quality of life, maintaining functional independence, and reducing health care costs associated with frailty-related complications [4,5].

Primary care facilities are uniquely positioned to play a pivotal role in the early detection and management of frailty due to their accessibility and continuous engagement with the aging population [6]. Implementing effective screening tools within primary care can facilitate timely interventions, thereby mitigating the progression of frailty and its associated adverse outcomes [7]. However, the integration of comprehensive frailty assessments into routine primary care practice remains limited, often due to time constraints, lack of standardized tools, and insufficient training among primary care providers [8].

Body composition variables, particularly those related to muscle mass and tissue quality, are essential in identifying and predicting frailty syndrome [9]. Techniques such as dual-energy X-ray absorptiometry (DXA), bioelectrical impedance analysis (BIA), and muscle ultrasound (US) have been extensively used to assess body composition and muscle status in older adults [10]. The whole-body phase angle (WBPhA), obtained through BIA, serves as an indicator of cellular health and nutritional status, with lower values associated with increased frailty and poorer clinical outcomes [11,12]. Similarly, muscle US offers a noninvasive way to assess muscle thickness and quality, aiding in the detection of sarcopenia and frailty [13]. Although DXA is considered the gold standard for measuring bone and muscle mass, its high cost and limited accessibility in primary care facilities make it necessary to explore alternative assessment methods [14].

In recent years, the advent of mobile health (mHealth) apps has introduced innovative solutions for the assessment and monitoring of complex geriatric syndromes, including frailty. The PowerFrail app represents a pioneering effort in this domain, being the first clinical and scientifically validated app designed to assess muscle power and frailty in older adults in a user-friendly manner [15,16]. This app not only facilitates the screening process but also provides individualized recommendations for improvement and tailored physical activity regimens, thereby supporting personalized intervention strategies. The utilization of validated mobile apps and new trends around artificial intelligence in primary care hold significant promise for enhancing the early detection and management of frailty, offering advantages such as accessibility, ease of use, and the ability to provide real-time feedback and recommendations [17,18].

Moreover, integrating mHealth tools into primary care can bridge gaps in health care delivery by enabling continuous monitoring and follow-up, which are critical for managing chronic conditions and preventing the escalation of frailty [18]. Previous studies have highlighted the effectiveness of mobile apps in improving health outcomes among older adults by facilitating timely interventions and enhancing patient engagement [19]. These findings underscore the potential of mHealth solutions to complement traditional assessment methods, providing a comprehensive approach to frailty management in primary care settings.

From above, the main objective of this study is to analyze the differences in variables related to anthropometric characteristics, physical function, nutritional status, cognitive status, and body composition in phenotypes of frail, prefrail, and robust older adults identified in primary care services. Frailty levels will be classified using the PowerFrail app. Additionally, the second objective is to assess the predictive capacity of body composition variables (US, bioimpedance, and DXA) in identifying older adults with frailty and to evaluate their implementation in primary care services. We used the technological tools WBPhA, US for rectus femoris muscle thickness, and DXA for bone mineral density and lean mass assessment. Our results could demonstrate that these parameters are useful predictors for the identification of frailty, in line with previous findings, thus supporting the potential integration of these tools into primary care practices for the early detection and management of frailty, integrating for the first time mHealth technologies with advanced body composition analysis systems.

Methods

Ethical Considerations

This was a descriptive cross-sectional study that evaluated clinical, physiological, body composition, and psychometric variables in a sample of older adult participants. Recruitment and data collection took place between March and June of 2023. Participants were recruited through advertisements from the public Andalusian Health Service system, Spain. Participants were recruited from primary care centers through referrals by health care professionals. Recruitment was conducted in collaboration with general practitioners, who identified potential

XSL•FO
RenderX

participants meeting the inclusion criteria. The study adhered to the ethical principles of the Declaration of Helsinki for medical research involving human subjects. All participants provided written informed consent. This study was approved by the Costa del Sol Institutional Ethics Committee, under protocol number BON22, on December 23, 2022. All participants provided written informed consent prior to their inclusion in the study. Participants' privacy and confidentiality were ensured throughout the study: all data were anonymized prior to analysis, and identifying information was stored securely and separately from the study data. No identifiable images or information of participants are included in this publication. Participants did not receive compensation for their participation..

Participants

Inclusion criteria for the study were as follows:

- Individuals aged between 70 and 80 years, inclusive.
- Absence or presence of mild cognitive impairment as determined by a Barthel index score [20] greater than 95.
- Sit-to-stand test score [21] between 2.5 and 3.6 for men or between 1.9 and 3 for women.
- Signed informed consent.

Exclusion criteria were the following:

- Individuals younger than 70 years or older than 80 years.
- Individuals with moderate or severe cognitive impairment.
- Sit-to-stand test score [21] less than 2.5 or greater than 3.6 for men or less than 1.9 or greater than 3 for women.
- Individuals living in institutions.
- Individuals with pacemakers or metal prostheses.

Variables and Procedure

The aim of this study was to identify differences in measured parameters to classify individuals into different states of frailty within primary care. To identify different states of frailty, the sit-to-stand test was used, and relative power was calculated using the equations validated by Losa-Reyna et al [16]. Using the cutoff points determined by Losa-Reyna et al [22], participants were classified into 3 groups: frail, prefrail, and robust. This test was performed in the health center's office.

After identifying the study subjects, a detailed evaluation of the remaining variables was carried out in the Functional Testing Laboratory of the Physical Education and Sports Area of the University of Málaga. Participants came to the laboratory fasting (a minimum of 3 hours) and without having done any previous exercise, wearing comfortable and light clothing without metal objects. The tests were carried out between 9:30 AM and 2:00 PM. Once in the laboratory, 2 qualified researchers administered the different tests and assessments; body composition determinations were performed fasting and in the early morning, and the rest of the scheduled evaluations were carried out after breakfast.

Clinical and Demographic Variables

We collected the following clinical and demographic variables:

- Age and sex: Recorded during the initial interview (age in years; sex as male or female).
- Body mass index: Calculated by dividing weight (measured in kilograms using a Digital Scale Extra Large Seca Robusta 813) by height (measured in meters using a stadiometer) squared (m^2).
- Number of medications (drugs): Extracted from the clinical history of the Diraya system (Andalusian Health Service database), with the participants' consent.
- Education level: Recorded during the initial interview.

Body Composition Variables

We collected the following body composition variables:

- Muscle architecture: Muscle thickness and pennation angle of the rectus femoris muscle of the dominant leg were measured using US (Logiq Book XP Ultrasound System and 8L linear transducer). The rectus femoris was examined with the participant in a supine position, with the US operator standing on the ipsilateral side of the participant. The evaluation protocol previously described by Mateos-Angulo et al [23] was used.
- DXA: Lean mass of arms and legs, total lean body mass, skeletal muscle index, and bone mineral density were determined using a Hologic Horizon A DXA scanner (Hologic Inc). Each subject was examined by a certified technician. The distinction between bone and soft tissue, the detection of edges, and regional demarcations were performed using computer algorithms with APEX Corporation Software (version 5.6.0.7). For each scan, patients were asked to remove all materials that could attenuate the X-ray beam, including jewelry. Due to the sensitivity of the soft tissue analysis, the patient should only wear a paper gown for the scan. There should be no pillow on the scan, as the material would affect the soft tissue measurement. The densitometer calibration was checked daily with the standard calibration block supplied by the manufacturer.
- BIA: Total body water, intracellular, extracellular water, and phase angle (WBPhA) variables were determined by multifrequency bioimpedance using the Inbody 770 model. Multifrequency segmental data were obtained that accurately determined total body water, intracellular and extracellular water, impedance (Xc and R), and phase angle (Z) in the 5 body segments (right arm, left arm, trunk, right leg, and left leg).

Cognitive and Nutritional Status

To assess cognitive and nutritional status, the following questionnaires were administered digitally using the Google Forms application.

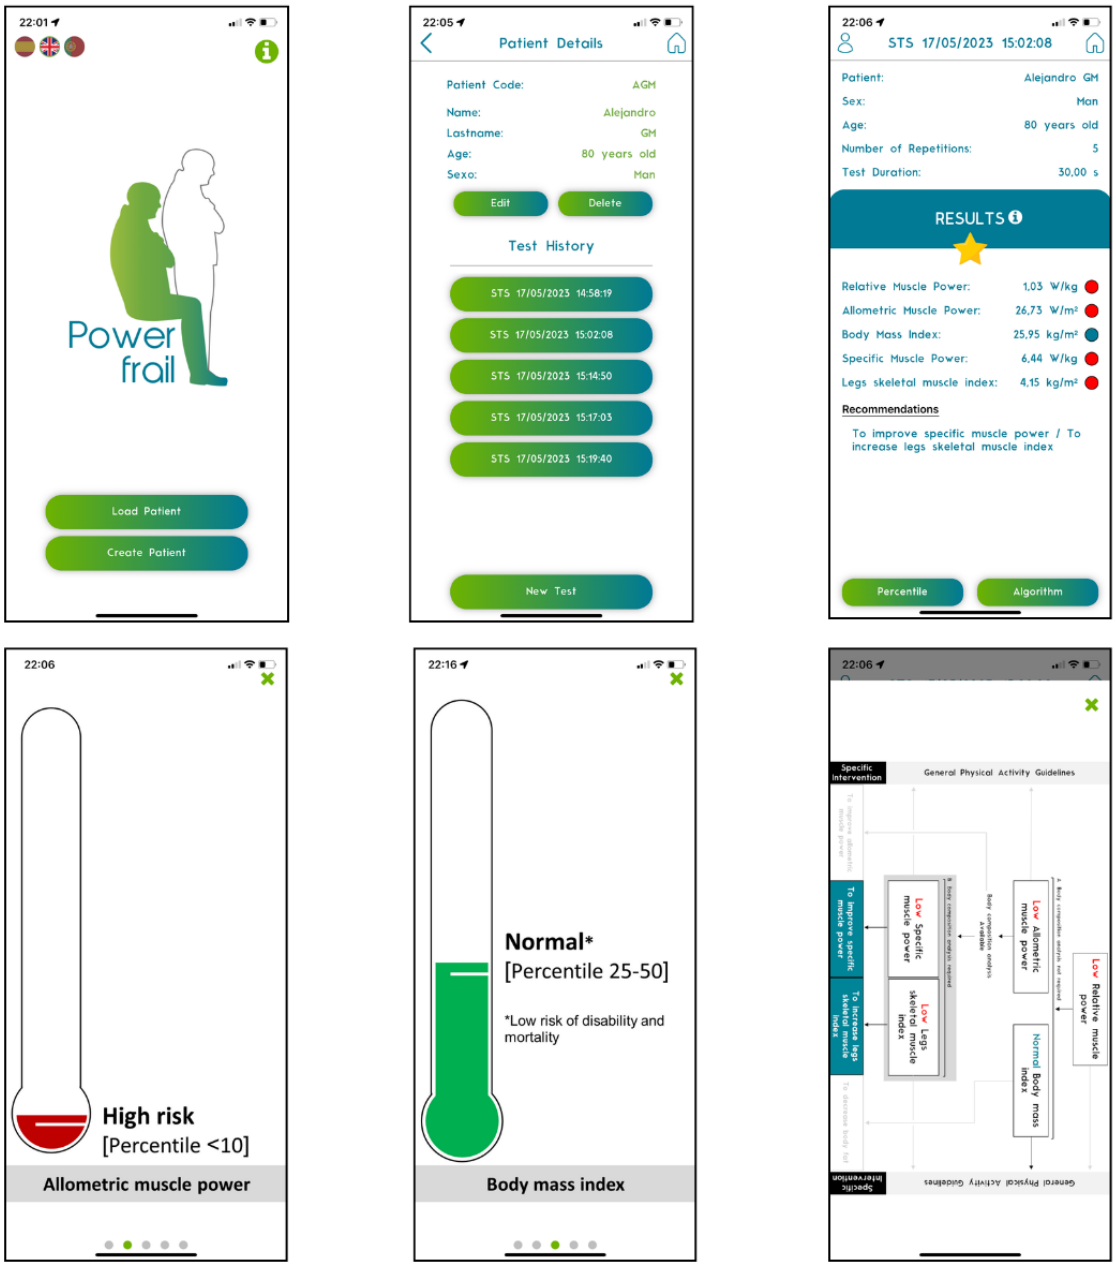
- Cognitive capacity: Cognitive status was evaluated [24] using the General Practitioner Assessment of Cognition, score 0 to 8, a rapid, reliable, and specific test for the detection of dementia in primary care. This instrument is considered an efficient alternative to others, such as the Mini-Mental State Examination, due to its rapid administration and lack of bias related to gender, education level, or mental health.
- Nutritional status screening: Nutritional status was assessed using the Mini Nutritional Assessment (MNA) [25], score

XSL•FO
RenderX

0 to 14, a widely used scale in the geriatric population. The first part of this test serves as a screening tool to detect the risk of malnutrition, with a cutoff value of 10 points or less. It is a widely used method in older adults and has been validated in different clinical contexts.

Physical Function Evaluation

To evaluate the physical function of the participants, the Short Physical Performance Battery (SPPB) was used, score 0 to 12 [26]. This battery includes three tests:



- Walking speed: Measured over a 4-meter distance, expressed in meters per second. Given that gait speed measurement is used as a tool for detecting frailty in older adults from the general population due to its high sensitivity, simplicity, and feasibility, we also used the cutoff points for frailty and prefrailty related to gait speed and sarcopenia in accordance with the consensus document developed by Cruz-Jentoft et al [27]. In this framework, values below 0.6 m/s are identified as frail, between 0.6 and 1 m/s as prefrail, and above 1 m/s as robust [27].
- Static balance: Assessed in 3 different positions.
- Sit-to-stand test: Evaluation of the time it takes for participants to stand up and sit down from a chair 5 times.

In addition to the tests included in the SPPB, two tests were performed:

- Mobile lower limb relative muscle power (RPOW): To measure RPOW, participants performed 5 repetitions of standing up from and sitting down onto a chair with a height of 0.46 m, following the protocol validated by Alcazar et al [15]. The test was performed using the PowerFrail app (Figure 1), developed and validated by Losa-Reyna et al [16], installed on a stable smartphone.
- Handgrip strength: Isometric handgrip strength, expressed in kilograms, was measured using a Takei Physical Fitness Test adjustable dynamometer, following a standardized protocol, as indicated by Roberts et al [28]. Participants performed the test in an erect standing position, with shoulders adducted and arms extended parallel to the body, without touching their torso. Two attempts were made for each extremity, and the maximum value was considered, regardless of hand dominance.

RenderX

Figure 1. PowerFrail mobile app screenshots.

Sample Size Calculation

The sample size was estimated using an ANOVA model for 3 independent groups (robust, prefrail, and frail). The calculation was performed using the G*Power software. For the sample size calculation, a power of 90% (1–β=.90), a significance level of 5% (α=.05), and an effect size of 0.4 were used. The result was a total sample size of 84 participants. This size was obtained with a noncentrality parameter (λ) of 13.44 and a critical *F* of 3.11, with 2 degrees of freedom in the numerator and 81 in the denominator. To avoid losses in the initial calculation, enough participants were recruited to maintain the robustness of the study. Finally, 94 subjects participated in the study, distributed across 3 groups: robust, prefrail, and frail.

Statistical Analysis

To compare the differences on all variables between robust participants and those with frailty and prefrailty, a 1-way ANOVA was performed on the total sample. Logistic regression analysis was performed to investigate the relationship between body composition and frailty. WBPhA, thickness US, and DXA lean muscle from the lower limbs were entered into the regression model as independent variables, as they were found to have significant differences between the studied groups. Considering that age and sex may influence the relationship between body composition and frailty, these factors were introduced as a confounding variable into an adjusted regression model, treating age as a continuous covariate and sex as a categorical factor. The dependent variable was a binary indicator of frailty, coded as 1 for participants with frailty and 0 for robust participants and those with prefrailty.

XSL•FO
RenderX

To extract values for body composition to identify the presence of prefrailty or frailty, we conducted an analysis using the receiver operating characteristic (ROC) curve. This analysis was applied only to body composition that was significant in the logistic regression analysis. In the ROC analysis, the outcome variable was the presence or absence of frailty. The test variable was the body composition that was significantly associated with frailty. Youden index [29] was calculated with the following formula: Youden index = sensitivity + specificity – 1. The area under the curve (AUC), sensitivity, and specificity were calculated to evaluate the accuracy of the identified predictive models. The AUC could distinguish between nonpredictive (AUC<0.5), less predictive (0.5<AUC<0.7), moderately predictive (0.7<AUC<0.9), and highly predictive (0.9<AUC<1) values, as well as perfect prediction (AUC=1) [30].

Results

The background information of the participants is shown in Table 1. Of the 94 participants in this study, 28 were frail, 33 were prefrail, and 33 had a robust profile. The average age for each frailty category was 76.5, 75.3, and 74.0 years, respectively. The percentages of men and women with frailty and prefrailty were 32% and 52% for men and 68% and 48% for women, respectively. All investigated variables were significantly different among the frailty categories, except BMI, MNA score, skeletal mass index, left arm lean mass, right arm lean mass, and total body lean mass.

The correlation analysis is presented through a heat map in Figures 2-4. Starting with the primary variable identified as a frailty criterion (RPOW), we initially analyzed the behavior of this variable in relation to the other studied variables. Additional correlation analyses were also explored, such as examining the behavior and relationship of handgrip strength. In this regard, we conducted a first analysis on the entire sample (Figure 2), then one each for women (Figure 3) and men (Figure 4). In the entire sample (Figure 1), we found strong positive and negative correlations between the RPOW and all the variables, except MNA score, however, these relationships changed for the women-only and men-only samples. In the complete sample (Figure 2), the results identified stronger correlations between SPPB and RPOW, 5 sit-to-stand time and RPOW, drugs and RPOW, GS4m and RPOW, and handgrip and RPOW. Regarding the analysis of the correlations separately for women and men (Figures 3 and 4), the results were as expected. Specifically, as observed in the cited figures, there were relationships involving body composition variables (BIA, DXA, and US) and expressions of strength, such as lower limb power and, more markedly, handgrip strength. The observed differences in correlations between sexes are consistent with expectations, given the complex biological, hormonal, and social interactions that affect males and females differently during the aging process. It is important to consider these factors when interpreting the results and when designing interventions that address frailty and functional decline in older adults effectively and equitably.

The logistic regression analyses presented in Table 2 demonstrate the predictive capacity of various diagnostic factors for frailty in older adults. The Nagelkerke R^2 values indicate the proportion of variance in frailty status explained by each model, both before and after adjusting for age and sex. The initial model for US shows that US measurements of the rectus femoris explained 10.1% of the variance in frailty (Nagelkerke R^2=0.101; P=.009). After adjusting for age and sex, the explained variance increases to 20.6% (adjusted Nagelkerke R^2=0.206; P=.002), indicating a stronger association when these factors are considered. WBPhA exhibited a significant association with frailty, explaining 16.4% of the variance in the unadjusted model (Nagelkerke R^2=0.164; P=.001). The adjusted model further enhanced the explained variance to 24.5% (adjusted Nagelkerke R^2=0.245; P<.001), underscoring its robustness as a predictive factor. Both left leg lean mass and right leg lean mass (LeanM RL) were significant predictors of frailty. The unadjusted models explained 12.4% (P=.003) and 16.4% (P<.001) of the variance, respectively. After adjustment, the explained variance increased to 21.5% for the left leg (P=.001) and 24.6% for the right leg (P<.001).

XSL•FO
RenderX

Table . Results of the logistic regression analyses (n=94).

	Nagelkerke R^2	*P* value	Adjusted Nagelkerke R^{2a}	*P* value
Ultrasound on rectus femoris	0.101	.009	0.206	.002
WBPhA[b]	0.164	.001	0.245	<.001
Lean mass, left leg	0.124	.003	0.215	.001
Lean mass, right leg	0.164	<.001	0.246	<.001

[a]Adjusted Nagelkerke R^2 included age as a covariable and sex as a factor.

[b]WBPhA: whole-body phase angle.

The ROC analyses indicated that all evaluated measures demonstrated a high degree of specificity in detecting frailty in older adults. It is notable that unadjusted muscle US demonstrated a high level of specificity, although sensitivity was relatively low. The WBPhA and LeanM RL also exhibited significant predictive capabilities, with AUC and *P* values indicating good discrimination. When adjusting for sex and age, there was a notable improvement in sensitivity, particularly in the case of LeanM RL, which maintained statistical significance (*P*=.045). These findings suggest that the lean mass of the right leg, adjusted for demographic factors, may be a promising indicator for predicting frailty in this population. On the other hand, it is worth noting that the adjusted WBPhA presented the highest Youden index value (0.417), which suggests that it may be the most effective measure in terms of balancing sensitivity and specificity for predicting frailty. Similarly, the adjusted LeanM RL also had a high Youden index (0.296), which establishes it as another promising measure.

Discussion

Principal Findings

This study provides significant evidence on the predictive capacity of body composition variables and their relationship with frailty syndrome in older adults. Technology tools such as BIA, WBPhA, US of the anterior rectus quadriceps muscle thickness, and DXA, were used in this study. The older adult frailty status was calculated using the PowerFrail mobile app [15] (Figure 1). This app is the first scientifically based app that allows the assessment of the muscle power and frailty of older adults in a simple way. Our results showed that these parameters are useful predictors for identifying frailty, in line with previous findings.

This study found several significant correlations between variables related to body composition, physical performance, and cognitive status in female participants, but these were not the same as the values observed in their male counterparts. This may be because women experience more functional limitations than men during the aging process [31]. Women tend to suffer a greater decline in physical function with age, which has been attributed to hormonal changes, particularly the decrease in estrogen levels during menopause [32]. Menopause is associated with changes in body composition characterized by an increase in body fat and a progressive decrease in muscle mass and strength [33]. These alterations can lead to a higher prevalence of sarcopenia and frailty in older women compared to men.

Based on these postmenopausal changes, muscle and fat composition might be more closely related to physical performance in women, which we observed in our correlation results from Figures 2-4. Specifically, the associations between body composition measures (evaluated through BIA, DXA, and US) and expressions of strength, such as lower limb power from the mobile app and handgrip strength, were more pronounced in women. This suggests that changes in muscle quality and quantity may have a greater impact on the physical function of older women.

Although previous research has indicated that muscle quality contributes to physical capacity in older adults, the effect of sex differences on this association has not been thoroughly investigated [34]. Some studies have suggested that muscle quality independently predicts physical function in older men but not in women [35]. However, our findings differ, as we observed significant correlations in women. Unlike previous studies, we included analyses of physical function status, which may explain the different results. The underlying mechanisms of these sex-specific differences still need to be investigated and clarified.

Contributing factors may include differences in muscle structure composition, hormonal influences, and neuromuscular activation patterns between men and women [36]. Additionally, the accuracy and sensitivity of measurement techniques, such as BIA and US, may vary between sexes due to differences in body fat distribution and hydration status [37]. Further research is needed to explore these factors and understand how they influence the relationship between body composition and physical function in older adults.

The connection between body composition and frailty indicators has been the focus of extensive research. However, to our knowledge, no studies have simultaneously compared DXA, BIA, and US, specifically for the identification of frailty syndrome in a primary care setting. Our study addresses this gap by evaluating the predictive capacities of these 3 modalities, offering a comprehensive analysis that can inform clinical practice regarding the most suitable and practical tools for frailty assessment in older adults. Although previous studies have compared two modalities, our inclusion of a third (US) provides a broader perspective on body composition assessment tools available for primary care settings. For instance, research has demonstrated that muscle US is an emerging tool for diagnosing sarcopenia, with studies summarizing its diagnostic accuracy [38]. Additionally, studies have evaluated the reliability and

XSL•FO
RenderX

validity of sarcopenia diagnosis using BIA compared with the gold standard, DXA, assessing the predictive accuracy of BIA for diagnosis [39,40]. However, these studies did not include US in their comparisons. Rossini-Venturini et al [41] highlighted that the anthropometric prediction equations developed in their study provide a reliable, practical, and low-cost instrument to assess the components that change the most during the aging process, corroborating our findings. This perspective emphasizes the significance of considering diverse elements of body composition in the evaluation of health among older adults. Although some studies have recognized muscle mass, assessed via DXA or BIA, as a critical element in forecasting frailty [42,43], our analysis demonstrated that lower extremity lean mass (left left lean mass and LeanM RL) did reveal a direct relationship in the models. The present results are in line with findings that indicate muscle mass reduction alone does not suffice to predict frailty without factoring in physical performance [44]. In fact, physical performance, which can be measured through functional tests such as gait speed or grip strength, is vital for evaluating frailty status among older adults [45].

There has been a growing acknowledgment in recent literature regarding the significance of assessing both the quantity and quality of muscle. Xu et al [46] demonstrated that body composition, encompassing both muscle mass and quality, is significantly associated with frailty in older adult inpatients. The current literature suggests that it is not enough to analyze the quantity of muscle mass in absolute terms; quality is equally important. Quality can be assessed through methods such as US and BIA, which provide insights into muscle integrity and performance in terms of its functional capacity. In this context, analyzing muscle quality through US could effectively complement DXA, which has traditionally been considered the gold standard in the assessment of body composition. Although DXA provides valuable information on lean mass and fat mass, it does not provide details on muscle distribution and quality, critical for understanding frailty in older adults [47].

Moreover, our findings indicated that muscle strength and gait speed are important indicators of frailty, corroborating the work of Tsukasaki et al [48], who found a strong association between muscle strength, gait speed, and cross-sectional muscle area determined by midthigh computed tomography. These findings reinforce the idea that comprehensive evaluations of muscle function should be integrated into frailty assessments. Therefore, muscle composition emerges as a potential public health assessment by enabling the clinical quantification of muscle mass and an estimation of physical function in the older adult population [49].

Our findings demonstrated that all measures exhibited high specificity but varying sensitivity in detecting frailty (Table 3). Our ROC analysis showed moderate predictive ability for WBPhA, US thickness, and lean mass of legs from DXA, with an AUC between 0.678 and 0.749. This aligns with the results from previous studies [50,51], which emphasized that models combining body composition measurements with physical performance tests can improve the predictive ability of frailty. Unadjusted US showed perfect specificity but low sensitivity (10.7%), indicating it is highly effective at correctly identifying nonfrail individuals but less capable of detecting those who are frail. This aligns with previous studies suggesting that muscle US, while precise in measuring muscle thickness, may have limitations in sensitivity due to operator dependency and variability [52].

Table . Results of receiver operating characteristic analysis (n=94)

	Sensitivity	Specificity	Youden index[a]	AUC[b]	*P* value
US[c]	0.107	1.000	0.107	0.678	.02
US (adjusted)[d]	0.321	0.939	0.260	0.732	.24
WBPhA[e]	0.240	0.952	0.192	0.704	.003
WBPhA (adjusted)[d]	0.480	0.937	0.417	0.762	.09
LeanM LL[f]	0.107	0.985	0.092	0.683	.009
LeanM LL (adjusted)[d]	0.250	0.924	0.174	0.741	.17
LeanM RL[g]	0.286	0.939	0.225	0.703	.003
LeanM RL (adjusted)[d]	0.357	0.939	0.296	0.749	.045

[a]Youden index = sensitivity + specificity – 1.

[b]AUC: area under the curve.

[c]US: ultrasound on rectus femoris.

[d]Model adjusted by sex and age.

[e]WBPhA: whole-body phase angle.

[f]LeanM LL: left leg lean mass.

[g]LeanM RL: right leg lean mass.

Adjusting the US measure for age and sex increased sensitivity to 32.1% but reduced specificity to 93.9%, and the adjusted model did not reach statistical significance (*P*=.24). This suggests that while adjustments improve sensitivity, they may

XSL•FO
RenderX

not be sufficient to make US a standalone diagnostic tool for frailty in primary care settings. The WBPhA showed an unadjusted sensitivity of 24% and specificity of 95.2%, with an AUC of 0.704 (*P*=.003). After adjusting for age and sex, sensitivity improved to 48%, specificity slightly decreased to 93.7%, and AUC increased to 0.762, although the *P* value was nonsignificant (*P*=.09). These results suggest that WBPhA, particularly when adjusted for sex and age factors, has potential as a screening tool for frailty. Previous research has shown that lower phase angle values are associated with decreased muscle function, poor nutritional status, and higher frailty risk [12,53]. The noninvasive nature and ease of use of BIA make WBPhA a practical option for primary care, although standardization of measurement protocols is necessary.

LeanM RL emerged as a significant predictor when adjusted for age and sex (*P*=.045), with sensitivity and specificity of 35.7% and 93.9%, respectively, and an AUC of 0.749. This indicates that the adjusted LeanM RL model had a good balance between sensitivity and specificity and may be valuable in predicting frailty. The importance of lower limb muscle mass in frailty assessment is well-documented. For instance, [54] reported that decreased appendicular lean mass is associated with physical disability and increased risk of adverse outcomes in older adults. However, the use of DXA in primary care is limited due to cost, accessibility, and exposure to low-dose radiation.

In comparison, the unadjusted left leg lean mass showed similar specificity (98.5%) but low sensitivity (10.7%), and the adjusted model did not achieve statistical significance. This suggests that while lean mass measurements are informative, the right leg may provide more predictive value than the left in this context, possibly due to dominance or functional differences, although further research is needed to confirm this observation. Overall, our results indicated that LeanM RL, adjusted for age and sex, may be the most effective measure among those studied for predicting frailty. This is significant because identifying reliable, accessible markers for frailty is crucial for early intervention. Given the limitations of DXA in primary care, exploring alternative methods to estimate lean mass, such as predictive equations or portable devices, could enhance feasibility. The high specificity observed across all measures suggests they are effective in ruling out frailty in individuals without frailty. However, the variable sensitivity underscores the need for multicomponent assessment tools. The Comprehensive Geriatric Assessment remains the gold standard for frailty evaluation but is resource-intensive [55]. Incorporating measures like WBPhA and simplified lean mass assessments could enhance screening efficiency in primary care.

Limitations, Clinical Implications, and Future Directions

Limitations of the study include the sample size and homogeneity in some variables, such as BMI and arm lean mass (left arm and right arm), which could have affected the accuracy of the predictive results. Heterogeneity in these measurements has been reported in previous research [56], suggesting that variability in body composition could influence frailty prediction. There is potential for the integration of advanced body composition analysis tools and mobile technology into primary care services for the early identification and management of frailty syndrome in older adults. Methods such as WBPhA, US of the rectus femoris muscle, and DXA analysis proved to be effective predictors of frailty, offering high specificity in detection. The implementation of the PowerFrail mobile app enables rapid and personalized assessments, optimizing preventive interventions. These tools not only improve the accuracy of clinical evaluations but also reduce costs associated with frailty-related complications, promoting healthier aging and alleviating the burden on public health care systems. In addition, while this study incorporated a range of assessment tools, it is essential for future research to concentrate on validating these measures in larger and more diverse cohorts to ensure their wider applicability. The cross-sectional design of this study further restricts the ability to infer causal relationships between body composition variables and frailty. Longitudinal investigations could provide valuable information on how variations in body composition affect the progression of frailty over time. Understanding these dynamics could facilitate developing more effective and personalized interventions for the older adult population. Finally, future studies should explore the integration of these mHealth technologies with advanced body composition analysis systems to optimize early detection and management of frailty.

Conclusions

The findings of this study reinforce the utility of various body composition evaluations, such as WBPhA, LeanM RL measured by DXA, and quadriceps thickness assessed by US, as effective indicators for predicting frailty in older adults, aligning with previous research. However, our results highlight the necessity of not relying exclusively on muscle mass as a predictor of frailty. It is essential to incorporate assessments of muscle function and physical performance into clinical evaluations to enhance the accuracy of identifying individuals susceptible to frailty. The combination of tools such as WBPhA, bioimpedance, and US, along with the PowerFrail app, could provide a more complete and accurate assessment of the health status of older adults, allowing effective preventive interventions to be implemented in primary care services.

Acknowledgments

This study received funding from the Call for Biomedical Research and Innovation Projects from the Biomedical Research Institute of Cádiz, Andalusian Health System Grant (PP11-004-2023); PUENTE Project Call for the Enhancement of Proposals from the State Plan of the University (PR2022-018); and Plan Andaluz de Investigación, Desarrollo e Innovación (PAIDI 2020; DOC_01412) from the Andalusian Government.

Abstract

Background: Frailty is a common issue among hospitalized older adult patients and is associated with numerous adverse health outcomes. Assessing frailty facilitates better decision-making for treatment plans, patient placement, and discharge planning. Approximately a decade ago, the frailty index based on laboratory tests (FI-Lab) metric was introduced. Although this index has been shown in numerous studies to predict adverse medical outcomes, including mortality, it has not been extensively evaluated among patients hospitalized in internal medicine departments for diverse indications.

Objective: The aim of the study was to investigate the relationship between FI-Lab at admission and all-cause mortality during hospitalization and after discharge in patients aged 65 years and older admitted for diverse clinical indications to internal medicine departments.

Methods: This retrospective cohort study included patients aged 65 years and older hospitalized in the internal medicine departments of a large tertiary hospital. Data included demographic variables, comorbidity, and all-cause mortality. The FI-Lab was calculated based on 16 available blood tests, as well as blood pressure and heart rate measurements. We used Cox proportional hazards regression models to evaluate associations with mortality. Model performance was assessed using the C-index and time-dependent receiver operating characteristic (ROC) curves. Hospitalization data were collected from December 25, 2016, to January 7, 2023.

Results: During the study period, 31,443 patients were hospitalized in internal medicine departments, and FI-Lab was calculable for 31,398 of them. The mean age of the patients was 77.6 (SD 8.2) years, and 52.1% (16,346/31,443) were women. The mean FI-Lab score was 0.38 (SD 0.15). Based on FI-Lab scores, patients were categorized into 4 groups: robust, mildly prefrail, moderately prefrail, and frail. After adjusting for age, sex, and comorbidities, frail and prefrail patients exhibited higher mortality rates than robust patients. For each 0.01 increase in the FI-Lab score (as a continuous variable), adjusted analyses revealed a 5.5% increase in in-hospital mortality, a 2.9% increase in mortality within the first year after hospitalization, and a 1.9% increase in mortality beyond the first year.

Conclusions: The FI-Lab is a readily available and informative metric of frailty in older hospitalized patients. Calculating this index can assist physicians with identifying patients at high risk of mortality and provide meaningful information to support clinical decision-making.

KEYWORDS

FI-Lab; all-cause mortality; hospitalized; older adults; risk factor

Introduction

Frailty is a condition of increased vulnerability to impaired recovery of homeostasis following stress [1]. Frailty is highly prevalent among adults. In a nationally representative sample of Medicare enrollees aged 65 years and older, the prevalence of prefrail individuals was 45.5%, while the prevalence of frail individuals was 15.3% [2]. The rate of frailty among hospitalized

XSL•FO
RenderX

patients is even higher. In a study of more than 22,000 individuals aged 65 years and older admitted to internal medicine departments, 43% were classified as prefrail, and 20% were classified as frail [3]. A higher prevalence was found in a meta-analysis by Ligthart-Melis et al [4], with 47% classified as prefrail and 36% classified as frail.

Among older hospitalized patients, frailty is associated with longer hospital stays [3,5-7], a higher likelihood of admission to an intensive care unit (ICU) and extended time in it [3], falls during hospitalization [6], delirium [6], pressure ulcers [6], an increased likelihood of institutionalization after discharge [3,6], a greater risk of readmission [3,8], higher hospitalization costs [9], and even increased mortality [3,5,6,10,11].

In 2001, two primary models of frailty were introduced: the cumulative deficit model [12] and the phenotype model [13]. Based on these two models, more than 65 tests have been developed to assess frailty [14]. Identifying frailty among hospitalized patients is essential as it enables, on one hand, risk stratification [7,15] and, on the other hand, the development of an intervention plan tailored for frail patients. Such interventions have been shown to shorten hospital stay [16], reduce the need for medical services after discharge, lower the likelihood of readmission, increase patient satisfaction, and even decrease mortality [17]. Despite this, frailty assessment among hospitalized patients is limited because it requires completion of a long checklist, a time-consuming process that clinicians in busy departments often cannot handle [18]. Some frailty assessment tools rely on self-reported data (eg, weight loss in the absence of objective data, information on physical activity, or feelings of exhaustion) or require patient cooperation during assessment (eg, walking speed and handgrip strength measurements) [19]. It is quite likely that such assessments would be difficult to conduct during acute hospitalization. To address these challenges, a frailty index based on laboratory tests (FI-Lab) was introduced for the first time in 2014 [20]. Since then, numerous studies have been conducted using various versions of FI-Lab. These have demonstrated its association with adverse health outcomes, including longer hospital stays [21-25]; an increased likelihood of ICU admission or prolonged ICU stays [22,23]; a greater risk for readmission [21,22,26,27]; institutionalization after discharge [24,27]; greater postdischarge care needs [21]; and increased in-hospital mortality [24,25,27-32], mortality within the first year after discharge [18,27,28,33-37], and even beyond 1 year after discharge [19,21,32,36,38-41].

As demonstrated in our literature review (see Multimedia Appendix 1), the majority of studies have focused on populations with specific medical conditions (eg, heart failure, pneumonia, sepsis). Only a limited number of studies (eg, [38,40]) have examined populations admitted to internal medicine departments for diverse indications. Moreover, to our knowledge, no studies to date have explored the relationship between FI-Lab and all-cause mortality among hospitalized patients in Israel.

The aim of this study was to evaluate the association between FI-Lab at the time of admission and mortality, both during hospitalization and following discharge, among patients aged 65 years and older admitted for diverse indications to internal medicine departments in a large tertiary care hospital in Israel.

Methods

Study Setting and Population

This was a retrospective cohort study using data from electronic medical records (EMRs) for patients aged 65 years and older who were hospitalized for any reason in the Internal Medicine Division at Soroka University Medical Center (SUMC) in southern Israel. SUMC is the third-largest tertiary medical center in Israel and the largest in southern Israel, with a capacity of 1200 beds. The Division of Internal Medicine consists of 7 internal medicine wards.

The study population included men and women 65 years of age and older who were hospitalized in one of the study wards for any reason during the 6-year period from December 25, 2016, to January 1, 2023. The follow-up period for mortality ended on November 16, 2024. It should be noted that, if a patient had multiple hospitalizations during the follow-up period, the first hospitalization was considered the index event.

Data Collection

The following data were collected from the EMR: sociodemographic, clinical, laboratory, and mortality.

Sociodemographic data included age, sex, and ethnicity.

Clinical data included the primary reason for hospital admission (according to the emergency department diagnosis) and comorbid diseases. The Charlson Comorbidity Index (CCI) [42] was automatically calculated. The first measurement of systolic and diastolic blood pressures and heart rate at triage in the emergency department was recorded.

Laboratory data included venous blood tests performed during evaluations in the emergency department or within the first 48 hours of hospitalization. We focused on 16 blood tests, at least 14 of which are routinely performed in the emergency department: hemoglobin, hematocrit, mean corpuscular volume, mean corpuscular hemoglobin, white blood cells, lymphocyte number, platelets, mean platelet volume, glucose, creatinine, urea, sodium, potassium, chloride, protein, and albumin. The latter two were usually performed during hospitalization.

All-cause mortality was defined as in-hospital mortality, mortality within 1 year after discharge, and mortality during the entire study period. Data on all-cause mortality were obtained from the SUMC computerized system, which is regularly updated with information from the Ministry of Interior's database.

F1-Lab Construction

A total of 19 items were used to construct the FI-Lab, including 16 blood tests from venous blood samples and 3 vital signs recorded during triage in the emergency department: systolic blood pressure, diastolic blood pressure, and heart rate. Each item was dichotomized based on the normal reference intervals defined by the SUMC laboratory norms. Values outside the reference range were assigned a score of 1, while values within the reference range were assigned a score of 0. The FI-Lab score

XSL•FO
RenderX

was calculated by summing the number of deficits present and dividing the total by the number of items included. The FI-Lab score ranged from 0 to 1, with higher scores indicating greater frailty. Only patients who had more than 85% of the necessary items (n>16) were included. The FI-Lab scores were categorized by quartiles and as a continuous variable (0.01-point increase).

Power Analysis

To estimate statistical power, we assumed exponentially distributed survival times and relied on outcome rates from a previously published cohort study with a military veteran population [27] in which 27.5% of the high-risk group and 8.2% of the low-risk group died within 1 year. Based on these mortality rates and an expected research population of 30,000 patients, with approximately 12% classified as high risk, we estimated the hazard ratio (HR) to be 3.76.

Power analysis for time-to-event outcomes was conducted using the method for proportional hazards regression by Schoenfeld [43].

This calculation was implemented in R, using standard functions to compute the normal quantiles and logarithmic transformation of the HR. The resulting estimate showed that only 116 events were required to achieve 99% power. Given the expected >2000 events in our study, we concluded that the study was well-powered to detect a significant difference in survival outcomes.

Statistical Analysis

Statistical analyses were performed using the SPSS version 29 (IBM Corp) and R software (version 4.4.3). A *P* value <.05 was considered statistically significant. All tests were 2-sided. Categorical variables are described as frequencies and percentiles. Continuous variables, such as age, are described as mean (SD). The comparison of specific characteristics between frailty status groups, as assessed using FI-Lab scores, was carried out using the χ^2 test for categorical variables and Kruskal-Wallis test for continuous variables, such as length of hospital stay, which did not meet the assumption of normal distribution.

Cox proportional hazards assumptions were evaluated using the Schoenfeld residuals test (cox.zph function in R) and by visual inspection of log(-log[survival]) plots. No significant violations of the proportional hazards assumption were detected for the variables included in the models (global test *P*>.05).

Cox regression models were built for all-cause mortality according to frailty status, as assessed using FI-Lab scores, at 4 different points in time: in-hospital mortality, mortality during the first year after discharge, mortality beyond the first year after discharge, and mortality at any time. These models are presented as adjusted survival curves for all-cause mortality at different levels of frailty status, as assessed using FI-Lab scores, and as adjusted HRs for FI-Lab scores, age, gender, CCI scores, and the 4 main indications for hospitalization (cardiovascular, musculoskeletal, respiratory, and fever).

To evaluate the predictive performance of FI-Lab, we used the Harrell C-index (concordance index) and time-dependent receiver operating characteristic (ROC) curves based on Cox proportional hazards models. Adjusted survival curves were generated using the *adjustedCurves* package (version 0.6.2) in R (version 4.4.3) [44,45]. The analysis was based on Cox proportional hazards models fitted with the coxph() function from the *survival* package [46], and adjusted estimates were visualized using *ggplot2* [47] and the *survminer* package (version 0.4.9) [48].

Each plot illustrates the ROC curves for the multivariable model with and without the FI-Lab variable. The comparison between models with and without the FI-Lab variable was performed using time-dependent areas under the curve (AUCs), and statistical differences were tested using a bootstrap method with 2000 resamples. The AUC values are provided for both models, along with the *P* values from the statistical comparison of AUCs.

Ethical Considerations

The study was approved by the Helsinki Committee of the Soroka Medical Center (SOR-0297 - 23). The study was based on retrospective analysis of anonymized EMR data. Informed consent was not required according to national regulations and institutional review board policy. All data were handled in compliance with institutional data privacy and confidentiality standards.

Results

Study Population Characteristics

During the study period, 31,443 patients aged 65 years and older were hospitalized in the Internal Medicine Division at SUMC. Of these, 31,398 had sufficient data to calculate FI-Lab.

The key characteristics of the 31,443 patients for whom FI-Lab was calculated are presented in Table 1. The average age was 77.6 (SD 8.2) years, 16,346 (52.1%) were women, and 27,824 (88.7%) were Jewish. The 3 primary reasons for hospitalization, as recorded in the emergency department, were cardiovascular problems (6491/31,443, 20.7%), musculoskeletal issues (5460/31,443, 17.4%), and respiratory problems (3141/31,443, 10%). The average CCI score was 3.7 (SD 2.8).

[b]FI-Lab: frailty index based on laboratory tests.

[c]Not applicable.

F1-Lab Scores

The mean FI-Lab score was 0.38 (SD 0.15), with a median of 0.37 (range 0.0-0.94).

Since the FI-Lab scores were not normally distributed, each quartile contained an unequal number of patients. The first quartile consisted of 8628 patients (8628/31,443, 27.5%) who had an FI-Lab score <0.2632 and were classified as "robust." The second quartile consisted of 6335 patients (6335/31,443, 20.2%) who had an FI-Lab score between 0.2633 and 0.3684 and were classified as "mildly prefrail." The third quartile consisted of 9930 patients (9930/31,443, 29.7%) who had an FI-Lab score between 0.3685 and 0.4737 and were classified as "moderately prefrail." The fourth quartile consisted of 7105 patients (7105/31,443, 22.6%) who had an FI-Lab score >0.4737 and were classified as "frail."

The minimum follow-up time was 1 day, and the maximum was 7.8 years, with an average of 3.4 (SD 2.4) years and a median of 3.2 years. During the follow-up period, 15,138 patients passed away. Of the entire sample of 31,398 patients, 1658 (5.3%) died during hospitalization, 5174 (16.5%) died within the first year after discharge, and 8306 (26.5%) died after the first year and up to the end of the follow-up period.

There were no statistically significant differences between the 45 patients excluded from the sample and the 31,443 patients included in the sample, in terms of age (P=.83), gender (P=.35), ethnicity (P=.80), CCI score (P=.46), or length of hospital stay (P=.25). In-hospital mortality rates were higher among the 45 patients excluded from the sample (15.6% vs 5.3%, P=.02). Differences in mortality rates during the first year after discharge (13.2% vs 17.4%, P=.66) and beyond the first year after discharge (39.4% vs 33.8%, P=.61) were not statistically significant.

The distribution of patient characteristics according to frailty status groups assessed using FI-Lab scores is presented in Table 2. As the FI-Lab score increased, patients in the group tended to be older (P<.001) and have a higher burden of comorbidities, as measured using the CCI (P<.001). Male representation was lower in both extreme groups (robust and frail) compared with the other 2 groups (P<.001). No differences in FI-Lab scores were found between Jewish and Arab patients.

The length of hospital stay was higher in the robust group than in the mildly prefrail group, but as the severity of frailty increased, a longer hospital stay was observed (P<.001).

Hospitalization duration (days), mean (SD)	2.76 (6.1)	2.45 (4.5)	4.0 (7.4)	5.1 (8.8)	<.001

[a]CCI: Charlson Comorbidity Index.

Mortality

In-hospital mortality rates within the first year after discharge and beyond that increased with higher FI-Lab scores. For example, in the robust group, in-hospital mortality was 1.2% (105/8628), compared with 2% (128/6335) in the mildly prefrail group, 5.5% (515/9330) in the moderately frail group, and 12.8% (910/7105) in the frail group. Overall, only 2165 patients (2165/7105, 30.5%) in the frail group were alive at the end of the follow-up period, whereas 6083 (70.5%) of the 8628 patients in the robust group survived until the end of the follow-up period (*P*<.001).

Table 3 presents the results of the Cox proportional hazard models for FI-Lab as a predictor of all-cause mortality. In the unadjusted model (Model 1); after adjustment for age and gender (Model 2); after adjustment for age, gender, and CCI (Model 3); and after adjustment for age, gender, CCI, and primary indication for hospitalization (Model 4), FI-Lab, categorized dichotomously into frailty groups (model type a) or used as a continuous variable (model type b), was consistently associated with an increased risk for mortality.

FI-Lab score (continuous)	1.05 (1.05-1.06)	<.001	1.03 (1.02-1.03)	<.001	1.02 (1.02-1.02)	<.001

[a]Not applicable.

It can be seen that, in all models, the crude model (Model 1); the model adjusted for age and sex (Model 2); the model adjusted for age, sex, and CCI (Model 3); and the model adjusted for age, sex, CCI, and the primary indication for hospitalization (Model 4), an increase in frailty level, as measured using the FI-Lab, was associated with an increase in all-cause mortality during hospitalization, within the first year postdischarge, and throughout the entire follow-up period.

This association was evident when FI-Lab was treated as a categorical variable (robust, mildly prefrail, moderately prefrail, and frail) as well as when it was treated as a continuous variable (per 0.01-point increase in FI-Lab).

For example, in Model 4a (adjusted for age, gender, CCI, and the primary indication for hospitalization), the odds of a patient in the frail group not surviving hospitalization were more than 7 times higher than for those in the robust group (*P*<.001). Similarly, the odds of a patient in the moderately prefrail group dying during hospitalization were more than 3 times higher than for robust patients (*P*<.001). When analyzed as a continuous variable, in Model 4b, every 0.01 increase in the FI-Lab score was associated with a 5.3% increase in in-hospital mortality (*P*<.001), a 2.6% increase in mortality during the first year after discharge (*P*<.001), and a 1.7% increase in mortality by the end of the follow-up period (*P*<.001).

The full multivariable Cox regression results models, including all core confounders (age, gender, CCI, and main reason for hospitalization), are presented in Multimedia Appendix 1 for reference and comprehensive interpretation.

Figure 1 presents the adjusted survival curves for age, gender, CCI, and primary indication for hospitalization of the study population during hospitalization (Figure 1A), during the first year after discharge (Figure 1B), beyond the first year (Figure 1C), and any time (Figure 1D), stratified by FI-Lab–based frailty status. In all frail groups, patients had the lowest survival rates in all the examined time frames (all *P*<.001).

According to the ROC analysis (Figure 2), the inclusion of FI-Lab significantly improved the model performance for (Figure 2A) mortality during index hospitalization (AUC=0.783 vs 0.704, *P*<.001). All the other models were statistically significant but with a lower impact of the FI-Lab: (Figure 2B) mortality within the first year after hospitalization (AUC=0.729 vs 0.712, *P*<.001), (Figure 2C) mortality beyond the first year after hospitalization (AUC=0.655 vs 0.655, *P*=.02), and (Figure 2D) mortality at any time (AUC=0.789 vs 0.773, *P*<.001). This reflects the method's high sensitivity in large datasets and should be interpreted in light of the limited clinical impact of small AUC gains.

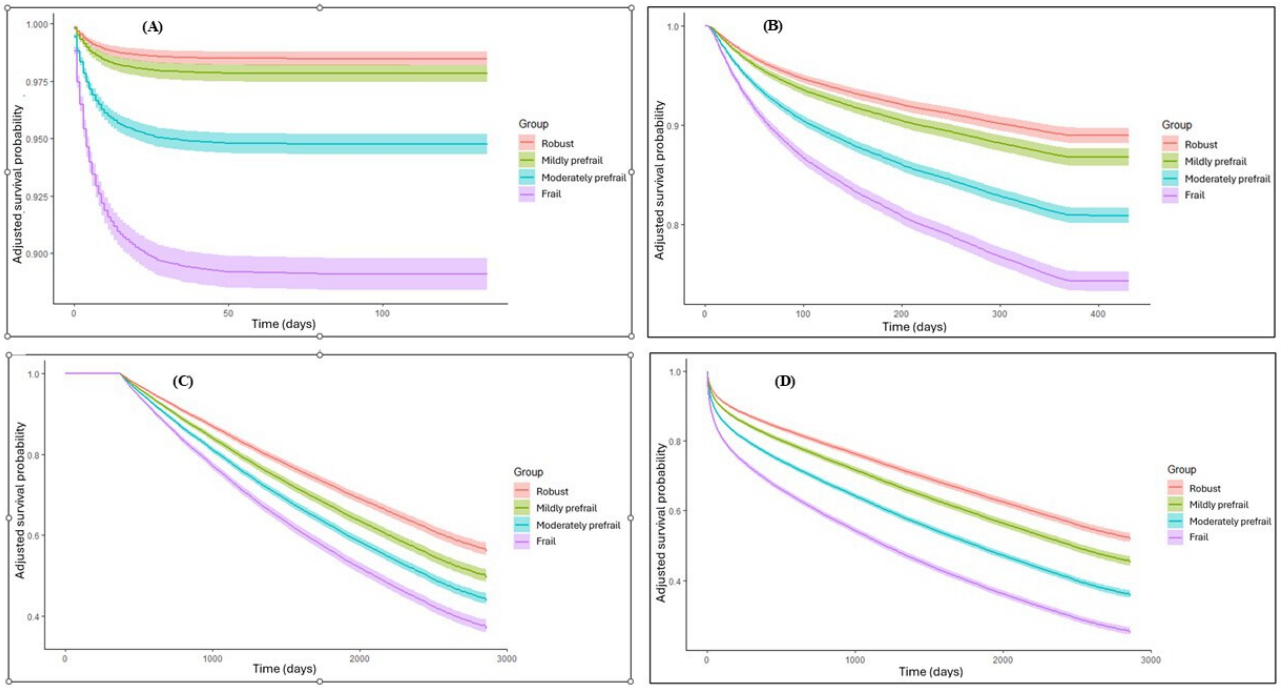
Figure 1. Confounder-adjusted survival curves for all-cause mortality according to frailty status assessed using frailty index based on laboratory tests (FI-Lab) scores (A) during the index hospitalization, (B) during the first year after the index hospitalization, (C) beyond the first year after discharge, and (D) at any time.



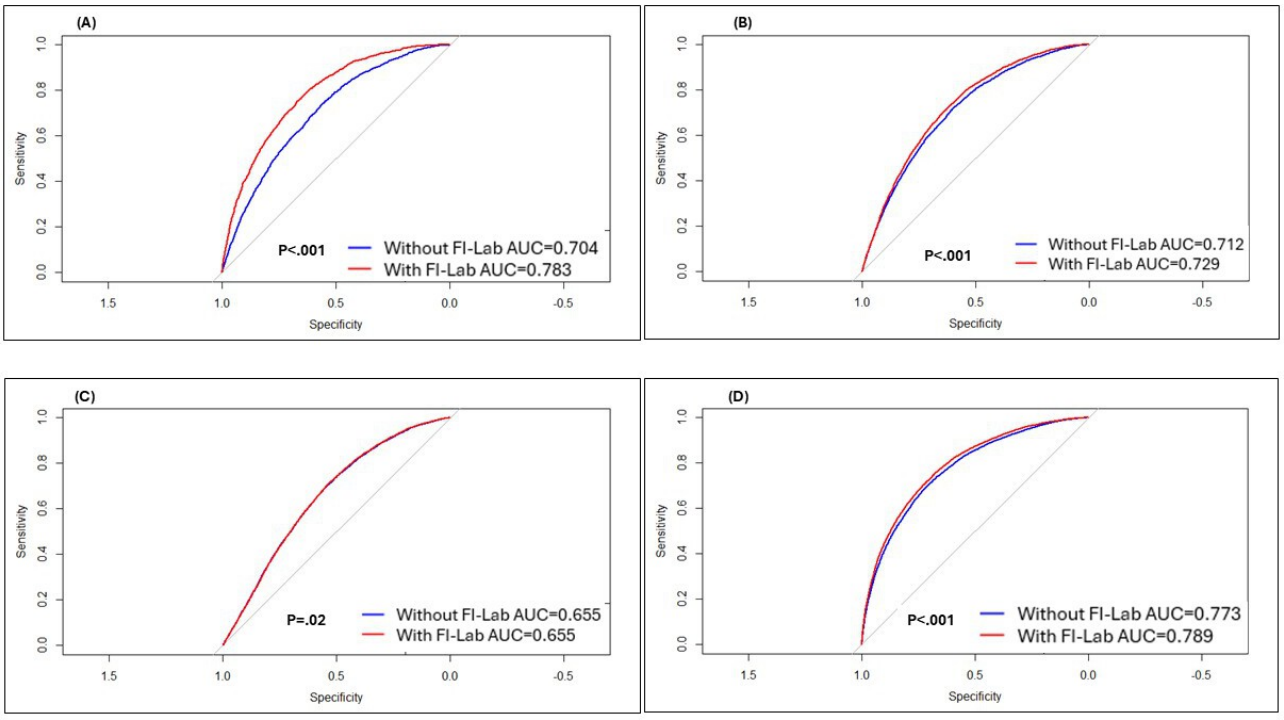


Figure 2. Comparison of receiver operating characteristic (ROC) curves for mortality (A) during the index hospitalization, (B) during the first year after the index hospitalization, (C) beyond the first year after the index hospitalization, and (D) at any time. AUC: area under the curve; FI-Lab: frailty index based on laboratory tests.

Discussion

In this study, involving a sample of more than 33,000 patients aged 65 years and older who were hospitalized in the internal medicine departments of a tertiary medical center, FI-Lab was found to be an independent prognostic factor for increased mortality, both in the short term and long term, whether analyzed as a dichotomous or continuous variable. These results are consistent with prior research with older hospitalized populations. Multimedia Appendix 2 summarizes 25 studies, all of which demonstrated that FI-Lab is a reliable predictor of mortality in this patient group.

Variations can be seen among the studies in terms of mortality rates, even during comparable periods. For example, in the study by Ding et al [29], each 0.01 increase in FI-Lab was associated

XSL•FO
RenderX

with a 3% increase in in-hospital mortality, whereas in the study by Nakashima et al [25], an identical increase in the FI-Lab resulted in a 9.8% increase in in-hospital mortality. This could depend, of course, on the type of study (the first study was retrospective, while the second was prospective); different in-hospital mortality rates (21.6% vs 7.4%), which probably were associated with many variables; the type of patient (patients with sepsis in the first study vs acutely admitted to the geriatric wards in the second study); the number of FI-Lab variables (33 vs 40); and other factors.

Although the association between FI-Lab and all-cause mortality in this study was statistically significant across all time points (during hospitalization, 1-year postdischarge, and throughout the entire follow-up period; see Table 3), the strength of this association declined over time. This is also reflected in the decrease in AUC in the ROC analysis (Figure 2), which was higher during hospitalization than in later time periods.

Additionally, the lower difference in AUC with and without the inclusion of FI-Lab for predicting mortality beyond the first year and for mortality at any time further suggests that the association between FI-Lab and mortality weakens over time. A similar trend has been observed in several other studies in the field (eg, [25,28]). This phenomenon is likely due to the emergence of new variables over time, such as changes in comorbidities, frailty status, and functional status, which may influence mortality and, in turn, alter the relationship between FI-Lab measured at the time of hospitalization and subsequent mortality. A future prospective study that accounts for these evolving variables throughout the follow-up period could help confirm this hypothesis.

The use of FI-Lab in hospitalization offers several notable advantages. As aforementioned, frailty assessment during hospitalization using “classical” models may involve completing a lengthy checklist of data [18]. In some cases, these assessments rely on subjective data (such as a patient’s self-report of physical activity and weight loss) or require the patient’s cooperation (eg, grip strength or walking speed tests) [19]. Therefore, performing frailty assessments using these models can be challenging in a time- and resource-constrained clinical setting.

In contrast, FI-Lab is typically based on laboratory tests that are routinely performed upon admission and, in some cases, supplemented by basic clinical data such as blood pressure and heart rate measurements. As a result, obtaining the data required for FI-Lab calculations generally does not involve additional effort on the part of clinicians [22,24,31]. In cases of acute illness, laboratory results may remain within normal ranges if there is sufficient reserve capacity in the affected organs. A higher FI-Lab score reflects the severity of the damage, number of affected organs and systems, and individual’s level of frailty [40]. FI-Lab likely captures subclinical changes at the organ and system level and may indicate acute or chronic conditions that have the potential to lead to adverse medical outcomes [18]. However, since FI-Lab assesses the current level of acute or chronic accumulated organ dysfunction, it does not necessarily reflect the patient’s comorbidity status prior to the acute illness [25]. In fact, FI-Lab may assess the current state of biological reserves and predict mortality better than comorbidity indices [34]. For these reasons, FI-Lab can serve as a readily available and effective tool for assessing frailty in older hospitalized patients.

However, it is also important to recognize the tool’s limitations. The results of a study by Jäger et al [35] showed that FI-Lab values may vary between the time of hospital admission and subsequent measurements, and these changes significantly impact the prediction of mortality within 6 months and 1 year. Therefore, in cases of prolonged hospitalization, it may be necessary to reassess FI-Lab periodically.

Another significant limitation of the FI-Lab is that it does not assess functional status and cannot replace clinical frailty assessments or comprehensive geriatric evaluations. Relying solely on FI-Lab without a complementary geriatric assessment may lead to significant errors in prognosis prediction and the development of intervention plans [49]. Over-reliance on FI-Lab can, on one hand, prevent patients with high scores from receiving intensive treatment [23] and, on the other, deprive patients with low scores of the support required for frail patients, such as prevention of delirium and functional decline. Therefore, although this method may serve as an initial tool, it *should not be* the sole approach for frailty assessment during hospitalization.

This study has several advantages. First, to our knowledge, it is the largest study conducted among hospitalized patients aged 65 years and older. The applicability of the tool was highlighted by the finding that, among more than 33,000 patients admitted to SUMC during the study period, FI-Lab could not be calculated for only 45 patients. The study included patients treated for a broad spectrum of medical problems across all internal medicine departments of the medical center, minimizing the influence of specific departmental policies on treatment and prognosis. The research is based on data from SUMC’s EMR, which was established nearly 3 decades ago and is considered highly reliable. Additionally, mortality data were obtained through linkage with the Ministry of Interior, ensuring the reliability of these records. Finally, the extended follow-up period in our study represents yet another significant advantage.

This study has several limitations. It was conducted in a single center using a retrospective design, which inherently introduces risks of selection bias and limits the availability of key clinical parameters such as functional, cognitive, and social status, as well as other frailty measures and environmental factors. These data, which are critical for a comprehensive assessment of a patient’s prognosis, are typically not recorded in the medical records of internal medicine departments and could not be retrospectively obtained. Additionally, although the inclusion of a heterogeneous population of hospitalized patients may enhance the generalizability of our findings, it also limits applicability to specific clinical subgroups (eg, patients with pneumonia, sepsis, or myocardial infarction). The primary outcome examined was all-cause mortality, without exploring other clinically relevant outcomes such as delirium, in-hospital falls, institutionalization, readmissions, or length of stay. FI-Lab was assessed only once using laboratory data obtained at admission and during the first days of hospitalization, which may not reflect a consistent time point due to potential changes

XSL•FO
RenderX

in lab values over time. Furthermore, the FI-Lab used in this study was based on 19 laboratory variables; some potentially important tests (eg, liver function) were excluded due to inconsistent availability. As demonstrated in prior studies (see Multimedia Appendix 1), there is no consensus on the optimal number or type of variables to include in FI-Lab, with considerable variability across cohorts. Although our primary aim was to evaluate the predictive utility of FI-Lab, we were unable to incorporate other validated frailty measures (eg, such as the 7-point Clinical Frailty Scale [50] or the Hospital Frailty Risk Score [51]) due to data limitations. It is important to note that previous research in the field has reported inconsistent associations between FI-Lab and other frailty indices [18,20,21,25-27,33,34,38,49,52-58].

Finally, although many associations reached statistical significance—likely due to the large sample size—some effect sizes were small and may not be clinically meaningful at the individual level. Nonetheless, such modest associations may have important implications at the population level, reinforcing the potential of FI-Lab as a scalable tool for risk stratification in hospital settings.

Although many of the associations observed in this study reached statistical significance (eg, $P<.001$), this is not unexpected given the large sample size (>31,000 patients). It is important to distinguish between statistical and clinical significance. For example, the HR of 1.017 per unit increase in FI-Lab reflects a modest effect size that may not be clinically meaningful at the individual level. However, at the population level, even small shifts in risk associated with frailty—as captured by laboratory values—may lead to substantial differences in outcomes across large health care systems. These findings support the utility of FI-Lab as a scalable risk stratification tool while also emphasizing the need for cautious interpretation of small effect sizes in clinical decision-making.

In conclusion, this study, conducted with a large cohort of patients aged 65 years and older who were hospitalized for diverse indications in the internal medicine departments of a large tertiary hospital, demonstrated that FI-Lab is an independent predictor of all-cause mortality during and after hospitalization, even after adjusting for multiple covariates, including the primary indication for admission.

FI-Lab may serve as an effective and easily accessible tool, though not a standalone method, for assessing frailty in older hospitalized patients. Automating FI-Lab calculation at the time of hospital admission could provide emergency department clinicians with additional, meaningful information to support clinical decision-making.

Abstract

Background: Mild cognitive impairment (MCI) is a precursor of dementia. Therefore, MCI identification and monitoring are crucial to delaying dementia onset. Given the limits of existing clinical tests, objective support tools are needed.

Objective: This work investigates quantitative handwriting analysis, tailored to enable domestic monitoring, as a noninvasive approach for MCI screening and assessment.

Methods: A sensorized ink pen, used on paper and equipped with sensors, memory, and a communication unit, was used for data acquisition. The tasks included writing a grocery list and free text to mimic daily life handwriting, and a clinical dictation test (parole-non-parole [PnP] test), featuring regular, irregular, and made-up words, aimed at assessing MCI dysgraphia. From the recorded data, 106 indicators describing the performance in terms of time, fluency, exerted force, and pen inclination were computed. A total of 57 patients with MCI were recruited, of whom 45 performed a test-retest protocol. The indicators were examined to assess their test-retest reliability. The indicators from the test repetition were used to assess their relationship with the scores of clinical tests via correlation analysis. For the PnP test, differences in the indicators among the 3 types of words were statistically investigated. These analyses were conducted separately for the cursive (2/3 of the sample) and block letters (1/3 of the sample) allographs, with the level of significance set at 5%. Data from healthy older adults were available for the grocery list (34 participants) and free text (45 participants) tasks. These were exploited to build machine learning classification models for the distinction between patients with MCI and healthy controls.

Results: When dealing with reliability, 93% and 44% of the indicators were characterized by a significant reliability of at least moderate intensity for cursive and block letters respectively. As for the correlation analysis, patients with preserved cognitive status and daily life functionality were associated with significantly better temporal performances, both in free writing and PnP. The analysis of PnP highlighted the presence of surface dysgraphia in the recruited sample, as irregular words showed significantly worse temporal indicators with respect to regular and made-up ones. The classification models' built-in free writing data achieved accuracies ranging from 0.80 to 0.93 and F_1-scores from 0.81 to 0.92 according to the input dataset.

Conclusions: The presented results suggest the suitability of ecological handwriting analysis for the all-around monitoring of MCI, from early screening to disease progression evaluation.

Introduction

In the last decades, the world has witnessed progressive aging. This trend brings about various challenges at the social, economic, and health care levels, as it directly affects citizens' health, compromising several aspects of their daily lives [1]. First, older individuals experience greater difficulty in responding to external stimuli, a condition that leads to isolation and inertia. Second, a gradual, albeit sometimes slow, decline is observed, causing a state referred to as "frailty" [2]. In this state, the individual becomes more susceptible to motor-related accidents, resulting in disability and an increase in hospitalization. Furthermore, aging is linked to a higher prevalence of neurodegenerative diseases, for which treatments that slow down the progression of the disease are the only available interventions.

Among these disorders, dementia is one of the most prevalent, being characterized by a decline in cognitive function, memory loss, and changes in behavior [3]. Dementia leads to a gradual loss in the ability to perform daily tasks independently, causing patients to often require round-the-clock care and supervision. This can translate into emotional and physical toll on family members and caregivers, who may experience stress, burnout, and financial strain. The health care systems are not immune to the negative consequences of the disorder, since it is associated with extensive long-term care, medications, and support services [4].

Clinically, a transitional phase between the healthy state and dementia has been identified and denoted as mild cognitive impairment (MCI) [1]. MCI can manifest heterogeneously. While patients with amnestic MCI experience memory-related cognitive loss, participants diagnosed with nonamnestic MCI face impairments in the domains of attention, language, and visuospatial ability [5]. From an epidemiological standpoint, the aggregate prevalence of MCI among older people ranges from 15% to 20% [6-9]. The problem lies in the relevant yearly percentage (up to 15%) of cases that are diagnosed with dementia after having previously been in the MCI state. This underscores the need for MCI early screening, aimed at preventing the progression to dementia [10]. Unfortunately, the broad spectrum of symptoms and the typically nonsignificant impact on the participants' independent life make the detection of MCI quite challenging.

Cognitive tests are typically used in clinical practice for this purpose since they are quicker and cheaper than imaging techniques [11,12]. The existing tests, all conducted under the clinician's supervision, vary in the assessed cognitive domains (eg, memory, language, attention) and in the tasks proposed to the individual, but are in general capable of providing a snapshot of one's cognitive status. The most common are the Mini-Mental State Examination (MMSE) [12], the Montreal Cognitive Assessment (MoCA) [13], and the clock drawing test (CDT) [14]. Despite being largely used, such clinical tests experience a few drawbacks. As they depend on the clinician administering the test, interrater reliability and subjectivity in the assessment are a concern. Moreover, to assess all the relevant cognitive domains, a combination of different tests should be considered, thus leading to increased administration time. Finally, the scales are usually characterized by low granularity, thus making it difficult to establish universally accepted cutoff scores. Thus, there is a need for a cheap, noninvasive, objective solution to complement the standard clinical procedure for MCI screening [6].

In this sense, the recent literature claimed the importance of handwriting: given its complexity, it can serve as a biomarker for cognitive decline [15]. This is because handwriting is the result of the interaction between various cognitive processes: attention, language, short and long-term memory, motor planning, visual-spatial skills, in-hand manipulation, fine motor control, and sensory awareness of the fingers [16]. With the goal of characterizing the handwriting gesture of patients with MCI or with dementia with respect to healthy participants, several studies have been conducted. In Werner et al [17], a group of 41 controls, 31 patients with MCI, and 22 patients with mild dementia were recruited and performed copying tasks of increasing complexity on a digitizer. Significant differences emerged, with both groups of patients showing increased execution times and reduced pressure during the motor task. Conversely, the Livescribe Echo Pen, used on the Livescribe paper sheet, was used in Kawa et al [16] to compare the handwriting of 37 controls and 37 patients diagnosed with MCI. Again, writing slowness emerged as a peculiar characteristic of the latter group. This was coupled with significantly higher and wider written traces. The extracted features were then used to build a linear discriminant classifier, achieving an accuracy of 70%. The combination of a specific digital pen and paper was also adopted in [18], investigating Chinese handwriting in patients affected by Alzheimer disease, for which MCI is a common precursor. The results confirmed the existing literature, as worse temporal measures, both on paper and in the air, were associated with the disease. A higher degree of pressure applied to the writing surface and a poorer control of the same were revealed as well. A classification study, aimed at distinguishing patients in the early stage of dementia from healthy participants, was conducted in [19]. Cursive loops were acquired with a WACOM digitizer, to then apply unsupervised clustering followed by a Bayesian-based classifier. The approach reached an accuracy of 74%. Execution speed, kinematics complexity, acceleration, and pressure were computed from the data recorded by a WACOM digital graphic tablet in [20]. Handwriting tasks, ranging from drawings to spontaneous sentence production, were performed on a paper sheet fixed onto the tablet surface by a group of 17 healthy participants (healthy control [HC]), 12 patients with MCI, and 23 patients with dementia (AD). Performance results ranged from 69.2% (HC vs MCI vs AD) to 96.6% (HC vs MCI). Pressure features were the most influential in the model output. In Chai et al [21], simple graphic tasks, going from repeatedly writing the letter "T" to drawing a pentagram, were performed by 39 HCs and 40 patients with MCI on a commercial tablet using a digital pen. After extracting 8 features, a binary support vector classifier achieved an F_1-score of 83.1%.

Given the evidence that emerged in the literature, this work aims to evaluate handwriting in patients with MCI by changing the paradigm in terms of the acquisition tool and the proposed

XSL•FO
RenderX

handwriting tasks, with an eye on the feasibility of remote, ecological monitoring. Indeed, while able to provide relevant, objective data on the handwriting performance, limitations can be pointed out for the approaches found in the literature. Digitizers can still represent a barrier for older adults [22], who are typically the ones affected by MCI. Moreover, the writing execution on the digitizer surface, characterized by a reduced friction with respect to paper, is inevitably altered [23]. On the other hand, the methods proposed in studies by Kawa et al [16] and Qi et al [18] rely on the combination of a digital device and writing surface, potentially hampering their everyday employment. For these reasons, in this study, handwriting data were collected with a sensorized ink pen [24] that writes on normal paper. As for the tasks, the "Parole-non-Parole" test (PnP), aimed at assessing the origin of dysgraphic manifestations associated with MCI, was administered together with 2 unconstrained exercises, aimed at mimicking the natural handwriting one could perform in the domestic scenario. From the collected data, a series of indicators was extracted, and 3 specific objectives were investigated. First, the test-retest reliability of the indicators was assessed, both for the clinical PnP test and the 2 ecological tasks, to evaluate whether the proposed approach could be suitable for the longitudinal monitoring of handwriting in patients with MCI. Second, the indicators were examined in terms of their quantitative support for the clinical evaluation. This was done by assessing the indicators' correlation with the scores of clinical tests. Moreover, the PnP was specifically analyzed to understand whether the indicators can be used to support the identification of lexical and phonological dysgraphia. Last, the unconstrained handwriting tasks were considered to build classification models to distinguish between patients with MCI and healthy participants, with the aim of enabling the ecological, domestic monitoring of handwriting as a screening tool for the first signs of cognitive decline.

Methods

Ethical Considerations

The protocol received the approval (ID 07_20/05/2021) from the Ethical Committee of the section IRCCS Fondazione Don Carlo Gnocchi of the Ethical Committee IRCCS Regione Lombardia. An information sheet for study participation was provided to all eligible participants, and informed consent was obtained from each of them.

Participants and Protocol

Participants were recruited by IRCCS Fondazione Don Carlo Gnocchi Milano. The inclusion criteria were (1) confirmed diagnosis of MCI according to the recommendations by Albert et al [25]; (2) being aged older than 65 years; (3) having completed elementary school; (4) having a Clinical Dementia Rating (CDR) scale [26] score less than or equal to 1; (5) obtaining negative neurological examination results for both lateral and extrapyramidal signs; (6) having trail making test A (TMT-A) results within the normal range for age and education according to the Italian calibration by Giovagnoli et al [27]; and (7) not having motor limitations that hinder task performance. Candidates were excluded in case of the presence of cognitive impairment of other origin (cerebral stroke, multiple sclerosis, and Parkinson disease), psychiatric disorders in either recent or remote anamnesis, severe sensory or intellectual deficits, and history of substance abuse or alcohol misuse. The recruited patients underwent clinical assessment, including MMSE, CDR, CDT, TMT-A, basic activity of daily living (B-ADL) [28], and instrumental activity of daily living (I-ADL) [29].

The sample size was determined by taking the assessment of the extracted indicators' test-retest reliability as the main aim, since the scientific literature lacks similar works on patients with MCI. The only comparable study pertains to a systematic review that reports the psychometric properties of motor assessments (mobility, walking, balance, and functional performance) for patients with dementia, yielding intraclass correlation coefficients (ICC) between 0.42 and 0.99 [30]. On the other hand, the reliability of the proposed sensorized pen was demonstrated, the results showing $0.68<ICC<0.99$, only in older adults without any diagnoses [24]. Given the scarcity of specific evidence in the population with MCI, a conservative approach was selected. Considering the minimum ICC value of 0.42 as a target, a statistical power of 80% and a dropout rate of 10%, the sample size was set to 40.

The protocol was administered under the clinician's supervision in a test-retest fashion on the same day, with at least a 30-minute interval between the 2 repetitions (test and retest) of the protocol. The time interval was chosen to ensure that the participants were under the same conditions between test and retest. In this sense, potential learning effects were not a concern given the nature of the protocol (no memory-related tasks were administered). Each patient was provided with blank sheets of paper to perform three writing tasks in random order, 1 minute apart: (1) writing a grocery list of at least 6 items (List); (2) composing a content-free text of at most 7 lines (Text); and (3) executing the PnP test [31], where the participant wrote a series of 15 words under dictation. These included 7 regular words (simple and easily understandable Italian words: "tavolo," "cartone," "attore," "sorella," "postini," "cuoceva," and "democratiche"), 3 irregular words (requiring proper semantic and lexical comprehension of the Italian language to be written correctly: "cieco," "nacquero," and "conoscenza"), and 5 made-up (MU) words (words that do not exist in the Italian dictionary: "sabomi," "fule," "descia," "sterpanzi," and "getrunna"). The order in which words were presented was fixed across participants and protocol repetitions. Orthographic errors were then evaluated to assess the eventual presence of lexical dysgraphia, which is associated with errors in irregular words, or phonological dysgraphia, linked with errors in MU words.

Sensorized Ink Pen

The handwriting exercises were carried out using a sensorized ink pen [24], able to record linear acceleration and angular velocity on 3 orthogonal axes, together with the force applied on the pen tip with a sampling frequency of 50 Hz. The device was successfully used for the quantitative analysis of drawing tasks in patients with Parkinson disease [32] and demonstrated to be capable of recognizing healthy, older adults of different ages from unconstrained handwriting samples [33]. Data acquisition was controlled by the operator administering the

XSL•FO
RenderX

protocol through a custom iOS app. On top of managing the start and stop of the recordings, the app allows users to store 4 different types of labels upon pressing buttons displayed on the user interface. Labels were used to tag the 3 types of words of the PnP test, so that they could be successively analyzed.

Data Analysis

The data recorded by the sensorized ink pen were elaborated in MATLAB R2022b (MathWorks, Inc) to extract 106 indicators measuring heterogeneous characteristics of the handwriting gesture, namely the temporal performance, the force patterns applied on the writing surface, the movement fluency, the pen inclination with respect to the vertical axis (tilt), the high frequency oscillations both in the domains of time and frequency. The complete description of the indicators can be found in [32-35]. The indicators presented in the Results section are described in Textbox 1 for each domain. The details on their computation can be found in the Multimedia Appendix 1. The ones with (S) after the name were selected a priori for the analysis of reliability, relationships with clinical scores, and MCI dysgraphia characterization. If all the indicators within a domain were selected a priori, (S) is found at the end of the name of the domain.

XSL•FO
RenderX

Textbox 1. Description of the indicators extracted from the sensorized ink pen data, divided by domain.

Temporal domain (S):

- Execution time: the time in seconds required to complete the execution.
- Rel stroke num: the number of strokes (tracts on paper) generated in the time unit.
- Mean on sheet: the average time in seconds required to produce a stroke.
- On sheet CV: the coefficient of variation (CV) of the time required to produce a stroke.
- On sheet ratio: the percentage of time spent with the tip in contact with the paper with respect to the total time required to complete the execution.
- Mean in air: the average time in seconds spent with the pen in the air.
- In air CV: the CV of the time spent with the pen in the air.
- Mean pause: the average duration in seconds of pauses (in air moments longer than 2 seconds).
- Pause num: the number of pauses in the execution.
- Air sheet ratio: the ratio between the mean in air and the mean on the sheet.

Fluency domain:

- LDLJ A (S): the logarithmic dimensionless jerk of the acceleration signal.
- LDLJ G (S): the logarithmic dimensionless jerk of the angular velocity signal.
- SPARC (S): the spectral arc length of the angular velocity signal.
- G NC (S): the number of changes (NC) in the time unit in the angular velocity signal.
- A NC: the number of changes (NC) in the time unit in the acceleration signal.
- Cons peak diff G (S): the absolute average difference in deg/s between consecutive extrema in the angular velocity signal.

Force domain (S):

- Mean force: the mean force in arbitrary units exerted while the tip is on paper.
- Force overshoot: the difference between the maximum and median exerted force, in arbitrary units.
- Force NC: the NC in the time unit in the force signal.
- Cons peak diff F: the absolute average difference in arbitrary units between consecutive extrema in the force signal.

Pen inclination domain:

- Mean tilt (S): the average pen inclination with respect to gravity in degrees.
- Tilt CV (S): the CV of the pen inclination with respect to gravity.
- Tilt median bandwidth: the width of the frequency interval that contains 50% of the tilt power spectrum total power.

High frequency oscillations (time domain):

- A ApEn: approximate entropy of the acceleration signal.

High frequency oscillations (frequency domain):

- G peak power: the power at the angular velocity power spectrum peak.
- G RPW 8: the median relative power of the angular velocity power spectrum in a 3 Hz interval centered around 8 Hz.
- G RPW 11: the median relative power of the angular velocity power spectrum in a 3 Hz interval centered around 11 Hz.
- G Dom RPW 11: the relative power of the dominant angular velocity power spectrum in a 3 Hz interval centered around 11 Hz
- A peak frequency: the frequency at which the peak in the acceleration power spectrum is found.
- A peak power: the power at the acceleration power spectrum peak.
- A median bandwidth: the width of the frequency interval that contains 50% of the acceleration power spectrum total power.
- A Dom 68% Peak Bandwidth: the width of the frequency interval, centered around the spectral peak, that contains 68% of the acceleration power spectrum total power.

Statistical Analysis

Overview

The same software was used to run the statistical analyses, with the significance level set at 5%. Given the differences in the indicators in cursive and block letters (BL) handwriting—the choice of the allograph was left free to the participant—the analyses were conducted separately for the 2 allographs. The pipeline was common for each goal: after testing for the indicator normality with the Lilliefors test, the proper statistical test was applied.

Reliability

The indicators test-retest reliability in the MCI group for the List, Text, and PnP tasks, as well as for PnP regular, irregular, and MU words separately, was the first aspect to be evaluated. Before computing the reliability, a paired sample test was conducted, namely the *t* test for normally distributed indicators, the Wilcoxon test otherwise. If the paired test rejected the null hypothesis (ie, the mean/median of the difference between test and retest value is equal to 0), the indicator was deemed not reliable. Otherwise, the ICC (absolute agreement) or the Kendall W was computed if the indicator was normal or nonnormal, respectively. Both parameters range between 0 and 1. The indicator reliability was interpreted as follows: nonreliable if ICC<0.5 or W<0.2; fairly reliable if 0.2≤W<0.4; moderately reliable if 0.5≤ICC< 0.75 or 0.4≤W<0.6; good reliability if 0.75≤ICC<0.9 or 0.6≤W<0.8; optimal reliability if ICC≥0.9 or W≥0.8. Notably, the test-retest reliability analysis did not involve the indicators measuring variability (namely, all the indicators measuring variance or coefficient of variation [CV]).

The successive statistical analyses were solely based on the indicators extracted from the first repetition of the task, to avoid including eventual learning phenomenon in the data.

Relationship With Clinical Scores

For the second aim (ie, support to the clinical evaluation), the correlation between the indicators and the clinical parameters (MMSE, CDT, B-ADL, I-ADL, TMT-A, and number of errors in PnP test, either globally and divided by word type) was computed to measure to which extent the former can be used to approximate the results of cognitive/functional tests. Either the Pearson (*r*, normal) or Spearman (ρ, nonnormal) correlation coefficients were considered with the following interpretation: weak correlation, $0.2 \leq |r, \rho| < 0.4$; moderate correlation, $0.4 \leq |r, \rho| < 0.6$; strong correlation, $0.6 \leq |r, \rho| < 0.8$; very strong correlation, $|r, \rho| \geq 0.8$. In this case, the PnP task was considered as a whole (ie, no differentiation among word types).

MCI Dysgraphia Characterization

To provide quantitative information for the detection of lexical and phonetical dysgraphia, handwriting indicators were statistically compared among the different types of words in the PnP task. After averaging the indicators across words of the same type, the differences among the 3 types were studied using statistical methods for paired samples: repeated measures analysis of variance for normal data and Friedman test for the nonnormal case. Following such tests, in case the null hypothesis was rejected, a post hoc comparison was conducted to determine which word groups exhibited significant differences using the Bonferroni method.

Classification of Unconstrained Handwriting Tasks

Last, binary classification models for the distinction between patients diagnosed with MCI and HC participants were developed in Python (version 3.10; Python Software Foundation). The models were based only on the unconstrained writing tasks presented in this study (List and Text) to collect evidence on the suitability of ecological handwriting for MCI detection. The data for HC participants were collected during other acquisition campaigns, using the same device. These participants signed an informed consent for their voluntary participation. It is worth noting that only participants with age ≥65 years and MMSE ≥27 were included in the HC group, to avoid considering participants with possibly relevant cognitive deterioration [36]. The age threshold of 65 years was based on the age of the youngest participant in the MCI group. Importantly, HCs were excluded if diagnosed with any neurological, musculoskeletal, or cardiovascular conditions that could impair handwriting.

The starting datasets were as follows: (1) List in cursive allograph, L (C); (2) Text in cursive allograph, T (C); (3) List and Text in cursive allograph, L+T (C); (4) List in BL allograph, L (BL); (5) Text in BL allograph, T (BL); (6) List in all allographs (L); and (7) Text in all allographs (T). Independent of the considered dataset, the model's input consisted of handwriting indicators only, excluding the ones showing a correlation coefficient greater than 0.9 in absolute value with at least another indicator [37]. A 10-fold stratified repeated cross-validation approach was adopted in the training phase, setting the F_1-score as the metric to be optimized, given that, in general, the datasets were not balanced. At each iteration, the seed was changed and the whole dataset was divided into train, validation, and test sets, adopting 0.70, 0.15, and 0.15 ratios, respectively. The validation set was exploited to optimize the algorithm hyperparameters through a randomized search approach running 30 iterations. The test set was used to evaluate the model's performance on data not seen by the algorithm in the previous phases. The global performances were then assessed by averaging the classification metrics (accuracy, recall, precision, F_1-score, and area under the precision recall curve) over the 10 folds. Within this framework, several strategies were adopted. Given the general imbalance of the target classes, both undersampling and oversampling techniques were implemented in the training and validation sets through the *imbalanced-learn* library [38]. The former included random undersampling, the NearMiss method, and the Estimated Nearest Neighbors method. As for the latter, Synthetic Minority Over-sampling Technique (SMOTE), SMOTE-support vector machine (SVMSMOTE), Borderline SMOTE, and ADASYN were considered. Last, the selectKBest feature selection method [39] was used to reduce the dataset dimensionality, with the number of features K to be tried ranging from 10 to 50 with discrete steps of 10. Support vector classifier, random forest, and a pool of boosting algorithms—namely AdaBoost, gradient boosting classifier (GBC), XGBoost (XGB), LightGBM (LGBM), and CatBoost—were tried. The details on the space

XSL•FO
RenderX

of explored hyperparameters for each model are provided in the Multimedia Appendix 1. After the identification of the best performing models on the test set, the importance of indicators in their predictions was evaluated through Shapley Additive Explanations (SHAP) analysis [40]. The results of the SHAP analysis were used to qualitatively explore the patterns of misclassified samples: for each model, the trend of the 5 most relevant indicators for the predictions in misclassified samples was compared with the median trend of the same indicators in the MCI and HC groups through polar plots. To do so, the indicators were normalized between 0 and 1 for visualization purposes.

Results

Participants and Dataset

The characteristics of the recruited participants are reported in Table 1, separately for the whole sample of patients with MCI, which was exploited for the classification analysis, and for the sample that performed test and retest acquisitions, considered for the statistical analyses. Among the 57 patients with MCI enrolled, 40 were amnestic and 17 were nonamnestic. In more detail, the sample included: 3 pure amnestic MCIs (with isolated memory disturbance); 37 multiple-domain amnestic MCIs (with memory disturbance associated with disturbance of other cognitive faculties); 8 multiple-domain nonamnestic MCIs (with disturbance of other cognitive faculties, eg, attention, executive, spatial, and language, without memory disturbance); 9 single-domain nonamnestic MCIs (with disturbance of a single cognitive faculty, mostly dysexecutive).

As for the HC sample, information is displayed separately for the List and Text tasks. For this group, only the MMSE score was available. When comparing the MMSE score of participants with MCI and HC, the score of the MCI whole group was significantly lower than that of the HC sample who performed the List (P=5.4×10^{-05}) and the HC sample who performed the Text (P=6.4×10^{-07}).

The time required for completing the PnP test, given in seconds as median (IQR), was 126.42 (102.56-155.27) seconds at test and 122.56 (95.16-141.47) seconds at retest.

The allographs adopted by patients who underwent the test-retest protocol are reported hereafter:

- List, 29 cursive, 12 BL, 4 mixed (ie, BL in one repetition and cursive in the other).
- Text, 33 cursive, 11 BL, 1 mixed.
- PnP, 31 cursive, 11 BL, 3 mixed.

The allograph distribution of the data used in the classification problem is shown in Table 2. Here, the information refers to the available handwriting data, since both the test and retest acquisitions of the MCI group were considered, while HC participants performed the tasks multiple times.

[b]MCI: mild cognitive impairment.

[c]HC: healthy control.

Reliability

The analysis regarded the data collected from participants with MCI, denoted as "MCI Test-Retest" in Table 1. Participants who adopted different allographs across the test-retest protocol were excluded. For the sake of brevity, the results are reported for a subset of temporal, force, fluency, and tilt indicators, since these domains are the most commonly investigated in the literature.

Table 3 displays the results obtained on the 2 unconstrained handwriting tasks, separately for cursive ("C" columns) and block letters ("BL" columns) allograph.

In the List executed in cursive, optimal, good, and moderate reliability was revealed for 6 of 15, 8 of 15 (mean pause not reaching significance), and 1 of 15 indicators, respectively. The trend was confirmed in the Text task, with 7, 5, and 2 indicators showing optimal, good, and moderate reliability. Only a single unreliable indicator emerged, namely "Mean Force." When dealing with BL, the results were comparable for the Text, with only 2 indicators being not reliable. Among the reliable ones, statistical significance was not reached in 4 of 13 cases (mean in air, mean pause, LDLJ A, mean tilt). The situation was instead slightly worse for the List task: reliability was mostly of moderate intensity (10/15 indicators), coupled with 8 cases with a *P* value greater than the critical threshold of .05.

The indicators' reliability related to the PnP task performed in cursive (Table 4) was optimal, as the analysis yielded 14 out of 15 significant results of at least good reliability. Significance was not revealed only for the mean in air. The breakdown of the 3 types of words (Table 4) revealed that the positive results obtained on the whole task were due to the contribution of regular (Force NC being the only nonreliable indicator) and irregular words (besides cons peak diff G, all the indicators were significantly reliable). MU words were indeed characterized by 5 out of 15 unreliable indicators and 2 nonsignificant results among the reliable ones. Furthermore, in this case, the BL allograph was associated with worse outcomes in the whole PnP (Table 5: 5 unreliable indicators and 6 at least moderately reliable but not significant ones). Here, the poorest results happened with irregular words (6 reliable indicators reaching significance, 6 not reliable), while MU words revealed better reliability values than the corresponding in cursive, although only 4 showed a *P* value lower than .05.

Figure 1 displays a heatmap of the overall reliability intensity across indicators—the same reported in Tables 3-5—and tasks.

Figure 1. Reliability heatmap. Each row represents an indicator extracted from the sensorized ink pen with its measurement unit (if absent, the indicator is dimensionless), while each column represents a task. The color bar on the right encodes the reliability intensity. For the sake of visualization, here there is no distinct interpretation between ICC and Kendall W for the color coding: only the reliability value is considered. BL: block letters; C: cursive; I: irregular words in PnP; L: list; LDLJ A: logarithmic dimensionless jerk of the acceleration signal; LDLJ G: logarithmic dimensionless jerk of the angular velocity signal; MU: made-up words in PnP; NC: number of changes; OVS: overshoot; PnP: parole-non-parole; R: regular words in PnP; SPARC: spectral arc length of the angular velocity signal; T: text.

Relationship With Clinical Scores

The statistically significant correlations of handwriting indicators with clinical parameters are reported in Table 6. Overall, significant correlations were identified mainly for the unconstrained tasks in BL allograph. The I-ADL score was also significantly correlated with the indicators extracted from the Text in cursive allograph, while the cursive List exhibited no significant results at all. The PnP test, on the other hand, revealed relationships with the computed indicators mainly when considering the number of errors in the irregular words. The correlation absolute values ranged from moderate to strong, and their direction followed the expected trends.

XSL•FO
RenderX

Table 6. Correlation results. The correlation coefficient value and its corresponding *P* value are reported for all the tasks, separately for cursive (C) and block letters (BL) allographs. The clinical parameter "PnP errors - I" refers to the number of errors with irregular words in the parole-non-parole test (PnP) test. The correlations, in this case, were computed only with the indicators extracted from irregular words. Refer to Textbox 1 for descriptions of the indicators.

MCI Dysgraphia Characterization

The statistically significant results of the post hoc comparison of indicators (ie, the indicators for which the repeated measures ANOVA or Friedman test rejected the null hypothesis) among regular, irregular, and MU words are reported in Table 7 for both cursive ("C" columns) and block letters ("BL" columns). Most significances regarded irregular words.

XSL•FO
RenderX

Table 7. Results of the parole-non-parole test post-hoc comparison among different word types. "Type 1" and "Type 2" indicate the type of words being compared. The columns "LB," "Diff," and "UB" represent, respectively, the lower bound, the estimate, and the upper bound of the difference in the indicator between the type 1 and type 2 words. Refer to Textbox 1 for descriptions of the indicators.

Classification of Unconstrained Handwriting Tasks

The best classification performances for each dataset are displayed in Table 8, together with the adopted training strategy in terms of under- or oversampling and feature selection. Classification metrics on the test set are given as average (SD) over the 10 folds of stratified repeated cross-validation.

Table 8. Binary classification performances on the test set. For details, see the Methods section (Data Analysis subsection).

The top 5 most important indicators for each model, according to the SHAP analysis, are presented in Table 9.

A total of 21 indicators resulted among the possible 35 (5 top relevant indicators for 7 datasets), the most relevant ones. The most prevalent was Tilt CV, being present in 5 out of 7 datasets (one occurrence of Tilt CV_T in the L+T [C] dataset), followed by G peak power (4/7). The indicators A peak frequency and force NC were found in 3/7 cases, while cons peak diff G, A ApEn, and execution time resulted in 2/7 datasets. The remaining indicators occurred only once. Importantly, the indicators occurring multiple times were always characterized by the same direction in the MCI group. A high degree of consistency was revealed for the 3 models trained on cursive samples. Indeed, Tilt CV was the most important indicator in all 3 cases, while cons peak diff G, A ApEn, and G peak power were found in the 2 models trained with List cursive samples (L [C]; L+T [C]). For the 2 models trained on BL samples, the opposite trend occurred, with no superpositions among their 5 most relevant indicators.

Given these outcomes, the analysis of misclassified samples was carried out for cursive-samples models only.

In the L (C) model, G peak power showed trends compatible with those of patients with MCI in 50% (5/10) of false positive (FP) samples. The other recurrent altered indicators in FPs were cons peak diff G and air sheet ratio (4/10, 40%). Tilt CV and G peak power were found to be in line with that of HC participants in 83% (5/6) and 67% (4/6) of the false negatives (FNs), respectively.

In T (C), FPs were mainly associated with problems in temporal indicators (execution time: 11/16, 69%; mean pause: 10/16, 63%) and in a peak frequency (11/16, 69%). This last indicator was the main contributor to the presence of FNs (12/16, 75%), together with Tilt CV and mean pause (10/16, 63%).

When combining the information of the 2 tasks (L+T [C]), Tilt CV_T was found to deviate from the expected values in most misclassified samples: 67% in both FPs (4/6) and FNs (2/3). The other main contributor to FPs was A NC (3/6, 50%).

[a]L: list.

[b]C: cursive.

[c]+ denotes increased indicator values.

[d]T: text.

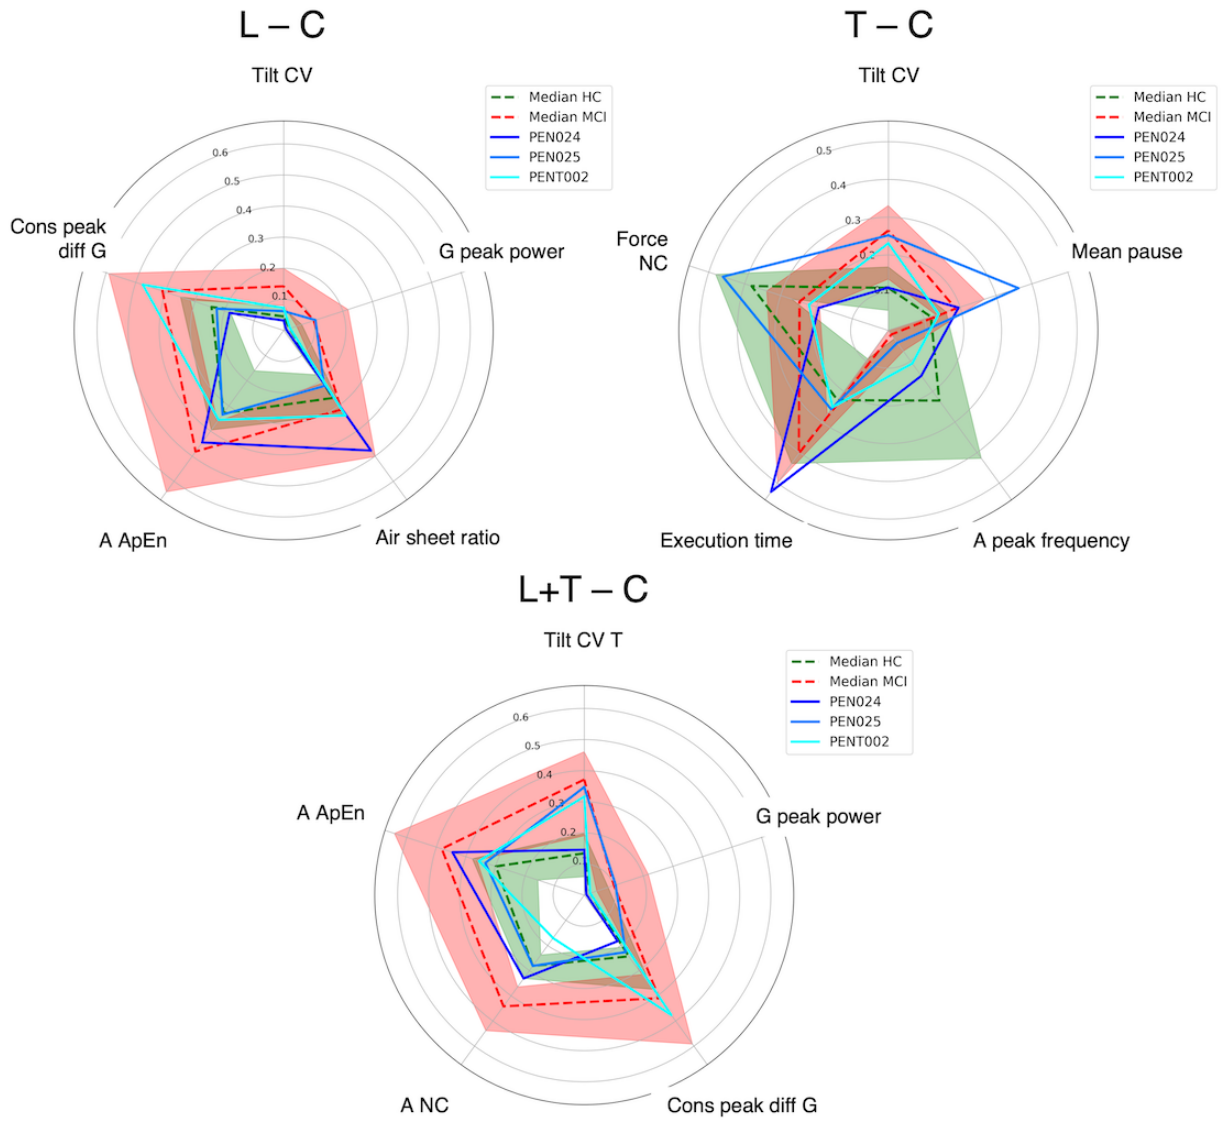
[e]Tilt CV_T in the L+T (C) dataset refers to the Tilt CV indicator in the text task. The other indicators in the row refer to the list task.

[f]BL: block letters.

[g]– denotes decreased indicator values.

Interestingly, 3 HCs and 2 MCIs were misclassified across all 3 cursive datasets. As for the HC group:

- PEN024 was consistently misclassified because of trends in A ApEn and temporal indicators (execution time, mean pause, and air sheet ratio) compatible with those of patients with MCI.
- PEN025 instead showed alterations in the kinematics of the handwriting movement, with high values of Tilt CV in the T (C) task and great angular velocity oscillations power in both tasks (G peak power).
- PENT002 exhibited a heterogeneous pattern, with difficulties in the force and pen inclination domains in the T (C) task. Altered values of cons peak diff G were among the reasons for the wrong prediction both in L (C) and L+T (C).



Moving to the patients with MCI:

- DGSMN07 revealed a high coherence across tasks. The modulation of rotational kinematics (cons peak diff G and G peak power) was similar to that of HCs, in turn causing the same behavior in Tilt CV.
- DGMSN17 was misclassified in all datasets due to the trend of Tilt CV. The effect of temporal indicators was identified in the T (C) task.

The indicators' trend for these samples is presented in the following radar plots for each classification model (in order, L [C], T [C], and L+T [C]). For each model, the most relevant indicator is displayed at the top of the radar. Then, indicators are displayed counterclockwise in decreasing order of relevance. All the values are normalized between 0 and 1 for visualization purposes. The dashed green line represents the indicators' median value, while the green area represents the interval between the 25th and the 75th percentile in the HC group. The red elements represent the same for the group of patients with MCI. The solid lines represent the indicator's value for the sample under examination. Blue hues are used for HC samples in Figure 2, while orange hues are used for MCI samples in Figure 3.

Discussion

Principal Findings

This work presented the quantitative analysis of handwriting in a population of patients diagnosed with MCI. With respect to the existing body of literature on the topic, an ecological approach for data acquisition was proposed. Handwriting tasks were executed on traditional paper using a sensorized ink pen able to record kinematic and dynamic signals. Moreover, content-free handwriting composition tasks were proposed to the participants to mirror the writing that can be carried out in everyday life. These aspects were deemed necessary for the development of a solution that potentially unlocks the monitoring of handwriting in the home environment. However, such features alone are not sufficient for the purpose.

That is why the first goal of the work was the assessment of the test-retest reliability of the information extracted from the acquisition protocol. High reliability is an essential requirement for any measurement instrument, particularly for solutions meant to detect anomalies in unsupervised longitudinal frameworks, in order to avoid high FP rates and alert fatigue. Importantly, the reliability analysis was conducted by separating different writing styles, namely cursive and BL, given that they differ in both temporal and kinematic parameters. The results were excellent for the cursive allograph, considering the 3 tasks, 42 out of the 45 presented indicators resulted significantly reliable, with reliability values mostly rated as good or optimal. This percentage dropped for BL: this was caused mainly by *P* values not reaching statistical significance, rather than by low reliability values. The outcome could be explained by the reduced number of participants who adopted the BL allograph in the recruited sample, which could also be the reason behind the overall better results found for cursive. Interestingly, the best results were achieved with the unconstrained tasks (List and Text), regardless of the adopted allograph. This could imply that one's peculiar handwriting process characteristics are preserved independently of the content itself, thus making the analysis of unsupervised

XSL•FO
RenderX

handwriting activity a promising approach for the remote tracking of MCI progression. On the other hand, the reliability of the indicators from the standardized PnP test in BL was not always verified. The unreliability of the mean pause indicator, measuring the average duration of moments longer than 2 seconds spent with the pen in the air, could, in theory, be due to differences in the dictation timing of the operator between test and retest acquisitions.

Regarding the support for the clinical evaluation, the correlation analysis revealed a scarce presence of significant results (around 10% of the total correlation values). Such an outcome should not be interpreted negatively for 2 reasons. First, the administered clinical tests are not meant to assess the handwriting performance specifically. Even the CDT and the TMT-A, which require the patients to draw and trace lines for their completion, are not evaluated according to the graphomotor performance itself, but rather on their accuracy. The same holds for the PnP test: the scoring is based on the orthographic correctness of the written words, while the proposed indicators are aimed at characterizing the handwriting process. Thus, a direct correspondence between the clinical scores and the handwriting indicators does not exist. Moreover, the CDR and B-ADL scores were characterized by low granularity (the former presented with only 2 distinct values, namely 0.5 and 1), resulting in poor significance. Second, and most importantly, the obtained significant correlations were of at least moderate intensity and in line with the existing literature [17]. Diving into detail, the highest number of correlations was found between temporal handwriting indicators and the MMSE and the I-ADL scores. As the MMSE and I-ADL increased, rel stroke num and on on-sheet ratio increased as well, while the mean in air, the mean pause, pause num, and air sheet ratio decreased. Therefore, in the recruited sample, participants who are more cognitively intact and functional in daily life tend to write faster thanks to a reduced degree of hesitation. Another relevant finding concerns the 2 tests involving the use of a pen or pencil. Those who performed well in the CDT and TMT-A applied a greater force on the writing surface, coupled with a higher number of changes in the force signal direction (the opposite signs of the correlation values are due to the opposite interpretation of the tests score). Such a pattern is associated in the literature with the healthy status [19]. Last, significant correlations between indicators and the number of errors in the PnP test emerged only for the errors in Irregular words. Here, when the BL allograph was used, a higher number of errors was associated with a faster performance on the sheet: the mean time spent with the pen on paper (mean on sheet) and the percentage of time spent on paper when writing a word (on sheet ratio) both showed a negative correlation. This could suggest that errors in irregular words occurred because the participants paid reduced attention (hence the increased speed on the sheet) to the words to be written, despite requiring orthographic knowledge to be written correctly. Linking the observed correlation patterns with specific domains of cognitive function is not trivial. The clinical tests used in the correlational study are useful in providing general measures of one's cognitive functioning or some of its high-level variables, such as processing speed, or measures of the patient's level of autonomy. In contrast, they are not thought of, nor have they shown particular accuracy and validity in detecting dysfunctions of individual cognitive functions such as memory, attention, executive functions, critical thinking, language, spatial abilities, visual perception, and so on. Any attempt to explain the obtained correlations in terms of individual cognitive domains would therefore be highly speculative and unsupportable with the available data. However, to a first approximation, the correlations between temporal indicators and MMSE and I-ADL scores seem to closely resemble what clinicians call cognitive hesitancy, an aspect of general insecurity in test responses that can be framed in the context of executive function dysfunctionality.

Dealing with the quantitative information derived from the PnP test, another neat trend emerged for irregular words. Independent of the handwriting style and orthographic errors, irregular words posed the greatest challenge to the recruited sample. With respect to the other types of words, irregular ones were consistently and significantly associated with worse in-air temporal performances (ie, longer times spent with the pen in the air), as revealed by mean in air and mean pause. This translated into a significantly slower rate of grapheme production (Rel stroke num) and, consequently, into the longest times required to write the words (execution time). In the BL allograph, alterations were also found in the on-sheet execution, as irregular words exhibited around 10% less time spent with the pen on the writing surface (on-sheet ratio). Last, irregular words were linked to a reduced variability in the pen inclination (Tilt CV), possibly suggesting an impaired manipulation of the writing instrument when dealing with this type of word. According to the classical cognitive models of handwriting, the marked alteration of the handwriting process found in the current work for irregular words, which require semantic and lexical knowledge to be written correctly compared with regular and MU words, could underline alterations in the lexical pathways as a result of dysfunctions in the orthographic retrieval process.

Overall, the implemented quantitative indicators seem able to capture relevant aspects of the handwriting gesture that are linked to the participant's general conditions. On top of that, the indicators can also identify altered patterns that can provide a deeper understanding of the nature of the patient's handwriting impairments. This stresses once again the suitability of handwriting monitoring in the population with MCI, as impairments in the gesture could be associated with a cognitive or functional decline.

The last evaluated aspect was the ability of the indicators to distinguish unconstrained handwriting samples generated by patients with MCI from those written by older adults without any diagnoses and MMSE ≥ 27. The choice of focusing on the List and Text tasks was motivated by their potential application in the domestic scenario. In such a condition, the information could be gathered in ecological modality without the need for the operator's supervision. The classification performances were good, with F_1-scores selected as the evaluation criterion given the datasets' imbalance, ranging from 0.81 to 0.92. Importantly, the results do not appear to be task or allograph-dependent. These results highlight the power of the proposed analysis: the extracted handwriting process indicators do provide relevant

XSL•FO
RenderX

information on the participants' cognitive status, regardless of the writing content and the allograph adopted to realize it. When comparing with the existing literature, the current results are placed between the accuracies of 74% in [19] and 96.6% in [20]. It is, however, worth pointing out that the latter classification performance, related to the execution of a spontaneous sentence, was obtained in different conditions. A digitizer was used, thus providing information also on the written trace, not available in this study, on a narrow sample size (12 patients with MCI and 17 controls). Moreover, the authors reported the participants' age, which was not balanced between groups, as one of the most discriminative features for the model. Such a variable was not included in the models presented here.

The exploration of the relevance of indicators in the predictions of models provided great insight into the aspects that mostly differentiate the execution of patients with MCI and HC participants. This was true particularly for the cursive allograph, since heterogeneous results were found in the models based on BL samples, likely because of the reduced sample size. In general, the outcome of the SHAP analysis was not the expected one. Despite anticipating temporal indicators to carry the highest discriminative power, reflecting hesitations and greater processing times for patients with MCI, their occurrence among the most relevant was somewhat limited: only 5 out of 35 temporal indicators emerged, never placed in first or second position. The biggest determinant in the classification models was the variability of the pen inclination with respect to the vertical axis (Tilt CV), as it was found among the 5 most relevant indicators in 6 out of 7 models, being in the first place in 4 cases. In the classification models built on the cursive List samples (L [C] and L+T [C]), the relevance of Tilt CV, with high values always steering the classification towards the MCI group, was coherently associated with the presence of other kinematic indicators, both in the fluency and in the frequency domains. Such an outcome could open new perspectives on the evaluation of the handwriting performance of patients with MCI, traditionally focused on execution time, product quality, and orthographic accuracy. Researchers and clinicians should also consider the handwriting process kinematics that underlie the generation of the written trace. The results of the SHAP analysis were the basis for the inspection of misclassification patterns in the cursive-based models. These were homogeneous in FNs, for whom Tilt CV was the main reason why the models predicted them as belonging to the HC group. When this was not the case, the cause was still found in the handwriting kinematics. The situation was variable for FPs. In L (C), three archetypes emerged: (1) the participants who experience alterations in the variability of pen inclination; (2) the participants with excessive amplitude in rotational movements; (3) a heterogeneous group, with difficulties both in kinematics and in-air durations. The same number of patterns showed up in T (C). The first was again characterized by abnormal values of Tilt CV, while the second exhibited the opposite behavior, with no impairments in Tilt CV. The last archetype was the most anticipated one, where increased times were the sole reason for misclassifications. When combining List and Text in cursive, 2 main patterns were highlighted. Once again, the most prevalent had Tilt CV_T as the cause of FPs occurrence, while the other one was the entropy of the acceleration signal. Overall, the analysis revealed the multifaceted nature of the handwriting process in older adults, highlighting the importance of the participant-specific exploration of the model predictions. This would allow one to unveil one's peculiar pattern of handwriting impairments, thus helping the clinician in identifying the motor and cognitive aspects that need a thorough assessment.

It is important to highlight the limitations found in this work. Regarding the recruitment, depression and anxiety disorders, relevant for various aspects of cognitive motor processes, were not formally measured during patients' assessment. However, patients with a history of anxiety disorders or depression were excluded from the sample. So, caution should be placed when trying to generalize the presented findings to the population with MCI. As for the inclusion of control participants, their selection was solely based on their MMSE score. While they did not report any neurological diagnoses, they did not undergo any thorough clinical examination aimed at assessing their cognitive status. Thus, the presence of cognitively impaired participants in the control group cannot be excluded. In the statistical analysis of the available data, the percentage of recruited patients who adopted the BL allograph (around 1/3 of the total) was limited with respect to cursive. This translated into a reduced number of statistical significances in the reliability analysis, while the binary classification models trained on BL samples were characterized by greater SDs of the classification metrics across the 10 folds of the stratified repeated cross-validation, with respect to their cursive counterparts. Despite the imbalance in the adopted allograph, we do believe that the performance difference between BL-trained and cursive-trained classification models does not imply a reduced discriminative power of the former writing style. Although additional BL samples are needed to prove this hypothesis, this allograph should be better suited for the binary classification problem based on the proposed tool and indicators. Indeed, being the allograph characterized by a highly standardized motor pattern of stroke generation, the main source of variability between MCI and HC participants should be found in the indicators measuring the in-air performance, which should reflect longer processing times and hesitations in the former group. When dealing with cursive, the participants' personal handwriting style comes into play, making the classification task more challenging. Just as an example, greater times on-sheet could indicate either slowness of movement or a writing style characterized by longer, interconnected strokes. In general, the choice of the allograph was left free to the participant to guarantee an ecological execution of the task and to align with the PnP test instructions, which do not specify how the participant should write, but the presented findings should be confirmed by increasing the BL sample size. The free choice turned out to be a liability in a limited number of cases, where patients adopted different allographs in the test and retest acquisitions, thus making them unsuitable for the reliability analysis. Given the impossibility of characterizing specific cognitive domains with the battery of clinical tests used in this work, the inclusion of more specific clinical tests for different cognitive domains is planned as a next step to refine the

XSL•FO
RenderX

correlation analysis. In this regard, the positive results obtained with the words and nonwords writing test, which is the only instrument investigating a specific cognitive function in the study, indicate that such a research objective seems promising and feasible. With respect to the digitizers, the used sensorized ink pen cannot directly provide information on the trace made on paper. Future work should focus on proper methods for the extraction of product-related handwriting information to reduce this gap, particularly for the cursive allograph. Other promising directions can be found in multimodal approaches for the classification of patients with MCI. For example, the authors in [21] demonstrated that the fusion of handwriting and EEG parameters can improve the classification performance with respect to considering a single data source alone. Of course, the feasibility and user friendliness of the protocol should be carefully designed in such a case. The results also found the basis for additional research: a longitudinal study could be conducted, possibly in an unsupervised scenario. Last, the clinical community would benefit from comparative investigations on the discriminative efficacy of various handwriting-based screening methods. They should also consider their implementation complexity to provide an all-around informed documentation regarding the utility and feasibility of their integration into clinical practice.

Conclusions

The relevance of handwriting in the population with MCI was confirmed in this work, which described a novel approach for its quantitative characterization. The analyses revealed 2 potential complementary scenarios for its fruitful application. On one side, information related to the participant's clinical conditions can be quickly and noninvasively extracted, both through the PnP test and unconstrained handwriting. On the other hand, the handwriting tool emerges as a viable solution to track old adults' conditions in a transparent and ecological way, fostering MCI remote monitoring in a home setting.

Abstract

Background: Digital health twins (DHTs) have been evolving with their diverse applications in medicine, particularly in care settings for older adults, in response to the increasing demands of older adults. Despite its numerous benefits, the optimal implementation of DHTs has faced several challenges, particularly in terms of ethics and quality of care. Given the continuous rise in the need for such care and the evident potential for DHTs to meet these needs, this review seeks to identify and address the gaps in research knowledge to enhance DHT implementation.

Objective: The review aims to compile and synthesize the best available evidence regarding the issues associated with quality of care, the ethical implications of DHTs, and the strategies undertaken to overcome those challenges in care settings for older adults.

Methods: The review followed the Joanna Briggs Institute (JBI) methodology as a guide. The published studies were searched through CINAHL, MEDLINE, JBI, and Web of Science. The unpublished studies were searched through Mednar, Trove, OCLC WorldCat, and Dissertations and Theses. Studies published in English from 2016 were considered. This review included studies of older individuals (aged 60 years and older) undergoing care delivery associated with DHTs and respective care providers. The concept involved the application of technology, and the context included studies based on care settings for older adults. A broad scope of evidence, including quantitative, qualitative, text, and opinion studies, was considered. In addition, 2 independent reviewers screened the titles and abstracts and reviewed the full text.

Results: The results will be presented in a PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flow diagram. A total of 2 draft charting tables were developed and presented. A summary of the characteristics of the included studies was then described in terms of location, study sites, timing, participants, and outcomes measured or phenomena of interest. A result-based convergent (integrated) synthesis design was used to identify 5 key challenges. Those challenges included (1) data security and privacy concerns, (2) equity and accessibility of health care, (3) effectiveness concerning context, timing, and location, (4) ethical implications regarding autonomy, consent, and overdiagnosis, and (5) the impact of DHTs on health care workflows and provider workload.

Conclusions: The studies reviewed reveal several critical characteristics regarding the implementation of DHT technologies and their associated ethical considerations, particularly in terms of safety, equity, timing, location, participant characteristics, and workflow impact. The implications of these challenges emphasize the necessity for more practical ethical guidelines and policy frameworks to mitigate the potential risks associated with DHT application in older care. Further research should be conducted to examine other dimensions of the quality of care, such as access, timeliness, acceptability, and appropriateness.

Introduction

Digital health, with its tools for telemedicine, remote monitoring, medication management, and social connection, is a reassuring presence in the care of older adults. It is not just about enhancing their health, independence, and quality of life, but also about promoting healthy aging. This is achieved through the promotion of preventive care, disease self-management, and the personalized interventions that address the specific needs of older adults [1,2]. Digital health interventions can be tailored to individual needs and abilities (personalized care), addressing specific health concerns like falls, sarcopenia, and mental health challenges to support independence and well-being [3,4].

The advent of digital health twins (DHTs) marks a pivotal evolution in health care and social care, particularly in the management of care for older adults. These sophisticated virtual representations simulate individual health profiles by integrating extensive datasets, promising personalized health and social care interventions that can significantly enhance patient outcomes [5,6]. Despite the considerable advantages that DHTs present—improvements in effectiveness, safety, and accessibility of care—their implementation raises critical ethical dilemmas and challenges related to the quality of care that necessitate rigorous examination [7,8]. DHTs can be more than just a digital replica or a virtual model of patients (physical twins); they can be a sophisticated representation designed to faithfully mirror the real-world system in real time, analyze their behavior, and provide predictive insights using advanced simulation, machine learning, and reasoning to inform decision-making. The analytical and predictive capability of a digital twin makes it distinct from a dummy replica of the physical system [9,10]. DHTs are generated from multimodal patient data, population data, and real-time updates on patient and environmental variables [11]. For the convenience of the reader, the term “digital health twins” (DHTs) has been consistently maintained throughout the article. However, several other related terms, such as “digital twins” and “personal digital twins,” have also been used to depict the findings, thereby maintaining the originality and credibility of the included studies, primarily in the results section and tables.

DHTs are considered the pinnacle of personalized health care due to their ability to create a virtual replica of a patient’s health information, created using various data sources—from genetic information to real-time biometric data [6,12]. One of the primary concerns associated with DHTs is their potential to redefine established health norms. Creating personalized health models could inadvertently establish new benchmarks affecting the safety and effectiveness of health and social care interventions across diverse patient populations [13]. This technology has the potential to vastly improve the accuracy and efficiency of health care delivery, leading to better outcomes for patients and providers alike [12].

However, deploying such innovations must be approached with caution to mitigate risks related to data privacy and security, particularly among older adults who are often more susceptible to data breaches [14]. DHTs present heightened privacy and security risks compared to other technologies due to their reliance on sensitive, real-time patient data and their complex, interconnected nature. The continuous and urgent influx of personal health information, combined with the potential for remote access and manipulation, makes DHTs a prime target for cyberattacks and privacy breaches, highlighting the need for collaborative efforts among professionals to address this issue [15]. As digital health solutions become increasingly pervasive, the ethical ramifications surrounding data ownership, consent, and potential misuse warrant careful consideration [16,17].

DHTs can revolutionize personalized care planning. Numerous studies have demonstrated that these models can enhance the customization of interventions, leading to improved health outcomes [16]. However, the inherent personalization also introduces ethical considerations regarding data representation and equitable access to care. Bahrami et al [18] emphasized concerns regarding equitable access to tailored drug therapies, which may inadvertently exacerbate existing disparities in health and social care.

The potential of DHTs to facilitate early detection of health issues, such as dementia, is widely acknowledged [19]. These systems can enhance care safety and effectiveness through timely interventions and provoke significant privacy and autonomy concerns [20]. The ethical implications of using technology for health monitoring necessitate the development of robust frameworks that prioritize patient autonomy while promoting engagement with digital health solutions [21]. This highlights the importance of considering ethical aspects of DHT in health and social care.

Furthermore, the intersection of DHTs with traditional health and social care practices raises profound ethical questions concerning the equilibrium between potential benefits and harms. For instance, Lin et al [22] scrutinized the risk of overdiagnosis in colorectal cancer screening programs, highlighting the likely exacerbation of this issue by DHTs. The unintended consequences of digital health interventions include patient anxiety and unnecessary medical procedures, underscoring the necessity for thorough ethical scrutiny [23]. As health and social care transitions toward a data-driven paradigm, integrating emerging technologies must be guided by ethical principles that prioritize patient welfare.

Incorporating innovative technologies, including virtual reality (VR), within DHT frameworks opens new avenues for training and treatment [24]. While VR simulations can enhance health and social care training and improve treatment outcomes, they also present ethical challenges regarding informed consent and data use. Ensuring these technologies are used ethically and responsibly is paramount to maintaining public trust in digital health innovations.

This research investigates the ethical and quality of care-related challenges associated with DHTs in older adult care settings. A scoping review has been chosen because it is designed to map key concepts and examine the literature in a research area, providing an overview of the current evidence available. By synthesizing existing literature and identifying knowledge gaps, particularly as articulated in the protocol by Jabin et al [8], this study aims to provide a comprehensive understanding of the

XSL•FO
RenderX

implications of DHTs. In doing so, it will underscore the necessity for frameworks that ensure technological advancements in health and social care do not compromise the fundamental ethical principles of equity, autonomy, and patient-centered care. This reinforces the need for ethical guidelines in the digital health field, where integrating novel technologies must be closely aligned with ethical considerations without compromising the quality of health and social care. Specifically, the review questions are:

- What problems are faced by older individuals (their family and relatives), and health and social care providers, associated with the application of DHTs in care settings for older adults?
- What are the documented issues related to the quality of care for older adults, such as safety, equity, effectiveness, and accessibility, concerning DHTs?
- What are the ethical challenges concerning the application of DHTs used in care settings for older adults?
- What strategies have been evaluated and implemented in care settings for older adults that address the challenges associated with DHTs?

Methods

The proposed scoping review was conducted under the guidance provided by the Joanna Briggs Institute (JBI) methodology for scoping reviews [25]. The JBI methodology for scoping reviews offers a systematic and structured approach for mapping and reviewing vast areas of study.

Eligibility Criteria

Overview

This scoping review included studies by following the population, concept, and context (PCC) mnemonics. These mnemonics were used as a guide (not a policy); therefore, the inclusion criteria of this scoping review included a detailed description of the types of participants, concepts, and context, as well as search strategies, data extraction, charting, analysis, and presentation of the results. The eligibility criteria are listed and described in detail (see Table 1 and Table S1 in Multimedia Appendix 1) of the original protocol published by Jabin et al [8].

[a]Not available.

[b]CPS: Cyber-Physical System.

[c]CPS-AAL: Cyber-Physical System for Ambient Assisted Living.

[d]VR: virtual reality.

[e]DHT: digital health twin.

[f]CRC: colorectal cancer.

[g]HDT: health digital twin.

[h]STRIDE: Specific context needed, often refers to "Strategies for Risk Identification and Development" or other frameworks.

[i]ADRD: Alzheimer disease and related dementias.

[j]MDR: multidrug resistance.

[k]DL: deep learning.

Participants

This review included studies of older individuals (aged 60 years and older) undergoing older care associated with DHTs, irrespective of gender and diversity, including age, ethnicity, socioeconomic status, disorders, and disability. Studies on caregivers (family or friends—paid or unpaid) and care providers (licensed or unlicensed) involved in older care concerning DHT were also included.

Concept

The key concept in this scoping review is the process and application of DHT. Studies evaluated the application of DHT involving older care providers, older individuals, or family, friends, and relatives.

Context

The scoping review considered studies in care settings for older adults associated with DHT, such as geriatric wards of primary health care, hospitals or clinics, old-age homes, nursing homes, care homes, and home care facilities for older individuals.

Search Strategy

Databases were searched for both published and unpublished studies. The approach to searching for studies for a scoping review followed the standard 3-step method [8]. The first step involved an initial limited search of relevant databases, followed by an analysis of the text words in the title and abstract, as well as the index terms used to describe the article. The search for published studies included a 2-way search strategy. One way was to search the journal and reference databases, such as CINAHL, MEDLINE, JBI, and Web of Science. Another way was to search article-based (journal) databases, such as ACM Digital Library, IEEE Xplore, and BMJ Journals. The search for unpublished studies included Mednar, Trove, OCLC WorldCat, and Dissertations and Theses. A second search was undertaken across all included databases using all identified keywords and index terms. Additional search strategies, including citation searches for specific researchers or articles (eg, gold-standard articles) and chain searches (reviewing the reference lists of systematically selected articles), were included to complement the search for published and unpublished papers. Studies, such as reviews (systematic, scoping, and umbrella) and letters to editors, were excluded. Studies published in English were considered. While the precise origin of the specific phrase “digital health twin” is hard to pinpoint, the foundational concepts of digital twins began gaining significant traction in healthcare around 2016, driven by advancements in related fields like the internet of medical things and artificial intelligence [24].

Types of Studies

This scoping review considered experimental and quasi-experimental study designs, including randomized controlled trials, nonrandomized controlled trials, before-and-after studies, and interrupted time-series studies. In addition, analytical observational studies, including prospective and retrospective cohort studies, case-control studies, and analytical cross-sectional studies, were also considered for inclusion. This review considered descriptive observational study designs, including case series, individual case reports, and descriptive cross-sectional studies for inclusion.

Qualitative studies were also considered, focusing on qualitative data, including, but not limited to, designs such as phenomenology, grounded theory, ethnography, qualitative description, and action research. Text and opinion papers regarding the benefits, challenges, and strategies to overcome the challenges posed by DHT were also considered, as the scoping review includes a broad scope of evidence.

Source of Evidence Selection

Following the search, all identified citations were collated and uploaded into EndNote 20 (Clarivate Analytics), and duplicates were removed. Following a pilot test, titles and abstracts were then screened by 2 or more independent reviewers for assessment against the inclusion criteria for the review. Potentially relevant sources were retrieved in full, and their citation details were imported into a Microsoft Excel sheet instead of the JBI System for the Unified Management, Assessment, and Review of Information [35] due to a lack of resources. In addition, 2 independent reviewers assessed the full text of selected citations in detail against the inclusion criteria. Reasons for excluding sources of evidence in full text that did not meet the inclusion criteria were recorded and reported in the scoping review. Any disagreements that arose between the reviewers at each stage of the selection process were resolved through discussion or with the assistance of an additional reviewer (as an arbitrator). The search results and the study inclusion process were reported in full in the final scoping review and presented in the PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses Extension for Scoping Reviews) flow diagram [36,37].

XSL•FO
RenderX

Data Extraction

A total of 2 independent reviewers used a data extraction tool they had developed to extract data from the papers included in the scoping review (see Table 1). The data extracted included specific details about the participants, concept, context, study methods, and key findings relevant to the review questions.

A draft charting table was developed as a data extraction tool. While extracting data from each included evidence source, the charting table was modified and revised as necessary. The modifications were detailed in the scoping review. Any reviewer disagreements were resolved either by the reviewer or with the assistance of an additional reviewer (as an arbitrator).

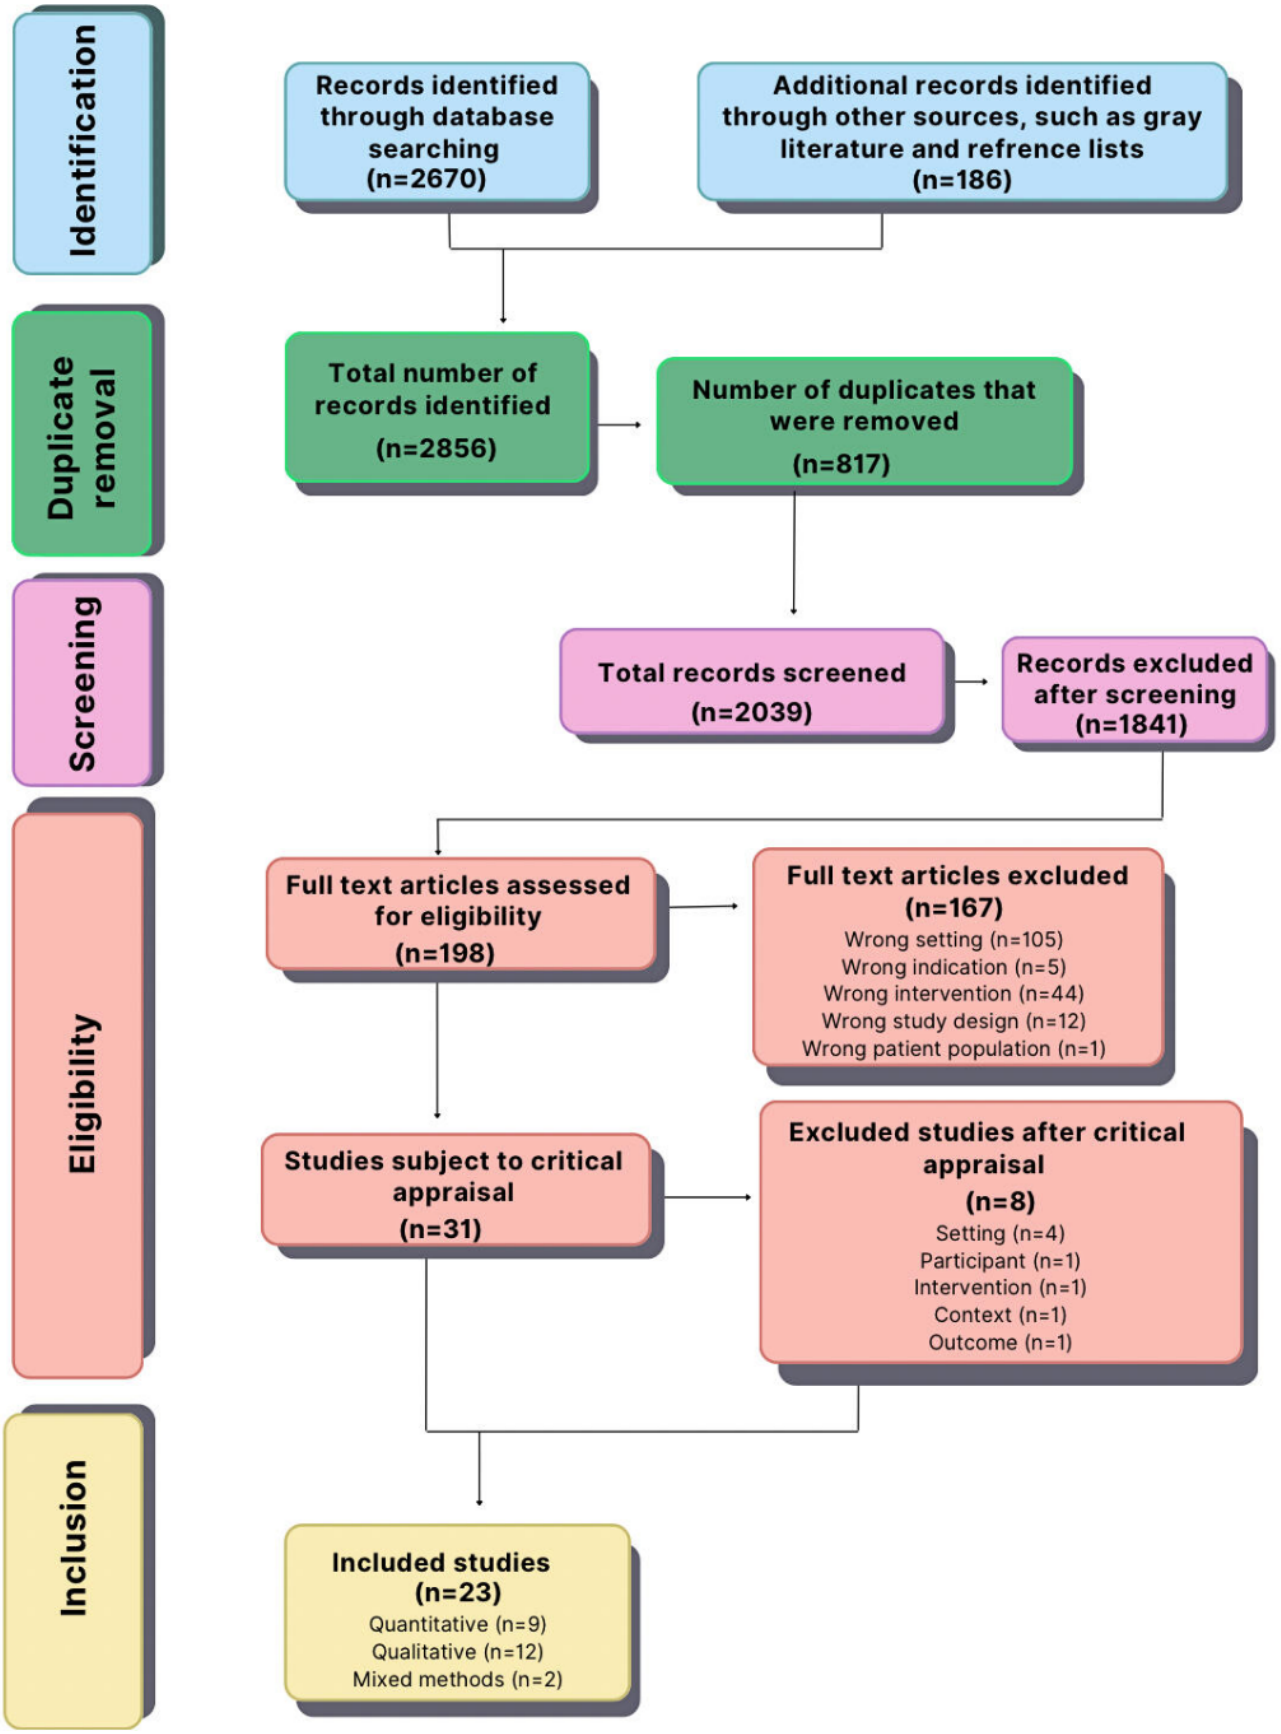
We extracted variables to ensure alignment with our research questions, while some variables may emerge during full-text screening; therefore, it was essential to predefine the key data extraction elements (as the protocol is structured). Clearly outlining these variables ensured consistency in data collection, enhanced transparency in the scoping review methodology, and strengthened the study's replicability. We also followed the JBI Manual for Evidence Synthesis as a guide, which provided a basic data extraction table template to ensure completeness, methodological consistency, and adherence to best practices in data extraction [38].

Results

Overview

The results are presented as a "map" of the data extracted from the included papers, in a tabular form (as necessary) and in a descriptive format that aligns with the review's objective and scope. A clear explanation for each category is provided, accompanied by a narrative summary that describes how the results relate to the review's objectives and questions. This scoping review synthesizes key findings from the literature on the application of DHTs in older adult care settings.

A result-based convergent synthesis design was used in which all types of studies, such as quantitative and qualitative, were analyzed and presented [39]. The findings were then integrated using convergent synthesis, which identified five key challenges. Those challenges included (1) data security and privacy concerns, (2) equity and accessibility of health care, (3) effectiveness concerning context, timing, and location, (4) ethical implications regarding autonomy, consent, and overdiagnosis, and (5) the impact of DHTs on health care workflows and provider workload.



Search Strategies and Screening

Figure 1 shows the results of the search strategy and inclusion of studies as a Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) flow diagram. The total number of studies identified was 856, which included searching bibliographic databases (n=786 studies) and searching for gray literature and other sources, such as reference lists of included studies (n=70 studies). After removing 344 duplicates, a total of 512 records were screened. The titles and abstracts of each of the 512 studies were screened independently by 2 reviewers (the principal author as the first reviewer of all studies and the contributing authors as second reviewers on a similar number of studies each); 354 studies were excluded after screening because they were not relevant to the review question. A full-text review assessing the eligibility of the remaining 158 studies resulted in 20 studies being advanced to the final list of included studies, while 138 studies were excluded (see Figure 1).

A search strategy using Boolean search strings in databases is provided in Table S2 in Multimedia Appendix 2, and the inclusion and exclusion criteria used during the review process are outlined in Table S3 in Multimedia Appendix 2.

Summary of the Characteristics of the Included Studies

The studies reviewed emphasize the integration of DHTs in health care, offering a wide range of applications, including virtual simulations, disease monitoring, and health care delivery.

Location, Study Sites, and Timing

The studies vary in terms of location and timing (see Table S1 in Multimedia Appendix 1). For example, Bruynseels et al [12] explore the potential of DHTs in health care settings, but do not specify particular sites or study duration. On the other hand, Khan et al [30] use microwave sensors in a static care-home model, which likely involves specific care-home locations, showcasing a practical implementation of DHTs in elderly care. The studies span different periods, with some focusing on contemporary advancements [32] and others taking a longer-term view of digital health transformation [26]. All included studies encompass a range of countries (n=14) globally, with the majority originating from the United Kingdom and Europe. The publication of these 20 studies, spanning from 2018 to 2023, suggests that DHT has gained attention only recently.

Participants

Participant involvement varies across the studies (see Table S1 in Multimedia Appendix 1). For example, Jovanovic et al [29] focus on vaccination strategy simulations, meaning their study does not involve direct patient participation but relies on data for modeling purposes. In contrast, the model by Bahrami et al [7] drug diffusion in an online patient, suggesting that their study could involve patient-based data for the creation of DHTs. Studies like those delve into ethical issues related to using DHTs in care settings for older adults, which would likely involve patient consent and ethical considerations for vulnerable groups [12,22,28].

Outcomes Measured/Phenomenon of Interest

The outcomes measured in the studies often focus on the effectiveness of DHT technology in improving health care outcomes (see Table S1 in Multimedia Appendix 1). For example, Liu et al [26] assess the use of cloud-based DHTs for elderly health care services, measuring outcomes such as patient monitoring and health service optimization. In contrast, studies like the one by Cai et al [34] focus on the early detection of Alzheimer disease, aiming to measure how DHTs could assist in identifying disease risk early, ultimately improving diagnosis and treatment outcomes.

Claims and Findings

The reviewed literature consistently highlighted that DHTs and associated technologies offer transformative potential for improving health care delivery, particularly through personalization, predictive analytics, and real-time monitoring (see Multimedia Appendix 1). However, shared concerns about ethics, equity, and data privacy were repeatedly emphasized across the studies. For example, Bruynseels et al [12] argued that DHTs raise significant ethical, legal, and societal issues, particularly regarding equality and potential discrimination, which resonated with Chakshu et al [16], who, although focusing on noninvasive detection of carotid stenosis, implicitly align with Bruynseels and colleagues' [12] ethical stance by advocating for procedural alignment and ethical validation in clinical application. Both stressed the need for patient autonomy and safeguarding rights in digital health innovation [12,16].

Similarly, the concerns around data privacy and security raised by Khan et al [30], who examined unobtrusive microwave sensors in care homes, were mirrored in Kobayashi et al [19], who discussed privacy and autonomy concerns in their dementia detection system. Both highlighted that the collection of personal health data—whether through sensors or DHTs—demands robust ethical and legal frameworks to protect vulnerable populations, particularly older adults [19,30].

In terms of personalized care and equity, Bahrami et al [7] proposed a physics-based digital twin for tailored drug therapy, focusing on personalized medicine, which aligned closely with Barbiero et al [11], who developed a general digital twin framework emphasizing modularity and scalability in representing biomedical data. Both studies demonstrated how, although helpful for precision treatment, personalized health care models could worsen disparities if access is not sufficiently addressed [7,11]. Wickramasinghe et al [31], who emphasized the necessity of inclusive clinical decision support in dementia care, share this issue.

Further illustrating a shared commitment to enhancing health care efficiency and safety, while acknowledging ethical concerns such as informed consent and data governance, is the integration of cutting-edge technologies, including VR simulators by Alves et al [5] and personal digital twins (PDTs) by Sahal et al [32]. Alves and colleagues' [5] focus on online training environments and Sahal and colleagues' [32] blockchain-enabled PDT framework were both operating in tandem, suggesting technological steps to ensure openness and confidence [5,32]. Sahal and colleagues' [32] blockchain-enabled PDT framework and Alves' emphasis on online training environments complemented each other by recommending technological measures to guarantee transparency and trust [5,32].

A notable similarity existed between Jovanovic et al [29] and Lin et al [22] in their use of simulation and modeling to guide public health interventions—Jovanovic et al through vaccination strategy simulations and Lin et al via overdiagnosis assessments in colorectal cancer screening [22,29]. Both emphasized the importance of data-driven decision-making to optimize health outcomes and minimize unintended consequences, such as overdiagnosis or inefficient resource allocation [22,29].

Finally, the user perception and adoption challenges explored by Bui [21], regarding older adults' attitudes toward DHTs, were closely reflected in Zhao et al [20], who examined older users' expectations of intelligent technologies. Both studies concluded that user acceptance was influenced by privacy concerns, ease of use, and perceived benefits, underlining the critical need for human-centered design in DHT solutions [20,21].

Integrated Synthesis

This review identified a range of challenges based on the key characteristics of the included studies (see Table 1), which are briefly described hereinafter:

XSL•FO
RenderX

Safety Concerns and Data Privacy

Safety remains a primary concern in the deployment of DHTs, particularly regarding patient data security and privacy.

Risks to Patient Privacy

DHTs, as virtual representations of patients, relied on integrating extensive multimodal datasets [12], including health records, environmental data, and real-time monitoring information [5]. While these technologies offered the potential to improve safety through personalized health monitoring and predictive capabilities, they also raised significant risks to patient privacy.

Unauthorized Data Access and Misuse

Older adults are often more vulnerable to data breaches due to cognitive impairments or a lack of digital literacy [21], and require additional safeguards [34]. Studies by Liu et al [26] and Khan et al emphasized the potential for unauthorized data access and misuse [26], which could undermine trust in DHT technologies. This concern is amplified in older populations [30] who may lack familiarity with digital systems and are more susceptible to exploitation.

Protecting patient data through secure and transparent privacy protocols is essential to ensure the safe adoption of these technologies in care settings for older adults.

Equity and Access to Care

Equity in access to DHT technologies is another significant concern, especially in the context of older adult care. Although DHTs hold promise for personalized care, disparities in access to technology may exacerbate existing health inequities [16].

Technological Barriers Affect Older Care

Older adults, particularly those from disadvantaged socioeconomic backgrounds, may have limited access to the required digital infrastructure or struggle with digital literacy. Furthermore, some older individuals may face technological barriers, such as a lack of internet access or difficulty operating digital devices, which limit their ability to benefit from DHT-based care solutions.

Disparities in Health Outcomes

Research studies by Bahrami et al [7,18] highlighted how inequitable access to tailored drug therapies and health interventions could worsen disparities in health outcomes if these technologies were not broadly accessible or affordable. Barbiero et al [11] similarly argued that without equitable distribution and access to DHT-based care models, exacerbating the social determinants of health and creating new forms of inequality in health care delivery were at risk.

To achieve true personalization of care, DHTs must be deployed with an emphasis on overcoming these access barriers, ensuring that all older adults benefit equally from these advancements.

Effectiveness of DHT Implementation in Relation to Location, Timing, and Context

The location and timing of DHT implementation significantly influence its effectiveness in care settings for older adults. Liu et al [26] and Bruynseels [12] showed that the efficacy of DHTs could vary considerably across different care environments, including home care, nursing homes, and hospital settings.

Limited Resources Cause Challenges in DHT Implementation

The technological infrastructure of these settings played a crucial role in determining the feasibility and success of DHT integration. For example, in-home care environments, where resources might be limited, implementing DHTs could be more challenging compared to well-equipped health care facilities [29].

Rapid Deployment Leads to Insufficient Validation of DHT Implementation

Furthermore, the timing of DHT deployment can influence its impact. This then emphasized the integration of DHTs during a health crisis (such as the COVID-19 pandemic), accelerated adoption, but also raised challenges related to rapid deployment [21], including insufficient validation and potential overreliance on untested technologies. The timing of DHT use in disease progression was also critical—early-stage interventions, particularly in conditions such as dementia, are most beneficial, as they could significantly improve patient outcomes [34].

Therefore, the contextual environment in which DHTs are deployed must be carefully considered to maximize the benefits of these technologies.

Ethical Concerns: Autonomy, Consent, and Overdiagnosis

Ethical concerns are central to implementing DHTs, particularly in terms of patient autonomy, informed consent, and the risk of overdiagnosis.

Informed Consent Becomes a Complex Ethical Issue

Many older adults, especially those with cognitive impairments, might face challenges in providing informed consent for digital health interventions [30]. Informed consent in these contexts became a complex ethical issue, as health care providers must balance the benefits of personalized care with the need to protect vulnerable patients' rights to autonomy and decision-making [22,26,28].

The Issue of Overdiagnosis Leads to Harmful Side Effects and Unnecessary Treatments

In addition to autonomy and consent, the issue of overdiagnosis was another significant ethical concern. Lin et al pointed out that the predictive capabilities of DHTs might lead to overdiagnosis, particularly in screening programs, resulting in unnecessary treatments and interventions. This concern was especially relevant for older populations [22], where the risks associated with overdiagnosis—such as the potential for harmful side effects or unnecessary treatments—are more pronounced due to comorbidities and frailty [26].

While DHTs offer the potential for early detection, they must be used judiciously to avoid these unintended consequences and ensure that interventions are genuinely beneficial rather than causing harm.

XSL•FO
RenderX

Impact on Care Workflow and Provider Workload

Introducing DHTs into care settings for older adults may significantly alter the care workflow, with both positive and negative implications.

The Need for Enhancing Care Efficiency

Studies by Bahrami et al [7] and Bui [21] highlighted that DHTs could enhance care efficiency by automating specific tasks [21], such as continuous health monitoring, data collection, and decision-making support [7]. These improvements could reduce the burden on health care providers and streamline care coordination. However, integrating these technologies also required adaptation to new systems and workflows, which might lead to initial disruptions and increased workload.

The Need for an Increase in Training Requirements for Existing Practices

Furthermore, as health care providers become familiar with DHT technologies, there may be an increase in training requirements and adjustments to existing practices, which could potentially lead to a higher workload in the short term. While the long-term benefits of DHTs, such as reduced manual tasks and improved diagnostic accuracy, are clear, the transition period must be carefully managed to avoid burnout or resistance among health care staff.

Therefore, successfully integrating DHTs into care settings for older adults requires thoughtful planning to balance the expected workflow improvements with the challenges of training and adapting health care staff to new technologies.

Strategies to Mitigate DHT Challenges

Several studies propose strategies to mitigate these ethical challenges that prioritize inclusivity, transparency, and patient autonomy (see Multimedia Appendix 1). Governance frameworks were aimed at ensuring the data had openness and privacy [12]. On the other hand, Sahal et al [32] and Zhou et al [33] advocated for integrating blockchain technologies and decentralized models to enhance data security and user control. In addition, Vidal et al [28] and Wickramasinghe et al [31] highlighted the importance of multidisciplinary collaboration and integrated care models, such as integrated living models, which promoted coordinated care and supported the ethical implementation of DHTs in practice [28,31].

Collectively, these studies illustrated a shared understanding of both the opportunities and ethical responsibilities associated with the deployment of DHTs in older adult care settings. There has been a consistent call for robust ethical oversight, patient-centered governance, and policies that ensure equitable access to these technologies [12,21,23].

Further Suggestions

Several studies offer suggestions for improving DHT integration into health care. Most studies highlighted ethical and quality of care challenges in care settings for older adults and recommend developing clear guidelines for using DHT (see Multimedia Appendix 1). For instance, Venkatesh et al [9] suggested considering computation, implementation, and regulation challenges to ensure the proper functioning of health digital twins for precision medicine. These suggestions highlighted the importance of addressing technical and ethical hurdles for DHTs to integrate into health and care systems fully.

Discussion

Principal Findings

The implementation of DHTs in health and social care for older adults presents both significant opportunities and inherent risks. In this scoping review, 20 studies were included from a total of 856 identified through a systematic literature search. This review aims to gain insights into the best available evidence on the implementation of DHTs for older adults in health and social care. This discussion critically examines five key challenges that emerge from the literature. These challenges include (1) data security and privacy concerns; (2) equity and accessibility of health care; (3) effectiveness in relation to context, timing, and location; (4) ethical implications regarding autonomy, consent, and overdiagnosis; and (5) the impact of DHTs on health care workflows and provider workload. Overcoming such issues will ensure that DHTs contribute to the quality of care of older individuals and do not take away from it.

The increasing reliance on DHTs requires robust data protection, particularly for vulnerable populations, such as older individuals. DHTs are based on large multimodal datasets, including biometric data, health records, and real-time environmental sensing, which raise significant ethical and privacy concerns [26,30]. Several studies highlight the risks associated with unauthorized data access and potential misuse, particularly for older individuals who may lack familiarity with digital systems and, consequently, are more vulnerable to exploitation [5,12]. Although DHTs provide substantial benefits, such as continuous health monitoring [40] and predictive health care analytics [7], they also introduce risks, including data breaches and unwarranted surveillance [19]. The establishment of ethical guidelines that mandate transparency, accountability, and patient consent is essential in curbing these threats [20]. Blockchain technology, as proposed by Sahal et al [32], could potentially provide a safe manner of data management; nonetheless, empirical investigations are required to ascertain its usefulness in real-life health care settings.

While DHTs offer potential advancements in personalized health care, concerns remain regarding equitable access. The digital divide, particularly amongst older cohorts within lower socioeconomic segments, stands to exacerbate health care disparities [21]. Furthermore, digital twin-controlled drug therapies and individualized health interventions may inadvertently become privileged health care solutions, accessible predominantly to wealthy populations, thereby further aggravating existing disparities [11]. Equity must take precedence while deploying DHTs, with policy measures to curb accessibility barriers through government policies, ring-fenced finances, and digital literacy programs. Otherwise, integrating DHTs will likely widen health and care inequalities rather than bridge them.

The performance of any digital health technology dramatically depends on the environment in which they are implemented

XSL•FO
RenderX

[41,42]. Studies show that DHTs perform optimally in well-structured health care settings, such as hospitals and specialist clinics, with strong technological infrastructures that support real-time patient location and accurate data integration [26]. The usefulness of such technologies in home-care environments where technology and care capabilities are limited has not been adequately established [27]. On the other hand, the timing of DHT implementation is also a critical factor influencing its success. The rapid adoption of DHTs during the COVID-19 pandemic raised concerns regarding premature reliance on untested digital health solutions [20]. Similarly, DHT interventions conducted early in the course of dementia care are more beneficial than interventions done in later stages [19], and improve pain management and reduce patient outcome variability with the effect of physiological features on the achieved pain relief [18]. Therefore, strategies for implementing DHT must be customized according to individual health status, disease stages, and diverse care settings to optimize their impact.

The application of DHTs generates complex ethical questions, primarily about patient autonomy and informed consent. Older people with impaired cognition may be unable to fully grasp the implications of consenting to continuous digital health monitoring [29]. In addition, coercion, the compulsion that persons may feel in adopting DHTs by virtue of health care policy or social culture, is of interest to voluntary involvement [21]. The second ethical concern is overdiagnosis [43,44]. DHT predictive algorithms can lead to an overestimation of disease risk and, consequently, unnecessary medical procedures that increase patient anxiety and place additional pressures on health care systems (Lin et al [22]). While early diagnosis is one of the significant advantages of DHTs, careful calibration is necessary to distinguish between necessary interventions and overmedicalization. Ethical guidelines governing the use of DHT must prioritize informed patient choice over algorithmic assumptions, so that clinical decisions are made appropriately based on clinical need [28,45].

The presence of DHTs in geriatric care settings has conflicting effects on health care workers. On the one hand, DHTs can streamline care processes, reducing administrative workload through automated data collection and real-time patient monitoring, thereby enhancing clinical decision-making [7,20]. On the other hand, the transition to DHT-based care models necessitates significant changes to clinical workflows, potentially increasing short-term workload and requiring extensive training [31]. This necessitates that health care professionals be adequately trained to interpret and apply DHT-generated insights to patient care plans. Research by Alves et al [5] suggests that virtual reality (VR)-based training simulations facilitate the integration of digital twin technology before full-scale implementation. However, unless carefully managed, there is a risk of overreliance on automated decision-support systems, potentially undermining the clinical judgment of health care professionals [23]. Consequently, the integration of DHTs must be approached with caution, ensuring a balance between technological efficiency and the human expertise essential to high-quality patient care.

Strengths and Limitations of the Study

The study provides a strong ethical analysis, but it would benefit from more involvement of health care professionals and older adults, which could have enriched the findings with practical insights. The study highlights the importance of balancing technological innovation with ethical considerations to ensure DHTs enhance, rather than compromise, the quality of care for older adults. One of the key advantages is that this provides valuable insight into the benefits. A key strength is a systematic approach; the guidelines by JBI's methodology for scoping reviews ensure methodological rigor. This study is comprehensive, as it consolidates evidence from various studies on the safety, equity, practicality, ethics, and impact on care workflow of these digital clinical points of care. This illustrates the potential of DHTs in early disease detection and dementia, particularly in highlighting their potential contribution to preventive health care [19]. However, concerns over overdiagnosed patients and unintended consequences, including heightened anxiety and unnecessary procedures, highlight the lack of empirical validation [22].

A significant limitation is the use of secondary data drawn mostly from the published literature, which may exhibit bias or an evidence gap, particularly in the context of mask implementation for DHTs in practice. Another drawback of the study is that the latest search was conducted in October 2023; no further search could have been performed due to lack of resources, including funding and the research team's time commitment. For the same reason, that is, the lack of resources, we also did not follow the JBI Methodology strictly, but instead used it as a guide. Although the search identified 786 studies, some may have been missed. Due to the strict adherence to quality assurance in the gray literature search, including the credibility, objectivity, and accuracy of non–peer-reviewed sources, no unpublished articles could have been included in this review, except the study by Bui [21] (thesis) in 2023. Another limitation is that only studies published in English were included. However, the findings of 20 included studies relate to a range of 14 countries worldwide, with most studies emanating from the United Kingdom and Europe.

Ethical Frameworks and Policy Development

The following key considerations should guide future practice and policy:

- The implications of this study emphasize the necessity for solid ethical guidelines and policy frameworks to mitigate the potential risks associated with DHT application in older adult care and to ensure that the patient remains the ultimate decision-maker [30,46,47].
- Patients' autonomy and data privacy should be protected while fair access to technology that has the potential to enhance patient care is maintained [20,21].

Health Care System: Adaptation

To support the effective integration of DHTs into care for older adults, several key considerations for system adaptation can be identified:

XSL•FO
RenderX

- This study clearly highlights the pressing need for health and social care providers and institutions to integrate DHTs thoughtfully [48].
- It is imperative to strike a balance between the benefits offered by these technologies, particularly their predictive and monitoring capabilities. Concerns may then be related to overdiagnosis, increased workloads, and the potential for disparities in care delivery [7,22].
- Limitations associated with relying solely on secondary data could indicate that future research should prioritize empirical validation through direct engagement with health care professionals, caregivers, and older adults [49,50].
- Engagement is essential for refining the practical applications of DHTs and effectively assessing their real-world impact [9,19,29].

Future Research and Stakeholder Engagement

The following key directions are proposed to guide future research and strengthen stakeholder engagement:

- Given the limitations of relying on secondary data, future studies should prioritize empirical validation through co-design with stakeholders, such as health care professionals, caregivers, and older adults.
- All to refine the practical applications of DHTs and assess their real-world impact [19,29].
- To address stakeholder engagement and practical relevance, the findings can be effectively translated into practice through the development of guidelines and frameworks.
- Further research can examine other dimensions of the quality of care, such as access, timeliness, acceptability, and appropriateness.

Conclusion

This scoping review was conducted to assess the available evidence on implementing DHTs for the care of older adults, highlighting both significant opportunities and inherent risks. A systematic search of the literature yielded 20 studies from an initial 856 records. The studies revealed several critical characteristics regarding the implementation and ethical considerations of DHT technologies, particularly in terms of safety, equity, timing, location, participant characteristics, and their impact on workflow. A total of 5 key challenges were identified through the integrated synthesis, which is crucial for understanding the potential and limitations of DHTs in enhancing care for older adults. The challenges included (1) data security and privacy concerns; (2) equity and accessibility of health care; (3) effectiveness concerning context, timing, and location; (4) ethical implications regarding autonomy, consent, and overdiagnosis; and (5) the impact of DHTs on health care workflows and provider workload. The implications of these challenges underscore the need for more practical ethical guidelines and policy frameworks to mitigate the potential risks associated with DHT application in older care, ensuring that patients remain the ultimate decision-makers. Further research should be conducted to examine other dimensions of the quality of care, such as timeliness, acceptability, and appropriateness.

Acknowledgments

The authors would like to thank Evalill Nilsson and the librarians from Linnaeus University and the University of Bradford for their guidance and assistance in this research. A small grant, specifically the Brad-Attain Research Placement, was received from the University of Bradford for a student working on this project. A publishing grant has been obtained from Linnaeus University as a part of the University Library's research support.

Data Availability

All data generated or analyzed during this study are included in this published article.

Abstract

Background: Lighting, especially circadian lighting, significantly affects people with dementia, influencing sleep patterns, daytime alertness, and behavioral symptoms such as agitation. Since individuals experience and respond to light differently, measuring personal lighting exposure is essential for understanding its impact on health. Without individual data, the connection between lighting and health outcomes remains unclear. Wearable sensors provide a practical way to track personal light exposure, helping researchers better assess its effects on circadian rhythms and overall well-being.

Objective: This study aims to develop and validate both calibration and predictive models using wearable lighting sensors to assess individual circadian lighting exposure accurately. By leveraging machine learning techniques and empirical data, we seek to establish a reliable method for health care researchers and practitioners to investigate and optimize lighting conditions for improved circadian health in nursing homes, especially for residents with dementia.

Methods: A combination of controlled laboratory experiments and on-site data collection was conducted using professional spectrophotometer measurements as ground truth. Calibration models were developed for photopic lux and correlated color temperature, while predictive models estimated circadian metrics such as circadian stimulus. The sensors and the developed models were implemented in a real-world health care research project about bright light therapy intervention at 2 assisted-living facilities.

Results: The calibration models for photopic lux and correlated color temperature demonstrated strong accuracy, with an adjusted R^2 of 0.858 and 0.982, respectively, ensuring reliable sensor measurements. Predictive models for circadian stimulus were developed using both simple regression and machine learning techniques. The random forest model outperformed linear regression, achieving an adjusted R^2 of 0.915 and a cross-validation R^2 of 0.857, demonstrating high generalization capability. Upon the implementation of these models, significant individual variations in circadian light exposure were found in the study, highlighting the significance of customized lighting evaluations. These results confirm the effectiveness of wearable sensors, combined with the developed calibration and predictive modeling, in accurately assessing personal circadian light exposure and supporting lighting-related health care research.

Conclusions: This study introduces an effective and scalable approach to circadian light assessment using wearable sensors and predictive modeling. By replacing labor-intensive and costly spectrometer measurements, the proposed methodology enables continuous, cost-effective monitoring in health care environments. However, challenges related to sensor wearability, durability, and user compliance were identified, underscoring the need for further sensor design refinements. Future research should focus on refining sensor integration, expanding case studies, and developing adaptive lighting interventions to enhance circadian health in vulnerable populations.

Introduction

Background of Circadian Lighting and Health

The human circadian system is a complex biological mechanism that regulates various physiological and behavioral processes, including sleep-wake cycles, hormone secretion, and cognitive function [1]. This system is primarily entrained by light-dark cycles, with exposure to light during the day and darkness at night being crucial for maintaining a healthy circadian rhythm [2,3]. Disruption of the circadian system, commonly known as circadian rhythm disruption, has been associated with a wide range of adverse health outcomes, including sleep disorders, metabolic disorders, cardiovascular diseases, and even certain types of cancer [1,4].

Lighting plays a crucial role in the entrainment of the circadian system. Exposure to light, particularly blue-enriched short-wavelength light, during the biological night can suppress the production of melatonin, a key hormone involved in the regulation of the sleep-wake cycle [5,6]. This suppression can lead to disruptions in the circadian rhythm and associated health problems. Conversely, exposure to appropriate lighting during the day can help maintain a healthy circadian rhythm and promote various physiological and cognitive benefits [7].

In the context of nursing homes, residents often experience disruptions in their circadian rhythms due to a variety of factors, including reduced exposure to natural light, irregular sleep-wake patterns, and the use of artificial lighting that may not be optimized for circadian entrainment [8,9]. These disruptions can have significant negative impacts on the health and well-being of nursing home residents, leading to an increased risk of sleep disorders, cognitive impairment, and other chronic health conditions [9]. Recent studies have further highlighted the importance of circadian-effective lighting interventions in improving sleep quality, circadian rhythms, and depression in older adults with dementia [10-12].

Moreover, researchers have emphasized the need for tailored lighting solutions that consider the specific needs and characteristics of the nursing home population. For example, Figueiro et al [13,14] have discussed the importance of circadian lighting for older adults with dementia, as well as explored the role of light and circadian rhythms in this population.

Personal Circadian Lighting Exposure

Assessing individual circadian lighting exposure has become increasingly vital in the health care sector, especially in long-term care facilities, where individuals' circadian rhythms can be profoundly affected by their lighting conditions. In recent years, there has been an increasing focus on the advancement of wearable sensor technologies capable of precisely and conveniently quantifying an individual's light exposure throughout the day. This is crucial for comprehending the effects of lighting on circadian rhythms, hormonal balance, and overall health and wellness.

The significance of precisely quantifying individual circadian lighting exposure in nursing homes is paramount. Multiple studies have underscored the significant impact of lighting on the physical and mental health of older adults, especially those with dementia. A study by Figueiro et al [15] demonstrated that customized lighting interventions in long-term care facilities resulted in notable enhancements in sleep, depression, and agitation among individuals with dementia. This highlights the necessity for precise and individualized lighting exposure data to guide the design and execution of these interventions.

Nonetheless, the existing spectrometer-based methods for quantifying individual circadian lighting exposure are frequently unfeasible for extensive application in nursing homes and other health care environments. These devices are generally cumbersome, expensive, and labor-intensive, rendering them inappropriate for prolonged monitoring and ongoing data collecting. Markvart et al [16] underscored the difficulties in calibrating and rectifying the output from wearable light exposure devices, stressing the necessity for more efficient but effective measuring technology.

Proposed Work

In this study, we developed predictive models to assess personal circadian lighting exposure using wearable lighting sensors. These sensors measured key lighting parameters, including correlated color temperature (CCT), photopic lux, and irradiance levels at the RGB channels. The calibration of these measurements was meticulously conducted through controlled laboratory experiments under various electrical lighting conditions, supplemented by on-site data collection using professional instruments to ensure accuracy. The predictive models, built upon these calibrated lighting parameters, were designed to predict circadian melanopic lux, melanopic equivalent daylight illuminance, and circadian stimulus (CS) values. To demonstrate the practical application of these wearable sensors and the developed models, we employed them in a bright light therapy project within 2 nursing homes. Here, we analyzed variations in circadian lighting exposure across different individuals, showcasing the models' effectiveness in capturing personal circadian light (CL) environments and their potential impact on health and well-being.

Scientific Contributions

This work makes significant scientific contributions by introducing calibration and predictive models built upon machine learning algorithms and rigorous datasets, which effectively replace the costly and complex processes of spectrometer measurement and circadian lighting calculations. These models enable accurate prediction of circadian melanopic lux and CS values via basic lighting measures, making long-term monitoring of personal circadian lighting exposure feasible with wearable sensors.

Furthermore, by showcasing the application of these models in real-world settings, the study highlights the significant variability in CL exposure among individuals, underscoring the importance of personalized lighting assessments.

Finally, by facilitating wearable technology for CL assessment, this study paves the way for more accessible and practical approaches to understanding and optimizing light environments for individual circadian health and well-being, particularly in contexts such as nursing homes where continuous monitoring is crucial.

Literature Review: Current Circadian Lighting Measurement Methods

Accurate measurement of CL exposure is essential for understanding the impact of lighting on the human circadian system and for developing effective lighting interventions. One of the primary instruments used for measuring CL exposure is the spectroradiometer, which is capable of providing detailed spectral information about the light environment [17,18].

Spectroradiometers are sophisticated instruments that can measure the spectral power distribution (SPD) of light, which is the relative energy of the different wavelengths of light present in a given environment. This information can be used to calculate various metrics related to CL exposure, such as the CL adjusted (CL_A) and the CS [19,20].

In addition to spectroradiometers, other instruments such as wearable light sensors and calibrated digital cameras have also been used to measure CL exposure [17,18,21]. These methods offer the advantage of being able to capture light exposure data over an extended period, providing a more comprehensive understanding of an individual's CL exposure patterns.

Predictive modeling approaches have also been developed to estimate CL exposure based on various environmental and personal factors. For example, models have been proposed that use information about the location, time of day, and weather conditions to predict the spectral composition and intensity of light in a given environment [7,22]. These models can be particularly useful in situations where direct measurement of light exposure is not feasible, such as in large-scale studies or in environments where spectroradiometers are not available.

In the context of nursing homes, the use of wearable sensors and predictive modeling techniques can be particularly valuable for assessing the CL exposure of residents. By combining these methods with the data obtained from spectroradiometers, researchers and health care professionals can gain a more comprehensive understanding of the lighting conditions in nursing homes and develop targeted interventions to optimize circadian entrainment and improve the health and well-being of residents [17,23].

Wearable Sensors for Circadian Lighting Measurements

Recent years have witnessed initiatives to create more compact, cost-effective, and user-friendly wearable sensor devices for tracking personal circadian lighting exposure. These devices seek to address the shortcomings of conventional spectrometer-based solutions, offering a practical and accessible method for evaluating an individual's light exposure throughout the day.

A primary difficulty in the development of wearable sensor systems is the compromise between measurement precision and user comfort. Figueiro et al [17] evaluated the efficacy of 3 practical field devices for measuring individual light exposures and activity levels, underscoring the necessity for more adaptable and precise wearable sensor technologies. The contemporary generation of spectrometer-based systems frequently compromises wearability because of their dimensions and measurement principles, in addition to being expensive and labor-intensive to operate.

Researchers are investigating alternate methods for measuring human circadian illumination exposure to tackle these problems. A recent work by Wang et al [24] introduced an innovative wearable sensor device that integrates a tiny light sensor with a microcontroller and wireless communication features, facilitating continuous and discreet monitoring of an individual's light exposure. This integrated sensor system has the potential to address the shortcomings of conventional spectrometer-based solutions, facilitating broader implementation in nursing homes and other health care environments.

Kubicki et al [25] created a wearable sensor platform that integrates numerous light sensors and a machine learning algorithm to assess circadian-effective light exposure, offering a more precise and user-friendly option than current systems. This advanced sensor technology, together with predictive modeling and data analysis, enables health care providers to comprehend the correlation between lighting and the health and well-being of nursing home residents more effectively.

Emerging sensor technologies may provide exciting opportunities to assist people with dementia and their carers in the context of an aging population. Lu et al [26] provided an in-depth examination of how wearable health devices can noninvasively measure vital signs, activity, and sleep in people with vulnerabilities, such as cognitive impairment. Such technologies offer the advantage of being passive (ie, no active engagement necessary on the part of the person with dementia) and are capable of continuous data collection. On this basis, Tiersen et al [27] used user-centered design to design smart home sensing solutions for dementia households, highlighting the need for personalized monitoring solutions that address the issues both patients and caregivers face in their day-to-day life.

Furthermore, Rose et al [28] addressed the emotional and psychological consequences of the introduction of such technologies and reported family caregivers' overall acceptability of using digital technology to record stress, but significant concerns were expressed about privacy invasion and technical complexity. Taking these concerns head-on, Berridge et al [29] created a new self-administered decision support tool to facilitate early advance planning for technology use in dementia care, allowing people in the early stages of cognitive impairment to continue to communicate their preferences about future monitoring and assistance technologies before declining to more advanced impairment. Together, these studies provide evidence that, albeit advantages of sensor technologies for monitoring and providing services to individuals with dementia, implementation should take into account user preferences, safeguarding the patient's privacy, and integrating sensors in existing care practices.

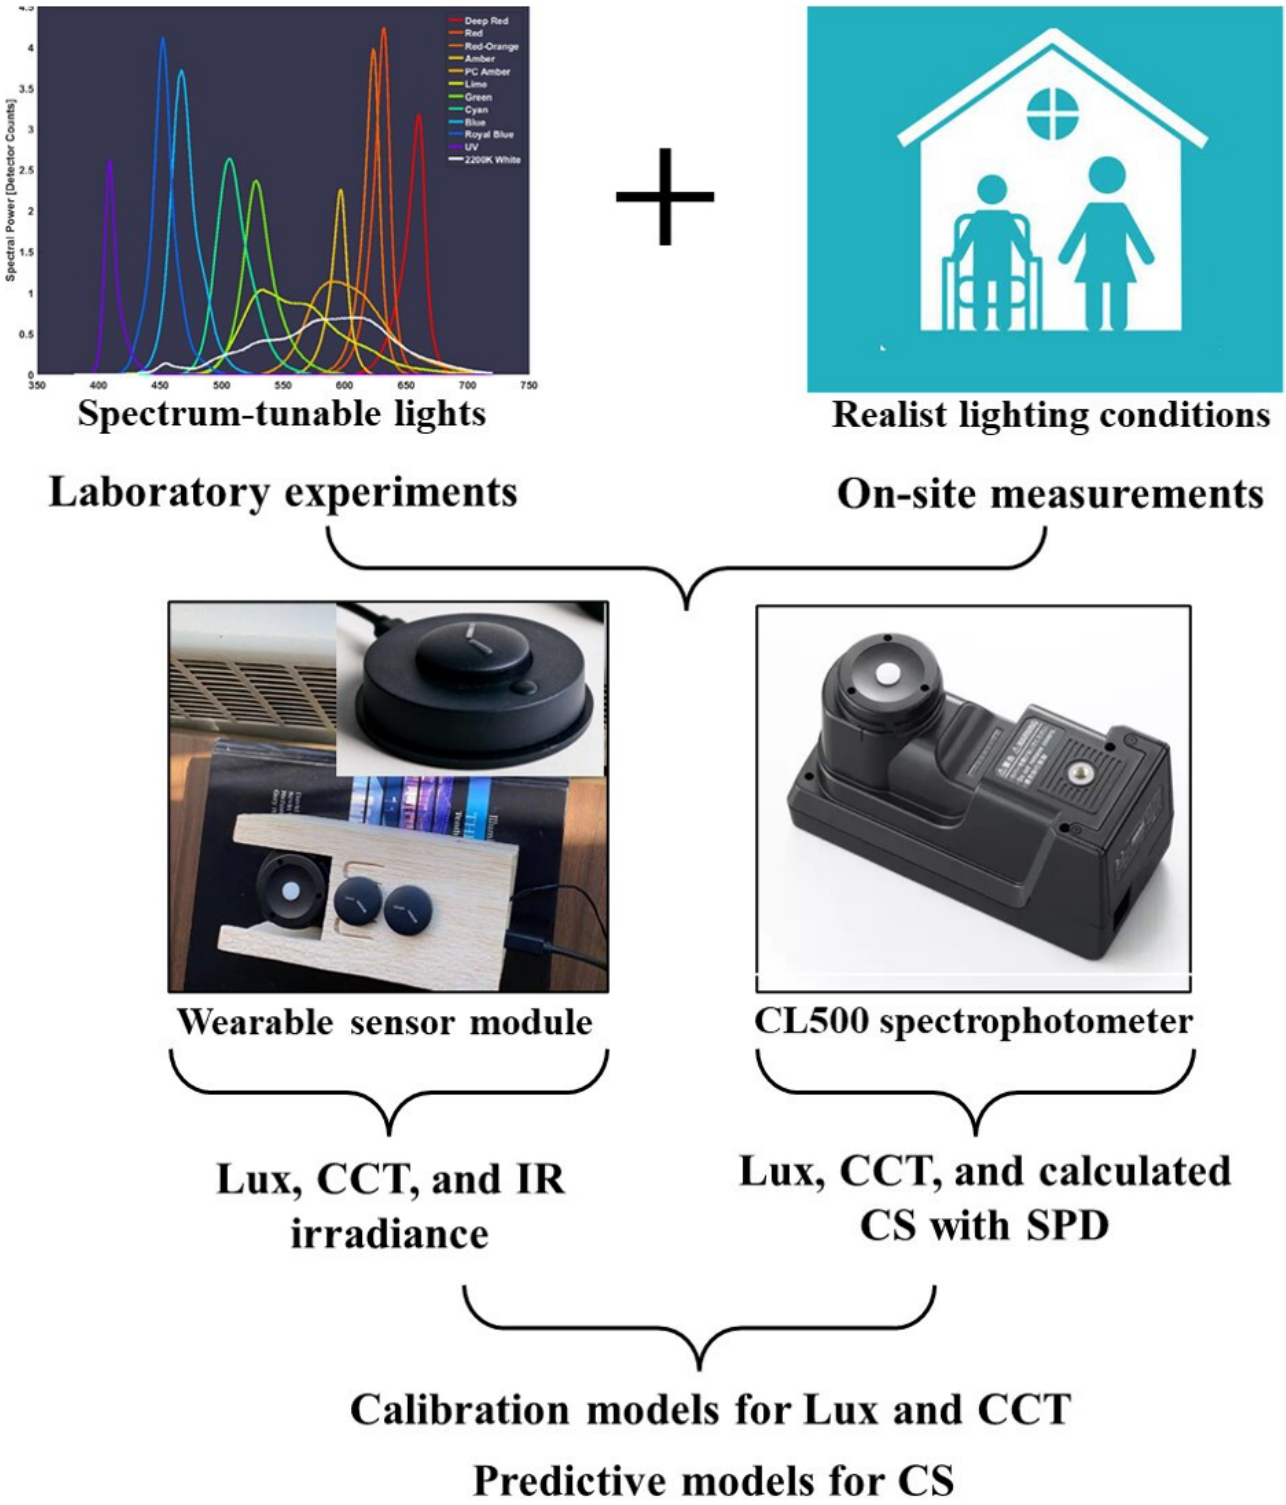
Methods

Ethical Considerations

The study was approved by the institutional review board at The Pennsylvania State University (hereinafter referred to as "Penn State") (STUDY00020216). Resident participants were

XSL•FO
RenderX

assessed for their capacity to provide informed consent using the evaluation to sign consent form. Informed consent was obtained from all residents who were deemed capable. For all residents, regardless of their ability to consent, consent was also obtained from their legally authorized representatives. Resident participants did not receive compensation. However, nursing home staff who contributed information related to residents' mood and behavioral assessments received a US $25 gift card per visit. All hard copy documents containing identifiable information were stored in locked, secure cabinets accessible only to institutional review board–approved research team members. Electronic research data were deidentified and stored on a secure research drive at Penn State, accessible only to authorized members of the research team.



Experiments and Data Collection Procedure

To obtain comprehensive and sufficient datasets (Multimedia Appendix 1) for subsequent calibration and modeling, we conducted both laboratory experiments and field data collection in 2 assisted-living facilities. The laboratory experiments and data collection were completed at the Penn State Architectural Engineering Lighting Laboratory.

Using a professional spectrophotometer, we obtained ground truth data by placing 3 randomly selected wearable sensors and the spectrophotometer in the same position in the laboratory under various electrical lighting conditions. Moreover, to ensure the accuracy and reliability of using such models in assisted living facilities, we also conducted a similar procedure and setup in 2 selected nursing homes. In the laboratory, we simulated relatively more controllable lighting scenarios compared with the field, where we conducted several site visits on different days to capture variations related to weather, room conditions, and interior setup. The same set of instruments, wearable sensors, methods, and experimental setup was used for both laboratory and field measurements. Figure 1 shows the diagram of the major instruments used in this study. The spectrophotometer (CL500) output for photopic lux and CCT served as the reference for calibrating the wearable sensors through regression models. Additionally, the spectrophotometer's SPD data were used to calculate CL_A and CS, which then acted as ground truth data for building predictive models based on the wearable sensor data. Detailed information on the instruments, experimental setup, lighting conditions, and metrics is provided in the subsequent sections. It is of importance to note that both laboratory lighting scenarios and real-world lighting scenarios included daylighting, due to its direct impact on human biology as one of the main themes for our experiment.

Wearable Light Sensor

In this study, we adopted the LYS Button as one of our data collection tools. The LYS Button is incorporated with the LYS app, enabling users to collect data on individual daily CL exposure. The LYS wearable button is a compact and lightweight device and is ideal for individuals such as our human participants and assisted-living residents impacted by mild to moderate dementia, who tend to not respond well to large objects hanging off their clothing. The wearable sensor is an ideal tool when optimizing lighting environments. The LYS Button can track various parameters including photopic illuminance, color temperature, irradiance at R (465 nm), G (525 nm), B (615 nm), and infrared (IR) (1100 nm) channels, and motion. The key features of this wearable sensor are shown in Table 1. One of the drawbacks of the LYS Button is that it does not directly output circadian lighting levels, such as melanopic lux and CS. The availability of light data through the R, G, and B channels using the LYS device, which can be converted to melanopic

XSL•FO
RenderX

data, was of importance and value, hence why it was selected for this study.

Table . LYS Button: key features.

Feature	Specification
Illuminance measurement	0.1-100,000 lux
Color temperature measurement	1800-10,000 K
Continuous monitoring and data logging	Enabled
Connectivity	Bluetooth to mobile app
Battery life	Up to 7 days per charge
Design	Compact, discreet, and wearable
Companion mobile app	Data visualization and analysis

Spectrophotometer

CL500A Illuminance Spectrophotometer (Konica Minolta) was used In this study, as the tool to obtain the ground truth data for developing calibration and predictive models (Multimedia Appendix 2) from the wearable sensor data. It can measure illuminance, CCT, color-rendering index, and many other color or light parameters. Also, the instrument uses a silicon photodiode array and a diffraction grating to provide full SPD data, which can be then computed to obtain CL_A and CS. The other key features of CL500A are listed in Table 2.

Table . CL500A Spectroradiometer: key features.

Feature	Specification
Spectral measurement range	360-780 nm, 1-nm resolution
Illuminance measurement range	0.01-100,000 lx
Calculated parameters	Chromaticity coordinates, CCT[a], and CRI[b]
Display	Large, easy-to-read color liquid crystal display
Data transfer	USB interface to a computer
Design	Compact and lightweight, portable
Calibration	Traceable to national standards

[a]CCT: correlated color temperature.

[b]CRI: color-rendering index.

Laboratory Data Collection

Overview

We conducted our experiment at the Penn State University Architectural Engineering Lighting Laboratory, adhering to specified standards to ensure the precision and dependability of our results. Our methods conform to relevant international standards, including ISO 17025 for laboratory quality management. The laboratory is equipped with NIST-traceable luminaires, which allowed us to create a variety of electrical lighting conditions. Photopic lux levels ranged from 10 to 10,000, and CCT values spanned a broad range between 1500 to 10,500 K. The CCT distribution was achieved using 4 primary indoor light sources with CCT of 1500 K, 3000 K, 4200 K, and 6500 K. These sources were used individually or in combination, and—along with natural daylight entering through windows—they enabled coverage of the broad CCT range. Illuminance levels were similarly generated using these 4 dimmable light sources, allowing fine control over light intensity. Higher data density was intentionally designed and collected around 2 key illuminance ranges: one representing typical indoor artificial lighting and another corresponding to daylight-accessible conditions. As a result, we generated 100 different lighting scenarios by combining various lighting intensities and CCT conditions in the lighting laboratory. For each scenario, we waited approximately 10 minutes to ensure stability before logging 5 data points. The LYS Button wearable sensors automatically documented and uploaded the measured data to a central cloud, while the CL500A's data were transmitted directly to a computer via cable connection.

daylight-accessible conditions. As a result, we generated 100 different lighting scenarios by combining various lighting intensities and CCT conditions in the lighting laboratory. For each scenario, we waited approximately 10 minutes to ensure stability before logging 5 data points. The LYS Button wearable sensors automatically documented and uploaded the measured data to a central cloud, while the CL500A's data were transmitted directly to a computer via cable connection.

We affixed 3 randomly selected wearable sensors to the CL500A spectrophotometer at the same position within the laboratory, enabling the study team to obtain concurrent readings from both instruments. This method facilitated a direct comparison of the measurements and the detection of any inconsistencies between the 2 sensors (Figure 2). The CL500A's output for photopic lux and CCT served as reference points to calibrate the wearable sensors through regression models. Additionally, the CL500A's SPD data were used to calculate CS and melanopic lux, which then acted as ground truth data for building predictive models based on the wearable sensor data.

Figure 2. Data collection at Penn State University lighting laboratory.

On-Site Data Collection

The on-site data collection with the CL500A and LYS Buttons was executed in different residential rooms of 2 assisted-living facilities located in Pennsylvania. We intentionally visited the nursing homes under varying conditions, such as different weather, times of day, weekdays and weekends, and room types (resident rooms, hallway, dining hall, and activity rooms). Furthermore, in each room, the measurements were conducted at various distances from the windows, spanning from 0 to 9 feet, to evaluate the devices' reactions to varying amounts of daylight. The electrical lights were also modulated to form different daylight-electrical light combination scenarios. The window blinds were positioned at 4 distinct slat angles, 135°, 45°, and 90°, as well as the fully retracted position, to evaluate the effect of window shade on illumination conditions. The measurement stations were arranged at multiple viewing angles, ranging from 0°, directly facing the window, to 270° to assess their effectiveness across diverse orientations. The primary light sources in the 2 nursing homes consisted of 3 different CCT types: 1800 K, 2700 K, and 4000 K. Through controlled switching of these sources and adjustment of blinds to modulate daylight access, a broad range of illuminance and CCT variations was achieved. Similar to the laboratory settings, illuminance levels were primarily concentrated in lower ranges typical of dim indoor environments without daylight and in moderate ranges when daylight was present. CCT values were predominantly in the lower spectrum due to the warm indoor lighting but extended to higher levels when daylight contributed to the scene. All these steps and setups aimed to capture sufficient variations in lighting conditions from the window zone (Figure 3A) and the main bed area (Figure 3B) for subsequent calibration and prediction as displayed.

Circadian Metrics Used for Data Processing

CS, closely associated with CL_A, is a metric that directly quantifies the extent of circadian system activation resulting from specific light exposure [20]. Because neither spectrophotometers (CL500A) nor wearable sensors (LYS Button) can output CS directly, we had to extract the raw spectral data from CL500A and then input them into the CS calculator developed by Rensselaer Polytechnic Institute [19,30-32] as seen in equation 1. CS [33], shown in equation 2, is derived from the CL_A value.

.

(2)CS=0.7∗[1−11+(CLA355.7)1.1026]

Equation values and parameters are shown in Textbox 1.

Textbox 1. Equation values and parameters.

CL_A: circadian light adjusted.

Calibration and Predictive Modeling Methods

Calibration Modeling of Photopic Lux and CCT

The calibration process was implemented to ensure the measurement accuracy for the parameters of photopic lux and CCT from LYS. Simple regression calibration was applied first using the data obtained from the reference devices. The original data can be found in Multimedia Appendix 2. The candidate parameters from the reference devices included red, green, and blue (RGB) value, IR light, illuminance, and color temperature.

The photopic lux was calibrated based on the illuminance measurements from CL500A and the measurements from LYS about illuminance, RGB, IR, and CCT. The measurement accuracy of LYS was calibrated for its performance under different lighting conditions. Similarly, CCT from LYS was also calibrated based on the CCT measurements from CL500A. The data screening process was first conducted to check the negative values that were invalid and to enhance the data quality. The feature selection of these candidate parameters for the simple regression model was based on their significant test results. The models were developed and evaluated using a train-test split for the assessment of modeling metrics. In the train-test split method, 70% of the total data were used as a training set to train the model, and 30% were used as test data to value the model's performance. Evaluation metrics including R^2, mean squared error (MSE), and mean absolute error (MAE) were used to indicate the goodness of fit of the model. Equations 3-5 show the mathematical formula used for each of the implemented evaluation metrics.

$$(3)\ MAE=1N\sum i=1N|yi-y\hat{}|$$

$$(4)\ MSE=1N\sum i=1N(yi-y\hat{})2$$

$$(5)\ R2=1-\sum(yi-y\hat{})2\sum(yi-\bar{y})2$$

where $y\hat{}$ is the predicted value of y, and $\bar{y}$ is the mean.

Predictive Modeling of CS

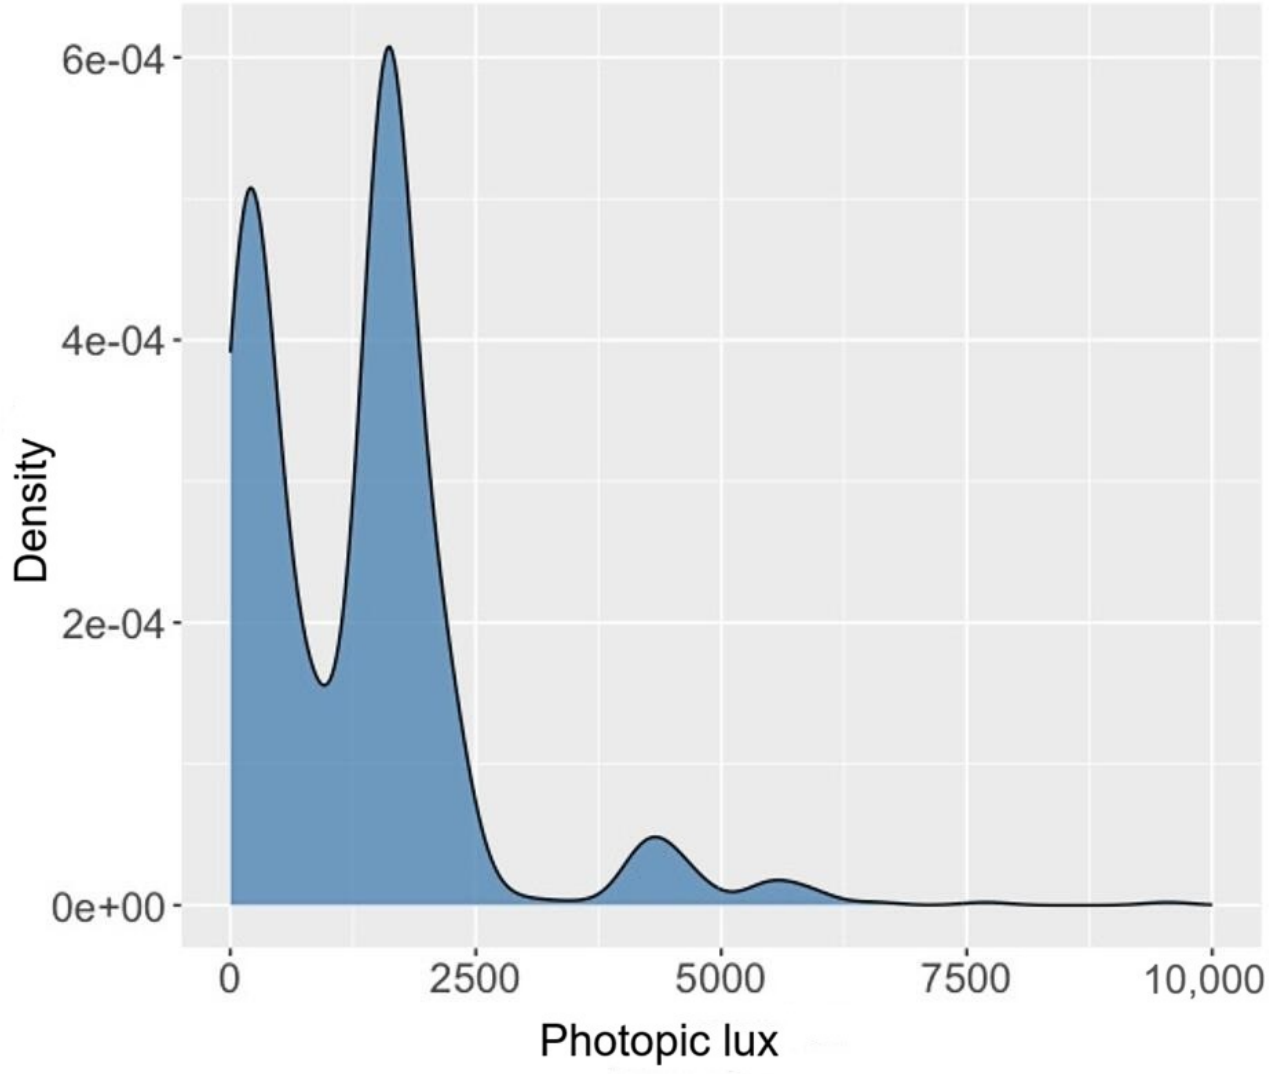
The prediction models were developed based on the available parameters' information for the CS from CL500A. The original data can be found in Multimedia Appendix 2. The calculation of CS has been studied in diverse ways for quick and efficient computation. The LRC Circadian Light Combined Calculator was applied in the study in section "Circadian Metrics Used for Data Processing." The calculator was programmed to enable the output of CS by the input of SPD for a lighting source. The spectral lighting with the wavelength from 360 to 780 nm could be obtained from the CL500A and thus the values of CS were obtained using the CS calculator. The spectral lighting data with a 1-nm interval were first integrated into a 5-nm increment for an efficient computation in the calculator.

After the calculation of the CS, a CL prediction model was developed based on the measured values from LYS including RGB value, IR light, illuminance, and color temperature. The simple regression model was applied first based on the train-test split to check the prediction accuracy using evaluation metrics of R2, MAE, and MSE. To better evaluate the reliability of a prediction model, especially for the data collected under different lighting environments, the 5-fold cross-validation shown in equation 6 was further used to identify the optimal simple regression model.

$$(6)\ CV(k)=1k\sum i=1nerrori$$

where the error can refer to evaluation metrics such as MAE, MSE, and R^2.

To achieve high and satisfactory prediction accuracy, a random forest model was used for predictive analysis if the simple regression model did not meet the desired performance criteria. A random forest model enabled a multitude of decision trees during training and output the mean prediction for regression of the individual trees. This bagging technique, where different subsets of the dataset are used to train each decision tree, made the overall model more robust and less prone to overfitting. Compared with a linear regression, it could provide a comparison of the feature importance which can contribute to the understanding of the influence of the input variables on the output.



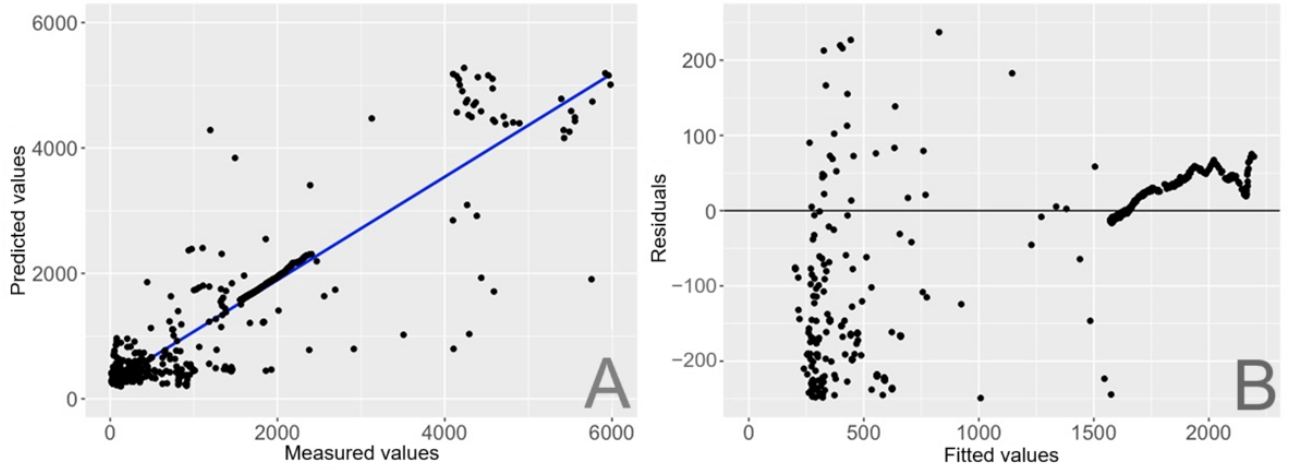
Results

Calibration Model for Photopic Lux

Figure 4 shows the distribution of photopic lux measurements collected from our experiments at both the laboratory and on-site. The data covered a range from ultra-low to high lighting levels, corresponding to 2 main locations. The first peak (at lower lux values) likely represented interior spaces illuminated by artificial lighting, while the second peak (at higher lux values) corresponded to areas near windows with natural daylight exposure.

XSL•FO
RenderX

Figure 4. Photopic lux distribution during data measurement.



For the photopic lux calibration, a simple regression model with acceptable accuracy was obtained. The input parameters, including the LYS Button's output, which include CCT (Kelvin), IR channel irradiance, and illuminance (lux), were selected during the modeling analysis. The calibration function is shown in equation 7. This calibration function adjusts the original measurements from the LYS Button (CCT', IR, and lux') to more accurately reflect true photopic lux (Y). The coefficients (0.0596, 1.6064, and 0·8432) represent the contribution of each parameter to the final calibrated value.

$$(7)\ Y(\text{Photopiclux}) = 0.0596 * CCT' + 1.6064 * IR + 0.8432 * \text{lux}$$

Where CCT', IR, and lux' refer to the original output from the LYS Button—CCT (Kelvin), irradiance of near-IR wavebands at the peak of 1100 nm (W/m²), and illuminance level (lux), respectively—the comma differentiates the final calibrated parameters, CCT, and lux. This may be due to small changes in solar light or daylight, which can significantly boost the lux measurement, as near-IR sources are primarily from daylight. In contrast, the original lux' measurement has a smaller coefficient, suggesting that it was initially less accurate and thus required a substantial adjustment. The CCT' shows a minor but necessary adjustment. Together, these coefficients correct the original sensor outputs to better match the true photopic lux values. The overall adjusted R^2 and MAE for this calibration model are 0.858 and 355, respectively. The goodness-of-fit plot is shown in Figure 5 (A), indicating that the predicted values generally correspond to the measured values. Plot (B) in Figure 5 shows the residuals against the fitted values, in which the residuals are widely dispersed especially at lower fitted values. However, at the higher fitted value range, there is a clear pattern, possibly suggesting model misspecification on the presence of nonlinear relationships. However, for general indoor lighting conditions, the calibration model shows a general trend of aligning with the measured values.

XSL•FO
RenderX

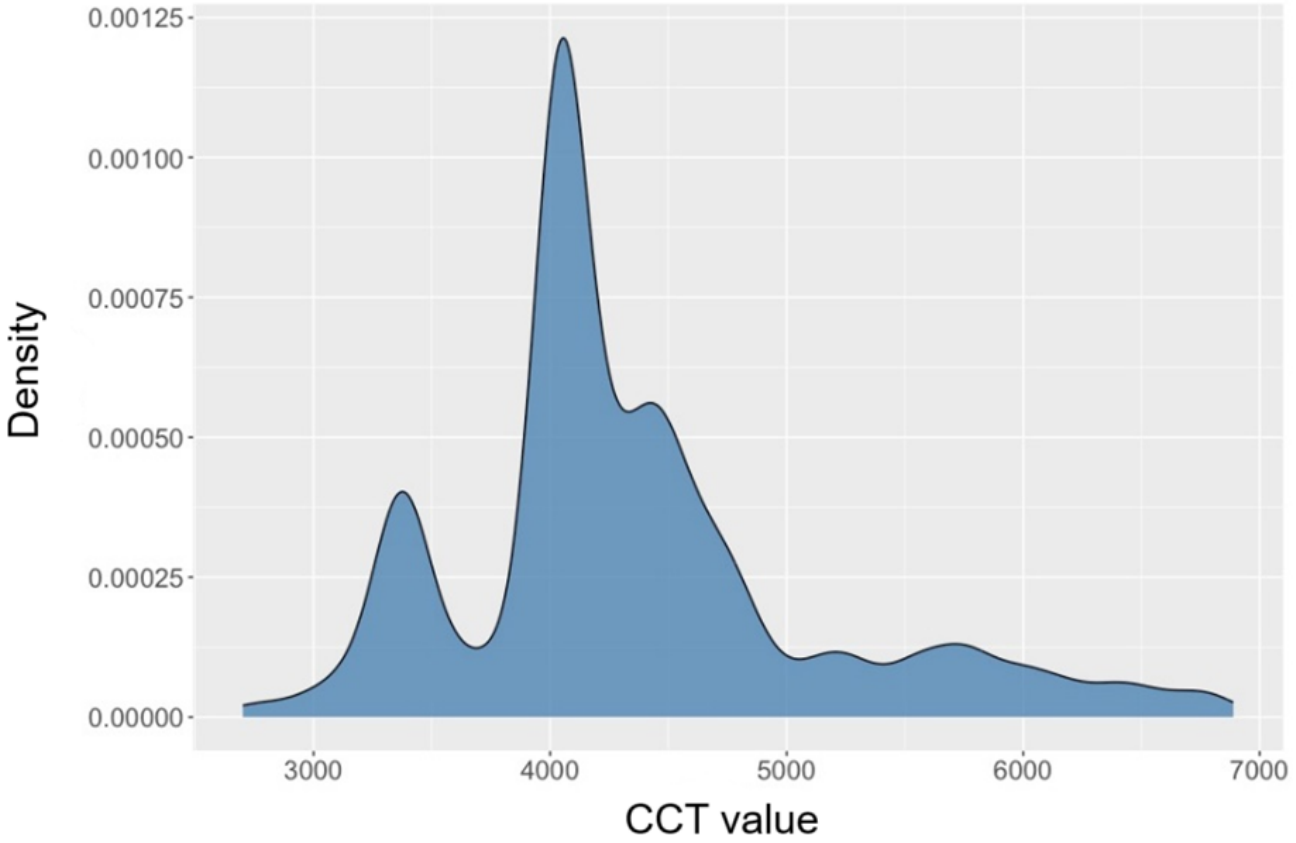


Figure 5. Calibration results for photopic lux: (A) Predicted versus measured values. (B) Residuals versus fitted values.

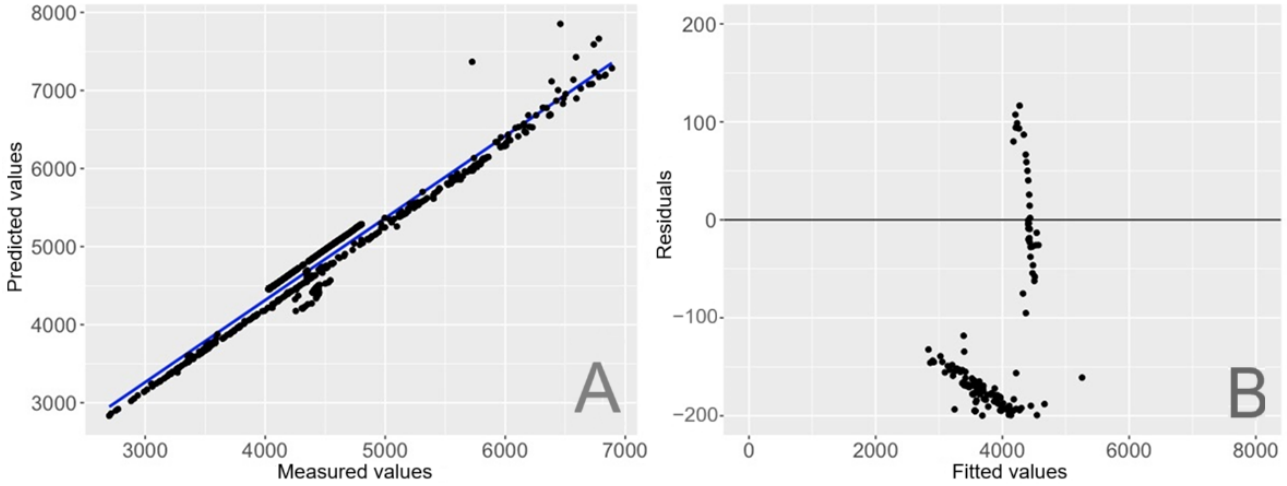
Calibration Model for CCT

Figure 6 illustrates the distribution of CCT values recorded during the data collection procedure. Similar to the distribution of photopic lux, it represents 2 key environments. The initial peak (around 3000 - 4000 K) likely corresponds to artificial interior lighting with a warmer color temperature, while the subsequent distribution (around 4000 - 5000 K) may represent areas near windows with daylight, featuring a cooler color temperature.

Figure 6. Correlated color temperature distribution during data measurement. CCT: correlated color temperature.

Similar to the calibration model of photopic lux, for the CCT calibration, a simple regression model with satisfactory accuracy was also obtained. The input parameters, including the LYS Button's output—CCT (Kelvin), IR channel irradiance, and illuminance (Lux)—were selected again during the CCT calibration model development. The calibration equation is shown in equation 8:



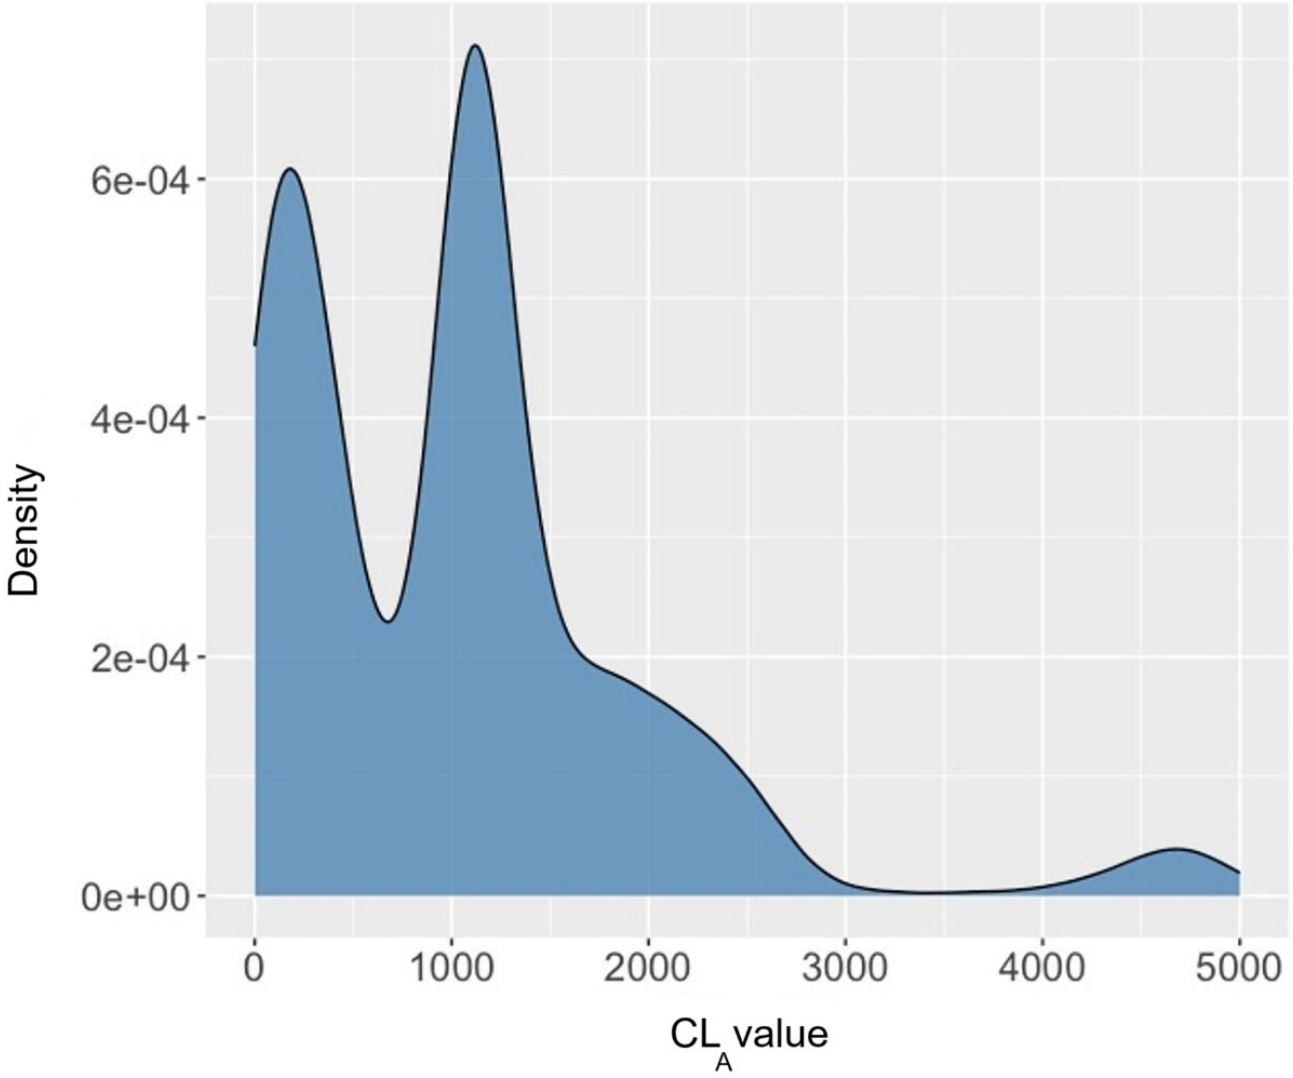
$$(8)\quad Y(CCT)=1.048\times CCT'-0.5427\times IR+0.1761\times lux'$$

In the calibration model, the Kelvin component, with a coefficient of 1.025, shows a strong correlation with the true CCT, indicating that the original CCT values are quite close but require a slight adjustment. The IR component has a relatively strong negative influence on the CCT, highlighting the significant impact of solar IR on the calibration process, likely due to its effect on perceived color temperature, particularly from daylight sources. Together, these coefficients adjust the original sensor outputs to better match the true CCT

XSL•FO
RenderX

values. The overall adjusted R^2 and MAE for this calibration model are 0.982 and 342, respectively. The goodness-of-fit plot is shown in Figure 7A, and the model bias and variance patterns in Figure 7B.

Figure 7. Calibration for correlated color temperature. (A) Predicted versus measured values. (B) Residuals versus fitted values.



Evaluation of Predictive Models for CL_A

Figure 8 represents the distribution of CL_A values collected, which also reflects 2 major lighting conditions. The first peak (at lower CL_A values) likely corresponds to areas with artificial lighting, providing minimal circadian stimulation. The second peak (at higher CL_A values) likely represents zones near windows with natural daylight, which contribute more significantly to CL_A exposure. The remaining distribution tail illustrates sporadic occurrences of very high CL_A values, likely in brightly lit areas with substantial daylight, which is also aligned with the photopic lux data distribution.

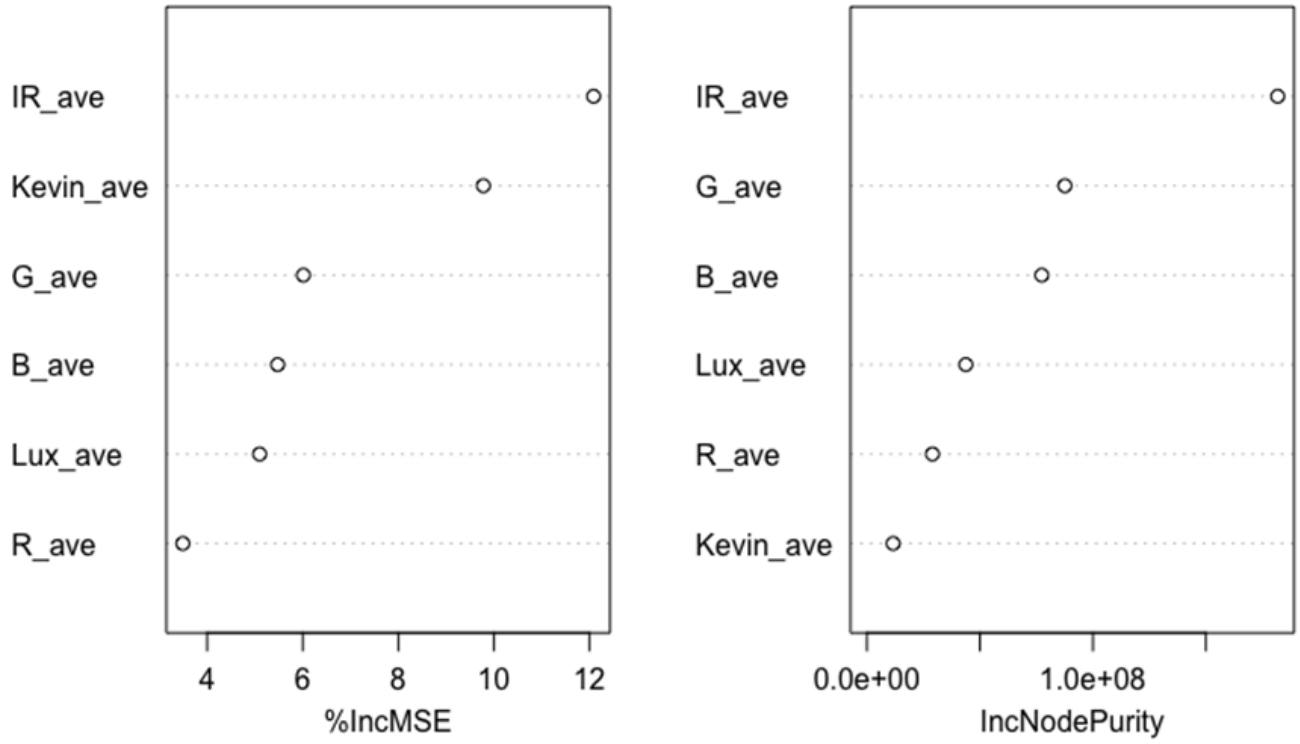
XSL•FO
RenderX

Figure 8. Circadian light adjusted (CLA) distribution during data measurement.

Based on the modeling procedure illustrated in section "Laboratory Data Collection," we obtained both simple regression models and machine learning–based models. As shown in Table 3, the machine learning–based model shows much more accurate performance relative to the linear regression model, with an adjusted R^2 of 0.86.

Regarding the machine learning models, we also conducted the importance feature ranking analysis. Figure 9 shows the variable importance ranking results using 2 metrics %IncMSE (percentage increase in MSE) and IncNodePurity (increase in Node Purity). %IncMSE measures the increase in the model's prediction error when a particular variable is randomly permuted while all others are kept constant. A higher value indicates greater importance, while IncNodePurity is based on the total decrease in node impurities contributed by a variable across all the trees in the forest. As shown in this context, the IR value has the highest in both metrics consistently, which is similar to the calibration model results in CCT and photopic Lux calibration—the potential daylight effects on indoor IR levels drive the variations of circadian lighting level changes. The sensor's original CCT value had a strong direct impact on the model's predictive accuracy, while it might not be crucial for creating pure or homogenous nodes, meaning it did not contribute much to the structure of the decision trees.

Table . Model comparison.



Modeling techniques	Performance	MAE[a]	RMSE[b]
Random forest	0.8567 (cross-validation R^2)	180.53	645
Linear regression	0.645 (adjusted R^2)	491.5	1050

[a]MAE: mean absolute error.

[b]RMSE: root-mean-square error.

Applications in Circadian Lighting Health Research in Nursing Homes

To understand the functionality and usage of the wearable sensors with calibrated and predicted models, we applied the sensors to 29 older adults with dementia in 2 assisted-living facilities as part of a National Institutes of Health–supported project. A post hoc power analysis using GPower 3.1 [36] indicated that with a total sample size of 29 and α=.05, the study had 87 % power [37] to detect a medium effect size (Cohen *d*=0.53), as reported in the previous studies [14,15]. During the personalized data collection from residents, the LYS device was pendant-worn or clipped on the upper body area (eg, upper chest, shirt collar, and shoulder) to more closely approximate eye light exposure. Staff and nurses have been guided to make sure that the attachment of devices is in secure positions as well as constant monitoring of the residents to ensure that the device has not been accidentally removed from the human participant. Researchers also visited sites twice a week to ensure the sensor attachment. Additionally, the LYS device supports real-time remote monitoring. We implement automated algorithms on the cloud to detect potential nonwear or malfunction events (eg, no change in light and motion data readings for more than 2 hours during the daytime and 4 hours during the nighttime). When such events were identified, alerts would be sent to the research team who would follow up with on-site verification and resolution as needed.

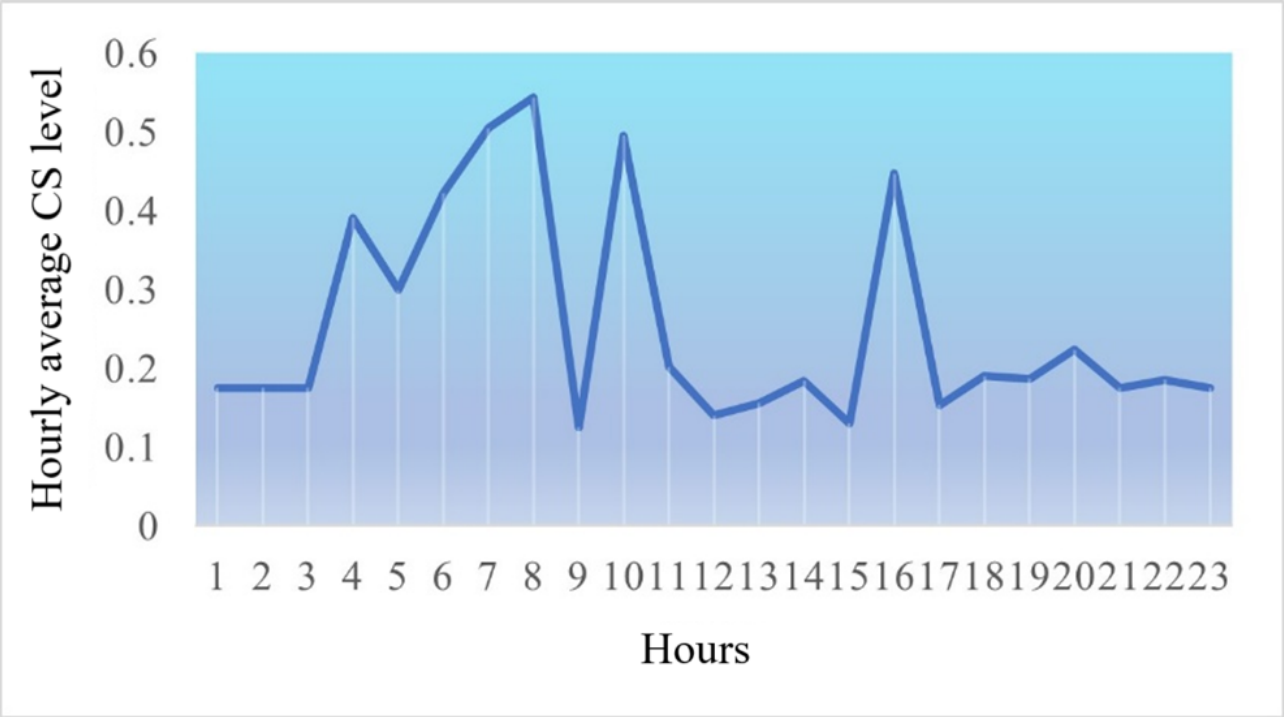
The sensor data for each individual was automatically uploaded to a central computer (Mac Mini) located in the dining hall of the nursing homes to ensure Bluetooth connectivity to all participant residents and then retrieved through a remote connection. By using the calibrated and predicted sensor measurement methods developed in this work, we were able to analyze each resident's circadian lighting exposure, enabling more rigorous and effective intervention analysis.

We then selected specific residents with the widest range of variabilities and differences to demonstrate the applicability of our developed methods within the following sections. It is important to note that any analysis shown in this section is of exploratory value; the relatively small focus of the study in this section was to illustrate the measurement methodology for potential use in future studies on circadian lighting health.

Intervariability of Residents' Lighting Exposures

Understanding the intervariability of residents' lighting exposures is crucial for accurately analyzing the effects of interventions, as it accounts for the differences in physical environments and personal factors among individuals. These 2 residents were particularly selected due to their differences in the dementia stages, the room's window orientation direction, and daily routine and schedules. To do this, we particularly extracted 2 residents' hourly sensor data and then calculated weekly averages of photopic lux, CCT, and CS. Resident 1's room faced south, and resident 2's faced east. Resident 1 had mild dementia, and resident 2 had moderate dementia. It was also observed that resident 1 benefited from the facility's activities such as spending several hours during the day in the sun-lit dining area and having scheduled outdoor visits more frequently than resident 2. Table 4 denotes key differences between the 2 residents selected for detailed analysis in this study, providing context for the observed variations in CS, lux, and CCT measurements in the subsequent sections.

Figures 10-12 are the detailed comparisons in terms of their variations in CS, Lux, and CCT based on our calibrated and predicted measurement models, using a total of 268 data points collected across 5 project weeks and processed using the machine learning and regression models in section "Calibration



XSL•FO
RenderX

and Predictive Modeling Methods" in R Studio [Posit] and visualized using Python features (the main coding information used in this work can be found in Multimedia Appendix 1).

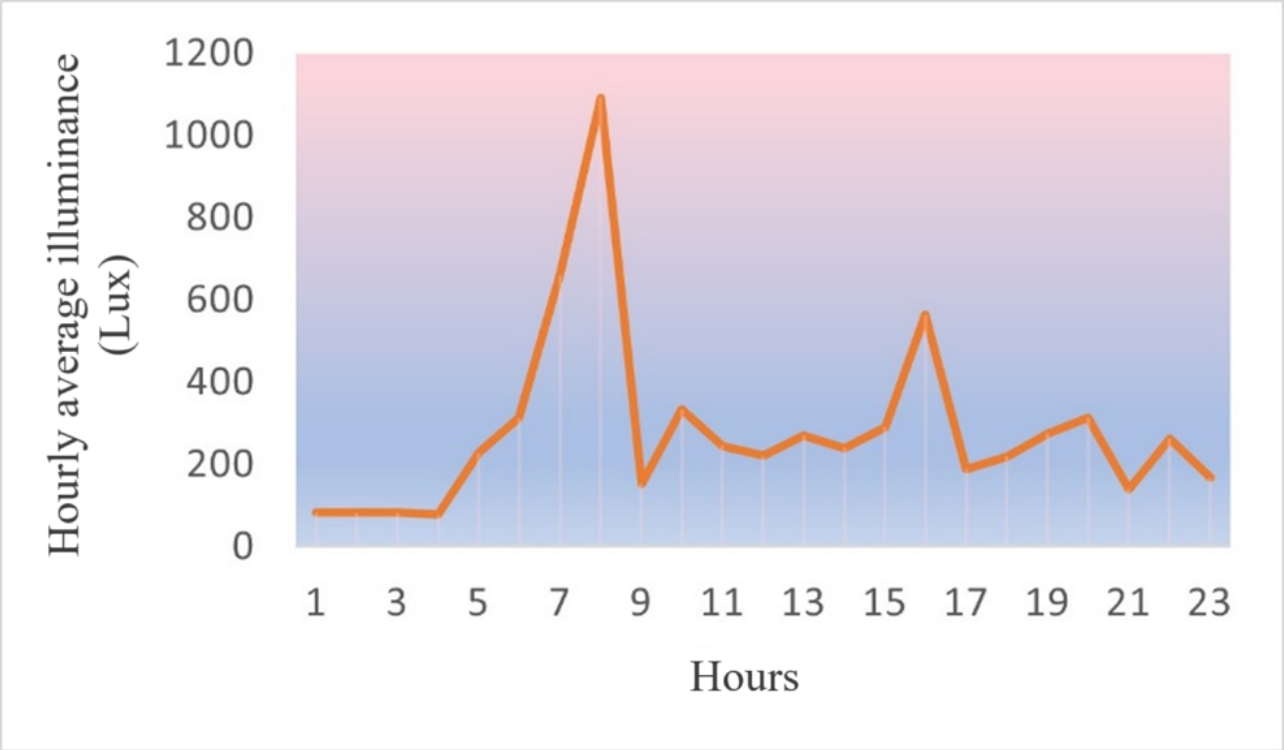
Table . Comparative characteristics of selected study residents.

Characteristic	Resident 1	Resident 2
Dementia stage	Mild	Moderate
Room orientation	South-facing	East-facing
Activity level	High; regular participation	Limited; infrequent participation
Outdoor access	Frequent scheduled visits	Minimal exposure
Daily routine	Structured; time in sun-lit areas	Less structured; more time in room
Sleep pattern	Generally stable	Erratic; disrupted
Light exposure	Consistent throughout day	Morning-dominant
Daytime behavior	Alert; minimal sundowning	Variable alertness; evening agitation

Figure 10. Hourly circadian stimulus intravariability. CS: circadian stimulus.

XSL•FO
RenderX

Figure 11. Hourly illuminance intravariability.



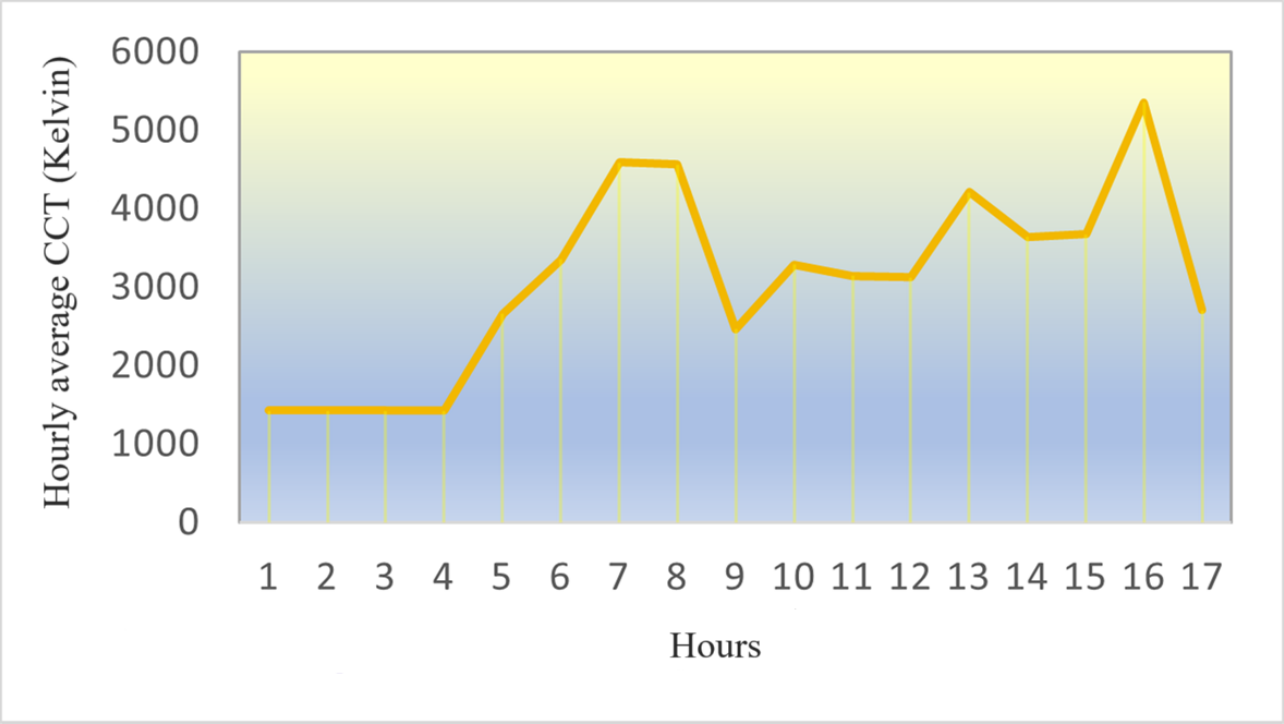


Figure 12. Hourly daytime correlated color temperature variations. CCT: correlated color temperature.

CS Intervariability

Multimedia Appendix 3 visualizes the weekly daytime and nighttime CS value variations of the selected 2 residents across the project. When comparing nighttime CS levels between resident 1 (mean 0.196, variance 0.00223) and resident 2 (mean 0.228, variance 0.00167), the paired *t* test analysis revealed no statistically significant difference between the 2 residents (2-tailed t^4=−1.01; *P*=.368). Although resident 2 showed a slightly higher mean nighttime CS value, this difference was not substantial enough to reach statistical significance at the α level of .05. Analysis of daytime CS levels revealed that resident 1 (mean 0.414, variance 0.00418) demonstrated marginally higher values than resident 2 (mean 0.326, variance 0.00113). This difference approached statistical significance in the paired *t* test (2-tailed t^4=2.43; *P*=.072). While not meeting the conventional *P*<.05 threshold for statistical significance, this trend suggested that resident 1 potentially experienced greater

XSL•FO
RenderX

circadian-effective light exposure during daytime hours than resident 2.

Both residents have higher CS levels during the daytime compared with nighttime throughout the period. Comparatively, across those weeks, resident 1 with moderate dementia generally had higher daytime CS levels and lower nighttime CS levels than resident 2 in most weeks, with the highest average daytime CS of 0.5 for resident 1 during week 5 and 0.38 for resident 2 during week 2, and the highest average nighttime CS of 0.29 for resident 2 during week 5 and 0.24 for resident 1 during week 4. The differences in both daytime and nighttime CS levels between the 2 residents can be attributed to several factors, in particular their different dementia stages, different daytime activity participation levels, and bedroom orientations as pointed out in section "Intervariability of Residents' Lighting Exposures."

Resident 2 with moderate dementia (reported erratic nighttime behaviors and activities) living in an east-facing room and lower daytime CS levels had less participation in the facility's activities and as a result had reduced daylight exposure. As expected, resident 2 displayed higher nighttime CS due to disrupted sleep. Their east-facing orientation provided less consistent and intense daylight than the south-facing room of resident 1, impacting the overall daytime and nighttime CS-level variations between the two.

Lux Intervariability

With regard to weekly daytime and nighttime illuminance level comparisons, there were notable differences between the 2 residents. For nighttime illumination levels, statistical analysis revealed a significant difference between resident 1 (mean 141.58 lux, variance 2558.22) and resident 2 (mean 233.58 lux, variance 4042.12), with the paired *t* test showing statistical significance (2-tailed t^4=−2.78; *P*=.050). This finding indicates that resident 2 experienced significantly higher illumination levels during nighttime hours than resident 1, which aligns with observations of resident 2's reported sleep disturbances and increased nighttime activity. For daytime illumination levels, data analysis comparing resident 1 (mean 422.24 lux, variance 4438.70) and resident 2 (mean 376.36 lux, variance 493.39) showed no statistically significant difference (2-tailed t^4=1.32; *P*=.258). While resident 1 experienced somewhat higher average daytime illumination levels, the considerable variance in resident 1's measurements and the relatively small sample size likely contributed to the nonsignificant finding. This suggests that both residents received comparable amounts of light exposure during daytime hours despite their different room orientations and activity patterns.

As seen in Multimedia Appendix 3, resident 1, who had a milder dementia stage than resident 2 and resided in a south-facing bedroom, was exposed to a sufficient amount of daytime light exposure. This abundance of natural light not only supported resident 1's circadian rhythms, as discussed in section "Intervariability of Residents' Lighting Exposures," but also had the potential to positively impact their mood, alertness, and overall well-being according to the observations. In contrast, resident 2, who had a moderate dementia stage and an east-facing bedroom, experienced slightly lower daytime lux levels than resident 1. However, it is important to note that resident 2's room would still receive natural light exposure, particularly during the early morning hours when the direct sunrise exposure provides a high level of illumination, as both residents ultimately had sufficient average amounts of lux close to 400 per recommendations and standards.

It is worth mentioning that the differences in daytime lux levels between the 2 residents can also be attributed to their varying levels of participation in daily activities and programs. Resident 1, with a lower dementia stage, was likely more engaged in general activities scheduled by the facility, which made a further contribution to their increased exposure to daytime light, due to the activity area being sun-lit from morning to afternoon. In contrast, resident 2, with a moderate dementia stage, may have had reduced participation in activities and programs, leading to slightly lower daytime lux levels. Resident 2 also had significantly higher nighttime illuminance exposure due to erratic sleep patterns.

CCT Intervariability: Accuracy Challenges of CCT Measurements in Dim Conditions

A primary obstacle in quantifying CCT in low-light conditions is the intrinsic difficulty in precisely measuring the SPD of the light source. Rea and Freyssinier [38] emphasize that under low-light situations, the spectral sensitivity of the human eye alters, resulting in possible disparities between the measured CCT and the perceived CCT. This may lead to mistakes when using conventional colorimetric systems, which are calibrated for elevated light levels. Chen et al [39] examined the efficacy of different CCT measurement methods in low-light conditions, showcasing that these challenges are especially evident in low-light conditions, where the signal-to-noise ratio of the measurement may be considerably diminished. Li et al [40] assert that conventional CCT calculation methods may be inadequate for these light sources, as they can display intricate SPDs that may result in erroneous CCT estimations. Owing to these constraints, we exclusively examined the daytime CCT to align more closely with reality.

Analysis of nighttime CCT levels revealed a notable difference between resident 1 (mean 2098.10 K, variance 515642.97) and resident 2 (mean 3733.34 K, variance 1760014.09), with results approaching statistical significance (2-tailed t^4=−2.26; *P*=.086). This trend suggests that resident 2 was exposed to lighting with a substantially cooler color temperature during nighttime hours compared with resident 1, which may help explain some of the observed differences in nighttime behavior and sleep quality, as cooler (bluer) light is known to potentially disrupt circadian rhythms and melatonin production during evening hours. Examination of daytime CCT values revealed no statistically significant difference between resident 1 (mean 4219.44 K, variance 226319.65) and resident 2 (mean 3880.88 K, variance 520702.89) according to the paired *t* test analysis (2-tailed t^4=0.81; *P*=.465). While resident 1 experienced slightly higher color temperature exposure during daytime hours, suggesting some exposure to cooler, more bluish light that typically enhances alertness, the substantial variance in measurements and small sample size resulted in a nonsignificant finding. This

XSL•FO
RenderX

indicates that both residents generally experienced comparable light spectral qualities during daytime, despite differences in room orientation and activity patterns.

With regard to the CCT variations seen in Multimedia Appendix 3, resident 1 tended to experience a slightly higher daytime CCT than resident 2. This can be primarily attributed to the consistent natural light exposures that resident 1 receives for a longer duration throughout the day, due to the south-facing orientation of their room. The increased exposure to this cooler, bluer-toned light can have beneficial effects on the resident's circadian rhythms, cognitive function, and overall well-being.

In contrast, resident 2's east-facing room receives less direct sunlight exposure throughout the day, leading to a relatively lower daytime weekly average CCT. While resident 2's daytime CCT levels are lower than those of resident 1, it is important to note that the early morning sunlight coming from the east, even with a lower CCT, can still help entrain the resident's sleep-wake cycle and promote better synchronization with the natural light-dark cycle. It is seen that resident 1's higher average levels of CCT are also partly due to their participation in outdoor activities, while resident 2 did not participate as frequently.

In sum, the analysis of lighting exposure intervariability among residents, using the regression and machine learning models developed in this study, may provide help to identify moderating factors that may influence the effectiveness of lighting interventions across different residents.

Intravariability of Residents' Lighting Exposures

Examining the intravariability of each resident's light exposure provides insights into the daily fluctuations and consistency of their lighting environments. Especially for circadian lighting intervention studies, this understanding allows researchers to understand individual characteristics and adjust lighting interventions to ensure that target conditions are maintained. From a long-term application perspective, this can also enable lighting system adjustments and personalization to maintain optimal circadian lighting exposure. As such, we particularly select 1 resident who exhibits a mild stage of dementia, with intermittent reports of midnight roaming behaviors.

The hourly data shown in Figures 10-12 were obtained from this resident on 1 weekend day in October with partly cloudy sky conditions. Their room was oriented toward the east, which allows for direct sunshine exposure from sunrise until approximately 9 AM. During the afternoon hours, this resident tended to spend more time in their bedroom, where they received minimal sunshine exposure. In particular, this specific room orientation and the resident's daily routine help explain the observed surge in CS, lux, and CCT measurements during the morning hours.

This resident's CS levels can be explained by their room orientation (east-facing window) as well as their daily schedule on the specific day of data collection. During the lunch and early dinner hours (before 11 AM and around 4 PM), the resident was seated in the dining room, which has large windows and receives abundant natural light throughout the day (Figure 10). Throughout the night, they had low CCT levels, which points to their uninterrupted sleep that evening.

As the sun rises, it shines directly through this resident's east-facing room, contributing to a high level of illumination. Later in the day, around 4 PM, the resident was exposed to the direct, lower-angle rays of the setting sun on the western side of the building (Figure 11). During the evening, illuminance remained at a low level and it was in accordance with the observation of their normal sleep.

The daytime CCT for this resident seems to plummet between 4 PM and 5 PM. This occurrence was likely due to the resident stepping outside briefly scheduled by their daily routine and then going back to the interior where there were much lower CCT conditions (Figure 12). Nighttime CCT data were not processed due to the constraints mentioned in section "CCT Intervariability."

The detailed analysis of this resident's lighting exposure and daily activities highlights the significant role of factors such as room orientation, daily routines, and engagement in facility programs in shaping their overall circadian rhythms and well-being. The data collected showcased the potential benefits of optimizing lighting and daily schedules for residents with mild dementia to promote better engagement and awareness, and the data processing with the models we developed in this study provided insights into the relationship between their circadian lighting exposure and engagement in daily activities. These results can help health care providers, nurses, and families of older adults with dementia to ensure that they are making the necessary lighting and routine adjustments for these residents.

Summary of Application Findings

The application here demonstrated the effectiveness of wearable sensors, combined with calibration and predictive models, in assessing individual circadian lighting exposure. By capturing personal light exposure data, these models enabled a detailed analysis of how factors such as room orientation, daily routines, and activity engagement influence circadian rhythms. This approach highlights the significant variability in lighting experiences among individuals, which traditional group-level assessments may overlook.

The small focus of the study was to validate the measurement methodology for use in future studies of health impacts. We recognize that additional validated research will be needed to perform robust effect analyses in larger and more diverse populations and to determine the broader impact on health. Such efforts can greatly enhance circadian lighting research, enabling more targeted interventions and improving data-driven decision-making in health care environments.

Discussion

Principal Findings

Despite its contributions, this study encountered several challenges related to sensor wearability, durability, and data collection. In the application projects, some dementia residents found the sensors uncomfortable, reducing adherence, while

XSL•FO
RenderX

others unintentionally removed or misplaced them, leading to a 40% loss or damage rate in that project. This highlights the need for more discreet, lightweight, and tamper-resistant sensor designs that seamlessly integrate into daily wear. Data collection also faced limitations, as site-specific environmental conditions and seasonal variations may have influenced results. The study's reliance on a single type of sensor raises concerns about generalizability, particularly in RGB and IR channel sensitivity. Future research should include multisite, long-term studies across diverse lighting conditions and validate models using multiple sensor types to improve accuracy and applicability.

To recapitulate, although the use of LYS Button wearable sensors enabled us to collect continuous personal CL exposure data, factors such as sensor placement variability, individual characteristics, and environmental complexities inherent in nursing homes might affect the generalizability of the developed measurement method. We stress that these issues are common when pioneering new methodologies in real-world settings. By advancing sensor design, expanding case studies, and integrating adaptive lighting solutions, future research can enhance the scalability and effectiveness of personalized circadian lighting assessments. These improvements will support more precise data-driven health care interventions, ultimately contributing to better sleep, cognitive function, and overall well-being in long-term care residents.

Conclusions and Future Work

Using wearable lighting sensors, we developed and validated calibration and predictive models to evaluate individual lighting exposure in terms of photopic lux, CCT, and circadian lighting levels. Controlled laboratory studies and on-site data collection were conducted to calibrate sensor values, as follows: To adjust the raw data from the LYS Button and improve its accuracy, we developed a simple regression calibration using key sensor outputs—CCT (CCT in Kelvin), IR channel irradiance, and raw illuminance (lux). The regression analysis generated coefficients that reflect each parameter's contribution to estimating true photopic lux, with the IR measurement showing a particularly strong influence likely due to its sensitivity to daylight variations. Overall, the calibration model, with an adjusted R^2 of 0.858 and with reasonable MAE, shows that although some deviations remain (especially under low light conditions), it reliably aligns the sensor's outputs with the measured lux values in general indoor lighting scenarios.

As with photopic lux calibration, a simple regression model was developed for CCT using the raw outputs (CCT, IR, and lux) from the LYS Button. The model adjusted the raw CCT values by attributing a strong positive weight to the original CCT output and incorporating the effects of IR and lux, which helped account for variations due to daylight influence. With an adjusted R^2 of 0.982 and an MAE of 342, the calibration effectively corrects the sensor outputs to match the true CCT observed in various lighting environments.

Predictive models were then developed to forecast CS levels based on the calibrated lighting factors, with the random forest model outperforming linear regression, achieving an adjusted R^2 (test) of 0.915 and a cross-validation R^2 of 0.857. The IR value was identified as the most influential factor in predicting circadian lighting levels, further reinforcing the reliability of the model. These results demonstrate the robustness of data-driven modeling for CL assessment, providing a highly accurate and scalable method for personal circadian exposure evaluation.

We then implemented wearable sensors and developed models in a bright light therapy project in 2 assisted-living facilities to demonstrate how these models can be used practically. These field applications in 2 assisted-living facilities revealed notable interindividual variations in CL exposure, with room orientation, daily routines, and engagement in facility activities playing key roles. For instance, residents with higher daytime light exposure, particularly from natural sources, demonstrated more stable circadian patterns, whereas those with limited exposure exhibited signs of disrupted rhythms. Similarly, the residents who have increased engagement in everyday routines, and activities, and availability to steady daylight in the south-facing orientation also had relatively high and stable circadian lighting exposure. When assessed individually only, a specific resident with mild dementia, an east-facing room, and reported nighttime wandering were selected for study on 1 weekend day for 24 hours, and their lighting exposure data were very much in accordance with their behavior and activity patterns within that period. These findings underscore the importance of the lighting assessments at the individual resident level in investigating and optimizing environmental conditions for residents with dementia and related health conditions.

Abstract

Background: Sarcopenia (loss of muscle mass and strength) increases adverse outcomes risk and contributes to cognitive decline in older adults. Accurate methods to quantify muscle mass and predict adverse outcomes, particularly in older persons with dementia, are still lacking.

Objective: This study's main objective was to assess the feasibility of using deep learning techniques for segmentation and quantification of musculoskeletal tissues in magnetic resonance imaging (MRI) scans of the head in patients with neurocognitive disorders. This study aimed to pave the way for using automated techniques for opportunistic detection of sarcopenia in patients with neurocognitive disorder.

Methods: In a cross-sectional analysis of 53 participants, we used 7 U-Net-like deep learning models to segment 5 different tissues in head MRI images and used the Dice similarity coefficient and average symmetric surface distance as main assessment techniques to compare results. We also analyzed the relationship between BMI and muscle and fat volumes.

Results: Our framework accurately quantified masseter and subcutaneous fat on the left and right sides of the head and tongue muscle (mean Dice similarity coefficient 92.4%). A significant correlation exists between the area and volume of tongue muscle, left masseter muscle, and BMI.

Conclusions: Our study demonstrates the successful application of a deep learning model to quantify muscle volumes in head MRI in patients with neurocognitive disorders. This is a promising first step toward clinically applicable artificial intelligence and deep learning methods for estimating masseter and tongue muscle and predicting adverse outcomes in this population.

Introduction

Age-related muscle wasting and neurodegeneration, clinically presented as sarcopenia and dementia, respectively, are the major drivers of frailty, falls, and disability in older adults worldwide [1]. Sarcopenia is characterized by loss of muscle mass, strength, and function in older adults. Aging is the leading risk factor, but conditions such as chronic diseases, inflammation, sedentarism, and malnutrition promote sarcopenia onset and progression [2]. Sarcopenia has a 10% overall prevalence globally in older persons, 29% in the community, 14%-33% in long-term care settings, and up to 50% in the very old (>80) [3,4]. Despite being a common and relevant health-related condition, it is unseen and underdiagnosed,

XSL•FO
RenderX

particularly in older persons with cognitive disorders. To diagnose sarcopenia, measurement of muscle mass, muscle performance, and strength is necessary [2]. Estimating muscle performance and strength is accessible and cheap with traditional methods, such as gait speed and grip strength, respectively [5]. However, techniques such as dual X-ray absorptiometry or body magnetic resonance imaging (MRI) are necessary to accurately assess lean or muscle mass. These methods can increase costs and time and are impractical in settings such as dementia clinics [6].

Dementia patients are highly affected by sarcopenia, with a prevalence of around 60% - 70% [7,8]. People living with neurodegenerative diseases are more prone to experience difficulties due to malnutrition, being sedentary, and falling; therefore, having sarcopenia increases the risk of adverse outcomes. Sarcopenia is not only a risk factor for adverse outcomes for those with dementia but also promotes cognitive loss in healthy older adults [9]. Therefore, diagnosing sarcopenia in people with neurodegenerative diseases is relevant and necessary.

Head MRI is a widely used diagnostic method for assessing dementia and Alzheimer disease (AD), as it offers intricate representations of the brain's anatomy and physiology. In clinical practice, MRI is often combined with other imaging techniques and cognitive assessments to support the diagnosis of these conditions. The utilization of MRI has seen an upward trend in recent times, as it has become an instrumental tool for the early detection and tracking of the evolution of dementia and AD. According to estimates, 60% - 80% of patients diagnosed with dementia or AD undergo MRI as part of their diagnostic evaluation [6].

Mastication and deglutition muscles such as the masseter and tongue are visible in brain MRI scans [10,11]. These muscles can reflect not only age-associated general muscle decline but also systemic processes due to highly complex interactions with the immune system and the inflammatory response, the nervous system, and the crossroads of several components of the frailty syndrome [12,13]. Indeed, in a previous publication, we have reported that manually segmented masseter predicts mortality and clinical short-term and long-term outcomes in several contexts [14]. Moreover, head muscles such as the tongue and masseter could be cost-effective alternatives to estimate muscle mass in dementia and other common conditions such as head cancer, stroke, or cranioencephalic trauma [14,15]. However, manual and semi-automatic techniques are labor-intensive and time-consuming, making the image processing task for large studies difficult, expensive, and, most importantly, impractical to apply in a clinical setting. Therefore, in the present study, we aimed to use MRI scans of the head opportunistically to develop an automated deep learning method to evaluate sarcopenia.

Methods

Population and Data Source

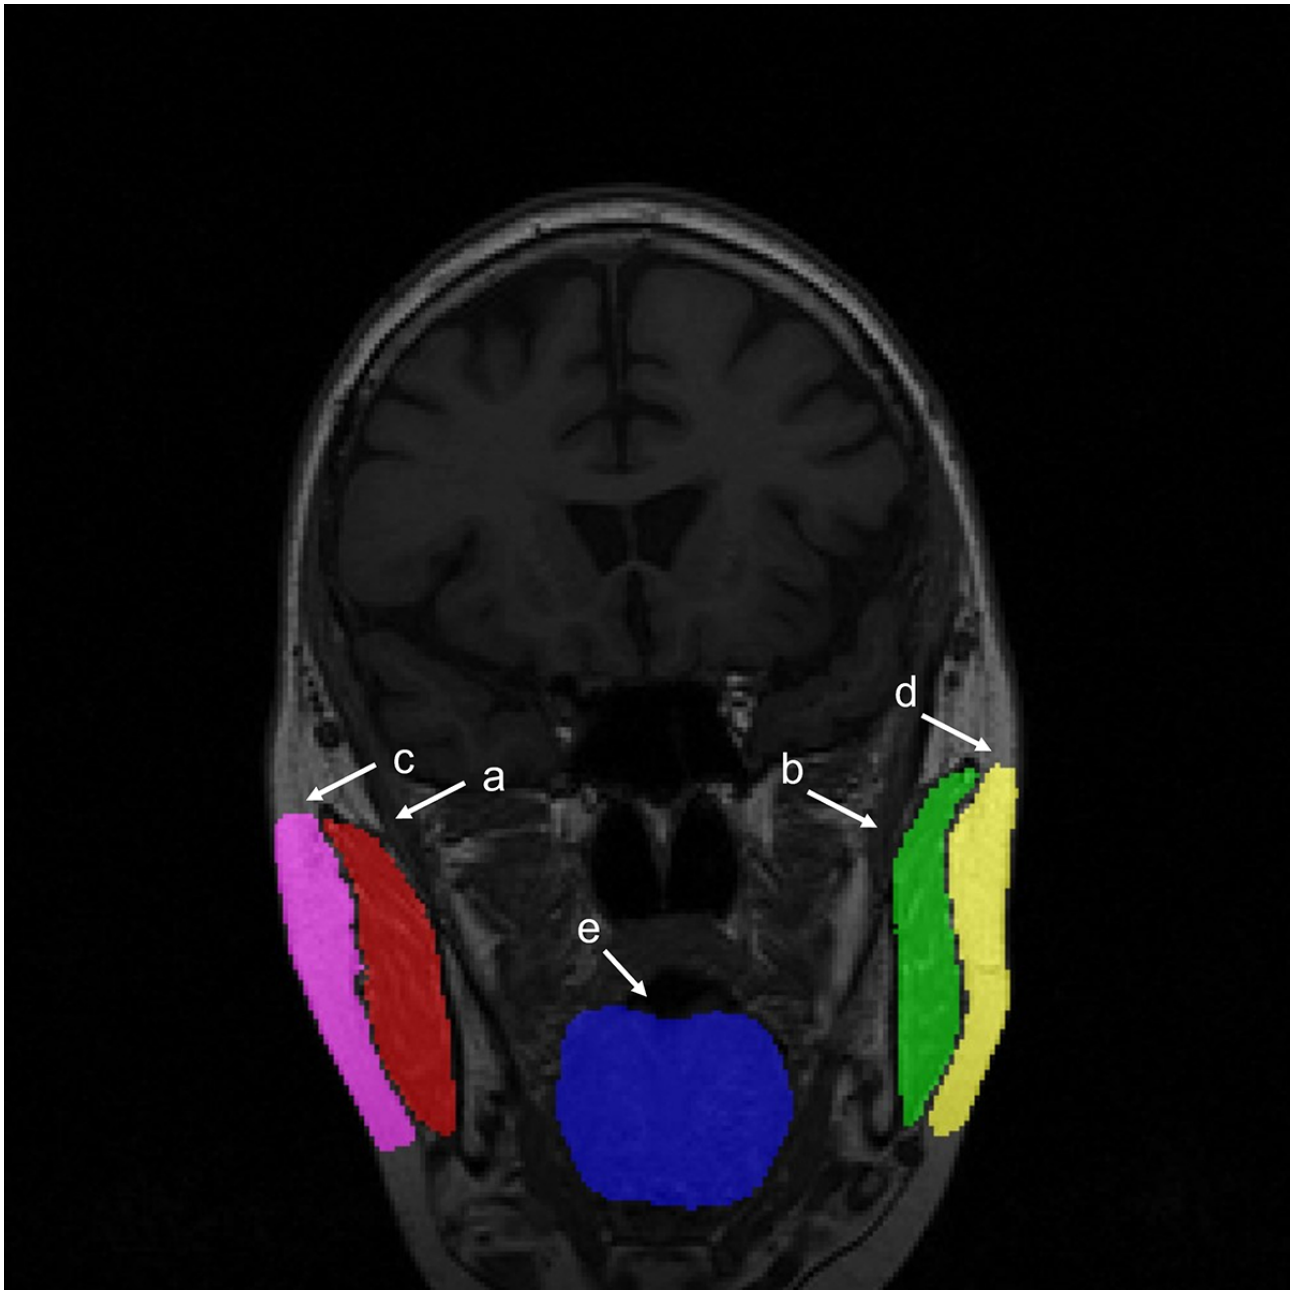
The "Dementia Study of Western Norway" (DemVest) is a long-term study between 2005 and 2013, with ongoing follow-up assessments. Participants were referred from dementia clinics in Hordaland and Rogaland and were insured by the same national insurance scheme. The study's methodology is described elsewhere [15]. Those with moderate or severe dementia, delirium, past bipolar or psychotic conditions, terminal illness, or newly diagnosed somatic diseases impacting cognition, function, or participation were excluded.

For this study, subjects with dementia with Lewy bodies (DLB) or mild AD who had baseline MRI scans were included. Out of 111 participants (85 AD and 26 DLB), 33 AD and 20 DLB participants with MRI images for brain and muscle measurement were selected based on the quality of the images and clear delineation of the regions of interest. The diagnosis of dementia was made in accordance with the Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition (DSM-IV) criteria, and patients were classified as AD or DLB [16]. A mini-mental state examination score of ≥20 or a clinical dementia rating global score of 1 was chosen as the definition for mild dementia. The diagnosis was based on inclusion but could be modified with clinical evolution, consensus, and autopsy [15]. Participants were evaluated through structured assessments, and medical records were used to gather complete medical history and comorbidity data. In total, 56 participants had pathological diagnoses with 80% accuracy compared to clinical criteria, which reflects a reliable initial clinical diagnosis [17].

Ethical Considerations

This study was approved by the regional ethics committee (approval code: 2010/633) and the Norwegian authorities for the collection of medical data. All data were handled and kept following national data privacy protocols. All participants signed an informed consent form before inclusion in the study.

Imaging



All images were acquired at baseline. A 1.5-T Philips Intera-scanner was used to obtain MRI images. The acquisition protocol for 3D T1-weighted sequence was as follows: flip angle of 30°, repetition time/echo time of 10.0/4.6 ms, number of excitations of 2, 2-mm slice thickness with 1-mm spacing between the slices (1-mm slices with no gap), matrix of 256×256 pixels, and field of view of 26 cm. Those with movement artifacts and inadequate image quality were removed from the data using visual quality checks. A standardized preprocessing method for harmonizing multiple collections of MRIs was applied, which consisted of movement correction and intensity normalization following previously validated techniques [15].

Ground Truth Image Segmentation

Ground truth (GT) images were segmented using interactive pixel techniques made available by SliceOmatic software (TomoVision) following a manual method previously reported [18]. The size of the masseter muscle was used as a reference for the selection criteria of the slices. In total, 5 slices were selected from the ones with both right and left masseter muscles at their largest. For each slice, 5 tissues were segmented: left and right masseter muscles, left and right subcutaneous fat, and tongue muscle (Figure 1). The masseter muscle on each side was used as a reference to segment subcutaneous fat.

Network Architecture

We studied and compared 6 different U-Net-like architectures. The original U-Net architecture [19] was first designed to segment medical images, and many other researchers have tried to improve its performance by integrating additional techniques into its architecture [20]. U-Net consists of a contracting path (encoder) and an expansive path (decoder) with skip connections between these 2 paths. The network learns features from the provided image and the mask at increasingly higher spatial scales by gradually down-sampling to lower resolutions through the encoding path. The expansive path then gradually increases the resolution of the output from the encoding path to the original image size, resulting in a probability map as an output, indicating the chance of each pixel belonging to a specific tissue. One important feature of U-Net is its skip connections, which concatenate feature maps from the encoding path to the corresponding block in the expansive path, making it possible to maintain small details crucial in medical image segmentation.

We have included 5 variants of U-Net in this study, including Attention U-Net, Dense U-Net, Residual U-Net, Inception U-Net, and U-Net++. Attention U-Net is desirable since it allows the model to focus on specific objects and ignore unnecessary areas [21]. In Dense U-Net, the traditional U-Net blocks are replaced with a dense block, enabling the model to segment objects with greater distinction. This feature is important in medical practice since tissues are often very close and sometimes overlap [22]. Residual U-Net architecture tries to tackle the vanishing gradient issue, a common problem in designing deep neural networks [23]. In most cases, the same organ's size can vary between patients, which can cause limitations on the segmentation capability of the model. By using filters with

XSL•FO
RenderX

different sizes, Inception U-Net attempts to overcome this problem [24]. Lastly, U-Net++ aids the classic U-Net model to more accurately segment images by providing semantic information from a dense network of skip connections as an intermediary grid between the encoding and decoding paths [25]. We also included a Wide U-Net architecture to eliminate the effect of increased trainable parameters. This model has the same architecture as U-Net but with more feature maps per layer (30, 60, 120, 240, and 480) compared to the original U-Net (16, 32, 64, 128, and 256). Hence, it will serve as a control to compare the models with larger numbers of trainable parameters with the base U-Net (Table 1).

Table . Number of trainable parameters for each model.

Model	Trainable parameters
U-Net	2,164,390
Attention U-Net	2,233,270
U-Net++	2,555,702
Inception U-Net	5,529,526
Residual U-Net	6,877,110
Dense U-Net	7,666,320
Wide U-Net	7,596,306

Training Procedure

All models were trained with the mini-batch stochastic gradient descent algorithm using the Adam optimizer. A batch size of 8 was selected. The learning rate was 0.0001. The training was done for 200 epochs. The values of hyperparameters were empirically tuned for best performance. Categorical cross-entropy (CSE) was selected as the loss function for this study [26]. The CSE loss function minimizes the distance between 2 distributions (the predicted labels and the GT labels). CSE is one of the most popular loss functions for image segmentation and has shown excellent performance in muscle segmentation [27,28]. All experiments were implemented with open-source software: Python (version 3.7.13), TensorFlow (version 2.8.2), and Keras (version 2.8.0).

Model Evaluation

The results of the experiments were evaluated using 2 main measures: Dice similarity coefficient (DSC) and average symmetric surface distance (ASSD). The DSC represents the agreement between the GT labels and predicted labels that models generate:

$$DSC_{P,G} = 2(P \cap G)(P+G)$$

where $\cap$ is the intersection and P and G are the 2 labels. DSC ranges between 0 and 1, where 0 indicates no agreement and 1 indicates perfect agreement. In our study, DSC is presented as a percentage.

The ASSD measures the average distance from pixels on the boundary of predicted labels to corresponding pixels on the boundary of the GT labels:

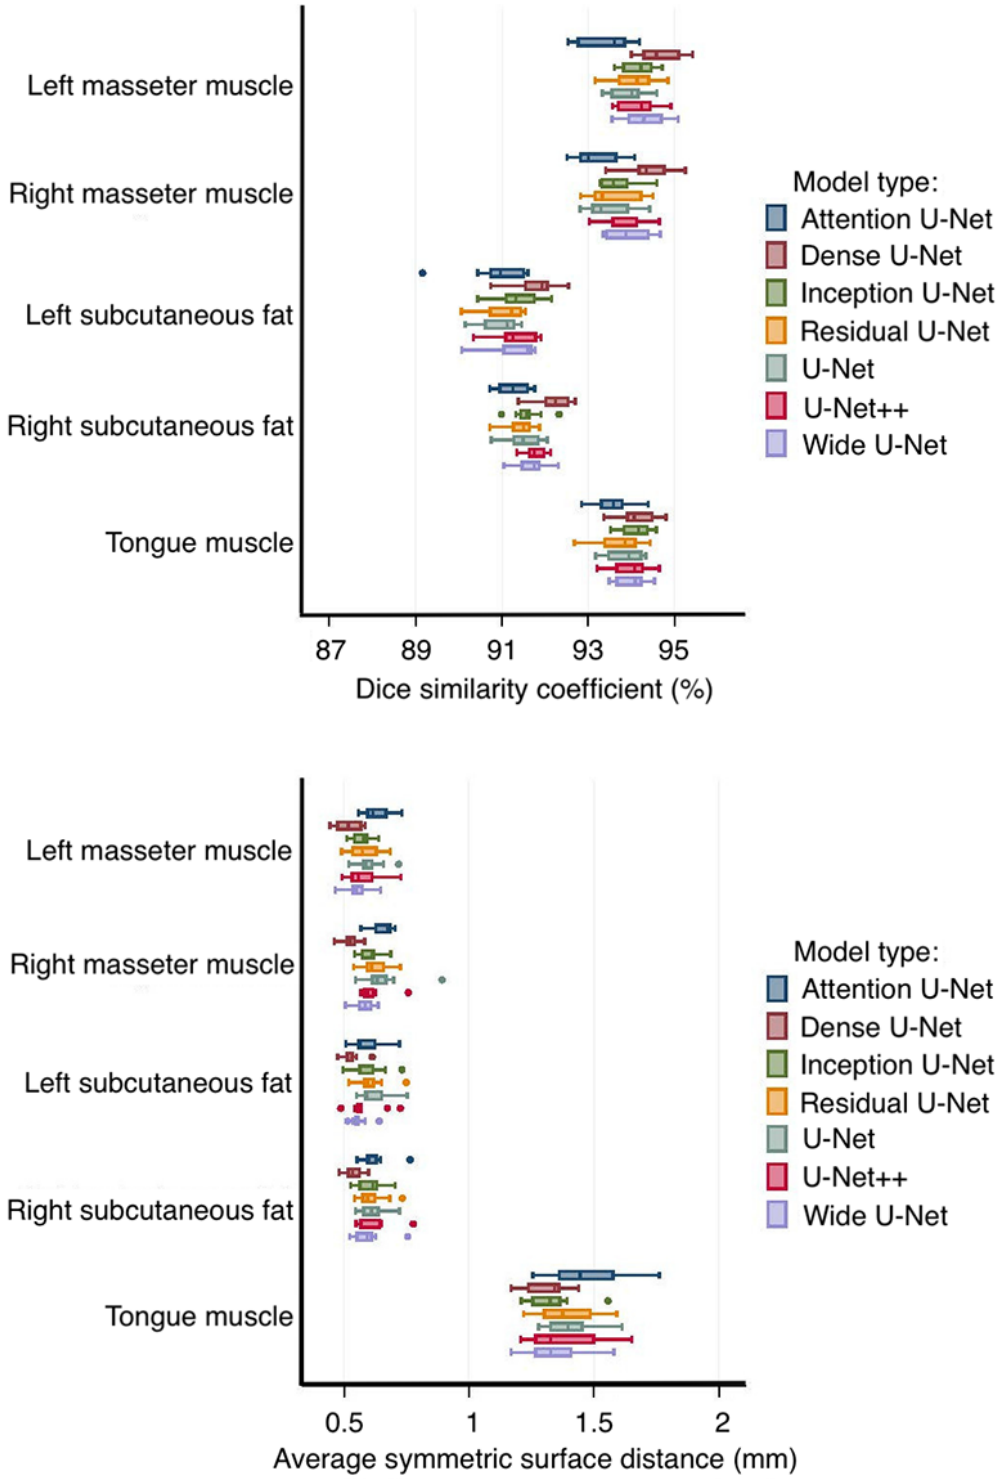
where BP and BG are the boundaries of predicted labels and corresponding reference labels, respectively. d(v,B) is the shortest Euclidean distance between voxel v and boundary B. An ASSD of 0 indicates a perfect match between predicted and reference labels. The ASSD was measured in mm.

We used k-fold cross-validation in evaluating the models. This technique splits the data set into k subsets (folds). The deep learning models are trained on all but one of the subsets (k–1), and then the models are evaluated on the subset that was not used for training. This process is repeated k times, and the average of the results is reported. We used k=10.

Additional metrics, including Jaccard coefficient, precision, recall, sensitivity, specificity, and F_1-score, are presented in Multimedia Appendix 1. The results are shown as mean and standard deviation and median and interquartile range across k-fold (k=10) cross-validation.

Statistical Methods

We explored the association between the BMI and the muscle and fat areas and volumes in the MRI images using individual linear regression models adjusted by sex and age. No adjustments for multiple testing were made. All assumptions were checked. All *P*-values were evaluated at a 5% level. The analysis and graphs were carried out using R (version 4.2.2).



Results

Segmentation

DSC and ASSD were used to quantitatively analyze the segmentation results (Figure 2 and Table 2). The Dense U-Net model has a higher average DSC and lower ASSD than other models. In contrast, Attention U-Net has the lowest average DSC score compared to other models. This result is confirmed by the higher ASSD for Attention U-Net for all tissues. Other models have shown almost similar results for all areas. Additional metrics have been presented in Multimedia Appendix 1. The results from these metrics confirm the findings of the study mentioned in this section; hence, they were omitted from the main manuscript.

Clinical Validation

To prove the clinical validity of the measurements, we evaluated the association between the segmented muscles and subcutaneous fat and BMI. We found a significant positive association between tongue muscle, left masseter muscle, and left and right subcutaneous fat and BMI (Figure 3). The area of a single slice as well as the volume of 5 slices per patient was calculated for this experiment. The results were adjusted by age and sex with $P<.05$ (Multimedia Appendix 2).

Discussion

In this study, we evaluated the performance of six deep learning models for segmentation of the masseter muscles, subcutaneous fat, and tongue muscle in MRI images of the head. Several variations of the U-Net architecture were trained and tested using k-fold cross-validation. The use of deep neural networks for segmenting musculoskeletal tissues in patients with AD and LBD is a novel experimental contribution to the deep learning-based segmentation literature as well as the clinical literature.

Our study demonstrated that the Dense U-Net model performed superiorly to the other models in all evaluated regions by achieving an overall DSC of 93.43% and ASSD of 0.68 mm on the test data. The remaining models demonstrated comparable outcomes, except the Attention U-Net, which achieved slightly

XSL•FO
RenderX

less accurate results in all regions with an overall DSC of 92.46% and ASSD of 0.79 mm on the test data. Notably, despite having a comparable number of trainable parameters, the Dense U-Net model demonstrated a higher DSC and lower ASSD than the Wide U-Net model. The Dense U-Net model achieves superior performance with a similar number of parameters, suggesting that its architectural efficiency, rather than parameter quantity alone, drives this improvement.

The validation set produced similar results to the training set, indicating that the trained models did not suffer from overfitting. Although we applied data augmentation to the training data set (results not shown), it did not significantly improve the accuracy of the segmentation models.

Furthermore, we observed a significant correlation between the results and BMI, a well-established measure of nutrition and body composition. This underscores the validity and clinical relevance of this method. If these localized muscle measurements correlate with BMI, it suggests that they may reflect broader nutritional and body composition states.

Sarcopenia is a relatively newly recognized condition for which neuromuscular degeneration, central nervous system alpha motor unit loss, and fat infiltration into muscle are the most distinctive proven and observed pathogenic features, leading to loss of muscle mass and strength and predisposing to physical frailty [2]. We have proposed that non-invasive assessment of intermuscular adipose tissue and muscle mass by image analysis could constitute a viable method to diagnose sarcopenia and predict its associated outcomes, the clinical impact of which is also under study by our group [29].

The validity and clinical implications of measuring the masseter muscle have been shown in previous studies [30,31]. In recent work by our group, we compared the diagnostic capacity for sarcopenia between the gold-standard dual X-ray absorptiometry and our measurements of head muscles. The results showed that both methods had equivalent accuracy [32]. In older adults with glioblastoma, a decreased masseter diameter on preoperative imaging was associated with shorter overall survival and 90-day mortality after surgical resection [33]. In addition, low masseter muscle was significantly associated with worse overall survival in patients aged 65 years or older, diagnosed with squamous cell carcinoma of the head and neck and treated with curative intent [34]. Another study evaluated post-operative results after carotid endarterectomy; low masseter mass was associated with a prolonged hospital stay and recurrent stroke within 5 years [35]. In another study, preoperative masseter mass was a predictor of postoperative pneumonia in patients with esophageal cancer [36]. Additionally, other studies have shown that the masseter muscle can be used as a nutritional biomarker. The masseter muscle, analyzed via computed tomography (CT) anthropometry, showed a statistically significant association with systemic nutritional biomarkers [37]. On the other hand, the tongue has shown to be a good marker of prognosis, as tongue strength has shown to be helpful in diagnosing sarcopenia [38]. Previous studies from our group also report that tongue muscle volume is correlated with malnutrition and even brain structures in patients with dementia [18,29].

Therefore, the approach we present in this paper can be opportunistically used to quantify muscle volumes and investigate the implications of having low muscle mass in the masseter or the tongue in people with brain, head, and neck diseases. Thus, it is an important first step toward developing a more efficient method to estimate masseter and tongue muscle with a better capacity to be implemented in clinical practice. Manual and semi-automatic techniques have been employed in several studies for masseter muscle segmentation in MRI [39]. A recent study used shape determination to segment the masseter muscle in MRI images [40]. In this approach, a manual contour for 8 slices must be defined by the user, and the model then determines the shape for the remaining scans, reducing the time and labor required for segmentation. However, this technique still requires manual segmentation, which can be time-consuming and prone to user error compared to our approach.

Model-based techniques have also been explored for the segmentation of the mastication muscle [41,42]. Although these techniques have shown high accuracy (>90%), there must be a distinct boundary between the masseter muscle and surrounding tissues to ensure accuracy. This distinct boundary refers to visible differences in intensity, texture, or anatomical structure on imaging, which enable the models to accurately separate the muscle from adjacent tissues, such as fat or bone.

Machine and deep learning approaches have been widely used to segment muscles in various body parts. CT scans and cone beam CT scans have primarily been investigated for measuring the head organs, including masseter muscle using these techniques [43-45]. In a previous study, a basic U-Net model was applied to segment the masseter muscle in head CT scans to investigate hemifacial microsomia [46]. The mean DSC reported in that study was 79.4% for the experimental group and 82.4% for the group with mandible deformities, which are lower compared to the results obtained in our study. In a study using CT scan of the head for segmentation of masticatory muscles, deep learning techniques were superior to atlas-based techniques, achieving a mean DSC of 83% [47]. To the best of our knowledge, the techniques considered in our study have not yet been used to segment musculoskeletal tissues in MRI images of the head.

Our study had some limitations. The Attention U-Net model demonstrated the lowest DSC values and the highest ASSD values among the evaluated models, indicating suboptimal segmentation accuracy across tissues. This underperformance may be attributed to the Attention mechanism's inability to effectively focus on the target tissue, leading to dispersed attention, particularly in smaller structures or regions with indistinct boundaries. To address this limitation, future work could involve refining the Attention mechanism to enhance its specificity and focus on regions of interest. Alternatively, exploring models that prioritize multi-scale feature extraction and detail preservation may provide improved segmentation performance, particularly for small or complex anatomical regions.

The DemVest study had some limitations that may have impacted the results. Selection bias might have been present if

XSL•FO
RenderX

patients with more complex health conditions were included, as primary care referrals were used. The study was not specifically designed for the paper's purpose, which could limit the data analysis and interaction control. For example, the absence of a healthy control group prevents us from determining whether the observed muscle volume characteristics are specific to individuals with AD or neurocognitive disorders, or if they represent normal variations associated with aging. However, the primary objective of this study was to demonstrate the feasibility and accuracy of our deep learning model in quantifying muscle volumes using head MRI, rather than to establish definitive differences between diseased and healthy populations. In addition, the sample size is relatively small, and there is a risk that our results may not generalize to larger populations. Additionally, the MRI scans were obtained from a single center using a single MRI machine, which may affect the model's generalizability. Longitudinal analyses were not conducted because imaging was only performed at baseline, in line with the initial primary objectives of the DemVest study and the resources allocated for image acquisition.

These limitations should be considered when interpreting this study's results and addressed in future studies seeking broader application of the proposed approach. Whether masseter and tongue volumes in these muscles correlate with lean body mass and inflammaging and could be predictors of neurocognitive conditions and their associated outcomes remains unknown.

On the other hand, this study has several strengths, including well-characterized data, detailed and exhaustive diagnosis to correctly identify people with dementia, and an automated quality control and analysis pipeline. Additionally, the results fill a gap in the literature and provide insights into a possible method to efficiently diagnose sarcopenia in context when a head MRI is already available.

In summary, to our knowledge, this is the first study that validates deep learning methods that could be easily implemented in clinical practice to measure masseter and tongue muscle volumes with a solid potential to become biomarkers with strong predictive value for adverse outcomes in older persons with dementia. Since imaging is widely used in memory clinics worldwide, this opportunistic approach to image analyses could become standard practice in those settings. However, further large longitudinal studies are still required.

Acknowledgments

We want to thank the participants, researchers, and technical staff that made the DemVest study possible, as well as the staff and facilities provided by (SESAM) Centre for age-related medicine at Stavanger, Norway. This work was supported by the Norwegian government, through hospital owner Helse Vest (Western Norway Regional Health Authority) number 911973. It is also funded by the National Institute for Health Research (NIHR) Biomedical Research Centre at South London and Maudsley NHS Foundation Trust, King's College London, and the Australian Institute for Musculoskeletal Science (AIMSS). Mahdi Imani is supported by an Australian Government Research Training Program (TRP) Scholarship.

Abstract

Background: Artificial intelligence (AI) is increasingly being applied in various health care services due to its enhanced efficiency and accuracy. As the population ages, AI-based health technologies could be a potent tool in older adults' health care to address growing, complex, and challenging health needs. This study aimed to investigate perspectives on and acceptability of the use of AI-led health technologies among older adults and the potential challenges that they face in adopting them. The findings from this inquiry could inform the designing of more acceptable and user-friendly AI-based health technologies.

Objective: The objectives of the study were (1) to investigate the attitudes and perceptions of older adults toward the use of AI-based health technologies; (2) to identify potential facilitators, barriers, and challenges influencing older adults' preferences toward AI-based health technologies; and (3) to inform strategies that can promote and facilitate the use of AI-based health technologies among older adults.

Methods: This study adopted a qualitative descriptive design. A total of 27 community-dwelling older adults were recruited from a local community center. Three sessions of semistructured interviews were conducted, each lasting 1 hour. The sessions covered five key areas: (1) general impressions of AI-based health technologies; (2) previous experiences with AI-based health technologies; (3) perceptions and attitudes toward AI-based health technologies; (4) anticipated difficulties in using AI-based health technologies and underlying reasons; and (5) willingness, preferences, and motivations for accepting AI-based health technologies. Thematic analysis was applied for data analysis. The Theoretical Domains Framework and the Capability, Opportunity, Motivation, and Behavior (COM-B) model behavior change wheel were integrated into the analysis. Identified theoretical domains were mapped directly to the COM-B model to determine corresponding strategies for enhancing the acceptability of AI-based health technologies among older adults.

Results: The analysis identified 9 of the 14 Theoretical Domains Framework domains—knowledge, skills, social influences, environmental context and resources, beliefs about capabilities, beliefs about consequences, intentions, goals, and emotion. These domains were mapped to 6 components of the COM-B model. While most participants acknowledged the potential benefits of AI-based health technologies, they emphasized the irreplaceable role of human expertise and interaction. Participants expressed concerns about the usability of AI technologies, highlighting the need for user-friendly and tailored AI solutions. Privacy concerns and the importance of robust security measures were also emphasized as critical factors affecting their willingness to adopt AI-based health technologies.

Conclusions: Integrating AI as a supportive tool alongside health care providers, rather than regarding it as a replacement, was highlighted as a key strategy for promoting acceptance. Government support and clear guidelines are needed to promote ethical AI implementation in health care. These measures can improve health outcomes in the older adult population by encouraging the adoption of AI-driven health technologies.

Introduction

Background

Artificial intelligence (AI) refers to a computerized system that is capable of executing a wide range of tasks that typically involve human intelligence—ranging from physical tasks, cognitive functions, and problem-solving to decision-making—and can be performed without explicit instructions from humans [1]. AI can be classified into 4 main subsets—machine learning, natural language processing (NLP), physical robots, and robotic process automation. The field of AI is rapidly advancing, and AI technologies have been widely applied in different aspects of health care services, including diagnostic assistance, health screening, and imaging interpretations [2]. It has been described as a "second set of eyes" for medical practitioners [3]. Furthermore, over the past decade, the application of AI systems has increasingly centered on empowering patients to actively manage their health and boost their participation in the shared decision-making process, giving rise to diverse AI-driven products such as robots, smart assistants, virtual or augmented reality, wearable devices, and mobile apps [4]. Particularly notable is the emergence of AI-powered chatbot services, which permit patients to seek medical advice and receive triage for their conditions in a prompt and cost-effective manner [5]. With the debut of ChatGPT by OpenAI in November 2022 and the popularity it has gained, it is envisioned that AI-based conversational large language models with NLP abilities could conceivably revolutionize health care practice and education, contributing to substantial transformative shifts [6,7].

The world is currently encountering a significant expansion in the aging population, with the number of people aged 60 years or above anticipated to rise to 1.4 billion by 2030 and 2.1 billion by 2050 [8]. Conventional older adult health care has relied heavily on in-person monitoring; however, the further intensification of the shortage of health care workers could in the long run present a global challenge to the sustainability of delivering quality medical care [9]. In recent years, digital technologies, such as smart older adult health care products, which involve the deep integration of AI, have been used in older adult health care sectors [10]. Evidence has shown that AI-based technologies can play a constructive role in improving the physical and psychological well-being, quality of life, and independent living of older adults [11]. However, there is a great digital divide between the older and younger generations, with the former being the age group that is the least likely to have access to computers and the internet, due to physical obstacles such as physical disabilities and to psychological factors such as a lack confidence in using technology as well as ethical concerns [12,13].

While AI-based health technologies have rapidly evolved, and some studies have comprehensively discussed the advantages of applying them in the field of geriatrics, insufficient academic attention has been paid to acquiring a clear understanding of the attitudes, perceptions, and experiences of seniors toward these technologies [10]. This gap may implicitly influence the acceptance of, and motivation to use, these technologies in the future. In addition, while studies have primarily focused on the perceptions of medical practitioners and patients regarding AI health technologies, the perspectives of older adults—a key user group—have received limited attention [14-16]. For instance, although some research has explored older adults' views on general AI-powered technologies, their relevance to AI health technologies remains uncertain [17]. Concerns about accuracy, reliability, and trust in AI tools compared with in-person medical advice further underscore the need for targeted investigation. This study addresses this gap by exploring older adults' perceptions of and acceptability toward AI-based health technologies, with a specific focus on practical strategies to enhance adoption. By identifying barriers, facilitators, and preferences, the findings have clear clinical implications, offering actionable insights for health care providers, policy makers, and AI developers. These insights can inform the design of tailored, user-friendly AI tools and guide their ethical implementation in health care, ultimately improving older adults' health outcomes.

Theoretical Framework

The interview guide for this study was developed using the Theoretical Domains Framework (TDF) and the Capability, Opportunity, Motivation, and Behavior (COM-B) model behavior change wheel to comprehensively explore factors influencing the acceptability of AI-based health technologies among older adults. The TDF consists of 14 domains that integrate behavioral determinants derived from over 30 psychological theories [18]. To ensure comprehensive coverage of these domains, the interview guide focused on five key areas: (1) general impressions of AI, (2) previous experiences with AI-based technologies, (3) perceptions and attitudes toward AI-based health technologies, (4) expected difficulties and underlying reasons, and (5) willingness. These focus areas were aligned with the study objectives and systematically mapped to the relevant TDF domains, as summarized in Table 1. This approach ensured that all 14 domains were addressed, either directly or indirectly, during the interviews.

XSL•FO
RenderX

Table . The interview questions guided by the Theoretical Domains Framework (TDF).

Focus area	Aligned TDF domains	Example question
General impressions of AI[a]	Knowledge, emotion, and optimism	"What comes to mind when you think about artificial intelligence and its role in health technologies?"
Previous experiences with AI-based technologies	Memory, attention, and decision processes; knowledge; and skills	"Have you used any AI-based technologies before? Can you describe your experience?"
Perceptions and attitudes toward AI-based health technologies	Social or professional role and identity; beliefs about capabilities; beliefs about consequences; emotion; and optimism	"What are your thoughts about using AI-based technologies for managing your health?"
Expected difficulties and underlying reasons	Environmental context and resources; skills; social influences; behavioral regulation; and memory, attention, and decision processes	"What challenges do you think you might face when using AI-based health technologies? Why do you think these occur?"
Willingness	Intentions; goals; beliefs about capabilities; and reinforcement	"Would you be willing to use AI-based health technologies? Why or why not?"

[a]AI: artificial intelligence.

To further enhance the applicability of findings, the identified TDF domains were mapped to the COM-B behavior change wheel (Table 2). The COM-B model summarizes 6 sources of behavior—social or physical opportunity, automatic or reflective motivation, and physical or psychological capability. This model provided a practical framework for identifying specific behavior change factors and strategies to improve the acceptance and adoption of AI-based health technologies among older adults [19].

Table . Capability, Opportunity, Motivation, and Behavior (COM-B) model components and its relation to Theoretical Domains Framework (TDF) domains.

COM-B components		TDF domains
Capability		
	Psychological capability	• Knowledge • Skills • Memory, attention, and decision processes
	Physical capability	• Behavioral regulation • Skills
Opportunity		
	Social opportunity	• Social influences
	Physical opportunity	• Environmental context and resources
Motivation		
	Reflective motivation	• Social or professional role and identity • Beliefs about capabilities • Optimism • Beliefs about consequences • Intentions • Goals
	Automatic motivation	• Social or professional role and identity • Optimism • Reinforcement • Emotion

The interview guide included open-ended questions designed to elicit rich, detailed responses.

This structured mapping ensured that the interview guide covered all 14 TDF domains comprehensively, while tailoring the questions to elicit insights into factors influencing the acceptability of AI-based health technologies among older adults. While alternative models, such as the technology acceptance model and the unified theory of acceptance and use of technology are commonly used in technology adoption studies, these models primarily focus on individual perceptions, such as perceived usefulness and ease of use (technology acceptance model) or performance expectancy and effort expectancy (unified theory of acceptance and use of technology).

XSL•FO
RenderX

These constructs, while valuable, may not fully capture the complex interplay of factors influencing older adults' adoption of AI technologies.

The systematic alignment between the interview guide and the TDF framework facilitated the identification of theoretical mediators and behavioral determinants. This mapping subsequently informed the integration of the findings with the COM-B behavior change wheel, allowing for the development of tailored strategies to promote the use of AI-based health technologies in this population.

Objectives

The objectives of the study were (1) to investigate the attitudes and perceptions of older adults toward the use of AI-based health technologies; (2) to identify potential facilitators, barriers, and challenges influencing older adults' preferences toward AI-based health technologies; and (3) to inform strategies that can promote and facilitate the use of AI-based health technologies among older adults.

Methods

Study Design

A qualitative descriptive design was adopted for this study [20]. This approach helps in the effort to uncover and understand the experiences, attitudes, and perceptions of people, making it appropriate for this study. The findings from a qualitative descriptive study are able to inform strategies that promote and facilitate the use of AI-based health technologies, which makes it particularly useful for this research. To explore perceptions on and acceptability of the use of AI-based technologies in health maintenance among older adults, and to provide insights into their subjective views, in-depth semistructured interviews guided by an interview guide were conducted.

Participants and Recruitment

Community-dwelling older adults aged 60 years or above were recruited from a local community center using a convenience sampling method. Eligible participants included those with or without previous exposure to AI tools who were willing to participate and share their experiences. Exclusion criteria included underlying physical, psychological, or neurodevelopmental problems that impaired interaction, mental instability, cognitive impairments such as traumatic brain injury, substance abuse, dementia, severe psychiatric disorders, intellectual disability, or being bedridden.

Sampling and Sample Size

Convenience sampling approach was employed, guided by the principle of data saturation. The target sample size was 25 participants, which is commonly regarded as sufficient for qualitative descriptive studies to achieve thematic depth and richness [21]. Ultimately, 27 older adults were recruited, providing adequate data to explore the study's focus areas.

Data Collection

Data collection involved 3 sessions of semistructured interviews with each participant, each lasting 1 hour. To minimize ambiguity, AI was classified into 4 categories: machine learning, NLP, physical robots, and robotic process automation. Interviews covered five focus areas: (1) general impressions of AI; (2) previous experiences with AI-based technologies; (3) perceptions and attitudes toward AI-based health technologies; (4) anticipated difficulties in using AI-based health technologies and their underlying reasons; and (5) willingness, preferences, and motivations in accepting AI-based health technologies.

In the first focus area, examples of AI tools were not initially provided to elicit spontaneous responses. However, recognizing that participants might not be fully aware of everyday interactions with AI, the second focus area included real-life examples to clarify potential misconceptions. Examples of machine learning technologies included fitness tracking devices, such as Google Fitbit and Apple Watch, which monitor physical activity and provide insights into health trends. For NLP, the interviewer referenced virtual assistants like Siri (Apple Inc) and Alexa (Amazon Inc), as well as health care chatbots that answer patient inquiries. Computer vision was illustrated with examples of AI systems that analyze medical images, such as detecting abnormalities in x-rays or CT scans. This approach enabled a nuanced exploration of participants' experiences with general AI technologies versus their attitudes toward AI for health purposes. The data were securely stored in Cloud storage, accessible only to the research team.

Data Analysis

Thematic analysis was used in this study [22]. The interview recordings were first translated into English, transcribed, read, and reread to gain a sense of the participants' experiences. Initial ideas were noted down. Next, the data were coded to extract key insights from the transcript. The codes were reviewed in a weekly discussion with the supervisor to obtain agreement on the interpretations. The underlying subthemes that emerged from the codes were identified and the subthemes were further clustered into themes. The themes, subthemes, and representative quotes were used to present the findings. Data were mapped to TDF to identify underlying theoretical mediators that influenced the perceptions and acceptability to the older adults of the use of AI-based health technologies. Once these theoretical domains were identified, they were mapped to components of the COM-B behavior change wheel that matched theoretical mediators with corresponding key strategies.

Ethical Considerations

The study protocol and procedures were approved by the Ethical Committee of the Hong Kong Polytechnic University (approval HSEARS20230810006) on August 29, 2023, and adhered to the ethical standards of the Declaration of Helsinki. Before starting the study, all participants provided informed consent during a face-to-face interview with the researcher. All the participants were fully informed about the nature and purpose of the study. They were guaranteed the right to withdraw from the study at any time without adverse consequences. The collected data were encrypted and stored in a password-protected database. Although the researchers did not foresee any significant risks associated with the proposed study, the researchers recognized that older adults might experience discomfort or fatigue from sitting through the interviews. To address this, the researchers ensured that participants were given

XSL•FO
RenderX

scheduled breaks throughout the interview. In addition, participants were encouraged to request breaks as needed to ensure that they were comfortable during the entire interview process. Participants who completed the interviews received an HK $100 (US $12.80) supermarket gift voucher to compensate for transportation costs.

Results

Participant Characteristics

The study included 27 participants, with 18 females (66.7%) and 9 males (33.3%). The mean age was 69.44 (SD 6.7) years. Most participants were married (19/27, 70.4%) and had a high school education (14/27, 51.9%). A majority lived with family (19/27, 70.4%) and rated their health as good (14/27, 58.3%). In addition, 66.7% (18/27) reported having chronic diseases. Regarding technology, 51.9% (14/27) felt somewhat comfortable using smartphones or tablets, and 59.3% (16/27) were somewhat familiar with tech products. Over 80% (23/27, 85.2%) of participants had heard of AI health technology, though their familiarity was limited. AI product usage varied, with approximately half of the participants reporting they used AI products often or occasionally, while the other half reported they used them seldom or were unfamiliar with them. Most participants (21/27, 77.8%) believed AI was to some extent helpful in health management, and 66.7% (18/27) had a positive overall impression of AI. Further details about the characteristics of the participants are provided in Table 3.

[a]AI: artificial intelligence.

Objective 1: Investigate Older Adults' Attitudes and Perceptions Related to the Use of AI-Based Health Technologies

General Impressions of AI-Based Health Technologies

Most participants had positive views of AI-based health technologies, recognizing their potential to improve health outcomes by enhancing health monitoring, providing personalized recommendations, and assisting in decision-making. However, there was also limited awareness and understanding of specific AI-based health technologies, with some participants confusing them with general technologies such as smartphones. In addition, concerns were raised about fraud and scams associated with AI-based health technologies.

Attitudes and Perceptions Toward AI-Based Health Technologies

Privacy and data security were recurring themes in participants' discussions of AI-based health technologies. Many participants expressed concerns about the potential misuse of personal data and highlighted the importance of robust security measures. These concerns were particularly pronounced among participants with limited experience using technology or those influenced by media reports of data breaches. However, a subset of participants viewed privacy as a societal issue rather than a specific risk associated with AI-based technologies. For instance, one participant remarked:

> *Yes, it's acceptable.…Uh, what privacy do you have? There is no privacy in the whole world. Everyone's mobile phone is being monitored.* [Participant 3]

Another noted:

> *Not to mention privacy nowadays, from where we sit now there is completely no privacy…even if you listen to this song now, then this song will automatically appear (on your phone). When you are viewing clothes, then you will see the clothes later on (on your phone).* [Participant 5]

These contrasting perspectives highlight the varying levels of concern about privacy among older adults and underscore the need for transparent communication about data security in the development and deployment of AI-based health technologies.

Trustworthiness and Accuracy

Trust in AI-based health technologies varied among participants, influenced by previous experiences, information sources, and perceptions of accuracy. While some acknowledged the utility of AI in self-monitoring, others expressed reservations about its accuracy and trustworthiness, stressing the irreplaceable value of human judgment and expertise in health care.

XSL•FO
RenderX

Objective 2: Identify Potential Facilitators, Barriers, and Challenges That Influence Older Adults' Preferences Toward AI-Based Health Technologies

Technological Barriers

Participants identified multiple technological challenges that hindered their ability to use AI-based health technologies effectively. These challenges included operational difficulties, limited digital literacy, and lack of access to required resources, such as hardware or stable internet connectivity. These barriers were particularly evident among participants with physical or cognitive impairments due to age-related degeneration.

For instance, 1 participant described how physical limitations affected their interaction with technology:

> *I have degeneration, too. I could remember a lot of things before. But now I can't. My body movements are slow now, so it's difficult for me to use AI-based health technologies.* [Participant 3]

Another significant barrier was self-perceived incompetence in using digital tools, often leading to frustration or feelings of inadequacy:

> *"I feel like I am stupid after learning something...."* [Participant 7]

In addition, resource-related challenges, such as a lack of access to necessary hardware (eg, smartphones) and stable internet connections, were raised, further limiting participants' ability to engage with AI technologies.

Emotional and Psychological Barriers

Emotional and psychological factors emerged as significant barriers to the adoption of AI-based health technologies. These included fear of technology, skepticism regarding its reliability, and concerns about losing human connection in health care interactions. The prevalence of scams and fraudulent activities in the digital age further compounded participants' fears, making them hesitant to trust digital tools.

For example, 1 participant expressed a deep apprehension about interacting with technology:

> *I don't feel comfortable with these technologies because they seem complicated, and I worry about making mistakes.* [Participant 6]

Concerns about scams were also prevalent, with another participant noting:

> *Nowadays, you hear so much about fraud. It makes me scared to trust anything online, even if it looks helpful.* [Participant 4]

These findings illustrate that emotional and psychological barriers are not only about individual fears but also reflect broader societal concerns regarding trust and safety in the digital world.

Perceived Usefulness and Relevance

Participants perceived AI-based health technologies as useful, particularly those that addressed specific health needs such as the monitoring of blood pressure, blood sugar, and cholesterol. They also appreciated technologies that could assist with health monitoring, reminders, and personalized care.

> *I hope that these three things could be more mature, help to reduce blood pressure, blood sugar, or blood cholesterol, whatever. At least I know whether my blood sugar is good or not; if it is not good, I will eat something and exercise to increase my physical capacity.* [Participant 3]

> *Yeah, like an alarm. As a reminder to alert you. Well, high blood pressure, high blood sugar, high cholesterol level, those we get when are older. If AI can help with these three things, it is definitely good.* [Participant 2]

Acknowledgment by Authorities

The endorsement of AI-based health technologies by official authorities or regulatory bodies significantly facilitated their acceptance and adoption. Participants felt more confident and trusting when these technologies were validated by reputable sources, such as health care agencies or government bodies.

> *If it is something organized by the Hospital Authority or the government, it will be more trustworthy. Because sometimes, if it is made by pharmaceutical companies, it may not necessarily be that clear.* [Participant 2]

> *Well, if you talk about it being official, like the doctors and government, I will assume that this AI is reliable, you will basically feel at ease.* [Participant 1]

> *I have to see if the AI comes from a large or a small company. For example, Hong Kong Polytechnic University, Baptist University — they are more reliable then.* [Participant 4]

Objective 3: Inform Strategies That Promote and Facilitate the Use of AI-Based Health Technologies Among Older Adults

Integration of Human Expertise

While recognizing the potential benefits of AI, participants emphasized the need for AI technologies to complement rather than replace human expertise in health care. They suggested that AI could be useful as an auxiliary tool for making preliminary medical suggestions, but that the final decision-making should involve consultations with a human being.

> *I just ask the AI, but I can ignore its answers or I will think about it again. It is just a reference and I won't believe it completely. Well, when you see a doctor, you won't just see one doctor, you will see many many right?...AI is just the first contact point.* [Participant 2]

User-Friendly Design

To enhance the acceptability of AI-based health technologies, it is crucial to develop solutions that are user-friendly and tailored to the specific needs of older adults. A user-friendly design should include simplified and intuitive interfaces that

XSL•FO
RenderX

minimize cognitive load, with features such as large, high-contrast text and icons for better visibility and ease of use. Voice command functionality can further improve accessibility for users with limited dexterity or vision impairments. In addition, providing step-by-step tutorials, user manuals in multiple formats (eg, videos and print), and accessible customer support can address challenges related to digital literacy. These features collectively ensure that the technology is not only easy to use but also aligns with the physical and cognitive capabilities of older adults, thereby fostering greater adoption and satisfaction.

Addressing Privacy and Security Concerns

Given the concerns around privacy and data security, the development of AI-based health technologies should include robust security measures to protect the personal information of users. Addressing these concerns is essential to building trust and encouraging adoption among older adults.

Government and Regulatory Support

Participants highlighted the importance of government and regulatory support in promoting the ethical implementation of AI in health care. Clear guidelines and endorsements from authoritative bodies can foster trust and enhance the acceptability of AI-based health technologies among older adults.

Table 4 provides a detailed description of how the identified barriers and facilitators toward the use of AI-based health technologies were mapped to the TDF domains and corresponding COM-B components. These mappings were derived from participants' responses during the interviews. The barriers and facilitators were categorized based on their alignment with the TDF domains and subsequently mapped to the COM-B components to identify actionable strategies for behavior change.

Table . Identified Theoretical Domains Framework (TDF) domains and Capability, Opportunity, Motivation, and Behavior (COM-B) components related to the adoption of artificial intelligence (AI)–based health technologies.

Barrier or facilitator	COM-B components	TDF domains	Illustrative participant quote
Barrier: limited technological skills	Capability	Knowledge and skills	"I find it difficult to use these technologies because my body movements are slow, and I don't know how to start." [P3]
Facilitator: perceived usefulness and relevance	Motivation	Beliefs about consequences, intentions, and goals	"If AI can help monitor my blood pressure or remind me, it would be very helpful." [P2]
Barrier: lack of official recognition or endorsement	Opportunity	Social influences	"If it's recognized by the government or hospitals, I would trust it more." [P1]
Facilitator: confidence in trustworthiness and accuracy	Motivation	Beliefs about capabilities	"If the results are accurate, I can rely on it for some guidance." [P4]
Barrier: privacy and data security concerns	Motivation	Emotion	"I worry about my personal information being stolen if I use this technology." [P5]
Facilitator: AI as an auxiliary tool for initial suggestions	Motivation	Beliefs about consequences and intentions	"I can use AI for some advice, but I still prefer to consult a doctor for the final decision." [P2]

Discussion

Principal Findings

The aim of the study was to provide insights into the perceptions and acceptability of AI-based health technologies among older adults, using the TDF and the COM-B behavior change wheel as theoretical frameworks. These frameworks were instrumental in identifying key behavioral determinants and mapping them to actionable strategies for enhancing AI adoption. In total, 9 of the 14 TDF domains (knowledge, skills, social influences, environmental context and resources, beliefs about capabilities, beliefs about consequences, intentions, goals, and emotion) were identified and mapped to 6 COM-B components (psychological capability, physical capability, social opportunity, physical opportunity, reflective motivation, and automatic motivation). By applying these frameworks, the study provided a structured approach to understanding the factors influencing older adults' behavior toward AI adoption. The responses of the participants shed light on various aspects of the adoption and utilization of AI-based health technologies among older adults. First, the participants expressed a range of attitudes and perceptions toward AI-based health technologies, including curiosity, skepticism, and enthusiasm toward the use of AI in the management and maintenance of health. These perceptions align with the TDF domains of knowledge and beliefs about consequences, which underscore the need to enhance understanding of AI and clearly communicate its benefits to older adults. The interviews provided a deeper understanding of the factors influencing these attitudes and the potential benefits and concerns associated with AI adoption in the context of the participants' health. They shared their perceptions of AI technologies, addressing aspects such as reliability, trustworthiness, and their perception of the impacts on health care outcomes. These insights informed the reflective motivation component of the COM-B framework, highlighting the

XSL•FO
RenderX

importance of fostering trust and reliability in AI-based technologies to enhance adoption.

In addition, the study revealed an interesting finding regarding older adults' preferences for using AI in asking for advice and self-health maintenance. Contrary to expectations, participants expressed a higher level of trust and reliability in real persons, particularly physicians, when making decisions about pharmacological interventions such as changing drug dosages. Participants believed that AI could play a valuable role in providing information and acting as a reference tool for self-health maintenance. However, they expressed reservations about relying solely on AI for decisions related to medication management. This finding is linked to the TDF domain of social influences and the social opportunity component of the COM-B framework, as participants emphasized the irreplaceable role of human expertise and interpersonal trust in health care decision-making. They viewed AI as a useful source of information but considered the expertise and experience of physicians and other health care professionals to be more reliable and crucial in making decisions regarding medical interventions and treatment. The emotion domain of TDF also played a role, as participants' skepticism and emotional barriers highlighted the importance of addressing concerns through education and reassurance. The findings were also in line with a mixed methods study indicating that the lack of empathy and a professional human approach made AI chatbots less acceptable to some users [15]. This insight has significant implications for the development of AI-based health technologies. It might indicate that older adults desire a collaborative approach that combines the benefits of AI with the guidance and expertise of real-person health care providers [23-25]. Developers could focus on creating AI systems that could provide accurate and evidence-based information, acting as a reference tool to support older adults' self-health maintenance efforts. In this context, AI could assist older adults in accessing reliable and up-to-date information about medications, potential side effects, and alternative treatment options. AI-based systems could also offer personalized recommendations for lifestyle modifications, nonpharmacological interventions, and self-care strategies that align with the preferences and needs of older adults.

While privacy and confidentiality are often considered to be potential concerns when using AI in health care, surprisingly, many expressed a relaxed and relatively pessimistic attitude toward privacy. One of the reasons for this was that the perceived benefits outweighed the concerns. Most expressed the view that the potential benefits of AI-based health technologies have overshadowed any concerns about privacy or confidentiality. They may have viewed the potential improvement in their health outcomes or access to personalized care as more significant than the potential risks to their privacy. Another underlying reason may be that the participants may have had other concerns that they considered more important than privacy and confidentiality in the context of AI-based health technologies. For example, they may have been more focused on the usability, effectiveness, or reliability of the technology. Regardless, the absence of expressed concerns does not necessarily indicate the lack of importance of privacy and confidentiality. Rather, it highlights the need for researchers and developers to proactively address these concerns and ensure that robust privacy and security measures are in place when designing and implementing AI-based health technologies. It is crucial for future research and development efforts to emphasize the importance of privacy and confidentiality in AI-based health technologies, which involves implementing strong data protection measures, obtaining informed consent from users, and transparently communicating how their data will be used and safeguarded.

To enhance older adults' acceptance of AI-based health technologies, strategies should focus on improving technological skills through tailored training programs, securing official recognition and endorsement from health care authorities, addressing concerns over privacy and data security with robust protocols, emphasizing the trustworthiness and accuracy of AI tools, positioning AI as auxiliary aids for medical suggestions, highlighting the usefulness and relevance of AI applications, and providing emotional support to mitigate psychological barriers. These strategies are directly informed by the COM-B framework, targeting capability, opportunity, and motivation as the key drivers of behavior change. By implementing these targeted strategies, older adults might be encouraged to embrace AI technologies, leading to improved health care outcomes and increased engagement with innovative health care solutions. Meanwhile, government endorsements could also contribute to the establishment of guidelines, standards, and regulations that ensure the ethical use of AI in health care, addressing concerns related to privacy, data security, and quality assurance.

Limitations

The limitations of this study were the sample size and representativeness of participants. While we recognize that this sample size may not fully capture the diversity of the population, the study aimed to offer initial, in-depth insights into older adults' perceptions of AI-based health technologies. Future studies could address subgroup comparisons by incorporating stratified sampling to examine variations across different demographic or socioeconomic groups. In addition, while quantitative comparisons were not a focus of this study, future research could include mixed method approaches to statistically assess participant perceptions and examine their relationships with demographic and contextual factors by using validated survey tools. Last but not the least, many participants had limited before knowledge or experience with AI-driven health technologies. Some participants conflated AI technologies with general digital tools, such as mobile apps, due to a lack of familiarity with the distinction. To address this, the interviewer provided concise explanations and real-life examples of AI subsets, including machine learning, NLP, computer vision, and expert systems. While this approach helped participants better understand the discussion, their responses were still shaped by their interpretations and familiarity with technology. Consequently, the findings reflect older adults' perceptions and acceptance of health technologies they associate with AI, rather than definitive perspectives on AI-driven health technologies.

Conclusion

While the majority of participants recognized the potential advantages of AI-based health technologies, they underscored

XSL•FO
RenderX

the indispensable role of human expertise and interaction. Vital strategies for improving acceptability include crafting user-friendly and customized AI solutions, addressing privacy concerns, ensuring robust security measures, and integrating AI as a complementary tool alongside health care providers. Government backing and guidelines can play a pivotal role in advancing ethical AI integration in health care, fostering trust, and enhancing personalized care for older adults, ultimately leading to improved health outcomes in this population.

Abstract

Background: Depression, characterized by persistent sadness and loss of interest in daily activities, greatly reduces quality of life. Early detection is vital for effective treatment and intervention. While many studies use wearable devices to classify depression based on physical activity, these often rely on intrusive methods. Additionally, most depression classification studies involve large participant groups and use single-stage classifiers without explainability.

Objective: This study aims to assess the feasibility of classifying depression using nonintrusive Wi-Fi–based motion sensor data using a novel machine learning model on a limited number of participants. We also conduct an explainability analysis to interpret the model's predictions and identify key features associated with depression classification.

Methods: In this study, we recruited adults aged 65 years and older through web-based and in-person methods, supported by a McGill University health care facility directory. Participants provided consent, and we collected 6 months of activity and sleep data via nonintrusive Wi-Fi–based sensors, along with Edmonton Frailty Scale and Geriatric Depression Scale data. For depression classification, we proposed a HOPE (Home-Based Older Adults' Depression Prediction) machine learning model with feature selection, dimensionality reduction, and classification stages, evaluating various model combinations using accuracy, sensitivity, precision, and F_1-score. Shapely addictive explanations and local interpretable model-agnostic explanations were used to explain the model's predictions.

Results: A total of 6 participants were enrolled in this study; however, 2 participants withdrew later due to internet connectivity issues. Among the 4 remaining participants, 3 participants were classified as not having depression, while 1 participant was identified as having depression. The most accurate classification model, which combined sequential forward selection for feature selection, principal component analysis for dimensionality reduction, and a decision tree for classification, achieved an accuracy of 87.5%, sensitivity of 90%, and precision of 88.3%, effectively distinguishing individuals with and those without depression. The explainability analysis revealed that the most influential features in depression classification, in order of importance, were

XSL•FO
RenderX

"average sleep duration," "total number of sleep interruptions," "percentage of nights with sleep interruptions," "average duration of sleep interruptions," and "Edmonton Frailty Scale."

Conclusions: The findings from this preliminary study demonstrate the feasibility of using Wi-Fi–based motion sensors for depression classification and highlight the effectiveness of our proposed HOPE machine learning model, even with a small sample size. These results suggest the potential for further research with a larger cohort for more comprehensive validation. Additionally, the nonintrusive data collection method and model architecture proposed in this study offer promising applications in remote health monitoring, particularly for older adults who may face challenges in using wearable devices. Furthermore, the importance of sleep patterns identified in our explainability analysis aligns with findings from previous research, emphasizing the need for more in-depth studies on the role of sleep in mental health, as suggested in the explainable machine learning study.

KEYWORDS

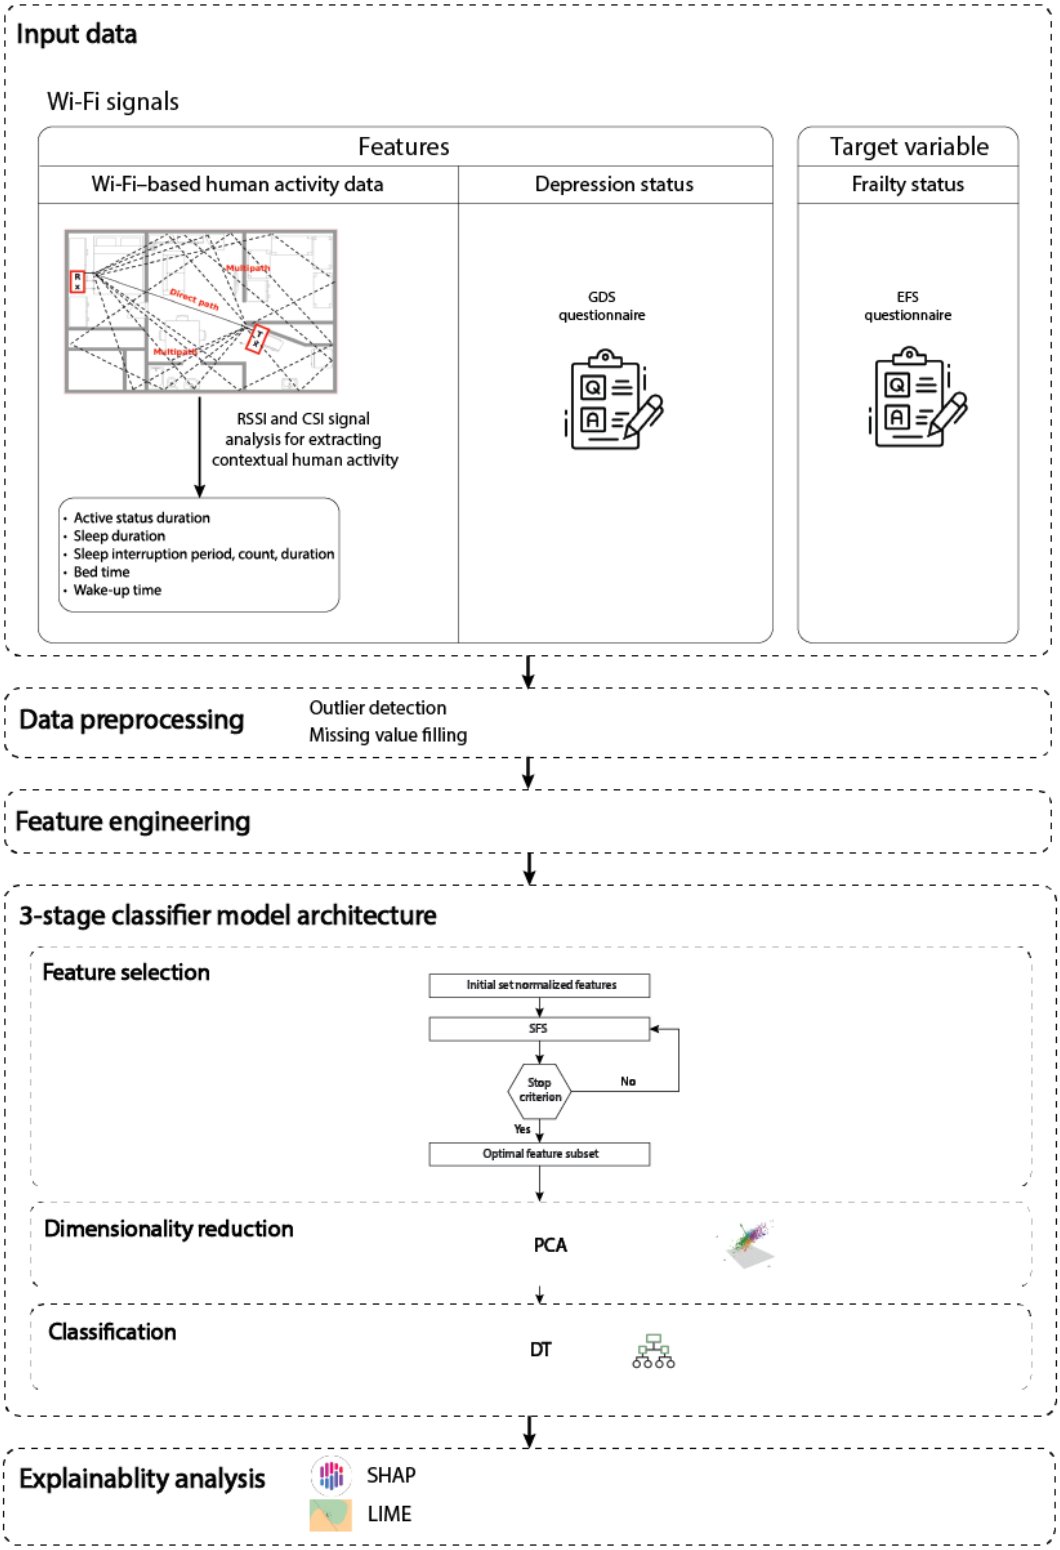
depression; classification; machine learning; artificial intelligence; older adults

Introduction

Depression is a prevalent mental health disorder characterized by emotional dysregulation, leading to persistent sadness, loss of interest, and anhedonia [1-3]. The rising incidence of depression among older adults has become a significant public health issue [4-6]. Early detection of depression and corresponding intervention are vital for improving mental health outcomes and reducing the overall burden on individuals and health care systems [7-9]. Traditional methods for assessing depression include various approaches that typically require in-person evaluations, specialized training in comprehensive geriatric assessments, and reliance on clinical judgment and questionnaires, which can be challenging and resource-intensive [10-12]. These methods require older adults to visit clinical settings frequently, increasing strain on health care facilities and reducing data collection opportunities. Additionally, many older adults prefer to remain in their homes and be remotely monitored in that environment, highlighting the need for remote care solutions in this demographic [13,14].

Physical activity and mobility are among the important factors in evaluating depression, with strong correlations established between these parameters and depression assessments [1,15]. The advent of the Internet of Things has enabled continuous and remote monitoring of physical activity. Several studies have used statistical methods to analyze the relationship between physical activity, as measured by wearable devices, and depression [16-21]. As the field of artificial intelligence (AI) advances, machine learning models have emerged as promising tools for depression classification using physical activity data [22]. For instance, Adamczyk and Malawski [23] used data from wearable actigraph watches in 3 classification models: logistic regression (LR), support vector machine (SVM), and random forest (RF) comparing automatic and manual feature engineering for depression classification. Bai et al [24] used phone use, sleep data, and step counts from 334 participants, using 2 feature selection methods (L1-based feature selection) and 6 machine learning models (decision tree [DT], k-nearest neighbors, naive Bayes, LR, SVM, and RF) for mood classification. Chikersal et al [25] analyzed data from smartphones and fitness trackers of 138 college students to identify those experiencing depressive symptoms, using nested randomized LR for feature selection and AdaBoost with gradient boosting classifier. Dai et al [26] used heart rate, energy expenditure, sleep, and other activity data from wearable Fitbit devices for depression remission detection in 106 participants within 2 intervention and control groups, using a multitask learning algorithm comprising 2 dense layers with shared parameters. Similarly, Griffiths et al [27] classified depression using activity and sleep data from Fitbit devices of 24 participants through an RF model. Espino-Salinas et al [28] used wrist-worn accelerometers to measure physical activity in 55 participants, applying a 2D-convolutional neural network (CNN) and a deep neural network for depression classification. Jakobsen et al [29] used RF, deep neural network, and CNN algorithms for depression classification with wrist-worn actigraph data from 55 participants. Jung et al [30] used gait accelerometry data and a bidirectional long short-term memory network–based classifier to assess depression in 45 older adults. Other studies have also explored the use of wearable device data combined with various classification methods, such as 1D-CNN [31], deep convolutional neuro-fuzzy [32], Ensemble models [33], and extreme gradient boosting [34].

These recent studies highlight the integration of wearable devices with machine learning algorithms as a promising approach for continuous, remote, home-based monitoring and early detection of depression. However, wearable device-based approaches face challenges due to their intrusive nature [35]. Participants are required to wear sensors or devices, which may lead to issues with compliance, comfort, and data accuracy, especially over extended periods [36], particularly among older adults [37]. These challenges can result in inaccurate data collection [38]. Nonwearable methods, such as remote monitoring through ambient sensors, offer potential solutions to these issues [37,39,40]. These approaches can alleviate concerns related to device adherence and physical discomfort, providing a more seamless integration into daily life. Additionally, our literature review indicates that most studies on depression classification use a relatively large number of participants and primarily use single-stage classifiers. Many studies also focus on detailed aspects of physical activity data (eg, body displacement, acceleration) using intrusive wearable sensors, which, while effective, present challenges related to user comfort and compliance. This reliance on wearable technology underscores the need for exploring alternative, less intrusive methods.



XSL•FO
RenderX

Recently, Wi-Fi–based sensing in smart homes has emerged as an alternative method for detecting and monitoring contextual human activity and movement [41]. Wi-Fi–based technologies are increasingly adopted due to their existing infrastructure in homes and minimal additional setup costs [42]. These technologies use signal metrics such as received signal strength indicator (RSSI) and channel state information (CSI) to analyze Wi-Fi signal characteristics, offering human activity identification compared to invasive wearable sensors, image analysis, or video-based systems [43]. Leveraging Wi-Fi–based activity data with machine learning presents a viable approach for different diseases, specifically depression classification, which is the focus of this study.

Technological and AI-based methods for depression classification predominantly rely on wearable sensors and are often conducted on large participant groups and typically use statistical techniques or single-stage machine learning classifiers. Furthermore, these approaches often overlook the explainability analysis of the models, which causes a lack of understanding of the underlying decision-making processes and the contribution of individual features to the model's predictions. To address these challenges, this feasibility study introduces a novel 3-stage machine learning model that incorporates feature selection, dimensionality reduction, and classification for depression classification. This model is specifically designed for a limited number of participants using low cost, easily installable Wi-Fi data, which provides continuous insights into human indoor activities. In addition to creating a model that functions effectively with small sample sizes, this study integrates explainable AI techniques to enhance the interpretability of the model's predictions. This approach ensures that the insights derived from the model are transparent and comprehensible, providing clarity on how specific features contribute to the classification outcomes. Figure 1 illustrates a schematic overview of our proposed framework.

Methods

Data Acquisition

We begin by outlining the data acquisition process for the participants, followed by an in-depth explanation of our proposed HOPE model.

Study Cohort

Our recruitment approach used both digital and in-person strategies. Digital outreach was conducted through email campaigns, social media platforms, and digital posters. Prospective participants were provided with detailed information about the study, and those who expressed interest received a consent form. A member of the research team then coordinated

XSL•FO
RenderX

the setup of the monitoring equipment. Participants were compensated for their time and involvement with an e-gift card.

Participants in this study were required to be aged 65 years or older, capable of communicating in English or French, and have access to an internet connection at home. Exclusion criteria were as follows: (1) individuals with mental or physical conditions that would impede their ability to participate in the study and its 6-month follow-up, such as gait or balance disorders, active mental health issues, or the use of mobility aids such as canes; and (2) individuals with current substance use disorder, including alcohol or drugs, due to their potential impact on physical mobility. However, individuals with a history of substance use disorder who were no longer consuming were considered eligible.

Experimental Protocol

This study used a nonintrusive Wi-Fi–based motion sensor system to facilitate remote monitoring of human activity. Initially, we collected demographic information (ie, age and gender) from the participants. Subsequently, Wi-Fi data were acquired through our remote monitoring technology [44]. This device, installed at the network access point, detects Wi-Fi signals in environments conducive to passive sensing, including private residences and public spaces where Wi-Fi is prevalent [45]. In such indoor settings, Wi-Fi signals exhibit stability in the absence of individuals but fluctuate significantly with the presence and movement of people [45]. These signal variations correspond to distinct patterns associated with human movements and activities, thus providing valuable data for activity monitoring [46]. The collected data were subsequently transferred to secure cloud storage via an internet connection. Our team has developed advanced signal processing and AI-based algorithms to process raw Wi-Fi RSSI and CSI measurements. These algorithms standardize signal variations and translate RSSI and CSI fluctuations into a detailed set of contextual information related to human activity [45]. This information encompasses daily activity duration, bedtime, wake-up time, total sleep duration, and sleep interruption information. In addition to using Wi-Fi–based activity data, frailty and depression statuses were also assessed using validated assessment tools. The Edmonton Frailty Scale (EFS), which measures multiple dimensions of frailty [47-49], and the 15-item Geriatric Depression Scale (GDS) [50] were administered at the end of the experiment.

Analytical Framework

The methodical steps of our proposed model are detailed in the following subsections. During the development, implementation, and reporting, we adhered to the Minimum Information About Clinical Artificial Intelligence Modeling (MI-CLAIM) guidelines [51], following best practices designed to promote transparency and reproducibility of our AI model.

Data Preparation and Feature Extraction

To prepare the contextual human activity data as input for depression classification, obtained from our Wi-Fi signal analysis software, we designed a preprocessing stage. This process involves handling missing values and outliers to ensure the integrity of the data [52,53]. To enhance analytical depth and improve model performance, we implemented feature engineering on contextual human activity data. This process involves extracting a variety of new features, such as the mean and SD of bedtime and wake-up times, mean and SD of sleep duration (in hours), total count and mean of sleep interruptions, total duration and mean duration of sleep interruptions (in hours), longest continuous sleep duration (in hours), percentage of nights with sleep disturbances, and metrics related to daily activity, including the mean and SD of total daily activity and hourly activity durations, as well as peak activity hour. These derived features, combined with EFS data, were incorporated into our 3-stage machine learning classification model. The depression status, determined using the GDS, was used to label the samples for classification purposes.

HOPE Model Development

The proposed HOPE Model was designed for depression classification in older adults using nonintrusive Wi-Fi–based motion sensor data. Due to the limited number of participants, it is necessary to provide an efficient pipeline for preprocessing, feature extraction, and classification. The limited number of participants and high dimensionality of features required a tailored multistage machine learning pipeline to maximize classification accuracy. Furthermore, ensuring that our depression classification model is explainable to clinicians is important, as highlighted in our previous works [54,55]. To address this, we incorporated explainable machine learning techniques such as Shapley additive explanations (SHAP) and local interpretable model-agnostic explanations (LIME). To achieve these goals, our proposed HOPE model was structured into 3 stages of machine learning architecture: feature selection, dimensionality reduction, and classification followed by post hoc explainability analysis using SHAP and LIME. Each stage plays a critical role in refining the data and ensuring that the final classification is both accurate and interpretable. Table 1 provides details on the various techniques used and evaluated at each stage.

Feature selection is performed to reduce the dimensionality of the dataset by identifying the most relevant features for depression classification, enhancing both the speed and accuracy of the classification model [79]. The reduced subset of features serves as input for the subsequent dimensionality reduction stage. The validity of the chosen selected features is investigated using correlation analysis in the Results section. Dimensionality reduction techniques are applied to further refine the feature set compared to the initial feature selection stage [80] and to minimize overfitting. The dimensionally reduced features from the second stage were then processed in the third stage, which focused on classification. In this stage, the classification model processes the features derived from the earlier stages to categorize samples into 2 target classes: "participants with depression" and "participants without depression." The classification algorithm leverages the patterns identified in the features, such as sleep duration and interruptions, to make predictions. The classification task involved assigning a probability score to each sample, determining the likelihood of belonging to either class based on the relationships in the feature set. A decision boundary was then established to assign the final class label for each sample. The classification process was systematically evaluated to ensure robustness and reliability, focusing on separating the 2 groups effectively even with the small dataset. The machine learning classification pipeline was designed to minimize the risk of overfitting by using techniques such as feature selection and dimensionality reduction, ensuring that the most informative and relevant features were used for prediction. To conclude, we used explainable AI techniques to interpret the model's predictions, focusing on identifying the most influential features and their impact on classification outcomes.

Following the training and evaluation of all potential combinations for each stage, the architecture using sequential forward selection (SFS) for feature selection, principal component analysis (PCA) for dimensionality reduction, and DT for classification emerged as the most effective configuration. This SFS-PCA-DT framework (Figure 1)

XSL•FO
RenderX

demonstrated superior performance compared to other combinations.

Our proposed model is supported by different considerations. The SFS algorithm incrementally selects features to improve classification performance and is particularly suited for datasets with a smaller number of participants [81]. Unlike filter methods, SFS acts as a wrapper technique that pairs with a machine learning classification algorithm, providing greater stability in performance [81]. The method starts with no selected features and progressively adds them based on their ability to enhance cross-validation outcomes. In the second stage, PCA serves as a highly effective tool for reducing the dimensionality of data in an unsupervised manner [82]. It converts the initial set of features into a reduced number of uncorrelated components, maintaining the bulk of the data's variance. This reduction is important for preventing overfitting, especially with limited sample sizes. As a classification algorithm, DT algorithm, known for its strength in binary classification tasks, effectively uses the streamlined feature set generated in earlier stages. It models data by learning simple decision rules inferred from the input features, creating a tree-like structure. Each internal node in the tree represents a decision based on a feature, each branch represents an outcome of the decision, and each leaf node represents a class label [83]. The integration of SFS, PCA, and DT results in an efficient model that aligns with established methodologies and theoretical principles in the field. In this study, comprising only 4 participants, the training and validation procedure were carefully designed to minimize overfitting and to achieve reliable model generalization. To this end, we used a 4-fold cross-validation strategy. Each fold consisted of 3 participants for training and 1 participant for testing, ensuring that every participant contributed to both training and testing in separate iterations. This approach was repeated 10 times with different random seeds to account for variations in the training process, further enhancing the robustness of the performance metrics. During the training phase, a range of hyperparameter optimization techniques, including random search [84], Bayesian optimization [85], and Hyperband [86] was performed for each component of the 3-stage pipeline. For example, the DT classifier's maximum depth, minimum sample split, and criterion parameters are tuned using Bayesian optimization within predefined search spaces. Similarly, for PCA, the optimal number of components is optimized to maximize variance retention while preventing overfitting. The SFS algorithm was guided by internal cross-validation within the training set to identify the most predictive subset of features.

Evaluation Metrics

To validate the effectiveness of our depression classification method, we used 4 evaluation metrics: accuracy [87], sensitivity [87], precision [87], and F_1-score. Accuracy provides a comprehensive measure of the model's overall performance. Sensitivity helps ensure that the model accurately identifies as many true cases of depression as possible, minimizing the risk of missing individuals who actually have the condition [88]. To further validate the stability of the model, we present the training and test accuracies against the hyperparameter variations, demonstrating the model convergence.

Ethical Considerations

The study received approval from McGill University's Institutional Ethics Committee (A06-B18-21A), allowing data collection and analysis for this project. Written informed consent was collected from all participants prior to their involvement in the study. All collected data were anonymized immediately after collection, with no personally identifiable information retained to ensure participant confidentiality. Participants received a $20 e-gift card as compensation for their time. At every stage of the research, we adhered to the ethical principles outlined in the Declaration of Helsinki [89] and the Tri-Council Policy Statement [90].

Results

Clinical Study Insights

Six community-dwelling older adults residing in Montreal, Canada, were recruited for this study between May 2022 and September 2022. However, 2 participants withdrew due to internet connectivity issues, resulting in the use of data from the remaining 4 participants for the analysis. The EFS results indicated that 2 participants exhibited moderate frailty (scores ranging from 6 to 11), while the other 2 participants were classified as nonfrail (scores of 5 or below). GDS results suggested that 1 participant had depressive symptoms (score=10), while the other 3 participants did not (score range=0-4).

Some of the participants' demographic and clinical characteristics are detailed in Table 2. Over a 6-month period, the activities of each participant were continuously monitored at 15-minute intervals using Wi-Fi motion sensors. Following the identification of potential input features derived from Wi-Fi signals and questionnaire data, we designed and developed a 3-stage architecture as outlined in the methodology section. To support future research and ensure the reproducibility of our findings, the code for our model is openly accessible on our lab's GitHub repository [91].

Table 2. Demographic and clinical characteristics of the participants of this study.

	Participant without depression (n=3)	Participant with depression (n=1)
Sex (female/male), n/n	1/2	1/0
Age (years), mean (SD)	67.05 (3.70)	65.50 (0.00)
Edmonton frailty scale, mean (SD)	3.34 (3.21)	7.00 (0.00)
Geriatric depression scale, mean (SD)	4.00 (1.00)	10.00 (0.00)

XSL•FO
RenderX

We assessed a total of 240 model configurations, which resulted from the combination of 5 feature selection methods, 4 dimensionality reduction techniques, and 12 classifiers. Each configuration was trained 10 times to account for variations in performance metrics, ensuring the robustness of our findings. To mitigate the overfitting risk, we used k-fold cross-validation [92]. We experimented with different initial feature sets to optimize model performance, and among the various hyperparameter tuning methods, Bayesian optimization consistently yielded superior results.

Model Performance and Validation

This section presents the outcomes of our classification model evaluation. Table 3 summarizes the top-performing configurations among the 240 model variations that we tested. The SFS-PCA-DT model, which integrates SFS, PCA, and DT, emerged as the leading performer across multiple metrics. Its relatively high accuracy indicates the model's ability to distinguish between individuals with and without depression. The model's high sensitivity ensures that individuals with depression are correctly identified. This is critical in clinical settings, where depression, particularly among older adults, often goes unrecognized despite its severe impact on cognitive function [93-96], quality of life [97,98], and mortality risk [99,100]. Ensuring high sensitivity reduces the likelihood of missed diagnoses, which is important for timely and effective treatment. However, the relatively high standard deviation in both accuracy and sensitivity suggests that the model's performance may vary, indicating occasional instances of less reliable predictions.

Table 3. Average classification performance of the top 5 architectures.

Model	Accuracy (%)	Sensitivity (%)	Precision (%)	F_1-score (%)
SFS[a] – PCA[b] – DT[c]	87.50 (12.50)	90.00 (20.00)	88.34 (18.34)	86.00 (14.74)
SFS + FA[d] + DT	85.00 (16.58)	83.34 (25.82)	90.00 (20.00)	81.67 (18.93)
SFS + PCA + LR[e]	82.50 (19.53)	85.00 (22.91)	83.34 (25.82)	80.00 (20.82)
SFS + PCA + SVM[f]	82.50 (19.53)	90.00 (20.00)	75.00 (22.42)	80.00 (20.82)
MI[g] + PCA + LR	80.00 (10.00)	85.00 (22.91)	78.34 (22.42)	76.00 (13.06)

[a]SFS: sequential forward selection.

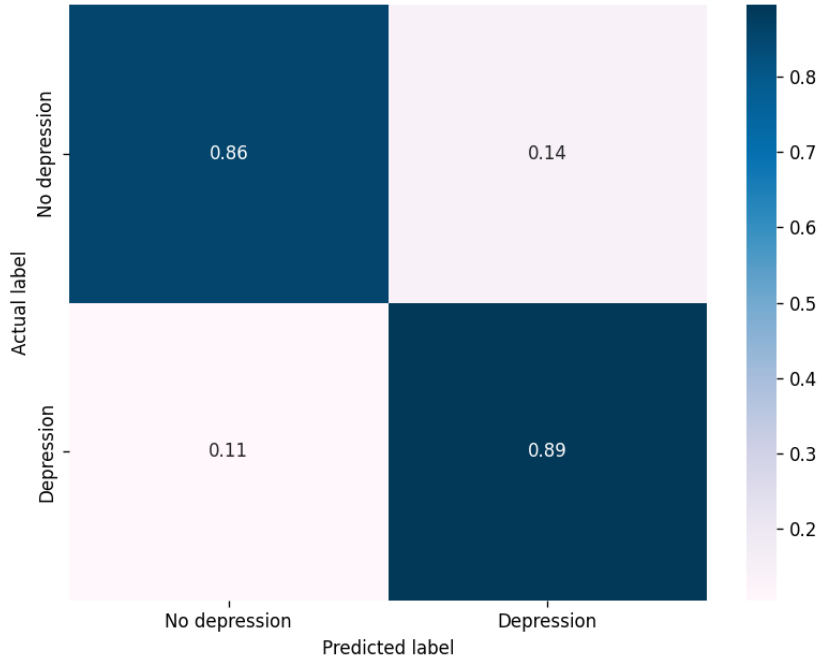
[b]PCA: principal component analysis.

[c]DT: decision tree.

[d]FA: factor analysis.

[e]LR: logistic regression.

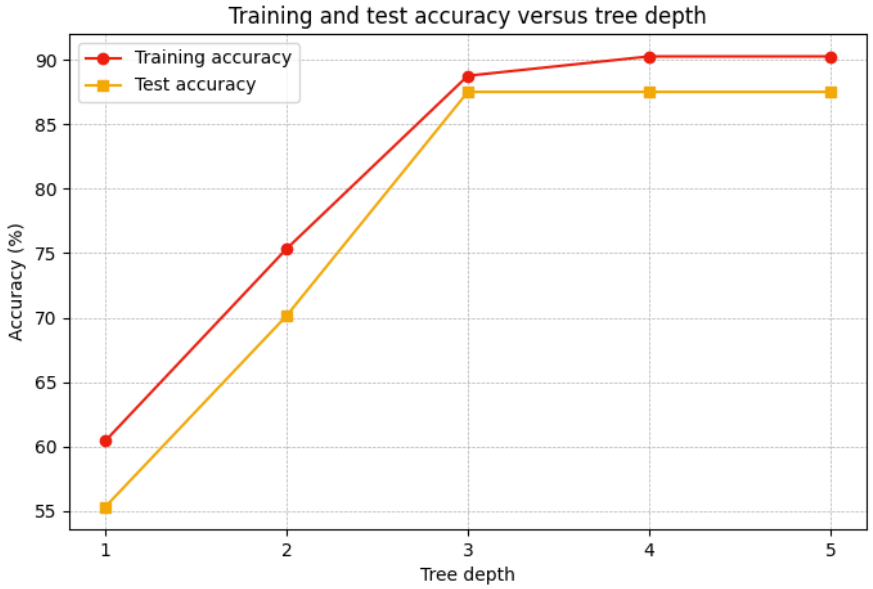
[f]SVM: support vector machine.



[g]MI: mutual information.

Table 3 illustrates that SFS is frequently featured among the highest-performing models, including the top model with 87.50% accuracy, and 3 other strong contenders. Mutual information also proves effective, appearing in 1 model with 80.00% accuracy, indicating that both SFS and mutual information are potent feature selection techniques for depression classification with limited samples. PCA seems to be the preferred method for dimensionality reduction, being used in 4 of the top 5 models. Among classifiers, DT stands out, featuring in the top 2 models with 87.50% and 85.00% accuracy. Other classifiers, such as LR and SVM, also perform well, each appearing in models with an accuracy exceeding 80%. The results highlight interesting tradeoffs, such as the SFS + PCA + SVM model, which, while slightly lower in accuracy (82.50%), maintains a high sensitivity (90.00%). This supports the practice of evaluating models using multiple metrics, especially in situations where the application involves clinical diagnoses, where accurately identifying true positives is crucial.

Figure 2 displays the averaged confusion matrix for the top-performing SFS – PCA – DT model used to classify depression status. Due to the constraint of having only 4 samples, we used a 4-fold cross-validation strategy, with each fold being tested 10 times to ensure a thorough evaluation. The model showed promising results, accurately classifying 86% of individuals without depression as not having depression and 89% of individuals with depression as having depression. The average false positive rate, where individuals without depression were incorrectly classified as having it, was 14%, while the average false negative rate, where individuals with depression were incorrectly classified as not having it, was 11%.

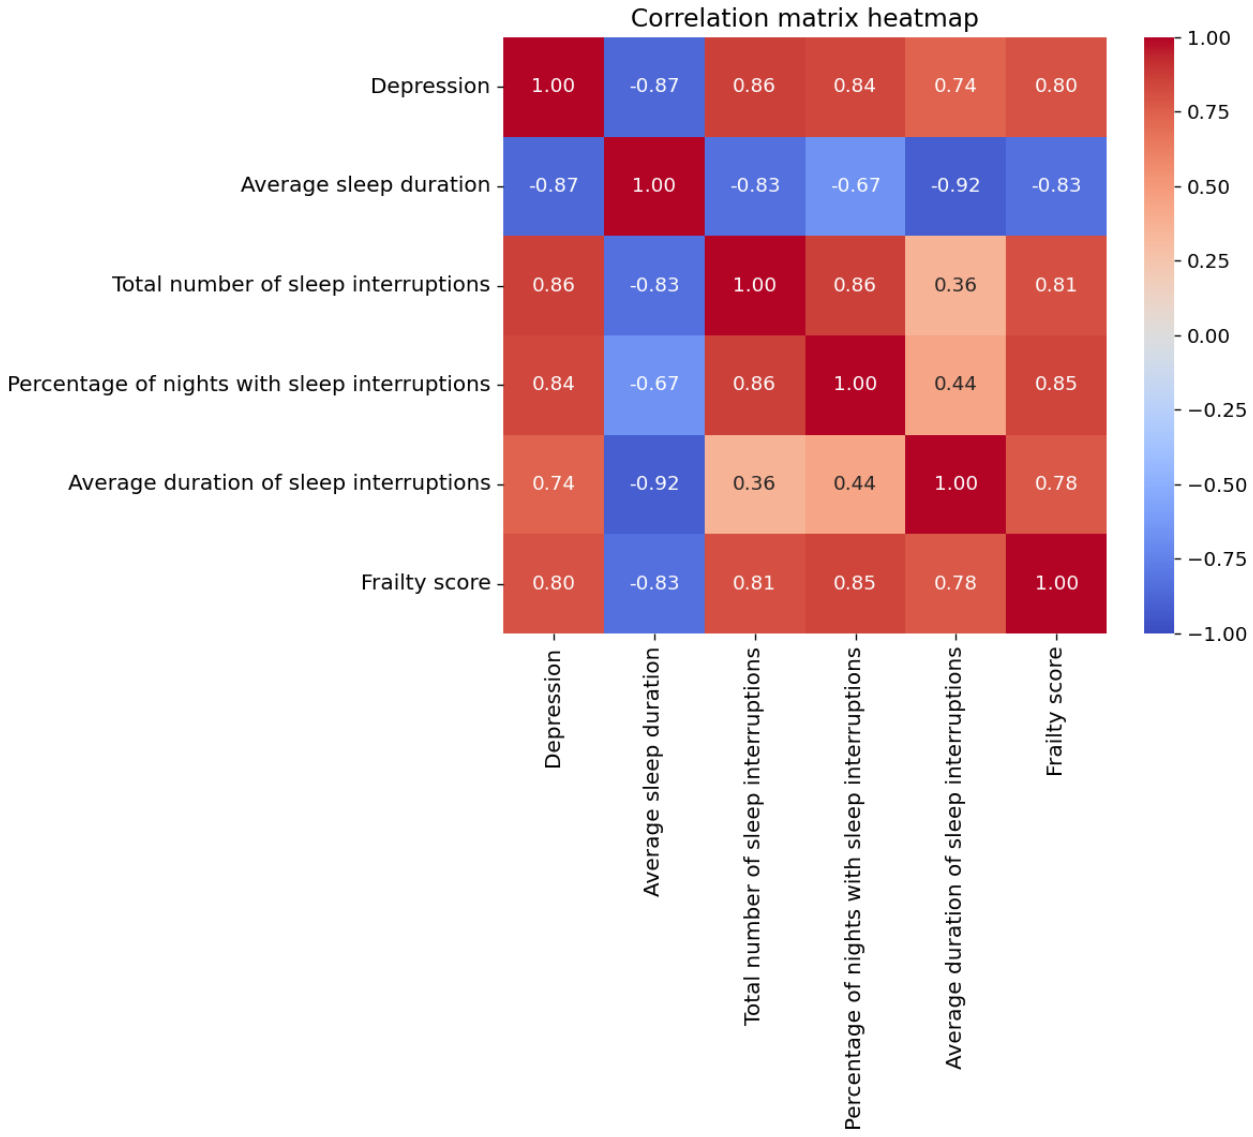


XSL•FO
RenderX

Figure 2. Confusion matrix for the top-performing model (SFS – PCA – DT). DT: decision tree; PCA: principal component analysis; SFS: sequential forward selection.

To validate the convergence of the proposed algorithm, we analyzed the relationship between tree depth and accuracy on both the training and test datasets. Figure 3 demonstrates the training and test accuracy of the best performing model (SFS – PCA – DT) as a function of tree depth. The training accuracy increases consistently with tree depth, stabilizing at its maximum, reflecting that the model can fully capture the training data as depth increases. The test accuracy improves initially with increasing tree depth but stabilizes beyond a depth of 3. These observations confirm that the proposed algorithm achieves convergence in terms of performance tradeoffs between model complexity and generalization.

Figure 3. Training and test accuracy as a function of tree depth, demonstrating convergence of our proposed model.



Feature Selection and Analysis

In our 3-stage classification model, we implement a combination of feature selection and dimensionality reduction techniques to improve the efficacy of our machine learning approach [80]. The features selected by SFS included “average sleep duration,” “total number of sleep interruptions,” “percentage of nights with sleep interruptions,” “average duration of sleep interruptions,” and “EFS.” Correlation analysis of these features revealed notable associations with depression status. Such analysis helps identify how variations in these features might be related to changes in depression, providing valuable insights for clinicians and researchers to develop more effective diagnostic tools and treatments.

XSL•FO
RenderX

Figure 4 illustrates a strong negative correlation between depression and average sleep duration. Conversely, depression was positively correlated with the total number of sleep interruptions, percentage of nights with sleep interruptions, average duration of sleep interruptions, and EFS. Blue cells indicate negative correlation values, while red cells represent positive correlations. Darker colors signify stronger correlations. The high correlation values highlight the significance of these factors in understanding and potentially classifying older adults with depression, aligning with findings from previous studies [101-105]. For example, Vallance et al [106] demonstrated that engaging in daily activities can alleviate the adverse effects of depression among older adults. Furthermore, several studies have highlighted a connection between depression and frailty [107,108]. Vaughan et al [109] showed that the prevalence of both depression and frailty among individuals aged 55 years and older exceeds 10%. These findings confirm the association between depression and the features incorporated in our model.

Figure 4. Correlation matrix heatmap between depression and selected features by sequential forward selection.

Comparative Analysis With Baseline Models

In this section, we evaluate the performance of our proposed 3-stage architecture for depression classification, which leverages Wi-Fi–based contextual human activity data, against baseline models previously outlined in the introduction. Although direct comparisons are inherently difficult due to differences in data acquisition methods (wearable devices), feature sets, and sample sizes, this analysis serves to contextualize the effectiveness of our approach for our case study with a limited number of participants.

For the baseline models, we selected the most current classification architectures used in the literature for depression classification. To ensure a fair comparison, each baseline model was trained and tested using the same feature set applied in our experiment. The resulting performance metrics for each baseline model are presented in Table 4. Despite the challenges associated with our smaller sample size, the comparison offers valuable insights into the relative efficacy of our method.

XSL•FO
RenderX

Table 4. Average performance across different baseline machine learning models.

Model architecture	Accuracy (%)	Sensitivity (%)	Precision (%)	F_1-score (%)
RF[a] [23,27]	12.50	5.00	5.00	N/A[b]

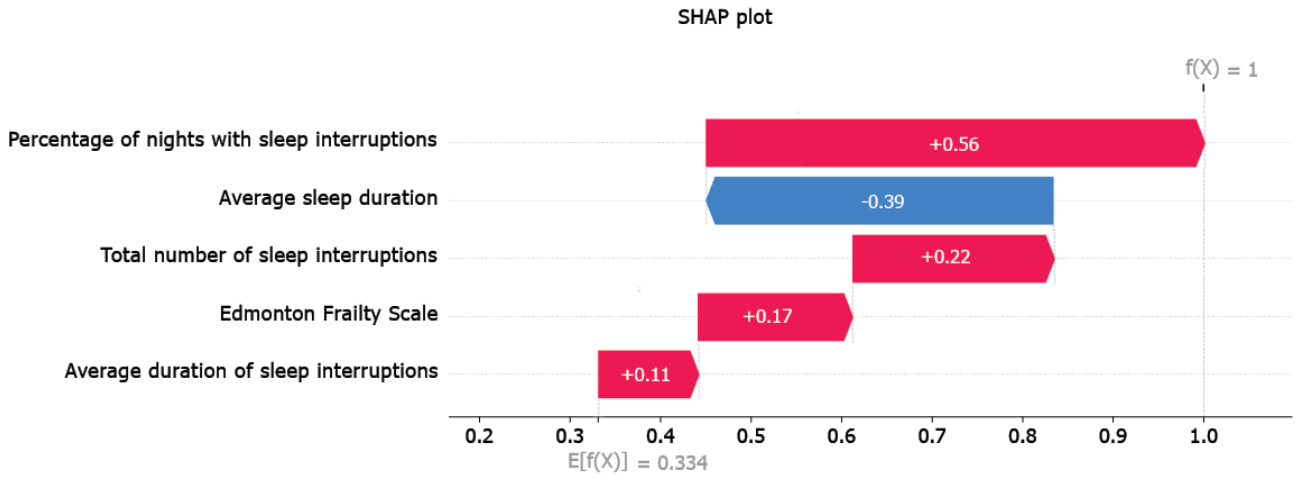
[f]kNN: k-nearest neighbor.

[g]NB: naive Bayes.

[h]Best performed proposed model.

As shown in Table 4, traditional single-stage machine learning classifiers such as RF, LR, and SVM demonstrate relatively lower performance, with accuracy ranging from 12.50% to 22.50%. Among these, LR achieves relatively higher accuracy. XGBoost exhibits better performance than the traditional models. Incorporating feature selection techniques further improves the performance of these models. Specifically, combining L1-based feature selection with various classifiers results in modest performance gains, while the randomized LR combined with AdaBoost achieves a significant improvement, reaching 55.00% accuracy and 73.33% sensitivity. Our proposed 3-stage architectures significantly surpass all other baseline models across all metrics. While most baseline models struggle with sensitivity and precision, often scoring below 15%, our best proposed model demonstrates substantial enhancements in these metrics with 90.00% sensitivity and 88.34% precision, indicating a superior capability to correctly identify positive cases and reduce false positives.

Model Explainability



To enhance our understanding of the decision-making processes within our proposed model, we used SHAP [50] and LIME [54] for model interpretability analysis. These model-agnostic methods can be applied across various machine learning models, providing valuable insights into our model's predictive behavior. By integrating these interpretability techniques, we aim to improve the transparency and potential clinical relevance of our depression classification framework. These methods help us identify which features most significantly influence the model's predictions, particularly in the context of depression classification.

SHAP Analysis

The SHAP waterfall plot (Figure 5) illustrates the relative importance of features for depression classification, with red and blue colors representing positive and negative contributions, respectively. Among the features, "the percentage of nights with sleep interruptions" is the most impactful, positively correlating with depression risk, indicating that frequent sleep disturbances are a strong predictor of depression. Conversely, the average sleep duration exhibits a substantial negative impact on depression prediction, suggesting that longer sleep durations are associated with a reduced likelihood of depression. Sleep-related variables continue to play a pivotal role in the model's predictions; both the total number of sleep interruptions and the average duration of these interruptions contribute positively to depression risk, further underscoring the importance of uninterrupted sleep in depression diagnosis. Although the frailty scale is included in the model, its influence is relatively minor compared to sleep-related features.

XSL•FO
RenderX

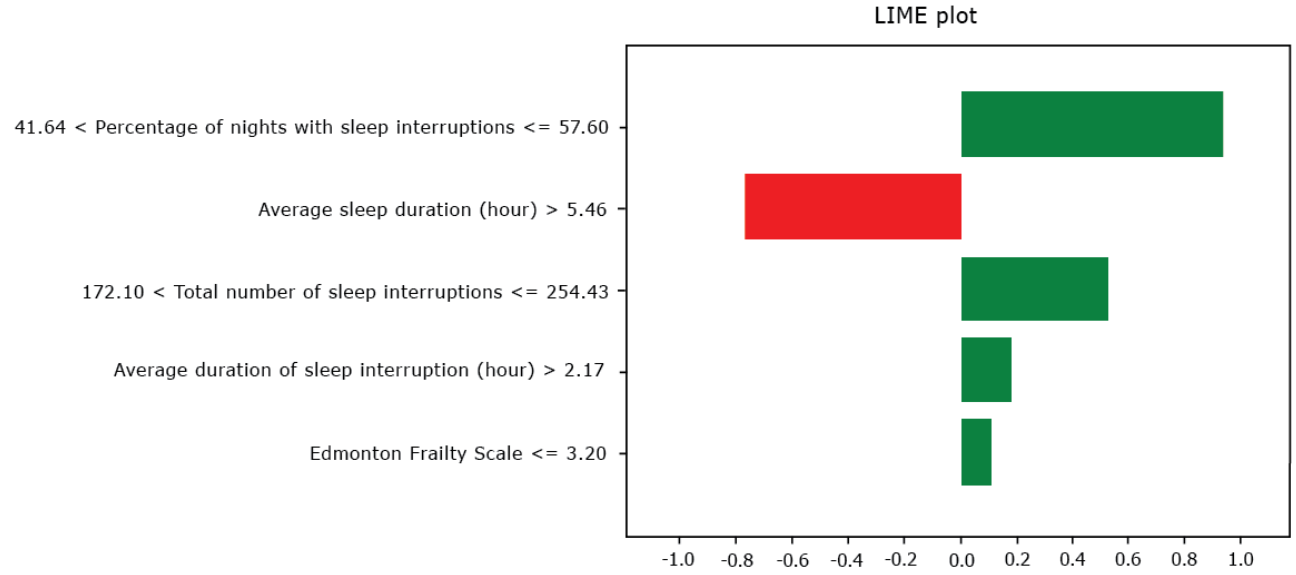


Figure 5. SHAP analysis. SHAP: Shapley additive explanations.

LIME Analysis

The LIME plot (Figure 6) provides a complementary view of feature importance, with green and red colors indicating positive and negative influences, respectively. Consistent with the SHAP results, LIME identifies "the percentage of nights with sleep interruptions" as the most critical feature in the classification of depression of our proposed model. Similarly, the average sleep duration is shown to have a significant negative impact on depression classification, in line with SHAP findings. The total number of sleep interruptions also ranks highly with a positive influence on depression risk, again aligning with SHAP results. A notable difference between the 2 methods is the relatively lower impact of the frailty scale in the LIME analysis, which requires further investigations.

Figure 6. LIME analysis. LIME: local interpretable model-agnostic explanations.

Discussion

Our research uses Wi-Fi–based motion sensors to extract daily activities, which are then used in our proposed machine learning method for depression classification.

Our study findings confirm the feasibility of using Wi-Fi–based motion sensors for depression classification among older adults. Our proposed HOPE (Home-Based Older Adults' Depression Prediction) model achieved an accuracy of 87.5%, sensitivity of 90%, and precision of 88.3%. The most influential features identified were sleep-related metrics, such as average sleep duration and sleep interruptions, highlighting the importance of sleep patterns in depression classification. These findings suggest that Wi-Fi–based monitoring offers a nonintrusive and effective alternative to conventional wearable technologies for depression assessment. These conventional methods, while effective, often present challenges in terms of participant compliance, particularly among older adults, due to their burdensome and sometimes uncomfortable nature. In contrast, our Wi-Fi–based approach is nonintrusive and allows for continuous monitoring without requiring participants to wear or interact with any devices. This can significantly enhance participant compliance and the integrity of the data collected over extended periods. Compared to other nonintrusive monitoring technologies, such as camera-based methods, our Wi-Fi–based approach has distinct advantages. Wi-Fi infrastructure is prevalent in most homes and does not pose

XSL•FO
RenderX

privacy risks, making it a cost-effective and scalable solution for continuous health monitoring. Furthermore, unlike previous studies that rely on microlevel body displacement and accelerometer data, our study emphasizes macrolevel physical activity features like sleep patterns and overall activity levels shift is crucial as it highlights the potential of using broader, more easily obtainable metrics to assess depression status. Our findings demonstrate that these macrolevel features are not only feasible but also effective measures for depression classification, broadening the scope of nonintrusive monitoring technologies in mental health research. The next steps can be extracting more detailed types of human activity using nonintrusive Wi-Fi data and expanding more on using this type of data acquisition for depression classification.

Additionally, our proposed model demonstrates relatively high performance compared to other classification models presented in existing depression classification studies, even with a limited sample size. Many studies using physical activity data from wearable devices often benefit from larger datasets and frequently use single-stage classifiers or deep neural networks. These models generally show strong performance with abundant data; however, their effectiveness diminishes when applied to smaller datasets, such as the one in this feasibility study. To address the limitations imposed by our smaller sample size, we designed a 3-stage machine learning classification architecture, which combines feature selection, dimensionality reduction, and classification into a multistep process. This approach allows for the extraction of the most relevant features while minimizing noise, thereby improving classification performance. Despite the small sample size, our model consistently outperformed conventional single-stage classifiers, highlighting the strength of both the machine learning architecture and the selected human activity features—particularly sleep patterns and activity levels—used for depression classification. This also underscores the adaptability of our model to different data scales, making it a more versatile option for future research where data availability might be limited. While this model shows promising results, however, caution is needed in interpreting these results. Future work should aim to enhance its robustness and generalizability by expanding the dataset. Collecting Wi-Fi–based physical activity data from a larger and more diverse sample would not only improve the model's statistical power but also allow for a more comprehensive evaluation of its performance across different population groups, such as varying age ranges and health conditions. This would be particularly valuable in developing a scalable solution for real-world applications. Additionally, the integration of advanced machine learning techniques, such as deep neural networks or hybrid models combining traditional classifiers with deep learning components, could further enhance classification accuracy.

Our study is distinctive not only in its methodological approach but also in its emphasis on model explainability, a crucial aspect often overlooked in prior research on depression classification. Explainability is essential in health care applications, where understanding the factors driving a model's decision is critical for clinical adoption and trust. By using SHAP and LIME, we were able to dissect the decision-making process of our model and pinpoint the most influential features for classifying depression. Both explainability analyses converge on the identification of sleep interruption features as key predictors in the depression classification of our proposed model. Among these, the "percentage of nights with sleep interruptions," "average sleep duration," and "total number of sleep interruptions" emerged as the primary driving factors. These findings align with existing literature that highlights the strong correlation between sleep disturbances and depression. However, our approach goes a step further by quantifying the impact of these features on the classification outcomes, providing a more nuanced understanding of their role. These findings suggest that future tools for depression assessment may benefit from a stronger focus on sleep quality and patterns and further investigations are required in this regard.

The integration of sensors and AI is transforming health care, yet the application of these technologies in depression classification remains underdeveloped and lacks extensive investigation. This study aimed to create an automated machine learning system for the continuous, remote monitoring and assessment of daily physical activity among older adults in a home setting, with the goal of distinguishing between individuals with and without depression.

In summary, although there were some challenges, our results suggest that using Wi-Fi–based data to capture contextual human activities is a promising and efficient method for classifying depression. The model we developed, leveraging data from Wi-Fi motion sensors, showed strong potential in accurately identifying early signs of depression and paving the way for more advanced and accessible mental health monitoring technologies among community dwelling older adults..

Acknowledgments

This study was funded by the Ministry of Innovation of Quebec, McGill University, Aerial Tech, and Mila—Quebec AI Institute. The authors acknowledge support from these institutions. SAR is Canada Research Chair (Tier II) in Artificial Intelligence and Advanced Digital Primary Health Care, received salary support from a Research Scholar Junior 1 Career Development Award from the Fonds de Recherche du Québec-Santé during part of this project, and her research program is supported by the Natural Sciences Research Council Discovery (grant 2020-05246).

Data Availability

The data analyzed during this study are not publicly available due to restrictions placed by the McGill University Institutional Ethics Committee, but the deidentified data are available from the corresponding author on reasonable request.

Authors' Contributions

Conceptualization was led by SAR, who established the study's goals, design, and research questions and obtained the funding for the project. The methodology was developed by SAR, and SN. The data collection was done by SAR and VK. Data curation was managed by SAR, SN, and VK. Formal analysis was conducted by SAR and SN. The original draft was written by SAR, and SN. Reviewing and editing were a collaborative effort with all authors. Supervision and overall project leadership were provided by SAR.

Conflicts of Interest

None declared.

Abstract

Background: Parkinson disease (PD) is a progressive neurodegenerative disorder that affects motor coordination, leading to gait abnormalities. Early detection of PD is crucial for effective management and treatment. Traditional diagnostic methods often require invasive procedures or are performed when the disease has significantly progressed. Therefore, there is a need for noninvasive techniques that can identify early motor symptoms, particularly those related to gait.

Objective: The study aimed to develop a noninvasive approach for the early detection of PD by analyzing model-based gait features. The primary focus is on identifying subtle gait abnormalities associated with PD using kinematic characteristics.

Methods: Data were collected through controlled video recordings of participants performing the timed up and go (TUG) assessment, with particular emphasis on the turning phase. The kinematic features analyzed include shoulder distance, step length, stride length, knee and hip angles, leg and arm symmetry, and trunk angles. These features were processed using advanced filtering techniques and analyzed through machine learning methods to distinguish between normal and PD-affected gait patterns.

Results: The analysis of kinematic features during the turning phase of the TUG assessment revealed that individuals with PD exhibited subtle gait abnormalities, such as freezing of gait, reduced step length, and asymmetrical movements. The model-based features proved effective in differentiating between normal and PD-affected gait, demonstrating the potential of this approach in early detection.

Conclusions: This study presents a promising noninvasive method for the early detection of PD by analyzing specific gait features during the turning phase of the TUG assessment. The findings suggest that this approach could serve as a sensitive and accurate tool for diagnosing and monitoring PD, potentially leading to earlier intervention and improved patient outcomes.

Introduction

Background

Parkinson disease (PD) is a common neurological disease that affects millions of individuals worldwide. This disorder gradually impairs a person's ability to move their body, resulting in a variety of crippling symptoms, including tremors, stiff muscles, and sluggish motions. To effectively manage PD and provide timely measures, accurate and early diagnosis is essential.

Traditionally, clinical evaluations conducted by medical professionals, which can be arbitrary and inconsistent, have

XSL•FO
RenderX

been used to diagnose PD. In distant or underdeveloped areas, access to specialized PD care may be restricted, delaying diagnosis and therapy. The prevalence of PD is predicted to rise as the world's population ages, placing additional demand on health care resources and highlighting the need for easily available and effective diagnostic methods.

In this regard, current technology has shown promise in addressing the difficulties associated with PD diagnosis, especially in the areas of machine learning and deep learning. The limits of conventional clinical procedures can be overcome with the promise of early and objective identification provided by machine learning techniques.

This study investigated the use of machine learning for PD identification with a focus on gait characteristics. The goal was to develop a simple and noninvasive method for screening PD symptoms early through analyzing gait patterns.

In this study, kinematic features during the turning phase of the timed up and go (TUG) assessment were extracted and analyzed. Gait variabilities occurring during body turning are more easily identified, as turning involves complex motor coordination and balance adjustments, making it a challenging movement. This increased complexity can accentuate subtle abnormalities in gait patterns that might not be as apparent during straight walking. Turning is particularly difficult for individuals with PD, as it requires precise control and stability, often revealing difficulties such as freezing of gait (FoG), reduced step length, and asymmetrical movements. Therefore, analyzing the turning phase allows for a more sensitive and accurate detection of PD symptoms, providing a reliable indicator of whether a participant exhibits PD-related gait abnormalities. This focus enhances the effectiveness of the diagnostic tool, which contributes to the facilitation of early and accurate identification of PD.

Conventional Methods

Challa et al [1] proposed an advanced predictive model for PD by using machine learning algorithms, such as multilayer perceptron, boosted logistic regression, random forest, and BayesNet. Their investigation applied the Parkinson Progression Markers Initiative dataset, an extensive dataset containing data from patients with PD and healthy participants. The experimental results showcased remarkable performance improvements over existing methods, boasting accuracy rates of 96.09% for training and 95.45% for testing in the multilayer perceptron algorithm, 96.5854% for training and 96.02% for testing in the BayesNet algorithm, 95.45% for training and 94.87% for testing in the random forest algorithm, and the highest accuracy achieved by the boosted logistic regression algorithm with 97.159% for training and 96.97% for testing. The area under the curve (AUC) of the receiver operating characteristic curve reached an impressive 98.9% for the boosted logistic regression algorithm, emphasizing its robust predictive capabilities. This research represents a significant stride in health care, providing a reliable model for early PD prediction, crucial for timely diagnosis and intervention in addressing this global public health challenge.

In 2019, Polat [2] investigated the recognition of FoG cases in individuals with PD, using a logistic regression classifier trained and tested on a dataset comprising 16 samples. The study meticulously assessed the classifier's performance using a comprehensive set of 10 performance measures, such as accuracy, miss rate, false discovery rate, false positive rate, false omission rate, sensitivity, specificity, precision, and negative predictive value. Impressively, the logistic regression classifier exhibited a noteworthy accuracy of 81.3% in accurately classifying FoG cases. The research further compared the performance of linear regression with 4 alternative models: linear support vector machine (SVM), quadratic SVM, cubic SVM, and k-nearest neighbors (KNN), revealing that the proposed logistic regression model surpassed its counterparts with the highest accuracy of 81.3% in classifying FoG datasets for individuals with PD. This outcome underscores the superior performance of the logistic regression model in the context of FoG classification.

Vidya and Sasikumar [3] conducted a comprehensive study on the application of multiclass SVM in using gait analysis to identify and grade the severity of PD. The researchers used a publicly accessible dataset containing Vertical Ground Reaction Force Sensors and implemented kinematic analysis to extract spatiotemporal features crucial for the diagnostic process. Their suggested framework included a multiregression strategy to normalize gait time series data and a correlation-based feature selection method. A total of 4 distinct SVM kernel functions such as linear, Gaussian, quadratic, and cubic were rigorously evaluated across 3 different walking tests to gauge their performance. Impressively, the quadratic SVM classifier emerged as the most effective, achieving an outstanding average accuracy of 98.65%. This result surpassed existing state-of-the-art methods, showcasing the robustness and efficacy of the proposed SVM-based approach for PD diagnosis and severity rating.

Moreover, Fang [4] performed a study focusing on predicting PD through the application of machine learning techniques. The research extensively compared the accuracy and recall of 3 distinct algorithms: KNN, random forest, and naive Bayesian. Addressing the inherent limitations of equal weighting in traditional KNN, the study introduced an entropy weight method to enhance KNN's performance, specifically mitigating equal-weighting issues. In addition, the research delved into a voice-based Unified Parkinson Disease Rating Scale (UPDRS) prediction scheme, leveraging algorithms to effectively predict UPDRS scores from voice data of patients with PD. Notably, the study used the University of California Irvine dataset, showcasing that the refined KNN algorithm surpassed its traditional counterpart, achieving a notable accuracy rate increase from 91.8% to 93.8%. This research contributes significantly to the advancement of PD prediction methodologies, particularly emphasizing the pivotal role of improved weighting mechanisms in enhancing algorithmic accuracy.

In addition, Gundala et al [5] conducted a comprehensive study using the random forest algorithm for the recognition of PD using the spiral handwritten dataset. The machine learning technique, widely recognized for its efficacy in processing handwritten designs, was applied by partitioning the dataset into subgroups on the basis of features and constructing decision

XSL•FO
RenderX

trees for each feature. The dataset, sourced from the Kaggle website, provided the foundation for training the random forest model. Notably, the algorithm's strength lies in its ability to combine outputs from multiple decision trees through majority voting, resulting in a remarkable accuracy rate of 91%. The study emphasizes the robustness of the random forest algorithm in accurately identifying PD on the basis of the features extracted from handwritten drawings. The results underscore the algorithm's effectiveness in leveraging the diversity of decision trees for enhanced predictive accuracy in the context of PD diagnosis.

Moreover, Govindu and Palwe [6] analyzed Multidimensional Voice Program audio data collected from both patients with PD and healthy individuals. Among the machine learning models evaluated, the random forest classifier emerged as the most effective, achieving a detection accuracy of 91.83% and a sensitivity of 0.95. This model outperformed other techniques, such as SVM, KNN and logistic regression, which were also assessed for their classification capabilities. The superior performance of the random forest classifier highlights its robustness and reliability for detecting PD in its early stages, demonstrating the promise of machine learning in enhancing diagnostic accuracy.

Deep Learning Methods

Pereira et al [7] proposed an innovative method for early identification of PD using a convolutional neural network (CNN) trained on handwritten dynamics data obtained by a smart pen. The CNN effectively learned relevant features from the signals generated during individual exams, enabling discrimination between individuals with and without PD on the basis of these learned features. Experimental results showcased the superiority of the CNN over raw data, with the ImageNet architecture, using 128 times 128 images and a 75% training dataset split, yielding the best overall accuracy of 83.77%. Despite these promising results, the study acknowledged challenges in achieving consistent recognition rates over control individuals, emphasizing the need for further refinement in the proposed approach.

Later, Grover et al [8] introduced a deep learning methodology using a deep neural network (DNN) constructed with TensorFlow and Keras, containing 3 hidden layers with 10, 20, and 10 neurons each and an input layer with 16 units, concluding with an output layer representing the classes *severe* and *nonsevere*. The DNN was trained on the Parkinson telemonitoring voice dataset from the University of California Irvine machine learning repository, comprising biomedical voice measurements from 42 participants. The experiments focused on predicting the severity of PD based on total UPDRS and motor UPDRS scores. The DNN exhibited substantial accuracy improvements over previous research, achieving a classification accuracy of 94.4422% for total UPDRS and 83.367% for motor UPDRS on the training dataset. While test dataset results were comparatively lower, with 62.7335% accuracy for total UPDRS and 81.6667% for motor UPDRS, the proposed DNN classifier showcased enhanced performance compared to previous studies, emphasizing its potential for accurate severity prediction in PD.

Aal et al [9] conducted an optimized approach for early PD detection, using speech features extracted from 2 datasets, dataset 1 and dataset 2, containing recordings from both healthy individuals and patients with PD. Using Mel-frequency cepstral coefficients and delta Mel-frequency cepstral coefficients, the authors proposed a deep learning model combining a recurrent neural network (RNN) with a long short-term memory (LSTM) layer. Comparative evaluation of alternative ML techniques, including SVM, KNN and RNN with stochastic gradient descent, revealed superior performance of the proposed RNN-LSTM model, optimized with the adaptive moment estimation optimizer. The model exhibited remarkable testing accuracy rates of 95.8% on dataset 1 and 90.24% on DS2, accompanied by high recall, precision, and F_1-score on both datasets. Aal et al [9] further demonstrated the model's superiority over existing methods for PD detection, solidifying its potential as an effective tool for early diagnosis.

Apart from that, Ouhmida et al [10] delved into the early recognition of voice-based PD through the application of CNN and artificial neural network (ANN). Using 2 distinct datasets, the study showcased the superior accuracy of CNN over ANN in their experiments. Dataset 1 encompassed 195 voice recordings from 31 individuals, while dataset 2 featured 240 recordings from 80 participants, with a balanced distribution of 40 patients with PD and 40 healthy individuals. The deep learning models, specifically CNN and ANN, underwent training and testing on both datasets, revealing CNN's accuracy rates of 93.10% and 88.89% for datasets 1 and 2, respectively. In contrast, the ANN model achieved slightly lower accuracies, with 82.76% for dataset 1 and 72.22% for dataset 2. Ouhmida et al [10] also highlighted the intricate layers comprising each model, with the ANN model featuring 2 hidden layers and the CNN model incorporating convolution, normalization, activation, softmax, and classification layers. The paper expressed an intent to extend the research by exploring additional deep learning methods and implementing a hybrid system integrating diverse techniques and datasets.

Biswas et al [11] proposed an approach for the early recognition of PD by proposing 2 distinct deep learning models tailored for hand-drawn graphics. The first model, a 2D CNN, processed preprocessed images of spirals, circles, and meanders as input, achieving notable accuracies of 83.6% on circles, 61.5% on spirals, and 67.8% on meanders. Another model, an innovative LSTM model, operated on timeline-series signals and demonstrated an overall accuracy of 0.78. Leveraging the NewHandPD dataset for training and testing, the authors conducted 4 comprehensive experiments, presenting the results. The study posited that early PD detection through these advanced models could potentially enhance treatment outcomes and elevate the overall quality of life for affected individuals.

Apart from that, Khaskhoussy and Ayed [12] evaluate the effectiveness of SVM CNN for classifying data obtained from speech tasks. Total 2 types of input data were analyzed: the raw speech signal values and i-vector features of dimensions 100, 200, and 300. The classification performance was assessed using 5 evaluation metrics: accuracy, precision, recall or sensitivity, specificity, and F_1-score. For a test dataset of 28 participants,

XSL•FO
RenderX

the approach achieved outstanding results, including 100% accuracy, a precision of 0.99, a recall of 0.98, a specificity of 0.96, and an F_1-score of 0.98. A table summarizing the state-of-the-art methods is presented in Table 1.

Table 1. A summary of the state-of-the-art methods.

Study	Methods	Input type	Dataset	Performance
Challa et al [1]	MLP[a], BayesNet, RF[b], and boosted logistic regression	Nonmotor symptoms	PPMI[c] dataset	Best overall accuracy: 96.97%
Polat [2]	Logistic regression	FoG[d]	FoG dataset (Parkinson disease)	81.3%
Vidya and Sasikumar [3]	SVM[e]	Gait features	Gait analysis dataset	98.65%

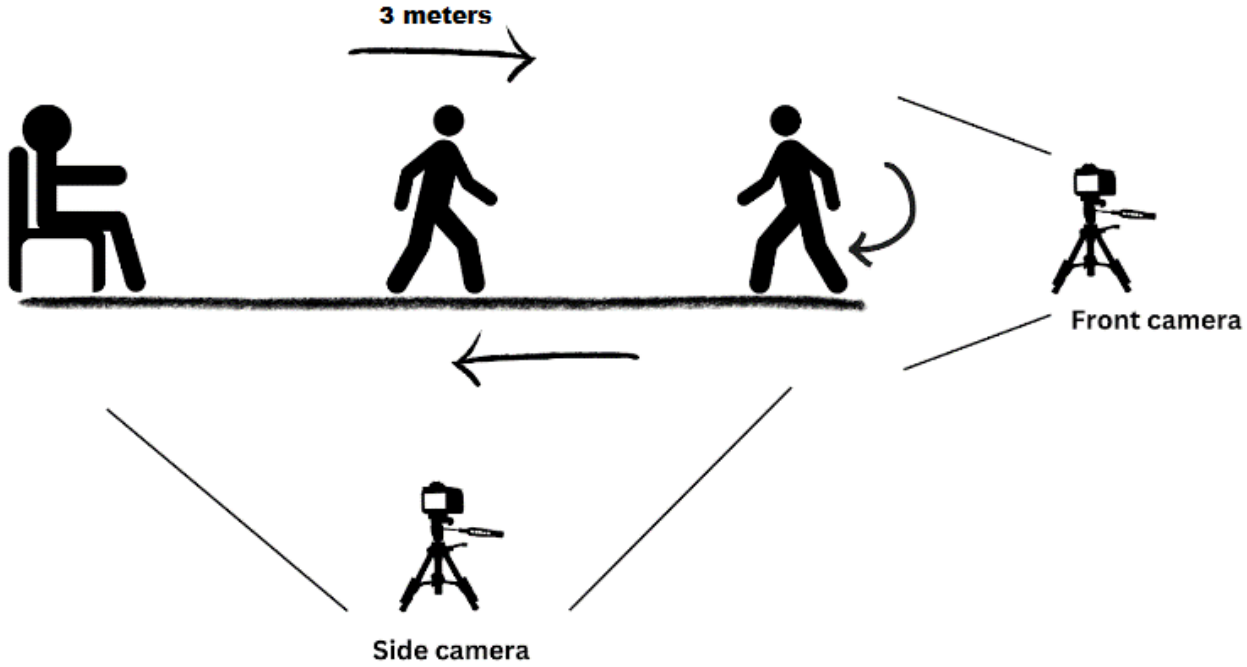
Methods

Overview

The study used a methodical approach that started with data collection from young adults, older adults, and patients with PD, followed by obtaining consent, particularly from those diagnosed with the disease. The TUG assessment was a key part of the data collection process. Video enhancements and preprocessing were performed to enhance the quality of the videos. After that, the key points on the human body were obtained using a human pose estimation technique. Next, features such as shoulder distance, step and stride lengths, cadence, and speed were extracted to analyze the gait patterns. The Butterworth filter was applied to refine the data, and peaks were identified to calculate steps and turning durations. Finally, SVM [2] was used to distinguish between the different groups based on the extracted features, aiming to improve the prediction and analysis of PD symptoms.

Dataset



The self-collected dataset comprised video recordings of 28 individuals performing the TUG assessment, a standard test used to evaluate mobility and balance. The dataset comprised 3 distinct cohorts: young adults aged between 21 and 33 years, older individuals aged >60 years, and older individuals diagnosed with PD. Consents were obtained from the participants before data collection. The videos captured various gait patterns, providing a comprehensive set of data for analyzing kinematic features, such as step length, stride length, and joint angles. This dataset allowed for controlled conditions and detailed annotations, ensuring high-quality data for feature extraction and analysis.

XSL•FO
RenderX

TUG Assessment

Figure 1 shows a TUG workflow, outlining the sequential steps involved in the activity. The process began with the individual seated at the designated starting point. Upon initiating the recording, the participant stood up and proceeded to walk a distance of 3 meters in a typical manner. Upon reaching the 3-meter mark, the individual executed a turn, walking back to the starting point, where they concluded the TUG process by returning to a seated position. This comprehensive description encapsulated the entire TUG procedure, providing a clear understanding of the task's progression. To enhance data capture, 2 phones were used, one on the front and the other on the side.

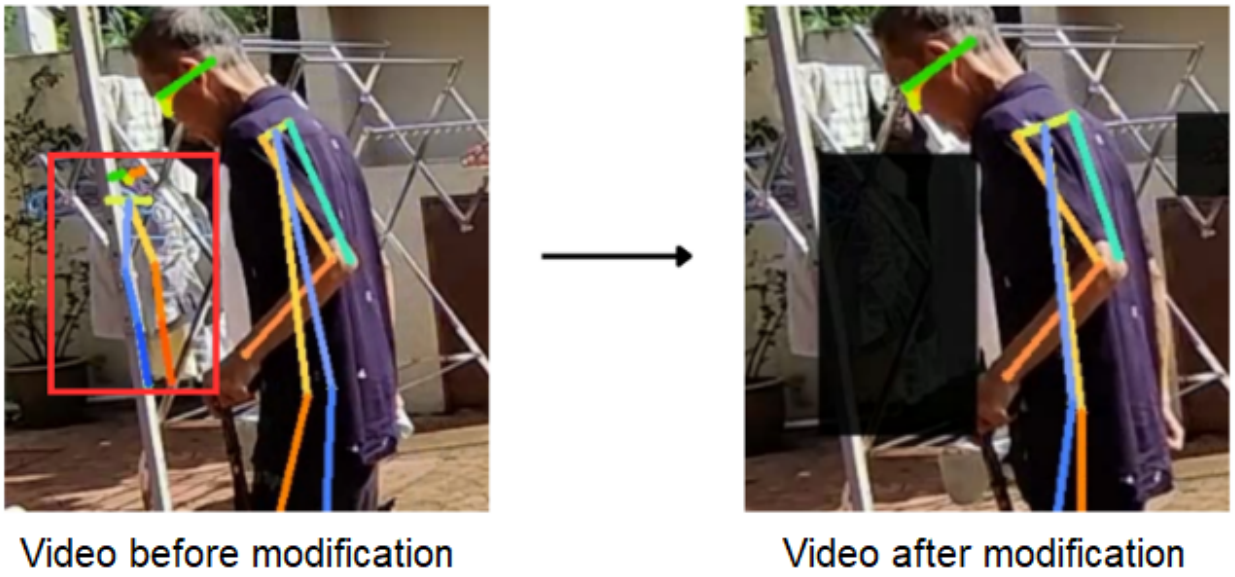


Figure 1. Timed up and go (TUG) assessment shooting site configuration plan.

Video Enhancement

The presence of background clutter in the original video introduces noise, which significantly affects the accuracy of letter pose extraction. Applying human pose estimation technique directly to unprocessed video may result in inaccurate keypoint coordinates, affecting the reliability of analysis results. To alleviate this problem, a preprocessing step was crucial. Specifically, the video was subjected to a customized processing method in which a black block was used to mask certain areas susceptible to noise. This strategic approach ensured that no noise interferes with the subsequent process, resulting in more precise and reliable coordination extraction. Figure 2 shows an example of enhancement performed on the video images.

Figure 2. Video enhancement.

Human Pose Estimation

In this study, AlphaPose was used to identify 17 key points from the human body, each corresponding to a specific anatomical location. The process yielded a JSON file containing coefficients for 17 key points. It is important to note that the JSON file, at this stage, has not undergone data processing. The raw file was populated with various elements, including image_id, category_id, key points, and scores within each set. The image_id represented the frame of the video, while the category_id served to identify the object (set as 1 for a person). The key points section contains coordinates for body part locations and corresponding detection confidence, formatted as x1, y1, c1, x2, y2, c2, and so forth, with "c" denoting the confidence score (Figure 3).

Figure 3. Gait analysis using AlphaPose.

Data Extraction

In the data preprocessing phase, the first step involved loading the JSON file and carefully filtering key points and image IDs. In addition, confidence scores were eliminated. The next focus was to mark the 17 identified body key points, including nose, left eye (LEye), right eye (REye), left ear (LEar), right ear (REar), left shoulder (LShoulder), right shoulder (RShoulder), left elbow (LElbow), right elbow (RElbow), left wrist (LWrist), right wrist (RWrist), left hip (LHip), right hip (RHip), left knee (LKnee), right knee (Rknee), left ankle (LAnkle), and right ankle (RAnkle). Next, according to the specific video file name, key point coordinates for each image ID (frame) were marked, ranging from Nose_x and Nose_y to RAnkle_x and RAnkle_y.

The results from the data preprocessing stage boasted a comprehensive structure, encompassing 36 columns that capture key information. Each column was curated to provide a detailed representation of the dataset. Starting with the file_name, which specified the associated video file, and the image_id indicating the frame or image ID corresponding to each set of key points, the subsequent 34 columns focus on the x and y coordinates of 17 distinct body key points.

Frame Segmentation

Frame segmentation is a process to assign a time interval to each frame in the video which helps to determine the occurrence of a turning event. The total duration of the video is divided by the total number of frames (rows). This calculation yields the time interval per frame, assuming a constant frame rate throughout the video. With this interval calculated, a new column named "time_duration" is added to the DataFrame. Each row in the "time_duration" column is populated with the cumulative time, calculated as the frame's index in the DataFrame multiplied by the time interval. This method provided a time stamp for each frame, which is essential for synchronizing the data with the video and analyzing the timing of the detected body turning events. The pseudocode presented in Figure 4 describes the step-by-step procedure for frame segmentation.

XSL•FO
RenderX

Figure 4. Pseudocode describing the step-by-step procedure for frame segmentation.

Algorithm 1: Pseudocode for Frame Segmentation

Data: *df*
Result: *turning_events*

```
function frame_segmentation(DataFrame df)
  for each row in df:
    shoulder_distance = sqrt((RShoulder_x − LShoulder_x)^2 + (RShoulder_y − LShoulder_y)^2)
    set df[shoulder_distance] to shoulder_distance
  end for

  for each row in df:
    if df[shoulder_distance] > threshold then
      set df[turning_event] to TRUE
    else
    set df[turning_event] to FALSE
  end if
 end for

 Return turning_events
End function

# Main Process
DataFrame df = Load data into a DataFrame
Float distance_threshold = Set the distance threshold

DataFrame turning_events = detect_turning_events(df)

Integer total_rows = Length of DataFrame df  # Total number of rows
Float total_duration_seconds = Set the total duration of the video in seconds

Float time_interval = total_duration_seconds / total_rows

For each row in DataFrame turning_events:
  Calculate time_duration = index_of_row * time_interval
  Add time_duration to DataFrame turning_events
```

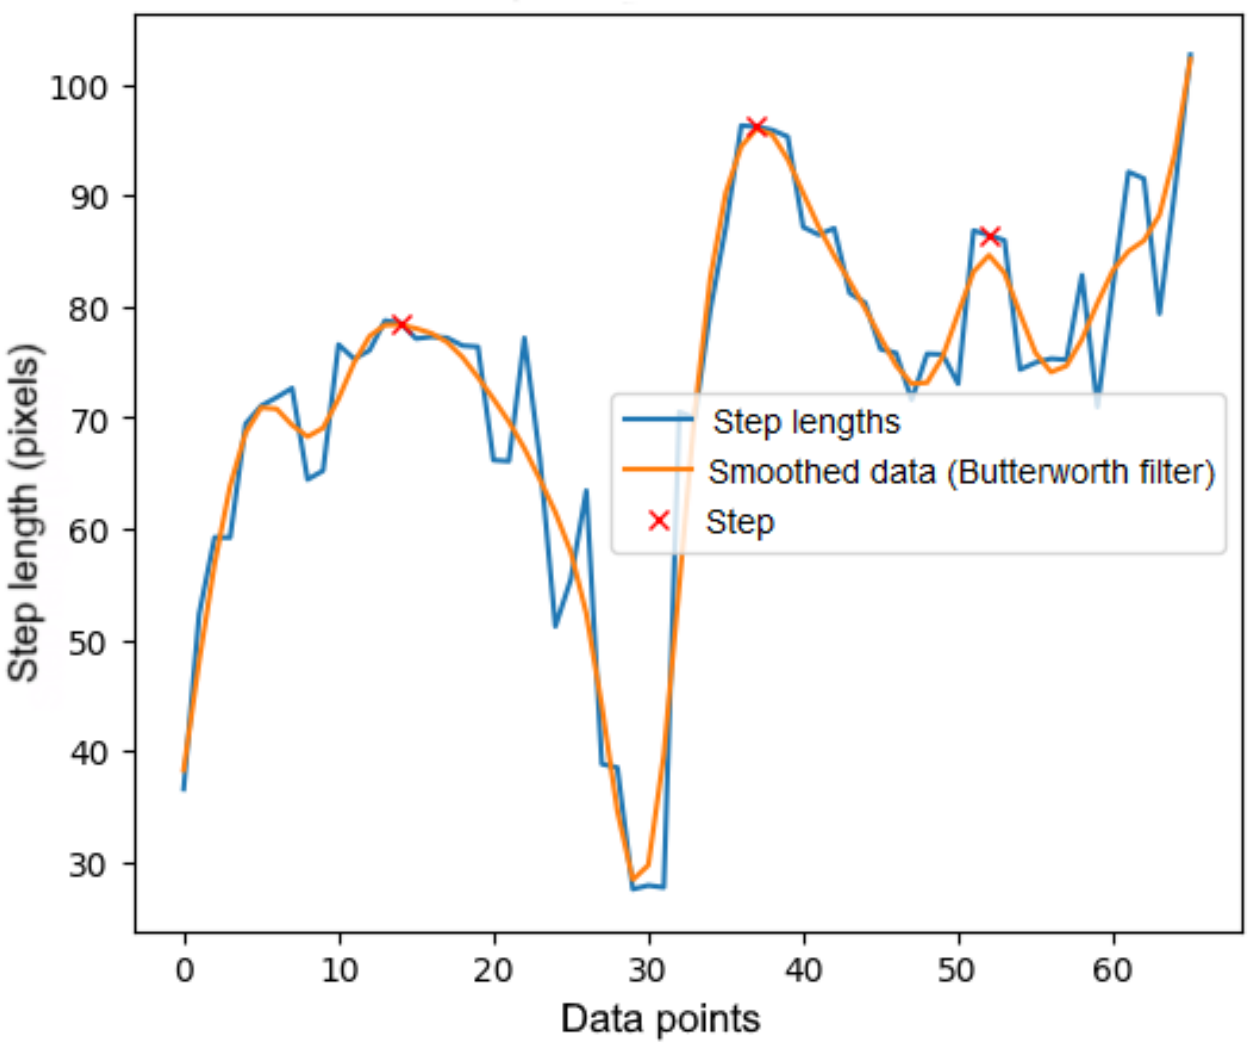
Noise Filtering

The Butterworth filter was used as the noise filtering tool in this study. The Butterworth filter is a type of signal processing filter that plays a pivotal role in enhancing the clarity of movement coordinate data extracted from videos. By applying the Butterworth filter to the raw coordinates, high-frequency noise is effectively attenuated, resulting in a smoother trajectory on the graph. This smoothed representation provides a clearer visualization of the participant's movements, reducing interference from irrelevant fluctuations.

Combined with the Butterworth filter, a peak detection algorithm was used to identify important points on the graph. These peaks correspond to key events in motion, such as steps taken by the participant. The peak identification process helped in extracting basic features such as the number of steps throughout the video. This kind of feature extraction is particularly valuable for specific PD aspects of analysis and quantification. The Butterworth filter is expressed using equation 1:

where $y(t)$ is the filtered signal; $x(t)$ is the input signal; fc is the cutoff frequency; f is the frequency of the signal; and n is the order of the filter.

In this study, an order of 4 was used for the Butterworth filters because it provides a smooth yet sufficiently steep roll-off in the transition band. While higher-order filters provide sharper roll-offs, they also require more computational resources. Therefore, a fourth-order filter appeared to be a reasonable compromise, being computationally efficient while providing adequate filtering. On the other hand, the peak detection equation is given by equation 2:



XSL•FO
RenderX

where $y(t)$ is the filtered signal; T is the set of all time points in the signal $y(t)$; t_i represents the time point where a peak occurs; and *height* is the threshold height for peak detection.

Only peaks that have an amplitude greater than or equal to the threshold, h, are detected and included in the output. In this study, the value for the height parameter was set to 100. An example of the graph for noise filtering with peaks is illustrated in Figure 5. This example demonstrates that the application of the Butterworth filter smooths the signal and yields an accurate step count during body turning.

Figure 5. An example of a graph processed with a Butterworth filter, showing peaks.

PD Recognition Using Model-Based Features

Certain gait features can help identify abnormalities or changes in walking patterns, which are particularly useful for diagnosing and monitoring conditions such as PD. By focusing on the body turning period, we aimed to capture the most challenging part of the gait cycle, where gait variabilities for PD are more easily observed. Turning involves complex motor coordination and balance adjustments, making it a difficult movement. This complexity can accentuate subtle abnormalities in gait patterns that might not be as apparent during straight walking. Therefore, analyzing gait features during turns provides a more sensitive and accurate assessment of PD-related gait abnormalities, enhancing the effectiveness of early diagnosis and monitoring. The gait features used in this study are summarized in Table 2.

XSL•FO
RenderX

Table 2. Gait analysis feature definitions and formulas.

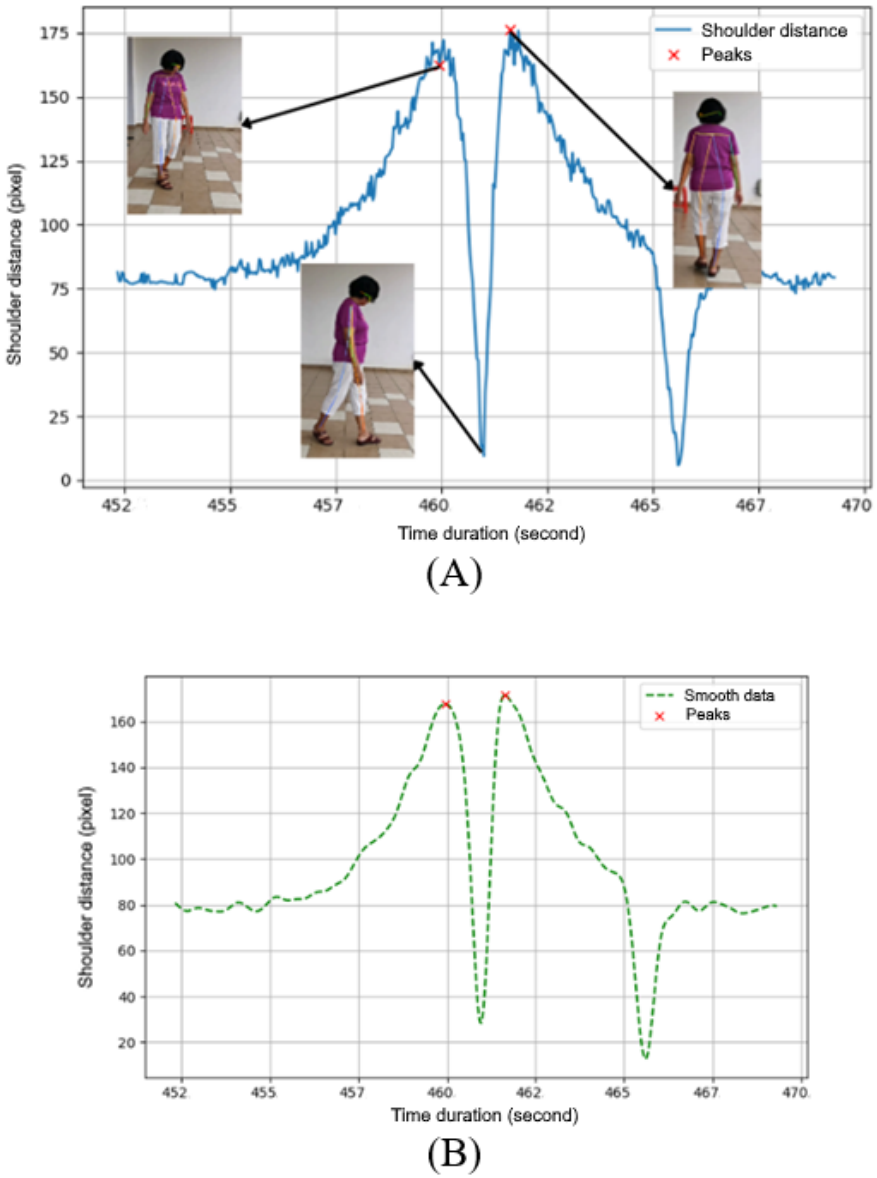
Feature	Definition	Formula
Shoulder distance	Average horizontal distance between the left and right shoulders	mean(Shoulder_Distance($LShoulder_x$,$LShoulder_y$,$RShoulder_x$,$LShoulder_y$))
Step length	Average distance between the left ankle and right ankle	mean(Step_Length($LAnkle_x$,$LAnkle_y$,$RAnkle_x$,$RAnkle_y$))
Stride length	Average distance covered in 1 full stride, which consists of 2 steps (1 by each foot)	mean(Stride_Length($RAnkle_x$,$RAnkle_y$))
Angle of both knees	Degrees at the knee joint by considering the vectors formed by the knee to hip and knee to ankle points	Θ_{Knee}(Hip_x,Hip_y,$Knee_x$,$Knee_y$,$Ankle_x$,$Ankle_y$)
Angle of both hips	Degrees at the hip joint by considering the vectors formed by the hip to knee and hip to shoulder midpoint	Θ_{Hip} ($Shoulder_{mid}$,$Shoulder_{midy}$, Hip_x. Hip_y, $Knee_x$, $Knee_y$)
Symmetrical leg	Degrees for each ankle by considering the vectors formed by the knee to hip midpoint and knee midpoint to hip midpoint	Θ_{Leg}($Knee_{mid}$,$Knee_{midy}$, Hip_{mid} . Hip_{midy}, $Knee_x$, $Knee_y$)
Symmetrical arm	Degrees for each arm by considering the vectors formed by the arm to shoulder midpoint and arm midpoint to shoulder midpoint	Θ_{Arm}($Shoulder_{mid}$,$Shoulder_{midy}$, $Elbow_{mid}$. $Elbow_{midy}$)
Trunk Angle 1 (vertical)	Degrees by considering the vertical reference vector and the vector from the hip midpoint to the nose	Θ_{Trunk1}(Hip_{mid} ,Hip_{midy}, $Nose_x$. $Nose_y$)
Trunk angle 2 (horizontal)	Degrees by considering the vector from the hip midpoint to the shoulder midpoint and a horizontal reference vector	Θ_{Trunk2}($Shoulder_{mid}$,$Shoulder_{midy}$, Hip_{mid} ,Hip_{midy})
Shank angle	Degrees at the hip joint by considering the vectors formed by the left ankle to knee midpoint and right ankle to knee midpoint	Θ_{Shank}($Ankle_x$,$Ankle_y$,$Shoulder_{mid}$,$Shoulder_{midy}$)

Body Turning Duration Calculation

Figure 6 presents 2 graphs related to the analysis of shoulder distance during a body turn. The left graph (Figure 6A) displays the original, unprocessed data, illustrating the raw measurements of shoulder distance over time. The fluctuations observed may correspond to the natural movement variations during a turn. In contrast, the right graph (Figure 6B) exhibits data that have been smoothed using a Butterworth filter, a technique that mitigates short-term fluctuations and reveals the underlying pattern of movement more clearly.

The smoothed data enables effective determination of the peaks of the signal, which identifies the significant turning points. These peaks are highlighted by the red "X" marks in the figure and represent moments where the shoulder distance reaches its maximum, indicating a complete turn or a change in direction. By focusing on the 2 highest peaks, the graph underscores the most substantial turning events, thereby minimizing the potential for misinterpreting minor variations as significant movements.

In the context of shoulder distance, *LShoulder* and *RShoulder* would correspond to the left and right shoulders, with their respective *x* and *y* coordinates. The shoulder distance, *Shoulder_Distance*, which is a measure of how far apart the shoulders are, is calculated as follows (equation 3):



The indexes between these 2 peaks are then taken to determine the exact time the turn occurred. The difference between these peak times is calculated to find the duration between consecutive turning points. Let $T_{peak,i}$ be the time of the *i*th peak and *n* is the total number of peaks detected. Equation 4 calculates the total time duration between the first and the last peak by adding up the durations between each pair of consecutive peaks,

Ethical Considerations

Ethical approval was granted by the Research Ethics Committee Multimedia University (approval number EA0422022). Informed consent was obtained from all the participants. A statement about this is given in the Methods section. Identifiable features of research participants are not visible in the manuscript. No compensation was provided to the participants.

Results

Overview

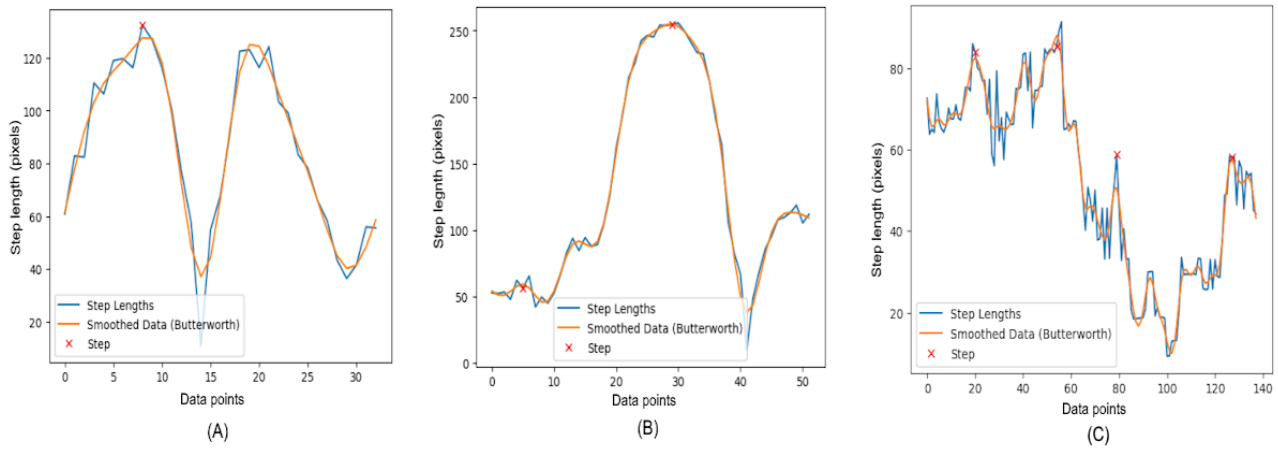
This section presents the experiment results and discussion for the gait features extracted from the self-collected dataset, focusing on the effectiveness of these features in distinguishing between normal and PD-affected gait patterns using a SVM classifier.

For the experiments, principal component analysis was applied to reduce the dimension of the dataset. The number of components for principal component analysis was set to 8, corresponding to the number of participants with PD. This step helps in capturing the most significant features while reducing computational complexity.

The dataset was additionally divided into a 70:30 ratio. This indicates that the model was trained using 70% of the data, with the remaining 30% set aside for testing and performance evaluation. By splitting the data this way, a significant portion of the data were used to train the model while maintaining enough for a thorough assessment. In total, 10 trials of the experiments were performed, and the average results were recorded.

Participant Details

There were 3 groups of participants in the self-collected dataset, namely, patients with PD, older adults, and adolescents. A significant portion of the participants (8/28, 29%) were diagnosed with PD, while the remaining participants were healthy (20/28, 71%). Most of the participants were Chinese (24/28, 85%), with a smaller representation of Indian (3/28, 11%) and Malay (1/28, 4%) individuals. There was a higher



XSL•FO
RenderX

proportion of male participants (21/28, 75%) compared to female participants (7/28, 25%). Finally, most participants fell within the age range of 60 to 69 years (14/28, 50%), followed by the age range of 20 to 29 years (9/28, 32%), and smaller proportions in other age ranges. These results collectively illustrate the diversity and focus of the study population.

Total Steps During Body Turning

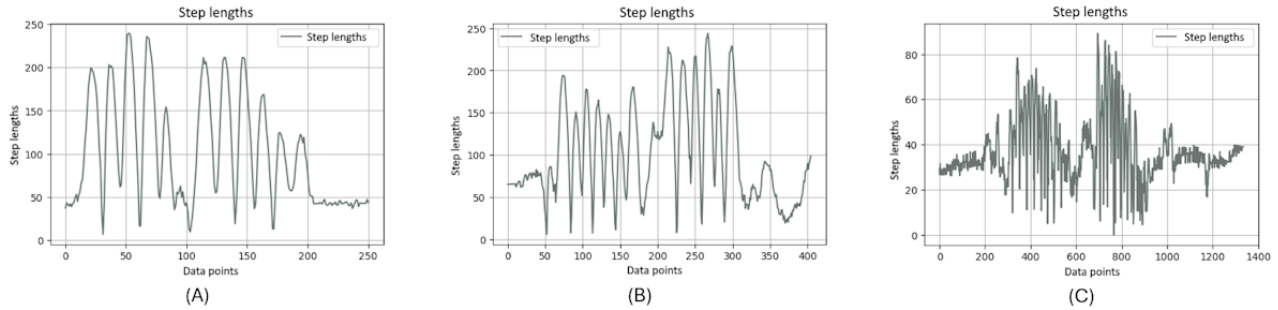
Figure 7 presents 3-line graphs that correspond to the step lengths for different demographic groups: younger individuals, older individuals, and individuals with PD. The step lengths are measured during a turning sequence.

Figure 7. A comparative step analysis by step length between different groups: (A) younger individuals, (B) older individuals, and (C) individuals with Parkinson disease.

The graph of younger individuals (Figure 7A) demonstrates a more variable stepping pattern with pronounced peaks, suggesting agility and a higher range of motion (ROM) during turns. The steps are uneven in length, but the peaks return to baseline quickly, indicating swift changes in direction and a potentially more dynamic gait.

In contrast, the graph of older individuals (Figure 7B) has fewer, more rounded peaks, indicative of a more cautious or steady turning strategy. The step lengths are generally more uniform, with smoother transitions between steps. This could reflect a more deliberate and potentially less stable gait, as is often seen with aging.

The graph of individuals with PD (Figure 7C) demonstrates a significantly different pattern, with smaller step lengths and a higher frequency of steps, which may point to the short, shuffling steps often associated with PD. The peaks are less pronounced and more erratic, highlighting the challenges individuals with PD may face in maintaining a regular stepping pattern.



Step Length

Step length refers to the distance between the left and right ankle for each step. It is determined by the coordinates of the left ankle ($LAnkle_x$, $LAnkle_y$) and the right ankle ($RAnkle_x$, $RAnkle_y$) at a particular instance in time. The formula to calculate step length is provided in equation 5. This formula gives the straight-line distance between 2 points in a 2D space, such as a video frame or a motion capture system's coordinate plane.

In Figure 8, the graphs illustrate the differences in gait patterns across 3 demographic groups during a TUG test. Each graph plots the variation in step lengths, which reflect the distance between the left and right ankle during individual steps.

Figure 8. A comparative step length analysis between different groups: (A) younger individuals, (B) older individuals, and (C) individuals with Parkinson disease.

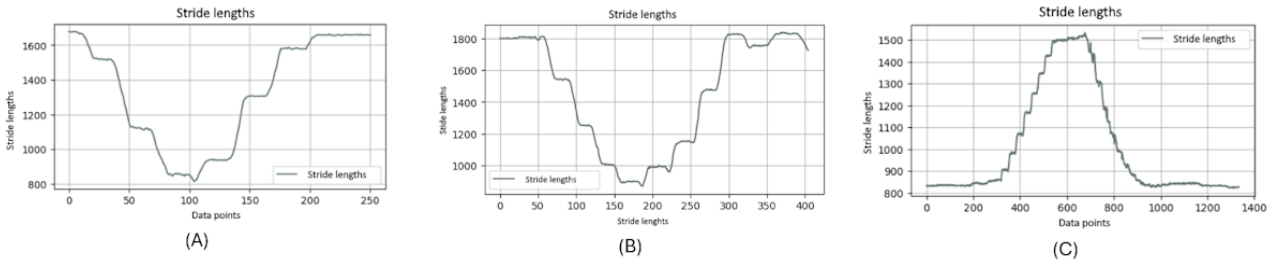
The graph of younger individuals (Figure 8A) is characterized by high peaks and deep valleys, indicating significant variability in step lengths. This could suggest a dynamic and robust gait, with the ability to take both long and short steps, perhaps adjusting speed or direction more frequently.

In contrast, the graph of older individuals (Figure 8B) shows a moderate level of variability with somewhat rounded peaks.

XSL•FO
RenderX

The reduced height of the peaks compared to the young group suggests shorter steps on average, which may be a sign of a more cautious approach to movement, possibly due to decreased mobility or balance concerns that come with age.

The graph of individuals with PD (Figure 8C) differs markedly from the other 2. It has a much higher frequency of smaller fluctuations, and the overall range of step lengths is noticeably lower. This pattern indicates the short, shuffling steps that are often observed in individuals with PD, reflecting the challenges they face with gait initiation and continuation.



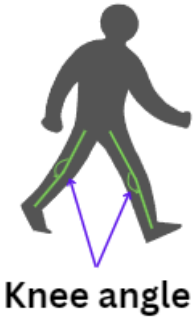
Stride Length

Stride length is typically defined as the distance covered in one full stride, consisting of 2 steps (one by each foot). The equation to calculate the stride length for each frame is presented in equation 6. It calculates the stride length as the Euclidean distance from a point (possibly the origin) to the coordinates of the right ankle for each frame.

Figure 9 shows the stride length of the right ankle throughout a single TUG video. The graph exhibits the dynamic nature of stride lengths, with the vertical axis representing the stride length and the horizontal axis corresponding to data points that likely represent sequential frames of the video.

Figure 9. A comparative stride length analysis between different groups: (A) younger individuals, (B) older individuals, and (C) individuals with Parkinson disease.

It is noteworthy that this graph clearly distinguishes between 2 types of motion: the rising and falling edges indicate the leg in motion, not in contact with the ground, and the flat regions signify the stance phase where the leg is stationary on the floor, awaiting the next step. The consistency in the flat regions indicates moments when the leg is at rest between strides.



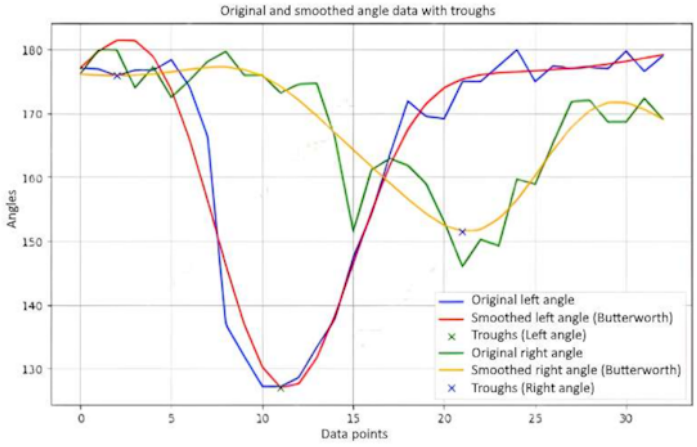
It is evident that the graphs of younger and older individuals (Figures 9A and 9B) display similar frequencies in stride patterns, whereas the graph of the individuals with PD (Figure 9C) significantly diverges. It illustrates a strikingly different frequency in stride lengths, standing out from the more consistent rhythmic patterns observed in the younger- and older-individual groups.

Moreover, from these charts, it is obvious that when younger and older people complete a stride, their feet leave the ground to a greater extent, because a normal stride will take a relatively large range. On the contrary, when patients with PD complete a stride, their feet leave the ground to a relatively smaller extent. The amplitude of the ground is relatively short, which can be considered a symptom of PD.

Angle of Both Knees

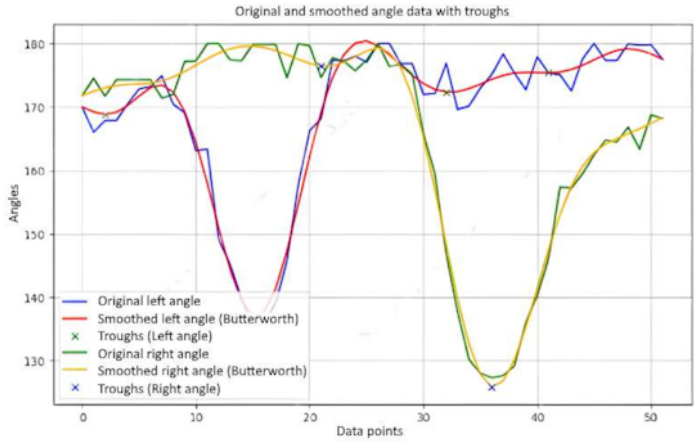
Analyzing the positions of the hip, knee, and ankle for each leg to determine the angles at both knees can assist in recognizing PD (Figure 10).

Figure 10. An illustration of the knee angle position.



The knee angles provide crucial insights into the degree of bending or extension at the knee joints, which are essential for understanding gait patterns. PD often affects movement and posture, leading to distinctive gait abnormalities. By quantifying these knee angles, the calculation helps in detecting and assessing these gait characteristics, aiding in the identification and monitoring of PD symptoms.

Given the knee, hip, and ankle joint positions, the knee angle and the Θ_{knee} can be computed as follows (equation 7):



XSL•FO
RenderX

Figure 11 presents 3-line graphs comparing the knee joint angles of the 3 groups: younger individuals, older individuals, and individuals with PD. The graph of the younger individuals group (Figure 11A) illustrates smooth and regular oscillations in knee joint angles for both the left and right legs. As they turn their body, the angles show significant flexion and extension, reflecting the youthful ability to execute the turn in a single, fluid step. The peaks and troughs are well-defined, indicating robust and agile movements typical of healthy, young individuals. This pattern highlights their efficient and coordinated gait.

Figure 11. A comparative analysis of the knee angle between different groups: (A) younger individuals, (B) older individuals, and (C) individuals with Parkinson disease.

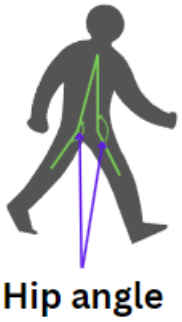
(A)

(B)

(C)

XSL•FO
RenderX

In the older-individual group graph (Figure 11B), the knee joint angles are more subdued, with 2 distinct curves for each turn. This indicates that older individuals take 2 steps to complete the body turn, reflecting a more cautious and segmented approach. The movement patterns are slower and less dynamic compared to the younger individual group, with a reduced ROM.



The graph for the group of individuals with PD (Figure 11C) shows highly irregular and erratic knee joint angles. The curves exhibit frequent sharp peaks and drops, indicating inconsistent and disrupted movement as individuals with PD attempt to turn their bodies. These fluctuations reflect the challenges faced by patients with PD, including tremors, rigidity, and difficulty maintaining smooth and coordinated movements. The graph captures their struggle to control knee flexion and extension, leading to a more disordered and interrupted gait pattern during the turning motion.

These graphs highlight clear differences in turning movements: young individuals exhibit fluid, single step turns; older individuals use a careful 2-step approach; and patients with PD show irregular, disrupted turning patterns.

Angle of Both Hips

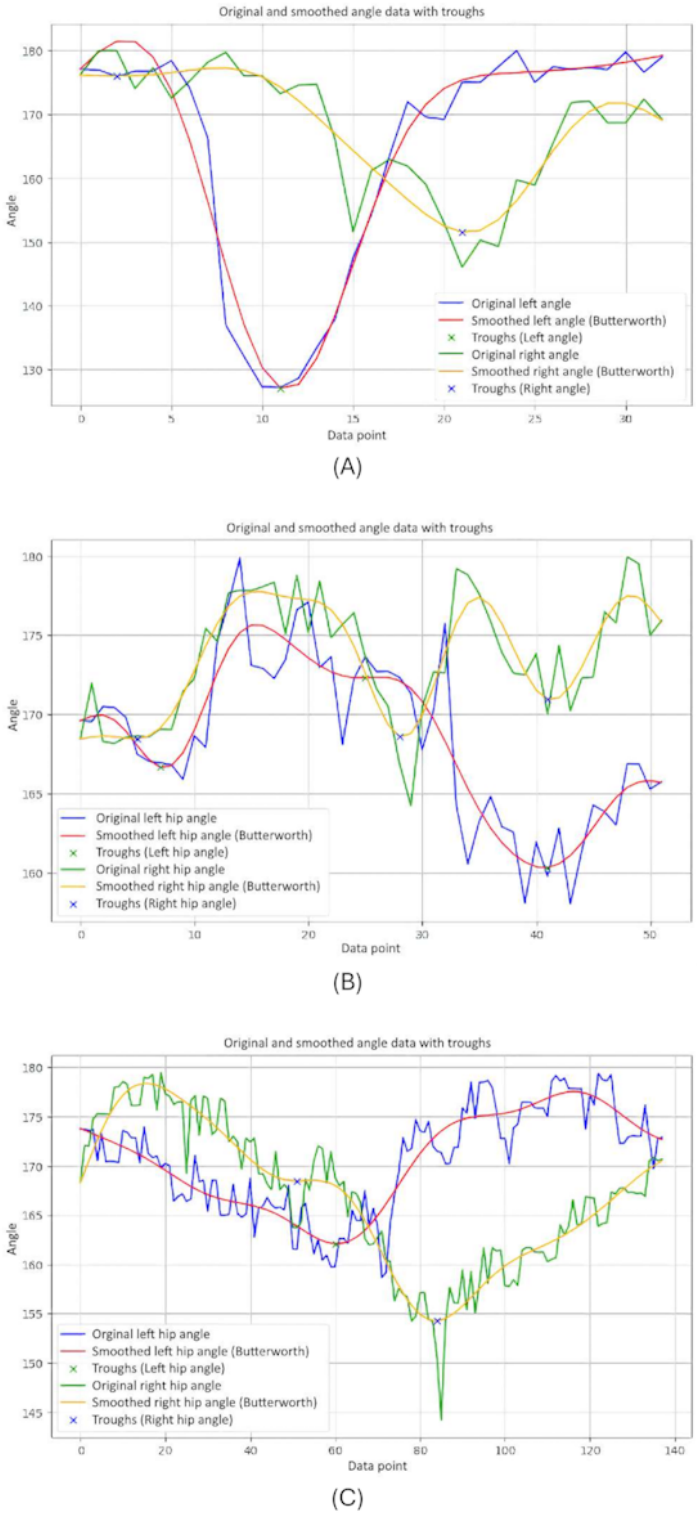
The ROM angle while turning the body is used to determine the angle of both hips (Figure 12). The positions of the hip, knee, and shoulder are used to find the angle formed at the hip joint. This measurement is crucial for assessing how the hip moves during turns, providing insights into the flexibility and coordination of the lower body. Understanding the hip ROM is especially valuable for identifying movement patterns in different populations, such as detecting mobility issues or assessing gait in individuals with PD.

Figure 12. An illustration of the hip angle position.

The hip angle is calculated as follows (equation 8):

The graphs showing the cosine of the hip angle are shown in Figure 12. The figure shows 3-line graphs comparing hip angles during body turns for the 3 groups. Each graph represents the hip angles for both the left and right sides, with lines depicting both the original and smoothed data.

The graph of the younger individuals group (Figure 12A) indicates relatively stable and moderate fluctuations in hip angles during body turns. Both hips show consistent movement with shallow peaks and troughs, reflecting balanced and controlled motion. Younger individuals maintain a steady range of hip angles, suggesting efficient and coordinated hip movement when turning.



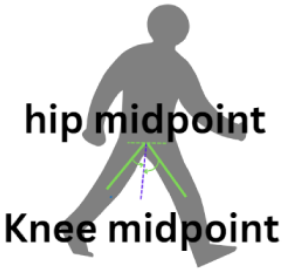
In the older-individual group graph (Figure 12B), the hip angles display more pronounced and variable fluctuations compared to the young group. The curves reveal that older individuals experience larger and more variable hip movements during turns. This increased variability suggests that older people adjust their hip movements significantly to maintain balance and stability, resulting in less smooth and more fluctuating hip angles.

The group of individuals with PD (Figure 12C) shows significant irregularity and instability in hip angles. The curves exhibit erratic and sharp changes, highlighting the difficulty individuals with PD face in maintaining consistent hip movement during turns. The frequent and abrupt fluctuations in hip angles are characteristic of the disease, where symptoms such as rigidity and tremors disrupt smooth and coordinated movements.

Figure 13 illustrates clear differences in hip angle dynamics during turns among the 3 groups. Younger individuals (Figure 13A) have controlled and consistent hip movements, older individuals (Figure 13B) show more variability and larger fluctuations in hip angles, and those with PD (Figure 13C) experience erratic and unstable hip movements. These patterns reflect how age and neurological conditions affect the coordination and efficiency of hip movement during body turns.

XSL•FO
RenderX

Figure 13. A comparative analysis of the hip angle between different groups: (A) younger individuals, (B) older individuals, and (C) individuals with Parkinson disease.



Leg Symmetry

The symmetry of leg movements is calculated using the angles at the knee joints (Figure 14). The goal was to measure and evaluate the balance and symmetry in the leg movements, which is crucial for understanding gait and stability, especially during turning motions. This information is particularly useful for analyzing the movement patterns in different populations, such as detecting gait irregularities in individuals with conditions such as PD.

XSL•FO
RenderX

Figure 14. An illustration of the symmetrical leg position.

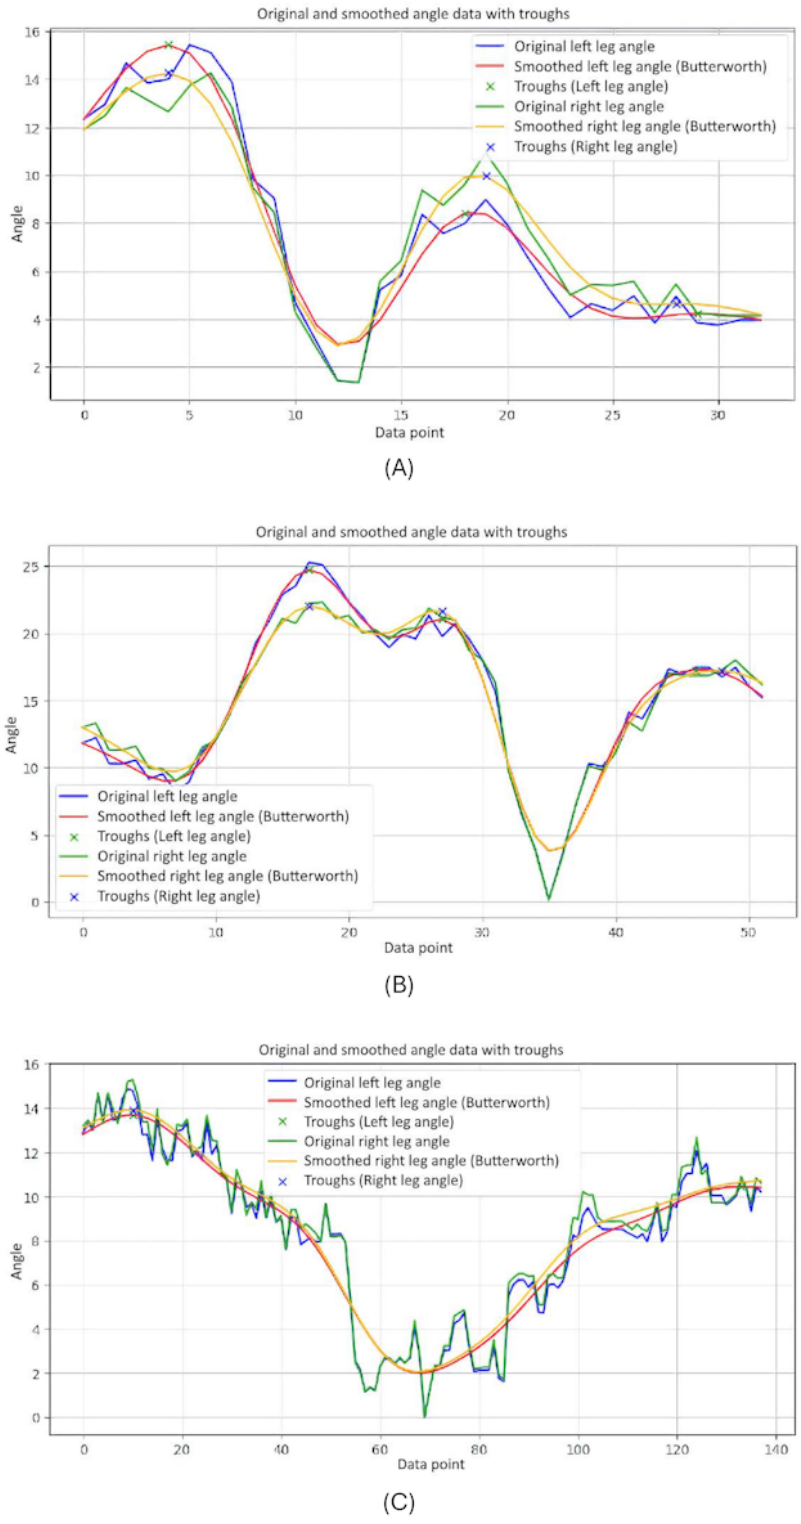
The leg angle is computed as follows (equations 9-11):

Next, the angles of the left and right legs are compared:

The leg symmetry is then assessed as:

Figure 15 displays 3-line graphs comparing the leg symmetry during body turns for the 3 participant groups. Each graph plots the symmetrical leg movements, showing the original and smoothed angles of the left and right legs as they turn.

The graph of the younger-individual group (Figure 15A) shows closely aligned curves for the left and right leg angles, indicating high symmetry in their leg movements during turns. Both legs exhibit similar patterns with minimal deviation between them. This close alignment reflects the balanced and coordinated movements typical of young, healthy individuals, suggesting that they maintain a consistent and symmetrical gait.



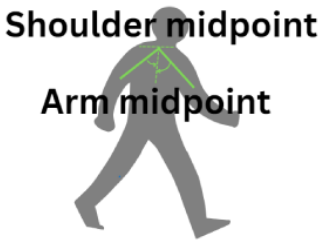
The older-individual group graph (Figure 15B) reveals more noticeable fluctuations between the left and right leg angles. While the overall patterns still follow a similar trajectory.

On the other hand, the graph of individuals with PD (Figure 15C) shows significant irregularities and less alignment between the left and right leg angles. The curves are erratic and display frequent sharp deviations, reflecting low symmetry in their leg movements. This lack of alignment is characteristic of PD, where symptoms such as tremors and rigidity cause disrupted and uncoordinated movements.

This comparison highlights how age, neurological conditions, and health status impact the ability to maintain balanced and symmetrical gait during turning motions.

XSL•FO
RenderX

Figure 15. A comparative analysis of the symmetrical leg between different groups: (A) younger individuals, (B) older individuals, and (C) individuals with Parkinson disease.



Arm Symmetry

The symmetry of arm movements was analyzed using the angles at the elbows to the shoulders (Figure 16). The purpose was to measure how balanced and coordinated the arm movements are, especially during activities such as turning the body. This assessment was important for understanding the ROM and the symmetry in arm movements, which can provide insights into overall body coordination and detect possible imbalances or movement disorders.

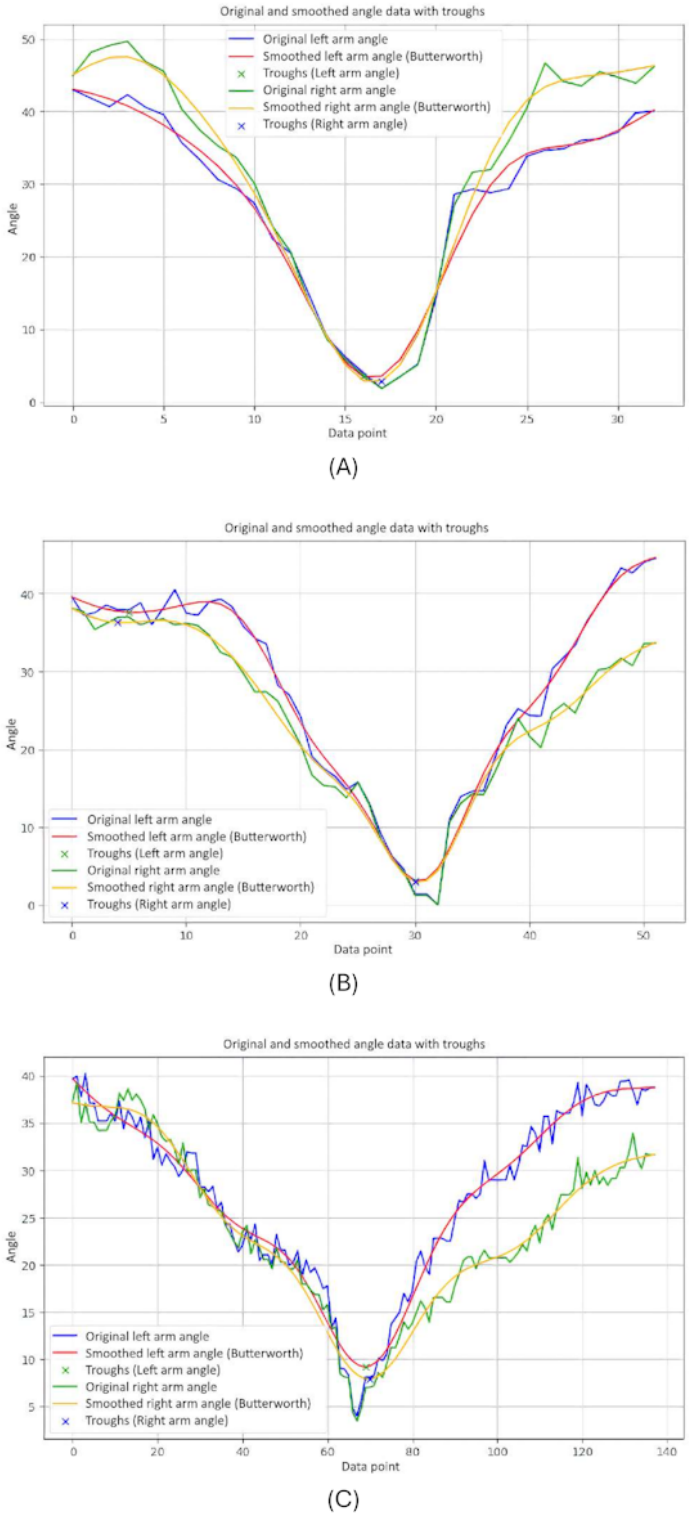
XSL•FO
RenderX

Figure 16. An illustration of the symmetrical arm position.

The calculation for arm symmetry was similar to that of finding the symmetry in legs (equation 12):

Figure 17 presents 3-line graphs comparing the arm symmetry during body movements for 3 groups. Each graph plots the angles of the left and right arms over time, showing both the original and smoothed data.

The graph of the younger-individual group (Figure 17A) displays closely aligned curves for the left and right arm angles. Both arms move in a highly synchronized manner, with minimal differences between the left and right angles throughout the motion.



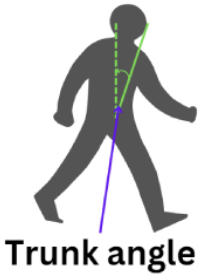
The older-individual group graph (Figure 17B) shows a slightly more varied pattern compared with the young group. While the overall movements of the left and right arms remain relatively synchronized, there are noticeable differences in the magnitude and timing of the angles.

The graph of individuals with PD (Figure 17C) exhibits significant irregularities and discrepancies between the left and right arm angles. The curves are erratic and often diverge sharply, indicating substantial asymmetry in arm movements.

We observed that younger individuals demonstrate highly synchronized and symmetrical arm movements, older individuals show moderate symmetry with some variability, and those with PD experience significant asymmetry and irregularity in their arm movements. These patterns underscore how age and neurological conditions impact the coordination and balance of arm movements during body turns.

XSL•FO
RenderX

Figure 17. A comparative analysis of the symmetrical arms between different groups: (A) younger individuals, (B) older individuals, and (C) individuals with Parkinson disease.



Trunk Angle 1 (Vertical)

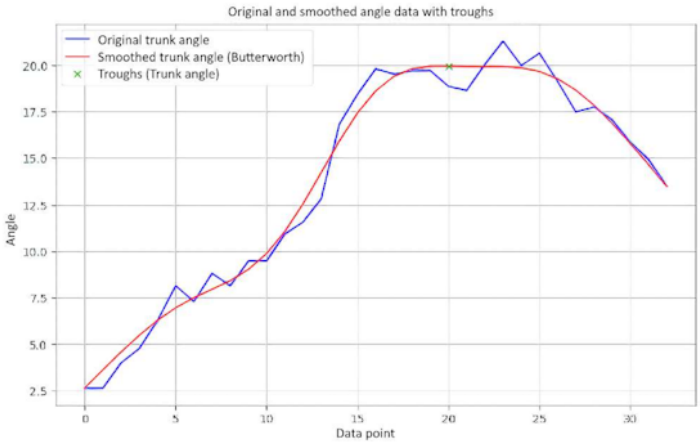
The relative positions of the hips and nose are used to calculate the trunk angle (Figure 18). The trunk angle helps to understand how much the upper body tilts or bends relative to the lower body, especially during activities such as turning. This angle helps in assessing posture and balance, providing insights into the coordination and alignment of the trunk with the hips during movement. It is particularly useful in evaluating movement patterns and detecting postural deviations in various populations, including those with movement disorders such as PD.

XSL•FO
RenderX

Figure 18. An illustration of the trunk angle 1 vertical position.

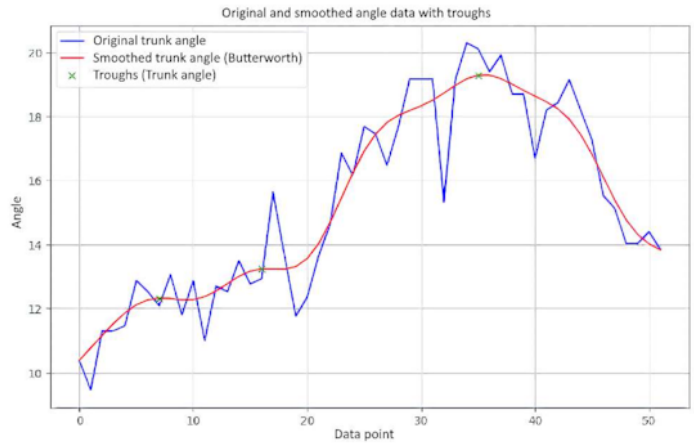
The calculation of the trunk angle 1 is given as follows (equation 13):

Figure 19 displays 3 graphs comparing trunk angles relative to the vertical axis for 3 groups. Each graph shows the trunk angle over a series of data points during body movements, with both original and smoothed data represented. The trunk angle is used to observe the severity of hunchback, providing insights into the degree of forward bending or curvature of the upper body.



The graph of the younger-individual group (Figure 19A) exhibits a consistent and smooth progression of trunk angles. The trunk angle gradually increases and decreases within a narrow range, reflecting a well-coordinated and balanced posture with minimal forward bending. Younger individuals maintain a steady alignment with minimal deviations, indicating a lack of significant hunchback severity.

The older-individual group graph (Figure 19B) shows more variability in trunk angles compared to the young group. The curves display noticeable fluctuations and less consistency, with several abrupt changes in angle. These variations suggest that older individuals experience more difficulty in maintaining a stable trunk posture, leading to less smooth and more erratic movements. The increased trunk angles and variability may indicate a greater tendency toward forward bending, suggesting a moderate severity of hunchback as they struggle to maintain an upright posture.



The graph of individuals with PD (Figure 19C) reveals significant irregularities and instability in trunk angles. The curves are highly erratic, with frequent sharp changes and a wide range of deviations from the vertical alignment. These abrupt shifts indicate substantial difficulties in maintaining consistent trunk posture. Individuals with PD struggle with controlling their trunk movements, leading to frequent tilting and misalignment relative to the vertical axis. The pronounced forward bending and high variability in trunk angles reflect severe hunchback, characteristic of the disease's impact on posture and movement control.

XSL•FO
RenderX

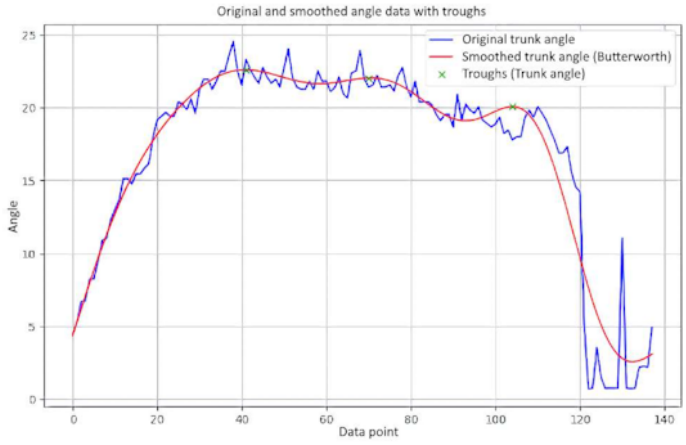


Figure 19. A comparative analysis of the trunk angle 1 between different groups: (A) younger individuals, (B) older individuals, and (C) individuals with Parkinson disease.

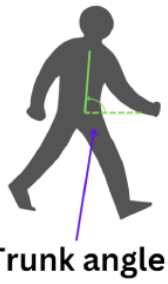
(A)

(B)



(C)

Trunk Angle 2 (Horizontal)

Trunk angle 2 analyzes the positions of the shoulders and hips (Figure 20). This angle is crucial for understanding the alignment of the trunk relative to the lower body, particularly during movements such as turning. By evaluating the trunk angle, we can assess the severity of hunchback or forward bending, which provides valuable insights into posture and stability.

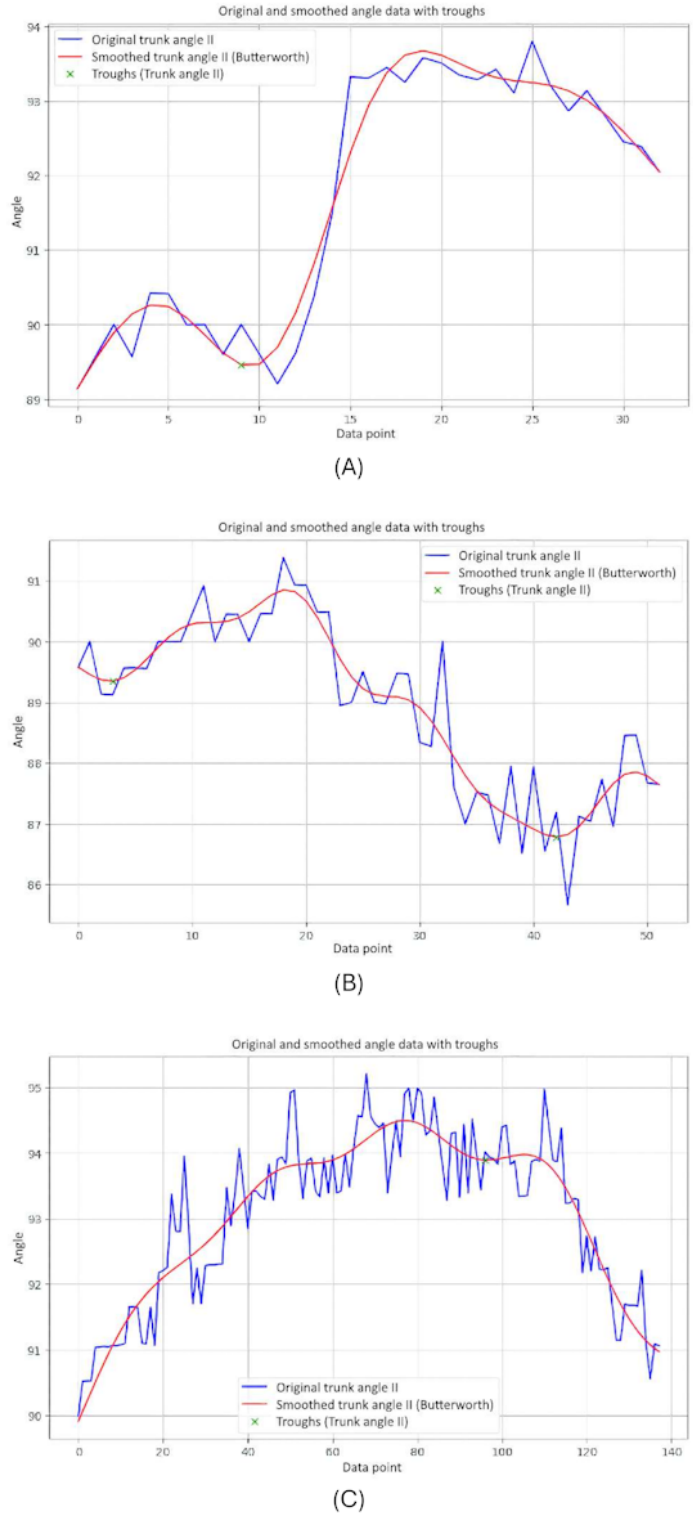
XSL•FO
RenderX

Figure 20. An illustration of the trunk angle 2 horizontal position.

The calculation for trunk angle 2 is similar to that for trunk angle 1. The only difference is that as trunk angle 2 is horizontal, the default value must be set at the *x* coordinate instead of the keypoint. The formula to calculate trunk angle 2 is given as follows (equation 14):

Figure 21 shows graphs comparing trunk angles relative to the horizontal axis for 3 groups. These angles help assess the severity of forward bending or misalignment.

The graph of the younger-individual group (Figure 21A) exhibits stable and controlled trunk angles with minimal deviations, indicating well-balanced posture and low severity of hunchback.



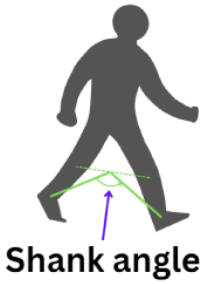
The graph of the older individuals' group (Figure 21B) showed more variability and sudden changes in trunk angle, reflecting moderate forward lean and greater difficulty maintaining stable horizontal alignment, indicating moderate kyphosis severity.

The graph of the individuals with PD (Figure 21C) shows significant instability and frequent sharp changes in trunk angles, indicating severe difficulties in maintaining consistent trunk posture and severe hunchback severity due to the disease's impact on movement control.

Overall, younger individuals maintain a low severity of hunchback, older individuals exhibit moderate severity, and those with PD show severe hunchback, reflecting their challenges in maintaining horizontal alignment.

XSL•FO
RenderX

Figure 21. A comparative analysis of the trunk angle 2 horizontal between different groups: (A) younger individuals, (B) older individuals, and (C) individuals with Parkinson disease.



Shank Angle

The shank angle computes the positions of the knees and ankles (Figure 22). This angle is useful to understand the alignment and movement of the lower leg, especially during activities such as turning. By evaluating the shank angle, we can assess the coordination and stability of the lower leg movements, providing valuable insights into gait patterns and detecting any abnormalities in movement, which is particularly useful for analyzing conditions such as PD.

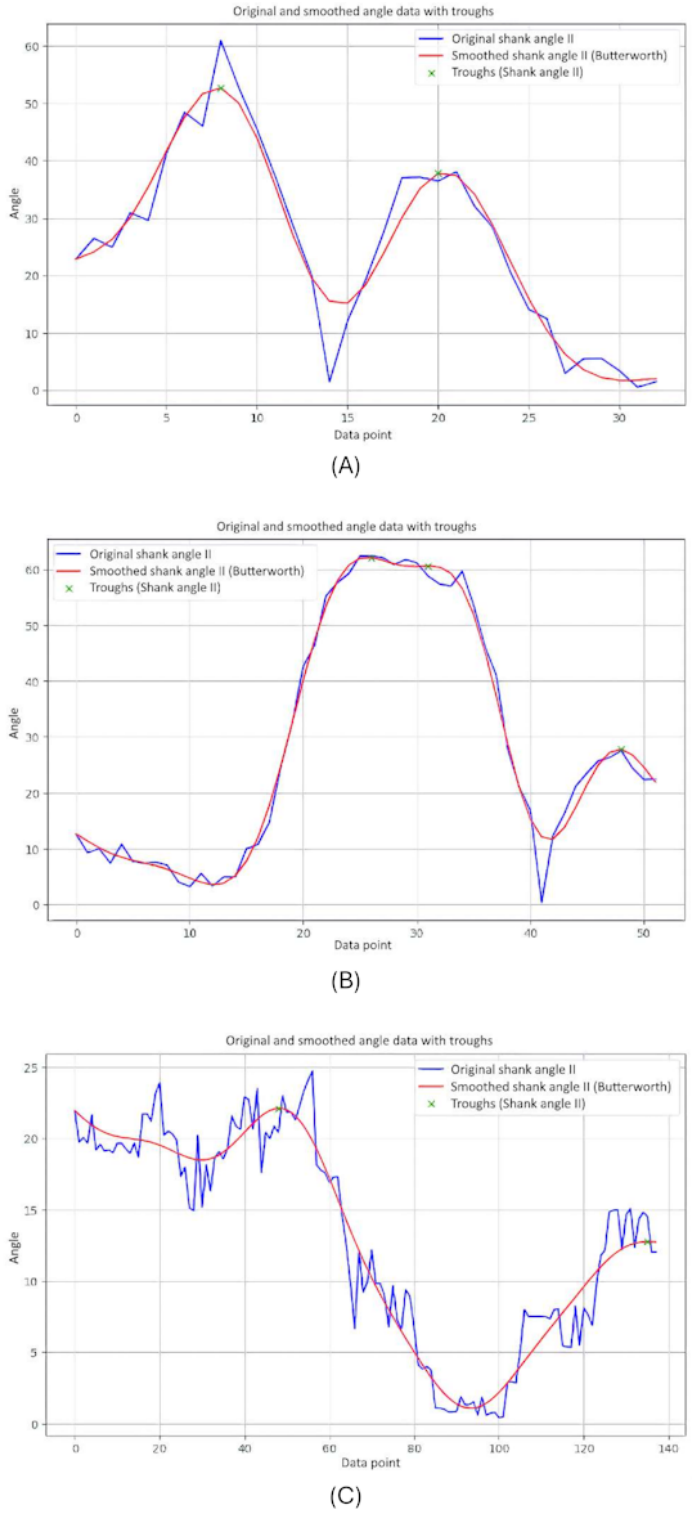
XSL•FO
RenderX

Figure 22. An illustration of the shank angle position.

The formula to calculate shank angle is provided in equation 15:

Figure 23 presents the graphs comparing shank angles during body movements for 3 groups. Each graph shows the shank angle over a series of data points, with both original and smoothed data represented.

The graph of the younger-individual group (Figure 23A) demonstrates relatively stable and consistent shank angles. Both the original and smoothed curves align closely, indicating smooth and coordinated movements. The angles show moderate fluctuations within a narrow range, reflecting balanced and controlled lower leg movements typical of healthy young individuals.



The older-individual group graph (Figure 23B) shows shank angles that are stable and consistent, such as the younger individuals group. Both the original and smoothed curves align closely, indicating smooth and coordinated lower leg movements. The angles show moderate fluctuations within a narrow range, reflecting balanced and controlled movements. This suggests that older individuals perform nicely, maintaining stable shank angles comparable to the younger individuals group.

The graph of individuals with PD (Figure 23C) reveals significant irregularities and instability in shank angles. The curves are highly erratic, with frequent sharp changes and a wide range of deviations. These abrupt shifts indicate substantial difficulties in maintaining consistent lower leg movements. Individuals with PD struggle with controlling their shank angles, leading to frequent misalignment and instability. This pattern is characteristic of the disease, where symptoms such as rigidity and tremors disrupt smooth and coordinated movements.

Figure 23 highlights the differences in shank angle behavior among the 3 groups. Younger and older individuals exhibit stable and coordinated shank movements with minimal variability, indicating balanced and controlled lower leg movements. In contrast, those with PD display significant instability and erratic shank movements, underscoring the impact of the condition on lower leg control and stability.

Classification Report

A comprehensive evaluation of the SVM model is provided by the classification report for the test set, as shown in Table 3. The report includes the overall accuracy of the model, as well as each class's recall, precision, and F_1-score. Although the training accuracy was 0.95, the test accuracy was 0.89, indicating that the model fit the training data well with minimal overfitting. The classification report shows that class 0 (normal class) had high precision and recall, while class 1 (PD class) has lower recall. This disparity in recall may be due to the smaller sample size of class 1.

Table 3. Classification report for distinguishing normal and PD[a] classes using gait features (test accuracy: 0.89 and train accuracy: 0.95).

Classes or metrics	Precision	Recall	F_1-score	Support
0 (normal)	0.88	1.00	0.93	7.00
1 (PD)	1.00	0.50	0.67	2.00
Accuracy	—[b]	—	0.89	9.00
Macroaverage	0.94	0.75	0.80	9.00
Weighted average	0.90	0.89	0.87	9.00

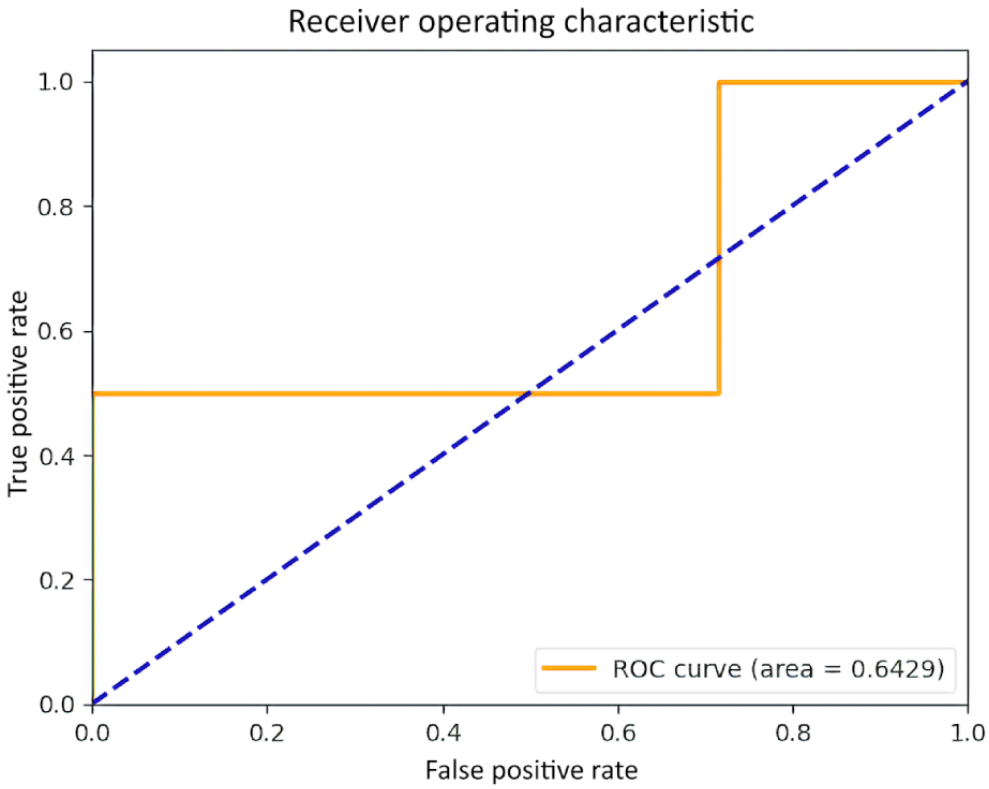
[a]PD: Parkinson disease.

[b]Not available.

AUC and Loss Curve

Figure 24 provides specifics regarding the model's capacity to distinguish between the 2 classes. Moderate discrimination capability is indicated by the test set's AUC of 0.6429. An indicator of how well the model performs across various training data subsets is provided by the cross-validation scores. With a mean cross-validation score of 0.9, the model's cross-validation scores are (0.75, 1.00, 1.00, 0.75, 1.00). This shows that the model continues to work well when the data are folded in different ways.

Figure 24. The receiver operating characteristic (ROC) curve.



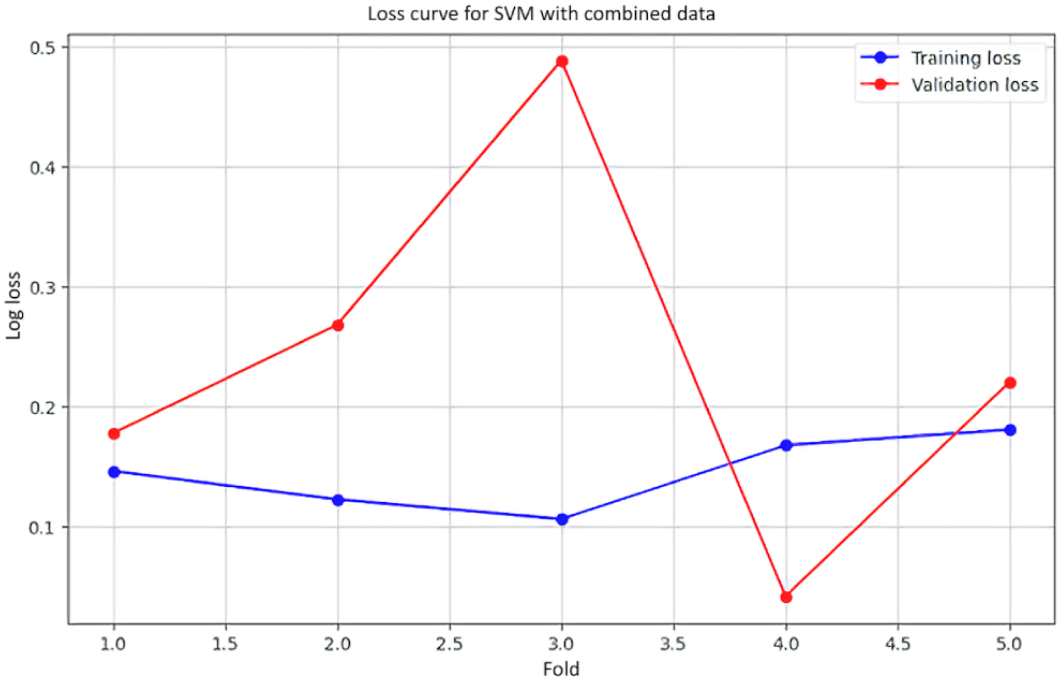


Figure 25 shows the training and validation loss curve, illustrating the log loss for both training and validation sets across various folds of cross-validation. The blue curve indicates the training loss, which stays relatively stable with minor fluctuations. In contrast, the red curve, representing the validation loss, exhibits significant fluctuations, peaking notably at fold 3. This implies that while the model fits the training data well, it experiences considerable variability in performance on unseen data, suggesting possible overfitting or sensitivity to specific data subsets. The difference between the training and validation loss also underscores the model's difficulty in generalizing from the training set to the validation set, highlighting the need for potential adjustments in model complexity or training strategy to achieve more consistent performance.

XSL•FO
RenderX

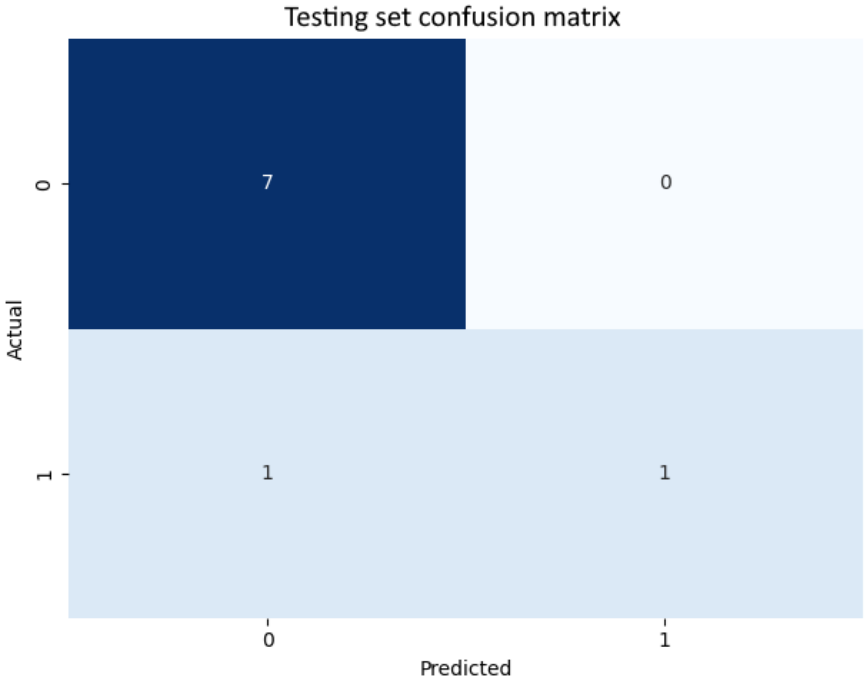

Figure 25. The training and validation loss curve for support vector machine (SVM) with combined data.

Confusion Matrix

The confusion matrix depicted in Figure 26 provides a thorough analysis of the predictions of the model on the test set. It reveals that while the model correctly predicted 7 out of 7 occurrences of class 0 (non-PD), it incorrectly classified 1 out of 2 instances of class 1 (PD). This suggests that although the model is highly accurate in predicting class 0, it faces challenges with class 1, likely due to class imbalance in the dataset.

Figure 26. The testing set confusion matrix for model-based features.

Discussion

This study presents a noninvasive approach for early detection of PD through the analysis of model-based gait features. Using kinematic characteristics, such as shoulder distance, step length, stride length, knee and hip angles, leg and arm symmetry, and trunk angles, we aimed to identify subtle gait abnormalities associated with PD. Data were collected through controlled video recordings of the TUG assessment, and the extracted features were processed using advanced filtering techniques and analyzed using SVM classifier.

XSL•FO
RenderX

The results demonstrate that the model-based features were highly effective in distinguishing between normal and PD-affected gait patterns, achieving high accuracy, precision, recall, and F_1-score. These findings support the potential of model-based gait analysis as a noninvasive, accessible tool for early diagnosis and monitoring of PD. The study also highlights the importance of addressing class imbalance and refining the feature extraction process to further enhance the performance of the classifier.

Future research should focus on validating these findings with larger datasets, exploring other machine learning models, and integrating additional features to improve the robustness and accuracy of PD detection systems. This approach could significantly benefit clinical settings, providing a reliable, noninvasive method for early diagnosis and improved patient outcomes.

Abstract

Background: Polypharmacy, the concurrent use of multiple medications, is prevalent among older adults and associated with increased risks for adverse drug events including falls. Deprescribing, the systematic process of discontinuing potentially inappropriate medications, aims to mitigate these risks. However, the practical application of deprescribing criteria in emergency settings remains limited due to time constraints and criteria complexity.

Objective: This study aims to evaluate the performance of a large language model (LLM)–based pipeline in identifying deprescribing opportunities for older emergency department (ED) patients with polypharmacy, using 3 different sets of criteria: Beers, Screening Tool of Older People's Prescriptions, and Geriatric Emergency Medication Safety Recommendations. The study further evaluates LLM confidence calibration and its ability to improve recommendation performance.

Methods: We conducted a retrospective cohort study of older adults presenting to an ED in a large academic medical center in the Northeast United States from January 2022 to March 2022. A random sample of 100 patients (712 total oral medications) was selected for detailed analysis. The LLM pipeline consisted of two steps: (1) filtering high-yield deprescribing criteria based on patients' medication lists, and (2) applying these criteria using both structured and unstructured patient data to recommend deprescribing. Model performance was assessed by comparing model recommendations to those of trained medical students, with discrepancies adjudicated by board-certified ED physicians. Selective prediction, a method that allows a model to abstain from low-confidence predictions to improve overall reliability, was applied to assess the model's confidence and decision-making thresholds.

XSL•FO
RenderX

Results: The LLM was significantly more effective in identifying deprescribing criteria (positive predictive value: 0.83; negative predictive value: 0.93; McNemar test for paired proportions: χ^2_1=5.985; *P*=.02) relative to medical students, but showed limitations in making specific deprescribing recommendations (positive predictive value=0.47; negative predictive value=0.93). Adjudication revealed that while the model excelled at identifying when there was a deprescribing criterion related to one of the patient's medications, it often struggled with determining whether that criterion applied to the specific case due to complex inclusion and exclusion criteria (54.5% of errors) and ambiguous clinical contexts (eg, missing information; 39.3% of errors). Selective prediction only marginally improved LLM performance due to poorly calibrated confidence estimates.

Conclusions: This study highlights the potential of LLMs to support deprescribing decisions in the ED by effectively filtering relevant criteria. However, challenges remain in applying these criteria to complex clinical scenarios, as the LLM demonstrated poor performance on more intricate decision-making tasks, with its reported confidence often failing to align with its actual success in these cases. The findings underscore the need for clearer deprescribing guidelines, improved LLM calibration for real-world use, and better integration of human–artificial intelligence workflows to balance artificial intelligence recommendations with clinician judgment.

Introduction

Polypharmacy, widely defined as the regular use of at least 5 medications, is common in older adults and at-risk populations [1]. In fact, approximately 30% of patients aged 65 years or older have polypharmacy [2], and nearly half of older emergency department (ED) patients are discharged with one or more new medications [3]. Although necessary and beneficial for some patients, polypharmacy can increase the risk of negative consequences for patients, including ED visits, adverse drug events, falls, disability, and inappropriate medication use [1]. While definitions differ, deprescribing is generally defined as a structured process by which potentially inappropriate medications (PIMs) are identified and withdrawn under the supervision of a health care provider. In some definitions, the process is described as evaluating the risk-benefit tradeoff, focusing on situations where the potential or actual harms of a medication outweigh its benefits, considering the patient's individual care goals and quality of life [2,4,5].

Deprescribing tools, such as the Screening Tool of Older People's Prescriptions (STOPP) [6] and Beers criteria [7], have been developed to help providers assess and identify PIMs based on a patient's medication list [7-9]. These explicit assessments are criterion-based with clear standards but are often impractical to implement in time-constrained clinical settings, such as ED, due to the need to evaluate multiple clinical indications and specialist-prescribed medications [10]. Attempts to digitize these criteria into electronic clinical decision support (CDS) have raised difficulties, typically requiring a labor-intensive coding process and unstructured information such as free text from patient records to contextualize certain criteria [11,12].

Large language models (LLMs) have been shown to interpret complex clinical situations and offer recommendations, from differential diagnoses to care management, leading to growing interest in their application in the medical field [13-16]. Moreover, they have been shown to extract medication-related data such as medication name, dosage, and frequency, necessary for the application of deprescribing criteria [17]. Finally, LLMs are excellent in-context learners, requiring very little labeled data to make predictions [18]. This reduces the annotation burden for time-constrained ED physicians while improving the use of unstructured patient records to contextualize patient medication lists. However, the majority of clinical reasoning evaluations on LLMs have been conducted using standardized exams (the United States Medical Licensing Examination) or digital case reports [14,19]. Their ability to perform clinical reasoning and calibrate responses over physician-generated text remains understudied.

Here, we propose to evaluate the performance of an LLM-based data pipeline in recommending deprescribing options for older adult ED patients at discharge based on 2 leading deprescribing criteria, Beers and STOPP. We have also included a recently developed list of criteria, Geriatric Emergency Medication Safety Recommendations (GEMS-Rx), intended to prevent the initiation of inappropriate medications in the acute care setting, as similar deprescribing lists specific to this care environment are not available [3]. Through this work, we hope to evaluate whether an LLM-based CDS system can effectively triage medications eligible for electronic deprescribing in older adults. Successful implementation of such a system would help address gaps in electronic deprescribing by using an LLM to contextualize recommendations within individual patient records and reduce manual development in CDS tools.

Methods

Ethical Considerations

This study was conducted with approval from the Institutional Review Board (IRB) at Yale University, under protocol number 2000035077. The IRB determined that this research qualifies for exemption as it involves secondary analysis of existing electronic health record (EHR) data, with no additional patient contact or data collection. The original data were collected with patient consent, and the current analysis adheres to the conditions of that consent and IRB approval, permitting

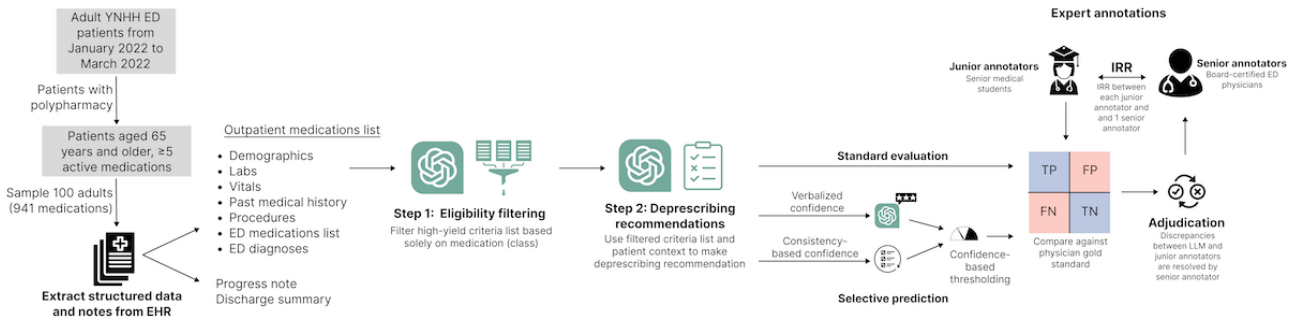
XSL•FO
RenderX

secondary analysis without the need for additional consent. All data were de-identified prior to analysis to ensure patient confidentiality. This study complies with ethical standards and guidelines for research involving human subjects.

Patient Cohort

All older adults (aged 65 years and older) with polypharmacy (5 or more active outpatient medications) presenting to an ED in a large academic medical center in the Northeast United States between January 2022 and March 2022 were identified. Due to budgetary constraints and a lack of prior evidence regarding the performance of LLMs in this task to guide a power calculation, we selected a random sample of 100 unique patients for evaluation.

Identification of Consensus-Based High-Yield Criteria



We conducted a consensus-based evaluation to filter three preexisting deprescribing lists (ie, STOPP [6], Beers [7], and GEMS-Rx [3]) into a focused set of high-yield deprescribing criteria for the LLM to use in its recommendations. High-yield criteria were defined as those posing a significant clinical risk to the patient and being identifiable within the electronic health records (EHRs). To identify these criteria, we evaluated 180 recommendations across 2 key dimensions: clinical risk and EHR computability. The consensus panel consisted of 6 board-certified physicians (in Emergency Medicine, Internal Medicine, and Clinical Informatics) and 1 ED pharmacist. Each member of the group individually reviewed each of the criteria and rated them on a 5-point Likert scale. We selected the top 50% of criteria with an average score greater than 3 on both dimensions, calculated across all experts, as high-yield criteria. We further elaborate on this consensus process and the final set of criteria in the Results section.

The need to filter the criteria before proceeding with the study was identified in our preliminary research [20], which revealed that one of the main causes of discrepancies between physicians and LLMs arose from ambiguous inclusion or exclusion conditions in deprescribing criteria. For example, criteria like "Statins for primary cardiovascular prevention in persons aged ≥85 with established frailty with expected life expectancy likely less than 3 years" include elements—such as "established frailty" and "expected life expectancy"—that are challenging to quantify and therefore difficult to implement computationally. The dimensions used to filter criteria were chosen to ensure that an LLM-enabled CDS tool prioritizes meaningful recommendations from high-quality EHR data, enabling accurate, actionable deprescribing recommendations and reduction of alert fatigue. We present the final set of high-yield criteria based on the average results of the consensus study.

Deprescribing Recommendations by GPT-4o

The study was approved under an exemption by the Yale University institutional review board prior to commencement (HIC# 2000035077). All patient-level data were deidentified prior to use with the LLM. We leveraged Microsoft's Azure OpenAI GPT-4o (GPT-4o model version: 2024-08-06 and OpenAI API version: 2024-02-15-preview) to produce deprescribing recommendations through a 2-stage process, as shown in Figure 1. In stage 1, GPT-4o was prompted to filter the full list of high-yield criteria solely based on the patient's medication list, ignoring inclusion or exclusion conditions. In stage 2, GPT-4o was prompted to use its previously filtered criteria list, along with structured (eg, demographics, lab values, vitals, and past medical history) and unstructured (most recent progress note and discharge summary) information, to determine if the patient satisfied any deprescribing criteria and the medication should be recommended for deprescribing. Each medication was evaluated individually to prevent errors from simultaneous processing, such as misattribution of criteria or medication omissions. To ensure optimal performance, we engineered prompts in an iterative fashion [21], using 1 patient at a time from a set of patients (up to 10% of the cohort) not used in the subsequent evaluation. After each evaluation, prompts were adjusted to correct any systematic errors (eg, instances where no relevant criteria in step 1 led to noncriteria-based deprescribing recommendations in step 2) by the LLM. After our third prompt yielded an output without any identifiable errors, we stopped the iterative prompt development process. Consequently, the final 2 patients initially reserved for this purpose were included in the final cohort evaluation (n=92 patients, 626 medications). Aside from the consistency-based method described later, all LLM calls were performed with a fixed temperature (temperature=0; low randomness in generated responses) and seed to ensure reproducibility and deterministic outputs.

Figure 1. Overview of the evaluation pipeline, consisting of a 2-step GPT-4o process, performance comparison with junior annotators (medical students), and final adjudication by senior annotators (board-certified physicians). ED: emergency department; EHR: electronic health record; FN: false negative; FP: false positive; IRR: interrater reliability; TN: true negative; TP: true positive; YNHH: Yale New Haven Hospital.

This 2-stage process was developed to correct errors identified when both stages were accomplished at once. Our initial testing revealed that providing the LLM with the full set of criteria and medications led to simple reasoning errors. The large number

XSL•FO
RenderX

of criteria, combined with the simultaneous processing of the complete patient medication list, resulted in inaccuracies in applying individual criteria to specific medications. Separating the process of criteria filtering and application both reduces confusion due to large input context sizes [22] and ensures that extraneous context does not distract the LLM [23]. The full prompts for step 1 and step 2 are included in Figures S5 and S6 in Multimedia Appendix 1.

Selective Prediction Methods

In addition to evaluating an LLM's ability to make deprescribing recommendations, we assessed whether its confidence estimates were well-calibrated and examined their impact on predictive performance. To do so, we collected GPT-4o's decision confidence for both steps using 2 validated confidence elicitation methods: chain-of-thought verbalized confidence and self-random sampling with average-confidence aggregation, referred to as consistency-based confidence [24]. In verbalized confidence, we asked the LLM to explicitly estimate its confidence for each step following its decision. For the consistency-based approach, we followed the best practices established in prior work [24] by sampling the LLM multiple times (number of samples=5) with high temperature (T=0.8; high randomness in generated responses) and used a majority vote weighted by the confidence of each response to determine the final deprescribing recommendation.

In a human-in-the-loop decision-making system, the LLM's confidence would be used to determine if the model should abstain due to low certainty regarding its own decision. In practice, this case would be considered too difficult for the LLM and forwarded to an expert reviewer. This human-in-the-loop decision-making pipeline is known as selective prediction and has been commonly found to improve performance in non–text-based applications [25,26]. We evaluated both selective prediction methods using risk-coverage curves [27,28], substituting risk for the F_1-score (a measure of the predictive performance of a model balancing precision and recall) to capture the full range of predictive performance. Coverage was also expressed inversely as the deferring fraction, representing the proportion of instances where the LLM abstained from making a decision. We conducted a more in-depth analysis of the method that proved to be more effective.

Comparison and Adjudication With Clinical Experts

In this study, we used a rigorous human review and adjudication process to assess model performance. Two trained senior medical students (M4) classified all medications in the test cohort using a 2-stage pipeline, after first computing interrater reliability (IRR) on an adjudication set of 75 medications from 5 patients. Similar to the LLM pipeline, for each medication, a medical student determined (1) if there exists a relevant high-yield criteria based on the medication list, and (2) whether the medication should be recommended for deprescribing. Discrepancies between the students (junior annotators) and the LLM across both stages were adjudicated by 2 board-certified ED physicians (senior annotators). Similarly to the junior annotators, we measured the IRR between the 2 senior ED physicians, prior to adjudication on the full set of discrepancies. Finally, we classified the errors leading to incorrect recommendations by the LLM, leveraging a prior evaluation framework [29]. We classified each error as 1 of 4 error types: incorrect reading comprehension, incorrect recall of knowledge, incorrect reasoning step, and not enough information, as described in Table 1.

Table 1. Definitions of GPT-4o error types inspired by framework from Lièven et al [29] relevant to deprescribing recommendations.

GPT-4o error types	Definition	Example
Incorrect reading comprehension	Includes misunderstanding of order of text, such as when a medication is dependent on another medication in a specific arrangement. Also includes ignoring information provided in the input text, such as missing a relevant category explicitly stated in the recommendations.	GPT failed to recognize acetaminophen by name from the list of STOPP[a] criteria in a patient at risk for malnutrition or liver disease.
Incorrect recall of knowledge	Includes failure to recognize classes of medications or other medical facts necessary to perform the task.	GPT correctly recognized amlodipine was a calcium channel blocker but failed to recognize it was more broadly an antihypertensive.
Incorrect reasoning step	Faulty reasoning, such as inappropriate assumptions or leads of logic unsupported by the clinical data.	GPT recommended discontinuing warfarin in a patient with a therapeutically elevated INR[b] after assuming that this elevated INR was due to a bleeding disorder.
Not enough information	Inappropriate application of missing data leading to potentially unreliable conclusions, such as assuming abnormality of a missing laboratory study.	GPT recommended discontinuing a QT[c] prolonging antidepressant based on the possibility of QT prolongation without any ECG[d] data or history of abnormal QT interval.

[a]STOPP: Screening Tool of Older People's Prescriptions.

[b]INR: International normalized ratio.

[c]QT: QT interval.

[d]ECG: electrocardiogram.

Data Analysis

We evaluated whether the LLM or the medical student was correct, using a gold standard derived from senior annotator (board-certified ED physicians) adjudication of discrepancies. To compare their proportions of correct responses, we applied the McNemar test, a statistical method commonly used to analyze paired nominal data, such as diagnostic accuracy from different assessments applied to the same cases [30]. All analysis was performed using Python (version 3.9; Python Software Foundation). Statistical testing was carried out using *statsmodels* (version 0.14.4) [31] and all visualizations were generated using *seaborn* (version 0.13.2) [32] and *matplotlib* (version 3.8.2) [33].

Results

Patient Cohort

In total, we identified 10,977 unique patients across 15,161 emergency department encounters from January 2022 to March 2022 meeting our selection criteria, from which 100 patients were randomly selected (Table 2). As our criteria only pertain to oral medication, nonoral medications were subsequently filtered out, resulting in 712 total oral medications across the cohort and a median of 6 oral medications per patient (Figure 2). From our initial study cohort of 100 patients, 10 patients were set aside for both prompt engineering and calculation of IRR between junior annotators. Fewer iterations were needed to refine the prompt than initially anticipated, so the remaining 2 patients were included in the final study cohort. This resulted in a final evaluation cohort of 92 patients, encompassing a total of 626 medications. Based on the mechanism of action, statins were the most common medication class (atorvastatin and rosuvastatin; 6.8% combined), followed by proton pump inhibitors (pantoprazole, esomeprazole, and omeprazole; 4.6% combined). When classified by therapeutic effect, antihypertensive agents were most prevalent (amlodipine, lisinopril, losartan, and valsartan; 10.6% combined).

Evaluation of Consensus-Based High-Yield Criteria

To streamline evaluation by the LLM, we filtered criteria using the average scores from an expert consensus panel. All criteria (n=180) were evaluated based on their scores for clinical risk (Q1) and EHR computability (Q2-Q5), as assessed by an expert panel; average scores by deprescribing list are shown in Figure 3. Any criteria scoring less than 3 on both clinical applicability and EHR computability were excluded resulting in 161 criteria. From the remaining set, the top 50% were selected, resulting in 81 high-yield criteria across all 3 deprescribing lists.

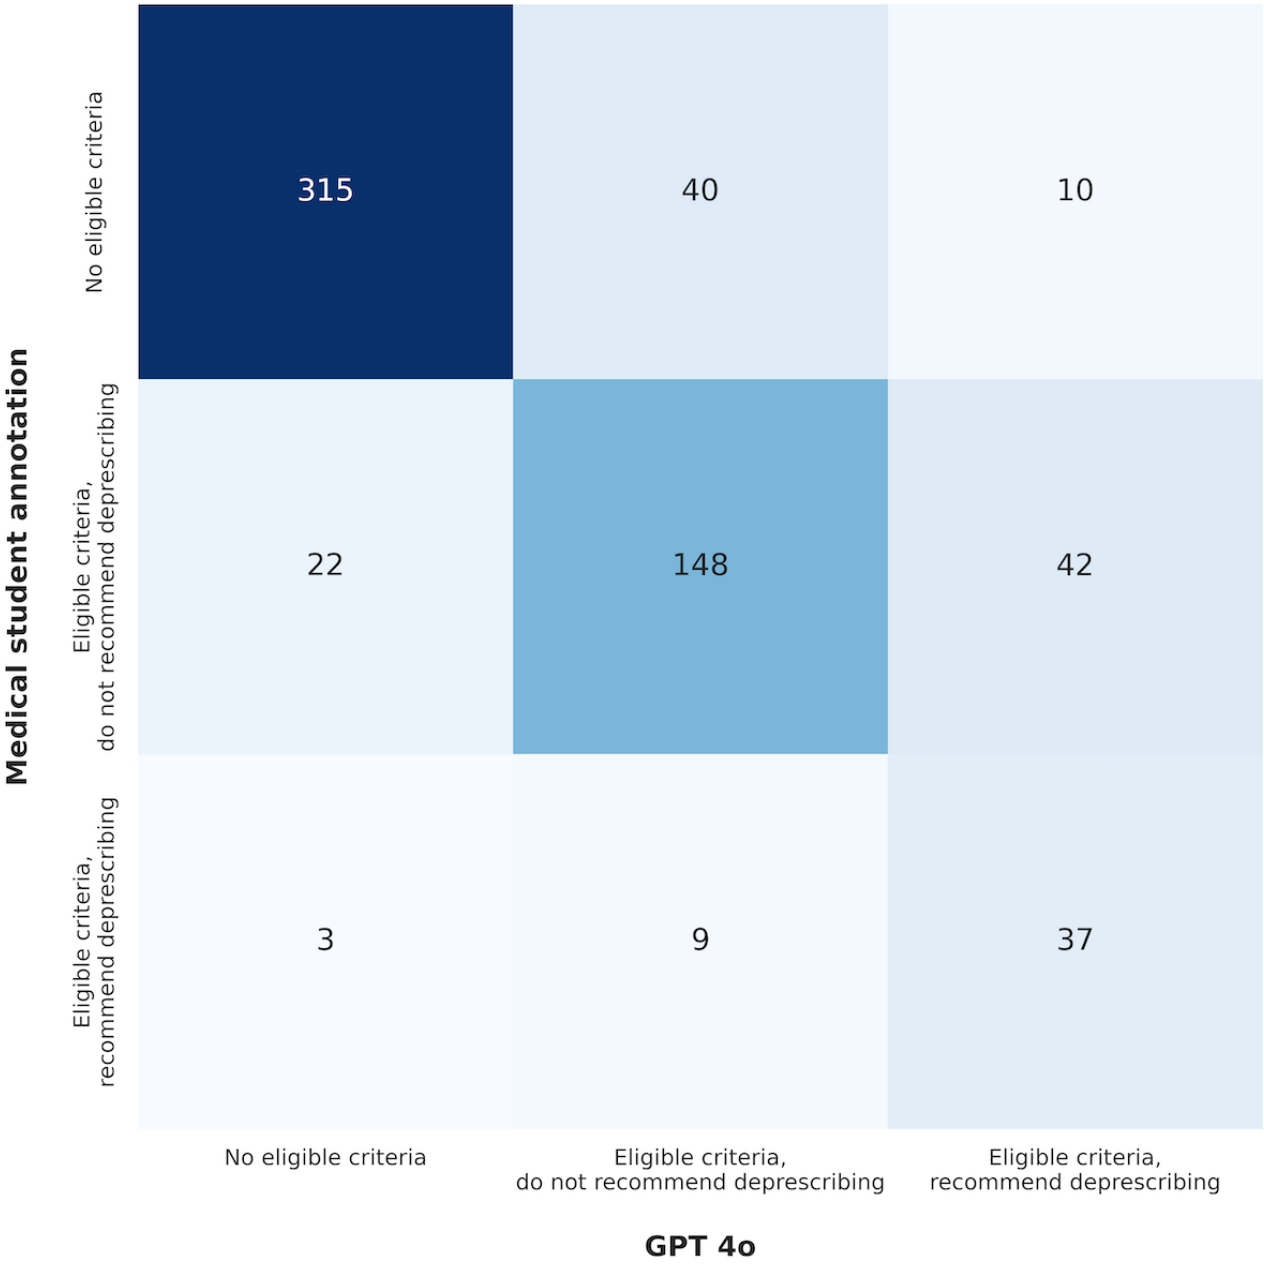
On average, STOPP criteria had the lowest clinical risk and EHR computability ratings, while the Beers criteria had the highest, contributing to their respective adoption rates of 45.9% and 62.5% among high-yield criteria. Reduced inclusion of STOPP criteria was primarily attributed to panelists' concerns that the information required was not readily accessible within the EHR and would necessitate additional data at the point of care. We also present the results of feasibility in various clinical settings by criteria list in Figure S1 in Multimedia Appendix 1, showing more likelihood for deprescribing in both outpatient and inpatient contexts, compared to the ED, across all 3 criteria lists. A scatter plot of risk versus EHR computability of high-yield criteria is presented in Figure S2 in Multimedia Appendix 1.

XSL•FO
RenderX

Figure 3. Average distribution of results used to filter high-yield criteria on a 5-point Likert scale from a consensus study by an expert panel (n=7) split by 3 criteria lists: Beers, GEMS-Rx, and STOPP. EHR: electronic health record; GEMS-Rx: Geriatric Emergency Medication Safety Recommendations; STOPP: Screening Tool of Older People's Prescriptions.

Deprescribing Recommendations by GPT-4o

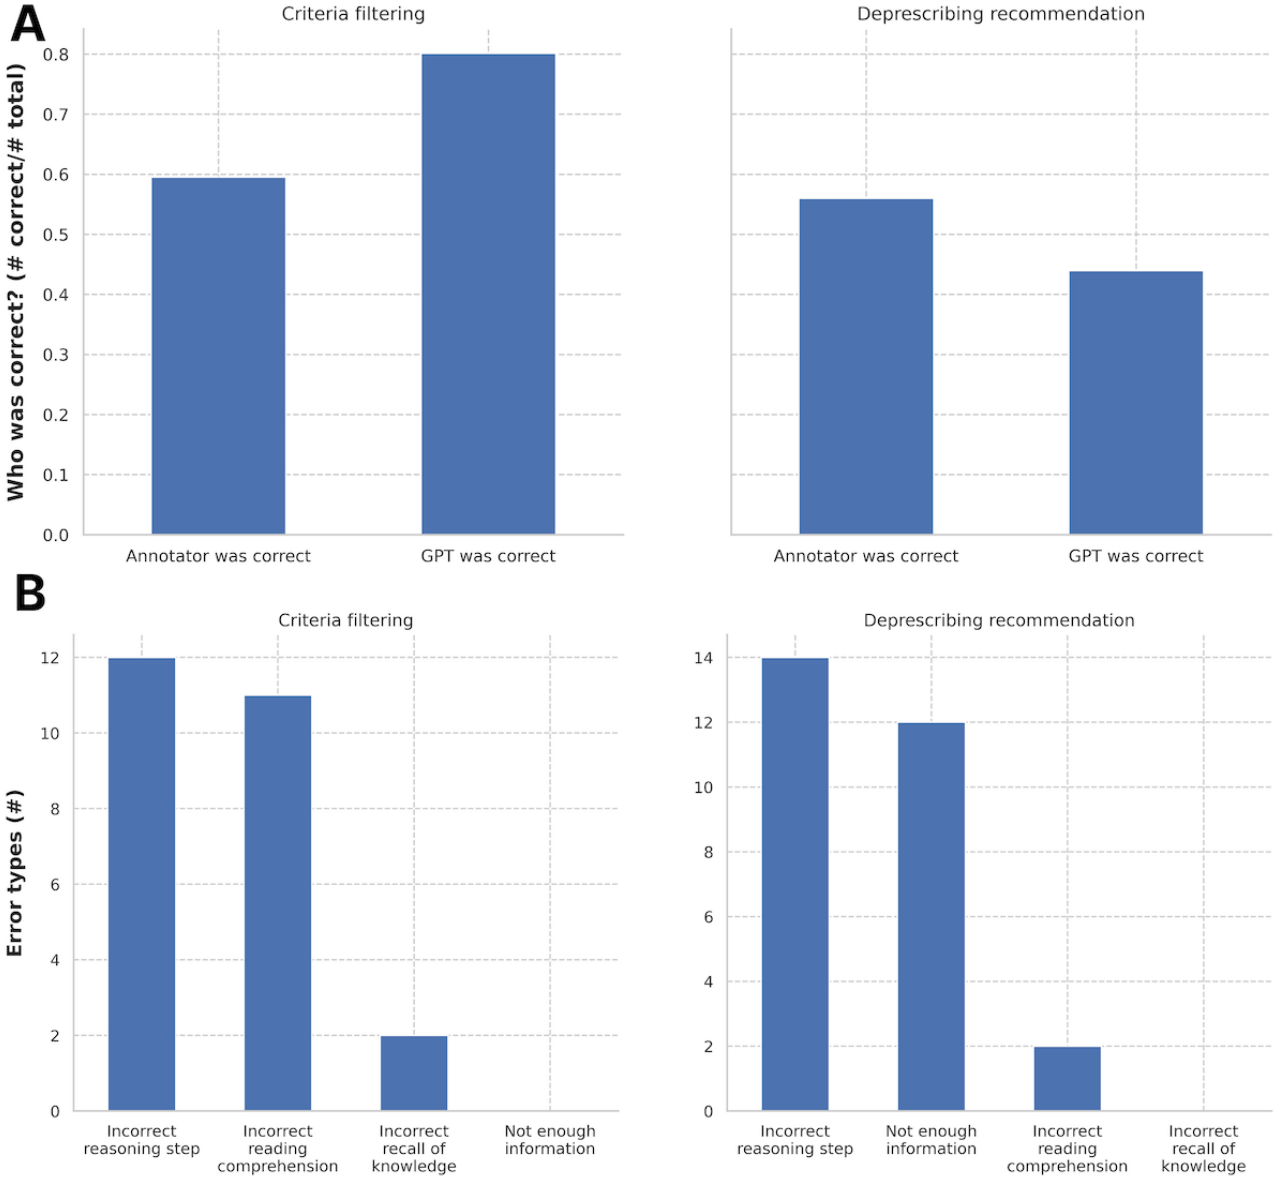
We next evaluated the LLM's deprescribing recommendations by comparing them to those of medical students, resolving any discrepancies through adjudication by board-certified EM physicians. As shown in Figure 4, 315 medications (50.3% of the total) lacked relevant high-yield deprescribing criteria. The LLM effectively identified these cases, achieving an F_1-score of 0.86 (precision=0.83, recall=0.90). Among those medications with relevant criteria, 64 (10.2% of the total) were cases where either GPT-4o or the medical student recommended deprescribing. In this second step, which involved applying relevant criteria to make a recommendation, the LLM performed less effectively, with an F_1-score of 0.58 (precision=0.47, recall=0.76).



For cases where the LLM and the medical students differed, 2 senior annotators (board-certified Emergency Medicine physicians) adjudicated 126 discrepancies after standardizing the codebook and verifying IRR (Cohen *k*: eligibility=0.795, deprescribing=0.745). Notably, the confusion matrix (Figure 4) revealed that a major source of discrepancy was the significantly higher likelihood of the LLM to recommend deprescribing (11.6%) compared to the medical students (1.91%). The confusion matrix describes all possible outcomes when comparing the LLM with the medical students (eg, the medical student recommended deprescribing with eligible criteria and the LLM found no eligible criteria). The adjudication yielded similar results to those observed in comparison with medical students (Figure 5A). Across all discrepancies, GPT-4o was significantly more effective in criteria filtering compared to the medical student (McNemar test for paired proportions [30]: χ^2_1=5.985; *P*=.015). However, in applying relevant criteria, GPT-4o performed worse than the medical students, though the difference was not statistically significant (McNemar test: χ^2_1=1.818; *P*=.178). Adjudication was chosen as the gold standard for resolving discrepancies because preliminary

XSL•FO
RenderX

research showed low IRR among medical students for both steps of the process (Cohen *k*: step 1=0.68, step 2=0.33) across 75 medications.



In cases where GPT-4o was incorrect, error analysis highlighted key patterns across the 2 steps. For criteria filtering, senior annotators observed that errors often stemmed from incorrect reasoning or reading comprehension issues (Figure 5B). Similarly, in making recommendations, the most common error was incorrect reasoning, followed by cases where the LLM lacked sufficient information to make an accurate determination and subsequently made inappropriate assumptions.

Figure 4. Confusion matrix (n=626 medications). The joint confusion matrix across both steps showing alignment and discrepancies between the GPT-4o model and medical students.

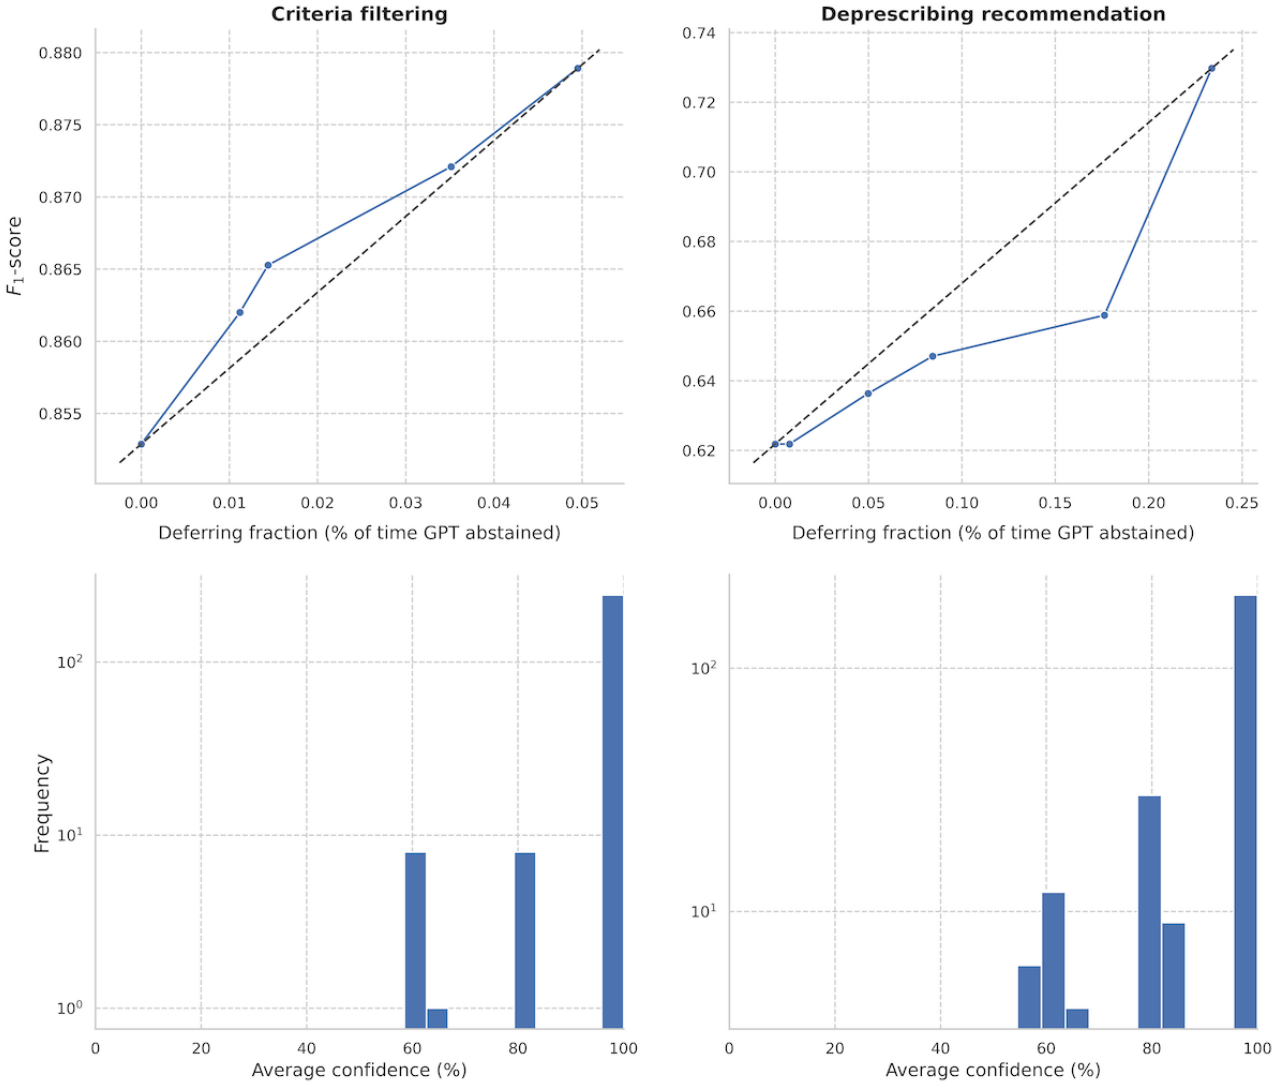
RenderX

Figure 5. (A) Expert adjudication (n=126). Adjudication by senior clinical expert comparing junior annotators and GPT-4o in both criteria filtering and deprescribing recommendation tasks. (B) GPT-4o error modes. Types of errors by GPT-4o in the adjudication set (n=126) for both criteria filtering and deprescribing recommendation tasks.



Selective Prediction Methods

Finally, we investigated the impact of incorporating confidence estimates from the LLM to guide selective prediction, allowing the model to abstain from making predictions in cases of low confidence. We compared 2 approaches: verbalized confidence and consistency-based confidence. Verbalized confidence demonstrated a narrower range of F_1-scores overall, with step 1 (eligibility) ranging from 0.860 to 0.863 and step 2 (deprescribing) from 0.58 to 0.69, as shown in Figure S3 in Multimedia Appendix 1. In contrast, consistency-based confidence exhibited broader and higher F_1-score ranges, with step 1 spanning 0.85 to 0.88 and step 2 ranging from 0.62 to 0.73 (Figure 6A). These results suggest that consistency-based confidence provides more flexibility and improved performance compared to verbalized confidence across both steps.

In particular, consistency-based selective prediction demonstrates a positive linear relationship between accuracy in deprescribing recommendations and deferring fractions. However, despite some minor improvements, we find that the LLM is poorly calibrated, as shown in Figure 6B. Despite consistency-based weighting, the confidence distribution is severely left-skewed with the minimum confidence being 58.5% in eligibility filtering and 54.5% in deprescribing recommendations.

XSL•FO
RenderX

Figure 6. Consistency-based selective prediction. (A) Range of F1-scores resulting from the application of consistency-based selective prediction in both steps of the deprescribing pipeline. The dotted line shows ideal performance as a function of deferring fraction. (B) Distribution of confidences for deprescribing recommendations from GPT-4o on a log scale.

Discussion

Principal Findings

In this retrospective cohort study evaluating deprescribing opportunities for PIMs among older adults with polypharmacy in the ED, we found that LLMs effectively identify relevant criteria from verified lists but are less adept at applying these criteria to individual patient cases. GPT-4o's performance was compared to that of medical students in a 2-step pipeline: filtering for criteria-eligible medications and making specific deprescribing recommendations. Adjudication by senior clinicians was used to resolve discrepancies, and selective prediction methods were tested to improve the model's reliability. The results offer insights into both the capabilities and limitations of LLMs in a real-world clinical context, highlighting key areas for improvement in both LLM frameworks and deprescribing guidelines.

Effectiveness of the 2-Step LLM Pipeline

The LLM demonstrated strengths in the initial filtering step, accurately identifying a high proportion of medications that matched deprescribing criteria, thus offering the potential to support clinicians in rapidly screening complex medication lists. In fact, the LLM outperformed medical students by a significant margin (80.1% vs 59.5% correct, McNemar test: P=.02). The adjudication, combined with strong overall performance (maximum F_1-score: 87.8%) using selective prediction methods, suggests that the LLM can effectively minimize the number of criteria requiring final review for deprescribing recommendations. Cases of misclassification were relatively uncommon and primarily related to nonstandard drug class names or overly broad groups, which could be improved with refined deprescribing criteria. However, in the second step—making specific deprescribing recommendations—the LLM encountered considerable difficulty, particularly when dealing with ambiguous criteria, missing information, and nuanced clinical scenarios. For example, thiazide diuretics are recommended for deprescribing in cases of significant hypokalemia, hyponatremia, hypercalcemia, or a history of gout. However, GPT-4o recommended deprescribing without access to current electrolyte values, instead basing its suggestion on a history of chronic kidney disease, a condition associated with

XSL•FO
RenderX

potential electrolyte imbalances but not meeting the relevant inclusion criteria. If implemented in clinical decision support, these inaccuracies might contribute to increased alert fatigue and extend the time required to interpret LLM-generated recommendations, potentially offsetting the intended efficiency gains in identifying deprescribing opportunities.

Our findings on the LLM's performance in identifying medications with relevant deprescribing criteria based on eligibility guidelines align with evidence from clinical trial matching literature [34], where LLMs have shown performance comparable to physicians in applying such criteria to identify eligible patients. One study used a similar "filter-and-apply" pipeline, in which trials were first filtered and then matched to patients, showcasing the effectiveness of this approach [35]. However, despite successes in eligibility filtering, challenges remain when applying complex criteria to specific patient cases. Similar errors to those observed in our work have been reported, such as incorrectly identifying patients who meet partial criteria, or assuming a patient with breast cancer does not have lung cancer simply because it is not explicitly mentioned [36,37]. Overall, while LLMs hold promise for reducing the time burden in determining deprescribing eligibility, their application requires careful consideration, particularly in tasks involving complex clinical reasoning.

Role of Selective Prediction in Clinical Decision-Making

To address the model's limitations in clinical decision-making, we implemented selective prediction methods, which allowed the LLM to "abstain" from making a recommendation in cases of low confidence. Selective prediction marginally improved the LLM's filtering accuracy by enabling it to defer uncertain cases to human reviewers. However, the effectiveness of this approach was limited by the poorly calibrated confidence levels assigned by the LLM to its decisions. Specifically, the LLM displayed a minimum confidence level of 54%, even in cases where its recommendations were incorrect. This indicates a tendency toward overconfidence, particularly in its deprescribing recommendations. While verbalized confidence is known to be overconfident in clinical question answering [38], our results contradict recent work that suggests that consistency-based methods alleviate some of these concerns [39]. This discrepancy underscores the importance of task-specific confidence thresholds and suggests that selective prediction, while useful, is not a one-size-fits-all solution in complex clinical applications.

Improved uncertainty calibration in LLMs could enhance selective prediction methods, optimizing physician-artificial intelligence (AI) workflows in clinical settings. Future applications of a well-calibrated deprescribing CDS tool could flag cases where critical information is missing (eg, antipsychotics at unchanged doses for more than 3 months without a documented medication review). This approach could streamline medication filtering while preserving human oversight, allowing clinicians to focus on complex cases where LLM reliability is limited.

Need for Clearer Deprescribing Guidelines

A notable finding from this study is the need for clearer and more consistent deprescribing guidelines. Ambiguities in criteria definitions, such as those related to medication administration routes and drug classes, present substantial barriers to automation and contribute to discrepancies between human and model interpretations. Additionally, the model often recommended deprescribing medications that, while potentially inappropriate, required specific contextual qualifiers (eg, patient's life expectancy, nutritional status, frailty status) to justify deprescribing—criteria that the LLM misapplied due to lack of explicit context or ambiguous language in the guidelines. It is important to note that current deprescribing criteria were not originally designed for direct implementation in CDS systems, but rather as general recommendations for prescribing physicians. Reorganizing these criteria into a structured, explicit framework tailored for CDS use could reduce ambiguity, improve the model's performance, and support more consistent application in clinical practice. In general, streamlining deprescribing criteria to ensure consistent application across clinical contexts could improve model reliability and help standardize deprescribing practices.

Implications for LLM Use in Clinical Practice and Future Directions

The results of this study underscore the promise of LLMs in enhancing deprescribing workflows by providing rapid filtering of PIMs, which could alleviate some of the burdens on health care providers. However, this work also highlights the limitations of current LLMs in complex, context-sensitive clinical decision-making tasks. The LLM's frequent tendency to overrecommend deprescribing, as compared to medical students, indicates that clear boundaries for medication eligibility and exclusion are critical for reducing false positives in automated recommendations. Cases with the potential for human harm were observed, such as suggesting deprescribing anticoagulation in a patient with recent thromboembolism. Additionally, cases were seen in which the LLM recommended deprescribing without citing a specific criterion. These behaviors suggest that strong guardrails on the LLM are needed to ensure safe, high-quality recommendations. Enhancing guideline specificity, particularly for complex inclusion or exclusion criteria, could reduce both human and model error rates and may foster greater acceptance of AI-assisted deprescribing tools among clinicians. Our findings highlight the potential value of human-AI collaboration frameworks. For example, a human-in-the-loop framework (a model in which humans review difficult cases the LLM cannot resolve) could involve LLMs assisting in the identification of deprescribing opportunities while deferring final recommendations to clinicians [40]. Alternatively, the LLM could focus on the initial filtering of relevant deprescribing criteria for specific medications, leaving the recommendation task entirely to the clinician, thereby leveraging the LLM's strength in mapping medications or medication classes to appropriate criteria efficiently [41]. These approaches not only leverage the model's efficiency in data processing but also mitigate risks associated with erroneous recommendations, particularly in this high-risk clinical context. Future research should focus on refining LLM architectures to better handle the nuances of clinical reasoning and context interpretation, perhaps by incorporating more advanced natural language processing techniques and domain-specific training.

XSL•FO
RenderX

Additionally, efforts to standardize deprescribing guidelines would greatly benefit the development of automated tools in this area, making them more reliable and broadly applicable.

Limitations

This study has several limitations that warrant consideration. First, the retrospective nature of our analysis, relying on historical data from EHRs, may not fully capture the complexity of real-time clinical decision-making in emergency settings. The study's focus on a single large academic medical center limits the generalizability of our findings to other settings with different patient populations, documentation patterns, and health care practices. Second, the selective prediction methods, while providing insights into the LLM's confidence, were not universally effective, particularly in the nuanced task of deprescribing recommendations. The model's performance in these recommendations highlights the challenge of translating structured criteria into actionable clinical decisions, especially when faced with ambiguous inclusion or exclusion conditions. Additionally, the model's reliance on textual prompts and structured EHR data may not fully account for nuanced clinical contexts that influence deprescribing decisions. Third, the small sample size for detailed analysis (100 patients) limits the statistical power and may not reflect broader patterns of medication use and deprescribing needs. Cost may be a barrier to larger sample sizes in the future, as the total application programming interface utilization fees were approximately US $300-$400 over these 100 patients and the cost to both evaluate and implement the system in the real world would scale linearly with the study population. Additionally, the study relied on medical students for initial annotation. While these annotations were reviewed and adjudicated by board-certified physicians, this process may introduce variability, potentially affecting the reliability of their use as a gold standard in selective prediction methods. Our process for selecting these criteria also did not explicitly include any geriatricians, though did include a range of individuals who regularly care for older adults. Finally, the criteria used (STOPP, Beers, and GEMS-Rx) were selected based on their perceived clinical risk and EHR computability, which may not encompass all relevant deprescribing scenarios. The lack of standardized guidelines for implementing deprescribing criteria in LLMs also poses a challenge to consistency and accuracy.

Conclusions

This study demonstrates the potential of LLMs to augment clinical decision support by effectively filtering deprescribing criteria for older adults with polypharmacy in ED. While the LLM showed promise in identifying medications eligible for deprescribing, it faced challenges in making nuanced deprescribing recommendations, underscoring the need for human oversight in AI-driven processes. Future research should prioritize refining the model by addressing ambiguities in deprescribing criteria and integrating broader clinical context, such as longitudinal data from prior progress notes and discharge summaries, to enable the detection of relevant clinical trends. Expanding the dataset and exploring more effective strategies for integrating human judgment with AI capabilities will help overcome limitations in generalizability, helping optimize patient care. The findings underscore the potential of LLMs in AI-enabled automated CDS tools for deprescribing while emphasizing the need to refine deprescribing criteria and establish clearer guidelines to support the integration of AI into clinical practice.

Acknowledgments

VS has received funding from the Yale University-Mayo Clinic Center of Excellence in Regulatory Science and Innovation for this work. MI receives funding through CTSA (grant UL1 TR001863) from the National Center for Advancing Translational Science, a component of the National Institutes of Health. This publication's contents are solely the responsibility of the authors and do not necessarily represent the official views of the National Institutes of Health.

Authors' Contributions

VS, MI, and RAT conceived of the study with help from DSW in the design of its analysis. VS, CD, and LC provided data engineering and analyzed the data. VS prepared figures. DSW, JA, BP, NSK, CXW, AL, and RAT participated in the consensus study. TH, SF, DSW, and MI annotated notes for model training and testing. VS, DSW, LC, and RAT drafted the manuscript, and all authors contributed substantially to its revision. RAT takes responsibility for the paper as a whole.

Conflicts of Interest

RAT receives unrelated support from grants from the National Institutes of Health, Gordon and Betty Moore Foundation, the Federal Drug Administration, the Agency for Healthcare Research & Quality, and Beckman Coulter, Inc as well as options from Vera Health for serving as an advisor. DC is the associate editor for *JMIR Medical Education*.

Abstract

Background: Frailty affects over 50% of older adults in long-term care (LTC), and early detection is critical due to its potential reversibility. Wearable sensors enable continuous monitoring of gait and physical activity, and machine learning has shown promise in detecting frailty among community-dwelling older adults. However, its applicability in LTC remains underexplored. Furthermore, dynamic gait outcomes (eg, gait stability and symmetry) may offer more sensitive frailty indicators than traditional measures like gait speed, yet their potential remains largely untapped.

Objective: This study aimed to evaluate whether frailty in LTC facilities could be effectively identified using machine learning models trained on gait and daily physical activity data derived from a single accelerometer.

Methods: This study is a cross-sectional secondary analysis of baseline data from a 2-arm cluster randomized controlled trial. Of the 164 individuals initially enrolled, 51 participants (age: mean 85.0, SD 9.0 years; female: n=24, 47.1%) met the inclusion criteria of completing all assessments required for this study and were included in the final analysis. Frailty status was assessed using the fatigue, resistance, ambulation, incontinence, loss of weight, nutritional approach, and help with dressing (FRAIL-NH) scale. Participants completed a 5-meter walking task while wearing a 3D accelerometer. Following this task, the accelerometer was used to record daily physical activity over approximately 1 week. A total of 34 dynamic and spatial-temporal gait outcomes, 3 physical activity variables, and 6 demographic characteristics were extracted. Five conventional machine learning models were trained to classify frailty status using a leave-one-out cross-validation approach. Model performance was evaluated based on accuracy and the area under the receiver operating characteristic curve. To enhance model interpretability, explainable artificial intelligence techniques were used to identify the most influential predictive outcomes.

Results: The extreme gradient boosting model demonstrated the optimal performance with an accuracy of 86.3% and an area under the curve of 0.92. Explainable artificial intelligence analysis revealed that older adults with frailty exhibited more variable, complex, and asymmetric gait patterns, which were characterized by higher stride length variability, increased sample entropy, and a lower gait symmetry score.

XSL•FO
RenderX

Conclusions: Our findings suggest that dynamic gait outcomes may serve as more sensitive indicators of frailty than spatial-temporal gait outcomes (eg, gait speed) in LTC settings, offering valuable insights for enhancing frailty detection and management.

KEYWORDS

frailty; long-term care; gait; physical activity; machine learning

Introduction

Frailty is associated with adverse health outcomes and increased dependency, severely increasing the risk of early mortality in older adults [1]. In long-term care (LTC) facilities, approximately 52.3% of older adults are affected by frailty [2], posing a significant threat to residents' well-being and sustainability in health care. Effective and efficient frailty screening methods are urgently needed to mitigate these negative outcomes and the progression of frailty among older adults in LTC facilities.

Currently, there is no internationally recognized gold standard for screening or diagnosing frailty for older adults, especially LTC residents. Over 60 different frailty assessment tools have been developed [3]. Fried's frailty phenotype (FFP) is widely used among community-dwelling older adults [4], while the fatigue, resistance, ambulation, incontinence, loss of weight, nutritional approach, and help with dressing (FRAIL-NH) scale is specifically designed for nursing home settings [5]. However, these assessments are time-consuming, require trained health care professionals, and are often conducted at a single time point, normally after a concern for declined intrinsic capacity has been raised [6]. Given that the transition from healthy aging to frailty is a dynamic and potentially reversible process [7], continuous monitoring is critical for early interventions, which may effectively prevent the frailty progression [8].

Wearable sensor technology and machine learning have emerged as promising alternatives to traditional frailty assessments [9-12]. Accelerometers can continuously monitor older adults' gait and daily physical activity, while machine learning has been successfully applied to analyze accelerometer data and detect frailty status in community-dwelling older adults [9-12]. Specifically, self-selected gait speed and moderate-to-vigorous physical activity (MVPA) time derived from accelerometer data are significantly correlated with frailty status in community-dwelling older adults [9-12]. However, it remains unclear whether these findings apply to the LTC population, as these individuals often have various physical and cognitive conditions that may affect their mobility [13]. Additionally, LTC residents tend to be more sedentary due to the constrained nature of their living environments [14]. Furthermore, beyond spatial-temporal gait outcomes, the role of dynamic gait outcomes, such as gait regularity and stability derived from accelerometer signals [13], remains underexplored in identifying older adults with frailty. These dynamic outcomes have demonstrated greater sensitivity in distinguishing between different patient groups, such as individuals with chronic low back pain [15-17], and may also be valuable for frailty prediction among older adults.

Apart from this, the emergence of explainable artificial intelligence techniques has addressed the critical challenge of interpreting complex machine learning models in health care applications. These techniques also support compliance with legal and regulatory requirements and help foster trust between clinicians and patients. Among them, Shapley additive explanations (SHAP) is a widely adopted approach grounded in cooperative game theory [16,18]. SHAP enables researchers and clinicians to understand not only which but also how outcomes such as gait variability contribute to the recognition of frailty. Incorporating SHAP enhances model transparency and strengthens clinical relevance, particularly in high-stakes settings like LTC facilities.

Therefore, this study aimed to evaluate whether gait outcomes and daily physical activity data derived from a single accelerometer could identify older adults with frailty in LTC facilities. We hypothesized that machine learning could accurately identify older adults with frailty. By incorporating SHAP, we further hypothesized that accelerometer-derived dynamic gait outcomes would be more sensitive than spatial-temporal gait outcomes in distinguishing between older adults with or without frailty in LTC facilities.

Methods

Study Design

This study is a cross-sectional, secondary analysis of baseline data from a 2-arm cluster randomized controlled trial [19]. Baseline data were collected from 20 LTC facilities in Hong Kong. The inclusion criteria were as follows: (1) aged 65 years or older; (2) able to rise from a chair and stand for at least 20 seconds; (3) confirmed by a physician as medically stable to participate in the study; and (4) able to wear an accelerometer continuously for 5 days to measure daily physical activity. Older adults were excluded if they (1) were unable to comprehend instructions, (2) could not complete the exercise program due to medical conditions, or (3) had legal blindness [19].

Ethical Considerations

The study adhered to the principles of the World Medical Association Declaration of Helsinki and Good Clinical Practice. All participants provided written informed consent, either personally or through a family member, prior to study enrollment. Ethics approval has been acquired from the Research Ethics Board at the Chinese University of Hong Kong and the Joint CUHK-NTEC Clinical Research Ethics Committee (SBRE-21-0413 and CREC-2022-459) [19].

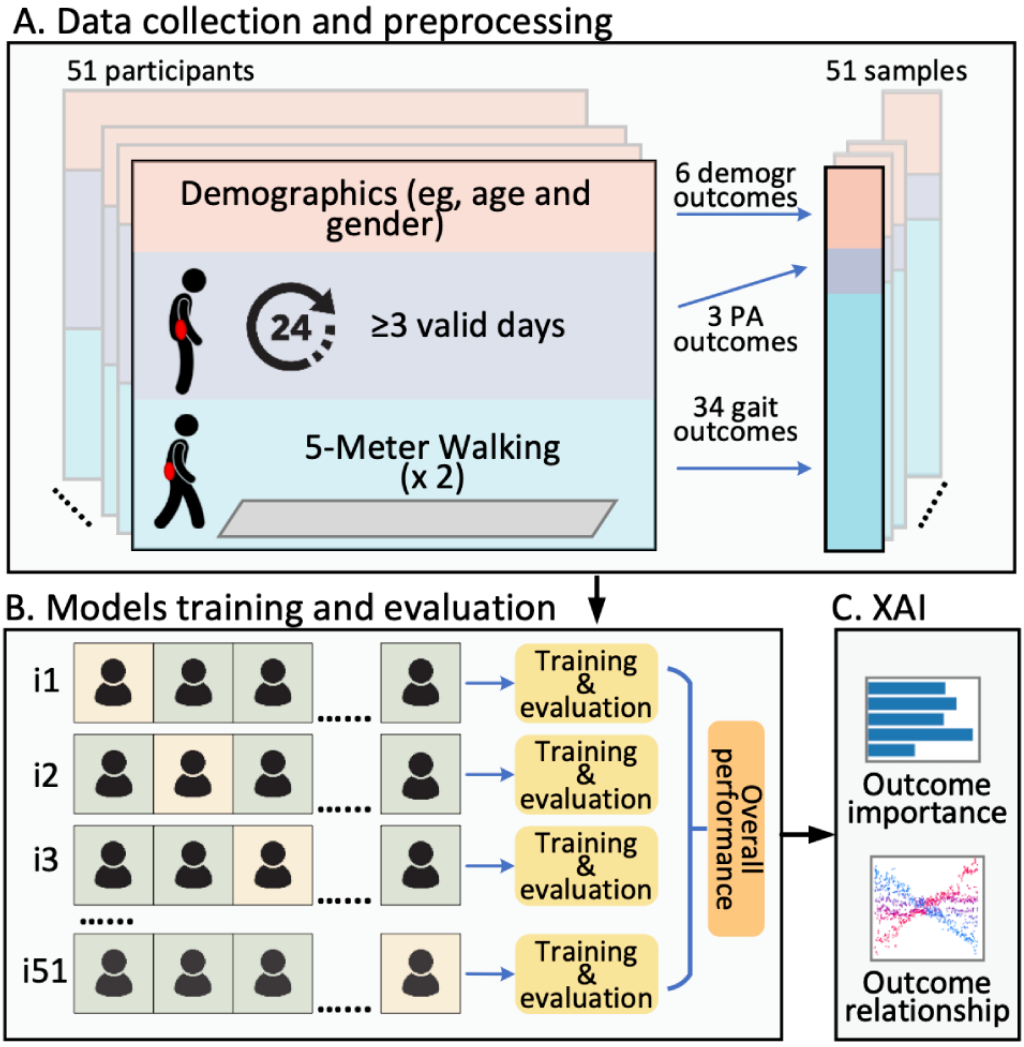
RenderX

Data Collection and Processing

Frailty was assessed using the FRAIL-NH scale, with a total score ranging from 0 to 14 [5]. Participants were categorized into 2 groups based on their total score following the cut-off values suggested in a previous study [20]: nonfrail (0-1) and frail (2-14).

During the study, a single accelerometer (ActiGraph GT9X Link IMU) was used, with a sampling frequency of 100 Hz and a range of ±16 gravitational acceleration units (g). Participants were instructed to walk at a comfortable speed over a 5-meter distance twice and the accelerometer was affixed near the L3 vertebra. From the accelerometer data, 34 gait outcomes were extracted from the data (details are provided in Multimedia Appendix 1). These outcomes represent the pace (gait speed, stride length, stride time, stride frequency, and acceleration root mean square), regularity (stride regularity and gait symmetry score), smoothness (index of harmonicity and harmonic ratio), predictability (sample entropy), and stability (maximal Lyapunov exponent and maximal Lyapunov exponent normalized per stride by time) of gait and have been described previously [15].

Regarding daily physical activity, participants were instructed to wear the accelerometer on the right side of their waist (at the anterior superior iliac spine) for 5 consecutive days, removing it only during bathing or before bed [21]. A valid day required at least 8 hours of wear time, and data from at least 3 valid days were included in the analysis using ActiLife software (version 6.13.4, ActiGraph LLC) [22]. Physical activity intensity was classified using established cut-off points for similar populations: sedentary behavior (0-50 counts/min), light physical activity (LPA; 51-759 counts/min), and MVPA (≥760 counts/min) [22]. Three outcomes, including the percentage of time spent in sedentary behavior, LPA, and MVPA, were extracted from the data.



Six demographic characteristics, specifically age, gender, height, body weight, BMI, and use of mobility aids, were collected. The use of mobility aids was categorized into 3 levels: independent, use of cane, and use of walker.

Model Development and Interpretation

The gait outcomes were averaged across 2 trials, and the daily physical activity outcomes were averaged across valid days. As a result, a total of 43 outcomes (Figure 1A) were used as input to train 5 machine learning classifiers, including extreme gradient boosting (XGBoost), random forest, support vector machine, naive Bayes, and K-nearest neighbors, with labels determined by the FRAIL-NH scale. Detailed descriptions of the corresponding data preprocessing of each model are provided in Multimedia Appendix 2.

XSL•FO
RenderX

Figure 1. Data processing and analysis. (A) Data collection and preprocessing for demographic, daily physical activity (PA), and gait data. (B) Models training and evaluation based on leave-one-out cross-validation. (C) Explainable artificial intelligence (XAI) for estimating the importance of each outcome and the relationships between different outcomes.

Model performance for each classifier was evaluated using leave-one-out cross-validation (LOO-CV), where the data from 1 participant was left out for testing, and the remaining participants were used for training (Figure 1B). This process was repeated for each participant to ensure an unbiased assessment of model performance. For each iteration, a Bayesian optimization approach [23] with 5-fold cross-validation was used to identify the best hyperparameters for the classifier. This process followed a nested cross-validation design [24]. The details of the parameter space and settings of each machine learning model are provided in Multimedia Appendix 3. Model performance was evaluated by aggregating results from LOO-CV to compute the following metrics: accuracy, sensitivity, specificity, area under the receiver operating characteristic curve (AUC), and F_1-score.

To explore the association between gait outcomes, daily physical activity, and frailty, SHAP was used to interpret the results of the best classifier. SHAP estimates the contribution of each outcome to the classification process, as well as the interactions between selected outcomes using principles from game theory (Figure 1C).

In this study, SHAP values were computed for each testing participant during each iteration of the LOO-CV, using the corresponding model trained without that participant. The SHAP values from all iterations were then aggregated, leveraging the additivity property of SHAP [16,18], to generate a global interpretation of feature importance across the entire dataset. This approach ensures faithful, subject-specific explanations while maintaining the validity of the cross-validation framework.

To allow for the verification and reproduction of results, the project repository has been made publicly available [25]. It includes the source code and log files of all experiments.

Statistical Analysis

Statistical analyses were conducted using SPSS version 27.0 (IBM Corporation) with a significance level set at $P<.05$. Continuous variables were presented as mean (SD) for normally distributed data or median (IQR) for non-normally distributed data. Categorical variables were expressed as frequency and percentage. The normality of continuous variables was assessed using the Shapiro-Wilk test. To compare demographic characteristics between the nonfrail and frail groups, independent samples *t* tests were used for normally distributed

XSL•FO
RenderX

variables, while the Mann-Whitney U test was applied for non-normally distributed variables. For categorical variables, the Chi-square test (or Fisher exact test, where appropriate) was used to compare proportions between the 2 groups.

Results

Participant Characteristics

Among the 164 participants recruited from 20 LTC facilities, 113 were excluded for the following reasons: aged younger than 65 years, deceased, or withdrew from participation (n=15); unwilling to wear an accelerometer or insufficient accelerometer data for daily activity (n=82); and missing accelerometer data for gait (n=16). This left 51 participants for data analysis, with their demographic characteristics summarized in Table 1. Statistically significant differences between the nonfrail and frail groups were observed in body weight (nonfrail: mean 57.3, SD 10 kg; frail: mean 50.7, SD 9.4 kg; *P*=.02) and the use of walking aids (*P*=.008).

Table 1. Demographic characteristics of participants, mean (SD).

Demographic	Nonfrail (n=26)	Frail (n=25)	*P* value
Age (years), mean (SD)	83.2 (10.6)	87.0 (7.0)	.14
Gender, n			.48
Female	11	13	
Male	15	12	
Height (cm), mean (SD)	159.0 (9.7)	157.2 (10.9)	.52
Body weight (kg), mean (SD)	57.3 (10.0)	50.7 (9.4)	.02
BMI (kg/m^2), mean (SD)	22.6 (3.5)	20.7 (4.0)	.07
Walking aids, n			.008
Independent	16	5	
Use of cane	9	16	
Use of walker	1	4	

Model Performance

Table 2 presents all performance metrics for each model and Figure 2 shows their confusion matrices to offer a detailed view of individual model performance. XGBoost demonstrated the best classification performance compared to other machine learning models, achieving an AUC of 0.92 (Figure 3), with an accuracy of 86.3%, sensitivity of 0.85, specificity of 0.88, and an F_1-score of 0.86.

Table 2. Performance metric comparison between machine learning models.

Model	Accuracy (%)	AUC[a]	Sensitivity	Specificity	F_1-score
NB[b]	68.6	0.73	0.65	0.72	0.68
KNN[c]	62.7	0.70	0.62	0.64	0.63

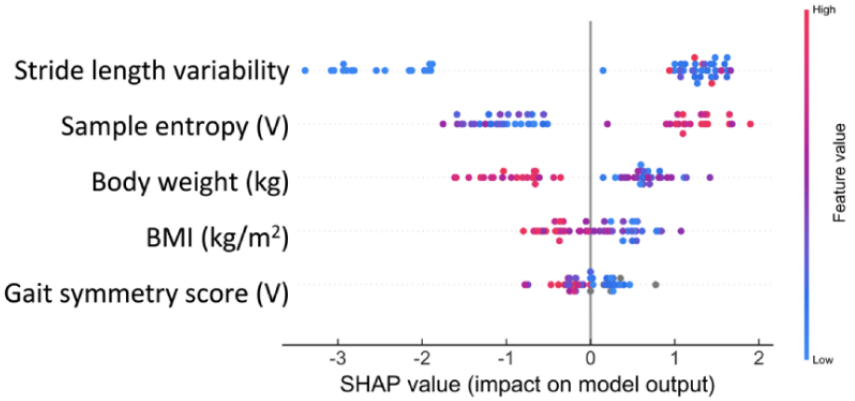
Figure 3. Comparison of the area under the curve between machine learning models. ROC: receiver operating characteristic curve; NB: naive Bayes; KNN: K-nearest neighbors; SVM: support vector machine. RF: random forest; XGBoost: extreme gradient boosting.

SHAP was used to interpret the classification process of XGBoost, as it demonstrated the best performance. The top 10 outcomes based on absolute SHAP values are presented in Multimedia Appendix 4. The elbow plot identified an "elbow" at 5, suggesting that the top 5 outcomes were the most influential in the classification. These key outcomes include stride length variability, sample entropy in the vertical direction, body weight, BMI, and gait symmetry score in the vertical direction.

Figure 4 illustrates the relationships between these outcomes and their corresponding SHAP values. Negative SHAP values indicate a contribution toward the nonfrail group, while positive values indicate a contribution toward the frail group. Larger absolute SHAP values represent a greater influence on classification. The figure shows that predicted older adults without frailty tend to have lower stride length variability, whereas participants with high sample entropy (greater gait complexity) are more likely to be classified as frail. Similarly, higher body weight and BMI values are associated with the nonfrail group. Higher gait symmetry score (indicating more symmetry; Multimedia Appendix 5) in the vertical direction contributes to the frail group, while lower values are associated with a nonfrailty classification.

Figure 4. Relationship between Shapley additive explanations (SHAP) value and key outcomes.



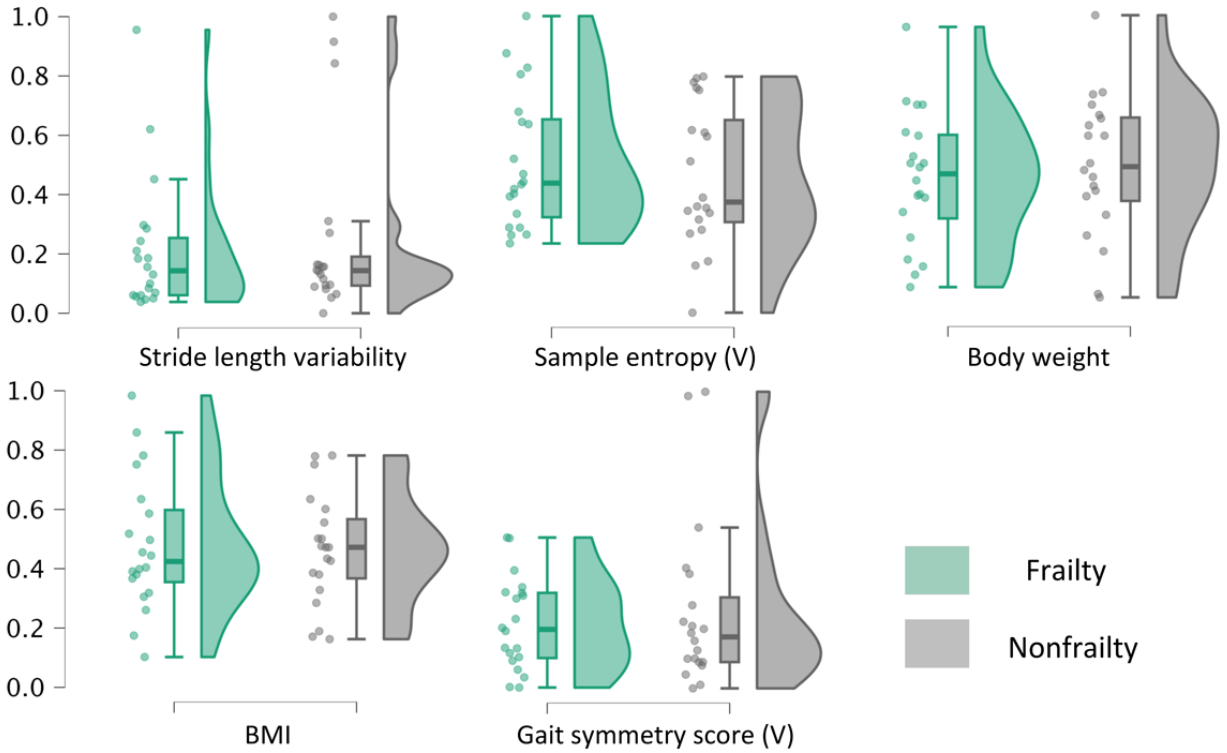


Figure 5 presents raincloud plots of the 5 key outcomes. The raincloud plot combines a kernel density plot with a box plot, with dots representing individual data points. All values were normalized to a 0-1 scale for comparability. Compared with the nonfrail group, the frail group exhibited higher stride length variability, greater sample entropy in the vertical direction, and decreased gait symmetry score in the vertical direction.

XSL•FO
RenderX

Figure 5. Raincloud plot for the top 5 key outcomes (normalized to a 0-1 scale). The dots represent individual data points; the thick line within each box plot represents the median, while the box boundaries show the interquartile range; the density plot reflects a kernel density estimate, illustrating the distribution of data across different values—wider sections indicate higher data concentration. V: vertical direction.

Discussion

Principal Findings

To the best of our knowledge, this study is among the first investigations that used machine learning in conjunction with accelerometer-derived gait and daily physical activity data to detect frailty among older adults in LTC facilities. Our results confirm that machine learning models, particularly XGBoost, demonstrated accurate classification performance in a LOO-CV (AUC=0.92, accuracy=86.3%). Consistent with our hypothesis, dynamic gait outcomes, including stride length variability, sample entropy (vertical direction), and gait symmetry (vertical direction), are more sensitive in distinguishing frailty status among LTC-dwelling older adults compared with traditional spatial-temporal parameters (eg, gait speed). These biomechanical markers, combined with anthropometric measures (body weight and BMI), emerged as the most influential predictors.

Stride length variability contributed the most to the classification process, with higher variability observed in the frail group. Previous research has reported similar findings, showing that older adults with frailty exhibit greater stride length variability in community settings [26,27]. Larger stride-to-stride fluctuations in stride length may reflect reduced accuracy and reliability of the neuromuscular systems that regulate gait rhythm [28]. Given that increased fall risk [29], age-related physical decline [30], and cognitive impairments are linked to frailty [31], it is not surprising that older adults with frailty exhibit higher gait variability [32-34]. Sample entropy was used to quantify gait predictability and complexity [35]. Higher entropy values (less predictability) in the frail group may suggest disrupted locomotor control, likely tied to neurological or neuromuscular dysfunction [36-38]. This aligns with findings that gait irregularity discriminates older adults with prefrailty from those without frailty [39] in community-dwelling settings and correlates with pathologies such as Parkinson disease and high fall risk [38]. Gait symmetry, which provides insight into the consistency between 2 consecutive steps, was lower in older adults with frailty, indicating greater degrees of asymmetry. Left-right gait coordination is primarily governed by localized neuronal networks, or central pattern generators, as observed in animal studies [40]. In healthy individuals, this coordination occurs automatically with limited cognitive input [41]. However, with aging, sarcopenia, or cognitive impairment, gait becomes less automatic and left-right coordination may increasingly depend on attentional demands, particularly in individuals with frailty [41,42]. Additionally, studies have shown no strong association between gait variability and asymmetry, suggesting that asymmetry represents an independent measure of gait impairment linked to distinct pathological causes [41]. Collectively, these findings suggest that older adults with frailty in LTC facilities exhibit more variable, irregular, and asymmetric gait patterns compared to those without frailty.

The frail group had significantly lower body weight compared with the nonfrail group, which aligns with sarcopenia's role in frailty pathogenesis, where muscle mass loss contributes to both weight reduction and functional decline [43]. Additionally, the lower BMI may reflect nutritional deficits commonly seen in older adults residing in LTC facilities, further exacerbating frailty progression [44]. These findings highlight the value of

XSL•FO
RenderX

integrating anthropometric data with dynamic gait metrics for comprehensive frailty screening in LTC settings.

Notably, dynamic gait outcomes contributed more to the classification process than gait speed. In community-dwelling older adults, self-selected gait speed has been widely recognized as a key indicator for distinguishing frailty from nonfrailty [11,12] and has been incorporated into screening tools like the FFP [45]. However, in this study, the low SHAP value of gait speed indicates its limited contribution to the classification process among older adults in LTC facilities. One possible explanation is that self-selected gait speed is influenced by multiple factors beyond walking capacity. For instance, in this study, 21.6% of older adults had experienced at least one fall in the past year. Due to fear of falling or other safety concerns, they may voluntarily reduce their gait speed despite being physically capable of walking faster [46]. Another possible explanation is the environmental constraints of LTC facilities in Hong Kong. The care homes in Hong Kong typically have narrow spaces, and gait measurements were conducted in hallways, which may have influenced gait speed. As a result, gait speed alone may not be a sufficiently sensitive measure for frailty classification in this population and settings.

Previous studies have reported that older adults with frailty tend to have lower levels of daily physical activity [47], and higher physical activity levels have been shown to protect against frailty [48]. In this study, the frail group exhibited a lower percentage of time spent in sedentary behavior (P=.001) and a higher percentage of time in LPA (P=.001), but no significant difference was observed in MVPA (Multimedia Appendix 6). However, SHAP values indicated that physical activity outcomes contributed minimally to model predictions. This suggests that in LTC settings, the current activity measures, based on time spent percentage, may not strongly differentiate frailty status (Multimedia Appendix 4). One possible reason is that the current physical activity metrics are relatively heterogeneous, covering a broad range of percentage values with considerable variability and outliers. To enhance frailty classification, more advanced measures such as postural transitions (eg, sit-to-stand [49]) and physical activity patterns [50] should be considered to develop a more robust model capable of accurately distinguishing between frail and nonfrail states among this vulnerable population.

Compared with traditional frailty assessment tools, such as the FFP and the short physical performance battery [51,52], the proposed method leverages wearable sensor-derived gait and physical activity outcomes analyzed through machine learning. This approach enables a more objective, continuous, and data-driven assessment of frailty. It also holds promise for the early detection of prefrailty and frailty in a scalable, unobtrusive, and real-time manner across diverse care settings, ultimately supporting more timely and targeted interventions.

Limitations

The walking task in this study was limited to a 5-meter distance due to space constraints in Hong Kong LTC facilities. While 2.4-, 4.6-, or 6-meter walking tests are commonly used for clinical gait analysis [53] and longer walks likely would have led to fatigue, a longer distance could have provide more reliable estimates of gait characteristics. For instance, sample entropy typically requires at least 10 seconds of signal data for reliable computation. In this study, the average walking speed was 0.46 m/s (SD 0.15 m/s), meaning that the recorded acceleration data exceeded 10 seconds, meeting the requirement for valid sample entropy calculations. Additionally, we tested the stability of sample entropy (Multimedia Appendix 7), which showed that using 70% of the current data length was sufficient to obtain stable results. Therefore, we believe that the sample entropy findings in this study are reliable. Given the limited number of participants in this study, a LOO-CV approach was used to improve the generalizability of the machine learning results and reduce the risk of overfitting. Lastly, the cross-sectional design precludes causal inferences, and the FRAIL-NH scale, though validated for LTC settings [5,20], may not fully capture frailty's dynamic progression. Longitudinal studies with repeated measures are warranted to validate these findings.

Conclusions

This study demonstrated that machine learning models, particularly XGBoost, effectively identify frailty in LTC older adults using accelerometer-derived gait and daily physical activity data. Our findings underscore the superiority of dynamic gait outcomes, including stride length variability, sample entropy (vertical direction), and gait symmetry (vertical direction), over traditional spatial-temporal outcomes in distinguishing frailty status. These outcomes reflect nuanced neuromuscular insights into frailty pathophysiology. The complementary role of anthropometric measures (body weight and BMI) further hints toward an interplay between sarcopenia, nutritional status, and functional decline in this population.

Abstract

Background: The transition of social and health services to digital platforms has significant implications for the inclusion and well-being of older adults. Digital literacy is a key determinant of health and equity, particularly as services shift to digital platforms. For older adults, this is crucial for accessing essential services and information, aiding in emergency resource navigation and information access.

Objective: This study examines how Canadian news media portray older adults' digital literacy, using the Unified Theory of Acceptance and Use of Technology 2 (UTAUT2) framework to guide the analysis.

Methods: News media articles from Canada, published from May 4, 2023, to July 4, 2024, were analyzed. Articles were identified through database searches and manual reviews, with inclusion criteria focusing on mentions of older adults and digital literacy. Critical discourse analysis was conducted using UTAUT2 factors to interpret the media narratives.

Results: Of the 103 articles reviewed, 54 met the inclusion criteria. Four key themes emerged: (1) Performance and effort expectancy: media frequently depicted older adults as needing significant help with digital technologies, indicating potential digital ageism. (2) Social influence: fearmongering narratives suggest insufficient technological skills could result in social exclusion and limited access to essential services. (3) Facilitating conditions: articles highlighted older adults' susceptibility to digital scams and fraud, reinforcing digital ageism. (4) Hedonic motivation: media portrayals emphasized active aging, illustrating how digital tools, such as home security systems, can enhance independence and quality of life.

Conclusions: Many media narratives on older adults' digital literacy perpetuate digital ageism. The study highlights how negative portrayals of older adults' digital skills and their exclusion from digital spaces underscore the need for more inclusive media representations. Findings suggest that media outlets could play a crucial role in shifting to more supportive portrayals of older adults' engagement with technology. Improving media portrayals can enhance digital engagement and preparedness among aging populations, contributing to better overall quality of life.

digital divide; media representation; older adults; disaster planning; digital technology

Introduction

Background

Digital literacy refers to the diverse skill levels individuals possess in using digital technologies and navigating their associated risks with discernment and confidence [1]. As a determinant of health, the ability to navigate digital environments shapes access to health resources and broader health equity outcomes [2-4]. Digital literacy involves the combination of cognitive abilities and technical skills, allowing individuals to effectively use digital technology for information retrieval, critical evaluation, content creation, and communication [4]. The rapid shift of social and health services to digital platforms has profound implications for the inclusion and well-being of older adults [5].

The intersection of an aging population with rapid technological advancements has fostered the misconception that older adults are technologically incompetent [6]. This belief exemplifies digital ageism, which encompasses age-related biases in how digital technology is developed, applied, and perceived by

XSL•FO
RenderX

society [7]. Digital ageism refers to the systemic exclusion or marginalization of older adults in digital environments and is embedded in both the design and dissemination of technology [8]. It has been categorized as occurring at both individual and organizational levels. At the individual level, digital ageism involves the failure to consider the specific needs, preferences, and abilities of older adults in the design and use of technology [9]. At the organizational level, it is perpetuated by a lack of training and awareness among technology developers, including website designers and service providers, leading to digital platforms that are not accessible or inclusive of older adult users [9]. These issues are further compounded by how emerging technologies, such as artificial intelligence, are developed and deployed often without adequate representation of older adults in training data or user testing processes [9]. Digital ageism fosters stereotypes that assume older adults lack digital skills [8]. In actuality, older adults possess diverse digital competencies and engage with information and communication technology in various ways [7].

Digital inclusion is essential not only for everyday activities, such as staying socially connected, but also for navigating high-stakes situations. The consequences of digital exclusion become particularly pronounced during emergencies, when timely access to digital information and services is critical. As digital ageism limits older adults' engagement with technology, it can reduce their ability to respond effectively in times of crisis. This was especially evident during the COVID-19 pandemic, which saw a rise in the use of telehealth [10], digital banking channels [11], and web-based grocery services [12] to mitigate contact exposure [13]. More broadly, digital platforms offer invaluable resources for accessing emergency services, support networks, and relief supplies during disasters [14]. The swift dissemination of accurate and timely information, often facilitated through digital channels, is thus necessary for informed decision-making and prompt action during disasters [15].

Digital literacy equips individuals with the skills to navigate digital platforms efficiently, enabling them to access emergency alerts, evacuation routes, and safety guidelines without delay [14]. Consequently, it is essential to promote digital literacy among older adults to enhance their ability to navigate digital resources effectively, stay informed about disaster risks, and access timely assistance during a crisis [16]. Empowering older adults with digital literacy skills can foster greater resilience and preparedness within aging populations, ultimately contributing to more effective disaster response and recovery efforts [17]. Of note, digital literacy includes a broad set of competencies such as the technical skills required to use digital devices, the ability to access, evaluate and manage information, critically assess media content, and navigate digital systems such as web browsers [18]. Given this broad definition, it is reductive to assume that low digital literacy is inherent to older adults solely because they did not come of age during the digital era [18]. This stereotype promotes the falsehood that older adults are less capable of digital engagement and that technology is a privilege reserved for younger users [18]. Such assumptions diminish older adults' self-efficacy and interest in being digitally active [19]. Therefore, it is essential to critically assess the language used when discussing older adults in digital contexts to avoid reinforcing the digital divide as a socially constructed and preventable inequity [19].

Theoretical Framework

The Unified Theory of Acceptance and Use of Technology (UTAUT) model has previously been used to explain behavior and intentions related to the adoption of digital technology [20,21]. Technology-related behaviors are evaluated based on 5 factors that influence acceptance and use: (1) performance expectancy; (2) effort expectancy; (3) social influence; (4) facilitating conditions; and (5) age, gender, and experience [22]. In 2012, the original UTAUT model was expanded into UTAUT2, incorporating additional factors such as hedonic motivation, price value, and habit [23].

Performance expectancy refers to the perceived usefulness of digital technology [21]. Effort expectancy assesses the ease of use of the technology. Social influence evaluates the extent to which an individual's social network values the use of digital technology. Facilitating conditions encompass the resources and support available to an individual for using the technology [21]. UTAUT suggests that behavioral intention is influenced by factors such as age, gender, and experience [21]. In UTAUT2, hedonic motivation relates to the enjoyment experienced when using digital technology [23]. Price value refers to the cognitive assessment of the balance between the perceived benefits and the monetary costs. Finally, habit describes the extent to which digital technology use is automatic (based on previous usage) [23].

In this study, we leverage UTAUT2 to evaluate news media representations of older adults' digital literacy within the context of disaster risk management. Specifically, we investigate how newspapers depict older adults as agents with varying degrees of digital proficiency using UTAUT2 factors. Our guiding question was: What prevailing narratives surround digital literacy and older adults, and how are they depicted in news media narratives related to disaster risk management? While this focus shaped our search strategy and inclusion criteria described below, we ultimately found few disaster media articles that addressed older adults' digital inclusion or exclusion. This absence became a significant finding in itself, prompting a broader examination of how digital literacy and older adults are framed in mainstream media more generally.

Methods

Positionality

As researchers, we acknowledge that our backgrounds and experiences shape our perspectives and approaches to this study. Our research team comprises 5 women, 2 of whom are aged 50 years and older, all of whom are digitally literate. These factors influence our understanding of digital literacy and our interpretation of media representations of older adults. Our collective experience as women, including those who have navigated digital landscapes for decades, informs our sensitivity to issues of age and gender bias in media portrayals. Our digital literacy enables us to critically assess the technical aspects of digital engagement, while our personal and professional

XSL•FO
RenderX

experiences with media analysis and expertise in ageism research provide a nuanced lens through which we view the data. We have been conscientious in our approach to the data and remained reflexive in our interpretations by holding weekly team meetings where we discussed our relational awareness to ensure that "while the data are interpreted through the eyes and cultural standards of the researcher, the effects of the latter are monitored and mitigated" [24].

Data Collection

We investigated digital Canadian news media articles related to older adults, digital literacy, and disaster risk management, shared from May 4, 2023, to July 4, 2024. These dates were selected to reflect the World Health Organization's downgrade of the COVID-19 pandemic [25], allowing us to evaluate postpandemic discourse [25]. The news databases ProQuest, Factiva, and Eureka were systematically searched with the help of a Research Librarian (TR) to uncover relevant articles. The keywords related to digital literacy and disasters were informed by government documents, including the Government of Canada, the United Nations Educational, Scientific, and Cultural Organization, and the Intergovernmental Panel on Climate Change. The search strategies for each database are presented in Multimedia Appendix 1. Furthermore, the Canadian Broadcasting Corporation, the Canadian Television Network, and Radio-Canada were manually searched using the terms "seniors," "elderly," "older," or "aged" in English, and "aîné," "aînée," "aînés," or "aînées" in French.

Included articles met the following criteria: (1) mention of older adults; (2) mention of digital literacy; and (3) written in English or French. At the outset, we established "mention of disasters" as an inclusion criterion. However, due to the scarcity of articles meeting this criterion during the initial data collection phase, we made the decision to remove it. This adjustment is reflected as an important finding in the results section. All articles were imported into Zotero (Corporation for Digital Scholarship) and initially checked by the primary author (A Ménard). The senior author then reviewed 50% of the articles (SF), while the remaining 50% were divided among the other research team members (A Maharaj, SH, and TO), each reviewing one-third of this portion for a second check.

Data Analysis

UTAUT2 was used to organize the data [23], and critical discourse analysis (CDA) was subsequently used for a deeper analysis of the data [26]. The UTAUT2 factors served as a priori constructs through which we organized the data deductively to represent the underlying discursive concept of digital literacy through technology acceptance in older adults [27]. In attempting to organize data according to UTAUT2 factors, we discovered that price value and habit were not discussed in media narratives, which led to their removal from our codebook. We also combined performance expectancy and effort expectancy because of their overlap, whereby articles described behavioral intention as being informed by ease of use, directly impacting perceived usefulness of technology. CDA was used to examine and interpret the construction and perpetuation of discourses [28] concerning digital literacy among older adults, particularly in the context of disaster risk management depicted in Canadian news media. CDA is based on the premise that the use of certain language is intentional, regardless of whether individuals are aware of their discursive choices [29]. Throughout our analysis, using CDA, news media language was understood as constructing social reality, not reflecting it [30]. Through this lens, we sought to understand theories of reality perpetuated in news media and relations of power encoded in the data [31] as they pertain to digital literacy among older adults. Further, CDA allowed us to examine how discourse reflects and perpetuates power structures and inequalities [29].

All authors first familiarized themselves with the data. Following this, the first author (A Ménard) conducted an inductive analysis of the data using open coding [32]. Subsequently, the coauthors (A Maharaj, SH, SF, and TO) independently coded a portion of the included articles. The research team met weekly to ensure consistency in coding, identify emerging patterns, and reach consensus on article inclusion. All codes were then grouped to produce a preliminary codebook, which was refined by the first author (A Ménard). The data were further analyzed by aligning the codes closely with the research question and organizing them deductively according to UTAUT2. Initial coding by all authors was conducted using Microsoft Excel, while the second round of coding by the first author was conducted using NVivo 12 (QSR International).

Ethical Considerations

This study involved a scan of publicly available digital newspaper articles and did not involve human participants, personal data, or an intervention. As such, it did not require ethics approval in accordance with the Tri-Council Policy Statement (TCPS 2) and the policies of the University of Ottawa.

Results

Overview

We identified a total of 103 articles after the removal of duplicate studies. Despite a thorough search, no articles emerged that addressed digital literacy in the context of disaster risk management for older adults. This notable absence of relevant disaster-related narratives necessitated a shift in focus, leading to an analysis centered solely on the portrayal of digital literacy among older adults as depicted in the available news media. Following this pivot, a total of 54 articles (Multimedia Appendix 2) [33-86] met the inclusion criteria and were retained. The included articles underwent re-evaluation by 3 members of the research team (A Ménard, SF, and TO) to further confirm their eligibility for inclusion. Of the included articles, 17 were from Ontario [33-49], 16 from Quebec [50-65], 9 from British Columbia [66-74], 3 from Nova Scotia [75-77], 1 from Alberta [78], 1 from New Brunswick [79], 2 from Manitoba [80,81], and 5 were Canada-wide [82-86]. A total of 30 articles [33-40,42-45,47,48,67-78,80,81] were written in English, while the remaining 24 [41,46,50-65,79,82-86] were written in French.

Here, we present the themes emerging from media discourses, according to a combination of 5 UTAUT2 factors: (1) performance and effort expectancy (combined) (ie, how the media portrays the benefits and ease of use of digital technologies for older adults); (2) social influence (ie, the

XSL•FO
RenderX

media's depiction of the impact of social circles, such as family, friends, and societal norms, on older adults' decisions to adopt and use digital technologies); (3) facilitating conditions (ie, how the media presents the availability of resources and support systems that enable older adults to use digital technologies), and (4) hedonic motivation (ie, how the media portrays the enjoyable aspects of digital technology use and how age-related characteristics impact older adults' motivation to engage with digital tools).

Theme 1: Performance and Effort Expectancy

The media discourse on digital technology and older adults revealed how narratives construct perceptions of performance and effort expectancy related to technology use within this population. The media depicted older adults as a homogeneous group with limited digital literacy, framing them with low performance expectancy and high effort expectancy. This portrayal reinforced a narrative that older adults require substantial assistance from younger generations to learn and navigate digital technologies. The media also emphasized the importance of older adults gaining digital literacy to ensure continuous or lifelong learning, shaping discourse around skill-building and access to digital technology. These narratives framed digital literacy as critical to the inclusion of older adults in society, reflecting a broader societal discourse that highlights both the anticipated benefits (performance expectancy) and perceived effort (effort expectancy) required for older adults to engage with digital technologies. Table 1 illustrates how these themes were represented in media narratives, reflecting the critical discourse on performance and effort expectancy.

XSL•FO
RenderX

Table . Performance and effort expectancy.

UTAUT2[a] factors	Contents	Items
Performance expectancy (PE)	• PE1: "[T]echnology is constantly oriented to younger and younger children, and less user-friendly for elders. Many seniors do not have computers and cell phones, but to navigate the challenges of our "modern" society, one can no longer rely on businesses or government offices having a human being at the end of a phone line, ready and available for help. (…) Seniors wait for hours on a phone call promising "customer help." They show up at 6 AM to get lab tests (with the lab opening at 7 AM), perhaps because they are not comfortable with being, or able to be, in a "text line." (Comox Valley Record, British Columbia) • PE2: "Other types of customers are also affected [by bank closures], those who are less comfortable with technology, such as seniors, who generally prefer face-to-face contact." (Le Droit, Ontario) • PE3: "I'm a senior and do so resent all the generalities that we 65-year-olds are not very adept with the technologies. I frequently adjust my digital watch, use the cellular mobile telephone to send voice calls, drive a fuel-injected horseless carriage, program the remote on my TV, change the taped message on my answering machine, and, hard to believe, back up the family files onto 51/4" floppy disks once per month." (Canadian Broadcasting Corporation, Ontario)	Limited performance and lifelong learning
Effort expectancy (EE)	• EE1: "Cyber Seniors Technology Tutoring is a free, one-on-one tutoring program aimed at seniors who have little or no experience with technology. The program partners each participant with a community volunteer tutor. The two work together on developing basic computer, tablet or cellphone skills targeted to the learner's specific device and goals." (Eagle Valley News, British Columbia) • EE2: "She helped me make notes, and then had me practice, so that she could see that the message got through to me." (The Brandon Sun, Manitoba) • EE3: "[T]hey have limited knowledge of or access to digital banking services." (The Brandon Sun, Manitoba)	Personalized instruction and tailored learning goals

[a]UTAUT2: Unified Theory of Acceptance and Use of Technology 2.

Theme 2: Social Influence

Media narratives surrounding digital literacy for older adults frequently used fearmongering tactics, suggesting a lack of technological skills could lead to social exclusion, difficulties in maintaining connections with grandchildren, and restricted access to essential services like telehealth. These portrayals framed digital literacy as crucial for bridging generational gaps and reinforcing intergenerational relationships, while also emphasizing its growing importance for accessing digital banking and web-based grocery services. Many articles depicted older adults as "vulnerable," portraying them as being left behind by technological advancements. Consequently, these narratives advocated for community centers and libraries to develop programs aimed at enhancing digital literacy, helping older adults remain socially active and integrated members of society. Textbox 1 illustrates the social influence affecting older adults' digital literacy, as depicted in these media narratives, highlighting factors such as societal expectations and community support.

XSL•FO
RenderX

Textbox 1. Social influence (Unified Theory of Acceptance and Use of Technology 2 factor).

Social influence (SI) captures how individuals' behavior is shaped by the perceptions, support, and encouragement of others in their community.

- SI1. "Community centers or libraries are often places seniors would need to visit in order to get their hands on technology. However, teaching a new skill to others costs nothing, according to Garcia. 'If you don't teach people, they will never know how to do it, so I think it is very beneficial for the seniors community to have people guide them on ways to keep them connected." (Richmond News, British Columbia)
- SI2. "It's all about keeping all levels of our community connected." (Saltwire, Nova Scotia)
- SI3. "Telehealth is becoming more accessible, many of the elderly, my grandparents included, lack computer skills to book online appointments." (Vancouver Province, British Columbia)

Themes: community support, staying connected, and intergenerational contact.

Theme 3: Facilitating Conditions

Media portrayals constructed older adults as needing protection from fraud or scams within the digital sphere, reflecting broader discourses of vulnerability and dependence. These portrayals underscore the necessity for digital safety measures, increased awareness of scams, and fraud prevention training specifically targeted toward this demographic. In addition, media narratives depicted older adults as "vulnerable" to loneliness and social isolation due to perceived deficiencies in digital literacy, framing social participation and connectivity as key solutions. The discourse highlighted the importance of facilitating conditions, such as access to technology, technical support, and training programs through local libraries, as crucial resources enabling older adults to engage with digital technologies. By focusing on these supportive measures, media narratives constructed a need for comprehensive systems to enhance digital literacy, reinforcing a view of older adults as needing assistance to navigate the digital landscape effectively. However, this framing of older adults as targets of digital scams may simultaneously discourage technology use and perpetuate negative stereotypes about their technological competencies compared with younger adults. Textbox 2 illustrates the facilitating conditions affecting older adults' digital literacy as depicted in these media narratives.

Textbox 2. Facilitating conditions (Unified Theory of Acceptance and Use of Technology 2 factor).

Facilitating conditions (FC) refer to the resources and support available to help older adults use digital technologies. These include training programs, access to devices, and institutional support to ensure safety and reduce isolation.

- FC1: "The purpose of the workshop was to equip seniors with the knowledge and tools to protect themselves from common scams in an increasingly digital world." (Wiarton Echo, Ontario)
- FC2: "Vancouver police are handing free mobile phones to low-income seniors to ensure they can call 911 in an emergency." (Vancouver Sun, British Columbia)
- FC3: "Learning computer skills helps seniors overcome feelings of isolation and loneliness." (The Chronicle Herald, Nova Scotia)

Themes: safety, scams, and loneliness.

Theme 4: Hedonic Motivation

In this context, hedonic motivation is defined as the enjoyment and pleasure derived from digital technology. Media depictions of older adults using digital technologies often construct a narrative of enjoyment and pleasure, reflecting the concept of active aging and its role in enhancing quality of life. The media highlighted the positive aspects of digital technology, such as its potential to support aging in place and promote independence and self-efficacy through tools like home security systems and voice-activated assistants. However, these portrayals often framed enjoyment not in terms of amusement or leisure, but through the lens of safety, control, and reassurance, reflecting a more utilitarian interpretation of hedonic motivation. These reinterpretations had age-attributed nuances, revealing how media narratives framed older adults' interactions with digital tools based on their specific needs and challenges rather than for amusement or pleasure. For instance, difficulties in navigating digital customer service, accessing government support, and managing telehealth were common barriers depicted. This suggests a shift in how "reward" is represented for older adults in digital contexts, highlighting satisfaction derived from security and autonomy, rather than entertainment as is normally described in younger adults. These representations illustrated how media discourse on hedonic motivation intersected with practical considerations, shaping perceived motivation and engagement of older adults with digital tools. Such framings may also reflect underlying ageist assumptions that older adults engage with technology primarily for functional rather than pleasurable purposes. Textbox 3 illustrates how hedonic motivation influences older adults' digital literacy as depicted in these media narratives.

XSL•FO
RenderX

Textbox 3. Hedonic motivation (Unified Theory of Acceptance and Use of Technology 2 factor).

Hedonic motivation (HM) refers to the enjoyment, satisfaction, or pleasure derived from using technology. For older adults, this motivation is often linked to enhanced quality of life, emotional comfort, and cognitive benefits.

- HM1: "Helping seniors get connected to important services and family members is essential in supporting their full participation in society and improving their quality of life." (Vernon Morning Star, British Columbia)
- HM2: "Just having a system welcome you home by turning the lights on can be a comfort, not to mention a safety precaution." (The Chronicle Herald, Nova Scotia)
- HM3: "By pursuing computer use, social activities, and games in both midlife (age 50 - 65) and late life, benefits were noted, and a reduced risk of mild cognitive impairment was found." (The Canadian Press, Canada-wide)

Themes: satisfaction, safety, and cognition.

Discussion

Principal Findings

Our exploration of media narratives on digital literacy and older adults highlighted several key themes. Performance and effort expectancy were often portrayed negatively, with older adults seen as having limited digital skills and facing significant challenges in learning new technologies, thus necessitating extensive support. Social influence was emphasized through fearmongering, depicting older adults as "vulnerable" to social exclusion and advocating for community-based digital literacy programs to address societal expectations and support. Facilitating conditions were portrayed as crucial, with media focusing on the need for access to digital technology, technical support, and fraud prevention, though this focus on vulnerabilities may inadvertently discourage digital technology adoption by older adults. Finally, hedonic motivation was reflected in media portrayals that emphasized the enjoyment and benefits of digital technology use for enhancing independence and quality of life, while also acknowledging age-attributed challenges. Overall, media narratives both highlighted and complicated the factors influencing older adults' digital literacy, intertwining practical and motivational aspects with underlying digital ageist undertones.

Older adults were predominantly depicted as deficient in digital literacy, reinforcing digital ageism by suggesting they will be left behind unless they adapt to new technologies [9]. These narratives often used fear tactics, emphasizing the potential loss of critical services such as banking, groceries, and health care if older adults do not embrace digital technology. In addition, there was recurring portrayal of older adults as particularly susceptible to scams and fraud, with reliance on younger adults to bridge the digital literacy gap. However, recent research has found no evidence that older adults are more likely than individuals of other ages to be victims of cyber fraud [87]. Research on susceptibility to scams indicates that older adults who are more susceptible typically have lower levels of cognition [88]. However, this finding does not apply to all older adults and may indicate ageist generalizations perpetuated by news media.

Comparison With Previous Work

The media portrayals described above not only reinforce stereotypes about older adults' digital competence but also highlight a critical issue: their exclusion from essential areas such as disaster risk preparedness [89]. The exclusion of older adults in the context of digital literacy and disaster risk leads to their systematic marginalization in disaster preparedness efforts [14]. In disaster scenarios, digital technology is crucial for supporting communication between individuals, their families, and health authorities; social media is often used to disseminate health information to the masses; and telehealth serves as the primary conduit for health care during public health emergencies and subsequent lockdowns [14]. As society increasingly relies on digital tools for disseminating crucial information and coordinating emergency responses, individuals with limited digital proficiency face heightened vulnerability [90]. This exclusion exacerbates their risk during disasters, underscoring the urgent need for inclusive strategies to enhance digital literacy and ensure equitable access to disaster preparedness resources [90]. As such, it is important to consider how the narrative of older adults lacking digital literacy and thus being "vulnerable" in disasters perpetuates digital ageism and deters them from meaningfully using digital technology [91].

Performance expectancy positively predicts behavioral intention, suggesting that individuals who perceive significant benefits from digital literacy are more likely to intend to use digital technology [92]. Similarly, effort expectancy is also a positive predictor, indicating that individuals who find digital technology easy to use are more likely to intend to adopt it, thereby enhancing their digital literacy [92]. That said, it is important to distinguish between ageist stereotypes and legitimate barriers that may affect older adults' engagement with digital technology. While media portrayals often attribute digital disengagement solely to age-related decline or resistance to change, they frequently overlook key structural and design-related challenges [93]. For example, small screen sizes, complex interfaces, limited accessibility features, sensory or cognitive impairments, and the cost of digital devices or internet access can all contribute to lower digital engagement among older adults [94]. These barriers are not inherent to aging but rather reflect gaps in inclusive design, digital equity, and the need to address concerns related to privacy and safety [95]. Recognizing these factors helps reframe the issue from individual "inability" to systemic inaccessibility. Moreover, some media narratives have begun to highlight initiatives that promote inclusive digital literacy, such as community-based training programs, intergenerational tech mentoring, and age-friendly design innovations, which represent important counter-narratives to digital ageism [96,97].

XSL•FO
RenderX

However, media portrayals of older adults as lonely and socially isolated, combined with depictions of their difficulties with digital technology, can negatively impact these predictors [98]. When media frames digital technology as a crucial tool for alleviating loneliness and overcoming isolation, it highlights the perceived benefits (performance expectancy) but simultaneously underscores the challenges (effort expectancy). This dual portrayal may diminish behavioral intention by emphasizing both the urgency and complexity of adopting digital technology, potentially discouraging older adults from engaging with digital technology [99]. Social influence positively predicts behavioral intention, meaning that individuals who perceive support from important people in their social networks are more likely to intend to use digital technology [100]. Conversely, those who do not feel such support are less likely to intend to adopt digital technology [100].

Media representations of older adults as "vulnerable" to social exclusion and reliant on community centers and libraries for digital literacy workshops highlight the role of social support in digital technology adoption [101]. Facilitating conditions positively predict behavioral intention, suggesting individuals who believe in the availability of resources to aid their digital technology use are more likely to intend to use it [92]. In contrast, those who perceive a lack of such resources are less inclined to adopt digital technology [92]. Media portrayals that depict older adults as "vulnerable" to scams and frauds exacerbate concerns about internet safety and complicate their digital technology use, reinforcing the need for supportive conditions [102].

Hedonic motivation, or the enjoyment derived from using digital technology, is another positive predictor of behavioral intention [92]. Individuals who find technology enjoyable are more likely to intend to use it [92]. Our findings further align with existing literature, which suggests social perceptions of older age act as a barrier to digital technology use among this population, reinforcing stereotypes about older adults and their use of technology [91,103,104]. Notably, literature suggests that ageism influences the use and acceptance of digital technology through the inferiorization, patronage, deprioritization, and exclusion of older adults in the digital age [7,9,105,106]. Our findings contribute to the literature by highlighting how the media perpetuates digital ageism and may discourage older adults from meaningfully engaging with digital technology. Information disseminated through news media has been recognized as a potential source of negative beliefs and biased behaviors toward older adults [107]. This underscores how news media are uniquely positioned to transform narratives surrounding older adults and digital literacy. Rather than reinforcing ageist stereotypes, media outlets can foster inclusion of older adults in the digital age, promote positive representations, and support their engagement with technology, which can enhance their quality of life and participation in society.

The findings from this study also highlight how older adults are forgotten within narratives around disaster risk preparedness using digital literacy. This exclusion reflects a broader pattern of ignoring the needs of older adults in critical areas such as disaster preparedness, further perpetuating ageism and limiting their access to essential information resources. Future research should explore strategies to better integrate older adults into disaster risk management narratives and assess the impact of inclusive digital literacy initiatives on their preparedness and resilience.

Limitations

This paper offers valuable insights into how Canadian news media portrayals of older adults and digital literacy reinforce digital ageism and marginalization of older adults in disaster risk preparedness. While our analysis highlights how certain media portrayals of older adults in digital contexts may reinforce ageist narratives, we acknowledge the risk of overinterpreting all negative depictions as inherently ageist. Some representations, such as those addressing digital scams or usability challenges, may reflect legitimate concerns rather than discriminatory assumptions. As ageism researchers, we approached the data critically but remained mindful of this interpretive tension, which we recognize as a limitation and a reflection of our analytical lens. This study benefits from a robust methodological approach, including a systematic search of multiple databases and detailed CDA using UTAUT2 [23,26]. The use of diverse media sources and languages adds depth to the findings [108]. However, limitations include the decision to constrain the focus of the study on Canadian media, which may not capture global perspectives on digital literacy for older adults in disaster risk preparedness. Future research could address these limitations by expanding the scope to include international media and by developing strategies to integrate digital literacy in older adults into disaster preparedness narratives more effectively. Furthermore, we did not include social media in our search and focused strictly on newspapers and broadcast news websites (eg, Canadian Broadcasting Corporation). Yet, we recognize that social media (eg, Instagram and Facebook) has become a key medium for news sharing [109], and has changed the production flow and delivery of news for many broadcasting corporations [110]. Future research should investigate perceptions of digital literacy in older adults as discussed on social media and explore user sentiment in the comments under posts from key news organizations.

Conclusion

While this study was initially designed to examine media narratives at the intersection of digital literacy and disaster resilience among older adults, the limited presence of such discussions in news media led to a necessary broadening of scope. This absence, however, is a significant finding in itself, highlighting the exclusion of older adults from critical public discourse on digital preparedness during crises. This paper underscores the critical impact of media narratives on the digital literacy of older adults, revealing how these portrayals perpetuate digital ageism and contribute to the marginalization of older adults in essential areas such as disaster risk preparedness. By highlighting the negative portrayal of older adults' digital competencies and their exclusion from disaster preparedness discussions, the study demonstrates the need for a shift in media representation. The findings suggest media outlets can fulfill a pivotal role in transforming the narrative, promoting more inclusive and supportive portrayals of older

XSL•FO
RenderX

adults' engagement with digital technology. Future research should seek to broaden the scope to include international perspectives and explore strategies for more effective integration of older adults into digital literacy and disaster preparedness narratives.

Acknowledgments

This work was supported by a grant from the Social Sciences and Humanities Research Council of Canada (435-2022-0718 to TO). The funders had no role in the study's design; collection, analyses, or interpretation of data; writing of the manuscript; or decision to publish the results. The authors thank Téa Rokolj, a research librarian (University of Ottawa), for devising the search strategies for newspaper databases and advising on searching the websites of the Canadian Broadcasting Corporation (CBC), Canadian Television Network (CTV), and Radio-Canada.

Abstract

Background: Older adults are the least active in our society and may face additional barriers to taking part in physical activity compared with those experienced by younger people because of factors such as lower digital literacy and negative stereotypes of aging.

Objective: This study aimed to explore how older adults navigate websites that provide access to physical activity opportunities and facilities and make judgments about their suitability.

Methods: Semistructured interviews were embedded within a think-aloud approach. Participants were shown a series of websites and asked to navigate through the websites as if they were going to take up what was on offer, articulating their thoughts and comments out loud as they progressed. Participants viewed up to 4 websites, rotated from a pool of 8, including leisure centers, exercise products, gyms, or community organizations. Additional questions were asked about perceptions of the inclusivity of the websites at the end of the interview. Digital recordings were made and transcribed verbatim, and analyzed using thematic analysis.

Results: Nineteen participants (6 male and 13 female) aged between 65 and 84 years were recruited from southern England; one-third reported having poor digital ability prior to taking part. Three overarching themes relating to the research question were identified as follows: (1) signals of age-inclusivity, (2) limiting beliefs, and (3) confidence in making judgments. Older adults inferred a lot of information about how welcome they would be in physical activity settings from the images and language used on websites. They showed a preference for imagery that was inclusive of age, body shape, and physical ability, not only for those depicting older adults themselves. Some adults reported firm views about the type and intensity of physical activity that is appropriate for older adults, and many expressed a specific dislike of gyms, based on both the (young) age of most users and perceived emphasis towards aesthetic rather than health-related exercise. While most participants could navigate websites successfully, they preferred to visit venues and speak to staff to gain greater confidence that they would feel welcome and that the activities would be at a suitable level.

Conclusions: Websites providing access to physical activity could be more inclusive of older adults by using more diverse imagery, providing clearer descriptions of the activities on offer, along with details of the level of fitness or ability needed to take part, and providing alternatives to web-based booking. Additional societal-level approaches to reducing age-limiting self-stereotyping may also be useful in expanding the opportunities for older adults to access mainstream provisions for physical activity.

Introduction

Older adults are the least active in our society [1], yet they could derive significant benefits from physical activity in terms of preventing and managing chronic disease, promoting strength and function [2], and reducing morbidity [3]. The UK government recommends 150 minutes of moderate-intensity activity per week for older adults, as well as breaking up sedentary periods and including exercise that improves muscle strength, balance, and flexibility [4,5]. Data for 2022 to 2023 from Sport England estimate that around 53% of people older than 65 years achieve this, with 36% achieving less than 30 minutes of activity per week [6]. Activity in later life reduces the risk of disability, the development of noncommunicable diseases, and the decline in functional capacity associated with aging [7]. There may also be benefits to cognitive health [8].

Older adults experience many of the same barriers reported by younger adults to physical activity, including time, cost, and enjoyment, and lack of confidence or fitness [9,10]. Additional barriers that are more commonly seen in older adulthood relate to physical function, such as ill health or disability, safety concerns, and fear of falling [10]. However, there are also indirect barriers that may influence engagement with facilities and activities in older age, including poorer digital literacy, digital exclusion [11], and negative stereotypes around aging [12]. Considering digital literacy, while many older adults do own smartphones or other digital devices, digital acceptability and access decline with age [13]. The physical activity industry mirrors the rest of society in having become more digitized, for example, through moving to web-based bookings, payments, and advertising, and the development of increasingly technical exercise equipment. These changes have an unintended negative impact on access for older adults.

Older adults face several age stereotypes relevant to the physical activity domain, often being portrayed as frail, easily fatigued, and physically inactive [14]. Some of this stereotyping can be observed in how older adults are treated by others, for example, fitness professionals commonly have (and communicate to greater or lesser degrees) low expectations of older adults' capabilities, which in turn discourages older adults from taking part [15]. Providing positive examples of the capabilities of older adults that present a very high level of ability (ie, exceptional fitness) can also be problematic to some older adults who feel they may not be able to match up to expectations, putting them off taking part [16]. Age stereotypes for physical activity are not only held by younger adults, older adults themselves often share these negative perceptions, for example, feeling that their aging body means they are less able to exercise, and that people their age are out of place in physical activity settings, such as gyms and health clubs [17].

The theory of stereotype embodiment sets out one way in which self-stereotyping may develop, proposing that people internalize negative stereotypes throughout their lives, developing negative attitudes toward older adults, which are directed toward themselves as they age [18]. This leads to unconscious effects on behavior, particularly in settings where age stereotypes are primed (eg, depictions of older adults with limited ability), impacting health behaviors [19]. Little research from this perspective has been undertaken specifically in relation to physical activity, and research exploring the impact of age stereotyping on physical activity from other theoretical perspectives has resulted in some conflicting results. For example, in response to age-based stereotype threats (ie, pressure to avoid confirming or exacerbating stereotypes when taking part in an activity; [20]), some studies show poorer performance in physical activities, such as walking speed [21], while others show improved performance, for example in fitness training [22]. Thus, research to provide greater insight into older adults' responses to how they are portrayed during their first approach to physical activity settings is warranted and could help us to understand the variation in effects.

The aim of this study was to explore how websites providing information about physical activity opportunities may influence the barriers or facilitators of physical activity for older adults. Using a "think aloud" approach, our objectives were to (1) explore the social signals older adults identified of inclusivity, fit, or welcome, and (2) capture their views about the digital capability required to find relevant information. Together, this would provide information on how older adults experience web-based gateways to access physical activity opportunities and what information they draw on in assessing whether the activity on offer was suitable for them.

Methods

Ethical Considerations

Ethics approval was granted by the Research Ethics Committee for Health at the University of Bath (EP 20/21 105). All participants provided informed written consent, and any identifying information was anonymized prior to data analysis. Interviews were conducted between January 2022 and August 2023.

Design

This study was situated within a constructivist research paradigm, selecting a "think aloud" approach in order to explore and understand people's subjective experiences and focus on meaning-making in real time [23]. The think aloud approach has shown previous utility in exploring human-computer interactions and decision-making [24] and the usability of websites in health settings [25].

The approach encourages participants to verbalize their thoughts or feelings while navigating web-based resources. In our study, this was embedded within semistructured interviews to ensure interviewees had been asked comparable questions when interpreting the findings, and to allow participants to express their thoughts and experiences at a more general level [26]. The interviews were all conducted in person by slim, White, young women (aged 18 - 23 years); we include this detail as it was commented on by some participants, so it may have influenced some of their responses.

Participants

For this study, we considered adults to be aged 65 years or older, in line with the UK Office for National Statistics [27]. The

XSL•FO
RenderX

inclusion criteria were individuals aged 65 years and older, who can read and speak fluent English, self-assessed as physically able to, and interested in taking part in physical activity. Participants were recruited through advertisements posted in local community centers, on local social media platforms (such as "Nextdoor"), and through the authors' existing networks. We aimed to recruit 20 older adults to provide a range of experiences, focusing on advertising in lower socioeconomic areas. Participants received travel expenses and refreshments but no payment for their time.

Procedure

Volunteers were sent a participant information sheet and consent form and invited to set up a time for their interview; these arrangements were typically made via email, but could be by phone or letter if preferred. Interviews were conducted in public spaces of the participants' choice (to ensure they would feel comfortable) using a laptop provided by the researcher. Participants were asked to nominate a café local to them or could choose to come to the University. At the start of the interview, the researcher talked through the process and obtained written consent. The researcher then presented between 1 and 4 example websites in turn, working through the think aloud process with each until the participant wished to stop or the 1 hour had passed; participants were offered the choice whether to continue at the end of each website viewing. The order in which websites were presented was rotated to ensure that the findings related to a variety of website designs and topics.

Participants were encouraged to provide an honest opinion on the websites, add any thoughts which came to mind [28], and were prompted to reflect on what they were doing as they browsed (eg, "why did you click on that?"; Multimedia Appendix 1 contains the full topic guide). In line with a relaxed think aloud approach, the interviewer only interacted with the participant when asking prompts or in response to a participant's request for help with navigating the websites [28]. At the end of browsing websites, participants were asked to evaluate the content overall. One example of the questions asked for this was "were there any aspects of the websites that made you feel included or excluded?".

The pool of example websites was chosen to reflect different aspects of the physical activity industry following public engagement activity with 7 older adults as part of a related study (ie, what they consider as part of the industry), and discussion with an advisor from a national representative body. Our aims were to include both commercial and noncommercial services, sites that advertise equipment as well as facilities, and ensure we featured a range of activities that are accessible to someone starting out (eg, activities that do not require extensive technical skills, and can be started at low intensity). The research team reviewed the final set to ensure we included variations in website designs (Multimedia Appendix 1 lists the specific websites chosen). Two examples were available from each of the following 5 categories: local authority providers of physical activity services; fitness industry providers (eg, generalist gyms that focused on building strength and endurance); fitness industry product providers (eg, personal fitness equipment and clothing); community organizations that encourage physical activity (eg, walking groups); and UK physical activity campaigns. The order in which the websites were presented was rotated.

After the interview, participants provided information on their demographics, usual physical activity level, and self-rated health.

Data Analysis

Interviews were audio-recorded using a digital voice recorder, transcribed verbatim by VC, and anonymized. Analysis was conducted using a 6-step thematic analysis [29], including familiarization, generating initial codes (including a code book), organizing codes into clusters of shared meaning (themes and subthemes), and refining and naming the themes with the wider research team. Two transcripts were coded by VC and FG to refine the codebook, and the remainder were then coded by VC and the themes were developed iteratively.

Website tracking software was used to generate a recording of participants' progress in order to verify which specific pages participants were looking at as they spoke. This information has been added in square brackets within quotes where appropriate.

Results

Sample

Participants (6 male and 13 female) were aged between 65 and 84 years and based in Southern England. Fourteen (74%) participants had postschool qualifications, and the majority of the participants considered themselves to be healthy (95% scored >7 on a 10-point scale), with moderate fitness (most reported a steady or brisk walking pace) (Table 1).

Around a third of participants considered that they had poor digital ability, but the majority were able to navigate the websites without difficulty, and the challenges experienced most came from using unfamiliar hardware (ie, using the researcher's laptop, rather than a usual PC at home) rather than difficulty using common website functions (scrolling down, search function, clicking through different pages). At the extremes, 2 participants were not confident in navigating websites unaided, so they asked the researcher to do this for them (P11 and P18), while one participant was a website designer prior to retiring (P4).

Three overarching themes relating to the research question were identified as follows: (1) signals of age-inclusivity, reflecting what participants read into the images and language used on websites; (2) limiting beliefs, reflecting how participants related beliefs about their own physical capability, and age stereotypes to website content; and (3) trust, reflecting older adults' reservations about what could be understood from web-based information alone.

Table . Participant characteristics.

	Age group (years)	Gender	Ethnic group	Highest educational attainment	Usual walking pace	Health rating[a]
1	65 - 69	Man	White	Bachelor degree	Steady	8
2	80 - 84	Woman	White	Bachelor degree	Brisk	7
3	75 - 79	Woman	White	Master or postgraduate qualification	Brisk	7
4	65 - 69	Woman	Black or African	GCSE/O level[b]	Slow	3
5	75 - 79	Woman	White	Master or postgraduate qualification	Steady	8
6	70 - 74	Man	White	GCSE/O level	Brisk	8
7	65 - 69	Man	White	Bachelor degree	Steady	7
8	70 - 74	Man	White	Master or postgraduate qualification	Steady	8
9	75 - 79	Man	White	Master or postgraduate qualification	Steady	7
10	65 - 69	Woman	White	Master or postgraduate qualification	Steady	7
11	65 - 69	Woman	White	Bachelor degree	Brisk	8
12	65 - 69	Woman	White	Bachelor degree	Steady	9
13	75 - 79	Woman	White	Master or postgraduate qualification	Slow	10
14	65 - 69	Woman	White	Master or postgraduate qualification	Steady	9
15	65 - 69	Woman	White	No formal qualifications	Slow	8
16	65 - 69	Woman	White	Master or postgraduate qualification	Brisk	8
17	80 - 84	Woman	White	A Level or equivalent	Steady	7
18	75 - 79	Woman	Asian or Asian British	No formal qualifications	Brisk	7
19	65 - 69	Man	Black or African	Master or postgraduate qualification	Slow	8

[a]Self-rated on a scale of 1 - 10 where 1 is very bad health and 10 is excellent health.

[b]GCSE/O level: General Certificate of Secondary Education Ordinary Level.

Theme 1: Signals of Age-Inclusivity

Images

Participants drew on images, language, and the type of physical activity or service offered in judging whether websites were relevant to them. Images were often the first source of information that participants considered ("I noticed almost immediately there was a mix you know, that in photos there were older people" [P9]) and were often taken very literally as an indication of who uses a particular facility. Participants extrapolated from who was depicted as to whether they would be welcome as a participant:

> *This is the gym… oh… group exercise... oh let's see if there's any for old people. [inspects the photograph]. There's a young lady… that's not for me! Absolutely not for me. If they had a photograph of a group with a couple of older people involved in the same group yep, I don't mind being with young people at all, except I wouldn't like to be the only one.* [P2]

> *It's modelled by people, young people without wobbly bits.* [P15]

While seeing older adults depicted was interpreted as a clear indicator that a website was offering something intended for them, most participants used a broader benchmark and judged websites as age-inclusive when they saw images of people of different ages, genders, races, and abilities, as well as people with disabilities. For example, on articulating why certain websites looked age-inclusive, participants stated:

> *[Because] they're all normal people, as in, of an age that I can relate to. So it's not, it's not big punchy*

XSL•FO
RenderX

> *"do this to build your muscle" type thing it's all about… it's all about keeping active and keeping healthy through, through activity, which is good.* [P6]

> *That one is, I think that's very, the seems quite welcoming that, I'd have a look at it, I would if I saw that picture... Because it's a family there, and there's a child there, it is not as though someone's just exercising and looks really fit (laughs). I mean, I'm not saying they don't look fit but I mean it's not a real over-fit.* [P17]

In addition to images, participants responded positively to clear statements that all ages are welcome:

> *Um… they [community rowing club] particularly stress the headline [ages] 13 to 100 so, it definitely was not focused just on the… you know the normally you associate the, I suppose I associate rowing with the boat race, young fit men or women from um from the Universities etc. That's my first reaction so um this seemed quite inclusive in that sense, quite friendly, seems quite informative.* [P9]

Similarly, images of people of all body sizes were considered positive and inclusive, regardless of their age. As such, body size appeared to serve as a proxy for participants believing an activity would be achievable for them:

> *But I mean, but you see that's still good to get people going isn't it because they're all shapes and sizes [in the image] and I'd rather do classes with people like that then just really old people so that's quite nice* [P17]

> *They are… women and they are older women, kind of thing that they are not… slim ones so they really appeal to the likes of me that it can be me, joining them, you see.* [P7]

While wanting to see older adults depicted, participants could be very particular in how old, or how active the older adults were. Some interviewees distanced themselves from websites where older adults were depicted as being too old or inactive:

> *They are very old people and they don't appeal to me at all. I couldn't interact with anybody like that. I mean, okay, they might get satisfaction out of it but nah. It's not me, it's just not me.* [P15]

Very few older adults expressed an interest in exercise sessions that are solely available to older adults, preferring to see indicators of inclusivity to the whole community, with older and larger people depicted as part of this. This may reflect (as suggested by the quote from P15) the degree to which participants have actively embraced an older identity.

Language

In some cases, the language used on websites signaled to participants that these services or facilities were not for them. This was particularly evident in websites relating to gyms and exercise classes, which included new "branded" terms such as classes called "SHRED," "Trax," and "Rush". Participants viewed this terminology as an immediate turn-off, and an indicator that such activities were not for them:

> *It's delving into a sort of more modern language that I don't necessarily understand, but that's probably more my problem than anybody else's!* [P6]

> *Oh… what are glute exercises? Oh… glute, did you know about glute muscles? I didn't.* [P13]

> *Shred (laughing)… see I, well I'm just looking I'm thinking right, so I immediately focused in on classes and I'm not going to go and do a class that says shred because um I just know that that is just, you know, I wouldn't do it.* [P12]

Some participants were explicit in describing the lack of explanation of such classes as discriminatory:

> *I don't think for my particular age group that they are informative enough and I find that they are a bit discriminative and they're… ageist. That's it.* [P15]

Theme 2: Limiting Beliefs

Perceived Physical Capability

Most participants recognized and described a deterioration in their physical ability as they had aged and expressed a desire to avoid injuries by attempting to do too much. While some participants had long-term conditions such as arthritis that limited their activity, for many, this reflected a fear of injury based on the perceived limitations of age alone. This caution influenced their responses to websites based on the type of exercise on offer:

> *With the equipment, I'd end up… tearing something or ending up injuring something of my body. So, I've come to the conclusion that you know, probably it's best not to be going into gyms.* [P4]

This concern was also reflected in participants' desire for more information about the intensity of activities than was provided on most websites. This is often related to expected levels of fitness and capability to start engaging in the exercise on offer, reflecting the fact that although they might have been experienced in some activities (ie, not a beginner), they knew they were much less fit than when they last took part. For example, 2 participants commented on the website of a local walking group that was marketed towards older adults, and depicted older adults in their imagery:

> *It would be helpful if there was a bit more information, to give you… the severity of the walk, is it rough terrain or not. Because obviously as you get older, the flatter the walk the more… probability that you'll actually go onto it…* [P6]

> *Older people do tend to walk a little bit slower so you want to know is this going to take me a couple of hours, or is this going to take all day?* [P6]

> *My concern would be walking out for the first time … I'd be worried about lagging behind and upsetting people who are experienced walkers. If they had a 'break me in walk' and then oh you are broken in a bit now so you can do the next one, and the next one.* [P15]

Similar concerns were offered about fitness classes:

XSL•FO
RenderX

> *It [the website] didn't exclude me, it's just I, my body and everything else that comes with it, makes me feel… a bit worried to try to go and lift weights or do some strenuous thing that I know my body can't take… Do I need to be a certain fitness level before? That's something I need to know.* [P4]

Others expressed concerns about potentially embarrassing themselves in mixed settings or pushing themselves too far. For example, on looking at a strength training class video, one participant commented:

> *If you're not fit I don't think you would ever look [to go] there because you would feel such a fool. You would, you would think I'm a wimp, I couldn't cope with that, so I wouldn't go.* [P17]

Some older adults also expressed concern that younger instructors or trainers would not be able to adapt to what was needed for older adults, and thus that what was demanded of them would be too great. These participants tended to use the age of instructors depicted on websites as a signal of whether a service or facility was appropriate for them:

> *I don't know whether I've just got more respect in general for older people because they've got more experience, maybe that, I just don't quite believe that someone – sorry about this [referring to the young age of the interviewer] – does a three-year course in whatever, fitness, can necessarily have all the information they need to help older people.* [P11]

> *[I'd need] way more support, but who's going to be supporting me, I mean, some squeaky chicky ain't going to come over and say 'Alright, old love let's sort you out!'* [P15]

Preference for older instructors was not a universally held view, and those who had more experience exercising in mixed-age groups provided examples of younger instructors who adapted classes well. They also flagged the need to differentiate people by ability rather than age:

> *My Pilates class is basically for over 50's but they want to stop it too because they say people don't like being defined by their age… so it's like how do you find another way of saying over 55 without patronising somebody?... But at the same time sometimes you don't know what you're looking for. There's some people who are over 65 and they don't need to look at an over 65 sort of over 50s class because they're really fit and they can still do stuff in an ordinary class.* [P12]

Stereotyping

While participants were generally pragmatic and objective in acknowledging age-related changes in physical capability, there was also some evidence of stereotypical thinking. Some of this appeared to relate to self-stereotyping of what types of physical activity older adults should be doing. The example below relates to a comment made while reading through a list of exercise classes at a municipal leisure center.

> *... I'd go for body balance but yoga, no, spin, sounds too fast, those aren't right for old people… If its high intensity, we [older adults] shouldn't be doing things high intensity.* [P2]

However, many of the interview excerpts coded into this theme related to gyms. It was often hard to disentangle participants' pre-existing attitudes towards gyms as a type of business (and their experience of them being predominantly used by young people), from the specific aspects of the website presented ("I'm actually a little bit against gyms anyway, because, it's a modern thing" [P7]). These views typically reflected participants' attitudes towards gyms rather than what was presented on a website, as well as their experience of gyms.

> *I didn't like going in the actual gym bit because it was all people a lot younger than me and they were all trying to outdo each other.* [P15]

> *I see these [gyms] and I only tend to see young people. You know, cool looking sort of young people going into (particular gym), and that doesn't, that doesn't do anything - this website - to disabuse me of that viewpoint. It comes across as a younger, commercial first [place].* [P9]

> *I mean I wouldn't go anywhere near that place [gym]. You know I, not being rude, but I mean cause to me that is just full of… people who are like nearly old enough to be my grandchild so I'm like just wouldn't (laughing), so I wouldn't go in there no.* [P12]

In some cases, the stereotypical thinking reflected assumptions that gyms are a place people go to do image—rather than health—enhancing activity. Often, the negative statements about young people are conflated with assumptions about why people use gyms, given the greater prevalence of young people using them.

> *It's all a bit showy-off-y to me [going to the gym], rather than, I suspect… intended just to get you fit and keep you fit. It's a bit, it's all a bit show-y.* [P7]

> *When I have been into the odd hotel gym there's generally some very, very narcissistic p- you know people there looking at themselves more in the mirror than they are [exercising], you know what I mean, it er, to a younger person you know a, beautiful blonde there or really fit young bloke you know, you know doing whatever I'm thinking, yep, you don't need that.* [P9]

Some participants were less critical of the reasons why people attend gyms, but in believing gyms are for building muscle, and that building muscle is something that only younger people do, they assumed that gyms were not for them. This was reinforced by images of young fit adults lifting weights:

> *When you get over 65, you're more interested probably in er… you're not going to build muscle, you're not going to, you know, attain any major goals. You want to, keep mobile keep flexible, and if there were more things to build upon flexibility, um… that would be more appealing to people of an older age*

XSL•FO
RenderX

group, yes… There doesn't seem to be any of that on this website. [P6]

They [images] all look quite frightening to me, because they all look so much younger and fitter! … I mean look at the, these guys are all pretty stacked, so. I'll never look like that. Not that I ever did! [P6]

Theme 3: Confidence in Making Judgments

Participants preferred websites where information was presented clearly on the first page, where the font was simple, without too many distractions from moving images. The majority considered information about the proximity of facilities ("See, straight away I think what I want to do is find out, where's the nearest one for me?" [P6]), costs, and links to a person they could contact to be of primary importance. They wanted to be able to see this information without needing to click through multiple screens.

I want to know what the membership is and it's giving me "hear from our members." I want to know where it is, how much it is, swimming pay as you go [P15]

So this is, they're not going to give me any information about courses until… until I open the portal and I'm not interested in that. [P5]

Even among those comfortable with using websites and digital tools, many participants expressed a preference to establish some personal contact before committing; they looked for a phone number of someone to talk to, or stated that they would not book via web, but would use the site to gather information and then visit the venue to book. For some, the need to verify information in person reflected a lack of trust in what is presented via web, rather than poor digital literacy.

It's all a marketing ploy, not really giving me the information that I really want. [P15]

I… can't tell, what they would be like from the website… but it's all part of an advertise-advertising their product um so, so yo-you… that's how I would expect it to be I'd expect it to be advertising a product I wouldn't expect to see any truth there [P7]

This hesitancy may also reflect participants' interest in factors that cannot be ascertained from a website, like the atmosphere of the venue or how they are treated by staff.

If I was going to join the gym, I'd go down there and physically look at it. So, um, but only based on having… drawn up a-a-a-a list of 3 say [from their websites]… and that's what I would do and then go and look at them, and see what I thought and judge it on, on um… the people that are um… are um running it so forth, do you get a welcome er a good welcome there, do they seem to know what they're talking about. [P7]

Hesitancy about using websites to make decisions on the appropriateness of physical activity opportunities appeared to differ from general comfort with digital devices or web-based shopping. For example, P7, who would not trust the "truth" of a leisure center website, was comfortable with buying sports equipment via web ("I buy my sports stuff online, or off mates"). Others reported being able to use a device, but not being comfortable with website bookings as a specific function:

Well I'm not very good at websites to be honest, and actually although I'm on it on my iPad with the gym, my son has to book me online all the time. I can't do it, it's sad init? [P18]

Discussion

Principal Findings

This study explored older adults' reactions and views of the age-inclusivity of websites providing access to physical activity opportunities. Together, the themes showed how older adults drew on the imagery and language of websites to inform their decisions, as well as some existing schemas of what types and intensities of activity are appropriate for older adults (ie, implicit ageism). Participants were encouraged by websites depicting people of mixed ages, body shapes, and abilities using their service, and were not looking for services offered purely for older adults. Many older adults judged whether an opportunity was appropriate for them from factors that signaled the intensity and challenge of the physical activity on offer, motivated by a wish to avoid injury or embarrassment, and felt the ability to keep up with others. Information on the level of ability of fitness required to take part was rarely presented directly, which may have caused participants to rely on images and language to make these inferences. Participants showed a greater preference for and trust in websites that provided clear and up-front information on basic considerations such as cost, location, and contact details. Nonetheless, they reported still being reluctant to believe an opportunity was for them without having visited a venue and spoken to staff.

The think aloud approach has been used in previous research to explore how people use and make sense of websites, and what they base their judgments on [28]. For example, users have been shown to use short case examples to understand the relevance of the site by drawing constant comparisons between the examples presented, their own experience [28]. While in this study few websites that we used included case studies (although these were popular where they did), we did observe a similar effect in how participants were extrapolating information from the individuals shown in the images based on their experience and existing attitudes; for example, some participants inferred knowledge about a "typical user's" motivation and fitness level just from a photo. This process was most closely observed in older adults' responses to images of young people, using this information to form judgments that a facility or service was not for them. In part, this reflected participants' explicit narratives of how their capability and motives for physical activity had changed over time, such that they judged what is suitable for young adults would not be suitable for them. While some settings (eg, gyms [30] and surfing [15]) are already considered a young adults' domain by default, our study showed that in other settings too, seeing images predominantly of young adults was used as a heuristic for assessing an activity as irrelevant or inappropriate. This response was diminished when images included mixed age groups, ethnicities, and body shapes alongside young adults.

XSL•FO
RenderX

Past work has described how older adults who take part in physical activity need to navigate the tension between experiencing the benefits of physical activity, noticing their own physical decline, and dealing with social norms about what type of physical activity is acceptable in older age [30]. This tension appeared to be visible in our study, acting as a lens through which participants were evaluating whether the activities that the website was promoting were relevant and welcoming to them. In line with other work [10], we found that older adults' beliefs about their capabilities were a common barrier to physical activity, and evidence of an apparent acceptance of the inevitability of physical decline [17]. Current health messaging, as well as marketing of physical activity facilities and opportunities, may assume that older adults are interested because they believe that there is scope for improvement, so exposing this alternative perspective—that older adults largely do not feel that improvement in strength and fitness is feasible—could be important to inform future approaches.

While participants in this study showed a good ability to navigate websites and good digital literacy, they still exhibited some lack of confidence in applying this. Two participants either asked for help from the Researcher in navigating the websites or reported that they normally ask a younger family member to make web-based bookings or purchases for them. This aligns with previous research demonstrating that even among those with high levels of competency in using websites, older adults may have lower perceptions of their usefulness [31] and acceptability [11]. In this study, this lower perceived usefulness may relate to the fact that information older adults consider crucial was not provided; websites rarely provided explicit statements about welcoming all ages, contact details, clarity about the level of starting fitness required, or information on how demands can be tailored. However, alternatives to web-based booking, whether by phone or in person, will likely remain an important part of providing an age-inclusive offer, to allow older adults to test out the atmosphere of a venue and sample interactions with staff.

Strengths and Limitations

The use of think aloud interviews worked well in this setting by encouraging participants to verbalize their thoughts and experiences while interacting with websites in "real time." It is argued that this often results in more honest accounts of user experience [32]. A limitation of this approach was that participants were navigating websites that they had not chosen for themselves, on a device that was not familiar to them. Participants may have been less distracted by the mechanics of navigating a website if using a familiar device. Our findings may also have been influenced by the specific websites we chose. While we attempted to mitigate this by identifying a range of different websites and rotating these through interviews, providing choice to participants (eg, allowing them to nominate the types of physical activity there were interested in) may have helped to provide a greater test of participants' views on the inclusivity of the website, rather than the type of activity it offered. In particular, it was hard to disentangle participants' comments on the desirability of gyms and the imagery that accompanied them, reported in theme 2, from their preexisting attitudes.

We attempted to recruit a diverse sample by advertising in areas populated by people of lower income and with greater ethnic diversity, and by seeking support from gatekeepers (eg, local Black and minority ethnic support groups for older adults). However, the majority of those willing to take part were White, highly educated, and living in urban areas, which is a limitation of this study. Other studies conducted with older adults report greater challenges with website navigation [25], which we may have found if we had recruited a sample with a more diverse socioeconomic background. Our participants were also relatively healthy; this is less a limitation and more a reflection of our design, as in order to address our research question, we recruited individuals for whom the websites were relevant, that is, those who are capable of engaging in physical activity. However, we may have discovered different barriers had we included more people with limited physical ability. Related to this, the age of our participants spanned around 2 decades from 65 to 84 years, from those still working to those who have been retired for 20 years. People at either end of this age group, as well as those experiencing greater or lesser physical decline or limitations, may have had different perspectives on who the websites depicted and what was offered. Within this small qualitative study, we were not able to tease out these differences.

Implications and Future Directions

The findings of this study suggest that older adults are more likely to consider that services and facilities are relevant and attractive to them when websites depict a diverse set of users, including an explicit statement indicating people of all ages are welcome, and present clear information to users to judge the level of fitness and ability likely to be required to take part. Remaining physically active for longer is key to reducing age-related disability and disease [7] and promoting good cognitive health [8]. In addition, including older adults in intergenerational settings can foster the mental and physical health benefits associated with social inclusion and connection [33,34]. If increased physical activity participation in the growing population of older adults is to be achieved, their needs need to be accommodated affordably within mainstream facilities and services.

A common reason why older adults wanted more information on the likely demands of the physical activity on offer was to reassure them that they would not be pushed too far, feel embarrassed, and that the activity could be adapted safely for someone of their age and level of ability. Classifications referring to the level of experience (beginner, intermediate, etc) may not be meaningful when someone has historical experience but has not taken part in many years, and a lack of explanation alongside activities that have nontraditional names can lead older adults to infer that this is not intended for them. Evidence of venues using older adults as instructors and coaches, and information to confirm that activities can be adapted to be appropriate for all ability levels and ages (where this is the case) would also increase older adults' confidence in trying out physical activity opportunities. While many older adults can navigate websites competently, they expressed a preference for simple information and were put off by too many moving images and the need to click through multiple links to find information.

Conclusions

This study has provided insight into what older adults notice and look for in websites when exploring opportunities to increase their physical activity. It flagged how their pre-existing beliefs and implicit assumptions may influence whether they consider new options for activity, taking into account perceptions of their own capability, social norms, and some stereotypes around age and motivation for physical activity. These existing beliefs may interact with web content to exacerbate or potentially challenge stereotypes, to encourage older adults to feel more welcome to use mainstream facilities and services that support physical activity.

Acknowledgments

We would like to thank Ms Natanya Cassidy and Ms Abigail Russell for their contribution to the interviews, as well as all the participants who gave up their time to take part. EG's time is supported by the National Institute for Health and Care Research Applied Research Collaboration West (NIHR ARC West)

Authors' Contributions

FG, JB, EG, and EB contributed to the conceptualization of the study. VC, EB, and AR were responsible for data collection. VC and FG conducted the analysis. FG and VC drafted the initial version of the manuscript. All authors contributed to further writing, editing, and refinement of the paper.

Conflicts of Interest

None declared.

Abstract

Background: The World Health Organization's (WHO) publication on age-friendly environments (AFEs) imagines future cities to become more age-friendly to harness the latent potential of older adults, especially those who have restricted mobility. AFE has important implications for older adults in maintaining social connections, independence, and successful aging-in-place. However, technology is notably absent in the 8 intersecting domains of AFEs that the WHO imagines improve older adult well-being, and we investigated whether technology should form a ninth domain. While mobility was severely restricted, the COVID-19 pandemic provided an opportunity to test how older adults' perceptions of their AFE changed and what role technology was playing.

Objective: This study examined how life-space mobility (LSM), a concept for assessing patterns of functional mobility over time, and loneliness impacted perceived AFEs and the moderating effect of technology. It also explores whether technology should play a greater role as the ninth domain of the WHO's imagination of the AFE of the future.

Methods: In this cross-sectional quantitative observation study, data from 92 older adults aged 65-89 years were collected in England from March 2020 to June 2021 during the COVID-19 pandemic. The Life-space Questionnaire, Technology Experience Questionnaire, UCLA (University of California, Los Angeles) Loneliness Scale, and age-friendly environment assessment tool were used. Correlation and moderation analyses were used to investigate relationships between variables.

Results: Most participants (86/92, 93%) had not left their immediate town in the previous 4 weeks before the interview. Restricted LSM was positively correlated to the age-friendly environment assessment tool, that is, rising physical isolation was linked to a better perception of AFEs; however, we discovered this result was due to the moderating impact of increased use of technology, and that restricted LSM actually had a negative effect on AFEs. Loneliness was correlated negatively with the perception of AFEs, but technology use was found to moderate the impact of loneliness.

Conclusions: Pandemic-related LSM restrictions impacted perceived AFEs and loneliness negatively, but technology played a moderating role. The findings demonstrate that technology could be considered as a ninth domain in the WHO's assessment of AFEs for older adults and that there is a need for its explicit acknowledgment.

Introduction

Background

Enabling the development of age-friendly environments (AFEs), defined as a physical and social setting that helps people age well and participate in their communities to promote "aging-in-place" for the mental and physical well-being of older adults, has become an increasingly important policy issue. This is in part a response to an aging population dynamic, urbanization, intensification of housing concerns, and community preferences, causing an increase in the deterioration of mental wellness, anxiety, stress, and depression among other disorders [1]. Older adults' perception of AFEs directly affects their quality of life (QOL) and known predictors of depression, including loneliness [2,3]. In urban environments, older adults tend to spend much of their time in their local neighborhoods and are therefore sensitive to change [4,5]. Environmental degradation, such as lack of resources, restricted access to health care, or crime, brings additional challenges.

Previous studies have demonstrated that the perception of AFEs affects the action space of older people, affecting their social participation [6]. It is known to positively moderate the relationship between frailty, mental well-being, and depression, particularly in older adults with poor health, limited mobility, and cognitive decline [1,7,8]. Moreover, a lack of social opportunities can result in loneliness, social isolation, and worsened depression, all of which exacerbate cognitive decline, QOL, and frailty [8-14]. Aboderin et al [15] and Ng et al [16] also noted a reduction in older adults' psychological resilience due to sustained stress and anxiety resulting from crowding, lack of space, and other issues that revolve around a poor age-centered environment. Other research has demonstrated a correlation between loneliness and AFEs [17-21], and identified factors linking the psychological health of economically disadvantaged older adults with their perception of AFE. Rantakokko et al [22] described the impact of person-environment interaction on mental well-being, demonstrating a mechanism by which older adults who experienced loneliness perceived obstacles with their environment. Stafford [23] demonstrated that older age insularity and the accompanying withdrawal from social interaction can result in deteriorating relationships, loneliness, poorer mental health, and a diminished perception of AFEs. If the environment is not conducive to aging-in-place, it causes difficulties in accessing services [24] and an increased risk of physical and mental health care needs [25]. As such, the perception of AFEs must be considered carefully to improve understanding of older adults aging-in-place and mental well-being.

Life-space mobility (LSM) describes the physical environment a person inhabits daily, structured into various zones (called life-space zones), centered on an anchor (eg, bedroom), and expanding outward into the rest of the house, house perimeter, local community, neighborhood, or town [26,27]. This concept corresponds to individuals' functional mobility enabling meaningful participation in community activities. It reflects how older adults move across life-space zones over a given period while incorporating frequency and independence.

According to the United Nations Development Program report "The Sustainable Development Goals and COVID-19" [28], there are unprecedented ongoing burdens on mental health for older adults. Social distancing orders during the COVID-19 pandemic were conceived as advantageous to protect potentially vulnerable populations, such as older adults [29], from disease transmission; however, it has led to long-lasting effects on mental well-being.

Restricted LSM impedes older adults' access to their [30-32] choice of environments and is associated with potential adverse mental health outcomes [27]. In addition, previous research has demonstrated that LSM restrictions reduce participation in out-of-home [33] activities and negatively affect QOL [9,34], which is in turn associated with loneliness [35].

Although pandemics create restricted mobility [36], older adults with knowledge of technology can capitalize on a digitally enabled AFE to avoid loneliness and LSM restrictions that create a strain on mental well-being. It enables older adults to engage in internet-based activities they may have enjoyed in person and gain access to health care, civic services, therapy, counseling [37], and resources that help with mental well-being [38,39]. We therefore expected both variables (LSM and loneliness) to impact AFEs negatively and for technology to moderate their impact.

Feldman and Oberlink [40] pioneered the concept of AFEs, identifying important components such as social engagement, enhancing independence, and optimizing mental functioning and well-being. Age-friendliness is derived from an ecological model of aging, in which a person's mental well-being results from the interaction between their functional and cognitive capacity (competencies) and the environmental characteristics that exert pressure on these competencies (environmental stress) [41].

The age-friendly environment assessment tool (AFEAT) was designed to assess older adults' perception of their environment and focuses on individual-oriented age-friendliness and individual-environment interaction, providing a more holistic picture [11,42,43]. Self-perceived AFEs are associated with improved QOL and mental health regardless of older adult frailty or abilities [8].

Although there is currently no universally accepted definition of an AFE, the World Health Organization (WHO) tentatively defines such communities as those where "policies, services, settings and structures support and enable people to age actively." The WHO [1] publication imagines future cities to become more age-friendly to harness the latent potential of older adults through 8 intersecting domains addressing obstacles to older adults' mental well-being: respect or social inclusion, outdoor spaces and buildings, housing, social participation, transportation, communication and information, civic

participation and employment, and community support and health services. Explicit mention of technology is notably absent.

The WHO framework has been criticized for the exiguous technology element in the domains, prompting a reexamination [44]. Incorporating technology into AFEs in its broadest sense has become an increasingly important area for aging independence and mental well-being [45] in recent years.

Marston and van Hoof [44] discussed the incorporation and use of technology within the AFE assessment agenda, and a recent systematic umbrella review elaborated on the advantages of technology interventions for social connectedness [46]. Their call for the inclusion of digital technology as a domain in AFE evaluations is beginning to resonate.

For example, Pedell et al [47,48] advocated for digital elements to encompass all aspects of environmental age-friendliness, in addition to mental and physical aspects, to realize benefits for older adults. Moreover, Reuter et al [49] acknowledged the WHO's age-friendly city initiative, considering an aging population amid increasing urbanization. However, they determined that such initiatives overlooked technology as a critical component of global digitalization.

Research Objectives

Our study aimed to examine the potentially complex relationship between internal (loneliness) and external (LSM) factors that influence older people's perception of AFEs and to determine whether technology moderates their impact. We aimed to answer a question with an important implication: should technology be included as a ninth domain in the WHO's global age-friendly cities guide in the assessment of AFEs in cities and communities for older adult mental well-being?

We set out to test the following hypotheses:

- Hypothesis (H1): LSM restriction is negatively correlated with perception of AFEs.
- H2: Increased feelings of loneliness are correlated with poor perception of AFEs.
- H3: Technology use moderates the impact of LSM restrictions on the perception of AFEs.
- H4: Technology use moderates the impact of loneliness on the perception of AFEs after considering the LSM restriction effect.

Methods

Study Design

This was a cross-sectional quantitative observational design. This report follows the STROBE (Strengthening Reporting of Observational Studies in Epidemiology) guidelines [50] (STROBE checklist mentioned in Multimedia Appendix 1).

Setting

Participants were recruited from the United Kingdom. Data were collected from January 16, 2020, to June 21, 2021, a period when social distancing mandates were enforced and social engagement outside the home was restricted.

Participants

Eligible participants were required to be living in their own home, be proficient in English, and be 65 years or older. Older people who lived in nursing or care homes or those with cognitive decline or mental health issues were excluded. Volunteers were recruited via advertisements posted in resource centers for older adults, housing associations, third-sector organizations, social activity clubs, local senior groups, direct human interaction, and word-of-mouth recommendations. Volunteers were instructed to either call and leave a voicemail or send an email indicating their willingness to participate; a return call confirmed their eligibility.

G*Power software (Version 3.1; Erdfelder, Faul, and Buchner) was used to calculate the minimum sample size required for the empirical validation of the tested moderation model. Multiple regression was used, with effect size f^2 of 0.15, power of 0.80, and 3 predictors. The recommended sample size was determined to be 87. A total of 110 participants enrolled; however, 18 did not complete all questionnaires and were excluded. The sample achieved included 92 people between the ages of 65 and 92 years (mean age 74.6, SD 7.23 years). All participants identified as either male or female, with more females (55/92, 60%) than males. More than 89% of the participants were White, with less than 11% of minority ethnicities (7 British Asian, 3 British Black). Having collated various demographic information such as age, gender, ethnicity, and education level, we were able to ascertain that participants emanated from diverse sociodemographic backgrounds.

Variables and Measures

All participants filled out a health history questionnaire based on the Scientific Advisory Group for Emergencies (SAGE) Encyclopedia of Communication Research Methods [51].

Loneliness was measured using the 20-item UCLA (University of California, Los Angeles) Loneliness Scale [52], with scores ranging from 20 to 80. Higher scores reflected higher loneliness (Cronbach α=0.88).

Utilization of technology was evaluated using the Technology Experience Questionnaire [53]. The participants were given a list of technologies (communication, computer, daily, health, recreational, and transportation technology) and asked to rate their familiarity with and use of each on a 5-point scale. Scores ranged from 0 to 180, with higher scores indicating greater use and familiarity with technology (Cronbach α=0.84).

The perception of the AFE was assessed by the AFEAT. This is a 10-item measure that uses a 5-point Likert scale, scoring items from (1) strongly disagree to (5) strongly agree and gauging participants' perceptions of their home, their local communities, the resources within the environment, and their appropriateness for meeting their daily needs. The scores ranged from 0 to 50, with higher scores representing a more positive perception of the age-friendliness of the environment (Cronbach α=0.75).

LSM was measured using the Life-Space Questionnaire [26]. Participants were asked yes or no questions about specific places they visited in the last 4 weeks, starting with another room in

XSL•FO
RenderX

their current residence and increasing the distance to a location outside England. The scores ranged from 9 to 18, with higher scores demonstrating greater restriction of LSM (Cronbach α=0.90).

Procedure

Telephone surveys collected information on loneliness, technology use, LSM, and perceptions of AFEs, in addition to basic demographic information (eg, age, education, gender, and ethnicity). Google Analytics was used to collect and tabulate the data. Participants completed the assessments across 14 months.

Statistical Analysis

Analyses were performed using IBM SPSS version 28, using a minimum significance level of 95% probability. There were no missing data, and participants completed all questions. The variables of AFEAT, loneliness, technology use, and LSM were inspected for kurtosis and skewness to assess their distribution deviations from normality via a histogram with simulated overlapping normal curves. Moreover, the homoscedasticity of the residuals was checked using a standardized residual versus a standardized predicted plot. Using the Mahalanobis (P<.001) and Cook distances, we determined whether high leverage points, significant outliers, or highly influential points exist by examining a scatterplot matrix of the dependent and continuous independent variables. A linear regression was performed to check the included variance caused by the data point and if it needed to be removed from the dataset. The criterion for discarding observations was the inability to meet 2 of the distance measures' 3 gauges. However, no outliers were found that would significantly impact the findings, and thus, none were removed. The confirmation of the independence of the observations and the assumption of no autocorrelation in the residuals was checked using the Durbin-Watson d-statistic.

The initial descriptive analyses contained means, frequencies, and SD. Pearson product-moment correlation coefficients (r) were calculated to determine whether associations exist between the variables. The same correlational analysis was used to determine whether the perception of AFE is correlated with LSM during the pandemic (H1) and whether loneliness is correlated with the perception of AFEs (H2).

Hayes' [54] PROCESS macro for SPSS with model 1 was applied to investigate the moderating effects of technology use on the relationship between LSM and AFE (H3) and technology use on the relationship between loneliness and AFEs. If the standardized coefficients of the interaction terms were significant (P<.05) or marginally significant (P<.09), we conducted a simple slope test to examine the interaction effect at different levels to reveal the nature of significant interactions to further explain the moderating effect.

Ethical Considerations

Participants accessed an information sheet either via email or read on the phone and were allowed to ask questions before giving their consent. Before completing the questionnaires, each participant gave informed consent to volunteer without compensation and participate in the study. All participants were fully anonymized.

All participants were informed of their rights to withdraw at any point in the research and informed about anonymity. The ethical procedures were aligned with the guidelines of the British Psychological Society, and the study received ethical approval from the Lancaster University Faculty of Health and Research Ethics Committee (reference number FHMREC19121). Data captured via telephone first confirmed the participant's identity and was recorded in spreadsheets and anonymized thereafter.

Results

Overview

Table 1 shows mean, SD, kurtosis, and skewness values and Shapiro Wilk test results. Kurtosis and skewness values had a relatively small range of ±1; we determined that the normal distribution deviation was insignificant. The distributions of the variables of loneliness, AFE, technology experience, and LSM were close to normal.

Table 1. Descriptive statistics for loneliness, life-space, age-friendly environment assessment tool, and technology experience (N=92).

	Scores					
	Minimum	Maximum	Mean (SD)	Skewness	Kurtosis	Shapiro Wilk test
UCLA[a] loneliness score	21	80	47.49 (17.814)	0.204	−1.630	0.192[b]

[a]UCLA: University of California, Los Angeles.

[b]P<.001 under moderate.

Participants demonstrated high levels of loneliness, with 44% of older adults demonstrating loneliness scores greater than 50, with scores above 40-50 considered moderate loneliness and scores greater than 50 considered high [55]. LSM scores were high, with more than 93% of the participants scoring >11, showing that they had not been outside their immediate town. Previous prepandemic studies with similar sample sizes and methodology reported almost half that score [26]. The

XSL•FO
RenderX

perceptions of AFEs were mixed, with a mean score of 19.51 (SD 9.69), demonstrating both positive and negative perceptions.

Prepandemic data from Garner and Holland's [8,56] studies provided a mean of 42.2, taken from 132 participants based in England, indicating a more positive perception of AFEs before the pandemic. Most participants scored above 125 (56%) for technology, demonstrating frequent use and familiarity with technology in general [53].

Next, we calculated the Pearson correlation coefficients to establish the relationships between loneliness, technology, LSM, and AFE perception to test H1 and H2. A correlation matrix of the variables was examined and is presented in Table 2.

Table 2. Correlational analysis between variables (N=92).

[c]Not applicable.

LSM is Negatively Correlated With the Perception of AFE During the Pandemic (H1)

The correlation between LSM and AFE perception was statistically significant (r=0.461, P<.001) but positively correlated, which was contrary to the hypothesis (Table 2). This meant that higher LSM scores associated with restricted mobility were correlated with a greater positive perception of AFEs. Although this rejected H1, it was a notable result.

Loneliness Is Negatively Correlated to a Perception of AFEs (H2)

The correlation between loneliness and AFE perception was statistically significant (r=−0.698, P<.001) and negatively correlated. This meant that greater loneliness was correlated with more negative perceptions of AFEs, thus confirming H2.

Technology Use Moderates the Impact of LSM Restriction on the Perception of AFEs (H3)

Model 1 was used in the PROCESS 4.0 macro for SPSS to examine the moderation effect proposed in H3 [54], as shown in Figure 1, which shows the moderation role played by technology use in the relationship between LSM and AFE perception.

Here, all continuous variables were converted to z scores for use in the model as suggested by Frazier et al [57] and Hayes [54] (ie, via z scoring, expressed as the deviation from their sample means in SD units). The unconditional interaction of LSM and technology use was insignificant (β=0.1921, t_1=1.963; P=.06; Table 3).

All variables in the model are standardized and brought into the regression equation.

Using the Aiken and West [58] method, a simple slope test was used to analyze the conditional effect of technology use between LSM and AFEs (ie, whether technology use moderates the relationship between LSM and AFEs). As illustrated in Figure 2, when technology experience was high, LSM and AFEs were significantly positively correlated (β simple: mean 1, SD 2.2037, t=3.2216; P=.003), indicating that older adults' perception of their environment was more positive when they used technology more.

In contrast, the relationship between LSM and AFEs was not obvious when the technology experience was low (β simple: mean −1, SD −0.3429, t=−0.3510; P=.73). Thus, there appears to be a positive relationship between LSM restriction and perception of AFEs when technology use was high but not when it was low (explaining the unexpected direction of H1). Furthermore, note the slight downward slope indicating the negative impact of LSM restrictions on the perception of AFEs when technology experience was low. This hints that in the absence of technology use, LSM restrictions had a detrimental impact on the perception of AFEs. This confirms H3 and

XSL•FO
RenderX

explains the initial rejection of the unconditional (overall) moderation impact of technology experience on LSM by a small margin (P=.06).

Technology Use Moderates the Impact of Loneliness on the Perception of AFEs After Considering the Impact of LSM (H4)

Model 1 was used in the PROCESS 4.0 macro for SPSS to examine the moderation effect of technology use on the relationship between loneliness and perception of AFEs, as proposed in H4 [54] and shown in Figure 3, which shows the moderating effect of technology experience on the relationship between loneliness and the perception of AFEs while controlling for LSM.

All continuous variables were converted to *z* scores. As shown in Table 4, the relationship between loneliness and technology experience was significant (β=−0.3829, t_{90}=−5.1518; P<.001), but the impact of LSM when added to the regression model was not significant (β=0.7151, t_{90}=1.665; P=.07), showing that

XSL•FO
RenderX

although technology use had a moderating impact on the relationship between loneliness and AFE perception, the contribution of LSM was not significant on the model once these other variables had been taken into account.

All variables in the model are standardized and brought into the regression equation.

We then used the simple slope test to analyze the conditional effect of technology on the impact of loneliness on the perception of AFEs to further understand the impact. As evidenced in Figure 4, the link between loneliness and AFEs was not as obvious when technology was low (β simple: mean −1, SD −0.0819, t_1=−1.5394; *P*=.13). Conversely, when technology was high, the impact of moderation was apparent more clearly (β simple: mean 1, SD −0.4983, t_{90}=−7.2636; *P*<.001). Thus, we can conclude that technology moderates the impact of loneliness on the perception of AFEs when the technology experience is high, confirming H4.

Discussion

Principal Findings

This study found higher levels of loneliness during the height of the COVID-19 pandemic among the older adult sample compared with the commonly available prepandemic data. For instance, Victor and Bowling [59] reported an average loneliness level of 30%, whereas Hawkley and Cacioppo [60] found the prevalence of loneliness in older adults to be approximately 25%, compared with the 44% found in this study. Numerous studies have found an increase in loneliness during the pandemic [61-63].

Higher loneliness was found to be correlated with a more negative perception of AFE, confirming H2 and in line with what has been theorized by the prevailing literature [18-20,22]. Shortfalls in emotional and social fulfillment have been highlighted as a predictor of loneliness, and the lack of opportunities for older adults to socialize, access important key services, and ability to engage with the community may have worsened perceptions. When older adults perceive that their desired quantity or quality of social engagements is met, they are less likely to experience loneliness and may also have favorable attitudes toward AFEs. Previous research has suggested that this relationship is likely to be complex [19] and bidirectional. AFE perception can be an indicator of a mechanism for aging-in-place, preserving older adults' physical setting of choice, providing a sense of community attachment, and allowing them to engage with a developed social network, with associated familiarity and better mental well-being.

This study found that greater use of technology clearly moderated the relationship between loneliness and the perception of AFEs. It also moderated the LSM-AFE relationship. Furthermore, the ability to use technology successfully to adapt to challenging experiences during lockdown emerged as a potential buffer against the impact of loneliness on AFE perception. Other studies that examined technology use during the pandemic revealed an increase, indicating adaptation to LSM restrictions via alternative pathways [37,64]. An increase in LSM restriction was linked to a positive perception of AFEs, rejecting H1, which at first seemed counterintuitive. However, the moderation effect of technology, such that this relationship existed only when technology use was high, explained the unexpected direction of the relationship. Older adults were overcoming physical restrictions barriers, where the ability to replace previously in-person activities with those online may have impacted perceptions. Other studies that examined AFEs also noted an increase in positive perception of AFEs as the pandemic progressed, but these could also have been linked to the easing of restrictions [56]. Overall, technology use may have improved the negative impacts of loneliness on the perception of AFEs helping with older adult mental health.

In testing H4, we determined that when technology experience was high, it had a moderation effect on the loneliness-AFE relationship. Ng et al [16] attempted to explain the relationship between internet use and loneliness through a moderation-mediation mechanism between internet use, perception of AFE, and loneliness, and depression. Their findings were consistent with those of Park et al [24] and Domènech-Abella et al [65], who confirmed the moderating effect of the internet on the age-friendliness-loneliness-depression mechanism, which may also explain our results. For example, Booth et al [66] discovered a partial mediation effect of feelings of helplessness, social isolation, depression, and distrust between psychological distress and perceived AFE (especially concerning security). Social isolation is a well-established predictor of loneliness and depression, and loneliness has also been linked in the literature. Taken together, these hint at a causal route between loneliness and perception of AFEs. Increased anxiety can lead to increased loneliness and mental health issues, potentially leading to a reduced fit between the older adult and the environment [67,68].

XSL•FO
RenderX

Despite studies highlighting the potential moderating role of technology between loneliness and AFE perception, previous results were always unclear about a direct link between these 3 variables. Our study found a clear moderating role for technology in the relationship between loneliness and AFEs, which is a notable finding.

When using the simple slope test, where technology use was low, we found that LSM negatively affected perceived AFEs when technology use was low. This explained our initial counterintuitive result and supported earlier findings [24]. To substitute or overcome confinement, older adults may have developed alternative routes of access to AFE domains, such as social, civic engagement, and access to services through technology.

Access to the internet may have helped reduce older people's boredom, and there have been examples from recent studies where older adults were able to access informal help networks, reading, or online game groups, as well as participate in community-based activities like attending virtual church gatherings [69,70]. Alternative social and emotional outlets to combat loneliness through access via the internet, to previously in-person services (eg, primary care, counseling) may have contributed to network socialization, allowing older adults to continue feeling like they are a part of their environment and reducing loneliness.

The implications of our study can be applied to situations outside of the pandemic context. Studies have highlighted that older adults prefer to live in their own homes and interact with their local community, where they have developed relationships over time and do so as long as possible [71,72]. A negative perception of AFEs can be viewed as a barometer indicating poor person-environment fit [72], associated with poorer mental health outcomes [25,71]. Therefore, technology could be a solution for those who ordinarily have limited LSM, are at risk for social isolation, and have a negative perception of AFEs.

Our study confirmed the link between LSM, loneliness, and perception of AFEs, as well as the moderating role technology played during the COVID-19 pandemic, advancing the findings of previous studies in this rapidly evolving body of literature. We also strengthened the argument that the WHO's Global Age-Friendly Cities framework would benefit older adults more by including technology use as an additional ninth domain.

Study Limitations

This study had several limitations. For example, the sampling could have been predisposed to participants literate in digital resources and more socially connected. Generally, such participants may have experienced less loneliness [73]. Furthermore, a cross-sectional design cannot establish causality [74]. Although the sample size was small, the statistical power, effect size, precision, type, complexity of analysis, study population variability, and homogeneity overcame this shortcoming. The results are an important contribution to the discourse on the role being played by AFEs in the mental well-being of older adults and the role of technology.

Although it is unlikely that participants will experience the same level of LSM restrictions after the pandemic, this allowed us to examine the studied measures in a normally inaccessible environment. However, we cannot conclude with certainty that the pandemic caused the observations because we did not have a prepandemic assessment for the same participants. Nevertheless, other prepandemic studies supported our hypothesis of mobility restrictions' impact on loneliness.

Conclusion

Despite the limitations, the results suggest that the vulnerability of older adults during the pandemic and their exposure to loneliness and negative perceptions of AFEs increased, and technology played an important role in moderating these influences. Given the advancements in technology, the WHO's 8 domains of AFEs may be obsolete with their narrow implicit recognition of technology. Our study demonstrates the significance of an explicit recognition of technology in the evaluation of AFEs as an integral component of all aspects of older adults' daily lives. Future studies may also wish to look further into the impact of demographics and differences between genders.

Community and mental health service access could be improved by providing online access. Older adults need cheap access to internet infrastructure, and health community centers should provide technology training, attend online meetings, or use mental health applications.

Researchers in the field of loneliness in older adults are encouraged to use our results to inform initiatives to reduce the mental health risks for older adults in vulnerable crises, such as the pandemic and civil insurrections [75,76]. Appropriate consideration of these factors will aid decision makers in developing robust and effective strategies during times of crisis, as well as in assisting an aging population with aging-in-place.

Abstract

Background: Loneliness has emerged as a global public health issue, with recent data indicating that 27.6% of adults aged 65 to 80 report feelings of loneliness despite the postpandemic resumption of social activities. Older caregivers face unique challenges that may exacerbate feelings of loneliness due to the demanding nature of caregiving responsibilities. While internet use has been suggested as a potential intervention to reduce loneliness, its moderating effect on the relationship between caregiving-related health effects and loneliness remains understudied.

Objective: This study aims to investigate: (1) the association between caregiving-related health effects and loneliness among older informal caregivers; (2) the relationship between internet use frequency and loneliness; and (3) whether internet use moderates the association between caregiving-related health effects and loneliness.

Methods: We analyzed cross-sectional data from the 2019‐2020 California Health Interview Survey, focusing on 3957 informal caregivers aged 65 and older. Loneliness was measured using a modified 3-item UCLA Loneliness Scale. Health effects of caregiving were assessed by self-reported physical or mental health problems due to caregiving responsibilities. Internet use frequency was measured on a 4-point scale. Multivariable linear regressions were used to test the study aims, adjusting for sociodemographic factors, health status, and caregiving-context characteristics.

Results: Among participants, 475 (12.0%) reported experiencing physical or mental health problems due to caregiving responsibilities. After adjusting for covariates, caregivers who experienced health problems related to caregiving reported higher levels of loneliness compared to those who did not (β=0.76, SE .07, *P*<.001). More frequent internet use was associated with a lower level of loneliness (β=−0.11, SE 0.03, *P*<.001). Additionally, internet use significantly moderated the relationship between caregiving-related health effects and loneliness (β=−.16, SE 0.07, *P*=.02), suggesting that the negative impact of caregiving-related health effects on loneliness was attenuated among caregivers who used the internet more frequently.

Conclusions: Caregiving-related health effects are associated with increased loneliness among older informal caregivers, but more frequent internet use may both directly reduce loneliness and buffer against the adverse impact of caregiving on loneliness. These findings align with recent research highlighting the potential of technology-based interventions to combat social disconnection among older adults. Health care providers and policy makers should consider implementing programs that enhance internet access among older caregivers as part of comprehensive strategies to address loneliness in this vulnerable population.

KEYWORDS

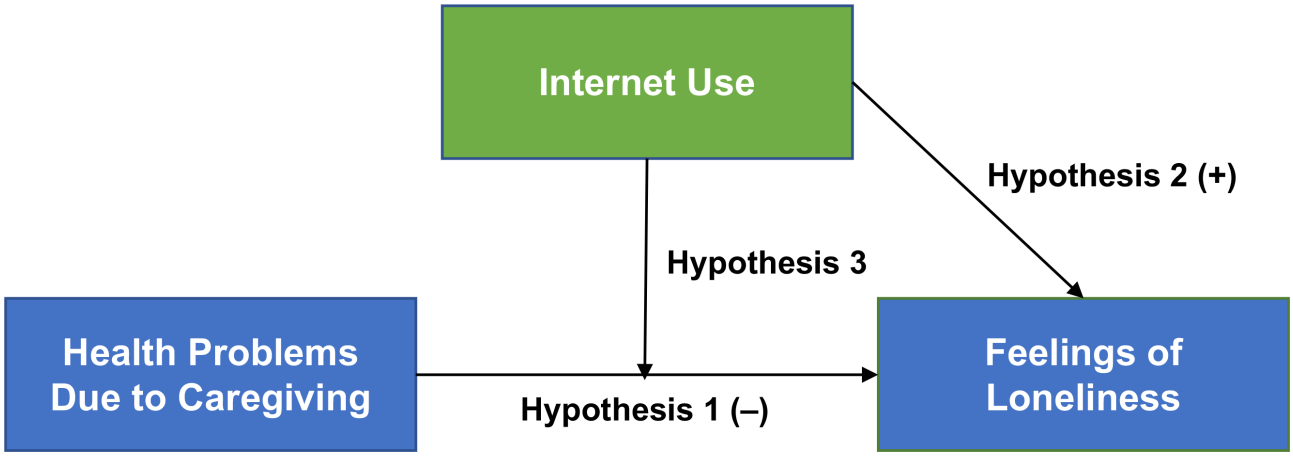
social isolation; social disconnection; family caregiving; information and communication technology; digital technology; stress-process model

Introduction

Loneliness in older adults has emerged as a growing global public health concern, with recent data indicating that 27.6% of adults aged 65 to 80 continue to experience feelings of loneliness despite the postpandemic resumption of social activities [1]. Loneliness is associated with multiple adverse health outcomes, including depression, heart disease, cognitive decline, sleep disturbance, and premature mortality [2-5]. The US Surgeon General's 2023 Advisory on social isolation and loneliness equated the health impact of lacking social connection to smoking 15 cigarettes daily, underscoring the severity of this issue [6].

The significance of this issue is magnified for older informal caregivers, who face unique challenges and heightened risks of

XSL•FO
RenderX



loneliness due to the demands and stress associated with caregiving responsibilities [7,8]. A recent analysis revealed that 15% of older caregivers experienced loneliness, with caregivers of persons with dementia having 1.62 times higher odds of experiencing loneliness compared to other caregivers [9]. For older informal caregivers, their advanced age can intensify their vulnerability to adverse health effects stemming from the burden of caregiving. In addition, older informal caregivers, who provide unpaid care to their family members or friends, often experience isolation due to the restrictive nature of caregiving duties that limit social interactions [7,8]. This isolation can exacerbate those adverse health effects associated with caregiving, creating a cycle of declining mental and physical health [10]. Given these challenges, identifying accessible interventions to alleviate loneliness in older caregivers is crucial. Increasingly, internet use has been considered a potential means to maintain social connections for those with limited in-person interaction opportunities.

While research on the general population has shown mixed or even negative associations between the widespread adoption of the internet and digital communication technologies and loneliness [11-13], the unique circumstances of informal caregivers may create a different context for digital engagement [14,15]. Caregivers face specific mobility constraints and social limitations that may make internet-based connections particularly valuable. For older informal caregivers, the internet may offer dual benefits: serving as a source of caregiving information and emotional support while facilitating social connections that reduce feelings of loneliness [16]. Recent evidence suggests that internet use may buffer against the negative health impacts of loneliness for older informal caregivers [17], enhance life satisfaction through improved interpersonal connections [18], and provide access to specialized support communities [15]. A recent scoping review indicated that technology-based interventions have shown preliminary evidence for reducing social isolation and loneliness among informal caregivers of persons with dementia [15]. However, despite the potential of internet use to serve as a resource for this population, research examining the intersection of caregiving, internet use, and loneliness within this population remains limited. This study aims to fill these gaps by examining the associations between caregiving-related health effects, internet use, and feelings of loneliness among older informal caregivers in California. Furthermore, it investigates whether internet use moderates the relationship between caregiving-related health effects and loneliness.

Using the Stress Process Model as a theoretical framework [19], this study considers how internet use may function as a coping resource that buffers against the adverse impact of caregiving stressors on feelings of loneliness. The Stress Process Model posits that caregiving experiences involve primary stressors (direct pressures of caregiving) and secondary stressors (indirect pressures such as financial strain), which can contribute to negative health outcomes, including loneliness [19]. In this study, we interpret caregiving-related health problems as a secondary stressor within the Stress Process Model framework, representing the negative consequences of primary caregiving stressors on caregivers' well-being. Within this framework, internet use may serve as a coping resource that provides both informational and emotional support, potentially mitigating the impact of caregiving-related stress on loneliness.

This study tests three hypotheses: (1) experiencing adverse health effects from caregiving is associated with a higher level of loneliness; (2) frequent internet use is associated with a lower level of loneliness; and (3) internet use protects against the adverse caregiving-related health effects on feelings of loneliness among older informal caregivers. The conceptual framework with three hypotheses is shown in Figure 1.

Figure 1. Conceptual framework.

Methods

Data Source and Sample Selection

This study used cross-sectional data from the 2019 - 2020 California Health Interview Survey (CHIS), which is the largest statewide health survey in the United States [20]. CHIS uses a complex, multistage sampling design to collect comprehensive health-related information from California's community-dwelling population [20,21]. The survey is conducted either online or by telephone and collects data on sociodemographic characteristics, health-related behaviors, health status, health care access, and utilization patterns. The 2019 - 2020 CHIS surveyed 44,109 adults with a screened response rate of 72.0%, producing a sample that is representative of California's diverse population. Notably, CHIS is conducted

XSL•FO
RenderX

in multiple languages and uses sampling strategies to reach various racial and ethnic and socioeconomic groups, ensuring broad representativeness of the state's population [20].

From the full CHIS sample, we restricted our analytic sample to respondents who met the following criteria: (1) aged 65 years or older; (2) reported providing unpaid help to family members or friends with illnesses or disabilities in the past year; and (3) had complete information on the key study variables (internet use, health effects of caregiving, and loneliness). After applying these criteria, our final analytic sample consisted of 3957 older informal caregivers.

Measurement

Dependent Variable: Loneliness

Loneliness was assessed using the modified version of the validated 3-item UCLA Loneliness Scale [22], demonstrating good reliability and validity in older adult populations [4,23]. Participants responded to three questions: "How much of the time do you feel (1) lack of companionship, (2) left out, and (3) isolated from others?" Each item was rated on a 3-point scale: "1=hardly ever or never," "2=some of the time," and "3=often." [22] Responses were summed to create a continuous loneliness score ranging from 3 to 9, with higher scores indicating greater levels of loneliness. The internal consistency of the 3-item UCLA Loneliness Scale in our sample was excellent (Cronbach α=0.974).

Independent Variables

Health effects of caregiving: The health impact of caregiving was measured by asking respondents "whether you had experienced physical or mental health problems as a result of their caregiving responsibilities in the past 12 months." Responses were dichotomized (yes/no), with "yes" indicating the presence of caregiving-related health problems.

Frequency of internet use: Internet use was measured by asking participants the question: "how often you used the internet?" Responses were coded on a 4-point scale: "1=less than a few times a day," "2=few times a day," "3=many times a day," and "4=almost constantly." Following previous research [24], we treated internet use frequency as a continuous variable, with higher scores indicating more frequent use of the internet.

Covariates

We included several potential covariates based on established associations with caregiving, internet, and mental health among older adults [25-28]. Sociodemographic covariates included age (continuous, in years), sex (0=male; 1=female), race/ethnicity (1=non-Hispanic White; 2=non-Hispanic Black; 3=Hispanic or Latino; 4=non-Hispanic Asian; and 5=others), U.S. born (0=not born in the U.S.; 1=born in the US), education level (0=less than high school; 1=high school or above), economic status measured by family income relative to the federal poverty level (0=<200%; 1=≥200%), and marital status (0=married/living with partner; 1=widowed/separated/divorced/never married). We also controlled for health status, including self-rated health (measured on a 5-point Likert scale from 1=poor to 5=excellent) and the number of self-reported chronic conditions (ie, hypertension, asthma, diabetes, heart disease, vision/hearing impairment). Additionally, we included caregiving context variables that might influence the relationship between our primary variables of interest: experiencing financial stress due to caregiving (measured on a 4-point Likert scale from 1=extremely stressful to 4=not at all stressful), caregiving hours per week (ranged 1 to 125), the care recipient's living arrangement (1=living alone; 2=living with caregiver or other family members; and 3=living in a nursing home/assisted-living facility/other living situations), relationship to the care recipient (1=spouse/partner; 2=parent/parent-in-law; 3=other relatives; and 4=nonrelative), and whether the caregiver supported the care recipient with Alzheimer disease and related dementia (0=nondementia caregiver; 1=dementia caregiver).

Statistical Analysis

We first conducted descriptive analyses of all study variables, presenting continuous variables as means (SD) and categorical variables as frequencies and percentages (%). To visually examine the relationship between internet use frequency and loneliness, we created violin plots displaying the distribution of UCLA Loneliness Scale scores across the four internet use frequency categories. We also performed one-way ANOVA tests with post hoc Tukey Honestly Significant Difference (HSD) comparisons to assess differences in mean loneliness scores across internet use frequency groups.

To test our hypotheses, we used a series of multivariable linear regression models with loneliness as the dependent variable. After adjustment for all covariates, Model 1 examined the association between caregiving-related health problems and loneliness. Model 2 examined the association between internet use and loneliness. Model 3 examined the associations of both caregiving-related health problems and internet use with loneliness. Model 4 incorporated an interaction term between caregiving-related health problems and internet use to assess whether internet use moderated the association between caregiving-related health problems and loneliness, while controlling for the same set of covariates.

To facilitate the interpretation of significant interaction effects, we conducted post hoc analyses and created visual representations showing the relationship between caregiving-related health problems and loneliness at different levels of internet use. We also calculated adjusted means of loneliness scores for different combinations of caregiving-related health problems and internet use frequency to illustrate the interaction effect.

All analyses incorporated the complex survey design features of CHIS, including stratification, clustering, and sampling weights, to ensure that results were representative of older informal caregivers in California. We addressed missing data using multiple imputations for covariates with missing values less than 5%; cases with missing values on key study variables were excluded as per our sample selection criteria. We conducted all statistical analyses using Stata MP (version 17.0; StataCorp, with a significance level set at P<.05 for all tests. All analyses were conducted by a multidisciplinary team with expertise in gerontology, nursing, and biostatistics, providing confidence in the study's methodological rigor.

Ethical Considerations

This study was exempt from the Institutional Review Board review at New York University as CHIS is a publicly available dataset.

Results

Participants' Characteristics

Table 1 displays the sociodemographic characteristics, health status, and caregiving context of the 3957 older informal caregivers in California who participated in the study. The participants had a mean age of 72.46 years (SD 5.88), with 58.6% (n=2,319) being female. The sample was predominantly non-Hispanic White (78.6%, n=3,109), with 11.7% (n=462) born outside the United States. Regarding educational attainment, most participants (86.7%, n=3,432) had at least some college education, and the majority (83.0%, n=3,283) reported family income at or above 200% of the federal poverty level.

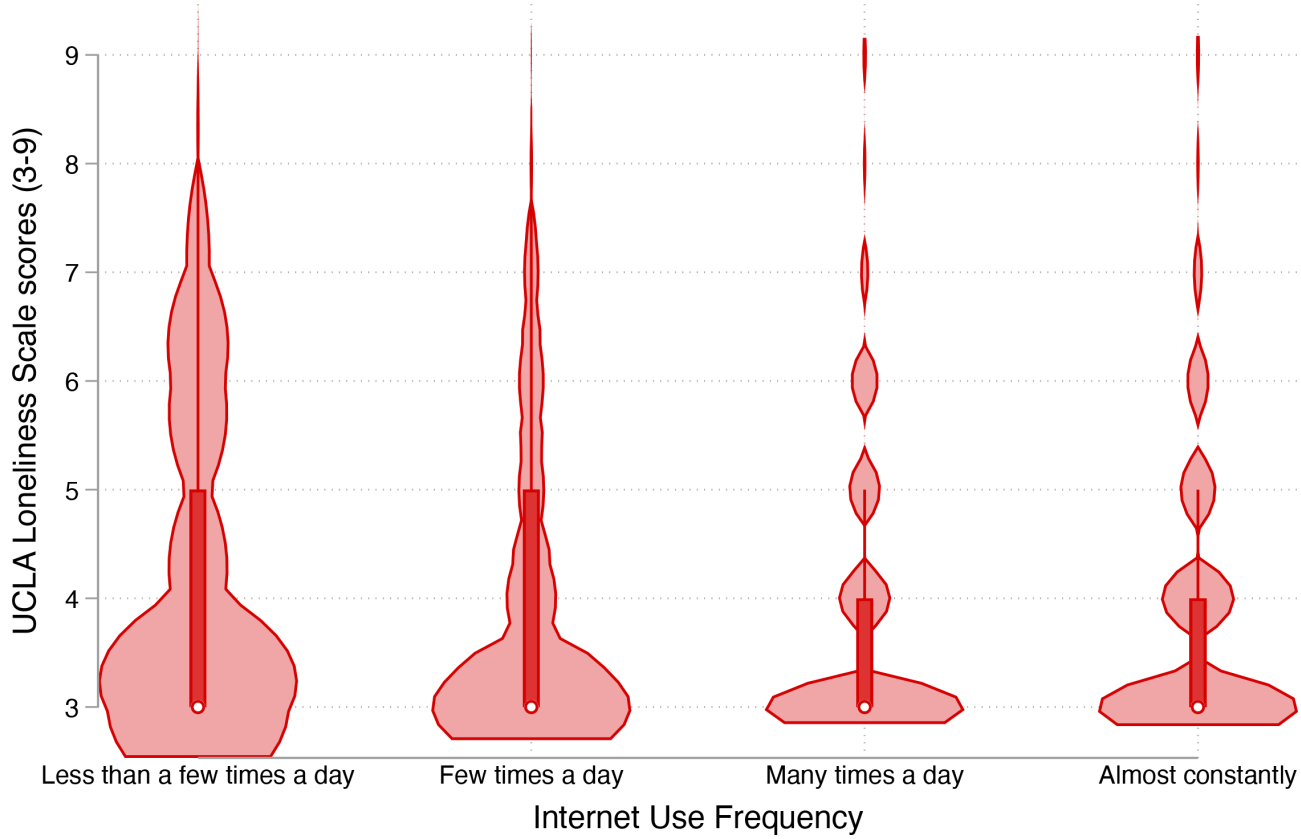
Loneliness, mean (SD; range)	3.98 (1.41; 3 - 9)

[a]Chronic conditions: hypertension, asthma, diabetes, heart disease, vision/hearing impairment.

In terms of caregiving context, participants reported low to moderate levels of financial stress due to caregiving, with a mean score of 3.47 (SD 0.81) on a 4-point scale, where higher scores indicate less stress. The mean caregiving hours per week were 15.39 (SD 21.24) on a scale ranging from 1 to 125. Approximately half (52.3%, n=2069) of the care recipients lived with the caregivers or other family members, while 1010 (25.5%) lived alone and 878 (22.2%) resided in nursing homes, assisted living facilities, or other living arrangements. The sample exhibited a fairly even distribution across caregiver relationship types: 27.8% (n=1099) were caring for spouses or partners, 24.5% (n=971) for parents or parents-in-law, 23.4% (n=925) for other relatives, and 24.3% (n=962) for nonrelatives such as friends or neighbors. In addition, a total of 911 (23.0%) care recipients had Alzheimer disease and related dementia. Notably, 12.0% (n=475) of the caregivers reported experiencing physical or mental health problems due to their caregiving responsibilities.



Regarding technology use, participants reported moderate levels of internet use, with a mean score of 2.71 (SD 0.84) on a 4-point scale, where a higher score indicates more frequent use. The mean UCLA Loneliness Scale score was 3.98 (SD 1.41) on a scale ranging from 3 to 9, indicating relatively low levels of loneliness in the overall sample.

Associations Between Health Effects of Caregiving, Internet Use, and Loneliness

Figure 2 presents the violin plot depicting the distribution of loneliness scores across the four internet use frequency categories. The distribution shape changes notably across categories, with the 'less than a few times a day' group showing the highest mean score of loneliness (4.14, SD 1.49) and the widest distribution, indicating greater variability in loneliness experience among infrequent internet users. In contrast, the 'almost constantly' group exhibited the lowest median score (3.85, SD 1.27), with a narrower distribution concentrated toward lower loneliness values. One-way ANOVA confirmed significant differences in loneliness across the four categories ($F_{3,\ 3953}$=7.05, P<.001). Post hoc tests revealed significant differences between all pairs of internet use frequency groups (all Ps<.05) except between the "many times a day" and "almost constantly" groups.

XSL•FO
RenderX

Figure 2. Violin plots of loneliness scores by internet use frequency categories among older informal caregivers (n=3957). The width of each violin represents the probability density of data at different values. White dots indicate medians, red boxes show interquartile ranges, and red lines represent the range excluding outliers. ANOVA testing confirmed significant differences between groups (*P*<.001). Mean and sample sizes: less than a few times a day (mean 4.14, SD1.49; n=188), few times a day (mean, SD 3.99, 1.47; n=1568), many times a day (mean 3.85, SD 1.33; n=1398), and almost constantly (mean 3.84, SD 1.27; n=803).

Regression Analysis of Caregiving-Related Health Effects, Internet Use, and Their Interaction

In Model 1 (Table 2), after adjusting for sociodemographic characteristics, health status, and caregiving context variables, caregivers who reported experiencing physical or mental health problems due to caregiving had significantly higher loneliness scores compared to those who did not report such problems (β=0.76, SE 0.07, *P*<.001). The regression analysis in Model 2 also revealed a significant inverse relationship between internet use frequency and loneliness (β=−0.11, SE 0.03; *P*<.001). Specifically, more frequent Internet use was associated with a lower level of loneliness after controlling for socio-demographic factors, health status, and caregiving context variables (Model 3). Additionally, we conducted a sensitivity analysis excluding self-rated health and number of chronic conditions from the regression models; the association between caregiving-related health problems and loneliness remained significant and of similar magnitude, suggesting that our findings were not driven by adjusting for overall health status.

To examine the moderating role of internet use on the association between caregiving-related health problems and loneliness, we included an interaction term between internet use and caregiving-related health problems in the multivariable regression model (Model 4 in Table 2). The interaction term was statistically significant (β=−.16, SE 0.07, *P*=.02), indicating that internet use significantly attenuated the negative impact of caregiving-related health problems on loneliness.

Figure 3 illustrates this interaction effect, showing that the positive association between caregiving-related health problems and loneliness was stronger among caregivers with low internet use compared to those with high internet use. For caregivers with low internet use, experiencing health problems due to caregiving was associated with a substantial increase in loneliness scores. In contrast, for caregivers with high internet use, the difference in loneliness scores between those with and without caregiving-related health problems was less pronounced.

Figure 3. The moderating effect of internet use on the association between caregiving-related health problems and loneliness (California Health Interview Survey 2019 - 2020). The model was controlled for sociodemographics, health status, and caregiving context characteristics.

Discussion

Principal Findings

We hypothesized that older caregivers who experienced caregiving-related health problems would report higher loneliness, that more frequent internet use would be associated with lower loneliness, and that internet use would buffer the impact of caregiving-related health problems on loneliness. Consistent with these hypotheses, our study revealed three key findings regarding loneliness among older informal caregivers.

XSL•FO
RenderX

First, caregivers who reported experiencing physical or mental health problems due to caregiving had significantly higher levels of loneliness compared to those who did not report such problems, supporting our first hypothesis. Second, more frequent internet use was associated with lower levels of loneliness, confirming our second hypothesis. Third, internet use significantly moderated the relationship between caregiving-related health problems and loneliness, supporting our third hypothesis.

The observed association between caregiving-related health problems and increased loneliness aligns with previous research on the mental health consequences of caregiving burden [29-31]. Loneliness among older caregivers can stem from various sources, including emotional loneliness within the relationship with their care recipients, especially if the care recipient has dementia [9]. The nature of caregiving often necessitates significant time commitment and can lead to social isolation, as caregivers frequently sacrifice their social lives and personal needs to provide care [7,31]. This isolation can be particularly pronounced for spousal caregivers, who typically bear the most intensive care duties and often experience diminished ability to participate in social activities. The continuous concern for their care recipients can result in a sacrifice of personal freedom and a decline in their sense of identity within societal roles [30].

Our finding that more frequent internet use is associated with lower loneliness scores among older caregivers contributes to the growing literature on the potential benefits of digital technology for this population [15,25]. This relationship may reflect the ability of internet-based communication to facilitate social connections despite the time and mobility constraints that often accompany caregiving responsibilities [32]. The internet can serve as a bridge that enhances the intergenerational connections, mitigates feelings of loneliness among older informal caregivers, and boosts their overall quality of life [15,25]. By mitigating space and time constraints, the internet provides a channel through which caregivers can boost interaction within their interpersonal networks, alleviate perceived isolation, and maintain good mental status [33]. These benefits may be particularly valuable for older caregivers who face challenges in maintaining in-person social connections due to their caregiving duties. Research has shown that technology-enabled support interventions can increase feelings of social bond, social support, and shared experiences [25,33,34], all of which can alleviate loneliness and its negative effects on mental health among older adults. Digital platforms can also foster social and coping skills and help change maladaptive perceptions and thoughts, thereby decreasing loneliness (eg, evidence from internet-based caregiver support interventions shows improved coping and reduced isolation) [33,34]. Our findings regarding the association between internet use and a lower level of loneliness among older caregivers align with these mechanisms.

Additionally, our study found that internet use moderates the association between caregiving-related health problems and loneliness. This suggests that internet use may serve as a protective factor against loneliness for caregivers experiencing health problems due to their caregiving responsibilities. Consistent with the Stress Process Model's framework—which suggests that coping resources buffer the negative effects of caregiving stressors on outcomes like loneliness – our findings indicate that frequent internet use likely served as a coping resource that attenuated the impact of caregiving-related health problems on loneliness [19]. The internet may offer dual benefits for older caregivers experiencing health problems, as it can serve both as a source of health information and a means of maintaining social connections despite physical limitations or time constraints [25,26,33,34]. Digital technology can enable caregivers to access health resources, connect with health care providers, and join support groups relevant to their specific health concerns, while simultaneously facilitating social interaction with friends and family.

Our findings have several implications for interventions targeting loneliness among older caregivers. First, they suggest that promoting internet use among older caregivers may be a promising strategy for reducing loneliness, particularly for those experiencing health problems due to caregiving. Improving digital health literacy is crucial for enabling older caregivers to effectively utilize online resources. Recent evidence shows that tailored interventions can significantly enhance eHealth literacy in older populations, thereby empowering caregivers to find, evaluate, and apply online health information [35,36]. Health care providers should consider assessing both caregiving-related health problems and internet use patterns when evaluating the risk of loneliness among older caregivers. Those with caregiving-related health problems and low internet use may be particularly vulnerable to loneliness and could benefit from targeted interventions. Moreover, policy makers should consider investing in infrastructure and programs that increase internet accessibility and digital literacy among older adults, particularly those with caregiving responsibilities. This could include subsidized internet access, device distribution programs, and community-based digital literacy training tailored to older adults. Government, policy makers, and society should prioritize their efforts to promote internet literacy among older informal caregivers, advance the development of internet and digital infrastructure, and bridge the urban-rural divides.

This study has several limitations that need to be acknowledged. First, CHIS's cross-sectional design precludes causal inferences regarding the relationships between caregiving-related health problems, internet use, and loneliness. Longitudinal studies are needed to examine how changes in caregiving-related health problems and internet use over time influence trajectories of loneliness among older caregivers. Second, our measure of internet use focused solely on frequency rather than specific types of internet activities or duration of online interactions. Future research should examine how different patterns and durations of internet use (eg, social media, entertainment, health information seeking) may differentially affect loneliness among older caregivers. Understanding internet use patterns and device adoption across older caregivers and care recipients is increasingly recognized in enhancing geriatric care [37]. Third, health problems due to caregiving measures are self-reported and may not exclusively reflect problems caused by caregiving alone. It is challenging to definitively attribute health issues solely to caregiving responsibilities with a cross-sectional self-report item, and we caution that this variable should be

XSL•FO
RenderX

interpreted as a perceived impact of caregiving on health. Finally, although our sample was representative of older informal caregivers in California, the generalizability of our findings to other geographic contexts may be limited. Future studies should examine these relationships in diverse populations and settings, including rural areas with limited internet infrastructure and communities with varying levels of technological integration. Future research should explore the development of tailored digital interventions specifically designed to address loneliness among older caregivers. These interventions could integrate components addressing both caregiving-related stressors and social connection, potentially leveraging artificial intelligence to personalize content based on individual caregiving contexts and preferences. In addition, emerging technologies such as social robots have shown promise in supporting older people with dementia and their informal caregivers [38] and could be explored as complementary tools to reduce loneliness in caregiving contexts.

Conclusion

Our study provides evidence that internet use is associated with lower levels of loneliness among older informal caregivers and could buffer against the negative impact of caregiving-related health problems on loneliness. This study highlights the potential of digital technology as a tool for addressing loneliness in this vulnerable population. As the population ages and the number of older caregivers increases, developing effective strategies to support their psychosocial well-being becomes increasingly important. Internet-based interventions represent a promising approach, particularly for caregivers facing health challenges related to caregiving responsibilities. Future research and policy efforts should focus on enhancing internet accessibility, promoting digital literacy, and developing age-friendly digital platforms that meet the specific needs of older caregivers.

Abstract

Background: Globally, various aging concepts (such as healthy aging, successful aging, and active aging) have emerged to promote the goal of "aging well" and have gained widespread attention in academia, policy, and practice to change the negative narrative on aging. However, whether and how these aging concepts have contributed to changing the negative narratives remains unclear. Moreover, they are not clearly defined nor widely agreed upon, often creating ambiguity and confusion.

Objective: This paper aims to provide a comprehensive review and comparative analysis of 16 aging concepts, with a particular focus on how their evolution in research has contributed to shifting the narrative surrounding aging.

Methods: This study used the bibliometric software VosViewer (Center for Science and Technology Studies) to visualize international collaboration among countries and cocitation networks among journals. This helped identify which countries and journals play central roles in research on aging concepts and revealed how academic contributions are distributed globally. Additionally, content analysis supported by the corpus linguistics software AntConc (Waseda University) was conducted to examine and compare the main focuses, applications, challenges, and future research directions of these concepts.

Results: The findings indicate that while all 16 aging concepts share the common goal of improving the quality of life for older adults, they offer different perspectives, encompassing health management, social participation, mental health, and technological innovation. Key challenges to achieving the goal of each aging concept were identified, including unequal access to health care resources, barriers to social participation, and difficulties in adopting technology.

Conclusions: The overall impact of these aging concepts on reshaping negative aging narratives remains relatively limited. Future efforts should focus on advancing technology, optimizing policies, enhancing social support systems, and fostering global collaboration to provide innovative and sustainable solutions that promote the overall well-being of older adults.

KEYWORDS

aging concepts; health aging; successful aging; active aging; bibliometric analysis

Introduction

The global trend of an aging population is accelerating, with a steadily increasing proportion of people older than 65 years of age worldwide [1,2]. Many governments view this demographic change as an increasingly pressing challenge, particularly in the areas of health and social security [3]. Policy makers commonly associate aging with higher incidences of chronic diseases and increased reliance on long-term care services, which places significant burdens on public health budgets and resource allocation [4-7]. Similarly, many researchers view aging as a growing challenge, emphasizing how the prevalence of neurodegenerative diseases, diabetes, and other chronic conditions in older populations significantly increases medical demands, thereby intensifying pressure on health care systems [8-11].

Governmental focus on fiscal sustainability, along with academia's emphasis on the challenges of the aging process, has fostered a prevailing negative narrative of aging as an inevitable social and economic burden. Policy documents frequently underscore the financial pressure aging places on pension systems and long-term care insurance, driving related legislation and measures [12]. This "cost-centric" perspective is also prevalent and echoed in academic studies, which highlight the strain aging poses to the labor market and its potential threat to national economic productivity [13-15].

XSL•FO
RenderX

In response to the prevalent focus on the negative impacts of aging, some researchers and international organizations (eg, World Health Organization [WHO]) have sought to reshape this narrative by introducing aging concepts like "healthy aging," "successful aging," and "active aging" [16]. These concepts seek to shift the focus from the diseases and functional decline associated with aging to the positive aspects of fostering holistic well-being and active social participation among older adults through preventive and supportive measures [17-21]. For example, the concept of active aging highlights the importance of continued participation in social, economic, cultural, and physical activities for older adults, and it emphasizes staying active in all areas of life to improve both the quality of life and overall health [22]. These concepts collectively aim to counteract the dominant "cost-centric" and deficit-based narratives of aging, promoting a more holistic view of older adults as active, valuable members of society.

However, despite the initial intentions behind these aging concepts, whether or not they have succeeded in counteracting the dominant negative narrative around aging remains largely unknown. In fact, some researchers even argue that these concepts may inadvertently reinforce certain aspects of the negative view of aging [23-25]. For example, Waddell et al [26] mentioned that achieving "successful aging" often emphasizes individual responsibility for maintaining health and well-being, overlooking broader social and environmental factors, setting unrealistic standards that marginalize those with health challenges, thus reinforcing a deficit-based view, and framing aging as a problem to be managed rather than a natural process. Additionally, the commercialization of "active aging" and "healthy aging" (eg, the "silver market" and "silver economy") reinforces the notion that aging requires continuous self-improvement, perpetuating ageist views that devalue individuals who do not meet ideals of productivity or health [27,28].

Moreover, the definitions and applications of these aging concepts often vary significantly, leading to confusion and misinterpretation in both academic and practical contexts. For instance, "successful aging" from biomedical research is commonly defined as the absence of major diseases and the maintenance of good physical function in older people [29]. In contrast, successful aging in sociological and psychological studies emphasizes the ability of older adults to maintain social connections and mental well-being [30]. These definitional inconsistencies hinder cross-disciplinary understanding and cooperation and introduce uncertainties into the development and implementation of public health strategies and policy implementation.

Therefore, this study aims to examine whether, and in what ways, the application of aging concepts in academic research has contributed to reframing the dominant negative narrative surrounding aging. To achieve this, a systematic review of aging-related literature was conducted, leading to the identification of 16 key aging concepts. These concepts were then used as keywords to retrieve relevant papers from the Scopus database. Scopus's built-in analysis tools, along with the bibliometric software VosViewer (Center for Science and Technology Studies), were used to map the distribution of publications across disciplines and journals, and to visualize international research collaborations and relationships between frequently cocited journals.

Furthermore, the linguistic software AntConc (Waseda University) supported a comprehensive content analysis, examining core themes, practical applications, persistent challenges, and emerging trends associated with these aging concepts. Based on these analyses, the study not only charts how aging concepts are defined, applied, and interpreted within academic discourse but also evaluates whether their application signals a shift from deficit-based to empowerment-oriented narratives.

To support this interpretive approach, the study draws on narrative theory (eg, [31]), which emphasizes how language and discourse shape the meanings ascribed to aging. Complementing this, the social construction of aging framework (eg, [32]) informs our understanding of aging concepts as dynamic constructs that are embedded in broader cultural, institutional, and policy contexts. Together, these theoretical models guide our analysis of how aging concepts contribute to either deficit-based or empowerment-oriented representations of later life.

Methods

Data Collection

This study adopts a systematic literature review approach, aiming to ensure the comprehensiveness and credibility of data through extensive searching, iterative reading, filtering, and cross-validation. The process began with the use of Google Scholar to identify aging concepts through close reading of academic journal papers, books, and conference proceedings. This initial stage was further enhanced by including authoritative documents from international organizations such as the WHO, the European Commission, and relevant government reports. This multilayered approach enabled the identification of 16 aging concepts as follows: (1) healthy aging, (2) successful aging, (3) active aging, (4) positive aging, (5) productive aging, (6) optimal aging, (7) social aging, (8) creative aging, (9) smart aging, (10) healthy-active aging, (11) adaptive aging, (12) robust aging, (13) resilient aging, (14) conscious aging, (15) intelligent aging, and (16) vital aging.

These 16 aging concepts were then used as keywords to search in the Scopus database. Scopus was selected for its extensive multidisciplinary coverage, inclusion of high-quality peer-reviewed journals across both biomedical and social sciences, and compatibility with bibliometric tools such as VosViewer. Its structured metadata and citation indexing made it especially suitable for large-scale quantitative and linguistic analysis. While Scopus provides a robust foundation for this study, future research may benefit from incorporating other databases (eg, Web of Science and PubMed) for triangulation and broader validation.

Initial searches occasionally returned irrelevant results, such as papers focused on animal aging or the degradation of materials and mechanical systems. To refine the dataset and focus on

XSL•FO
RenderX

human aging, population-specific terms were added. The final search string was:

TITLE-ABS-KEY(“healthy aging” OR “active aging” OR “healthy-active aging” OR “smart aging” OR “intelligent aging” OR “successful aging” OR “creative aging” OR “social aging” OR “conscious aging” OR “resilient aging” OR “adaptive aging” OR “positive aging” OR “productive aging” OR “robust aging” OR “optimal aging” OR “vital aging”)AND(“elderly” OR “elderly people” OR “elders” OR “the aged” OR “the elderly population” OR “older adults” OR “older individuals” OR “older persons” OR “older generation” OR “senior citizens” OR “senior population” OR “seniors” OR “golden-agers” OR “retirees” OR “pensioners” OR “aging population” OR “aging adults” OR “geriatric population”)

Both American (“aging”) and British (“ageing”) spellings were used to ensure comprehensive retrieval. For compound terms such as “healthy-active aging,” both hyphenated and nonhyphenated forms were included. As of October 21, 2024, the final search yielded 10,642 papers in English-language peer-reviewed journals.

Data Analysis

A combination of bibliometric, corpus linguistic, and qualitative content analysis methods was used to examine how aging concepts are applied and framed in academic literature. The built-in analytical tools of the Scopus database were used to perform an initial descriptive analysis of the dataset, including (1) the distribution of publications across various journals, (2) the trends in the number of publications over the years, (3) the spread of research across various academic disciplines, (4) and the emergence time of 16 aging concepts.

Following this, the bibliometric software VosViewer was used to visualize the co-occurrence of (1) geographic collaboration among countries, and (2) cocited journal references. The goal was to identify key regions contributing significantly to aging research and highlight highly influential journals. VosViewer is widely used for bibliometric analysis and scientific knowledge mapping, known for its exceptional capacity to manage large datasets, such as the 10,642 papers retrieved in this study. These network analyses offer insight into the structural dynamics of academic discourse, including disciplinary concentration and geographic dominance, which serve as contextual indicators for understanding the breadth and inclusivity of narrative development around aging concepts. In both cocitation and collaboration networks, total link strength (TLS) was used as a metric to quantify the strength of connections between nodes (eg, journals or countries). TLS is automatically calculated by VosViewer based on the frequency and intensity of co-occurrence—cocitation in journal networks, or coauthorship in country networks. A higher TLS value indicates stronger linkage and greater structural centrality within the network.

For the comparative analysis, 2 datasets were extracted:

- Dataset 1 consisted of a full set of 10,642 papers based on the 16 aging concepts, with extracted text from titles, abstracts, and keywords.
- Dataset 2 consisted of a focused set of 1402 papers retrieved using the keywords “age well,” “aging well,” and “ageing well,” also limited to titles, abstracts, and keywords.

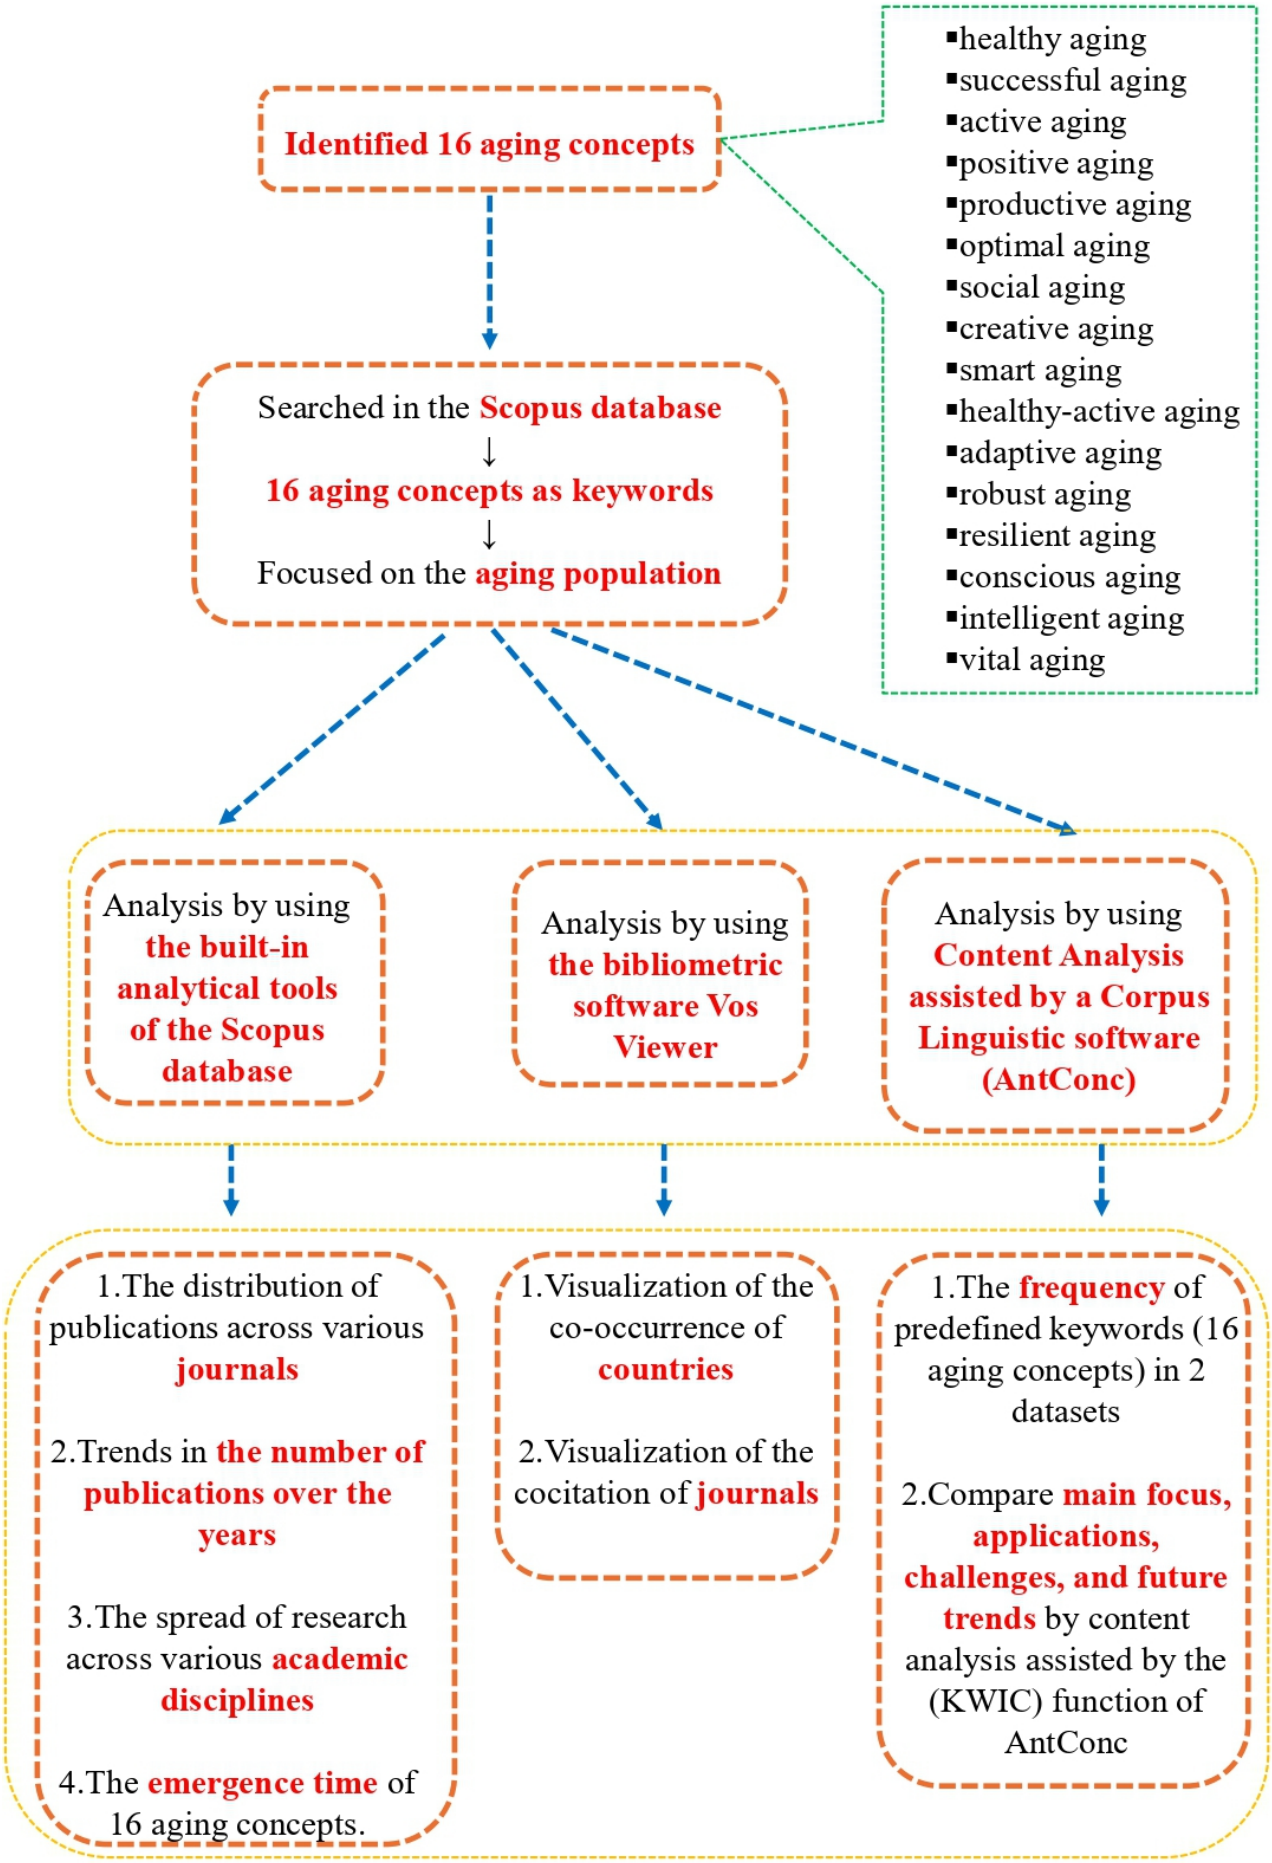
The first dataset was concept-driven, focusing on how predefined aging concepts are applied in scholarly research, while the second dataset was goal-oriented, capturing how the broader notion of “aging well” naturally emerges in academic discourse. The second dataset was provided as a comparative lens, enabling an assessment of whether and how the selected aging concepts were embedded within mainstream narratives surrounding positive aging outcomes.

Then, linguistic analysis was performed using the software AntConc. Word frequency counts identified how often each aging concept appeared in both datasets, providing a basis for comparing their relative prominence. AntConc’s Keywords in Context function supported in-depth qualitative content analysis by extracting 30-word windows surrounding each concept for further analysis. Specifically, the initial step involved analyzing text from Dataset 1, which formed the foundation for subsequent analysis. The Keywords in Context function was then used to locate occurrences of the aging concepts within the text, extracting 30 words before and after each keyword to form target sentences. In the first round of content analysis, these target sentences were categorized into several main themes. The primary themes included:

- Core content: describes the main ideas of each aging concept.
- Application areas: refer to the domains where these concepts have been applied, such as public health or social policy.
- Challenges: highlight the difficulties encountered in achieving the goals of these aging concepts.
- Future trends: focus on the development directions and potential applications of these concepts.

After completing the initial analysis, a second round of content analysis was conducted. In this phase, differences between the concepts were compared to provide a more summarized description—a “big picture,” so to speak. The process followed a clear and logical flow: beginning with large-scale text extraction, identifying keyword contexts, conducting 2 rounds of thematic content analysis, and concluding with a comparative synthesis. The analytical procedures are illustrated in Figure 1.

To evaluate whether aging concepts have contributed to shifting the negative narrative on aging, the content analysis examined the presence and emphasis of themes reflecting either deficit-based or empowerment-based narratives. Concepts framed primarily around disease, burden, and decline were interpreted as maintaining or even reinforcing a traditional negative discourse, while those emphasizing well-being, participation, adaptability, and holistic development were viewed as indicative of a shifting, more positive narrative change. The distribution of disciplines and publication trends also served as supporting indicators: a concentration of research within medical domains tended to reinforce traditional narratives, while an increasing presence in social, policy, or interdisciplinary domains suggested progress toward a more balanced narrative. These interpretive criteria guided the



XSL•FO
RenderX

qualitative assessment of whether and how narrative transformation is occurring in the academic literature.

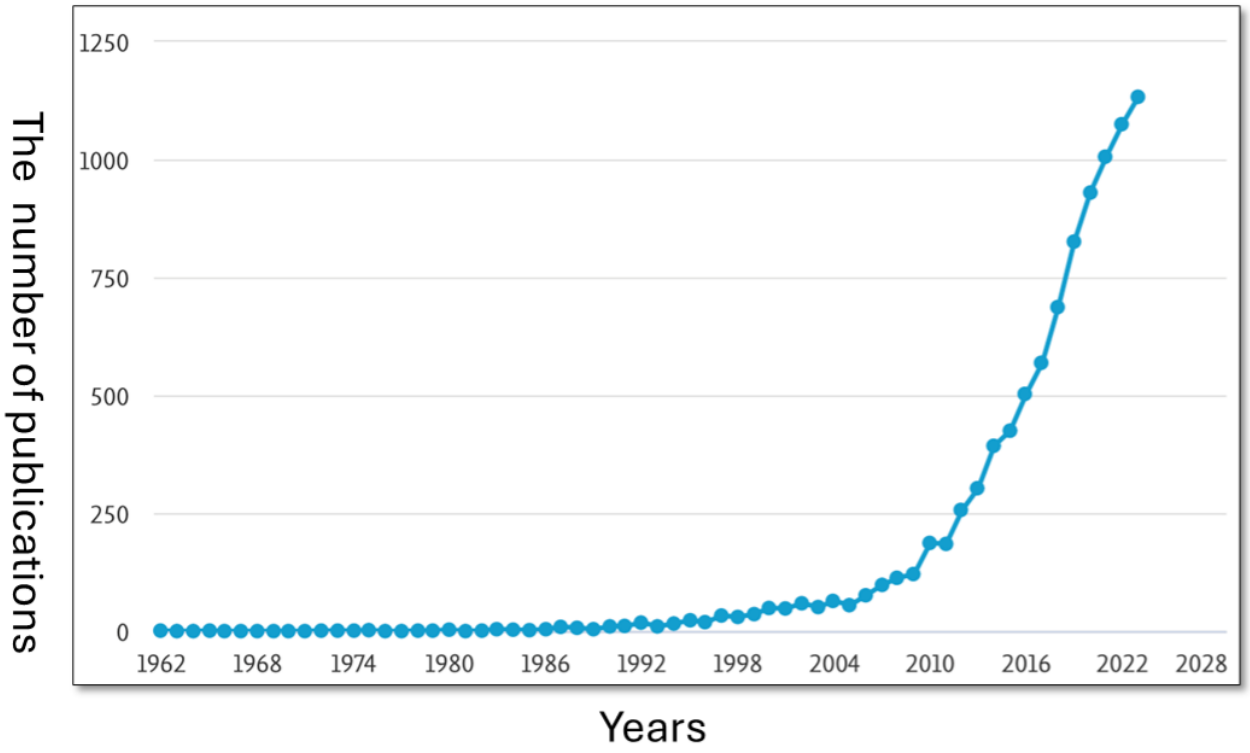
Results



Publication Trends and Disciplinary Distribution

Distributions of Publication Volume in Years

The line chart (Figure 2) illustrates the annual publication volume trend over the 62-year period from 1962 to 2023, based on 9465 papers out of the 10,642 retrieved, as data for 2024 represents only part of the year, which affects the trend line.

It is clearly shown that there is an exponential increase in the number of papers published, particularly after 2011, which indicates a growing interest and emphasis on research mentioning aging concepts. In the early 50 years (from 1962 to 2011), the number of publications remained steady, but slow growth, generally below 250 per year. Then, in the near-decade (from 2012 to 2020), the number of publications experienced a sharp increase, with the count reaching between 250 and 1000 papers. This upward trajectory continued between 2021 and 2023, when the number of publications exceeded 1000 papers.

Figure 2. Trends in publications mentioning aging concepts (2016-2023).

Distributions Cross Disciplines

The disciplinary distribution of publications is presented in Multimedia Appendix 1. Medicine takes the lead with 34.2%, clearly positioning it as the central discipline in research applying aging concepts. Social Sciences (12.4%) and Biochemistry and Genetics (9.8%) follow at a distance, indicating that the research disciplines extend beyond medicine to encompass the social sciences and biosciences. In contrast, Health Professions account for 3%, Environmental Science for 2.8%, and Computer Sciences for only 1.5%, indicating that these fields contribute fewer aging-related publications in absolute terms.

This distribution highlights an important structural feature of aging research: while it remains heavily concentrated in medical domains—often reflecting deficit-based narratives centered on disease, decline, and dependency—there is a gradual increase in contributions from disciplines that approach aging from more social, psychological, or interdisciplinary perspectives. This expansion suggests a modest shift toward a more multidimensional, empowerment-oriented discourse. However, it is worth noting that this analysis does not account for the total number of publications within each discipline. Therefore, it cannot measure the relative importance of aging within each field. Future studies could address this limitation by normalizing the data against overall publication volume within each discipline.

Distribution of Journals

Table 1 presents the distribution of the top 35 journals and the number of papers published in each (all with over 50 publications). This distribution reflects the broad scope and complexity across areas of research applying aging concepts, spanning fields such as public health, geriatrics, neuroscience, neurodegenerative diseases, aging psychology and mental health, sociology, social sciences, nutrition, and multidisciplinary aging studies. The top 5 journals in this list are the *International Journal of Environmental Research and Public Health*, with 322 papers; *BMC Geriatrics*, with 204 papers; *PLOS One*, with 148 papers; *Aging and Society*, with 144 papers; and *Frontiers in Aging Neuroscience*, with 142 papers.

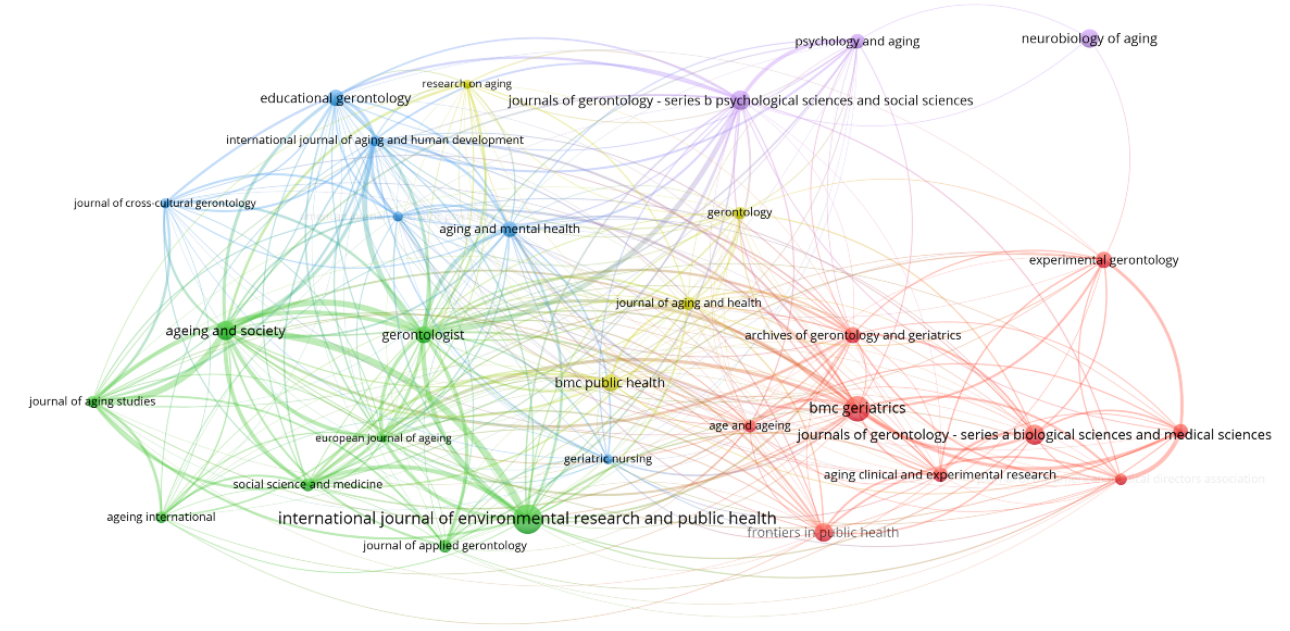
Co-Occurrence of Cocited Journals

Figure 3 presents a cocitation map of journals in research applying aging concepts generated using VosViewer software. Table 2 lists the top 30 journals ranked by the number of citations. Together, they show key journals' academic influence and interconnections.



Specifically, larger nodes, such as *Journals of Gerontology—Series A: Biological Sciences and Medical Sciences* (6981 citations), *Gerontologist* (6774 citations),

XSL•FO
RenderX

Journals of Gerontology—Series B: Psychological Sciences and Social Sciences (5016 citations), and *Aging and Society* (4784 citations), indicate that these journals hold considerable academic influence in research applying aging concepts. In addition to the node size, different colors in the network distinguish various research domains, such as social sciences and public health (green), clinical and biological aging (red), cognitive aging and neuroscience (purple), educational and developmental aspects of aging (blue), and a multidisciplinary approach combining medical and social sciences (yellow). Moreover, the thickness of the connecting lines between journals reflects the strength of their citation relationships, quantified by TLS, which indicates how frequently the journals are cocited.

The top 3 journals in terms of TLS are *Gerontologist* (TLS*:* 345), *Aging and Society* (TLS: 317), *and International Journal of Environmental Research and Public Health* (TLS: 230), highlighting strong citation linkages within the research network. As a cumulative metric automatically calculated by VosViewer, TLS represents the total strength of cocitation links a journal has with others. A higher TLS means the journal is frequently and widely cocited, suggesting its centrality in the knowledge network. This clustering of cocitation relationships, dominated by biomedical and gerontology-focused journals, reflects the structural concentration of aging discourse, indicating a limited narrative shift as defined in our methodological framework.

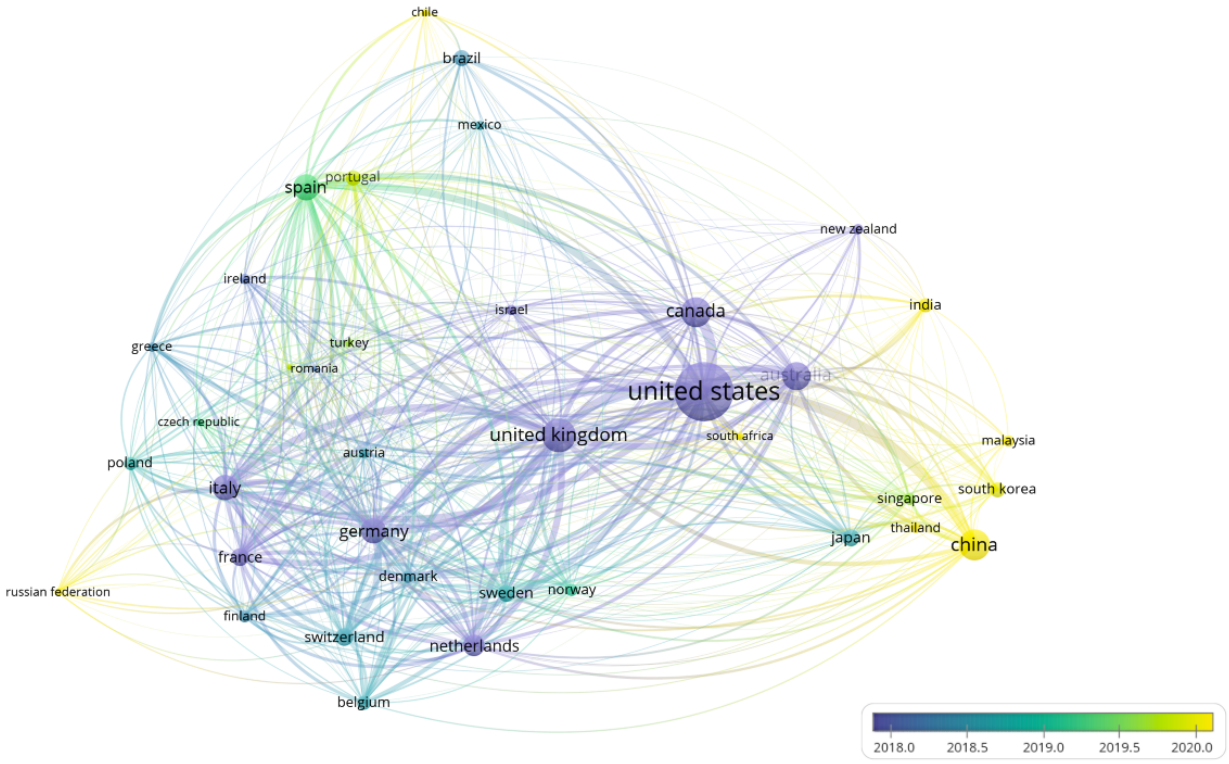
[a]TLS: total link strength.

XSL•FO
RenderX



Distributions in Geographical Areas

Figure 4 presents a collaboration map of countries generated by VOSviewer, while the number of papers ranked and the TLS for each country are listed in Table 3. These 2 tables provide a comprehensive overview of global collaboration in research applying aging concepts.

The countries such as the United States, China, and the United Kingdom play leading roles in the global collaboration network. Specifically, the size of the nodes reflects each country's importance in the network, with larger nodes indicating a higher number of published papers. The United States leads with 3262 papers, followed by China with 1447 papers, and the United Kingdom with 1094 papers (Table 3). The lines connecting the nodes represent the collaboration between countries, where thicker lines signify stronger collaborative relationships. This strength is quantified by the TLS, as shown in Table 3. In this regard, the United States, the United Kingdom, and China rank the highest in TLS as well, with values of 1792, 1425, and 779, respectively. In this case, TLS reflects the cumulative strength of coauthorship ties a country maintains with others, helping identify central players in the global landscape of aging research collaboration.

Additionally, in earlier years (eg, around 2017), collaborations were predominantly centered in Western countries such as the United States, Italy, Germany, France, Switzerland, and the Netherlands, as indicated by the blue and purple lines in Figure 4. In contrast, more recent collaborations (eg, around May 2019) are represented by green and yellow lines, showing a growing focus on research applying aging concepts in Asian countries, with China leading the way. This shift has also seen increased collaborations involving countries like South Korea, Thailand, Malaysia, and Singapore, reflecting a broadening of the global research network. Nevertheless, the persistent dominance of high-income Western countries in collaborative centrality suggests an imbalanced global discourse, potentially constraining the diversification of narrative perspectives in aging research.

Figure 4. Global collaboration network map generated by VosViewer.

Analysis of Aging Concepts: Frequencies, Emergence, and Categorization

Frequencies of 16 Aging Concepts in Aging-Related Research

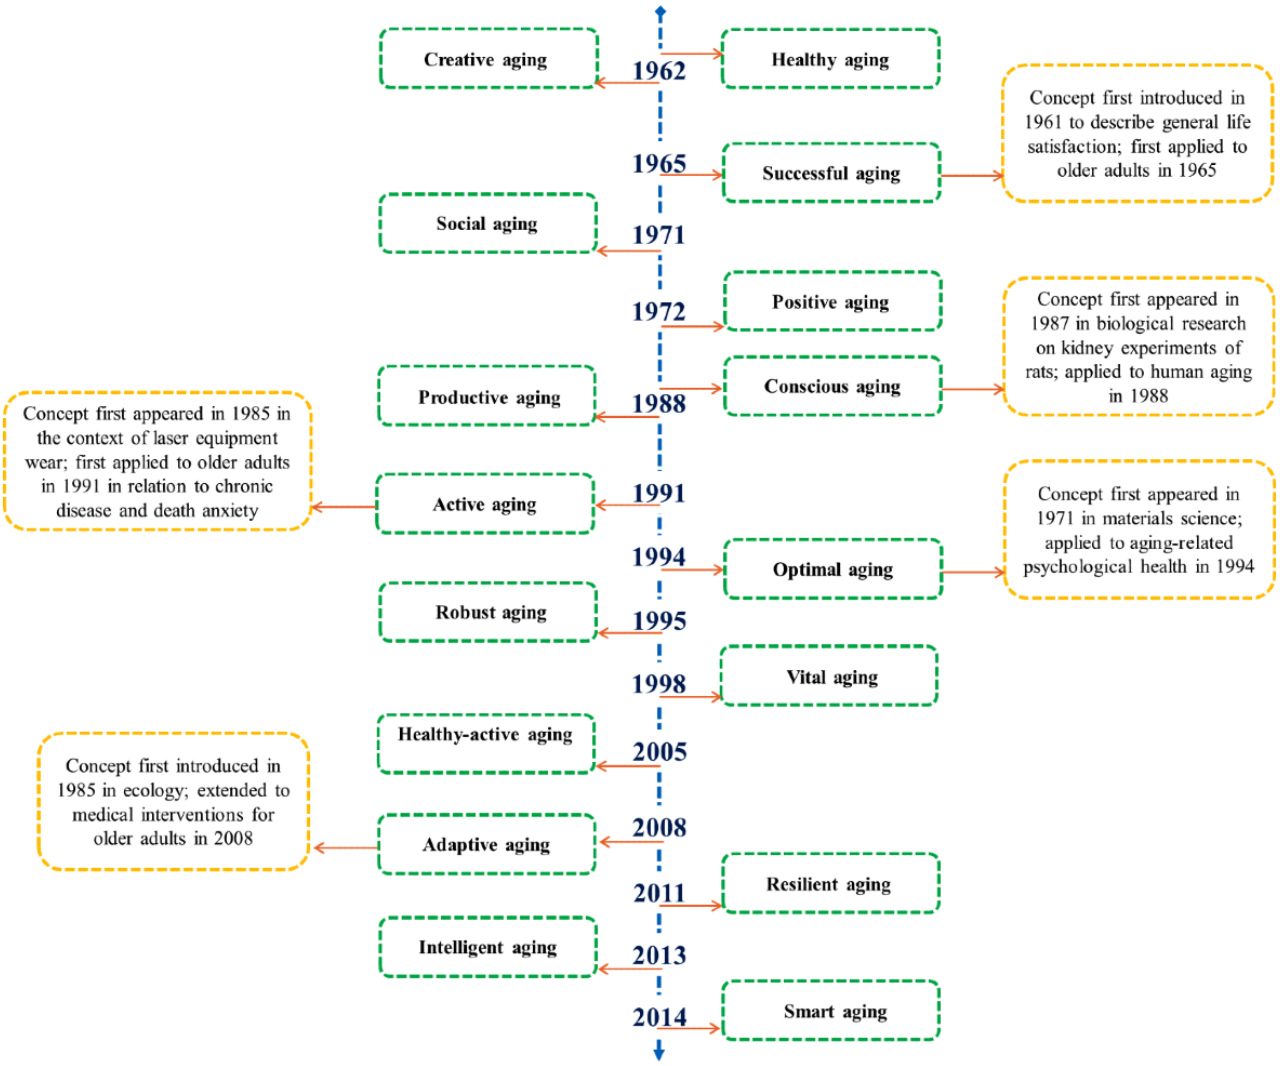
Multimedia Appendix 2 presents the frequency of aging concepts identified through the corpus linguistic software AntConc, analyzing titles, abstracts, and keywords across 10,642 papers (dataset 1). These frequency data reflect the academic attention given to different aging concepts, and higher frequencies suggest greater scholarly interest, while lower frequencies may indicate emerging or more niche research areas.

The most frequently used aging concept is “healthy aging,” which appears 9710 times and indicates that health is a major focus in aging-related research. Other commonly used aging concepts include “successful aging” (5237 times) and “active aging” (3210 times), reflecting attention on maintaining function and engagement in older age. On the other hand, less frequently mentioned concepts are “robust aging” (8 times) and “conscious aging” (17 times), suggesting that these concepts are less explored or emerging in aging-related research.

Emergence Time of 16 Aging Concepts

Figure 5 presents the years when aging concepts were first explicitly applied to older adult populations in academic literature, revealing their increasing diversity over time. Notably, to explore the differences in the initial emergence time and application of these concepts, a comparison was made between the search results of 16 aging concepts when used as standalone

XSL•FO
RenderX



keywords and when combined with keywords related to the aging population. In Figure 5, the emergence time of each aging concept reflects the first documented use in academic literature where the term is explicitly applied to human aging or older adults, rather than its first-ever mention in any unrelated scientific field.

In terms of the time dimension, the earliest aging concepts are "healthy aging" (1962), "creative aging" (1962), and "successful aging" (1965). These concepts were initially introduced from nutrition, gerontology, and medicine perspectives. The first concept was "healthy aging," which originated from a nutritional perspective, focusing on how nutrition can slow down physical decline and prevent diseases to improve the quality of life for older adults [33]. "Creative aging" initially encouraged reflection on the reasons behind the pursuit of longevity, emphasizing that beyond disease management, attention should be given to personal growth and the richness of life experiences [34,35]. The concept of "successful aging" first appeared in 1961 in general psychological literature, but its first explicit use in aging-related research occurred in 1965 [36]. Research in 1965, focusing on the facts of impacting aging for older adults, highlighted the need to distinguish between aspects of aging due to the natural aging process and those more closely related to individual lifestyles or situational factors unrelated to aging [37].

From the 1970s to the 2000s, perspectives on aging concepts gradually expanded, introducing a range of ideas, including social aging in 1971, optimal aging in 1994, positive aging in 1972, adaptive aging in 2008, active aging in 1991, conscious aging in 1988, productive aging in 1988, robust aging in 1995, and vital aging in 1998. Specifically, in 1971, the concept of "social aging" was introduced for the first time, emphasizing that the irreversible loss of an individual's ability to choose what they can do is the most important indicator of aging, whether social or physical aging [38]. That same year, the concept of "optimal aging" also emerged, initially referring to the aging process of metals [39]. It was not until 1994 that the term was applied to older adults, proposing that a positive mental outlook could help them cope constructively with the challenges of aging [40]. In 1972, the term "positive aging" appeared for the first time in the literature, mainly in relation to controlling Hodgkin's disease [41]. In 1985, "adaptive aging" was first mentioned in the field of ecology [42], and by 2008, the concept had been applied in medical research related to older adults [43]. The term "active aging" initially appeared in the literature related to laser equipment wear [44], but was first applied to human aging in 1991, when discussions on chronic disease and death anxiety associated the term with older adults [45]. In 1987, the term "conscious aging" first appeared in biological research related to kidney experiments on rats [46]. The year 1988 is used in the timeline to reflect the earliest application of the term to human aging. In 1988, the concept of "productive aging" emerged, which highlighted how aging amplified economic, political, and moral issues, shifting the focus toward social policy [47]. "Robust aging" was first introduced in 1995, with criteria including greater social interaction, better health and vision, and fewer significant life events for older individuals [48]. Finally, in 1998, the concept of "vital aging" was introduced in psychological health programs, focusing on the development of mental health skills and the effectiveness of changing attitudes, beliefs, and behaviors, providing the motivation and support needed for individuals to make important lifestyle changes and create a more vibrant and productive later life [49].

XSL•FO
RenderX

Figure 5. Timeline of aging concepts first applied to older adult populations in academic research. The main timeline indicates the year when each concept was first applied in academic research, focusing specifically on human aging or older adults. Additional dates in red indicate when the concept first appeared in academic literature, including in nonaging or nonhuman contexts such as materials science, ecology, or animal research.

In the 21st century, concepts like "healthy-active aging" (2005) and "resilient aging" (2011) were introduced, and with the rapid advancement of technology, newer concepts such as "intelligent aging" (2013) and "smart aging" (2014) also emerged. In particular, "healthy-active aging" was first introduced in 2005, suggesting that free health checks and financial advice can be effective for older adults, while knowledge acquisition and social activities enhance their sense of control, especially in impoverished areas [50]. The concept of "resilient aging" was introduced in 2011, offering a useful framework for understanding the mechanisms of aging in the context of disease-related pathologies [51]. "Intelligent aging" emerged in 2013 in response to the growing aging population and shrinking tax base, increasing demand for health care and housing services, while IAServ, a cloud-based platform, aims to provide personalized, scalable, and cost-effective home care through modern technology [52]. In 2014, the concept of "smart aging" was first introduced, emphasizing a positive acceptance of later life and framing aging as a developmental stage toward intellectual maturity [53].

In summary, the years presented in Figure 5 are selected based on a consistent criterion: only the first documented applications explicitly related to human aging or older adult populations are included. Aging concepts have evolved from a narrow focus on health and success to encompass a broader, multidimensional view that includes psychological, social, and technological aspects. Over time, society's understanding of aging has deepened, and future research in this field will likely emphasize interdisciplinary approaches to address the complex challenges of aging. This shift in perspective not only reflects changing societal needs but also provides more comprehensive strategies for dealing with the aging population.

Top 3 Aging Concepts: Publication Growth and Trends Comparison

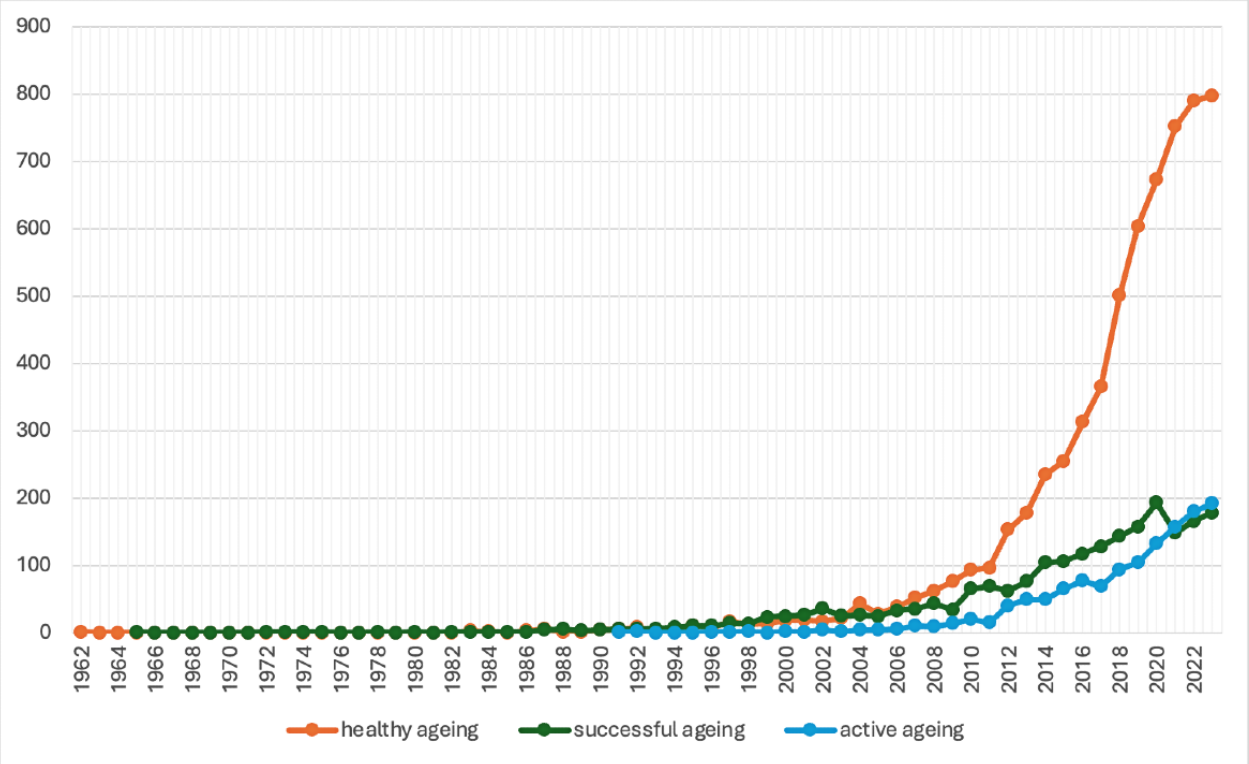


Figure 6 shows the top 3 popular aging concepts among the 16 identified: "healthy aging," "successful aging," and "active aging," reflecting significant growth from 1962 to 2023, but at varying rates. "Healthy aging" saw a sharp rise in attention after 2010, with a particularly rapid increase after 2020, becoming the dominant aging concept mentioned in research. On the other hand, "successful aging" and "active aging" gained more steady attention starting from the 1990s. "Active aging" experienced slightly faster growth after 2000, and especially after 2019,

XSL•FO
RenderX

surpassing "successful aging" in growth rate, reflecting an increased emphasis on older adults' participation in social activities and maintaining an active lifestyle.

This trend suggests that while "healthy aging" has become the dominant concept, the steady growth of "active aging," particularly its acceleration after 2019, highlights an increasing emphasis on the importance of older adults actively participating in society and maintaining an engaged lifestyle. Compared to other more established concepts, there is likely to be a greater future focus on leveraging "active aging" to improve the quality of life for older adults, encouraging their active social integration and promoting their overall well-being.

Figure 6. Successful aging, healthy aging, and active aging concepts: publication trends over time (1961-2023). Frequency of 16 aging concepts in achieving "age well."

Multimedia Appendix 3 shows the frequency of 16 aging concepts in the text of titles, abstracts, and keywords across 1402 papers (dataset 2: searched in the Scopus database using the keywords "age well" OR "aging well" OR "ageing well" limited to English-language journal papers), identified through the corpus linguistic software AntConc. This comparison evaluates how effectively the identified aging concepts from dataset 1 are reflected in the more naturalistic academic discourse surrounding "aging well," thereby indicating their narrative integration and relevance across different contexts. The comparison of the use frequency of different aging concepts reveals that "successful aging (417 times)" is the popular aging concept in discussions of how to achieve "age well," followed closely by "healthy aging (247 times)" and "active aging (180 times)."

Additionally, less frequently mentioned concepts, such as "positive aging" and "productive aging," are mentioned 70 and 14 times, indicating that while less prominent, there is still interest in aging's psychological and social contribution aspects. Aging concepts such as "adaptive aging" and "resilient aging" appear very rarely, with just 3 and 1 occurrences, suggesting that these concepts, though relevant to coping with aging challenges, have not yet gained significant traction in the literature. Likewise, concepts like "intelligent aging" and "smart aging" were not found, reflecting that while there may be much research into how technology supports older adults in adapting to their environments, they have yet to become mainstream but may hold potential for future exploration.

Categorization and Core Focus of 16 Aging Concepts

Table 4 summarizes 16 aging concepts, detailing their core focus and application areas and categorizing them into 4 groups, including (1) health and well-being, (2) social engagement, (3) technology and innovation, and (4) resilience and adaptation. Analyzing these concepts reveals how the academic community prioritizes different aspects of aging and applies them in practice. Although all the concepts share the common goal of improving the quality of life for older adults, each contributes a distinct perspective to the field of aging-related research.

The concepts of aging, such as healthy aging, successful aging, optimal aging, positive aging, and vital aging, can be categorized as part of the Health and Well-being Aspect. These concepts aim to promote health and overall well-being, yet they approach this goal from varying angles. Healthy aging primarily promotes overall health through public health initiatives and disease prevention. Successful aging highlights the importance of maintaining both physical and mental health, focusing on how psychological well-being and social support enhance quality of

XSL•FO
RenderX

life. Optimal aging takes a broader approach, addressing physical, emotional, and cognitive health, aiming to extend a healthy lifespan through community well-being and health promotion programs. Positive aging focuses more on mental well-being, such as maintaining a positive attitude and emotional resilience. Finally, vital aging stresses lifelong adaptation for their well-being, encouraging older adults to remain independent and active through lifelong learning and adaptability.

XSL•FO
RenderX

Table . Comparisons of the core focus of 16 aging-related concepts.

Categorizations and aging concepts	Core focus	Application areas
Health and well-being aspect		
Healthy aging	Focuses on achieving a high quality of life through promoting overall health and preventing disease during the aging process.	• Public health • Older people care • Disease prevention
Successful aging	Focuses on maintaining physical and mental health in later life and enhancing quality of life.	• Older people health management • Mental health • Social policy
Optimal aging	Focuses on promoting health, longevity, and overall well-being by addressing physical, emotional, and cognitive aspects of aging, ensuring individuals remain independent and active as they age.	• Health promotion • Community well-being • Emotional and sensory wellness • Public health programs • Evidence-based information • Dissemination
Positive aging	Focuses on the importance of maintaining a positive attitude, psychological resilience, and emotional well-being.	• Mental health • Emotional well-being • Psychological therapy
Vital aging	Emphasizes lifelong adaptation to maximize health, independence, and cognitive and emotional well-being, promoting active and successful aging through various programs and interventions.	• Lifelong adaptation • Mental fitness • Lifelong learning • Environmental policies • Cultural context • Community-based programs
Creative aging	Focuses on enhancing the psychological and social well-being of older adults through artistic and cultural activities.	• Art or culture engagement • Psychological therapy
Social engagement aspect		
Active aging	Focuses on the active participation of older adults in social activities and maintaining physical vitality.	• Social participation • Community activities • Sports and recreation
Social aging	Focuses on the roles and interactions of older adults in society, examining how social, economic, and cultural factors influence the aging process.	• Sociological research • Social policy • Analysis of older adults' social roles
Productive aging	Focuses on the active participation of older adults in socially productive activities, such as volunteering, caregiving, and work, contributing to society while enhancing individual well-being.	• Community volunteering • Social support • Health literacy • Cultural differences • Government policies • Workforce participation • Lifelong learning
Conscious aging	Emphasizes deep reflection on the aging process, spiritual growth, and contemplation of life.	• Spiritual requirements • Lifelong learning • Personal growth
Health and well-being and social engagement aspect		
Healthy-active aging	Combines elements of healthy aging and active aging to maintain vitality and health in older adults.	• Health promotion • Community health • Older people care
Technology and innovation aspect		

XSL•FO
RenderX

Categorizations and aging concepts	Core focus	Application areas
Smart aging	Focuses on supporting the quality of life of older adults through smart technologies such as virtual reality, data privacy protection, and smart cities.	• Smart homes • Health monitoring • Smart city development
Intelligent aging	Mainly involves the application of smart technology in health monitoring and management.	• Smart health monitoring • Personalized health care • AI[a]-assisted living
Resilience and adaptation aspect		
Adaptive aging	Emphasizes optimizing design and infrastructure to accommodate the physical and cognitive changes associated with aging.	• Public infrastructure design • Product design • Biomedical research
Resilient aging	Emphasizes the adaptability and psychological resilience of older adults in the face of challenges.	• Mental health • Coping strategies • Crisis management
Robust aging	Focuses on maintaining vitality across physical, emotional, cognitive, and social domains, with an emphasis on resilience and adaptability throughout the aging process.	• Productive involvement • Affective status • Functional status • Cognitive status • Physical activity • Social engagement • Cellular biomarkers • Cross-generational aging

[a]AI: artificial intelligence.

In a related area, aging concepts of active aging, social aging, productive aging, creative aging, and conscious aging all fall under the aspect of social engagement, but they each emphasize different areas. Active aging encourages older adults to stay involved in social and physical activities, promoting vitality. Social aging examines the social roles of older adults and the impact of social, economic, and cultural factors. Productive aging highlights older adults' contributions to society through activities like volunteering and work, enhancing well-being. Creative aging improves emotional health through engagement in art and culture, while conscious aging emphasizes personal and spiritual growth through reflection on life. Notably, healthy-active aging belongs to both healthy-active aging and social engagement aspects because it combines elements of both healthy and active lifestyles, supporting older adults in maintaining vitality and well-being by staying physically and mentally active.

The technology and innovation aspect encompasses aging concepts like smart aging and intelligent aging, both of which address the role of technology in supporting older adults. Although both concepts highlight the importance of smart technologies, they diverge in their specific applications. Smart aging focuses on enhancing daily life through technologies such as smart homes and health monitoring systems, while intelligent aging integrates artificial intelligence (AI) and data science to provide personalized health care solutions, illustrating the increasing role of AI in aging research. While both are grounded in technology-based theories, intelligent aging emphasizes more prominently data-driven approaches and AI.

Within the resilience and adaptation aspect, concepts like resilient aging, adaptive aging, and robust aging focus on older adults' capacity to adjust to the changes accompanying aging. Resilient aging highlights psychological resilience, emphasizing older adults' ability to cope with challenges. On the other hand, adaptive aging explores how design and infrastructure can be optimized to accommodate physical and cognitive changes in aging. Robust aging takes a more comprehensive approach, incorporating resilience across physical, cognitive, emotional, and social domains and integrating biological markers to assess longevity and health outcomes.

Challenges and Future Trends of Achieving Aging Concepts

The 16 aging concepts reflect the academic community's vision of promoting "aging well" from various perspectives. Through content analysis, Table 5 outlines the challenges in achieving the goal of each aging concept and future trends in applying each aging concept. Although the challenges—such as unequal access to resources, technological barriers, and cultural differences—are significant, there are promising opportunities for innovative and sustainable solutions. Advances in technology and a growing global focus on aging will create opportunities for policy makers, researchers, and communities to collaborate in addressing these challenges. By doing so, older adults worldwide can anticipate a safer, healthier, and more fulfilling aging process, regardless of their social, cultural, or economic backgrounds.

XSL•FO
RenderX

Table . Challenges and future work of 16 aging-related concepts.

Aging concepts	Challenges in achieving the goal of each aging concept	Future trends in applying each aging concept
Healthy aging	• Lack of interdisciplinary collaboration and long-term investment • Unequal access to medical resources globally	• Greater integration of healthy aging initiatives in public health policies • Growing focus on preventive health management due to accelerated global population aging
Successful aging	• Challenges in defining "success" across diverse cultural backgrounds • Difficulty in setting a universal standard due to significant variation in individual health status	• Increasing emphasis on social policies aimed at supporting older adults to maintain a high quality of life in their later years • Expanded community support, health care, and mental health services for older adults
Active aging	• Challenges of physical and environmental barriers for sustained participation • Difficulty for older adults in economically and infrastructurally disadvantaged areas	• Advances in technology enabling digital activities and remote participation as new means for older adults to engage socially • Increased participation of older adults in social activities through web-based communities and digital courses
Positive Aging	• Challenges due to negative stereotypes of aging hindering broad acceptance • Limited resources to address mental health issues in older adults across sectors	• Increasing awareness of mental health leading to greater focus on the mental health and emotional well-being of older adults • More mental health services and support programs emerging to address the needs of older adults
Smart aging	• Barriers due to high costs of technology application and unresolved data privacy issues • Challenges in older adults' acceptance of technology	• Further development and widespread adoption of smart homes, wearable devices, and health monitoring technologies • Enhanced safety and independence for older adults living at home through advanced technologies
Social aging	• Challenges arising from differences in social structure and culture for older adults • Difficulty in developing universal solutions due to varying social challenges across countries and communities	• Increased focus on aging issues leading to more policies and research on role transitions of older adults in society • Emphasis on cultural and social support to enhance social participation of older adults
Creative aging	• Insufficient resources for creative activities in certain areas • Limited opportunities for older adults in remote or resource-scarce communities	• Remote art programs and digital creative workshops providing opportunities for older adults to engage in creative activities when in-person participation is not possible • Growing importance of digital platforms postpandemic facilitating creative engagement for older adults
Adaptive aging	• Challenges due to the diversity and complexity of older adults' needs for product design • Significant time and financial resources required to promote and apply adaptive design in public infrastructure	• Increasing focus on adaptive and accessible design in the construction of future cities and public infrastructure • Ensuring safe and comfortable environments for older adults through improved urban and infrastructure design
Resilient aging	• Challenges due to considerable variability in individual psychological resilience • Imbalances in social support systems affecting older adults' ability to build resilience across countries and communities	• Fostering psychological resilience in older adults becoming a priority amid increasing global social and environmental crises • Further development of psychological support programs and community support networks for older adults

XSL•FO
RenderX

Aging concepts	Challenges in achieving the goal of each aging concept	Future trends in applying each aging concept
Healthy-active aging	• Challenges in coordinating resources across multiple fields for multidimensional health • Difficulty in achieving health goals in economically underdeveloped or resource-limited regions	• Expansion of community health programs, particularly through digital health platforms • Promotion of healthy behaviors among older adults via digital health initiatives
Intelligent aging	• Challenges due to high cost and complexity of technology limiting its application range • Difficulty in acceptance of smart technologies by older adults	• Increasing role of AI[a] and big data in personalized health management • Emergence of more AI-based health solutions for older adults
Conscious aging	• Challenges due to varying cultural importance placed on the spiritual life of older adults • Limited societal attention to spiritual health compared to physical health hindering development in this area	• Increasing global attention to mental and spiritual health leading to greater promotion of spiritual support programs for older adults • More widespread adoption of practices such as meditation and yoga among older adults
Productive aging	• Challenges due to disparities in access to social support and education • Varying cultural perspectives on aging as a barrier • Unequal access to workforce participation opportunities for older adults	• Increasing promotion of productive aging through policy initiatives, focusing on the integration of older adults in the community and workforce • Key trends of lifelong learning and flexible work opportunities for older adults
Robust aging	• Challenges due to variability of aging experiences across generations • Disparities in access to health care and social support systems • Differences in biomarker availability and interpretation	• Advancements in biotechnology and understanding of cellular aging driving robust aging strategies toward personalized health interventions • Importance of cross-generational health programs and adaptive aging practices in future public health initiatives
Optimal aging	• Challenges due to gender disparities in aging experiences • Unequal access to health care and wellness programs • Need for broader dissemination of reliable health information	• Growing emphasis on evidence-based health interventions and gender-specific aging strategies • Increasing focus on optimal aging through personalized health plans, community support systems, and stress management techniques
Vital aging	• Challenges due to disparities in educational opportunities • Environmental inequalities impacting aging experiences • Cultural differences in aging experiences across regions • Accessibility issues of programs in different regions	• Focus on expanding vital aging programs globally, emphasizing integration of environmental policies • Attention to mental fitness initiatives to enhance aging experiences across different cultural contexts

[a]AI: artificial intelligence.

One of the primary challenges in achieving the goal of these aging concepts is the global disparity in medical and health care resources, particularly in economically disadvantaged regions where access to medical services is limited. This inequality hampers older adults' ability to maintain both physical and mental health and benefit from preventive health care strategies. In the future, public health efforts should focus on integrating preventive health care with personalized interventions, ensuring that older adults have access to the necessary resources to support their well-being, regardless of location.

In addition to health care challenges, promoting social participation among older adults presents another major obstacle. Factors such as social structures, economic development, and cultural differences often create barriers to maintaining social connections and engaging with communities. Many societies prioritize physical health while neglecting emotional and spiritual needs. Cultural differences also influence the emphasis placed on spiritual life, making it difficult to implement universally applicable support systems. However, with growing global awareness of mental health, more programs are likely to address the emotional and spiritual well-being of older adults.

XSL•FO
RenderX

Practices such as meditation, yoga, and other spiritual activities are expected to become more widespread, fostering a sense of fulfillment and psychological balance. Additionally, in many regions, older adults struggle to fully participate in social life due to a lack of flexible employment options and inadequate lifelong learning opportunities, further limiting their engagement. Balancing physical health with mental and spiritual well-being remains crucial. To improve the quality of life for older adults, future policies should focus on strengthening social support networks and providing meaningful opportunities for social participation, which in turn will enhance their mental health and sense of belonging.

Adopting technology to improve older adults' lives also presents unique challenges. While technological solutions like smart homes, wearable devices, and health monitoring systems hold great potential, their high costs and complexity often limit widespread adoption, particularly in resource-constrained regions. Privacy concerns further complicate the integration of these technologies into everyday life. Future technological developments must focus on reducing costs, improving accessibility, and ensuring data security to make these tools more inclusive. Additionally, creative activities remain unevenly distributed, especially in remote areas, which are key to promoting older adults' emotional and social well-being. Expanding web-based platforms will provide older adults with greater access to creative opportunities, helping bridge the gap between regions with varying resource availability.

Finally, fostering older adults' adaptability to changing environments and promoting psychological resilience is crucial for their overall well-being. Developing these qualities requires significant time and financial investment. Public infrastructure and services must be optimized to meet the diverse needs of older adults, ensuring they can live in safe and comfortable environments. Building community support systems and mental health programs will also be critical in fostering psychological resilience, especially as global social and environmental crises increasingly affect vulnerable populations. Future urban planning efforts should prioritize adaptive design to create environments that support older adults' physical, mental, and emotional health.

These challenges and future trends were derived from the content analysis process and thematically coded based on recurring contextual patterns. They also provide insight into the limitations of existing aging narratives and help identify conceptual gaps that could inform a more inclusive and multidimensional shift in aging discourse.

Discussion

Principal Findings

This study found that although a wide range of aging concepts have been introduced in academic literature, their overall impact on reframing negative aging narratives remains limited. The analysis revealed that most applications of these concepts continue to be concentrated in biomedical fields, with relatively less integration of social and economic dimensions. While some concepts promote multidimensional perspectives, their practical influence on shifting aging discourse is still fragmented and uneven. The demographic shift toward an aging population has led to rising concerns about "ageism," which reinforces stereotypes of older adults as cognitively and physically declining, resistant to change, or burdensome to society [54,55]. These views contribute to social exclusion and negatively affect older adults' mental and physical well-being. Academic research plays a key role in challenging such narratives by adopting a more comprehensive view of aging that encompasses physical, cognitive, emotional, social, and economic dimensions [56,57]. Recognizing older adults' contributions—through work, caregiving, community participation, and cultural knowledge—can reshape how society perceives aging and promote age-inclusive policies [58-60].

The primary goal of this study is to explore whether and how research applying aging concepts contributes to shifting the negative narrative on aging in academia. The overall results show that while great efforts have been made, progress has been limited. As outlined in the Methods section, the dominance of biomedical framing and the lack of social and economic integration indicated a limited narrative shift. While the bibliometric analysis reveals a significant increase in aging concept research across disciplines, the concentration in medical fields and minimal attention to social and economic aspects still reflect an uneven narrative shift. Although many of these studies aim to promote "aging well," they often take a narrow approach, focusing mainly on medical aspects such as disease control, health maintenance, and longevity. This limited perspective, while contributing to a partial change in the perception of aging, can inadvertently reinforce stereotypes (thinking: equating aging with poor health), prejudice (feeling: viewing older adults as less capable), and discrimination (acting: excluding older adults from work and daily life) [61]. Aging is a natural part of life and requires medical support across the human lifespan, but a holistic perspective on aging should extend beyond medical aspects to include social, economic, and other dimensions, generating a more balanced and comprehensive understanding of aging [62-64].

While the emergence of diverse aging concepts reflects an aspirational effort to counter negative narratives, our findings suggest that their actual impact has been uneven and often limited. Several factors may help explain this discrepancy. Many aging concepts lack consistent definitions, making them difficult to operationalize across disciplines and policy settings. The continued dominance of a biomedical focus further restricts their narrative potential. Furthermore, some concepts—such as "successful" or "active" aging—have been critiqued for reinforcing idealized standards or placing the responsibility of healthy aging on individuals, which may unintentionally perpetuate ageist assumptions. These limitations highlight the gap between conceptual intention and actual discursive impact.

These findings can be further interpreted through the lens of narrative theory and the social construction of aging, which suggests that aging concepts do not merely describe reality but actively shape how aging is perceived and valued in society. This theoretical perspective helps explain the persistence of deficit-based frames, and the limited extent of narrative change remains despite growing conceptual diversification.

XSL•FO
RenderX

At the same time, however, research involving these aging concepts has also acknowledged the multidimensional nature of aging and highlighted the need to address it holistically in both research and policy. The content analysis of this study categorized all 16 aging concepts into four groups based on their main focus and application, contributing to a more comprehensive understanding: (1) health and well-being (eg, healthy aging, successful aging, optimal aging, positive aging, vital aging, and creative aging); (2) social engagement (eg, active aging, social aging, productive aging, and conscious aging); (3) technology and innovation (eg, smart aging and intelligent aging); and (4) resilience and adaptation (eg, adaptive aging, resilient aging, and robust aging). Although all these concepts are built upon the foundation of health, their differing emphases reflect the multidimensional nature of aging research in academia. For instance, concepts centered on health and well-being focus on enhancing physical health and quality of life, while social engagement concepts underscore the social roles and contributions of older adults.

Nevertheless, despite these expanded areas of focus, practical applications often remain fragmented, limiting their broader impact on societal perceptions of aging. Specifically, the content analysis in this study, which also explored challenges and future trends, revealed significant obstacles to achieving the goals of aging concepts, such as unequal access to health care, technological barriers, and cultural differences. For example, “smart aging” initiatives leveraging digital technology, though beneficial for enhancing independence, face barriers such as limited access and high costs, restricting their reach [65]. Similarly, resilience-oriented concepts that promote coping strategies for psychological and physical challenges often lack widespread implementation and do not significantly influence public policy or community practices [66]. These findings underscore the complexity of effectively implementing aging concepts and point to potential pathways for progress.

To drive a meaningful shift in the negative narrative on aging, interdisciplinary strategies are essential, bridging current gaps to create a cohesive and impactful transformation [67]. Several successful approaches from other domains offer promising models for adaptation in aging research. For example, universal design in urban planning can inform inclusive spaces and housing that support physical and cognitive aging. Lifelong learning platforms from the education sector can promote digital literacy and social engagement. Resilience-building frameworks, developed in clinical psychology and disaster management, offer coping strategies that can be tailored to later-life transitions. Integrating such practices into aging-focused interventions can help bring empowerment-based narratives into real-world application.

These strategies must ensure that technological advancements and global awareness translate into tangible benefits that are accessible, affordable, and inclusive for all [68,69]. Future policies should adopt a nuanced understanding of aging by fostering integrated research that unites medical, social, and technological aspects, thus enabling a holistic perspective that can reshape both academic and societal narratives on aging. For instance, practical strategies like expanding social networks, offering flexible employment, and fostering lifelong learning opportunities are crucial, as they not only enhance older adults’ sense of belonging and mental well-being but also drive a transformative shift in societal perceptions and approaches to aging [70-72]. Without such efforts, there is a risk of reinforcing existing inequalities rather than resolving them. As indicated by the cocitation and collaboration analyses, current aging research remains structurally concentrated within biomedical networks and Western regions, suggesting that future narrative shifts require more interdisciplinary and globally distributed scholarly engagement.

Limitations and Future Directions

While this study offers valuable insights for both researchers and policy makers, it has certain limitations. The exclusive reliance on the Scopus database may have led to the omission of relevant studies from other sources. Additionally, although multiple analytical tools such as VosViewer and AntConc were used, differences in their functionalities may introduce interpretation biases. Furthermore, this study did not fully explore these aging concepts’ roles in policy-making and cross-cultural contexts, leaving room for future research in these important areas.

Future research could address several areas identified in this study. First, expanding the data sources to include additional databases (eg, Web of Science or PubMed) may broaden disciplinary representation. Second, exploring how aging concepts are implemented and interpreted in policy settings would help assess their practical influence. Third, cross-cultural comparisons could reveal differences in how aging narratives are constructed globally. Finally, mixed method approaches combining bibliometric, linguistic, and qualitative data could provide a more comprehensive understanding of both academic and societal impacts of aging discourse.

Conclusions

This study comprehensively analyzes 16 aging concepts, elucidating their main focuses, applications, and the challenges and future trends associated with their implementation. The analysis reveals an overall picture of the academic landscape, including the distribution of journals and disciplines, as well as cocitation networks and regional collaborations. “Healthy aging” emerged as the most dominant concept according to its frequency in the 2 datasets. A content analysis further categorized the 16 concepts into four primary groups based on focus and application, enhancing our understanding of their roles: (1) health and well-being (eg, healthy aging, successful aging, optimal aging, positive aging, vital aging, and creative aging); (2) social engagement (eg, active aging, social aging, productive aging, and conscious aging); (3) technology and innovation (eg, smart aging and intelligent aging); and (4) resilience and adaptation (eg, adaptive aging, resilient aging, and robust aging). Notably, “healthy aging” and “creative aging” were the earliest concepts, first appearing in 1962, marking the beginning of an evolving discourse on aging. While these concepts collectively aim to enhance the quality of life for older adults and reshape the negative narrative on aging, progress has been uneven, with many efforts remaining siloed and largely focused on medical aspects. Although there has been a shift toward more holistic perspectives, including social engagement,

XSL•FO
RenderX

resilience, and technological adaptation, these approaches have yet to achieve widespread and integrated impact.

This classification was developed through systematic content analysis, grouping concepts by their primary thematic focus and area of application. It serves not only as a descriptive framework but also offers practical relevance. For researchers, it highlights patterns across disciplines and identifies gaps for future study. For policymakers, it enables more targeted approaches—for instance, by aligning interventions with specific conceptual clusters such as promoting social participation or enhancing technological access for older adults. This structured understanding of the aging discourse can guide more coordinated, interdisciplinary strategies in both research and policy development.

This study contributes uniquely to the existing literature in several ways. First, it provides a comprehensive cross-conceptual comparison of 16 aging frameworks, offering a panoramic view that is rarely achieved in prior studies focused on single concepts. Second, by integrating bibliometric mapping with corpus linguistic analysis, it introduces a multimethod approach that captures both the structural distribution and the narrative functions of aging discourse. Third, the study applies a theoretically grounded lens—drawing on narrative theory and the social construction of aging—to assess how conceptual framing influences the persistence or transformation of age-related narratives. Together, these contributions advance a more integrated and reflexive understanding of how academic discourse shapes societal perspectives on aging.

Significant challenges persist, including unequal access to health care, technological barriers, and cultural differences, which complicate the effective implementation of these aging concepts. Addressing these challenges requires coordinated strategies that ensure accessibility, affordability, and inclusivity, translating technological advancements and global awareness into tangible benefits for all older adults. Future policies must be informed by a nuanced understanding of aging, emphasizing preventive health care, personalized interventions, and social and psychological support. Practical measures like expanding social networks, offering flexible employment, and fostering lifelong learning opportunities are essential for promoting a sense of belonging and enhancing mental well-being among older adults.

Data Availability

The datasets analyzed during this study are available through the Scopus database (Elsevier, Amsterdam, Netherlands). The data are publicly accessible to researchers with institutional access to Scopus. The studies reported in the manuscript were not preregistered.

Abstract

Background: Pandemics, such as COVID-19, and climate change–related catastrophic weather events are increasing, impacting social connectedness within communities by disrupting social cohesion, increasing loneliness, and affecting mental health and social well-being. Digital technology, in addition to being used for communication, education, and business transactions, also plays a vital role in maintaining a country's health and well-being, as well as sustaining economic growth.

Objective: This study aimed to explore the experiences of Māori kaumātua in using digital technology to meet their health needs within Ngāti Kahungunu, North Island, New Zealand, during the COVID-19 pandemic and Cyclone Gabrielle.

Methods: This qualitative study employed the Kaupapa Māori methodology to understand the challenges, resilience, and approaches used by Māori to maintain connectedness and access essential services. An inductive approach to thematic analysis, as recommended by Braun and Clarke, was used to ensure a thorough and robust data analysis. The user characteristic was assessed on a semantic level using the information provided in the narrative text.

Results: The findings highlight the role of digital technology in disaster management and underscore the urgent need to address digital disparities in support of vulnerable populations. In this study, 14 individuals were interviewed, comprising 71% (n=10) women and 29% (n=4) men. These participants fell into different age groups, with 9 participants being 65 years or older (older adults). Of the total participants, 43% (n=6) were limited users, 43% (n=6) comprised confident users, and the rest (n=2; 14%) were normal users. A total of 6 themes emerged from the interview data: social connectedness and resilience, digital literacy and access to information, barriers to telecommunications and digital technology, cultural appropriateness and psychological barriers, perceived threats of feeling insecure, and impact on mental health and emotional well-being.

Conclusions: Vulnerable situations such as pandemics and extreme weather events can have tremendous effects on the lives of Indigenous people who live remotely. The study also focused on the actions that should be taken to mitigate these challenges and overcome difficult circumstances, such as the pandemic and the cyclone. The recommendations include a better health care system and improved coordination among care providers, user-friendly digital solutions, ensuring local funding and community services, establishing training processes for basic digital skills, and fostering leadership and partnerships with Indigenous New Zealanders.

(JMIR Aging 2025;8:e73974) doi:10.2196/73974

KEYWORDS

community service; COVID-19; Cyclone Gabrielle; digital exclusion; digital solutions; disaster management; health inequalities; Māori kaumātua; Ngāti Kahungunu; training and education

Introduction

Background

Pandemics, such as COVID-19, and climate change–related catastrophic weather events are increasing, impacting social connectedness within communities by disrupting social cohesion, increasing loneliness, and affecting mental health and social well-being [1,2]. Displaced populations and resource scarcity can reduce social functioning. However, the breakdown of local support systems is one of the key factors that maintain social functioning and can have a significant impact on communities. Psychological impacts such as anxiety and fear of future events diminish social engagement, particularly for

XSL•FO
RenderX

vulnerable groups such as older people [1,2]. Indigenous older people are generally more vulnerable (or at risk) in each of those domains, such as COVID-19, natural disasters such as Cyclone Gabrielle, and digital technologies [3-5].

The Context of the COVID-19 Pandemic in New Zealand

New Zealand, a small island nation with a population of approximately 5 million, is a diverse community, with significant representation from the Māori communities (16%), Asia (15%), and the Pacific Islands (7%), as well as Europe and other countries (62%) [6]. Māori are the Indigenous people of New Zealand. They migrated from Polynesia to New Zealand more than 800 years ago. Their tradition and culture are deeply rooted in respect for nature, community, and their kaumatua (elders) [7]. The New Zealand government introduced new strategies in response to the COVID-19 pandemic. One of the strategies includes a 4-tiered alert system that indicates the severity of the COVID-19 situation and corresponding measures [8]. This system, which ranges from Alert Level 1 (prepare) to Alert Level 4 (lockdown), was not only highly regarded worldwide but also proved effective in managing the crisis [9].

Most of the workforce, excluding essential workers such as staff from supermarkets, hospitals, and transport, was advised to work remotely during the lockdown period [9]. Daily media briefings, led by government officials like the Prime Minister and Director-General of Health, were broadcast on the radio to keep the population updated about the impact of the disease in the country and the plans to eliminate it [10]. Websites and the national emergency broadcast system were used to advise the public regarding safety measures [11]. Important information from the "Unite Against COVID-19 website" and the number for free helplines were also shared on social media platforms, such as Facebook, Twitter, Instagram, LinkedIn, and WhatsApp, by government agencies [4]. These ways of communication and working meant that people had to rely on digital technology during the crisis period.

The Context of Cyclone Gabrielle in New Zealand

Cataclysmic weather episodes are increasing globally, adversely contributing to the rise in health-related risks [12], food security, livelihoods, clean water supply, and human security [13]. Climate change–related health effects are variable for different populations as they depend on geographical positioning, health system capacity and capability, demographics, and the disease burden of communicable and non-communicable diseases [14]. The world faces a distinctive challenge with the rapidly changing climate and the rising frequency of extreme weather events. In the recent decade, the prevalence of extreme weather events has escalated due to climate change and global warming [12,14]. Coronese and colleagues established a compelling relationship between climate change and the heightened frequency and severity of extreme weather events in numerous regions of the globe [15]. The Intergovernmental Panel on Climate Change [16] delineates the implications of climate change and climate-induced extreme weather events on socioeconomic systems, including crop damage, heightened wildfire risk, more frequent power outages, increased susceptibility to food or water shortages, and political system vulnerability [5].

Within the context of New Zealand, severe weather and climate events are frequently experienced, primarily associated with flooding that disconnects different communities and groups of people from accessing support in the form of health care services, medical and food supplies, safe drinking water supply, and safe areas for rehabilitation during disaster occurrences [17]. The year 2023 began with a series of emergencies declared in Aotearoa, New Zealand [18]. Regions, such as Coromandel/Thames and Te Tairawhiti Bay of Plenty, were hit by Cyclone Hale [19,20], not only causing considerable damage to the livelihoods of the residents but also uprooting the entire coastal ecosystem from its essence [17]. Disastrously, this was followed by Cyclone Gabrielle, which caused significant flooding in many different parts of Tamaki Makaurau and caused the government to declare a national emergency [21,22]. The devastating impact of Cyclone Gabrielle was particularly evident in regions of Hawke's Bay and Gisborne [21]. The floodwater left thousands stranded and trapped in high-risk landslide areas [23].

The Use of Digital Technologies by Indigenous New Zealanders

Over the last 2 decades, significant use of technology has been seen, mainly for communication, education, and business purposes [24]. However, in 2019, the Department of Internal Affairs reported that 1 in 5 of the population, mainly people from Māori and Pacific Islands, people living in social housing or rural areas, older persons, and people self-identifying as the unemployed and the disabled, did not have access to or the skills to use digital technology [25]. Digital technology in this context refers to electronic devices, such as computers and mobile phones, and their infrastructure (connection modalities) used for communication and sharing information. The report also highlighted that digital exclusion affected their access to education and communication and significantly impacted a person's well-being, underscoring the urgent need to address this issue, and different recommendations were proposed to overcome digital exclusion [25].

Similarly, many studies have reported health inequalities with Māori, resulting in high morbidity and mortality rates [26,27]. The incidence rate of complications and deaths has been high in the Māori communities during previous outbreaks of influenza and other communicable diseases [28]. However, there is potential for introducing positive changes by understanding the lived experiences of Māori people in using digital technology to meet their health care needs.

Study Aims

The primary aim of this exploratory qualitative study was to understand the lived experience of Māori communities in using digital technologies to meet their health care needs during the simultaneous occurrence of the COVID-19 pandemic and Cyclone Gabrielle. This study focused on the experience of Māori communities, particularly the older generation (known as kaumātua), during the COVID-19 pandemic and Cyclone Gabrielle, emphasizing the importance of digital technology in maintaining social connectedness and accessing vital services. The study explored the following research questions:

XSL•FO
RenderX

1. What was the experience of day-to-day life using digital technologies for the Indigenous New Zealanders during the COVID-19 pandemic and Cyclone Gabrielle?
2. How did the pandemic and the natural disaster affect the use of digital technologies and access to information?
3. What recommendations should be considered for using digital technologies and information access during a pandemic and natural disaster?

Methods

Overview

This was an exploratory qualitative study based on the Kaupapa Māori methodology [29]. This methodology involves research developed, conducted, and reported by Māori to promote and support their community. This research approach is grounded in Māori worldviews, values, and practices. It is a decolonizing methodology developed by and for Māori, seeking to challenge Western-dominated ways of knowing and conducting research. The Kaupapa Māori methodology prioritizes Māori aspirations, language, culture, and autonomy throughout the research process [29-31]. Kaupapa Māori research is often participatory and collaborative, focusing on creating knowledge in partnership with Māori communities. In this sense, it aligns strongly with the interpretivist approach, as it emphasizes the importance of understanding people's subjective experiences, values, and cultural contexts [32].

Data Collection

In this study, 14 Māori families from various communities within the tribe or iwi, known as Ngāti Kahungunu, participated in semistructured interviews conducted between December 2022 and February 2023. A purposive sampling method and the interpretivist approach were employed to select participants from Māori communities, as this Phase 2 study builds upon a previous research conducted by Wepa and colleagues [30], which involved interviewing a small population group. The population group represented the senior members and older adults of Māori families since they are generally more vulnerable (or at risk) in each of those domains, such as COVID-19, natural disasters such as Cyclone Gabrielle, and digital technologies. Participants who were at increased risk for adverse events were excluded. Participants ranged in age from 45 to 90 years old. A participant information sheet was provided to all participants.

These families were interviewed as a group as per the Kaupapa Māori methodology. Under this methodology, research was developed, conducted, and reported by Māori to promote and support their community [29-31]. A research assistant connected to each community supported the primary investigator in conducting the semistructured interviews from December 10, 2022, to February 16, 2023. The interviews lasted an average of 40 minutes, with the longest interview being approximately 90 minutes. The interviews were targeted at the family's senior member, such as older adults; in some cases, other family members, such as daughters, sons, and grandchildren, participated in a support role. This is because some older adults experienced difficulties with hearing or vision, making it challenging for them to participate in an interview. In such cases, family members helped by clarifying questions and reading materials aloud. Semistructured interviews were conducted by JTH and RTH (research assistants) using the interview guide (Textbox 1). The research assistants were chosen since they were familiar with the values and cultural background of the Indigenous community in New Zealand. However, the interview was not only restricted to the interview guide but also included additional social demographic information, such as age, gender, location, living conditions, which were also collected. The interviews were audio-recorded and supplemented by written field notes.

Textbox 1. Interview guide for semistructured interviews.

Interview guide

1. How did you use digital technology (during COVID-19 and Cyclone Gabrielle)?
2. Given your experiences, do you have any suggestions for what improvements could be made?
3. What process do you think providers of services could consider?
4. What process do you think (whanau, hapu, iwi) people could consider?
5. Is there something else you would like to share?
6. Is there anything else you would like to ask me?

Data Analysis

The recordings were transcribed to free-text narratives by RS (research assistant), as the researcher's background, training, and familiarity with the Indigenous community aligned with the subject matter. The free-text narratives were analyzed by MSRJ and DW and reviewed by ST to minimize bias and enhance the validity of the results, since these researchers' expertise lies within the realm of qualitative thematic analysis. An inductive approach to thematic analysis, as recommended by Braun and Clarke, was used to ensure a thorough and robust data analysis. This comprehensive approach was chosen to ensure the validity and reliability of the results, instilling confidence in the research findings [33], which involved identifying keywords and phrases from the transcripts to indicate potential relevant concepts. The extracted concepts were then grouped into a number of themes of similar nature. Discussions were held between MSRJ, ST, and DW to achieve a consensus when there was a difference in opinion, ensuring a collaborative and inclusive research process [34,35]. This collaborative approach was chosen to ensure that all perspectives were

XSL•FO
RenderX

considered, making the research process more inclusive and comprehensive [34].

Ethical Considerations

Written informed consent was obtained from them before the interviews. The process of obtaining consent involved explaining the study, its potential risks and benefits, and the participants' rights. Participation in the study was voluntary, and the participants were given the option to attend interviews at their homes or a meeting place of their choice. Transportation was arranged for participants who attended interviews at a communal place. The research grant covered participant travel costs. Ethics approval was granted by the Auckland University of Technology Ethics Committee on 10 November 2022 (Ref No. 22/30). Any personal or sensitive information collected was deidentified, and the free-text narratives were aggregated for analysis.

Results

Participants Characteristics

For this study, 14 individuals were interviewed, comprising 71% (n=10) women and 29% (n=4) men. These participants fell into different age groups, with 9 participants being 65 years or older (older adults; Table 1).

Of 14 participants, 6 lived in a rural community, with 1 residing outside of it; 2 close to it; 2 in central Hastings, Hawkes Bay; and 1 at regional Ngati Kahungunu area. Among the remaining participants, 3 resided in Havelock North, 1 in Matahiwi Marae Base, 1 in regional Ngati Kahungunu area, 1 at the central location, and 1 outside Hastings, Hawkes Bay (Table 1). These are the places where Māori populations were mainly represented.

The participants older than 65 years and living with disabilities or preexisting health conditions were particularly vulnerable. The health conditions ranged from mobility, vision, hearing, cardiovascular or respiratory diseases, reliance on medication or health services for their daily needs and overall well-being.

All participants were isolated at home during the COVID-19 pandemic, with 64% (n=9) living with family members or dependents, such as sons, daughters, and grandchildren, and the rest (n=5; 36%) isolated alone with no family members. Of all, 36% (n=5) of the total participants, who were isolated alone, were dependent on others, such as friends, family (not living with them), and community members, for support (Table 1). Participants reported strong kinship networks as a substantial social capital central to the communities, enabling them to practice strong social connectedness or cohesion.

All participants except 1 received help from the local community (eg, Whānau, Marae) members, family members, or local health providers (eg, Māori; Table 1). They received food, water, sanitizing products, and other health needs. Some individuals were provided with services, such as pick-ups and drop-offs for health appointments and vaccinations, by local health providers. They could rely on community members and health providers for home visits, funding, access to COVID-19 information, and other medical needs.

Some participants felt comfortable and confident offering support and advice to other community members affected by COVID-19, as well as distributing food packages, sanitizing products, and medical kits. Other participants received little help during the COVID-19 pandemic; instead, they relied on non-family members for support and struggled to find information independently (Table 1). The person who did not receive support during the pandemic experienced worsening unmet needs, reduced access to care, increased distress, and heightened loneliness.

Of the total participants, 50% (n=7) had a good or excellent understanding of COVID-19 information and requirements (eg, isolation, staying home; Table 1). Of these 7 participants, 5 were either health workers, former health workers, or affiliated with health organizations within the community. This group of participants was proactive in offering health advice, including guidance on accessing information and selecting suitable digital media. Their support extended beyond the domain of information and technology, including vaccinations through local health providers and transportation for elderly individuals who were ill. The remaining 50% (n=7) lacked a good understanding (fair or basic) of COVID-19, needing help and heavily relying on other family members for information and health support (Table 1).

[a]P: participants.

[b]G: gender.

[c]FM: family member.

[d]DT: digital technology.

[e]M: male.

[f]F: female.

Sources of Information

A number of sources of information were identified: the Ministry of Health website, COVID number (eg, 0800), TV and radio news or updates, COVID app (eg, COVID Sign in), tracking app with QR code, and social media (eg, Facebook). To access information and health requirements, the participants used their own devices, including cellular phones, smartphones, telephones, TVs, computers, and laptops.

A total of 5 (36%) of the participants reported having access to the internet with no issues, while the rest (64%) described their internet access as inconsistent and expensive (Table 1).

Digital Technology User Characteristics

Of the total participants, 43% (n=6) were limited users, 43% (n=6) comprised confident users, and the rest (n=2; 14%) were normal users (Table 1). The user characteristic was assessed by using the information provided in the narrative text on the semantic level (without making any assumptions).

XSL•FO
RenderX

Before the pandemic and the cyclone, the limited users did not know how to use such technologies. Therefore, during the pandemic and the cyclone, these users had to depend on family members, such as daughters and grandchildren, to access government information or regular updates from the TV. The grandchildren indicated that the use of those technologies remained limited or did not improve among the senior family members after the pandemic and the cyclone.

> *I had to rely on my granddaughter, who could access information through Facebook.* [P13]

Confident users could navigate and access various information sources and the online world and regulate social media (eg, Facebook), frequently using different apps before the pandemic and the cyclone. The frequent use of digital technologies enabled these participants to quickly search for COVID-19 information during the pandemic. They could use a QR-scanning app to access information on health requirements and track the latest emergency updates from the government (eg, the Ministry of Health website). The increased use of technology during the pandemic and the cyclone also enabled the participants to connect with family members through social media. After the pandemic and the cyclone, confident users continued to use technologies more efficiently and regularly. They upgraded their knowledge and use of various other apps, such as Microsoft Teams (virtual meetings), and helped other family members with shared information.

> *Navigating information through various means made me feel confident and act on necessary actions.* [P12]

Before COVID-19 and the cyclone, most people used digital technology mainly for social media, such as Facebook. Their regular use of social media helped them keep in touch with their family, and apps such as "COVID Sign-in" supported them in accessing updated information from the government about the ongoing pandemic and the cyclone. Although this user group continued to use various social media and apps to a significant extent, they relied on their family members for extended usage of apps, such as QR scanning, after the pandemic.

> *I use Facebook regularly. This helped me accessing updated information from the government.* [P2]

Themes That Emerged as a Result of the Study

In total, 6 themes emerged from the interview data: social connectedness and resilience, digital literacy and access to information, barriers to telecommunications and digital technology; cultural appropriateness and psychological barriers, perceived threats of feeling insecure, and impact on mental health and emotional well-being.

Theme 1: Social Connectedness and Resilience

Kaumātua, with their resilience and adaptability, have been the cornerstone of fostering community resilience. Their effective use of digital platforms to stay connected with whānau and access health services has been a testament to their resourcefulness. Their collective action, community solidarity, and reliance on traditional support networks have been instrumental in overcoming the challenges posed by isolation during COVID-19 and Cyclone Gabrielle [3]. Most participants felt safe and fortunate to have family and friends to rely on during the COVID-19 pandemic. The importance of love and a sense of belonging within family and community was expressed by many participants, while experiencing social isolation during the pandemic and cyclone. They felt confident in the information provided by family members, such as grandchildren, and assessed their health needs, including vaccination for COVID-19. They could also rely on the community for help, as they felt safer and more confident within it. They felt the need to connect with relatives living outside New Zealand. This further enabled them to rely on digital technology (eg, smartphones) to stay updated and informed, not only for themselves but also for their family, the community, and the outside world.

> *A lot of good medicine is basic love, how do we support each other? Through aroha (love).* [P4]

> *No department knows me better than my moko (grandchild) does.* [P10]

The participants considered connectedness as an essential factor in maintaining good health and well-being. As such, social connectedness can help neutralize vulnerabilities within a socioeconomic context through neighborhood networks, community cohesion, and trustworthiness, which can empower community members to work toward shared goals and objectives during disasters.

> *You can only look to your community for help, nobody else.* [P10]

Theme 2: Digital Literacy and Access to Information

The digital divide was evident, with many participants relying on the tech-savvy younger generation for technology use and access to information. This intergenerational support has been crucial in bridging the gap. However, some community individuals lacked the basic digital skills needed to navigate the internet effectively, and others were required to develop advanced digital skills to enhance their confidence and motivation. The impact of limited digital literacy on independent access to health-related information is significant, and coupled with inconsistent internet connectivity and high costs, it hinders their ability to access health-related information independently [3].

> *First it was COVID-19 and now it's the cyclone, no coordinated approach by the government–where will it end?* [P6]

The participants relied heavily on social media to stay in touch with their family members. However, their lack of knowledge and access to digital devices hindered their ability to maintain communication during periods of isolation and the cyclone. Difficulty in using digital devices affected their ability to access online health facilities. They suggested introducing more user-friendly digital solutions to overcome these challenges. Moreover, local care providers demonstrated an apparent lack of coordination among themselves, which could have been further improved by exchanging and updating information promptly and delivering one-on-one services as needed.

XSL•FO
RenderX

> *We used to have a health clinic, now you're told to go online, nobody around to help do that if you don't have someone in the family to help.* [P3]

Theme 3: Barriers to Telecommunications and Digital Technology

During Cyclone Gabrielle, widespread power outages and telecommunications failures severely affected the community's ability to communicate and access emergency services [3]. Participants emphasized the need for improved infrastructure, better internet connections, and localized communication channels to address these challenges.

> *A rich man moved out to our beach and complained about the internet, then a new tower got built soon after.* [P11]
>
> *People are building empires, need to cut the red tape and put that money back into the people.*
>
> *[P9]*

It was a challenging situation for those who were not digitally savvy, as they had to rely heavily on others for health needs and information. The government should have played a more significant role in addressing these gaps; for example, providing appropriate "match support" could have improved the situation.

> *Good phone and internet coverage was only available with one company.* [P7]

Theme 4: Cultural Appropriateness and Psychological Barriers

A preference for face-to-face interactions over digital communication was evident for the Māori communities. Various concerns about online safety and privacy, as well as the potential fear of losing the value of their own culture and language, contributed to the reluctance to engage with digital technologies. This necessitated digital inclusion initiatives and online services to be designed through the lens of the local community, incorporating their cultural values, learning styles, and needs. Fostering local community-led digital projects and ensuring online environments are safe and respectful is required. Ensuring online safety is crucial to building trust and confidence in the digital world. It is equally important to provide access to culturally relevant content, making users feel understood and catered to.

> *If we are supposed to use QR codes, where is the privacy around that?* [P1]

Theme 5: Perceived Threats of Feeling Insecure

The frequent visits of health providers were seen as "unwanted people" turning up at home, posing a significant risk to security during the time of isolation. Social media would have been a better choice than meeting in person, as it reduced the risk of contracting COVID-19 associated with in-person visits. For example, one of the participants felt intense fear and uncertainty when returning to her own community, as she was unsure about how it might affect her if she contacted her community members.

> *She didn't like people or unwanted people turning up at her home (during Covid-19). She felt unsafe and insecure.* [P5]

Theme 6: Impact on Mental Health and Emotional Well-Being

Following the cyclone, the area experienced constant power cuts and load shedding, which was particularly worrisome since the internet and phone lines were down for most of the time. However, in the face of these challenges, the Māori community came together in a display of unity and support. The disruption to community services and communication, combined with the displacement from homes and separation from family and community, particularly elders and children, loss of property, and disruption to cultural practices, had a significant impact on the mental health and well-being of Māori communities. But the community's solidarity was a powerful force that helped overcome these difficulties.

> *At some point, I felt mentally disturbed and did not know what to do.* [P6]

Discussion

Principal Findings

This study aimed to explore the experiences of people from Māori communities in using digital technology to meet their personal health needs during the COVID-19 pandemic and Cyclone Gabrielle. It examined their ability to access digital devices and their skills and capabilities in using these devices to access vital information. Our study's findings provide valuable insights into the role of digital technology in disaster management and underscore the urgent need to address digital disparities in support of vulnerable populations, such as older adults. In total, 6 themes emerged from the interview data: social connectedness and resilience, digital literacy and access to information, barriers to telecommunications and digital technology, cultural appropriateness and psychological barriers, perceived threats of feeling insecure, and impact on mental health and emotional well-being. This section presents the interpretation of the results and their significance by relating them to existing research, particularly in terms of the impact of digital technologies during the pandemic and the natural disaster, followed by a set of recommendations, and the strengths and limitations of the study.

Maintaining social connectedness during disasters and pandemic situations is crucial for several reasons. Social connections provide emotional support, reducing feelings of isolation, stress, and anxiety that often accompany such crises [36,37]. During disasters, strong social networks can facilitate the sharing of vital information, resources, and aid, enhancing community resilience and individual well-being. Additionally, connectedness ensures that vulnerable populations, such as the elderly or those with disabilities, receive the necessary care and support [37,38]. In the context of pandemics, where physical distancing measures are implemented, maintaining social connections through virtual means helps uphold mental health and prevents the adverse effects of loneliness [39]. Social connectedness also fosters a sense of community and solidarity,

XSL•FO
RenderX

which is crucial for collective action and adherence to public health measures. Overall, maintaining social bonds during crises is vital for both psychological health and effective disaster response and recovery [25,40].

Impact of Digital Technologies During the COVID-19 Pandemic

Digital health technologies are applicable in various areas, such as chronic disease self-management, as well as storing, sharing, and transferring confidential clinical data. These apps have enhanced the adherence to therapeutic regimes and provided a reliable platform for communication with health care professionals, enabling timely interventions [41-43]. Previous research on telemedicine has demonstrated its ability to save costs and travel time, particularly benefiting older populations in underserved areas. It can also reduce waiting times for patients for medical appointments, thereby reducing the time to diagnosis [43,44]. Additionally, especially during times of pandemics, it can help to reduce the risk of contagion and infections [45].

Most older individuals in the community relied on local health care workers and family members for food, water, and sanitary supplies, exposing themselves to unwanted health and safety risks. During this period, information about support services and preventive measures was disseminated to the public through digital technologies, including television, radio, health websites, and social media. However, the results of this study revealed that nearly half of the community people had limited knowledge of using this technology and were dependent on family members to attain important information. Furthermore, two-thirds of respondents reported challenges associated with internet connections, including high costs, limited accessibility, and difficulties using the internet. These issues are compounded by a gap in communication and information sharing, suggesting that digital technology is not equally accessible, resulting in a disparity in its use. These findings align with the report published by the Department of Internal Affairs in 2019, which stated that Māori people had limited access to internet connections and digital technologies, and inadequate funding for basic digital training [25]. These challenges highlighted the need for training and education to enhance the foundational digital skills for Māori communities [46].

There was a clear need for improved communication and a more effective system to reach COVID-19 victims. Information and information-sharing hubs could be better utilized to facilitate community links and support client work. Although the use of a QR scanning app enabled easy access to and management of information, a more effective approach would have been to maintain an up-to-date database with each community registered. The database would have helped people understand COVID-19 requirements and contributed to building the community [47,48]. Moreover, the inconsistency in the information shared by local health providers clearly indicated a lack of coordination among service providers [49,50]. This could have been further improved by exchanging and updating information in a timely manner and delivering one-on-one service as required [50,51].

Impact of Digital Technologies During Cyclone Gabrielle

The frequent occurrences of extreme weather events have a significant impact on social connectedness within communities. Disasters can disrupt these social networks, displace individuals from their homes, and create feelings of isolation and loneliness. This is particularly important for elderly populations, who may rely heavily on their social connections for support and companionship. Recognizing and preserving social connectedness are crucial for effective disaster management and community resilience [52]. The findings of this study indicate that digital technology plays a key role in maintaining health and well-being during crises, as vital information can be shared through social connectedness. The lack of digital literacy and reliable telecommunications infrastructure disproportionately affected Māori communities' ability to access timely information on safe practices during the COVID-19 pandemic and Cyclone Gabrielle, highlighting the urgent need for targeted interventions. Strengthening community-driven initiatives and integrating indigenous knowledge into disaster management plans can enhance resilience and support [53].

According to a recent report, the displacement triggered by Cyclone Gabrielle has destroyed numerous houses and forced a significant number of evacuations, affecting approximately 10,500 individuals. In the Opotiki district alone, heavy rainfall led to the evacuation of 1335 individuals, accounting for a substantial 15% of the total population. Despite these challenges, the affected communities have shown remarkable resilience [54]. Our study, a detailed analysis of the impact of Cyclone Gabrielle on digital public health, employed a qualitative research method. Like most studies of extreme weather events, we have reported that Cyclone Gabrielle had severe and long-lasting effects on public health. The individuals who faced this cyclone, coupled with power cuts and loss of internet connection, have experienced a significant impact on their psychological well-being and quality of life. This led to an increased level of anxiety, depression, and post-traumatic stress, which are likely to persist in the long term [55]. Within the affected region, the long-term devastation of primary industries, coupled with widespread damage such as heavy flooding, landslides, and infrastructure destruction, has necessitated a national state of emergency. Immediate action is crucial to mitigate the long-term effects of this disaster [56].

During such extreme weather events, poor access to reliable telecommunication services (like phones and internet connections) is exacerbated within populations that already face challenges such as remoteness [57]. The reliance on care support is a significant factor influencing an individual's awareness of risks and ability to control them [58].

Recommendations

It is essential to remember that Indigenous communities are incredibly diverse, each with its unique challenges and opportunities for digital inclusion. Addressing these challenges necessitates a multifaceted, collaborative, and, most importantly, a long-term commitment from governments, technology companies, nonprofits, and Indigenous communities. Each stakeholder plays a crucial role in developing sustainable and

XSL•FO
RenderX

culturally appropriate solutions [3,59]. Therefore, based on the study findings and the considerations emerging from various literature and public reports, we suggest the following recommendations to help Indigenous communities overcome challenging situations, such as the pandemic and extreme weather events.

The need for a user-friendly and culturally relevant digital solution/technology was evident, as older individuals found it difficult to learn how to use digital technology. The frustration caused by the long waiting time for the national COVID 0800 number was accepted by those affected by the outbreak. A local COVID number could have replaced this to facilitate the needs of the local community and its people [50,60]. The need for a more user-friendly, culturally relevant, and simplified version of the digital solution is paramount, particularly for older individuals, to make it "fit for purpose" [25,61]. It is crucial that these programs are community-led, culturally safe, and accessible to people of all ages [3,62], especially to reduce digital disparity among Māori communities.

Ensure local funding—people directly linked to the local community were expected to have more access to food, water, and medical supplies [63]. There is sufficient evidence that the complex administrative requirements and logistical challenges associated with accessing government funding and programs can pose significant threats to Indigenous communities with limited resources [64]. More local funding needs to be provided for low-income families coping with isolation, food scarcity, and health conditions [60].

The need for additional community services—specifically, health care for older people—was needed. Further support (eg, doctor visits, regular phone calls to check up on health) for older individuals who would also have been considered [52], particularly helping them access the information and the health requirements [65], for example, how to download and use a mobile app [3]. The government needs to apply the lessons learned to those in most need and work with the local communities to provide additional services [50,60].

Establish a training program for the local community—focusing on digital apps such as online banking, social media, and email, as well as accessing information on the internet. Many community members, especially older adults, lack proficiency in these areas. By providing training and education, older adults will develop fundamental skills, enabling them to utilize technology for their future needs [56,66,67]. Government support is crucial in ensuring equitable access to digital technologies and resources, particularly for underserved communities and those lacking digital literacy. With the help of the relevant authority, necessary training and resources can be provided to help individuals develop the digital skills needed to participate more fully in the digital economy [68,69].

Fostering leadership and partnerships—governments and mainstream service providers may overlook the unique needs and priorities of diverse Indigenous communities, failing to tailor policies and programs to their specific contexts. The absence of Indigenous-led initiatives is particularly concerning, as they are not only crucial but also the most effective way to develop culturally relevant and effective digital inclusion strategies. Recognizing the expertise of Indigenous communities in understanding their own needs is essential for respectful and impactful policy-making [25,70]. The implementation of these strategies necessitates fostering collaboration between local health care providers, regional and government funding bodies, community health partners, and the national health service in New Zealand (Te Whatu Ora) [31].

Strengths and Limitations of the Study

The Kaupapa Māori was chosen for several reasons: first, the primary investigator identifies as Māori and is connected to the community through whakapapa or genealogical ties and developed a body of knowledge to improve Māori health status over her academic career; second, the elders from her community approached her to investigate their concerns about the lack of access to health services within rural and remote communities in their tribal region; and third, this publication is a continuation of a 3-phase study that utilized Kaupapa Māori methodology since its commencement [48]. This study also followed Standards for Reporting Qualitative Research (SRQR), which improved the clarity, completeness, transparency, and credibility of the study [71] (Checklist 1).

To ensure cultural safety protocols and kaupapa Māori methodology were adhered to, 2 female kaumatua or elders (RS and JT) assisted with access to the various communities and remained present throughout the interviews. This approach ensured that the elders provided a moderating influence on the research process, and Māori cultural protocols were adhered to. Unexpectedly, Cyclone Gabrielle occurred partway through the interviews, prompting the research team to include accounts from participants about this event during the data collection phase. However, a caution has been raised regarding the structured interviews to ensure they cover both the COVID-19 pandemic and Cyclone Gabrielle equally. Moreover, limitations include the small number of participants and reliance on family members to assist with interviews, which may affect data accuracy.

Another limitation was that the exact age of the participants was not collected or documented. The precise ages of individuals—especially older people—sometimes could not be determined. The exact age could only be determined if the birth was recorded. Moreover, in traditional Māori and Pacific societies prior to European contact, written birth records were not kept. People often tracked age in relation to events (such as wars, voyages, famines, and natural disasters) rather than exact dates.

Conclusions

Vulnerable situations such as pandemics and extreme weather events can have tremendous effects on the lives of Indigenous people who live remotely. This study provided insights into how the COVID-19 pandemic and Cyclone Gabrielle posed significant challenges for Māori communities, particularly for vulnerable older individuals, highlighting the importance of digital technology and telecommunication services in maintaining social connectedness and accessing health care services. The study also focused on the actions that should be taken to mitigate these challenges and overcome difficult

XSL•FO
RenderX

circumstances, such as the pandemic and Cyclone Gabrielle. The recommendations include a better health care system and improved coordination among care providers, user-friendly digital solutions, ensuring local funding and community services, establishing training processes for basic digital skills, and fostering leadership and partnerships with Indigenous New Zealanders.

Acknowledgments

The authors would like to thank Jean Te Huia, Rose Smith, and Rina Te Huia for their overall support, guidance, and assistance in this research. This research was funded by the Health Research Council's Māori Health Research Development Grant (No. 22/835). A small grant, that is, the Brad-Attain Research Placement for a student working in this project, was received from the University of Bradford, the Brad-Attain team. Moreover, a publishing grant was obtained from Linnaeus University as part of the University Library's research support.

Abstract

Background: With an aging population driven by advances in medical technology, digital literacy has become essential for improving the quality of life of older adults, enhancing access to health information, and promoting healthy lifestyles. Furthermore, the COVID-19 pandemic may have influenced the subjective health perceptions and healthy lifestyle behaviors of older adults. However, there is limited research exploring the relationship between digital literacy, subjective health perceptions, and healthy lifestyle behaviors in Korea.

Objective: This study aimed to investigate digital literacy's impact on Korean older adults' subjective health status and healthy lifestyle behaviors.

Methods: Data of 8664 respondents (aged 65 years and older) from the 2020 National Survey of the Older Koreans were analyzed. Digital literacy was measured based on the use of IT devices (ITDs), difficulty using online information, and inconvenience of ITDs. Statistical analyses, such as the Rao-Scott chi-square test, Wilcoxon rank sum test, and multiple regression analysis, were conducted.

Results: Respondents with above-average ITD use (adjusted odds ratio [aOR] 1.73, 95% CI 1.50 - 1.99) and less difficulty using online information (aOR 1.41, 95% CI 1.24 - 1.61) had higher odds of perceiving themselves as healthy. Conversely, high difficulty using ITDs was associated with lower odds of respondents perceiving themselves as healthy (aOR 0.84, 95% CI 0.82 - 0.87). Furthermore, high ITD use predicted engagement in healthy lifestyle behaviors (aOR 1.51, 95% CI 1.33 - 1.72), whereas high difficulty using ITDs predicted lower odds of engagement (aOR 0.94, 95% CI 0.92 - 0.97). In contrast, there was no difference in the odds of engaging in healthy lifestyle behaviors regardless of difficulty using online information (aOR 1.03, 95% CI 0.92 - 1.15).

Conclusions: This study underscores the significant association between digital literacy and improved health outcomes among older adults. Promotion of digital literacy and relevant policies is essential to help older adults effectively obtain health information online, thereby improving their quality of life and overall health.

Introduction

Advances in medical technology have increased life expectancy, thereby contributing to the growth of an aging population worldwide [1]. South Korea became an aging society in 2017, and it is predicted to transition to a super-aged society by 2025 [2]. Old age is characterized by a general decline in physical and mental functioning, leading to a range of health issues, including senile and chronic degenerative diseases and impaired daily functioning [3]. Prevention, treatment, and management of diseases are necessary to improve of older adults' health care and quality of life. In addition, health information and proactive responses for health care are important [4]. Particularly, the first generation of Korean "baby boomers" (born between 1955 and 1972), specifically those born in 1955, has been incorporated into the older adult population since 2020. Thus, this is a crucial time for discussion on older adults' health care.

Generally, older adults obtain health information from health care providers, friends and relatives, television, newspapers, radio, and other mass media to maintain their health [5]. However, rapid technological developments have increased the opportunities for acquiring health information and news on the internet, leading to digital literacy's increased importance [6-8]. Digital technology initially spread among young people, men, and highly educated people and is gradually spreading to older adults, women, and less educated people. The aging trend and the rapid development of new media technology suggest that older adults will have to use digital technology more in the future [9]. Digital literacy comprises the ability to understand the information generated on a digital device and implement it accordingly [10]. In an information society, digital literacy's importance is expanding to all areas of life as a key factor in improving quality of life [11,12].

The manner in which older adults perceive their health informs how they relate to society. In addition, their subjective well-being is intimately linked to their perceived health status [13]. Meanwhile, health concerns can be a primary motivation for searching health information online [14]. Specifically, the use of the internet promotes the health of older adults by improving access to health information, encouraging healthy lifestyles, and enhancing social interaction [15]. While older adults recognize the effectiveness and usefulness of using health information through digital media such as the internet for health care, they experience challenges when actually attempting to obtain health information online [16,17]. According to a 2022 report on the digital divide, vulnerable groups such as people with disabilities, low-income individuals, farmers, and older adults have markedly lower digital use capabilities, with the latter experiencing the highest level of information vulnerability [18].

The growing importance of digital literacy for older adults has prompted a variety of studies. However, most Korean research is survey-based or restricted to specific geographic regions or disease populations, focusing primarily on health knowledge, mental health aspects such as depression and self-efficacy, or quality of life [19-22]. While subjective health perceptions and healthy lifestyle behaviors of older adults may have been influenced by COVID-19 pandemic, these studies were conducted before the pandemic [23-25]. Furthermore, the rapid progress of aging and the advancement of IT, along with gaps in the acquisition of information, unchecked spread of health information, and dissemination of unverified information, have created growing concerns among the older adult population vis-à-vis the lack of reliable information [26-28].

This study seeks to examine 2 key hypotheses: (1) older adults with higher levels of digital literacy are more likely to perceive themselves as healthy and (2) higher levels of digital literacy among older adults are associated with a greater likelihood of engaging in health-promoting behaviors. Using a nationally representative sample, we aim to investigate the association between different aspects of digital literacy and older adults' subjective health status and healthy lifestyle behaviors.

Methods

Data Source and Study Population

This cross-sectional study used data from the 2020 National Survey of the Older Koreans (NSOK), conducted by the Ministry of Health and Welfare and the Korea Institute for Health and Social Affairs (KIHASA). The NSOK is a survey conducted every 3 years since 2008, in accordance with Article 5 of the Welfare of Senior Citizens Act. It systematically collects data from more than 10,000 older adults aged 65 years and older who are living in ordinary residences across 17 cities and provinces nationwide. Trained surveyors carry out the survey in 969 districts selected based on regional representation. They survey all households with older residents, considering factors such as area of residence, age, gender, education, and marital status [29]. This survey aimed to identify the living conditions, characteristics, and needs of older adults to develop welfare policies to improve their quality of life. In addition, it sought to develop policies in response to Korea's aging society by examining changes in the characteristics of older adults through the accumulation of time-series data [29].

NSOK calculates weights in 3 steps: using design weights, nonresponse-adjusted weights, and poststratification weights. First, the design weights are directly derived from the sampling design, using a 2-stage cluster sampling method. This method involves probability proportional to size (PPS) sampling, where sample areas are selected based on the number of households in each area, followed by the selection of households within each sampled area. Nonresponse adjustment is conducted by upweighting responding households using the reciprocal of the response rate. Final weights are calculated by applying a raking ratio method, and respondent weights, adjusted for design and nonresponse weights, are poststratified to match the distribution of older adults in the population, thereby enhancing the accuracy of estimates. The 2020 NSOK used data from the 2019 Census, the most recent available at the time of survey completion, to calculate final weights by applying population data for older adults by gender, age group (65 - 74 years or 75 years and older), and household size (1-person household, 2+ persons) across the 17 metropolitan areas [21].

XSL•FO
RenderX

The study excluded 1256 of the 10,097 respondents who answered "don't know" or "not applicable" to the digital literacy survey. In addition, if the respondent has a physical or mental illness, the cohabitant or a close representative of the study subject responds on their behalf. In this case, only the objective information of the older adults was surveyed, and the main focus of this study was not surveyed [28]. Therefore, the results were generalized to older Koreans by excluding the 177 respondents who responded on behalf of their cohabitant. These exclusions ensured the objectivity of the health indicator responses, as the survey focused on the subjective judgment of the original respondents [29]. Finally, the study included 8664 participants.

Ethical Considerations

The Institutional Review Board (IRB) of the Yonsei Medical Center approved a consent exemption for this study (No. 4-2023-0361). The 2020 Elderly Survey used in this study was anonymized by the data provider, KIHASA, and the tools and processes used in the survey were approved by the IRB of KIHASA (No. 2020 - 36).

Measurements

Subjective Health Status and Healthy Lifestyle Behaviors

The dependent variables of this study included subjective health status and healthy lifestyle behaviors. Subjective health status has been widely used in various studies as a valid proxy for actual health status, given its reliable predictive value for health outcomes [30-32]. It was categorized into good (very healthy and healthy) and poor (fair, poor, and very poor). Healthy lifestyle behaviors were defined as smoking cessation, decreased alcohol consumption, and exercise [33]. Smoking cessation was defined as having quit smoking, decreased alcohol consumption was defined as not drinking at all in the previous year or drinking less than twice a week, and exercise was defined as answering "yes" to the question, "Do you usually exercise for at least 10 minutes on a consistent basis?"

Digital Literacy

This study's main variable was digital literacy, which was divided into 3 subcategories. It was scored based on the degree of use of IT devices (ITDs), difficulty using information provided online, and inconvenience of ITD usage.

For the item on the degree of ITD usage, 1 point was assigned to each of the activities in Textbox 1, which involved using a PC, mobile phone, or tablet. The sample was divided into 2 groups according to the respondent's score, namely above average (3 points or more) and below average (3 points or less).

For the item on the difficulty of using information provided online, the degree of difficulty in using information or services required for daily life via the internet was categorized into "difficult" and "not difficult." The inconvenience of ITD usage was assessed considering tasks such as making online reservations, conducting purchases using machines such as kiosks and automated teller machines, and shopping at stores that only accept cards. For each task, the level of inconvenience was scored on a scale from 0 ("not at all inconvenient") to 2 ("inconvenient"). Finally, the overall level of inconvenience of using ITDs was rated on a scale from 0 ("not at all inconvenient") to 8 ("inconvenient"). A Cronbach α of 0.88 was identified for ITD usage, and 0.80 for inconvenience of using ITDs.

Textbox 1. Activities that involved using a PC, mobile phone, or tablet.

- Receiving messages.
- Sending messages.
- Searching for and viewing information.
- Taking photos and videos.
- Listening to music.
- Playing games.
- Watching videos.
- Using social media.
- Using e-commerce platforms.
- Using online financial transactions.
- Searching for and installing applications.
- Other activities.

Covariates

The covariates included sociodemographic characteristics and health-related factors. Sociodemographic characteristics included gender, age, residence, educational level, household types, and household income. Age was classified into five 5-year intervals (65 - 69, 70 - 74, 75 - 79, 80 - 84, and ≥85 years old). Residence was classified into "rural (eup/myeon)" and "urban (dong)." Educational status was classified into "elementary school or less," "middle and high school," and "university and above." Household type was classified into "single," "married couple," and "cohabitant (nonspouse)." Household income encompassed all household members' earned, business, property, and transfer incomes. This comprised the annualized gross household income for the most recent year (July 1, 2019, to

XSL•FO
RenderX

June 30, 2020), converted to a monthly basis and divided into quartiles.

Health-related factors included the number of chronic diseases respondents had. Chronic diseases included conditions that lasted for more than 3 months and had been diagnosed by a doctor. These were categorized as "none," "1‐2 chronic diseases," and "3 or more chronic diseases," encompassing 32 conditions.

Statistical Analysis

A frequency analysis was conducted to identify the participants' general characteristics. The Rao-Scott chi-square test and Wilcoxon rank sum test were conducted to evaluate and compare these characteristics. Multiple logistic regression analysis examined the associations of digital literacy with subjective health status and healthy lifestyle behaviors. In addition, a subgroup analysis was conducted to determine whether gender led to differences in the association of digital literacy with subjective health status and healthy lifestyle behaviors. All analyses were conducted using SAS software (version 9.4; SAS Institute), while statistical significance was set to $P<.05$. All analyses were weighted by NSOK to account for differences in survey completion rates across NSOK's survey regions.

Results

The participants' demographic and socioeconomic characteristics are summarized in Table 1. Of the 8664 study participants, all weighted by region, 55.9% (4649) had above-average scores in ITD usage, while 72.3% (6264) found it difficult to use information available online. The level of inconvenience of ITD usage was 4.2 out of 8.

Participants were mostly female (n=5077, 55.7%), aged 65‐69 years (n=3282, 35.8%), urban residents (n=6256, 76.1%), educated up to middle and high school (n=4571, 54.4%), married (n=4502, 59.7%), in household income level 4 (n=2169, 29.1%), and had 1‐2 chronic diseases (n=4936, 56.6%).

[a]Weighted percentage.

[b]Rao-Scott chi-squared probability for comparison between (1) healthy and nonhealthy groups, and (2) groups engaging in healthy lifestyle behaviors and those not engaging in healthy lifestyle behaviors.

[c]ITD: IT device.

Of participants with above-average ITD usage, 64.8% (n=3038) perceived themselves as healthy and 51.8% (n=2329) engaged in healthy lifestyle behaviors. Of participants who reported difficulty using online information, 45.6% (n=2898) perceived themselves as healthy and 46.1% (n=2773) engaged in healthy lifestyle behaviors. Participants who perceived themselves to be healthy exhibited an ITD inconvenience score of 3.7 and those who engaged in healthy lifestyle behaviors exhibited a score of 4.1.

The association of digital literacy with subjective health status and healthy lifestyle behaviors is shown in Table 2. Compared with participants with below-average ITD usage, the odds of participants with above-average ITD usage were 1.73-times more likely to perceive themselves as healthy (adjusted odds ratio [aOR] 1.73, 95% CI 1.50 - 1.99, *P*<.001) and 1.51-times more likely to engage in healthy lifestyle behaviors (aOR 1.51, 95% CI 1.33 - 1.72, *P*<.001). Participants who did not find it difficult to use information available online had 1.41-times (aOR 1.41, 95% CI 1.24 - 1.61, *P*<.001) higher odds of perceiving themselves as healthy, compared with those who found it difficult. Higher ITD difficulty scores were also associated with 0.84-times lower odds of respondents perceiving themselves as healthy (aOR 0.84, 95% CI 0.82 - 0.87, *P*<.001) and 0.94-times lower odds of engaging in healthy lifestyle behaviors (aOR 0.94, 95% CI 0.92 - 0.97, *P*<.001).

[e]Not applicable.

The association of digital literacy with subjective health status and healthy lifestyle behaviors by gender is shown in Tables 3 and 4. Both men and women with a higher than average degree of ITD usage were more likely to perceive themselves as healthy than those with an average or lower degree of ITD usage, and women in particular were nearly twice as likely (male aOR 1.64, 95% CI 1.34 - 1.99, *P*<.001; female aOR 1.91, 95% CI 1.60 - 2.27, *P*<.001). Similarly, people who did not experience any difficulties in using information provided online were more likely to perceive themselves as healthy than those who did experience difficulties, but this was more likely to be the case for men (male aOR 1.60, 95% CI 1.32 - 1.94, *P*<.001; female aOR 1.27, 95% CI 1.06 - 1.51, *P*=.01). Women with a higher degree of ITD usage were 1.54 times more likely to engage in healthy lifestyle behaviors than women with a lower degree of ITD usage, and this was slightly higher than for men (male aOR 1.47, 95% CI 1.20 - 1.81 *P*<.001; female aOR 1.54, 95% CI 1.30 - 1.82, *P*<.001). The less comfortable they were with using ITD, the less likely they were to perceive themselves as healthy (male aOR 0.84, 95% CI 0.80 - 0.88, *P*<.001; female aOR 0.85, 95% CI 0.81 - 0.88, *P*<.001) and to practice healthy lifestyles (male aOR 0.95, 95% CI 0.90 - 0.99, *P*=.02; female aOR 0.94, 95% CI 0.90 - 0.97, *P*<.001), with similar results for men and women.

Discussion

Principal Findings and Comparison With Previous Work

This study examined the association between older people's digital literacy and their subjective health status and healthy lifestyle behaviors. Research has shown that older people with a high level of digital literacy, those who actively use information devices, and those who have easy access to online information are more likely to feel healthy and maintain healthy lifestyle behaviors. Conversely, those who experience difficulty accessing information online and are uncomfortable using information devices are less likely to engage in healthy lifestyle behaviors.

This study's findings are consistent with those of previous studies showing that both the use and amount of information affect subjective health status. In addition, whether older people own digital devices, how often they use them, and the extent of their internet activity are likely to affect their digital literacy and health [34-36]. According to a study in the United States, searching for and mastering relevant medical knowledge on the internet is beneficial for older adults with high blood pressure and heart disease, improving their health care and reducing disease rates [37]. In addition, using the internet could improve the health of older individuals by increasing their ability to exercise; for example, internet intervention programs helped them select exercise activities in the areas of endurance, flexibility, strengthening, and balance enhancement, which helped older adults increase their exercise frequency, thereby improving their physical health [38,39]. In China, older people with a high frequency of digital device usage experience a positive impact on their lifestyle, including improvements in diet, sleep, and exercise [15,40].

Empowering older people with a wide range of digital skills, from simple computer use to usage of social networks, emails, and online meetings, could enrich their lives, enhance their cognitive capabilities, and make them more productive and efficient members of society [41]. This could significantly contribute to the improvement of their perceived health status [42]. People who understand health information available online can use it effectively in their daily life to acquire valuable insights regarding their illnesses, increase their involvement as patient in the treatment process, and positively assess their subjective health status [43]. The internet provides a wealth of information, creating and increasing thematic content, especially for groups intimately associated with older adults, which helps maintain intergenerational relationships and promotes connected social capital [44]. With this social capital, older adults with a high level of digital literacy could fulfill their desire for belonging and love, which in turn could enable them to evaluate their health more positively [45].

However, unlike previous studies, this study found no difference in healthy lifestyle behaviors between those with and without difficulty using online information. Older people with high digital literacy have easier access to health information and use it effectively to positively impact their health care. Furthermore, they regularly access the internet for health information [27,35]. A previous study reported that adults aged 50 - 60 years who are not in good health access the internet for health care purposes because they want to be actively involved in health care decisions [46]. A few older individuals use emails and social networking sites to promote cancer screening to colleagues [47]. Online mediation, such as effectively managing hemoglobin A_{1c} levels in patients with diabetes through social networking site–based interventions, improved knowledge about the disease and had a positive impact on health behaviors [48,49].

Also in South Korea, Min [50] reported that the use of internet information decreased with age, regardless of physical and environmental accessibility, but this measure of use was comparable with this study's degree of ITD usage. Previous

XSL•FO
RenderX

studies have also highlighted the positive effects of online health information seeking psychological and physical domains, such as increased self-efficacy and improved health behaviors [51,52]. However, these studies were conducted before the COVID-19 pandemic, leaving a gap in understanding health behaviors during and after the pandemic.

The 2020 NSOK survey was conducted during the COVID-19 pandemic—a period marked by reduced outings among older adults due to social distancing policies and concerns about weakened immune systems. This context likely contributed to an overall decline in healthy lifestyle behaviors, particularly exercise, regardless of difficulties in using online information [23-25]. The reliance of Korean older adults on interpersonal sources for health information is deeply rooted in cultural values such as Confucianism and collectivism [53,54]. For health-related information, older adults in South Korea often rely on various sources, including health care professionals, mass media, local health centers, and family members. Particularly, adult children act as intermediaries in accessing and interpreting digital health information. In addition, a strong cultural trust in health care professionals reinforces a preference for direct consultations rather than independent online searches [55-57]. These sources play an important role in supporting health behaviors, even without the use of the internet, and help create an environment where information remains accessible despite low levels of online information use. In addition, older adults may have relied on household members or health center staff to mediate and explain online information, rather than accessing it directly [58-60]. This indirect approach could have resulted in an underestimation of the actual challenges older adults face when navigating online information.

Limitations

The present study had a few limitations. First, this is a part-sectional study. As we measured the variables at the time of the survey, we could only derive meaning in relation to the association between older adults' digital literacy and the causal relationship between their subjective health status and health practices. Second, as life expectancy increases, it is possible to divide the older adult population aged 85 years or older into different age groups. However, the NSOK is limited to detailed age-specific analysis. Nevertheless, this study used the latest data from national units, which ensured the representation of South Korea's older adults. In this study, digital literacy was divided into specific categories such as the degree of ITD usage, the difficulty of accessing online information, and the inconvenience of ITDs. This highlights the importance of linking older people's digital literacy to their subjective health status and health practices.

Conclusions

This study expands the existing knowledge on the subject by using a national-scale survey of South Korea's older adult population. To improve the subjective health and health practices of older adults, digital literacy education and related policies must be promoted. Furthermore, it is important to provide information education, so that older individuals can identify the required information, even among commercial and vague content. Health care and public institutions should provide information, booking systems, guidance, and other services to help older adults make use of these resources. We hope that this study will serve to improve older adults' quality of life and contribute to their health and welfare.

Data Availability

The data can be accessed from the Ministry of Health and Welfare and the Korea Institute for Health and Social Affairs (KIHASA) homepage. However, restrictions apply to data availability. The data were used with permission for the current study and, therefore, are not publicly available. The data are available from the corresponding author upon reasonable request and with prior permission from the KIHASA. Applications to use the National Survey of the Older Koreans (NSOK) data will be reviewed by the inquiry committee of research support, and once approved, raw data will be provided to the applicant for a fee.

Authors' Contributions

SYL was involved in study conception, statistical design, and manuscript drafting. YK and BK were involved in study conception, statistical design, data analysis, and manuscript drafting. SGL and SYJ oversaw the manuscript's development and helped revise it. THK was involved in study conception, statistical design, manuscript development, and manuscript revision. All the authors critically revised the manuscript for important intellectual content and approved its final version.

Abstract

Background: With rapid digitalization, technologies are increasingly integrated as part of our everyday lives and are becoming increasingly essential for individuals to participate in society. Technology presents opportunities to support healthy aging. Examples include digital health monitoring and opportunities to maintain social connectedness through online platforms. However, the processes in which older adults select and integrate technologies into their daily lives have not been well examined.

Objectives: This study uses the Selection, Optimization, and Compensation (SOC) model to understand how older adults integrate technology into their everyday lives to live well. The two key research questions are as follows: (1) How do older adults describe their technology use and their choices, analyzed with respect to SOC processes? (2) How do older adults perceive that technology is a part of living well?

Methods: A descriptive qualitative study was conducted. Purposive sampling was used to recruit older adults who were aged 55 years and older, were living in the community, spoke and understood English, and resided in Australia. Five in-person focus groups comprising 20 older adults were conducted. Data were analyzed using hybrid inductive and deductive reflexive thematic analyses, based on the SOC model.

Results: All participants resided in Brisbane, Queensland. Older adults selected technology intentionally to enhance different aspects of their daily lives. Perceived "involuntary" selection of technology could lead to feelings of resentment or frustration. Optimization strategies included self-monitoring, integrating technology into daily routines, digital literacy and proficiency, and problem-solving skills. Compensatory strategies included choosing alternative technology that suited participants' abilities or skills and seeking support through informal or formal avenues.

Conclusions: These findings provide important considerations for technology developers to design technology in collaboration with older adults to ensure that they align with needs and preferences. Digital literacy is not sufficient to empower older adults to use technology; when empowering older adults to use technology, service providers should also consider facilitating other intrinsic and extrinsic resources and skills.

KEYWORDS

technology; healthy aging; selective optimization and compensation; aging well; older adults

Introduction

Background

According to the World Health Organization, healthy aging entails creating the environments and opportunities that enable people to be and do what they do throughout their lives [1]. As populations are aging globally, healthy aging is a priority in many countries, and interventions and programs have been developed to support older adults to avoid negative impacts associated with disability or to maintain or improve their functional ability. Interventions have also focused on supporting older people to sustain or enhance participation in social engagement and other meaningful activities [2]. Examples include education, problem-solving and goal setting, leisure exploration [2], and activities to improve physical capacities [3]. Synthesized evidence suggests that physical activity programs can improve healthy aging by reducing physical limitations and improving psychosocial outcomes [4]. Similarly, non–exercise-based interventions, such as leisure-based interventions or programs to increase older adults'

XSL•FO
RenderX

self-awareness or self-acceptance, have led to improvements in older adults' quality of life [2].

With rapid digitalization, technologies are increasingly integrated as part of our everyday lives and are becoming increasingly essential for individuals to participate in society. For instance, payments for services and goods have become digitized through mainstream telephone-based services, app-based services, and automated teller machines (ATMs) [5]. Correspondingly, technology presents new opportunities to digitize interventions aimed at supporting healthy aging [6]. Examples of technology that have been developed and leveraged to support healthy aging include web platforms, mobile health apps, and wearable technology, which have been designed to support older adults in self-monitoring and decision-making, measuring physiological, cognitive, or physical metrics, or delivering interventions [7]. While these technologies are intended to simplify and enhance older adults' daily lives, they can also make everyday lives more complex [5]. To understand how technologies can be best used to support healthy aging, it is necessary to understand how they have been assimilated in older adults' everyday lives. Several studies have been conducted to understand older adults' experiences with technologies. For instance, Reyes and colleagues conducted a study in Australia to understand older adults' choices of, and motivations to use technologies for health-related self-management [8]. They also sought to understand barriers and facilitators to technology use. The researchers found that older people leveraged technology for health monitoring and to remain active and connected. Facilitators include social and organizational influences, accessibility, and cost, whereas some barriers include perceived information overload, ease of use, and concerns about privacy and accuracy. These findings were echoed in other international studies conducted in Canada [9] and the United Kingdom [10]. While existing research has provided valuable collective insights into how older adults experience technology and barriers and facilitators to their use, the processes in which older adults select and integrate technologies into their daily lives have not been well examined.

Selective Optimization With Compensation

The Selective Optimization with Compensation (SOC) model [11] is a meta-theoretical model focusing on the "how" of aging well; it describes processes that older adults undertake to reach their goals, particularly considering that their resources may become more limited over time. According to the SOC, when personal and environmental resources become limited, individuals make decisions to allocate these resources to pursue and to achieve their goals. This involves (1) selection, (2) optimization, and (3) compensation. Selection entails setting or prioritizing goals through loss-based selection or elective selection. For instance, older adults might choose to cease participation in certain activities that might become more effortful and instead select other activities deemed to be more meaningful. Optimization entails acquiring and refining resources and skills. Examples include learning new skills or knowledge needed to engage in chosen activities. Finally, compensation involves acquiring or substituting resources to achieve their goals. For example, older adults might leverage technology or support services to help them participate in activities. According to Freund and Baltes, the orchestrated use of these 3 action strategies effectively manages the loss of resources across individuals' lifespans and conserves resources [12]. Given this, the SOC model could provide important theoretical guidance on bridging an established theory on successful aging with digital engagement. There is limited research on the application of the SOC model to the understanding of how technology is leveraged as part of, or integrated into, older adults' process of selection, optimization, and compensation. This study aims to understand how technology is integrated into older adults' everyday lives to live well using the SOC model. Specifically, the key research questions are as follows:

1. How do older adults describe their technology use and their choices, analyzed with respect to SOC processes?
2. How do older adults perceive that technology is a part of living well?

Methods

A qualitative descriptive approach [13,14] underpinned our qualitative inquiry, where we stayed close to the "surface of the data and events" to gather rich descriptions of the views of participants and describe the phenomena from the viewpoints of participants.

Sampling, Recruitment, and Context

Purposive sampling was used to identify and recruit participants who met the following criteria: (1) aged 55 years and older, (2) living independently in the community, (3) able to speak and understand English, and (4) residing in Australia. Different avenues were contacted to advertise this study to prospective participants. These included national and local senior networks, age-friendly university networks, and the University of Queensland's (UQ) Healthy Living, an interprofessional clinic promoting healthy aging and well-being. Individuals who were interested in participating in this study were invited to share their preferred contact information with the research team. The lead researcher (WQK) contacted potential participants by email and/or a phone call to provide more information about the study and to arrange a focus group session at their preferred time and date. Online and in-person focus group options were planned, and recruitment was not limited to specific states in Australia. However, all participants who volunteered to join this study lived in Brisbane, and all focus group sessions were conducted in-person. No prospective participants declined participation. Brisbane is the capital city in the state of Queensland in Australia, with older adults constituting approximately 17% of the population. The local government, Brisbane City Council (BCC), has several initiatives to support seniors in Brisbane, and these include centers with organized activities, exercise programs, and transport concessions [15]. Brisbane has good digital infrastructure, and efforts have been made to improve digital accessibility and close the digital divide [16].

Data Collection

Data collection took place between April and June 2024. Five face-to-face focus groups, comprising 20 participants in total, were conducted at a community health service for older adults.

XSL•FO
RenderX

Each focus group comprised 3–5 participants and lasted approximately an hour. The topic guide (Multimedia Appendix 1) was developed and discussed with a consumer advisor. Each focus group was facilitated by a moderator (WQK). At the outset of each session, the moderator reiterated the research purpose, explained the session structure, and answered any questions. All participants were offered a AU $20 (US $14) gift voucher as a token of appreciation for their time and participation. The average duration of focus groups was 67 minutes. All sessions were audio-recorded and transcribed verbatim.

Data Analysis

Data were imported into NVivo14 for data management. Data were analyzed using reflexive thematic analysis [17] both inductively and deductively based on SOC to identify strategies used by participants. First, WQK immersed herself in the data by reading and re-reading the transcripts and listening to the audio recording. During this process, data were coded descriptively and inductively through open coding. Next, codes were organized based on the SOC model and grouped into themes and subthemes. This was an iterative and reflective process, where the researcher moved back and forth between preliminary themes. Two meetings were arranged with the research team to discuss and explore the wider team's perspectives (JL, KL, and NP) on the data and codes. For example, after organizing codes based on the SOC model, team discussions provided a sounding board as to whether data fitted into the preliminary themes. From discussions, subthemes like "passive selection of technology" were created to avoid "force-fitting" data into the "selection" component of the existing SOC model, acknowledging that while participants "select" technology, this could be based solely on circumstantial reasons. This process provided valuable leverage of multidisciplinary expertise to achieve a richer and more holistic interpretation of the data and the interrelationships between themes.

Researcher Reflexivity

Considering the reflexive nature of our analytical approach, it is imperative to reflect on how the authors' background and experiences shaped data analysis and interpretation [17,18]. The interviewer (WQK) is a lecturer in occupational therapy and an experienced qualitative interviewer, with more than 7 years of experience working clinically with older adults. This allowed WQK to understand and embrace older adults' perspectives and drive to remain independent. As an international researcher from Singapore, WQK could miss out on participants' nuances relating to local contexts in Australia. Field notes were taken and discussed with the research team (JL, KL, and NP) who contributed their professional and research expertise during data analysis to situate our findings in both local and international contexts. They also contributed their expertise in situating findings with theoretical underpinning.

Trustworthiness

This study followed a methodologically rigorous process, based on Lincoln and Guba's criteria for trustworthiness [19]. First, to ensure transparency and confirmability, data management and analysis of the reflexive thematic analysis process took place on the NVivo software. Next, findings were discussed with the research team during the analysis process to obtain a more holistic, multidisciplinary perspective of the data collected, providing credibility. Another strength is in its use of an established theoretical framework (SOC) to guide data analysis. In addition, the criterion of transferability was aided through having clear descriptions of participants' characteristics and direct quotations. The Standards for Reporting Qualitative Research (SRQR) checklist was to report the conduct of this study (Checklist 1) [20].

Ethical Considerations

Ethical approval was obtained from the University of Queensland (Ref:2023/HE002389). Written informed consent was obtained from all participants, who were also provided with the opportunity to clarify questions prior to the commencement of data collection. Participants' data were stored securely and confidentially in alignment with approved institutional ethical guidelines. Each participant was provided a AU $20 (US $14) gift card as a token of appreciation for their time for participation. To ensure anonymity, participants were given pseudonyms for data analysis and reporting.

Results

Demographic Characteristics

Participants' demographic information is summarized in Table 1. Participants' mean age was 75.4 years, and there was a similar proportion of men and women. More than half of the sample (n=12, 60%) had a Bachelor's degree or higher, and most participants were unemployed or retired. All participants (n=20, 100%) were regular users of smartphones, computers, or laptops. Most described proficiency and daily use of these technologies. Approximately two out of three have had experiences using pedometers or smartwatches; one third are regular users (n=6, 30%) and others have seen or used them previously (n=7, 35%). None of the participants had used virtual reality technologies. Strategies relating to technology use will be described using the SOC model with 3 overarching themes: (1) elective selection of technology— which are further divided into 2 subthemes: "elective, active selection" and "passive selection"; (2) optimization strategies, and (3) compensation strategies.

Certificate III/IV (vocational qualification)	1 (5)
Employment status, n (%)	
Part-time or casual employment	2 (10)
Retired	18 (90)

Theme 1: Elective Selection of Technology

This theme described ways in which participants intentionally and unintentionally chose to use technology to facilitate different aspects of participation in daily living and well-being. The subthemes include (1) elective, "active" selection of technology and (2) passive selection of technology, where participants chose technology but perceived the choice as being "forced" or unavoidable.

Subtheme 1—Elective, "Active" Selection of Technology

All participants described regular use of their mobile phones, laptops, or personal computers, and a few used other technologies, such as iPads, tablets, and smartwatches. Participants conveyed that technologies and applications were purposively selected to help with daily life organization. For example, some described keeping digital records of their accounts or finances, organizing photographs or photobooks electronically, or moving from using physical diaries or calendars to digital versions for more effective management of schedules and appointments.

> *I never seem to have the calendar ... besides, I share it with my husband, so he can see what it's like. When you get older, as so many… medical, specialists… we're trying to keep track of it all.* [Olivia, 74]

Some participants described using technology as a means for leisure and social participation. For instance, a few shared their experiences engaging in mobile games such as quizzes or crosswords, which were described as fun or as means to pass time. Technology was said to provide opportunities for mental stimulation and lifelong learning through information seeking and learning through the internet. Examples included tracing family history and increasing knowledge in various topics of interest, such as medications, artificial intelligence (AI), or other educational topics. Participants expressed that technology provided opportunities to feel connected with the world:

> *Yeah. I'm a great believer in current affairs. If I have a few moments to scroll, I'm on Twitter … the commentary on things that are going on is amazing. You just feel so in touch with the world, you know?.* [Liam, 69]

A few participants described using activity tracking applications to monitor daily activities, such as physical activity levels (eg, step count) and physiological features (eg, heart rate and sleep). One participant expressed that this served as supplementary information that was provided to his general practitioner (GP) during medical consults:

> *It's handy to have, particularly in a medical interaction, like I go to my GP, and I've been recently regularly, two times a month perhaps, for a variety of different reasons, and I like to be able to say that this is what I'm doing, this is how I'm going, and she can monitor my overall activity rates and things like that … I find that particularly useful.* [John, 72]

In addition, participants reported using technology to stay socially connected with family and friends, particularly those living overseas; to reconnect with old friends; and to connect with new friends and likeminded people:

> *I use the cliche apps like Facebook to keep up with friends back in Hungary, family in Australia … Fair few discussion groups on various things like cooking.* [Liam, 69]

> *… maintain old friendships. Yeah. And renew old friendships … I didn't know that [name of friend] would age so well, oh that's great, I'm going to the hairdressers (laughs).* [Hazel, 69]

Subtheme 2—Passive Selection of Technology

Many participants described technology uptake as passive or "forced," where technology selection was seen as essential or unavoidable, regardless of their willingness to use them. This was described as resulting from rapid digitization of services such as banking and electronic commerce. Participants conveyed that this could affect or threaten older adults' participation in meaningful activities and daily routines:

> *We're forced into technology. The thing is you haven't got any choice anymore because essentially when I had to get the blue card for PCYC [Police Citizens*

XSL•FO
RenderX

> *Youth Club – a network of non-profit organisations], the only way you could do it was online… the other thing is that I just got my license renewed and I thought, well, I'll see if I can get this new digital license. The only way you can get your digital license is you've got to download an app.* [Jack, 76]

While most participants identified themselves as being relatively proficient in navigating technology, feelings of being forced into using technology in their day-to-day lives were expressed and described as frustrating and upsetting. They explained that this affected how they engage in activities:

> *I'm annoyed and angry with technology… for instance, now… you're running a book sale, but you've got to register it, and if you want to register it, you've got to have an account, and you've got to have a code name, a code word, and you've got to nominate a time. I've got friends up at [regional book club], people who love books, but they refuse to sign up because they can't nominate a time to get there from [regional area] by public transport ….* [Samuel, 80]

Theme 2: Optimization Strategies

This theme described strategies that were identified by participants to optimize the use of their selected technology to ensure meaningful life participation. It also described how participants optimized their life using technology. These included one's ability to self-monitor, to successfully adjust to and/or integrate technology to fit into daily lives, and to leverage one's digital literacy, positive attitude, and problem-solving skills.

Many described the importance of monitoring the relevance of technology, keeping in mind their intended use of technology for well-being. In other words, they described active deliberation about when technology can be, or has been, beneficial in helping them live well. Some participants expressed the importance of using technology purposefully to avoid time wastage or harmful effects:

> *I choose what I like to see, who I want to talk, and also connecting with family. WhatsApp, I call my sister once a month or once a week. We talk about things. It's something that I really like … not the silly thing of scrolling and scrolling and scrolling [social media], and spending hours doing … that young people do? No. I decide what to do.* [Evelyn, 76]

Participants explained that ongoing deliberation about the utility of technology encouraged them to continue to engage with their chosen technological mediums in some instances and disengage in other instances. For example, while some described leveraging mobile applications to track their daily activities (eg, step count) for self-monitoring, they reported eventually disengaging from these apps after gaining a sense of their activity levels to benefit from the activity without the drawback of the technology:

> *I found that helpful in the beginning, but I just don't use it anymore. I have an idea of how long my walks are … I'd rather enjoy the walk then look … if you go out and, you know, bush or national parks or something, you want to look at your surroundings. You don't want to be embedded in this thing [mobile phone].* [Amelia, 80]

Another optimization strategy was the investment in time and resources to keep updated with technology and be aware of potential risks, such as misinformation or financial scams. Some participants identified digital proficiency, previous professional experience, or personal experiences as assets that enable them to problem-solve through challenges. For example, to keep updated with technology updates, one participant actively acquires knowledge through searching for YouTube videos. A few participants also described the importance of having a positive attitude in seeking resources or in equipping oneself with skills to overcome current or prospective challenges, such as risk management or active problem-solving:

> *We'll have problems, but we need the confidence to think, 'Oh yeah, look, a little bit of sorting out.' I mean, you know, we'll be able to understand it, ask. Whereas some people are just so confused, it's too much for them. But I think if you have a healthy attitude towards aging, you think, 'Well look, I'll make sense eventually, I'll seek out help, I'll look at the YouTube videos, I'll work it out.* [Luke, 79]

Theme 3: Navigating Technology Use and Compensation Strategies

This theme described challenges that participants encountered during technology use and strategies that were discussed as ways to adapt to challenges or limitations; these included choosing alternative technologies that are better aligned with their knowledge and abilities and seeking formal and/or informal support. These strategies enabled them to continue engaging with technologies in ways that support their lifestyles and routines without perceived detractions.

Some participants described functional changes or disabilities that limited their abilities to use technology effectively and safely. One participant provided the example of visual fatigue when looking at smaller fonts, particularly through her mobile phone. Correspondingly, she described choosing an alternative technology that was more suited to her physical abilities (eg, laptop with a larger font size). Some participants also described experiencing challenges or feeling stuck when they experienced technical issues or when they were not able to navigate technology use:

> *I was doing a post to Facebook a couple of days ago, and I wanted to reorder the photographs that I was taking, and they were in an event, and I wanted them to be sequential, and I thought, 'Damn it, I don't know how to do it. I want to get this post out; I don't have time now.* [Luke, 79]

A few participants described seeking informal support from their friends or family members, particularly the younger generation whom they described as being more technology-savvy:

> *I must admit I call him [husband], as when I get stuck, he's very good with technology. And I just call him*

XSL•FO
RenderX

> *... if he fails, we call [a service] or whatever it is* [Emily, 71]
>
> *Or a 15-year-old grandchild* [Hazel, 69]

One participant expressed concerns that relying on family members to assist with technology could lead to burden:

> *My daughter occasionally drops in and tries to sort out things and explain things, but I don't want to burden her anymore.* [Samuel, 80]

A few participants described seeking external support from other sources, such as a local nonprofit organization that assists people who are aged older than 50 years to become competent in computer and internet use:

> *I am going to shortly join a group that's like a technical men's shed [non-profit organization to promote socialization and shared activities among men] … I'm hoping my technological problems like reordering the photographs on Facebook and that sort of thing will be handy … to figure out these little perks that I don't quite know at the moment yet.* [Luke, 79]

Discussion

Principal Findings

This research aimed to understand ways in which older adults perceive they use technology to live well. Specifically, this work utilized the SOC model to understand the "hows"; how older people select or opt out of using technology (selection), how they optimize their resources and skills to use technology to live well (optimization), and how they compensate for a lack of resources and skills (compensation) to maintain meaningful participation in the face of challenges. Corresponding with the "elective selection" ontology of the SOC model, findings revealed that older adults selected technology intentionally to enhance different aspects of their daily lives. Perceived "involuntary" selection of technology could lead to feelings of resentment or frustration. In some instances, this led to participation in activities or routines that did not involve technologies. Corresponding with the "optimization" component of the SOC model, optimization strategies where older adults used technology to improve daily living (and vice versa) included self-monitoring, technology integration into their daily routines, digital literacy and proficiency, and problem-solving skills. Corresponding with the "compensation" aspect of the SOC model, participants' compensatory strategies included choosing alternative technology that suited participants' abilities or skills and seeking support through informal or formal avenues. Our participant cohort was living in Brisbane, Queensland, with good digital infrastructure across the city; the cohort identified themselves as being relatively digitally savvy and well-educated. Given this, findings may be more resonant with this population.

Technology Selection—The "Whats" and "Whys"

Participants in our study reported voluntarily and purposefully selecting technologies that facilitated improvements in various aspects of their daily lives, such as improving the effectiveness and efficiency of self-management (eg, activities within daily routines, health management) and participating in leisure, social, cognitive, and physical activities. These are congruent with the literature on how older adults perceive successful aging [21]. The most frequently used technologies were smartphones, laptops, and/or desktop computers, and the most commonly discussed technological applications were social media and messaging apps, internet searches, digital organizers, and calendars. Purposeful and meaningful selection of technology appeared to encourage uptake and continued use. Our work bolsters findings from several studies showing that the perceived benefits of technology and their meaningfulness facilitated uptake [22], whereas low interest or a lack of understanding about the purpose of technology impeded older adults' use or continued use [23-25]. A possible explanation is that purposeful, autonomous selection of technologies empowers older adults with intrinsic motivation, which could in turn encourage sustainable use of technology beyond the novelty period [26]. On the contrary, some technologies were selected nonautonomously or, in some participants' words, being "forced" upon them with circumstantial changes. These might have been further affected by the COVID-19 pandemic, which has led to a particular acceleration of service digitalization [27,28]. When technology use is perceived as involuntary, this could lead to reduced satisfaction, a sense of oppression, or frustration [29]. These findings highlight the importance of ensuring autonomy and providing older adults with a choice in selecting technologies that are seen as meaningful in improving their daily living. This is particularly important given the continual interest and development of technology to support older adults to live well.

Technology Use—The 'Hows'

Participants in this study described leveraging different cognitive skills, including metacognition and problem-solving skills, to optimize the use of their selected technology. Metacognition entails actively monitoring and evaluating information to ascertain whether one is moving toward a goal and making decisions on how to make changes to achieve the goal [30]. In our study, older adults described metacognitive processes used to ensure that they use their selected technology in ways that aligned with their personal preferences, lifestyles, and routines. Such monitoring and self-regulation skills have been found to improve health outcomes, such as preventing illness and maintaining health [31].

Older adults also described ways in which they overcame problems that were encountered, such as technical issues or working around software or hardware updates. Such problem-solving skills have been viewed as an important aspect of successful aging [32]. According to Chen and colleagues, problem-solving entails having "fluid resources," which encompasses abstraction and performing mental operations, and crystallized resources, which entail gaining resources through cumulative experience and knowledge [32]. Given that fluid resources are based on reasoning and processing abilities, they can decline with age, particularly in later adulthood [33,34]. On the contrary, crystallized resources can be maintained or increased over time up to late adulthood [34]. Our participant cohort was generally highly educated. Most reported high digital literacy skills as part of their previous professional employment.

XSL•FO
RenderX

This might have contributed to the development of crystallized resources, which allowed them to work through issues and to consider other avenues, such as YouTube tutorials, as a means to equip themselves with the skills and knowledge to overcome challenges. In addition, technology is rapidly developing alongside potential benefits and risks such as misinformation and online scams or fraud. According to National Seniors Australia, more than 600,000 scam reports were made in 2023 with older adults being most impacted [35]. Likewise, the National Council of Aging revealed that worldwide, older adults aged 60 years and older reported US$3.4 billion total fraud loss in 2023 [36]. Accordingly, problem-solving skills appear to be requisite to afford older adults the confidence and abilities to use technologies in calculated ways. This includes ensuring that the benefits of technology outweigh their risks and for technology use to be meaningfully aligned with older adults' personal well-being goals.

Some participants described a positive outlook and a "can do" mentality as being an important strategy for technology use. Positive attitudes have been found to be a psychological resource in healthy aging [37,38] as studies have found that older people with a more positive attitude were more likely to have better self-reported health and well-being [39], participate in community and physical activities [40], and activate health-promoting behaviors [41]. In our study, such behaviors include trying to find solutions to overcome potential problems encountered to continue using technology in a meaningful way. This suggests that when designing interventions to support older adults to engage in technology, considerations should also be made to inculcate positive attitudes and consider measuring attitudinal changes as an outcome measure.

Some older adults may lack the confidence or ability to use technology in ways that they perceive as meaningful. For instance, some participants in this study expressed a lack of confidence to overcome issues encountered and may lack "crystallized resources" such as digital proficiency to navigate issues. In such instances, support appears crucial, including informal support from family members and formal support from organizations. While informal support is valuable, some study participants also expressed concerns about burdening their family, particularly if they sought help more frequently than they hoped. Such self-perceived burden can affect older adults' self-concept [42]. Considering that technology is continuously evolving, it is more than likely that any users of technology, including older adults, may require support to troubleshoot potential issues. While family members might be able to bridge obstacles [43], it is important to consider sustainable ways, such as community training hubs, which older adults can receive technological support as required. While such services might be available, many participants in this study did not seem aware of such services; this resonates with findings from other studies [43,44].

Implications for Practice

There is increasing interest in using technology to support healthy aging, as seen through continued development and research in this field, alongside trends of rapid development of digital infrastructure in developed countries worldwide. Despite this, a lack of technology uptake and sustained use remains a pertinent issue [25], and efforts continue to be made to improve digital uptake particularly among older adults nationally [45] and internationally [46]. Our findings provide practical implications to support aged care organizations, centers, and care providers to support older adults to use and integrate digital technologies into their daily lives. Regarding technology selection, our study suggests that meaningful selection of technology by older adults provides them with a sense of autonomy and motivation for sustained use. Selected technologies must serve a purpose, such as meaningfully supporting aspects of their daily lives. Moving forward, aged care organizations, centers for seniors, and health care professionals working to prescribe and equip older adults to use technologies should consider empowering them with the autonomy to reflect on their needs and abilities and to choose technologies that can be personalized to their routines and preferences [47]. Forced selection can be counterproductive in supporting older adults' well-being, and it must be acknowledged that older adults may opt out of using technologies. If forced selection occurs, additional supports are likely necessary to support older adults in using technologies and to mitigate the risk of excluding participation.

In terms of optimization strategies to use technology purposefully, cognitive processes, including metacognition and problem-solving, appear necessary to empower older adults with the confidence to navigate the use of technology in ways that align with their intended purpose. This is particularly true of technologies that are dynamic, which can affect ways of using or operating them [48]. Likewise, a positive attitude toward using technology and its challenges appears to be an important, facilitatory resource. Therefore, service developers or health care professionals working to equip older adults with technological skills should also consider the cognitive aspects of using technology and empower older adults to gain skills and knowledge to use them in reasoned ways. Examples might include empowering older adults with problem-solving skills [49], building self-efficacy and confidence in managing prospective challenges, or positive thinking training [50]. Regarding compensatory strategies, being supported to use technologies and navigate challenges is important [51]. Such resources may include family support and external support services like community hubs. Given that not all older adults may have family support, it is important to ensure that external support services are readily accessible to promote digital inclusion [52] and to minimize the negative repercussions of digital exclusion, such as poorer health outcomes and social isolation [53].

In terms of leveraging the SOC model as a theoretical framework—our findings underlined its utility and success in providing an established framework to guide our analysis and interpretation of the "how" of individual older adults could integrate technologies into their daily lives. However, individuals' goals and strategies are often interrelated with contextual demands. For example, our subtheme "passive selection of technology" was largely influenced by participants' perceptions and experiences of a rapidly developing digital infrastructure that influenced their uptake of technology.

XSL•FO
RenderX

However, the SOC model provides limited consideration of contextual and societal factors that can influence the aging process. Accordingly, researchers leveraging the SOC model to understand digital engagement should take into consideration its limitations and reflect how contextual demands influence individuals' goals and strategies.

Limitations

The limitations of this study must be acknowledged. While several recruitment avenues were used to recruit participants, all participants were recruited from a healthy aging clinic and were relatively physically active. There was no option in our demographic survey to capture data of frequency of technology use in a week, and this should be acknowledged as a limitation given that this knowledge could provide more information on participants' digital proficiency. However, most identified and described themselves as being technologically savvy and relatively well-educated, with all reporting weekly use of computers/laptops and smartphones. Participants' digital proficiency could lead to response bias, and findings from this research may be more resonant with this population and may be less representative considering other demographic groups, particularly older adults who are less active and technologically savvy. Finally, this study was limited to participants who could speak English, and as such, our findings may have excluded non-English speaking older adults' perspectives and experiences. Future studies might consider further exploring understanding technology use and non-use in other population groups.

Conclusions

Framed with respect to the SOC model, this study contributes to a theoretical understanding of how older adults use technology to live well. Older adults purposefully select technologies that align with their priorities in living well, and this appears to be a facilitator for technology uptake and sustained use. Older people leverage different resources and skills to use their selected technologies in meaningful ways. These include metacognitive skills, problem-solving skills, positive attitudes, and internal and external support. These findings provide important considerations for technology developers to design technology in collaboration with older adults to ensure that they align with needs and preferences. It is also evident that digital literacy is not sufficient to empower older adults to use technology; when empowering older adults to use technology, service providers should also consider facilitating other resources and skills.

Acknowledgments

We would like to thank all participants who contributed to this study and to UQ Healthy Living for supporting our recruitment and data collection process. This research was funded by the University of Queensland's School of Health and Rehabilitation Sciences New Staff Start-Up Grant.

Data Availability

The study was not preregistered. The data generated and analyzed in this study are not publicly available to maintain participant privacy and confidentiality. However, deidentified parts of the interview transcripts may be obtained from the corresponding author upon reasonable request.

Authors' Contributions

WQK planned the study, sought ethics approval, recruited participants, conducted focus groups and analyzed the data, and wrote the paper. JL, NAP, and KL contributed to the study design, interpretation of findings, and critical revision of the manuscript.

Conflicts of Interest

Abstract

Background: Little is known about how surrogates make end-of-life care choices for patients who lack the ability to make decisions for themselves.

Objective: The study aims (1) to identify key themes that emerged from participants' free-text responses to a large nationally representative vignette survey about surrogate decision-making in end-of-life care and (2) to determine if an advanced artificial intelligence (AI) chatbot could assist us in accurately and efficiently performing qualitative analyses.

Methods: Our dataset included 3931 free-text responses from a nationally representative survey of 6109 individuals. In this qualitative study, we first familiarized ourselves with the free-text responses and hand-coded the first 200 responses until we reached saturation. We then created a codebook, initial themes, subthemes, and illustrative quotes. Subsequently, we prompted ChatGPT-4o to analyze the entire dataset of 3931 responses and identify frequent keywords and generate themes and quotable quotes. We validated responses by comparing the AI's keyword counts to qualitative software (NVivo, Lumivero) counts and cross-validating AI-generated quotes with the original transcripts.

Results: We identified several key themes: surrogates more often chose comfort care for care recipients with dementia, particularly at advanced stages. They also strongly weighed the patients' perceived quality of life and functional status. Many reported making surrogate decisions based on their own lived experiences or values, rather than making decisions aligned with the patients' previously stated wishes. There was no significant difference between the AI and qualitative software's keyword counts. The most frequent keywords included "life" (2051/81,713, 2.51%), "quality" (903/81,713, 1.11%), and dementia (507/81,713, 0.62%). Overall, AI-generated themes closely aligned with aforementioned human-generated themes. Manual coding of the first 200 free-text responses required 4 hours, including codebook development. In contrast, ChatGPT-4o generated themes in <10 seconds using the predefined codebook. However, dataset preparation, output verification, iterative prompting, debugging, and validation required several weeks.

Conclusions: Surrogates often base end-of-life decisions on dementia stage, perceived quality of life, and their own lived experiences, rather than patient preferences. Using an AI chatbot to perform qualitative analysis on free-text responses may help extend the work of qualitatively trained investigators, especially for large datasets such as free-text responses to large surveys.

Chatbot; geriatrics; comfort care; life-extending care; qualitative research; survey

Introduction

Background

Many chronically ill older adults recognize the importance of discussing their end-of-life desires with their surrogates, family, friends, and clinicians, in the event they are unable to communicate during an emergency. Having advanced care directives reduces surrogate stress by avoiding the urgent decision-making process during emergencies and potential undesired treatment. It also may increase the likelihood that patients receive the care they desire, particularly in end-of-life situations where they may be unable to express their wishes [1].

XSL•FO
RenderX

Despite the increased use of advanced care directives, there are still incongruent care preferences between patients and their surrogates [2].

Gaps and Preliminary Studies

This discordance in end-of-life decision-making suggests that better facilitation and understanding of end-of-life decision-making are needed [3]. Previous studies have focused on the effectiveness of advanced care directives, caregiver communication, or physician influence only [1,4-6]. However, the end-of-life decision-making process is complex, and individuals must consider multiple factors when deciding. Our team created a vignette-based cross-randomized survey to better understand surrogate factors in making end-of-life decisions [7]. Quantitative results suggest that surrogates were less likely to recommend life-sustaining treatment for persons living with dementia, that surrogates were more likely to ignore patient preferences for life-extending treatments when the person had dementia, and that surrogates were more likely to choose treatments that matched their own preferences when patients' wishes were unclear.

Objectives

In this study, our *objective* was to analyze free-text responses to the survey question "What were the main considerations that led you to give the answers you provided in the module above (which captured your end-of-life care choice for your care recipient)?" Given this survey included 6109 individuals, we decided to leverage artificial intelligence (AI) to assist our team in performing a qualitative analysis. Alternative existing approaches to analyzing such a large volume of data, including qualitative thematic analysis, have drawbacks including the need to select and analyze a smaller subset of responses to avoid the extensive resource use needed to perform traditional qualitative analysis [8]. Here, we share the findings of our qualitative analysis of free-text responses relating to end-of-life care decision making and detail how we used an AI-generative chatbot, ChatGPT-4o, to facilitate the analysis.

Methods

Data Sources

Overview

We analyzed free-text responses from a nationally representative, web-based experimental survey that included 6109 adults aged ≥18 years [7]. Thirty-five percent of survey respondents did not provide a free-text response to the question soliciting a rationale for the end-of-life care choice made in the vignette and thus were not included in this analysis. This survey was developed by co-authors LHN and MM. Both are PhD health economists and professors with experience studying the interaction between health care use and economic outcomes through combining survey, administrative, and clinical data. No relationship was established between the research team and participants before study commencement. A professional survey company, Ipsos Knowledge Network survey platform, recruited participants between December 8, 2022, and December 19, 2022, and ensured complete anonymity to the researchers, reducing social-desirability bias and other experimenter-demand concerns [9]. Surveys were available in English and Spanish, and participants were provided with devices to complete the survey if they lacked home computers or internet. This vignette-style survey was intended to systematically investigate surrogate decision-making in the context of dementia-related cognitive impairment and end-of-life care for older adults [7]. Further details on the type of data collected, timeline of data collection, and procedures are detailed in our previously published paper [7].

The objective of this paper was to analyze all the free-text responses qualitatively that were provided to the question "What were the main considerations that led you to give the answers you provided (Comfort Care or Life-extending Care) in the module above (which captured your end-of-life care choice for your care recipient)?" We followed the Standards for Reporting Qualitative Research (SRQR) guidelines (Checklist 1) in reporting this work [10]. Our dataset did not include any personal health information as this was an anonymous survey to a nationally representative group. Thus, we did not provide any personal health information to ChatGPT. While ChatGPT was used as a tool to perform efficient coding and theme generation, it was not used for writing assistance.

Summary

We performed several steps to conduct this qualitative analysis of free-text responses including (1) following traditional thematic analysis procedures to code and generate themes on a subset of free-text responses [11], (2) prompting ChatGPT-4o to use our codebook to generate its own themes and quotable quotes, and (3) debugging and validating the AI responses. We first familiarized ourselves with the data by reading and rereading the first 200 responses to the free-text question. Then, we hand-coded the first 200 responses, generating a preliminary code book and iteratively improving it through team discussion. Next, we created a list of preliminary themes and illustrative quotes following traditional thematic analysis procedures.

After providing the data and our codebook to ChatGPT-4o (GPT-4 variant, May 13, 2024; used via Google Chrome browser), we prompted it to generate relevant keywords, keyword counts, themes, and illustrative quotes. We performed several steps to validate the AI-generated results, including comparing AI-generated themes and quotes with themes and quotes generated by qualitatively trained human professionals and comparing keyword counts with counts generated by a commonly used qualitative analytic software, NVivo (Lumivero) [12]. Finally, we put the findings into the context of the current literature.

Phase 1: Generating a Valid Approach

Prior to initiating the analysis, we conducted a literature review to identify how AI had been used in previous qualitative research. In particular, our methods were shaped by studies by Nashwan and Abukhadijah [13] and Van Veen et al [14], who provided prompt examples. Only limited studies have used AI approaches for analyzing free-text responses, so we also compared ideas on how to validate our AI findings with other academic teams doing similar work. These discussions yielded several suggestions, including comparing themes side by side

XSL•FO
RenderX

between AI and human-generated themes and doing a keyword count comparison with commonly used qualitative software.

Phase 2: Familiarization With the Data and Hand Coding

First, a physician scientist with experience caring for patients at the end of life and graduate-level qualitative training (EMG) and two other qualitatively trained research staff members (MB and JGP) read the first 200 participant responses. Then, 2 team members (EMG and MB) inductively coded the responses to the first 200 responses together. At this point, we reached thematic saturation, whereby no new significant themes continued to emerge, and concluded manual coding [15,16]. During this session, the team members created a preliminary coding schema in which we identified 6 major codes and several subcodes relating to end-of-life decision-making (Table S1 in Multimedia Appendix 1). The codebook was then iteratively refined through group discussion. Then, a third team member independently coded the same 200 responses (JGP). Finally, the principal investigator of the study (LHN), who designed the survey and had performed a preliminary human qualitative analysis after reading a sample of the responses, provided additional suggestions on the codes from her analysis, which we incorporated into the final codebook after team discussion.

Phase 3: Human-Identified Themes, Subthemes, and Illustrative Quotes

Once we felt confident that our codebook reflected the topics and scope of the data from the first 200 respondents, we generated themes and quotes that were illustrative of the major and minor themes. Investigator triangulation (multiple investigators with multiple areas of expertise) was used to establish the trustworthiness of our findings [17]. We compiled a table to display themes and quotes.

Phase 4: AI Analyses

Next, we used ChatGPT-4o to extend our human-generated analysis by providing it with the entire dataset of 3931 responders to the free-text question. We also piloted other generative AI tools (Microsoft Copilot and ChatGPT-3) but found that ChatGPT-4o provided the most usable responses and allowed us to upload larger amounts of data. Before entering the dataset in ChatGPT, we cleaned the data by removing all nonresponses. Free text containing responses of “none,” “n/a,” “na,” “no,” “nothing,” “no answer,” or “…,” were removed from the dataset submitted to ChatGPT to limit error. These responses were instead coded as “0” to indicate no free text was available. Data were uploaded via a Microsoft Word document containing a table with headings labeled “Free Text Responses,” “Age,” “Race/Ethnicity,” and “Gender.” ChatGPT processed the entire document at one time and required no chunking of information submission. No application programming interface or interface was used.

Our initial prompt to ChatGPT provided important context on the task, including that we planned to perform a qualitative analysis of free-text responses and that the AI should act as a qualitative analyst using our codebook and data to identify themes and quotable quotes. Although we considered having ChatGPT-4o inductively code the responses without human input, we anticipated that this would require much more investment by our team on the back end to iteratively prompt and refine themes. We also wanted to avoid the risk of irrelevant or erroneous themes or excessive AI “creativity.” We also prompted it to find the most common keywords in the text and generate keyword counts.

To illustrate how we completed this analysis, so it can be replicated, we share several sample prompts and how we validated responses:

1. The first prompt set up the research study context, its methods, and the AI’s role. An example prompt is: “This is a large survey study focused on end-of-life decisions, and you are a qualitative researcher analyzing the free-text responses to these questions.”
2. Next, we asked ChatGPT-4o to code the data using our codebook. A sample prompt includes: “This is a preliminary coding schema for our research. Using this codebook, code the entire sample. How did you do this?”
3. We asked ChatGPT-4o to create themes and subthemes and identify quotable quotes or key phrases that “make an impression on people from the text.” We then manually searched the dataset in NVivo to ensure the quote was verbatim and not fabricated.

Then, we asked the AI to create keywords identified in the entire dataset. We first quantified keywords by querying NVivo using the “word frequency/query” function. NVivo created a list of the most frequently used words in the dataset with the exception of proper names. NVivo provided the keyword, its frequency in the dataset, and the weighted percentage out of all words in the dataset. Then, we provided each keyword to ChatGPT-4o in addition to supplying it with a data file which included the full dataset of responses. We then queried ChatGPT-4o for exact keyword counts and weighted percentages, for example, “How often is the word ‘life’ found in this dataset, and what is the weighted percentage of ‘life’ among all words in the dataset?” by asking it to find how many times the specific keyword could be identified in the dataset.

Ethical Considerations

The study was found to be exempt by the Johns Hopkins Homewood institutional review board (HIRB00012400), and we followed SRQR guidelines in reporting this work. Our dataset did not include any personal health information as this was an anonymous survey of a nationally representative group. Thus, we did not provide any personal health information to ChatGPT. The survey participants received compensation for their participation; the amount is unknown and proprietary due to a lump sum getting paid to Ipsos, the survey company.

Results

Overview

Free-text responses were created by 3931 (65%) surveyed participants. Free-text responders were significantly older, had higher educational attainment, were less likely to be working full time, and were more likely to be a caregiver for another adult than nonresponders. They were also significantly more likely to be married, have higher income, and carry a diagnosis

XSL•FO
RenderX

of a chronic illness. Over half of free-text responders were people with chronic illnesses. A total of 1438 (37%) of them identified as caregivers, of which 601 (42%) stated that they provided ≥20 hours of care each week (Table 1). No significant differences were noted for sex, race, or region of the country.

[a]GED: General Educational Development.

Human coding identified six major themes: (1) rationales provided for making end-of-life decisions, (2) the role of physical function in decision-making surrounding end-of-life care, (3) the role of dementia in decision-making surrounding end-of-life care, (4) impact on caregivers, (5) quality of life, and (6) basing decision on personal preferences or "I would" statements. Subthemes identified by human coding included: expected trajectory, drawing on individual experiences to decide, the caregiver feels a duty to choose to extend life, patient autonomy or preferences, ethics, emotional strain on family, limited quality of life with dependence on others, and living a life with value (Table 2).

XSL•FO
RenderX

Table . Human-derived major themes, subthemes, and quotable quotes.

Major theme and subtheme	Quotable quotes
Rationales provided for making end-of-life decisions	
Expected trajectory	• *If there is no brain activity found then and no family to contest then make patient comfortable. Many things to be considered in all cases based on doctor advice and family concerns. All cases and circumstances are not the same!* [White non-Hispanic male with chronic disease, 72 y] • *Mr. Jones is not able to eat, speak and move around. He would be in bed for the rest of his life, and that's not how he should live his life. It's very hard to be living under his conditions.* [Hispanic female adult, 54 y]
Drawing on personal experiences to decide	• *My own mother has middle to late stage Alzheimer's and I know her quality of life is already so impaired that it's no way to live. She looks at a newspaper and asks if it contains the "numbers and directions for her"—she has trouble recognizing what a fork is. Alzheimer's is heartbreaking and undignified for her. She is no longer who she was and does not know her own family. This is why I would choose for not invasive methods.* [White non-Hispanic female adult, 57 y]
A caregiver feels a duty to choose to extend life	• *Even if the person can be kept alive, it's not really living if the person is kept alive only to ease the guilt of a caregiver or significant other. I think the caregiver feels guilty if they do not try everything possible to extend life.* [White non-Hispanic female adult, 72 y]
Deciding based on patient autonomy and preferences	• *She had decided before she became ill what she wanted so family wouldn't have to decide that for her. I truly believe we should follow the patient's wishes if written.* [Black non-Hispanic male caregiver, 73 y] • *If a patient has a do not resuscitate order it should be followed, if not measures to sustain life [should] be used.* [White non-Hispanic male with chronic disease, 72 y] • *Having had both parents in similar situations when in their 80s. Neither had an advanced directive, but me and sibs were clearly told for years from each that they did not want to live longer if bedridden.* [White, non-Hispanic male with chronic disease, 67 y]
Role of physical function in decision making surrounding end-of-life care	• *Life has value, Mr. Smith has limited mobility but otherwise is fully aware of his own existence. I believe Mr. Smith wants to live!* [White non-Hispanic male adult, 61 y]

XSL•FO
RenderX

Major theme and subtheme	Quotable quotes
Role of dementia in decision making surrounding end-of-life care	• *Mrs. Jones will never get better with the dementia. She will slowly lose her ability to talk and eat and the dementia will turn into Alzheimer's disease, and she will pass away a horrible and painful death.* [White non-Hispanic female with chronic disease, 65 y] • *She has dementia that will never improve and there is not much life after that diagnosis. In short there is very little quality of life and it will only get worse.* [White non-Hispanic male adult, 56 y] • *He has dementia already and extending his life would not make his life any better!!* [White non-Hispanic female with chronic disease, 70 y]
Impact on caregivers	
Emotional strain on family	• *I choose not to put the family through the pain of prolonging life that may not be beneficial and could hurt them more in the long run.* [Black non-Hispanic female adult, 55 y] • *I know of this happening to a friend's parent and it was an emotion[al] ride for both. Neither person had a good life until the parents passing.* [White non-Hispanic female adult, 67 y]
Quality of life	
Limited quality of life with dependence on others	• *Quality of life is extremely important to me. Being dependent on others is not a good quality of life.* [White non-Hispanic female with chronic disease, 75 y] • *If he is going to be treated with dignity, and respect, maybe he would have a half-way decent quality of life. Even if he isn't aware of it. I would certainly hope so.* [White non-Hispanic female caregiver, 70 y]
Live a life with value	• *If you can't have quality of life your better off dying.* [White non-Hispanic female adult, 68 y]
Basing decision on personal preferences or "I would" statements	• *If I was confined to bed for the rest of my life, I would choose comfort care if the opportunity arose.* [White non-Hispanic male with chronic disease, 31 y] • *I put myself in those situations, primarily. Since I would not want unnecessary life extension, especially at 85+, I would not want this for anyone else. Interestingly, although I can fluctuate on my religious beliefs, the fact that I can consider an afterlife is comforting, and a reason to not artificially extend a few years here at the end.* [White non-Hispanic male caregiver, 68 y]

ChatGPT-4o identified 7 major themes from the free-text responses and also identified subthemes and representative quotes (Table 3). We further asked ChatGPT-4o to indicate the demographics of the responder (Table S2 in Multimedia Appendix 2) and indicate if the proxy was choosing comfort care, life-extending care, or both, which it performed accurately

XSL•FO
RenderX

(Table S3 in Multimedia Appendix 3). In Table S3 in Multimedia Appendix 3, we also categorized errors made by the AI, including fabrication of quotes and substantial modifications of quotes. To aid in the replication of this work, we summarized the additional steps taken to ensure rigor in our analytic approach in Multimedia Appendix 4.

Table . ChatGPT-4o-derived themes using the codebook generated by humans.

Major theme and subtheme	Quotable quotes
Respect for advanced directives	
Honoring patient preferences	*The caregivers should follow the advanced directives.* [White non-Hispanic female, 51 y]
Clear directives prior to illness	*She said prior she did not want to have the invasive treatments. It is honoring her wishes.* [White non-Hispanic female, 67 y]
Quality of life	
Independence versus dependence	*If no quality of life, why take drastic measures to extend it?* [White non-Hispanic male, 88 y]
Burden of dementia	
Enjoyment of life and meaningful existence	*Life in bed is not a good life. Waste of resources that could be used on others.* [White non-Hispanic male, 75 y]
Loss of memory and cognitive decline	*With dementia, he lives in a state of confusion and fear. This will continue to get worse and quality of life will worsen even more.* [White non-Hispanic female, 54 y]
Emotional and financial toll on caregivers	*Having a caregiver 24-7 would cause an undue burden on family. Some family members would not be able to handle watching a family member deteriorate in front of their eyes.* [Black non-Hispanic male, 60 y]
Caregiver burden	
Emotional hardship for families	*The dementia has taken over, there is no quality of life. How much time are you buying to keep him in a state of no memory?* [White non-Hispanic female, 66 y]
Financial strain of prolonged care	*My father and my mother-in-law both had dementia, and it was very difficult and expensive to keep them alive.* [White non-Hispanic male, 62 y]
Ethical and religious considerations	
Sanctity of life	*Life, to all extents, is precious, given by a power greater than the limitations of medical care.* [White non-Hispanic male, 81 y]
Beliefs about life and death	*We are not the ones who should take away life.* [White non-Hispanic male, 87 y]
Patient dignity	
Maintaining respect during end-of-life care	*You should be able to die with dignity. Laying in bed is not living, it is existing.* [White non-Hispanic male, 72 y]
Avoiding perceived indignities	*End it so your son can get on with his own life.* [White non-Hispanic female, 75 y]
Decision-making challenges	
Lack of clear information	*It's a tough call to make when all the information is just a few paragraphs.* [White non-Hispanic male, 56 y]
Emotional difficulty in making choices	*I am unable to respond because I don't believe I should decide on another person's life.* [White non-Hispanic female, 83 y]

Validation and Lessons Learned Using Generative AI

In Table 4, we depict a comparison of human- and ChatGPT-4o-generated major themes and subthemes. Several themes overlapped between human (black text) and AI (purple text) thematic analysis. While the AI did not always name the theme the same as our human analysts, the meaning was similar. Overall, there were several differences observed between human-generated and AI-generated tables, including that the AI closely relied on the codebook to generate themes, representative quotes were shorter, and more themes were generated by the AI. In addition, AI-generated themes were more descriptive—summarizing directly what participants said—rather than interpretative (eg, offering latent meaning or suggesting why participants may have said what was stated). ChatGPT created themes such as "quality of life" without extrapolating underlying motivations or cultural values, such as human-derived "drawing on individual experiences to decide."

Table . Comparison of human-derived and artificial intelligence–derived thematic analysis.

Themes	Human-generated analysis	ChatGPT-4o analysis
Quality of life	✓	✓
Rationales provided for making end-of-life choices	✓	
Expected trajectory	✓	
Drawing on individual experiences to decide	✓	
Caregiver feels duty to choose to extend life	✓	
Deciding based on patient autonomy and preferences (respect for advanced directives)	✓	✓
Role of physical function in decision making surrounding end-of-life care	✓	
Role of dementia in decision making surrounding end-of-life care (burden of dementia)	✓	✓
Impact on caregivers (caregiver burden)	✓	✓
Basing decision on personal preferences or "I would" statements	✓	
Decision-making challenges		✓
Ethical and religious considerations		✓
Patient dignity		✓

We note that the AI generated 3 themes not included in our human-generated analysis: decision-making challenges, ethical and religious considerations, and patient dignity. While codes relevant to these topics existed in the human codebook, they were not prioritized in the final theme set due to their relatively lower frequency in the subset of responses reviewed manually. It is possible that these themes appeared more frequently across the full dataset analyzed by ChatGPT, which highlights the potential for AI methods to surface lower prevalence but potentially meaningful perspectives that might be missed in human review.

During the validation of ChatGPT-4o-generated quotable quotes by human analysts, we identified 3 major errors. First, ChatGPT-4o would often combine statements from multiple participants into one quote. Second, it sometimes ignored the prompt to create verbatim quotes and instead modified the quote to be more concise or grammatically correct. Third, it sometimes fabricated quotes entirely (hallucination). For the first error, combining statements, we addressed the challenge by reformatting the data into a table rather than using Microsoft Word, so the AI could more easily identify when one quote ended and another started. This improved ChatGPT-4o's quotable quote reliability substantially. Our previous data format separated participant responses with spaces only. For the second error, paraphrasing, we reprompted ChatGPT-4o that exact quotes were needed, and they could not be modified. With reprompting, ChatGPT-4o was able to list verbatim quotable quotes. Below we display an example of the second error. While the meaning is the same, the content is paraphrased. For the third error, complete fabrication of quotes, we removed these from the tables and reprompted the AI to choose new verbatim quotes followed by verifying their existence in the dataset. We show more examples of all 3 types of errors in Table S3 in Multimedia Appendix 3.

Original quote by responder:

> *Life is precious and we should not try to end it of our own accord. It is God's role to extend or end a life.*

ChatGPT-4o-generated quote:

> *Life is precious and should be preserved as long as possible, according to God's will.*

In Table 5, we listed the 11 most common keywords identified by NVivo within the free-text responses and provided the counts and weighted percentages for keywords in NVivo and ChatGPT-4o. We chose the 11 most common keywords because starting at the 12th keyword, the frequency of the count was

XSL•FO
RenderX

much lower. We identified that NVivo and ChatGPT-4o were using different methodologies to provide keyword counts and weighted percentages. Initial prompts to ChatGPT-4o generated counts and weighted percentages that were lower than NVivo, suggesting undercounting. We show how we corrected the discrepancy with the following example. To correct the count for the keyword "life," we told ChatGPT-4o that NVivo had come up with a count of 2051 for the keyword "life" and asked it what it had done incorrectly, as its initial count for life was 1984. ChatGPT-4o responded that the NVivo count was correct, and what it was doing wrong was "The initial discrepancy was due to not properly accounting for cases where 'life' was followed by punctuation or appeared at the end of a sentence or line." We then asked ChatGPT-4o to repeat the experiment using the correct method. Counts were still discrepant after this correction, though the ChatGPT-4o counts were closer overall to the NVivo counts after this reprompting. We then discovered that NVivo excluded "stop words," which were considered insignificant. When we changed the NVivo settings to include the stop words, we then produced considerably closer weighted percentages, which are shared in Table 5.

Table . Keywords generated by NVivo compared to ChatGPT-4o-generated keywords and their frequencies.

Keyword	NVivo keyword count (weighted percentage), n (%)	ChatGPT-4o keyword count (weighted percentage), n (%)
Life	2051 (2.51)	2051 (2.48)
Quality	903 (1.11)	904 (1.09)
Care	551 (0.68)	551 (0.67)
Dementia	507 (0.62)	509 (0.61)
Want	481 (0.59)	481 (0.58)
Able	366 (0.45)	366 (0.44)
Live	366 (0.45)	366 (0.44)
Wishes	351 (0.43)	351 (0.42)
Family	346 (0.42)	346 (0.42)
Still	321 (0.39)	321 (0.39)
Think	255 (0.31)	255 (0.31)

Time Considerations and Replication

Human coding was time-intensive; our team spent 4 hours coding the first 200 responses to the free-text question, recoding the first 200 responses, and creating and revising the initial codebook. ChatGPT-4o took <10 seconds to generate themes using our codebook. However, preparing the dataset for ChatGPT-4o, verifying the content, subsequent reprompting and verification, identifying methods for debugging, and validating took several weeks.

Due to ChatGPT-4o being a large language model (LLM), replication of similar outputs using the same prompt and dataset was challenging. We often received varying answers to the same command using ChatGPT-4o, although the overall major themes identified within the dataset remained relatively consistent. Once we reformatted responses into a table from the initial word file, ChatGPT-4o had more consistent response outputs to the same prompt.

Discussion

Principal Findings

In this ChatGPT-4o-assisted qualitative analysis, we identified several themes related to how surrogates make end-of-life care choices for patients. Proxies' decisions are informed by prior caregivers' prior lived experiences, expectations of quality of life, how advanced the stage of dementia is in the patient, and also personal values, including religious beliefs. In performing this analysis, we also learned several lessons about using AI tools to extend the capacity of our qualitative team. We learned that ChatGPT-4o is capable of using a human-created codebook to search free-text responses to create themes, representative quotes, and keywords. In addition, we learned that ChatGPT-4o-generated themes are primarily descriptive and closely match codes identified by humans. We also found that validation by humans is necessary, and ChatGPT-4o can sometimes provide insights on errors and correct them when prompted to do so.

This unique cross-randomized experiment allowed our team to provide new insights into what role dementia plays in surrogate decision-making. We found that many surrogates consider the stage of dementia to make end-of-life decisions. Caregivers may correctly identify that dementia is incurable and that extending life when dementia is advanced may not allow the individual to live the way they once did, free of the support of others. Others identified that quality of life in dementia may be tied to the ability to recognize and socialize with others, and when recognition diminishes, extending life may not be desired. Prior research also found that some surrogates equate dementia with loss of the "self" and view recognition as a key marker of dignity and quality of life [18]. Some felt extending life was warranted when the patient previously requested it or because of their religious beliefs.

Another common theme was drawing on individual experiences or preferences to make decisions. A key finding in the

XSL•FO
RenderX

quantitative survey and the AI qualitative analysis was that when preferences were not clear, surrogates made choices that aligned with their own wishes. Personal beliefs about how one would feel if faced with these life choices were weighed in making the decision. However, ethically, proxies should make choices in line with patient preferences and not their own [19]. In some cases, proxies chose comfort care after projecting what *their* future self may feel like when aged or if *they* had the functional status of the patient described in the vignette. These survey and qualitative findings could inform clinical practice in several important ways: (1) clinicians should feel empowered to inform proxies that decisions should be made that are in line with patient preferences and (2) education should be provided to proxies about advanced dementia and its impact on quality of life, as well as the impact life-extending care may have on patient comfort and well-being.

Other literature on end-of-life choices and surrogate choices have found that while 90% of caregivers acknowledge that dementia is incurable, only 40% see it as life-limiting [20]. One study indicates that caregivers of people living with dementia who have chronic illnesses and who discuss goals of care with clinicians are more likely to have accurate prognostic understanding on the end-of-life care for persons living with dementia [21]. In addition, caregivers with better prognostic understanding were more likely to state a preference for comfort-focused care, and their care recipients were less likely to receive burdensome interventions and have greater comfort during the dying process. Studies have also recognized racial differences in advanced care planning, with African American persons reporting lower rates of advanced care planning completion (89% vs 73%) and lower preference for comfort care [22]. Several studies indicate that more education of proxies about the stages of dementia and end-of-life care options would be helpful to improve the quality of proxy decision-making [21,22].

The use of natural language processing AI-augmented qualitative analysis has been described as the "Way of the Future" [23]; however, few investigators have used it to perform qualitative analysis [24]. One team used structured topic modeling coupled with thematic analysis to analyze free-text data from nearly 38,000 English patrons with the aim to improve the user experience of public-facing services in the United Kingdom [25]. This team tested models with 5 to 40 topics and differing covariates and then had 2 human coders conduct thematic analysis to interpret the topics. In contrast with this approach, our approach did not require team members to have requisite skills in machine-learning methods and thus may be more accessible for qualitatively trained teams. Other AI approaches to analyzing large quantities of free text have included using natural language processing and machine learning models to develop robust classification models [26], but this approach also requires data science or related technical expertise.

Other teams have used ChatGPT-4o and more accessible LLMs to analyze qualitative data [23,27,28]. Experiences of these investigators can be summarized as overall positive in that these LLMs were found to be capable of producing satisfactory analyses that come close to human-generated analyses, but the performance of different LLMs varied, was not predictable, and serial prompting was necessary. Many have stated that themes are more descriptive than interpretive, yet it was easy to use and required less effort than manual coding. We also found that AI themes often did not go beyond what was explicitly stated by the participant and failed to explore latent meaning or social context. This could pose a barrier to using these tools in research where interpretative themes are essential. In addition, researchers found that even when using the same prompts and dataset, slightly different output was generated as AI generative chatbots "learn" over time. While this could improve performance, it also introduces problems with reproducibility. Thus, our team found it important to carefully log all prompts and responses in a log. In contrast to our approach, Carvalho et al [27] used a "series of chain-of-thought prompts to dig deeper into the provided response." This approach had 2 advantages. It allowed the investigators to guide the chatbot to provide them with more positive themes when negative ones were initially suggested, and it surfaced less commonly encountered themes, allowing for more diversity of perspectives. Carvalho et al [27] also found that the paid version of ChatGPT-4o, which our team also used, generated the most accurate responses compared to the unpaid version and Google Gemini. This was particularly true when it was well-prompted and after multiple repetitions were performed in the same analysis.

Because there is currently no established gold standard for using advanced chatbots for qualitative analysis, our team made several deliberate methodological decisions. These included providing the AI a human-generated codebook rather than allowing it to inductively code responses and generate themes "independently." Other teams may choose to allow the AI full discretion in its coding, and this approach could be more efficient and lead to more novel themes. We made this choice because our team had ample qualitative expertise, which allowed for us to code a subset of responses and ensure the codebook reflected key domains of interest. However, this approach may have reduced the AI's ability to discover novel themes and constrained "creativity."

Barriers to the use of AI in qualitative research include concerns over data privacy, a need for upskilling in AI among trained qualitative investigators, and a lack of established approaches to use the tool [24]. Information such as transcripts uploaded to AI platforms is used to develop the underlying algorithms that allow the computer to learn, which some academics feel is problematic from a data privacy standpoint. It is important for academics to follow institutional best practices such as obtaining approval from their ethical review boards prior to engaging in this work. Some institutions may advise using enterprise AI solutions or other tools that allow investigators to select that inputted data will not be externally shared or used to improve the AI's algorithm. Another barrier has been that senior investigators trained in qualitative methods may not possess the skills to use AI for qualitative analysis or teach others how to use it. Similarly, a roadmap is not currently available that outlines how rigorous qualitative analysis can be done with AI assistance. We believe that AI will be increasingly used to analyze large qualitative datasets, and as its use and popularity grow, investigators must learn through trial and error how to best use it and debug it.

RenderX

Limitations

Free-text responses are an important source of data in surveys that collect quantitative measures because they can provide context to answer choices; however, unlike semistructured interviews, there is no opportunity to prompt the interviewee to elaborate on points or explain their statement when it is not clear. We found sentence fragments or short replies that made it difficult to understand what the surrogate's perspective was and could be interpreted differently depending on the person reading the text. Although our research team has a multidisciplinary background, we recognize that we bring our own bias to our work, and this may have affected our interpretation of our findings. We made efforts to increase the validity of ChatGPT-4o's analysis by asking it to show its work, comparing its output with existing qualitative software, and completing our own a priori human analysis on a subsample of the qualitative data, but the use of this tool for qualitative analysis is still new, and thus, there may be errors that we did not recognize.

Conclusions

Participants in a vignette-style nationally representative survey asked to act as proxies provided several different rationales for why they chose to extend care or focus on comfort care in their hypothetical care recipients. Choices were often made based on whether the care recipient had dementia and how advanced it was, perceived quality of life, or the caregivers' lived experiences or values, rather than making decisions aligned with the care recipients' previously stated wishes. This suggests that it is in an individual's best interest to share their care preferences with their intended proxy and engage in advance care planning prior to losing health care decision-making capacity.

Using an AI tool to perform qualitative analysis on free-text responses may help extend the work of qualitatively trained investigators, especially for large datasets such as free-text responses to large surveys. Our advice to investigators who aim to use ChatGPT-4o or other AI generative chatbots is to first complete a human-generated analysis using traditional qualitative coding, provide a codebook to the AI, anticipate the need for multiple prompts, try different LLMs, plan validation approaches and time for debugging, and keep a prompt and response log.

Acknowledgments

During the preparation of this work, the authors tested ChatGPT-4o's ability to qualitatively analyze the free-text responses for end-of-life choices. After using this tool or service, the authors reviewed and edited the content as needed and take full responsibility for the content of the publication. This project received funding from the National Institute on Aging (R01AG059205).

Data Availability

The data that support the findings of this study are available from the corresponding author upon reasonable request.

Authors' Contributions

EMG and LHN conceived of the paper. LHN and MM obtained funding, designed**,** curated, and quantitatively analyzed the survey data. EMG, MB, and JGP qualitatively analyzed the free-text responses and wrote the original manuscript. EMG, MB, and JGP executed the methods and validated the analysis. EMG supervised the investigation and administered the project. All authors had full access to all of the data and contributed to the methodological design, reviewed, and edited the final version of the manuscript.
