This section presents a framework, as depicted in Figure 2, which first outlines the global landscape with its corresponding policies, strategies, and the technologies to be implemented within each key area. Subsequently, a case study focused on Mexico is presented to illustrate the application of this framework in a specific environment. The intersection of regional policies, governance, and the social and cultural context is evaluated to identify constraints and barriers, thereby determining the viable options for this country.

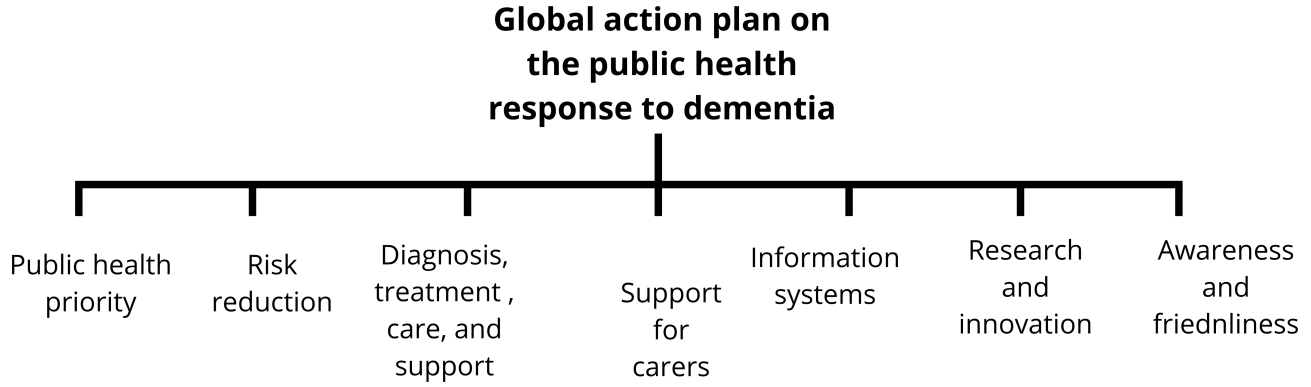

Figure 2. Conceptual framework for contextualizing global technology recommendations.

Following the analysis in the previous sections, the main areas where various policies converge were identified. Consequently, the action areas specified in the Global Action Plan on the Public Health Response to Dementia were selected as the foundational baseline, as shown in Figure 3. These areas serve to identify core priority approaches and determine which existing technologies can facilitate the fulfillment of their objectives.

RenderX

Figure 3. Key strategic areas of the World Health Organization (WHO) global action plan on dementia. Authors' own creation using data adapted from [17].

Based on the analysis, the main issues addressed in global plans and proposals were identified and summarized in Table 3. Along with each specific strategy, the table outlines key problems within each domain, the technologies previously applied to address these issues, and specific examples from the literature. A more detailed examination of these applications follows.

[a]BPSD: behavioral and psychological symptoms of dementia.

Integrating technology into dementia care improves effectiveness when each approach aligns with its intended support area. To facilitate this process, various technological solutions are identified for each strategy based on their relevance and potential applications. This framework serves as a practical decision-making guide to assist stakeholders in selecting suitable approaches based on their strategic priorities.

The areas of public health priority, as well as research and innovation, were excluded from this analysis, given that existing policies have already been evaluated. Furthermore, any technology integrated to support the fulfillment of these plans inherently drives innovation and, in many cases, requires research to ensure successful implementation.

Virtual reality is a type of technology that enables the creation of synthetic environments where users can engage emotionally,

XSL•FO
RenderX

cognitively, and behaviorally, resulting in immersive and meaningful experiences. In the context of dementia care, virtual reality offers several approaches that open new possibilities for early detection and more precise assessment in everyday situations. These include the use of eye-tracking technologies to support diagnostic processes [66], as well as systems that evaluate task performance in daily living [65]. Moreover, virtual reality has been used to train caregivers in the application of care techniques and in responding to behavioral and psychological symptoms [71,72], helping to create more supportive and calming environments. For people living with dementia, it has contributed to maintaining functionality in daily activities and encouraging social interaction [67,70]. It has also proven useful in promoting public understanding and empathy by simulating the sensory and cognitive experiences of a person with dementia [81].

Beyond immersive experiences, another key technological advancement is the use of machine learning algorithms, which offer the potential to identify early cognitive changes through pattern recognition across diverse data sources. Machine learning algorithms are useful tools in dementia research because they can detect subtle and complex patterns across different types of information. In the prediagnostic stage, they are often applied to analyze clinical histories, language use, and physiological indicators. These types of data contribute to identifying early cognitive changes that may not be evident through traditional clinical evaluations [57-59]. Machine learning has also been used to develop scoring instruments such as the Mini-Mental State Examination (MMSE) and the Clock Drawing Test [57-59], supporting the analysis of results and helping to identify individuals who may show signs of cognitive impairment.

Risk reduction is also an area to be addressed. To support these applications, it is necessary to develop longitudinal databases that organize and store diverse sources of information over time. This allows researchers to examine the progression of symptoms and identify traits shared by individuals at higher risk. Several countries have already established national databases with this purpose [63,64].

Smart environments offer a practical solution to provide this data by embedding sensors in the living spaces of people with dementia, enabling passive monitoring of daily activities and health indicators over time. These systems aim to monitor individuals living with dementia and enable them to remain in their homes for a longer period, preserving their autonomy and connection to familiar surroundings and their community. Smart environments can support daily living by tracking routines, providing reminders about medication, hydration, and other activities, and even issuing alerts to caregivers regarding the individual's condition or location.

As a more accessible and flexible alternative, wearable technologies provide real-time physiological and behavioral data, making them suitable for both urban and rural settings in dementia care. Wearable devices have become valuable tools for caregivers, largely due to their increasing accessibility. In countries such as Japan, these technologies have already been implemented with the primary goals of monitoring vital signs in people living with dementia, preventing wandering, and identifying behavioral patterns over time [82]. To complement this, mobile apps on smartphones and tablets offer a widely accessible means of raising public awareness and supporting early detection through interactive tools.

One of the most accessible ways to reach the general public is through apps available on smartphones and tablets. In some countries, these platforms have been used to raise awareness about the importance of brain health [82], while also providing ready-to-use apps that offer a general overview of an individual's cognitive status. Closely related to this are efforts to automate existing screening tools. These tools have the potential to expand the reach of detection efforts and support earlier identification of dementia. In addition, several tests have already been adapted into digital formats or modified to deliver fast and simple prediagnostic assessments to a larger segment of the population [67]. Despite their potential, these apps are often limited to predefined functions and lack the ability to adapt dynamically to users' specific needs.

Generative AI (GenAI) overcomes these limitations by enabling dynamic content creation and real-time conversational interactions, offering new ways to support both people with dementia and their caregivers. The emergence of GenAI has introduced new possibilities through technologies capable of producing text, images, and other multimedia formats using generative models [90]. These models are trained on large datasets to generate content based on learned patterns, with potential applications in dementia care. Their primary use has been to support social interaction and assist in managing the condition [80].

In particular, GenAI has been used to produce text designed to simulate social conversations, support reminiscence therapy, and assist caregivers by providing responses to common questions related to behavioral symptoms and everyday care scenarios. However, the development of these technologies requires advanced technical expertise, meaning that their application will likely come through ready-to-use apps or be driven by researchers and developers working in dementia care.

One particularly promising approach is the use of social robots to provide companionship for people living with dementia. Some of these robots are capable of verbal interaction or offer feedback based on users' responses. These features make them potentially valuable for supporting emotional well-being and engagement. However, this approach still presents important challenges. The high cost of these devices and the quantity required for use in clinical or institutional settings represent significant financial barriers. In addition, older adults may experience difficulties interacting with such technology, which can lead to resistance or rejection, especially given the digital divide often observed in this age group. Studying user interaction, acceptance, and functionality in local contexts would help identify improvements and inform future development.

Following the global identification of technologies aligned with broad needs, it is necessary to identify the specific strategies and requirements outlined in national or regional dementia plans. Based on these context-specific priorities, relevant technologies can be selected from Table 3. The opportunities for applying

XSL•FO
RenderX

these technologies must then be evaluated relative to the social context.

As a next step, current governance frameworks, laws, and regulations governing technology use in these specific environments must be identified. Subsequently, potential limitations and barriers arising from social, cultural, and broader regional characteristics should be determined. Finally, strategic actions can be proposed by synthesizing all contextual factors with available technologies.

The implementation of this framework is demonstrated below using the specific case study of Mexico.

Mexico as an Illustrative Case Study

Based on the public policies on Mexico analyzed in the previous sections, the identified areas of opportunity can be addressed using specific technologies, as outlined in Table 3.

Mexico, like many other countries, has low rates of dementia diagnosis, with cases often being detected only at advanced stages. Therefore, the development of technologies that enable early prediagnosis represents an essential area of focus. In this context, it is possible to build upon existing elements by integrating digital biomarkers into already established aging surveys, such as MHAS. Combined with the use of AI for pattern detection, this represents a significant opportunity for the development of AI models capable of identifying the main patterns associated with dementia specifically in the Mexican population, while considering the country's social and cultural context. These models could help inform public policies and support the development of risk indices with high specificity and sensitivity for the Mexican population.

The development of these risk indices could be used as a tool to identify populations with these characteristics or risk factors. In addition, the development of tools based on digital biomarkers, such as voice, gait, or facial expressions, could be used for screening at the primary care level and facilitate referral to specialist physicians. In particular, the creation of databases containing voice recordings from Mexican Spanish speakers is a major unmet need, since currently available databases of voices from people with dementia are predominantly in English, with only a limited number available in Spanish, but not specifically in Mexican Spanish. Consequently, potential biases may arise due to differences in linguistic and cultural characteristics, making localization and adaptation necessary.

MHAS, particularly the Cognitive Aging Ancillary Study (Mex-Cog) substudy, represents a valuable starting point [53]. Expanding the scope of collected data could further enhance its potential. Including additional variables commonly used in international research would strengthen early detection efforts and make it possible to generate risk profiles adapted to the characteristics of the Mexican population. However, the effectiveness of machine learning depends heavily on the availability of comprehensive, high-quality longitudinal data. Furthermore, the integration of digital biomarkers would contribute to the development of more complex and robust databases.

The integration of wearables into the health care system could represent an opportunity for digitalization through the incorporation of devices such as wristbands capable of monitoring vital signs and possible on/off states depending on the condition involved. The aim would be to integrate these data into electronic medical records and facilitate patient monitoring during treatment. These changes should be addressed in the short to medium term, since the health care system is still under development and regulations for the integration of such data into medical records are still required. Furthermore, the integration of digital biomarkers will require restructuring existing surveys, as well as clearly defining which data will be collected, how these data will be harmonized over time, and how they will be anonymized.

As discussed in previous sections, policies should not only focus on diagnosis but also address the context of caregiving. In Mexico, where informal care for older adults is predominantly provided by female family members [91], interventions should prioritize reducing caregiver burden and enhancing the quality of life of older adults. Care-related technologies could be implemented in 3 settings: the home environment, day-care centers, and caregiving systems. Their integration could also be considered the development of smart cities.

The application of technologies within public policies should be considered as part of a comprehensive strategy that also includes digital literacy. In Mexico, this could be promoted through free technology familiarization courses introducing care technologies in day-care centers, as well as through training programs directed toward primary users of these technologies. Furthermore, initiatives for technological familiarization could be delegated to institutions such as Instituto Nacional de las Personas Adultas Mayores (INAPAM), with the objective of improving digital literacy among populations at risk due to age while also promoting the acquisition of new knowledge.

Many caregivers have begun to show interest in implementing technologies in the care process; however, they often do not know how to use them, which represents a significant barrier. Some municipalities in Mexico have already implemented programs that provide wearable GPS devices free of charge to help ensure the safety of people with dementia and prevent them from getting lost [92-94]. Nevertheless, these initiatives have not yet been implemented throughout the entire country. Providing wearable devices that enable monitoring, together with the development of guidelines to support caregivers and disseminating these resources through day-care centers, Sistema Nacional para el Desarrollo Integral de la Familia (DIF) institutions, and health care centers, may represent a viable strategy to facilitate decision-making among caregivers. This approach could also help promote the appropriate use of technologies in ways that benefit both caregivers and people living with dementia.

With the increasing affordability and availability of virtual reality devices, the implementation of these tools in Mexico is becoming more feasible, with potential applications in home care, clinical settings, and day centers. Its implementation in adult day-care centers could be carried out in a phased and controlled manner. This approach would allow for initial user

XSL•FO
RenderX

familiarization, enabling subsequent implementation at home during visits from the proposed care system, specifically for rehabilitation purposes. Furthermore, this tool can facilitate personnel training in the early identification of symptoms and the administration of screening tests.

Beyond virtual reality, other technologies could support the care of people with dementia. In the Mexican context, this approach presents both opportunities and challenges. On the one hand, smart home technologies could help address the growing need for home-based care, especially in families where formal caregiving services are limited. On the other hand, the implementation of sensor-based environments may face obstacles such as high installation costs, technical complexity, and concerns about user privacy. These factors highlight the importance of considering culturally and economically appropriate adaptations to ensure the feasibility and acceptance of such technologies in Mexican households.

In fact, studies conducted in Mexico show that WhatsApp (Meta) is one of the most widely used technologies among older adults [95]. Therefore, older adults may be relatively familiar with mobile devices [96]. Consequently, the implementation of applications designed to support cognitive functions and adapted to the local context represents a promising alternative. This idea was reinforced by the Latin American Initiative for Lifestyle Intervention to Prevent Cognitive Decline (LatAm-FINGERS) study, in which cognitive interventions were provided through the use of mobile apps, and participants were instructed on how to use the devices [97].

Although the integration of GenAI into voice assistants represents an emerging area of technological innovation, empirical research regarding user acceptance of these systems in Mexico remains limited. However, existing studies indicate that the main difficulty is the accessibility of these devices, as only 3 of the 40 people interviewed reported having access to one [98]. Nevertheless, their potential for integration into homes and day-care centers was also identified.

This highlights the importance of supporting research and development in the field of health-related technologies. Furthermore, because these models are trained for specific cultural and linguistic contexts, their implementation in Mexico will require careful adaptation to the country's social and cultural environment.

Despite these limitations, acquiring a single unit for research purposes could offer a valuable opportunity to explore the necessary adaptations for implementation in Mexico. Studying user interaction, acceptance, and functionality in local contexts would help identify improvements and inform future development.

Given these challenges, the above approach offers a more accessible and scalable alternative that may be better suited for immediate integration into dementia care strategies in Mexico.

Data Management and Regulatory Governance

Although the use and management of data to support tools for treatment and diagnosis, as mentioned in the previous section, represent a significant opportunity for the digitalization of health care in Mexico, there are still no regulations capable of adequately governing these processes. Existing regulations are primarily limited to electronic medical records under NOM-024-SSA3-2012 and NOM-004-SSA3-2012 [99,100]. However, there are currently no specific regulations addressing the integration of wearable devices into these records or processes related to data collection, transfer from applications to clinical servers, and subsequent data use and management.

Furthermore, there are no clinical practice guidelines to support decisions about which devices should be integrated or recommended. This represents a major limitation for the implementation of these technologies in real-world clinical settings in Mexico.

Limitations and Barriers in Mexico

During the process of implementing technologies in Mexico, several factors arise that complicate their integration. When addressing dementia, the context of older adults cannot be overlooked. In Mexico, the living conditions of older adults vary considerably, resulting in socioeconomic, geographic, and educational differences that create multiple scenarios of difficulty for technology integration.

The integration of technologies often requires infrastructure capable of supporting their operation. For example, voice assistants require constant internet connectivity; however, in many rural areas of Mexico, this is not feasible, thereby creating additional gaps or inequalities in access to health care. Furthermore, the digital divide among older adults reflects differences in their circumstances and access to resources distributed across groups that reflect the limitations of their environment. While many older adults show interest in learning and using technology, they often lack the means to do so. Others may have little or no interest, possibly due to anxiety associated with interacting with technology or because of the lack of infrastructure necessary to sustain its usefulness [95,101,102].

Regarding the possible integration of precision medicine approaches supported by AI, this would require the centralization of data to enable the construction of well-founded individualized analyses. However, although electronic medical records have been mandatory for both public and private institutions in Mexico since 2026, their implementation is still ongoing [103]. In addition, the inclusion of digital biomarkers and data obtained from wearable devices has not yet been clearly defined or regulated.

Another important limitation is the fragmentation of the health care system, which prevents the establishment of a truly universal health care system applicable to the entire population [104]. This creates an additional barrier to the implementation of any public health policy.

Strategic Directions for Implementation

The integration of technologies into public policies will require a solid foundation for their implementation. At present, for Mexico, the short-term path appears to involve the development of these foundations, through which technologies may later be integrated more smoothly. In the short term, this includes the establishment of adequate infrastructure to guarantee internet

XSL•FO
RenderX

access for the entire population, as well as the promotion of digital literacy among older adults both with and without dementia. In addition, caregivers should also be trained through local programs on how to select appropriate devices or technologies according to their specific needs.

Furthermore, in the short term, regulations will also be required to guide health care professionals on how to integrate data obtained from wearable devices into electronic medical records in a precise and regulated manner.

With these foundations in place, and under the assumption of an already established care system, it would be possible to facilitate access for caregivers to basic monitoring devices that support daily life activities and enable integration into electronic medical records.

Once clear regulations regarding data storage and monitoring have been established, the next medium- to long-term step would be to develop dementia risk indices specific to the Mexican population, as well as standardizing metrics and criteria for decision-making based on these data. From this point onward, the pathway would involve the development and implementation of technologies specifically focused on the Mexican context.

Discussion

The prioritization of dementia as a critical issue has been increasing over time. However, the use of next-generation technologies is not yet fully considered. Therefore, it is necessary to leverage recent technological advances as an opportunity to reactivate the goals established in these international plans. Additionally, it is essential to include measures of the development and application in evaluations of new technologies, such as AI and smart environments.

Since dementia has been declared a global priority and aging has already impacted other countries, many technologies have been developed in those places. These technologies can guide the countries in deciding which paths to follow or avoid, always considering the cultural and social context. Although technology can bring many benefits, barriers such as cost and limited availability reduce its use. To move forward, it is necessary to create strategies that ensure access and promote the use of these tools in dementia care.

Moreover, the implementation of AI in the analysis of medical data can facilitate more accurate diagnoses and early identification of symptoms, which is crucial for appropriate treatment. Telemedicine platforms can also enable remote consultations with specialists, improving accessibility and reducing the burden on the health care system. These advancements can significantly contribute to enhancing the quality of life for individuals living with dementia and optimizing the time and effort of caregivers.

Leveraging these technological advancements requires increased investment in research and innovation. Increased funding for this field would not only improve existing tools but also drive the development of new solutions tailored to the specific needs of each population.

However, ethical issues must also be considered. Some technologies collect personal information, which raises questions about privacy and security. Other tools help people with daily tasks or social activities. In these cases, it is important that the technologies are reliable. There are also concerns about replacing human caregivers with machines, which could reduce the emotional connection in care.

Even if the technologies are available, their success will depend on how well they meet the needs of caregivers, people with dementia, and health care professionals. These tools must be useful, easy to use, and adapted to the reality of the people who need them.

Related to Mexico as a case study, integrating technology into dementia care can not only improve diagnostic and treatment processes but also help reduce geographical and economic barriers that limit access to specialized medical services. Digital tools, such as mobile apps for health monitoring, activity-tracking devices, and case management software, can provide effective solutions for continuous and personalized care, especially in rural areas or communities with limited resources. Although the proposed social programs have significant potential, Mexico’s health system is currently undergoing restructuring, and the effective integration of these technologies will depend on the final performance and organization of the new programs.

Abstract

Background: Technology-based rehabilitation is increasingly used for balance training in older adults. A 2023 network meta-analysis (NMA) found only exergaming with motion capture superior to no treatment; however, the evidence has since expanded, and no GRADE (Grading of Recommendations Assessment, Development, and Evaluation) appraisal has been applied.

Objective: This study aimed to update the comparative effectiveness of 5 technology categories—exergaming with balance platforms (EBP), exergaming with motion capture (EMC), other serious games, interventions with wearables, and telerehabilitation (Tele)—versus conventional exercise (CE), and no treatment (NT), applying GRADE adapted for NMA.

Methods: A systematic search of 4 databases from inception through April 2025, with an identical supplementary update search to January 31, 2026, identified 60 randomized controlled trials (N=3469; mean age 73.1, SD 5.2; range 63.3-86.2 y). Fifty-seven trials (2758 analyzed participants) contributed to 4 prespecified networks (all balance, functional scales, Timed Up and Go [TUG] test, and gait speed). A random-effects NMA was fitted using multivariate meta-regression. Treatment hierarchies were summarized by the surface under the cumulative ranking curve (SUCRA) and the probability of being best; certainty of evidence was rated with GRADE adapted for NMA.

Results: In the all-balance network, Tele (standardized mean difference [SMD] 0.69, 95% CI 0.08 - 1.29; *P*=.03), EBP (SMD 0.63, 95% CI 0.31 - 0.95; *P*<.001), EMC (SMD 0.58, 95% CI 0.22 - 0.95; *P*=.002), and CE (SMD 0.35, 95% CI 0.03 - 0.68; *P*=.03) were superior to NT, with consistent findings in the TUG network (EBP 0.81, 95% CI 0.42 - 1.20; Tele 0.82, 95% CI 0.16 - 1.49; EMC 0.79, 95% CI 0.36 - 1.21; all *P*<.05). Tele ranked first by SUCRA (76.3%), but its probability of being best was only approximately 41%, and the estimate rested on 5 trials (n=198). No technology-based intervention was superior to CE in any network. Certainty of evidence was moderate for EBP versus NT and EMC versus NT in the TUG network only; the 37 other comparisons were low or very low. Dropout did not differ between technology-based and control arms (odds ratio 1.10, 95% CI 0.87 - 1.40; *P*=.41).

Conclusions: Tele, EBP, and EMC were each associated with improved balance versus NT, although none exceeded CE. The first-place SUCRA ranking of Tele is preliminary. Certainty was moderate only for EBP and EMC versus NT on the TUG test; the remaining evidence is too uncertain for firm clinical recommendations. As no included trial reported falls, these findings are not direct evidence of fall prevention. Larger trials with standardized comparator intensity and posttraining follow-up are required.

Introduction

Background

Population aging is a major global health challenge. The global population aged ≥60 years is projected to surpass 2.2 billion by the late 2070s [1]. Falls are among the most common threats to health and independence in later life. The World Health Organization estimates that between 28% and 35% of adults aged ≥65 years experience at least one fall per year, a rate that rises to 32% to 42% among those aged >70 years [2]. The Global Burden of Disease Study 2021 documents approximately 45.7 million new falls among older adults annually, with an estimated 37.3 million requiring medical attention [3]. Falls also increase the risk of mortality and reduce quality of life through fear of falling, functional decline, and institutionalization [4].

Exercise is the best-supported intervention for fall prevention in older adults. The 2022 World Guidelines for Falls Prevention and Management assign a strong recommendation to multicomponent exercise programs targeting balance, strength, and functional mobility [4]. However, adherence to conventional exercise (CE) programs is often poor, and motivation, access, and travel to clinical settings are common barriers [5]. Technology-based approaches have attracted interest because they may improve engagement and reach people who cannot attend in person.

The rationale for technology-based rehabilitation derives largely from augmented sensory feedback. Augmented feedback (ie, extrinsic information about movement outcomes) supports motor learning and postural adaptation [6]. In balance training, real-time feedback on postural sway promotes lasting changes in motor control by facilitating corrective movement strategies [7]. Digital technologies deliver this feedback through several distinct modalities.

Exergaming with balance platforms (EBP) provides real-time feedback on center-of-pressure displacement via devices such as the Nintendo Wii Balance Board. Exergaming with motion capture (EMC) captures whole-body kinematics to generate on-screen visual feedback, as implemented via the Microsoft Kinect. Other serious games (OSG) are purpose-built rehabilitation software increasingly delivered through head-mounted displays. Interventions with wearables (IW) provide haptic or auditory postural feedback via body-worn sensors. Telerehabilitation (Tele) encompasses remotely supervised exercise programs delivered via digital communication platforms, with uptake accelerating substantially after the COVID-19 pandemic [8].

Prior Work and Rationale for an Update

Most previous systematic reviews and meta-analyses have examined each technology category separately, so their relative effectiveness and their place within fall prevention programs remain unclear [9,10]. Network meta-analysis (NMA) combines direct and indirect evidence in a single model and can rank treatments even where head-to-head comparisons are absent from the primary literature [11]. Cieślik et al [12] published the first NMA in this field in 2023 and found that EMC was the only technology significantly superior to no treatment (Timed Up and Go [TUG]: standardized mean difference [SMD] −0.70, 95% CI −1.16 to −0.23), while Tele, serious games, and wearable interventions lacked sufficient evidence for definitive conclusions.

The evidence base has expanded substantially since that review's search cutoff in June 2023. Newer randomized controlled trials (RCTs) have tested Tele protocols in larger samples and over longer periods than the trials available to the original review [12], head-mounted virtual reality systems have been studied more widely as platforms for serious games, and wearable sensors now support home-based programs [13,14]. The original NMA also did not apply GRADE (Grading of Recommendations Assessment, Development, and Evaluation), so no formal certainty rating exists for any pairwise comparison [12]. An updated synthesis is therefore warranted to incorporate the newer evidence and to formally assess the certainty of evidence.

Objectives

We aimed to (1) quantify the comparative effectiveness of 5 categories of technology-based rehabilitation intervention (EBP, EMC, OSG, IW, and Tele) relative to CE and no treatment (NT) across 4 prespecified outcome networks (all balance outcomes, functional scales, TUG, and gait speed); (2) establish a probabilistic treatment hierarchy using the surface under the cumulative ranking curve (SUCRA) and the probability of being the best treatment; and (3) appraise the certainty of evidence for each comparison using the GRADE framework adapted for NMA [15].

Methods

Study Design and Registration

This study was designed as a systematic review and NMA, conducted in accordance with the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) 2020 statement and its NMA extension (PRISMA-NMA) [16,17]. The completed PRISMA 2020 and PRISMA-NMA checklists are provided in Checklists 1 and 2, respectively. The protocol was registered with PROSPERO (International Prospective Register of Systematic Reviews; CRD420261380567) and constitutes an updated and expanded synthesis of the original review by Cieślik et al [12].

As the PROSPERO record was completed after the primary searches had been executed, this review is reported as a retrospectively registered update rather than as a prospectively registered de novo review. No eligibility criterion, outcome definition, or analytical decision was altered after the authors had inspected the effect estimates. Two departures from the registered protocol occurred and are reported here in full. First, the protocol specified the *netmeta* R package with P-score ranking, whereas the primary analysis was implemented in Stata using SUCRA; SUCRA and the netmeta P-score are numerically near-equivalent frequentist ranking metrics, and the treatment hierarchy was unaffected by this change. Second, the meta-regressions of training dose and of CE intensity, the treatment-ranking probabilities, and the quantitative transitivity summary were added in response to peer review; these are

XSL•FO
RenderX

reported throughout as post hoc exploratory analyses and are interpreted accordingly.

Literature Search

A systematic search was conducted across 4 electronic databases (PubMed, Embase, Cochrane Central Register of Controlled Trials, and Web of Science) from inception through April 2025. Database-specific search strategies combined controlled vocabulary terms with free-text synonyms covering older adult populations (aged ≥60 y), technology-based interventions (virtual reality, exergaming, telerehabilitation, and wearables), and balance and functional mobility outcomes. A randomized-design filter was applied in PubMed, Embase, and Web of Science; the Cochrane Central Register of Controlled Trials contains only trial records and required none. Each strategy also carried an exclusion block to remove records indexed with the neurological, neurodegenerative, orthopedic, oncological, and other comorbid conditions listed under eligibility, as well as reviews, meta-analyses, and study protocols. The complete search strings for each database, with the date each was executed, are provided in Table S1 in Multimedia Appendix 1.

As peer review and revision extended into 2026, an identical supplementary update search was executed across all 4 databases on January 31, 2026, to capture records that were published, or made available online ahead of print, after the primary search date. Screening and data extraction for the supplementary search followed the same procedures as for the primary search. The record counts, screening numbers, and PRISMA flow diagram reported in the "Results" section represent the combined yield of the primary and supplementary searches. The supplementary search contributed 4 additional eligible trials [18-21], all of which were incorporated into the quantitative synthesis; no study identified after the primary search was used for contextual discussion only. One of these trials appears with a 2026 citation year because it was assigned to a 2026 print issue after online publication [18]; it was retrieved by the supplementary search.

Eligibility Criteria and Study Selection

Studies were eligible if they (1) enrolled community-dwelling or facility-dwelling adults aged ≥60 years without neurodegenerative, neurological, major orthopedic, or oncological comorbidities; (2) examined an eligible technology-based rehabilitation intervention with at least one control group; (3) reported at least one prespecified primary outcome; and (4) adopted a randomized design. Studies were excluded if the intervention involved robotic exoskeletons or if data were reported only as conference abstracts without peer review. Two independent reviewers (FL and XL) screened all records, and disagreements were resolved through discussion with a third reviewer (DZ). The number of full-text articles excluded at the eligibility stage, broken down by reason for exclusion, is provided in Table S2 in Multimedia Appendix 1.

Intervention Classification

Eligible technology-based interventions were classified into 5 mutually exclusive categories following the taxonomy of Cieślik et al [12]: (1) EBP, real-time center-of-pressure feedback devices (eg, Wii Balance Board); (2) EMC, systems capturing full-body kinematics for on-screen visual feedback (eg, Microsoft Kinect); (3) OSG, rehabilitation software not relying on balance platforms or motion capture; (4) IW, exercise programs using wearable sensor feedback; and (5) Tele, remotely supervised exercise delivered via digital communication platforms. Two control categories were designated: CE and NT.

Classification was performed independently by 2 reviewers for every arm of every included trial, with disagreements resolved by discussion and, where necessary, by a third reviewer. Where an intervention displayed features of more than 1 category, assignment followed the dominant source of augmented feedback: interventions delivering feedback derived primarily from center-of-pressure displacement were assigned to EBP even when delivered remotely, whereas interventions whose defining feature was synchronous remote supervision were assigned to Tele. Arms combining a technology with CE in a factorial manner (2 arms in 2 trials) could not be assigned to a single node and were excluded from the networks, while the remaining arms of those trials were retained. The as-extracted description and resulting node assignment for every arm of every included trial are reported in Table S3 in Multimedia Appendix 1, so that each classification decision can be checked.

Outcome Measures and Network Structure

Outcomes were prespecified into 4 analytical networks: (1) network 1 (all balance), aggregating results from all eligible balance-related instruments, including the TUG, Berg Balance Scale (BBS), Mini-Balance Evaluation Systems Test (Mini-BESTest), Short Physical Performance Battery (SPPB), Fullerton Advanced Balance Scale (FAB), Tinetti Performance-Oriented Mobility Assessment (POMA), Functional Reach Test, single-leg stance, center-of-pressure (COP) parameters, and sit-to-stand tests; (2) network 2 (functional scales), restricted to multidimensional clinical scales (BBS, Mini-BESTest, SPPB, FAB, and Tinetti/POMA); (3) network 3 (TUG), the TUG test and its equivalent, the 8-Foot Up-and-Go test; and (4) network 4 (gait speed), quantitative gait speed from 4- or 10-m walk tests. Where a trial reported more than 1 instrument eligible for network 1, a single instrument per trial was selected using a prespecified hierarchy (TUG, followed by BBS, Mini-BESTest, SPPB, and other instruments), so that no trial contributed more than 1 estimate to any network. The secondary outcome was participant acceptability, defined as the all-cause dropout rate.

Network 1 is a composite of instruments that measure different constructs (dynamic functional mobility, multidimensional clinical rating scales, static postural sway, and lower-limb function). It was retained because it maximizes the evidence contributing to each comparison, but it is reported alongside, and not in preference to, the construct-specific networks; network 3 (TUG) provides the most clinically interpretable single-construct estimates and is the basis for the principal clinical conclusions of this review.

Data Extraction

Data were extracted by 1 reviewer and independently verified by a second reviewer. For each eligible arm, we recorded the number of participants analyzed for the outcome of interest,

XSL•FO
RenderX

together with the number randomized, the postintervention mean, and the postintervention SD. Analyzed rather than randomized denominators were used in the effect-size calculations because postintervention means and SDs are reported for analyzed participants; the 2 denominators differ appreciably in a minority of trials (most notably in the largest included trial [22], in which 503 participants were randomized and 226 contributed postintervention balance data), and both are reported per trial in Table S4 in Multimedia Appendix 1. Postintervention means and SDs were used throughout, as combining posttest and change-score SMDs within a single analysis is not recommended when SMD is the effect measure [23]. Studies reporting only change-from-baseline scores without accompanying postintervention values were therefore excluded from network synthesis. For studies reporting only median and IQR, values were estimated using the formula of Wan et al [24]. Dropout counts were extracted per randomized arm.

We also sought to extract adverse events, technology-related difficulties (eg, device malfunction, connectivity failure, and cybersickness), and participant-reported satisfaction or acceptability to characterize the feasibility and user burden of each modality. These data were too sparsely reported to be synthesized and are summarized descriptively in the "Results" section.

Risk of Bias Assessment

The methodological quality of included trials was evaluated by 2 independent reviewers using version 2 of the Cochrane Risk of Bias tool (RoB 2) [25], covering 5 domains: randomization (D1), deviations from intended interventions (D2), missing outcome data (D3), outcome measurement (D4), and selective reporting (D5). Overall risk was classified as low risk, some concerns, or high risk. As blinding of participants is structurally impossible in exercise trials, an elevated D2 rating attributable solely to the absence of participant blinding was not by itself treated as a reason to rate down for risk of bias in the GRADE assessment. Instead, following the reasoning that the relevant question is whether the absence of blinding plausibly influenced the result [15], D2 was treated as a source of serious risk of bias only where the trial reports also indicated differential cointerventions, differential attention or contact time, or an intention-to-treat principle that was not followed; D4 was rated based on the presence of blinded outcome assessment; and D5 was rated based on the availability of a prespecified protocol or registration. Domain-level judgments for every trial are provided in Table S5 and Figure S1 in Multimedia Appendix 1.

Statistical Analysis

The SMD (Hedges g) and its SE were calculated for each pairwise arm comparison from postintervention means and pooled postintervention SDs. For outcomes where lower scores indicate better performance (TUG, COP, and sit-to-stand time), the SMD sign was reversed to ensure consistent positive directionality across all outcomes.

All analyses were performed in Stata/SE (version 15.1; StataCorp LLC) using the network suite [26]. Data were structured in the augmented format to accommodate multiarm trials [27], so that the correlation between effect estimates from the same trial was respected and no participant was counted more than once within a comparison; 8 trials contributed 3 arms each to network 1, and the remainder contributed 2. The NMA was implemented as a multivariate meta-analysis via the mvmeta command [28], fitting a random-effects consistency model with restricted maximum likelihood estimation. The between-study SD (τ) was assumed common across comparisons, and between-study covariances were modeled with an exchangeable correlation structure (ρ=0.5) [26,27]. NT was specified as the reference category.

Transitivity was evaluated by comparing the distribution across treatment nodes of mean age, intervention duration, training frequency, total sessions, session length, and study setting (community vs facility dwelling), summarized in Table S6 and Figure S2 in Multimedia Appendix 1. Modifiers reported too inconsistently to evaluate—baseline balance impairment, fall risk or history, frailty, sex distribution, supervision level, comparator intensity, prior technology familiarity, and outcome measurement protocol—are identified as a limitation of the transitivity appraisal. Between-study heterogeneity was quantified by τ and τ^2. Global statistical inconsistency was assessed using the design-by-treatment interaction model. Local inconsistency for each pairwise contrast was evaluated by node splitting [29-31], decomposing each estimate into its direct and indirect components and testing their agreement.

Treatment hierarchies were estimated by computing SUCRA from 5000 parametric bootstrap draws. SUCRA summarizes a rank distribution and carries no information about the magnitude or the certainty of the underlying effects, so the probability that each intervention was the best treatment was also estimated from the multivariate normal distribution of the network estimates [11] and is reported alongside SUCRA throughout. The post hoc analyses added during peer review—the random-effects meta-regressions of training dose and of CE intensity, the ranking probabilities, and the quantitative transitivity summary—were conducted in Python (version 3.12; Python Software Foundation) using numpy, scipy, and pandas, with figures produced in Matplotlib, and each was cross-checked for numerical agreement against the primary Stata NMA. In the dose meta-regressions, study-level SMDs were regressed on intervention duration, training frequency, total sessions, session length, weekly training minutes, and mean age; the direct CE versus NT effect was separately regressed on CE dose parameters.

Small-study effects were assessed visually using comparison-adjusted funnel plots [32] generated via netfunnel. Formal regression-based testing of funnel plot asymmetry was not undertaken because no comparison in any network was informed by 10 or more trials conventionally regarded as the minimum for such a test to be interpretable; the consequences of this limitation for the assessment of publication bias are considered in the "Discussion" section. As these methods have very low power when fewer than 10 trials contribute to a comparison, they were interpreted as exploratory in networks 2 and 4, and no comparison was rated down for publication bias on the basis of funnel plot appearance alone.

XSL•FO
RenderX

A post hoc sensitivity analysis examined the source of the global inconsistency in network 3 (TUG), where 4 trials provided direct NT versus CE evidence. As any exclusion threshold is arbitrary, 2 specifications were run, and both are reported: specification 1 removed the 2 trials whose direct effect exceeded SMD 2.0, and specification 2 removed the 3 trials exceeding SMD 1.0. All 4 are 3-arm trials, so removal also withdraws technology arms; the effect of each specification on every estimate, every SUCRA value, and the direct-indirect discrepancy is reported in full (Table S7, Multimedia Appendix 1), with ranking stability assessed by the Spearman correlation of SUCRA before and after removal. These analyses characterize the influence of the discrepant contrast; they were not used to select a model, and the primary analysis retains all trials.

GRADE certainty was rated for all pairwise comparisons using the framework adapted for NMA [15], starting at high certainty. The following decision rules were fixed before rating and applied uniformly. Imprecision was rated down 1 level where the 95% CI included the null or a trivial effect (|SMD|<0.20), and 2 levels where it additionally spanned appreciable benefit and harm (|SMD|>0.50) or fewer than 3 trials contributed. In network 1, imprecision was judged against the 95% prediction interval rather than the CI because the heterogeneity of a composite outcome makes the CI understate the uncertainty that applies to any single instrument; all network 1 prediction intervals included the null. Inconsistency was rated down where the design-by-treatment interaction test was significant and node splitting localized the discrepancy to that comparison. Indirectness was not rated down anywhere because all trials were randomized comparisons in the target population using the intended outcomes. Publication bias was rated down only where funnel plot asymmetry coincided with a plausible mechanism and at least 10 contributing trials. Two reviewers rated independently and reached a final rating by consensus.

Results

Study Selection and Characteristics

The primary and supplementary searches together yielded 2459 records (PubMed: n=408, 16.6%; Embase: n=775, 31.5%; Web of Science: n=491, 20%; and Cochrane: n=785, 31.9%), of which 1213 (49.3%) were duplicates. After title and abstract screening of 1246 unique records, 188 (15.1%) full-text articles were assessed for eligibility; 128 (68.1%) were excluded (incorrect study type, n=21, 16.4%; incorrect outcomes, n=62, 48.4%; incorrect intervention, n=26, 20.3%; incorrect participants, n=19, 14.8%). Sixty RCTs [18-22,33-87] involving 3469 randomized participants met all inclusion criteria (Figure 1). Four of these trials [18-21] were identified by the supplementary update search.

Fifty-seven (95%) of the 60 included trials (randomized: n=3301; and analyzed arms: n=2758) contributed data to at least one of the 4 networks. Three trials could not contribute quantitative data; they were retained in the systematic review but not included in any network: 1 reported outcomes as change scores only [37]; 1 reported balance solely as a composite *z* score that could not be mapped onto any single network instrument [67]; and 1 randomized participants to 2 arms that were both classified into the same network node, so that it contributed no between-node contrast [56]. All 3 are described in Table S4 in Multimedia Appendix 1.

Ten included trials [18-21,43,68,71,76,78,86] were published, or appeared online, after the June 2023 search cutoff of the original review [12]. Sample sizes ranged from 12 to 503 randomized participants (median 43, IQR 34-64), and the mean age was 73.1 (SD 5.2; range 63.3 - 86.2) years (unweighted mean of trial means). EBP (21 arms) and EMC (18 arms) were the most frequently studied categories in the all-balance network (Table 1). Tele trials were much larger on average (mean 124 randomized participants across the 6 Tele trials); although the mean number of participants contributing to each Tele arm in network 1 was 39.6, the largest Tele trial having supplied postintervention data for only a subset of those randomized [22]. Participant characteristics and intervention details for all included studies are summarized in Table S4 in Multimedia Appendix 1.

XSL•FO
RenderX

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flow diagram of study identification, screening, and inclusion, showing the combined yield of the primary search (to April 2025) and the supplementary update search (to January 31, 2026).

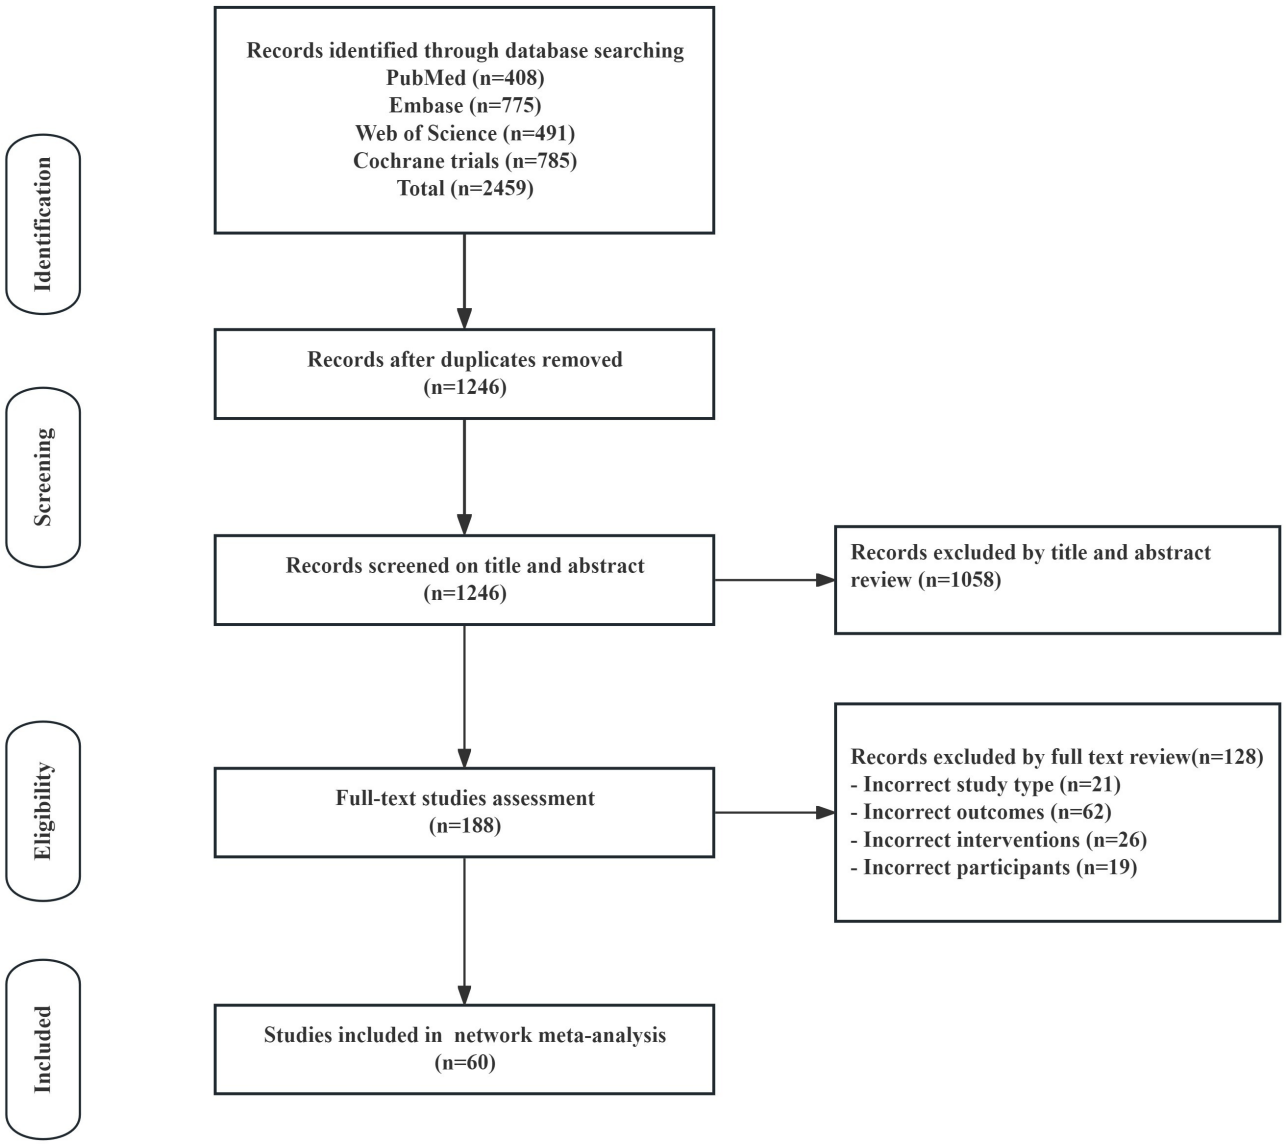

Table . Summary of trial arms and participants by intervention category in the primary (all-balance) network[a].

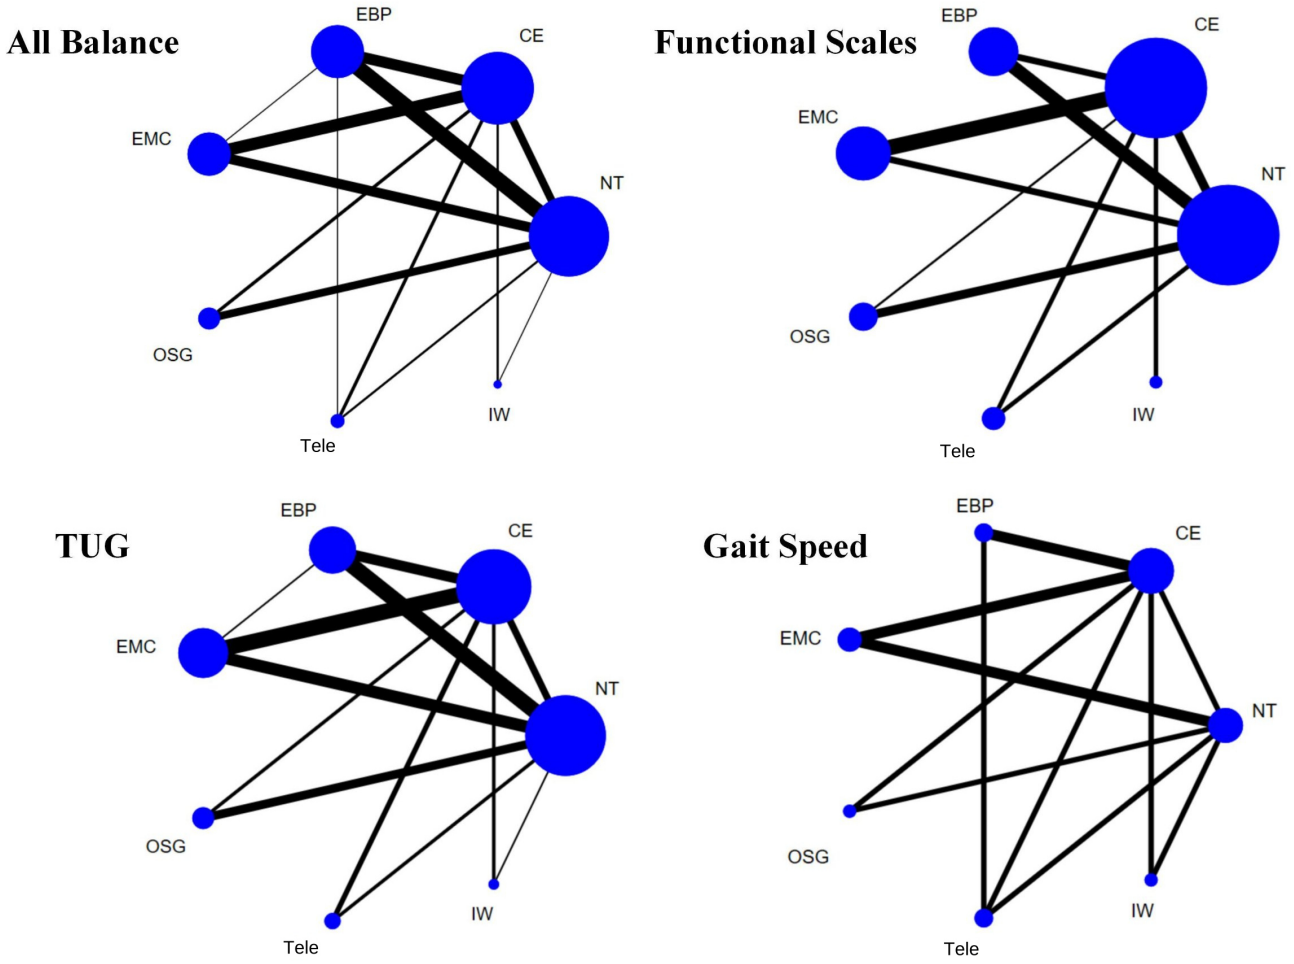
Intervention category	Trial arms (N=118), n (%)	Participants (N=2710), n (%)	Participants per arm, mean
Conventional exercise	29 (24.6)	581 (21.4)	20.0
Exergaming, balance platform	21 (17.8)	431 (15.9)	20.5
Exergaming, motion capture	18 (15.3)	360 (13.3)	20.0
Other serious games	10 (8.5)	318 (11.7)	31.8
Telerehabilitation	5 (4.2)	198 (7.3)	39.6
Interventions with wearables	3 (2.5)	29 (1.1)	9.7
No treatment	32 (27.1)	793 (29.3)	24.8

[a]Full per-study characteristics for all 60 included trials are provided in Table S4 in Multimedia Appendix 1. Values reflect arm-level contributions to network 1 (all balance outcomes). Network 1 included 55 (91.6%) of the 60 included trials; 2 further trials contributed only to the gait-speed network (network 4), and 3 trials contributed no quantitative data to any network. The 118 arms in the column header were contributed by 55 trials separately because 8 trials contributed 3 arms each and the remainder contributed 2.

Risk of Bias

RoB 2 assessment rated 2 (3%) of 60 studies at low overall risk of bias, 50 (83%) as having raised some concerns, and 8 (13%) at high risk. The predominant source of concern was D2 (deviations from intended interventions; 58/60, 97%, studies rated as having some concerns or high risk), attributable in large part to the structural impossibility of blinding participants to



XSL•FO
RenderX

exercise interventions. D4 (outcome measurement) was rated as high risk in 6 (10%) studies, primarily reflecting the absence of blinded outcome assessors. Domain-level judgments for every trial are reported in Table S5 in Multimedia Appendix 1, and the RoB 2 traffic-light plot is presented as Figure S1 in Multimedia Appendix 1.

Network Structure

Network plots for all 4 analytical networks are presented in Figure 2. Network 1 (all balance) incorporated 55 trials, network 2 (functional scales) incorporated 26 trials, network 3 (TUG) incorporated 41 trials, and network 4 (gait speed) incorporated 12 trials. All 4 networks comprised a single fully connected component. The CE and NT nodes served as the principal hubs across all networks. Direct evidence for comparisons between active treatments was available for only a small proportion of dyads; the number of trials and participants contributing direct evidence to each contrast is tabulated in Table S8 in Multimedia Appendix 1.

Figure 2. Network plots presenting the direct evidence structure for each of the 4 analytical networks. CE: conventional exercise; EBP: exergaming with balance platforms; EMC: exergaming with motion capture; IW: interventions with wearables; NT: no treatment; OSG: other serious games; Tele: telerehabilitation; TUG: Timed Up and Go.

NMA Results

Main results for all 4 networks are presented in Table 2. Complete league tables are provided in Figure 3, and all-pairwise forest plots are provided in Figure 4.

Tele	3	165	0.91 (−1.53 to 3.35)	−0.24 (−2.49 to 2.00)	52.6	⊕◯◯◯ Very low
IW	2	21	0.85 (−1.83 to 3.52)	−0.31 (−3.00 to 2.39)	50.4	⊕◯◯◯ Very low
OSG	2	99	0.39 (−2.23 to 3.00)	−0.76 (−3.39 to 1.86)	38.8	⊕◯◯◯ Very low

[a]SMD: standardized mean difference (Hedges *g*; positive values favor the row treatment).

[b]SUCRA: surface under the cumulative ranking curve.

[c]GRADE: Grading of Recommendations Assessment, Development, and Evaluation (⊕⊕⊕⊕ high, ⊕⊕⊕◯ moderate, ⊕⊕◯◯ low, ⊕◯◯◯ very low).

[d]Number of participants in the respective intervention arm across contributing studies, summed at the arm level; the participant counts in Table 3 are the sum of both arms of each pairwise comparison and therefore differ from those reported here.

[e]NT: no treatment.

[f]CE: conventional exercise.

XSL•FO
RenderX

[g]Tele: telerehabilitation.

[h]*P*<.05 vs NT.

[i]EBP: exergaming with balance platforms.

[j]*P*<.01 vs NT. Exact *P* values for every comparison are reported in Table S9 in Multimedia Appendix 1.

[k]EMC: exergaming with motion capture.

[l]OSG: other serious games.

[m]IW: interventions with wearables.

[n]Not applicable.

[o]Certainty additionally rated down 1 level for inconsistency (significant direct-indirect discrepancy on node splitting, localized to the NT vs CE comparison).

Figure 3. League tables presenting all pairwise network meta-analysis effect estimates (standardized mean difference, 95% CI) for the 4 analytical networks. In the league tables, orange cells indicate statistically significant treatment comparisons, and white cells indicate nonsignificant comparisons. CE: conventional exercise; EBP: exergaming with balance platforms; EMC: exergaming with motion capture; IW: interventions with wearables; NT: no treatment; OSG: other serious games; Tele: telerehabilitation; TUG: Timed Up and Go.

[a]GRADE: Grading of Recommendations Assessment, Development, and Evaluation (⊕⊕⊕⊕ high, ⊕⊕⊕◯ moderate, ⊕⊕◯◯ low, ⊕◯◯◯ very low).

[b]All evidence begins at high certainty (randomized trials) and is rated down 1 level (serious) or 2 levels (very serious) per domain. Prespecified decision rules: imprecision was rated down 1 level when the 95% CI included the null or a trivial effect (|SMD|<0.20) and 2 levels when the CI additionally spanned appreciable benefit and appreciable harm (|SMD|>0.50) or fewer than 3 trials contributed; inconsistency was rated down where the design-by-treatment interaction test was significant and node splitting localized the discrepancy to the comparison concerned; indirectness was not rated down for any comparison, as all trials were randomized comparisons in the target population using the intended outcomes; and publication bias was not rated down for any comparison, as no comparison was supported by the ≥10 trials required for a meaningful test of funnel plot asymmetry. GRADE ratings were performed independently by 2 reviewers and finalized by consensus, following the framework adapted for network meta-analysis [15]; risk of bias was assessed with RoB 2 [25].

[c]Sum of arm-level n across contributing studies for both arms of each comparison.

[d]SMD: standardized mean difference.

[e]EBP: exergaming with balance platforms.

[f]NT: no treatment.

[g]In network 1, imprecision was judged against the 95% prediction interval rather than the CI because the between-study heterogeneity of the composite outcome (τ=0.597) means the CI understates the uncertainty applying to any individual balance instrument; all network 1 prediction intervals included the null.

[h]EMC: exergaming with motion capture.

[i]Tele: telerehabilitation.

[j]OSG: other serious games.

[k]IW: interventions with wearables.

[l]CE: conventional exercise.

[m]Rating down for inconsistency applies to CE vs NT only: node-splitting showed a significant discrepancy between direct (SMD 1.61) and indirect (SMD 0.19) evidence (*P*<.001), whereas all technology-based comparisons showed nonsignificant direct-indirect differences (all *P*>.08).

Network 1: All Balance Outcomes

The consistency model (55 studies; τ=0.597; τ²=0.356) identified Tele (SMD 0.69, 95% CI 0.08 - 1.29; *P*=.03), EBP (SMD 0.63, 95% CI 0.31 - 0.95; *P*<.001), and EMC (SMD 0.58, 95% CI 0.22 - 0.95; *P*=.002) as significantly more effective than NT. CE was also significantly superior to NT (SMD 0.35, 95% CI 0.03 - 0.68; *P*=.03). OSG showed a numerically positive but nonsignificant effect versus NT (SMD 0.41, 95% CI −0.01 to 0.83; *P*=.06), as did IW (SMD 0.33, 95% CI −0.57 to 1.23; *P*=.47), the latter based on only 3 trials. No technology-based intervention was statistically superior to CE. SUCRA-based ranking placed Tele first (76.3%), followed by EBP (75.2%), EMC (68.7%), OSG (47.2%), IW (41.2%), CE (36.6%), and NT (4.8%). The narrow separation between the 3 leading nodes (7.6 SUCRA percentage points) should be read together with the ranking probabilities reported in the Ranking Probabilities section, which show that no single intervention emerged as clearly best.

Network 2: Functional Scales

The consistency model (26 studies) yielded no statistically significant treatment contrasts. IW ranked first by SUCRA (88.9%), although this estimate rested on only 2 trials contributing 14 participants and carried a very wide CI (SMD 1.10, 95% CI −0.28 to 2.48; *P*=.12), substantially limiting its interpretability. OSG (SUCRA 62.9%), EMC (60.9%), EBP (43.4%), Tele (39.7%), CE (32.5%), and NT (21.7%) occupied subsequent positions.

Network 3: Timed Up and Go Test

The consistency model (41 studies) demonstrated that EBP (SMD 0.81, 95% CI 0.42 - 1.20; *P*<.001), EMC (SMD 0.79, 95% CI 0.36 - 1.21; *P*<.001), Tele (SMD 0.82, 95% CI 0.16 - 1.49; *P*=.02), and CE (SMD 0.60, 95% CI 0.21 - 0.98; *P*=.002) were each significantly superior to NT. OSG did not reach significance (SMD 0.49, 95% CI −0.005 to 0.978; *P*=.05), and neither did IW (SMD 0.48, 95% CI −0.42 to 1.38; *P*=.30). None of the technology-based interventions was significantly superior to CE. SUCRA ranking identified EBP (74.8%), Tele (72.5%), and EMC (71.7%) as the 3 highest-ranked interventions, separated by 3.1 percentage points.

Network 4: Gait Speed

The gait speed network (12 trials) was characterized by extreme between-study heterogeneity and very wide CIs for all treatment contrasts, none of which attained statistical significance. Given the significant global inconsistency and the extreme heterogeneity, these estimates are unsuitable for treatment-effect inference. They are reported as supplementary and hypothesis generating only, are not used to support any conclusion of this review, and should not be cited as evidence that these interventions do or do not affect gait speed.

Inconsistency Testing

For network 1, the design-by-treatment interaction test was nonsignificant (χ^2_{13} =16.1; *P*=.25), providing no evidence of meaningful inconsistency. Network 2 similarly showed no

XSL•FO
RenderX

significant inconsistency (χ^2 =13.8; *P*=.13). Network 3 yielded a significant global statistic ($\chi^2_{1\ 2}$ =28.1; *P*=.005). Node splitting localized this to the NT versus CE comparison exclusively (direct SMD 1.612, SE 0.331 vs indirect SMD 0.189, SE 0.205; difference 1.423; *P*<.001); all 11 remaining contrasts showed nonsignificant direct-indirect differences (all *P*>.08). Network 4 also demonstrated significant global inconsistency (χ^2 =69.5; *P*<.001).

Two features of the direct evidence bear on how this discrepancy should be read. First, it does not arise from a small number of aberrant results: the 4 trials that carry this contrast, which span 3 study designs, each produced a large positive direct effect (Hedges *g*=0.90, 1.09, 2.36, and 2.53; Table S7, Multimedia Appendix 1), against an indirect estimate of 0.19. Second, the 4 trials share a distinctive structure rather than a distinctive dose—each is a 3-arm trial containing an NT arm, each randomized only 11 to 18 participants per arm, and each prescribed CE 3 times per week, which is the median frequency across the 29 CE arms in the review.

Both sensitivity specifications attenuated every treatment estimate, and neither eliminated the discrepancy (Table S7 and Figure S3, Multimedia Appendix 1). Under specification 1, the direct-indirect difference for CE versus NT remained significant, and under specification 2, only a single trial contributed direct evidence, so the contrast was no longer estimable. The treatment hierarchy was largely preserved under specification 1 (Spearman ρ=0.86) and less so under specification 2 (ρ=0.68), where removal of 1 of only 4 Tele arms substantially destabilized that node. Across both specifications, the 2 comparisons carrying moderate certainty in the primary analysis—EBP versus NT and EMC versus NT—remained statistically significant. We therefore do not claim that consistency was restored by removing trials; the primary analysis retains all trials, and the CE versus NT comparison is instead rated down for inconsistency in the GRADE assessment.

Transitivity Assessment

The distribution of the effect modifiers that could be extracted is summarized in Table S6 and Figure S2 in Multimedia Appendix 1. Across the 7 nodes of network 1, the mean of trial mean ages ranged from 70.7 years (Tele) to 78.6 years (IW), the mean intervention duration from 6.7 weeks (IW) to 30.0 weeks (Tele), and the mean session length from 33.8 minutes (Tele) to 50.0 minutes (IW). The 5 nodes supported by 10 or more trials (NT, CE, EBP, EMC, and OSG) were closely comparable to one another on every extracted modifier (mean age 71.7 - 73.8 years; mean duration 7.7 - 11.5 weeks; mean session length 38.8 - 48.9 minutes), and the transitivity assumption appears defensible for comparisons among them.

Two nodes depart from this pattern and require caution. The Tele node rests on 5 trials and has a much longer mean intervention duration (30.0 wk) than any other node; this is driven entirely by a single 104-week trial [22], and the median Tele duration is 8 weeks. The IW node rests on 3 trials whose participants were on average 5 to 7 years older than those in the other nodes. Comparisons involving Tele and IW are therefore more vulnerable to violation of transitivity than comparisons among the remaining nodes and are interpreted accordingly throughout.

A further limitation of this appraisal is that several effect modifiers of recognized importance for balance outcomes could not be evaluated because they were reported too inconsistently across trials: baseline balance impairment, baseline fall risk or fall history, frailty status, sex distribution, the level of therapist supervision, the intensity of the CE comparator, prior familiarity with the technology, and the outcome measurement protocol. Residual intransitivity attributable to these unmeasured modifiers cannot be excluded, and the CE-intensity analyses reported below indicate that at least one of them—comparator intensity—does materially influence effect estimates.

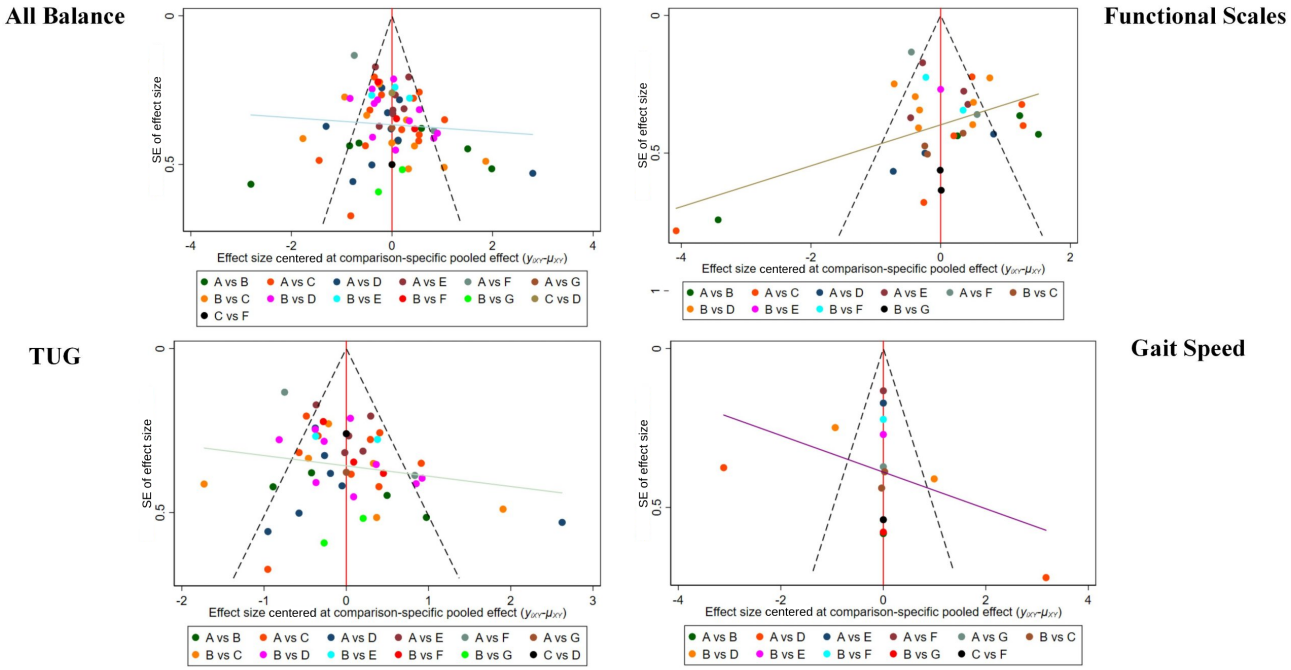
Meta-Regression of Training Dose

Post hoc random-effects meta-regressions found no statistically significant association between the technology versus control effect size and any training-dose parameter, in either the all-balance network or the TUG network (all *P*>.05; Table S10 and Figure S4, Multimedia Appendix 1). The inverse trend for session length and weekly training minutes approached but did not reach significance (*P*=.05-.10) and was opposite in direction to a simple “more-is-better” expectation, most plausibly reflecting confounding by baseline population severity: trials recruiting more impaired participants tended to prescribe longer sessions while achieving smaller standardized effects. As these analyses are based on study-level aggregate data, they are subject to ecological bias and are underpowered to detect modest dose-response relationships; the current evidence neither identifies an optimal training dose nor excludes one. What can be stated descriptively is the dose at which the observed effects were obtained: across the included trials, the median program ran for 8 weeks, with 3 sessions per week and 40 minutes per session. This describes the prescriptions that were tested rather than an established minimum effective dose, and the absence of a dose-response signal means it should not be read as a threshold below which benefit would be lost.

CE training frequency was associated with the magnitude of the direct CE versus NT effect (slope 1.46 per additional session per week; *P*=.04), while no other comparator-intensity parameter reached significance (Table S11 and Figure S5, Multimedia Appendix 1). This analysis rests on the 7 trials in network 1 that compared CE directly with NT and is hypothesis generating rather than confirmatory. It should also be noted that it does not, by itself, explain the direct-indirect discrepancy observed in the TUG network because all 4 trials contributing direct evidence to that contrast prescribed CE at the same frequency as the network median; comparator intensity is therefore a plausible general source of heterogeneity in the CE node, but not the specific explanation for the inconsistency detected in network 3.

Ranking Probabilities

Probabilities of being the best treatment temper the interpretation of the SUCRA hierarchy (Table S12 and Figure S6, Multimedia Appendix 1). In the all-balance network, Tele had a probability of approximately 41% of being the best treatment, followed by EBP (approximately 22%), EMC (approximately 16%), IW



XSL•FO
RenderX

(approximately 15%), and OSG (approximately 5%); the probabilities for CE and NT were negligible. In the TUG network, the corresponding values were approximately 36% for Tele, 26% for EBP, 21% for EMC, and 13% for IW. The substantial probability attaching to IW despite its fifth-place SUCRA position arises from the extreme width of its CI (−0.57 to 1.23 in the all-balance network, 3 trials, 29 participants) rather than from any robust signal of benefit, and this illustrates why ranking metrics must not be read independently of effect size, precision, and certainty of evidence. No intervention emerged as clearly the best option, and the SUCRA hierarchy should not be read as a definitive ordering of clinical effectiveness.

Small-Study Effects and Publication Bias

For networks 1 and 3, visual inspection of comparison-adjusted funnel plots suggested broad symmetry around the comparison-specific pooled effects. Network 2 exhibited marginal asymmetry in the IW comparisons (Figure 5). Network 4 showed notable asymmetry. However, networks 2 and 4 contribute only 26 and 12 trials, respectively, across 7 nodes, and no comparison in either network is supported by the 10 trials conventionally regarded as the minimum for a meaningful test of funnel plot asymmetry. The apparent asymmetry in these 2 networks is therefore uninterpretable, and no comparison was rated down for publication bias on this basis; the possibility of unpublished negative trials, particularly for the sparsely studied IW and OSG categories, cannot be excluded and is treated as an unresolved limitation rather than as a graded judgment.

Figure 5. Comparison-adjusted funnel plots for assessment of small-study effects and publication bias in the 4 analytical networks. TUG: Timed Up and Go.

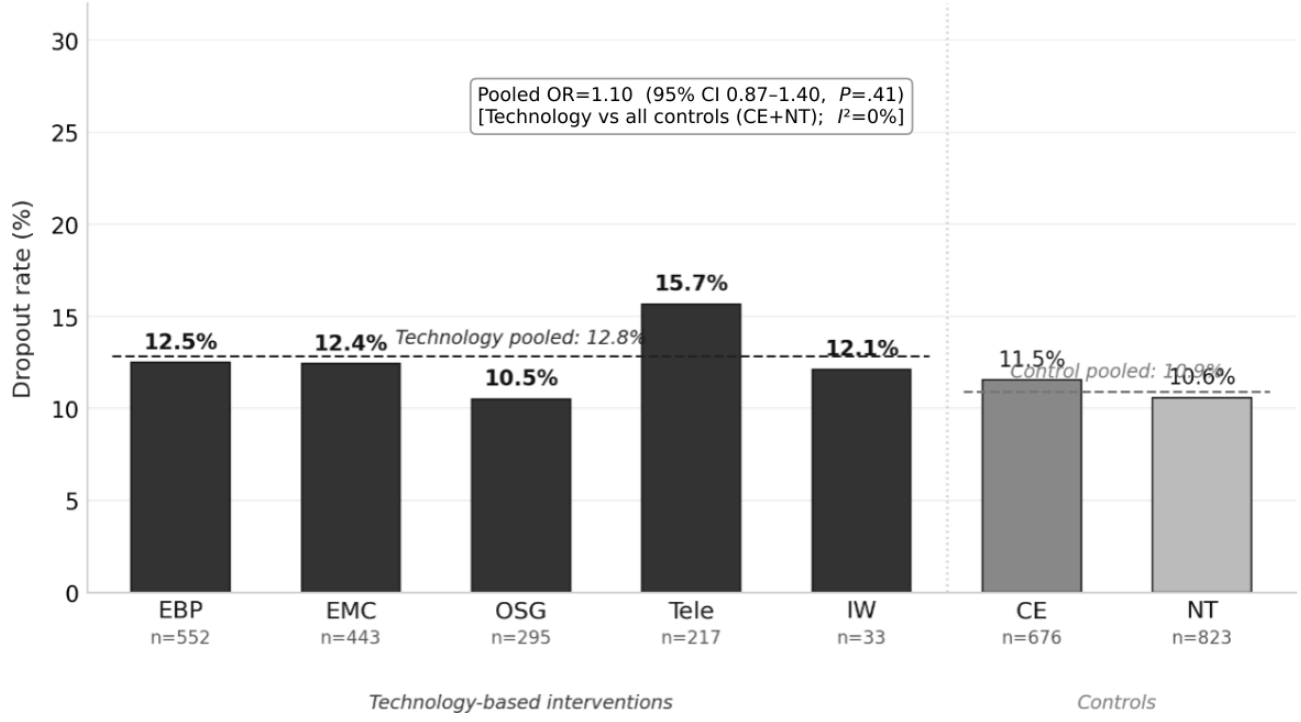
Certainty of Evidence

GRADE ratings are summarized in Table 3. Certainty was rated moderate for only 2 comparisons—EBP versus NT and EMC versus NT in the TUG network—both of which were rated down 1 level for risk of bias and met the prespecified precision criterion without further downgrading. Every other comparison in the review was rated low or very low. In network 1, all comparisons were rated down for imprecision because the 95% prediction interval included the null, reflecting the substantial between-study heterogeneity inherent to a composite balance outcome (τ=0.597). All comparisons involving IW were rated very low owing to very serious imprecision arising from 3 or fewer contributing trials. All network 4 comparisons were rated very low, being rated down for both very serious imprecision and serious inconsistency. No comparison was rated down for indirectness, and, for the reasons given above, none was rated down for publication bias. The explicit judgment reached for each of the 5 GRADE domains, for every comparison rated, is tabulated in Table S13 in Multimedia Appendix 1.

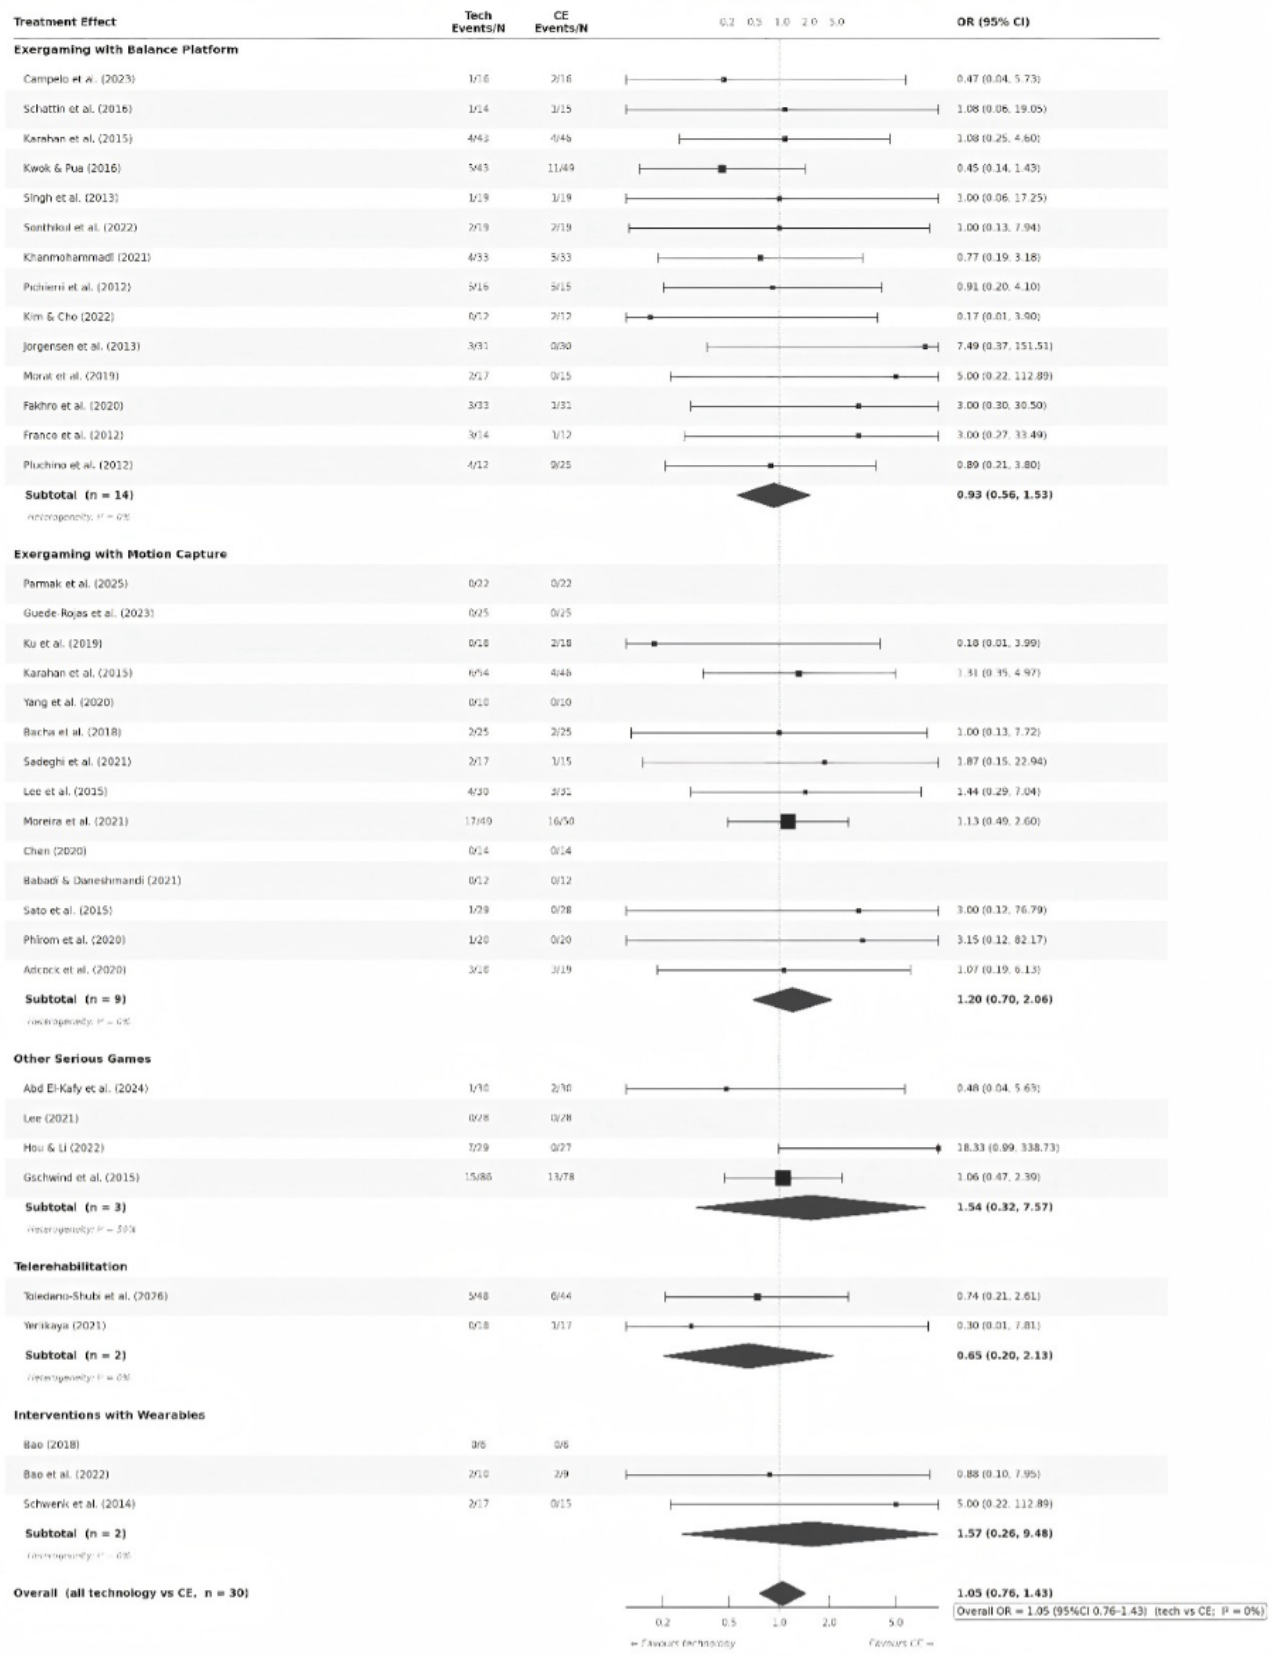
Acceptability, Adverse Events, and User Burden



Dropout data were available for 59 (98.3%) of the 60 included trials (all except 1 [52], for which attrition was not reported). The crude dropout rates per category were 12.5% (69/552) for EBP, 12.4% (55/443) for EMC, 15.7% (34/217) for Tele, 12% (4/33) for IW, 10.5% (31/295) for OSG, 11.5% (78/676) for CE, and 10.6% (87/823) for NT. These denominators are the numbers of participants randomized to arms that both reported attrition and were assignable to a single network node; they therefore sum to 3039 rather than to the 3469 participants randomized overall. Pairwise odds ratios for all 5 technology categories versus CE were nonsignificant (all P>.05; Figure 6), with a pooled overall estimate of odds ratio 1.05 (95% CI 0.76 - 1.43; I^2=0%). When NT was included as an additional control condition, the pooled overall odds ratio for

XSL•FO
RenderX

technology-based interventions versus all control arms was 1.10 (95% CI 0.87 - 1.40; *P*=.41; I^2=0%), indicating no statistically significant difference in acceptability between technology-based and conventional rehabilitation (Figures 6 and 7).



Reporting of the other feasibility outcomes was too sparse to permit synthesis. Only 3 (5%) of the 60 included trials reported a formal safety or adverse event outcome, and only 3 (5%) reported participant satisfaction or acceptability using a defined instrument; technology-related difficulties such as device malfunction, connectivity failure, or cybersickness were reported in a structured manner by a single trial [19], which used the Virtual Reality Sickness Questionnaire. Where adverse events were described, they were minor and were not attributed to the technology itself. The near-absence of standardized reporting of harms, usability, and satisfaction is an important evidence gap: for interventions whose principal claimed advantage is accessibility and engagement, these outcomes are as decision relevant as the effect on balance, and dropout alone is an inadequate proxy for them.

Figure 6. Pooled crude dropout rates by intervention category across all included trials with available dropout data (*N* below each bar denotes the total number of participants randomized per category). CE: conventional exercise; EBP: exergaming with balance platforms; EMC: exergaming with motion capture; IW: interventions with wearables; NT: no treatment; OR: odds ratio; OSG: other serious games; Tele: telerehabilitation.

Discussion

Principal Findings

This update includes 60 RCTs, of which 57 (95%) contributed data, and extends the evidence base by approximately 2 years beyond the original review [12]. Three findings stand out.

First, more technologies now show a benefit. The original review identified only EMC as statistically superior to no treatment, and only for TUG; here EBP, EMC, and Tele each improved outcomes significantly versus NT in both the all-balance composite and the TUG networks. This reflects the entry of larger, better-powered trials, particularly in the Tele and EBP categories, into nodes that previously lacked the precision to detect plausible effects.

Second, the treatment hierarchy has shifted. Tele rose from fifth of 7 ranked interventions in the original NMA (SUCRA 43%) to first in the all-balance network. However, the node contains only 5 trials and 198 participants, and Tele's probability of being the best treatment is approximately 41%, so this ranking is a hypothesis awaiting confirmation rather than an established hierarchy.

Third, GRADE appraisal, applied here for the first time in this technology category, shows that certainty is moderate at best and moderate for only 2 (5.1%) of the 39 pairwise comparisons rated. Risk of bias in the underlying literature is the main reason. The impossibility of blinding participants to an exercise intervention contributes to this, but it is not the whole explanation: blinded outcome assessment was absent or unclear in a substantial minority of trials, and fewer than half reported a prespecified protocol. Both deficiencies are remediable, and the moderate ratings for EBP and EMC versus NT in the TUG network show that the threshold is reachable in this field.

Telerehabilitation: Highest Ranked but Preliminary

Tele ranked highest across several outcome networks in this update, but the wide CI (SMD 0.69, 95% CI 0.08 - 1.29) and the small number of contributing trials call for caution. In the original review, only 3 Tele trials were available [12]. The addition of further large RCTs since 2023 contributed to statistically significant effects versus NT in both network 1 and network 3, consistent with a 2024 systematic review by Gamble et al [88], which found Tele to be noninferior to control interventions across 26 RCTs. The large randomized sample sizes of Tele trials (mean 124 participants per trial) confer greater statistical power per study, which may partly explain the elevation of the SUCRA ranking [22]. Three features of the evidence argue for restraint. The node rests on 5 trials, its 95% CI extends from a trivial effect (0.08) to a very large one (1.29), and its mean intervention duration is the longest and least typical of any node, driven by a single 104-week trial. The sensitivity analysis reported earlier, which removed 1 of the 4 Tele arms in the TUG network, widened the estimate further. Tele is therefore promising and highest ranked, but not demonstrably superior.

Tele works through a different mechanism from exergaming: expert supervision, error correction, and motivational support delivered in real time, which reproduces the cognitive behavioral elements of face-to-face physiotherapy without the access barriers [89,90]. The finding that Tele was not statistically superior to CE in any network is consistent with this and suggests a role as a scalable complement to in-person care rather than a replacement for it.

Convergence of Evidence for Exergaming Platforms and Motion Capture

EBP and EMC maintained significant effects versus NT across both the all-balance composite and TUG networks, with GRADE ratings of moderate certainty for EBP versus NT (SMD 0.81, 95% CI 0.42 - 1.20) and EMC versus NT (SMD 0.79, 95% CI 0.36 - 1.21) in network 3—the only moderate-certainty findings in this NMA. The comparable effect sizes of EBP and EMC are consistent with a recent meta-analysis [91] that found no significant difference between platforms, reflecting their shared therapeutic mechanism of real-time visual augmented feedback enabling immediate postural error correction [6]. Clinicians may reasonably select between them based on practical considerations, including equipment cost, installation requirements, and participant mobility constraints.

Serious Games and Wearable Interventions: Persistent Evidence Gaps

OSG fell just short of significance versus NT in network 3 (SMD 0.49, 95% CI −0.005 to 0.978; *P*=.05). This estimate should not be reported as a positive finding, and the accompanying certainty rating is low. Despite being purpose-built rehabilitation software, OSG did not outperform commercially available exergaming platforms in any network, suggesting that therapeutic benefits may depend more on movement engagement and practice volume than on software sophistication [92,93].

IW similarly failed to reach statistical significance in any comparison. The extreme width of the IW CIs reflects the small number of eligible trials (n=3), all involving custom-designed haptic or vibrotactile feedback systems. This gap has persisted over more than a decade of published work and is unlikely to reflect a lack of researcher interest. Three structural barriers are plausible. First, the wearable systems evaluated to date have been bespoke research prototypes requiring specialist calibration and supervision, which limits both trial size and clinical scalability; commercial devices with validated balance-feedback functions have only recently become available. Second, feedback modalities remain unstandardized—vibrotactile, auditory, and visual channels are used interchangeably across trials, so that the IW node aggregates mechanistically dissimilar interventions. Third, the cost of custom sensor arrays has kept sample sizes small: the 3 IW trials contributing to this review randomized 12, 16, and 33 participants, respectively. These findings indicate insufficient investigation rather than inefficacy. The priority for this category is agreement on a standardized feedback modality and outcome set that would make future trials poolable, not further small pilot trials [13].

The All-Balance Composite Network

Network 1 demonstrates that Tele, EBP, EMC, and CE each produced statistically significant improvements relative to NT (SMDs 0.35 - 0.69). The narrow span of effects across technically distinct platforms suggests a common minimum

XSL•FO
RenderX

benefit achievable through any adequately structured balance program, whatever the delivery mechanism. No technology exceeded CE in any network, consistent with technology acting as a delivery vehicle rather than a source of superior physiological stimulus.

How far this network can be interpreted is nevertheless limited by its construction. It pools instruments that measure genuinely different constructs—dynamic functional mobility (TUG), multidimensional clinical rating scales (BBS, Mini-BESTest, and SPPB), static postural sway (COP parameters and single-leg stance), and lower-limb function (sit-to-stand)—into a single standardized effect. A composite SMD of 0.63 does not tell a clinician which dimension of balance improved, and the substantial between-study heterogeneity (τ=0.597) is in part a direct expression of this structural pooling rather than of true clinical variability. For this reason, the prediction interval rather than the CI was used to rate imprecision in this network; every network 1 comparison is rated low or very low certainty, and the principal clinical conclusions of this review rest on network 3 (TUG), which is a single-construct outcome, is supported by the largest number of trials of any single instrument, and yields the only moderate-certainty estimates in the review. Network 1 therefore tests whether any balance benefit is detectable across the evidence base as a whole, while network 3 provides the estimate on which practice decisions should be based.

Outcome-Specific Results: Instrument Sensitivity and Task Alignment

The absence of significant effects in network 2 (functional scales) probably reflects the differential sensitivity of these instruments to the adaptations induced by short- to medium-duration technology-based training. The TUG mirrors the movement demands of many such programs, particularly sit-to-stand transitions, walking, and turning, giving it high construct validity and sensitivity to training-induced change [94]. Multidimensional scales such as the BBS, Mini-BESTest, and SPPB instead span a broader range of postural control domains, not all equally targeted by a typical exergaming program [95]. Future trials should adopt the TUG as the primary outcome for functional mobility, supplemented by domain-specific subscales where appropriate.

Network 3 (41 trials) yields the most internally consistent pattern of results and constitutes the primary basis for the moderate GRADE certainty ratings assigned to EBP and EMC. EBP (SMD 0.81), EMC (0.79), Tele (0.82), and CE (0.60) were each significantly superior to NT, while OSG (0.49) narrowly missed significance. The point estimates for EBP, EMC, and Tele were near-identical despite the mechanistically distinct pathways through which these platforms operate. The procedural demands of the TUG (rising from a chair, walking 3 m, turning, returning, and sitting) map directly onto the movement content targeted by all 3 platforms: balance board exergaming trains the postural transitions; motion capture training reinforces walking and turning kinematics; and Tele exercises typically incorporate functional mobility sequences supervised in real time. This task-training alignment plausibly explains why the TUG detects significant effects across a broader range of interventions than the functional scales network.

The gait speed network continued to yield no statistically significant treatment contrasts. This null result has now persisted across 2 successive NMAs, which points to a measurement problem: included trials used heterogeneous protocols (4-m vs 10-m tests, different starting conditions, single vs repeated trials), making meaningful pooling inherently difficult. Future trials should standardize gait speed assessment according to published consensus guidelines and should ideally supplement single-task gait speed with dual-task walking assessments, which may be more sensitive to the cognitive-motor integration benefits of technology-based training [96]. Until such standardization is achieved, gait-speed network estimates of this kind should not be used to draw treatment-effect conclusions.

Conventional Exercise as a Problematic Comparator

The significant global inconsistency in network 3, precisely localized by node splitting to the NT versus CE comparison (direct SMD 1.612 vs indirect SMD 0.189; P<.001), has important methodological implications. The aggregation of diverse exercise protocols into a single CE node implicitly assumes a uniform CE versus NT effect across study contexts. This assumption was violated.

The pattern of the underlying data constrains which explanations are tenable. The discrepancy is not driven by 1 or 2 aberrant trials: all 4 trials contributing direct CE versus NT evidence produced large effects (g=0.90 - 2.53; Table S7, Multimedia Appendix 1). Nor is it explained by comparator intensity, the hypothesis that the meta-regression reported earlier might be thought to support, because all 4 of these trials prescribed CE 3 times per week, the median frequency in the review. What the 4 trials do share is a structural feature: each is a small 3-arm trial (11 - 18 participants per arm) in which an NT arm ran alongside an active technology arm. Two mechanisms plausibly follow. Small-study effects would inflate all contrasts in such trials, and the direct CE versus NT evidence rests exclusively on them, whereas the indirect estimate is dominated by larger 2-arm technology versus CE trials. In addition, participants allocated to no treatment within a trial in which others visibly receive an engaging technology may disengage in a way that participants in a 2-arm design do not, depressing the NT arm and inflating every within-trial contrast against it.

The consequence is that removing the discrepant trials does not resolve the inconsistency: it attenuates every estimate, and the direct-indirect difference persists under the less aggressive threshold and becomes inestimable under the more aggressive one (Table S7, Multimedia Appendix 1). We therefore do not claim that the sensitivity analysis restored consistency, nor use it to justify the primary estimates. It supports only the narrower claim that the 2 comparisons on which our clinical conclusions rest, EBP versus NT and EMC versus NT in the TUG network, remain significant under every specification examined. The CE versus NT contrast itself is the least reliable estimate in the review, is rated down for inconsistency in GRADE accordingly, and should not be cited as this review's estimate of the effect of CE. The remedy is prospective. Future NMAs in this field should prespecify minimum comparator-intensity requirements or stratify the CE node, as emphasized in a 2024 Delphi process

XSL•FO
RenderX

[97], and trials comparing a technology with no treatment should report enough detail about the NT condition for its adequacy as a common comparator to be judged.

Acceptability

In contrast to the original review by Cieślik et al [12], which reported a marginally but significantly higher dropout probability in technology-based interventions versus controls (odds ratio 1.22, 95% CI 1.03 - 1.45; *P*=.02), the present updated analysis found no statistically significant difference in dropout rates between technology-based interventions and all control conditions (pooled odds ratio 1.10, 95% CI 0.87 - 1.40; *P*=.41; I^2=0%). This discrepancy likely reflects the expansion of the evidence base: the addition of 10 trials published since the original search, several of which reported zero or near-zero dropout, attenuated the modest signal detected in the smaller original dataset. Acceptability was comparable across all 5 technology categories, and the marginally elevated dropout risk identified in 2023 does not appear to be a stable feature of this intervention class as the literature matures.

The numerically highest crude dropout rate, observed in the Tele category (15.7%), did not differ significantly from that for CE (odds ratio 0.65, 95% CI 0.20 - 2.13) and reflects the composition of that node rather than poorer tolerability: it is driven by a single 104-week trial [22] whose comparator was no treatment, so that its attrition contributes to the crude Tele rate but not to the within-trial Tele versus CE comparison. In the trials that did compare Tele directly with CE, dropout was numerically lower in the Tele arms. A 2024 systematic review found high overall adherence (median >80%) to technology-based programs, with technology-related dropout accounting for only 3% of total withdrawals [98,99].

GRADE Certainty and Clinical Translation

This is the first formal certainty-of-evidence assessment for this technology category in older adults. The moderate ratings for EBP versus NT and EMC versus NT in the TUG network would support a conditional recommendation for EBP or EMC as options—not as proven superior alternatives—relative to no treatment for functional mobility. A recommendation of any strength, however, requires more than a certainty rating: a full GRADE Evidence-to-Decision appraisal [100] must weigh 3 further domains that this evidence base addresses only weakly.

On benefits and harms, the TUG effects for EBP and EMC (SMD approximately 0.8) are clinically appreciable, and attrition showed no excess; but harms were formally reported by only 3 (5%) of 60 trials, so that side of the balance rests on absence of data rather than evidence of safety. On values and preferences, no trial elicited older adults' preferences between technology-delivered and face-to-face exercise, and the choice is unlikely to be preference-neutral: some older adults value the social contact of supervised group exercise, whereas others value avoiding travel. As no technology exceeded CE, preference should carry substantial weight where both are available. On resource use, the technologies differ by more than an order of magnitude in acquisition, maintenance, and training costs, from consumer game consoles to bespoke sensor arrays, and no trial reported a cost outcome. In practical terms, where supervised CE is accessible and acceptable, this evidence provides no basis for substituting a technology-based program for it. These technologies are best placed to reach people for whom in-person supervised exercise is not accessible, the group for whom the comparison against no treatment, which carries the highest certainty, is the relevant one.

The predominance of low-certainty ratings reflects a structural feature of the current exercise rehabilitation literature rather than an absence of effect. As blinding of participants to an exercise intervention is not achievable, future GRADE assessments in this field would be better served by domain-specific rules that ask whether the absence of blinding plausibly affected adherence, cointerventions, outcome assessment, or selective reporting in the trial concerned, rather than by applying an automatic downgrade [25]. Applying that reasoning here, the remediable deficiencies are blinded outcome assessment and protocol prespecification, both of which are entirely feasible in this trial design.

Limitations

This review has several limitations. First, aggregation of heterogeneous exercise protocols within CE and within each technology node introduces within-node heterogeneity that the NMA model cannot fully accommodate; the CE-intensity meta-regression quantifies this for the comparator node, but analogous data were not available for every technology node. Second, IW and Tele remain underpowered relative to EBP and EMC, and the apparent elevation of Tele to first rank awaits confirmation. Third, restriction to postintervention means and SDs excluded change-score studies. Fourth, the very small number of head-to-head active-technology comparisons means that most technology versus technology estimates are wholly indirect and therefore depend on the transitivity assumption examined earlier. Fifth, several recognized effect modifiers—baseline balance impairment, fall history, frailty, sex distribution, supervision level, and technology familiarity—were too inconsistently reported to be assessed, so residual intransitivity cannot be excluded. Sixth, effect sizes were computed from analyzed rather than randomized denominators, which may introduce attrition bias in the minority of trials with substantial loss to follow-up. Finally, the gait speed network remained uninterpretable owing to extreme heterogeneity.

The absence of long-term follow-up data is a further limitation, and a clinically important one. All analyses used postintervention measurements obtained at the end of the training period; no study contributed follow-up data (eg, at 3, 6, or 12 mo after intervention cessation) to the quantitative synthesis. The present conclusions therefore apply to immediate, end-of-intervention effects and cannot be extrapolated to the durability of benefit or to long-term fall prevention outcomes. Durability is central to the clinical value of fall prevention interventions, and future trials should include follow-up of at least 6 months and report the trajectory of effects after training ends.

Related to this, the outcomes synthesized here are measures of balance, functional mobility, and gait speed, not of falls. No included trial contributed data on fall incidence, fall rate,

XSL•FO
RenderX

injurious falls, or time to first fall to any network. The interventions studied may plausibly reduce fall risk through the balance and mobility improvements demonstrated, and the instruments used are established predictors of falls, but this review provides no direct evidence that they prevent falls, and its findings should not be cited to that effect.

Implementation Considerations

Several practical considerations will determine whether these interventions can be deployed effectively in real-world aging care settings. Access to suitable devices and connectivity, digital literacy, usability for older users, the level of therapist or caregiver supervision required, data privacy, equipment and maintenance costs, and the digital divide among older adults may all influence uptake, adherence, and equity of access. These factors vary substantially across the technologies compared here and should be weighed alongside effectiveness when considering implementation, particularly for Tele and wearable systems whose real-world use may differ from the supervised conditions of the included trials.

Future Directions

The Tele evidence base most urgently requires expansion through large, rigorous RCTs that standardize the definition and intensity of remotely supervised exercise protocols. Standardizing the categorization of CE intensity across technology trial designs would substantially reduce the inconsistency problem identified in the TUG network. Trials should prioritize blinded outcome assessment, prospectively register their protocols, adopt at least 6 months of postintervention follow-up, report falls alongside balance outcomes, and report adverse events, technology-related difficulties, and participant satisfaction using standardized instruments. Two further design priorities follow from the present findings. First, instrumented or otherwise objective measurement of balance and functional mobility, applied by assessors blinded to allocation, would reduce the observer susceptibility that is inherent in timed and rated clinical tests and is the principal remediable source of risk of bias in this literature. Second, the near-absence of direct comparisons between technology categories means that almost every technology versus technology estimate reported here is wholly indirect; head-to-head trials, even of modest size, would contribute disproportionately to the precision and the certainty of the network.

Two further directions are worth noting. Individual participant data meta-analysis would overcome the ecological limitations of the study-level dose meta-regressions reported here and is the most promising route to identifying an optimal training dose. AI-adaptive exercise systems, in which machine learning continuously matches prescription to a dynamically assessed individual profile, form an emerging category that fell outside the present taxonomy because the available studies use outcome measures and designs that are not commensurable with network pooling [101-103]; incorporating them into future syntheses will require prior agreement on a core outcome set for digitally delivered exercise rather than further primary trials alone.

Conclusions

The evidence that technology-assisted rehabilitation improves balance and functional mobility in older adults has strengthened since the original 2023 review. EBP, EMC, and Tele each produced statistically significant improvements in functional mobility and overall balance versus no treatment. The emergence of Tele as the highest-ranked intervention by SUCRA is a preliminary observation resting on 5 trials with a wide CI and a probability of being best of only approximately 41%; it requires confirmation in larger trials. Moderate GRADE certainty for EBP and EMC versus no treatment on the TUG test may support their conditional use as options, rather than as proven superior alternatives, for improving functional mobility where supervised in-person exercise is not accessible; no technology exceeded CE in any network, and the low to very low certainty of the remaining 37 comparisons is insufficient to confirm effectiveness. As no included trial contributed fall outcomes, these findings should not be interpreted as direct evidence of fall prevention. Consolidating these findings will require rigorously designed, adequately powered RCTs, particularly for Tele, wearable interventions, and head-to-head technology comparisons, with standardized comparator intensity, blinded outcome assessment, and follow-up beyond the end of training.

Generative AI Use

Generative AI was used during the preparation and revision of this manuscript. Following the GAIDeT (Generative AI Delegation Taxonomy), the tasks delegated to the generative AI tool Claude were translation of text drafted by the authors into English and language editing (proofreading and polishing of style and readability). All AI-assisted text was critically reviewed, verified, and revised by the authors, who take full responsibility for the accuracy and integrity of the final manuscript. The generative AI tool is not listed as an author and bears no responsibility for the final content.

Abstract

Background: Although clustering techniques are commonly used in bibliometric analysis to identify research themes, few studies systematically assign these themes back to individual articles. This gap limits the interpretability of findings and hinders granular, article-level longitudinal analysis.

Objective: This study introduces the Theme Assignment Algorithm for Articles (TAAA), a data-driven framework designed to map clustered themes to individual publications. We demonstrate its utility by identifying dominant research patterns and thematic shifts within JMIR Aging.

Methods: TAAA was applied to 434 JMIR Aging articles published between 2020 and 2025. Keywords were harvested from 3 sources: Web of Science Core Collection (WoSCC) Keywords Plus, author-provided keywords, and abstract-derived terms. These were grouped into thematic clusters using the "following leader clustering algorithm". The TAAA, implemented via R and a web-based application, determined each article's primary theme using a statistical model to create a discrete article-level variable. Core themes were identified via h-index computation. Analytical visualization included Kano and Sankey diagrams, alongside volcano plots and heatmaps. The framework's robustness was further tested by applying a "differentially expressed genes" analogy to map "unknown" core metadata across "known" pre/post publication stages using Cohen kappa as the extent of mapping power.

Results: Analysis across the 3 keyword sources yielded 9, 7, and 9 core themes, respectively. The most prominent themes identified were HEALTH (39.4%), OLDER ADULTS (43.1%), and DEMENTIA (25.3%). Notably, DEMENTIA emerged as a consistent core theme across all sources and visual layers, validating the TAAA's ability to capture cross-source thematic coherence. The adaptation of dual heatmaps demonstrated the algorithm's capacity for comparative bibliometric mapping in JMIR Aging. A mapping precision of 0.33 provided quantitative evidence of a 2-stage publication pattern, though the separation between stages was not strictly confined to predefined time intervals.

Conclusions: The TAAA framework provides a replicable, scalable, and interpretable method for article-level thematic assignment. Its ability to uncover consistent research patterns—specifically the dominance of dementia-related studies in JMIR Aging—demonstrates its value for bibliometricians and its potential adaptability to other domains, such as bioinformatics-inspired meta-analyses.

Introduction

Overview

JMIR Aging is a peer-reviewed, open-access journal dedicated to advancing digital health, technology, and innovation for older adults [1]. It publishes research on eHealth interventions, gerontechnology, aging populations, and health services aimed at improving care and outcomes for aging societies [2]. Despite this clear mission, the underlying thematic structure of its publications remains underexplored, limiting the ability to systematically trace research foci, emerging trends, and evolving priorities [3]. Understanding the journal's intellectual landscape requires an approach that integrates bibliometric theory, network clustering, and theme identification into a coherent framework.

Theoretical Background: Themes and Co-Word Structures in Bibliometrics

In bibliometric research, thematic classification plays a central role in mapping intellectual structures and identifying research

XSL•FO
RenderX

frontiers [4-6]. The theoretical foundation lies in co-word analysis, which assumes that the co-occurrence of keywords reflects conceptual proximity among research topics [4-9]. Tools such as Bibliometrix, VOSviewer, and CiteSpace operationalize this principle by constructing keyword networks and identifying clusters that represent thematic communities [7-9].

However, existing methods primarily operate at the cluster level, identifying thematic groupings among keywords rather than assigning a single dominant theme to each article [4-6,10,11]. This limits the interpretability of bibliometric maps and constrains microlevel analyses, such as tracing thematic shifts across journals, institutions, or regions.

Need for Article-Level Theme Assignment

Although advanced methods such as the following leader clustering algorithm (FLCA) [12] and latent Dirichlet allocation–based topic modeling can uncover latent thematic structures, a key gap remains: Cluster-level theme discovery does not automatically translate into clear, article-level theme representation—for example, mapping text-driven patterns (from item/factor structures) into labels that describe article or person attributes.

To date, few bibliometric models explicitly address this gap with a formal mechanism for assigning cluster-derived themes to individual publications. Without this linkage, thematic labeling becomes less consistent, and cross-sectional or longitudinal analyses are harder to interpret and compare [4,5].

To address this theoretical and methodological gap, an article-level theme assignment algorithm (Theme Assignment Algorithm in Articles [TAAA]) is required. TAAA formalizes the process of identifying each article's dominant theme from multiple candidate clusters, enhancing both interpretability and reproducibility in bibliometric studies.

An Application or R-Based Framework for Thematic Assignment and Visualization

Although some prior studies have conceptually mentioned "theme-by-article" analyses [4,5], no standardized nor open-source R-based (or application) implementation currently exists [13]. The proposed framework, TAAA, operationalizes the statistical mode of an article's keyword cluster assignments to determine its most representative theme (ie, from item/bifactor structures into labels that describe article or person attributes). This method enhances computational efficiency while maintaining theoretical consistency with co-word analysis principles.

Furthermore, the framework integrates visual analytic tools via an application (for the general public) and R-based scripts (for academic researchers), including Kano diagrams [14,15] and Sankey visualizations [11], to illustrate how the newly created theme variable propagates across articles, institutions, and nations. This integration advances existing bibliometric visualization paradigms by enabling article-level interpretability within cluster-based systems.

Study Aim and Contribution

This study aimed to develop and demonstrate an application and R-based TAAA for assigning dominant themes to publications in JMIR Aging. The contribution of this work is 2-fold:

1. Conceptual: It extends bibliometric theory by linking cluster-level co-word analysis to article-level thematic representation, addressing a critical gap in interpretive granularity.
2. Methodological: It provides a transparent, reproducible, and scalable application or R-based workflow for theme assignment and visualization.

We hypothesized that TAAA can accurately capture each article's primary thematic focus and improve interpretability in large-scale bibliometric analyses. We further expected the framework to be adaptable to other journals and research domains, as demonstrated through several practical examples.

Methods

Data Source

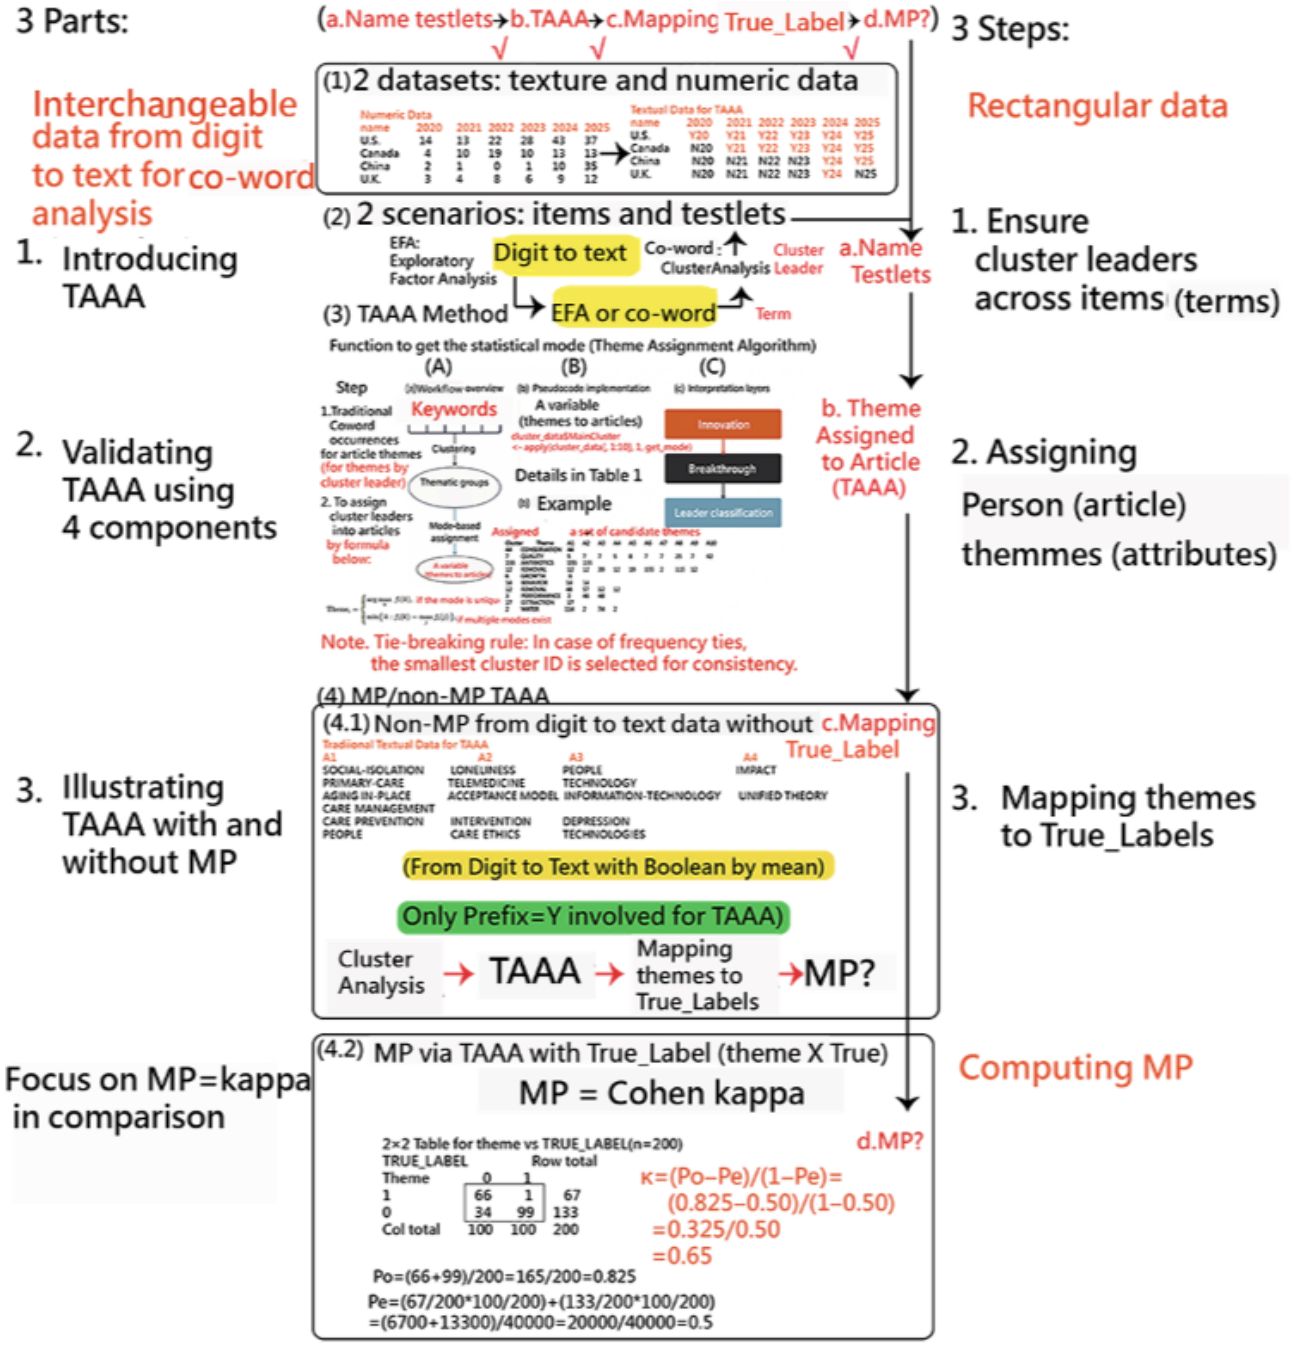
We retrieved metadata for 434 articles published in JMIR Aging from 2020 to 2025 using the Web of Science Core Collection (WoSCC) database. The dataset includes bibliographic information such as author names, affiliations, titles, abstracts, and keywords. Study data are provided in Multimedia Appendix 1. Since all records in WoSCC are publicly available and contain no identifiable patient information, institutional review board approval was not required.

Definition of Key Terms

To ensure conceptual clarity, the following key terms are defined within the context of this study: keyword source, item testlet, person theme, mapping power (MP), and theme variable.

Keyword source refers to the origin of the keywords used for analysis. This study distinguishes between 3 types: (1) author-provided keywords: terms explicitly selected by the authors; (2) Keywords Plus: terms automatically generated by the WoSCC; and (3) abstract-derived keywords: terms extracted from the article abstracts using a custom R script.

Item testlet draws from educational assessment terminology, where a "testlet" represents a cluster of keywords grouped by a common thematic thread. In this study, testlets were generated using FLCA [12], where each cluster reflects a cohesive research topic within the broader keyword network.



Person theme is the primary topical label assigned to an individual article. Using TAAA [4,5], the "person theme" is determined by identifying the statistical mode (the most frequent keyword cluster) associated with that specific article (or person).

MP is a metric used to validate the consistency of thematic classification. As illustrated in Figure 1, MP is computed by mapping keyword clusters (item testlets) to article-level classifications (person themes) and comparing them against established true labels.

XSL•FO
RenderX

For the theme variable, cluster leaders were first generated separately for each keyword source and then merged by mapping item-level terms to person-level themes. This design enables rigorous cross-source comparison and validation of mapping performance against external ground-truth labels (TRUE_LABEL), such as gender or cancer versus noncancer status.

Figure 1. Diagram showing the 3 parts and 3 steps for Theme Assignment Algorithm in Articles (TAAA) in 2 datasets and 2 scenarios (mapping power [MP] vs non-MP with and without True-Label for articles or persons).

Summary Performance Report

A clear and concise reporting format focusing on 10 key metadata elements, including top 10 themes, was used to improve readability and interpretation [11], offering an alternative to the extensive graphs and tables commonly found in traditional bibliometric analyses.

TAAA Applied to This Research

This research consists of 3 parts: (1) introducing TAAA, (2) validating TAAA, and (3) illustrating TAAA with and without MP.

XSL•FO
RenderX

Introducing TAAA

Creation of a Theme Variable for Co-Word Occurrence Analysis

This study used 3 scenarios to assign themes to articles using 3 keyword sources: Web of Science Keywords Plus, author keywords, and abstract keywords. These were processed via an R script [16] for the extraction of keywords in articles. Traditionally, article keywords are clustered into thematic groups using algorithms such as FLCA [12] or tools like CiteSpace [8], where the largest bubble typically represents the dominant theme in each cluster [10,11].

The TAAA was further implemented in R [17], leveraging the statistical mode to identify the most frequently occurring theme among a given article's clustered keyword assignments based on theme with the top one by count in each cluster. This newly created variable ("theme") was added to each article for downstream analysis as shown in part 3 in Figure 1 and Textbox 1.

Textbox 1. Conversion of multiple candidate clusters per article into a single dominant theme with R script.

```
# Function: get_mode()
# Purpose : Determine the dominant theme (mode) among candidate clusters
# Context : Used in the Theme Assignment Algorithm for Articles (TAAA) get_mode <- function(x) {
# Step 1. Clean input data
# Remove blank entries ("") and missing values (NA)
x <- x[x != "" & !is.na(x)]
# Step 2. Handle empty input case
# If no valid data remain after cleaning, return NA (no theme can be assigned)
if (length(x) == 0) return(NA)
# Step 3. Compute frequency table of cluster occurrences
# The 'table()' function counts how many times each cluster ID appears freq <- table(x)
# Step 4. Check for tie condition (all clusters occur equally often)
# If all frequencies are identical, select the smallest cluster number
# This ensures deterministic (non-random) and reproducible assignment
if (length(unique(freq)) == 1) {
return(min(as.numeric(names(freq)))) # smallest cluster ID (tie case)
# Step 5. Otherwise, return the most frequent cluster (the statistical mode)
} else {
return(names(freq)[which.max(freq)]) # dominant cluster (standard mode)
}
}
#Example usage:
# Apply the function across columns A1–A10 (keyword clusters per article)
# and create a new variable "MainCluster" representing the assigned theme cluster_data$MainCluster <- apply(cluster_data[, 1:10], 1, get_mode)
```

The approach improves interpretability and computational efficiency by resolving thematic ambiguity, as defined by Equation (1):

$$\text{Theme}_i = \begin{cases} \min\{k \mid f_i(k) = \max_j f_i(j)\}, & \text{if all } f_i(k) \text{ are equal} \\ \text{Mode}(\text{Cluster}_{\text{keywords}}), & \text{otherwise} \end{cases} \quad (1)$$

where $f_i(k)$ denotes the frequency of cluster k among the keywords of article i.

For instance, consider an article whose keywords are distributed across 3 clusters—Cluster 1, Cluster 2, and Cluster 3—with respective frequencies of 1, 3, and 2. The algorithm first computes the frequency of each cluster ($f_i(k)$) and identifies Cluster 2 as having the highest count. Therefore, the assigned theme for this article is Cluster 2, as it represents the statistical mode of the clustered keyword assignments.

If all clusters had occurred with equal frequency (eg, 2, 2, 2), the algorithm would select the smallest cluster identifier to ensure deterministic and reproducible assignment of the article's dominant theme, as shown in part 3 of Figure 1.

For each article, the assigned theme corresponds to the statistical mode of its keyword cluster assignments. In cases of ties (ie, multiple clusters with equal frequency), the cluster with the smallest numerical identifier is selected to ensure consistency and reduce thematic ambiguity.

XSL•FO
RenderX

TAAA in Bibliometric Analysis Based on Textual Data

The TAAA framework was applied using visual tools such as Kano [14,15] and Sankey [11] diagrams to illustrate thematic distributions across articles, countries, and journals based on co-word occurrence data (eg, "theme" and "country" variables in two columns). The R script [18] followed methods described in prior studies [11]. Additionally, leader classification was performed using the dimension coefficient (DC) [19,20], defining leadership categories as super (DC ≥0.8), quasisuper (DC≥0.7), strong (DC≥0.6), moderate (DC≥0.5), and weak (DC<0.5).

Venn Diagram Used to Identify the Common Themes From 3 Sources

A Venn diagram was used in R [21] to extract the overlaid themes from the 3 sources: Keywords Plus, author-defined keywords, and abstract. The screened themes denote the core elements in the studied journal.

Validating TAAA

We evaluated TAAA using 4 complementary validation components: interrater and intrarater validation, external validation and robustness across clustering methods, bootstrapping stability, and out-of-sample holdout robustness.

Interrater and Intrarater Validation (Core Theme Subsample)

A stratified subsample was drawn from dominant ("core") themes (86/431, 20% of core theme articles). Two independent reviewers (2 study authors) who were blinded to TAAA outputs assigned themes using the same predefined label set based on titles and abstracts. Agreement was assessed for TAAA vs Reviewer 1, TAAA vs Reviewer 2, and Reviewer 1 vs Reviewer 2 using confusion matrices and Cohen κ [22], where commonly cited cutoffs [23] are <0.00, poor; 0.00 - 0.20, slight; 0.21 - 0.40, fair; 0.41 - 0.60, moderate; 0.61 - 0.80, substantial; and 0.81 - 1.00, almost perfect.

External Validation and Robustness Across Clustering Methods

Because no universally accepted ground truth exists for topic clustering in keyword co-occurrence networks, we assessed robustness by comparing TAAA assignments under two clustering strategies applied to the same keyword set: (1) FLCA term-to-theme membership from our pipeline (terms_nodes.csv) and (2) Louvain communities from modularity optimization on the keyword co-occurrence graph.

Since cluster counts may differ, we evaluated concordance using (1) a majority-overlap mapping from Louvain communities to FLCA themes based on article-level cross-tabulation and (2) a top-*k* hierarchical criterion in which an article was counted as agreeing if its FLCA theme fell within the top-*k* most frequent FLCA themes inside its Louvain community (*k*=1, 2, 3, 4). Top-1 corresponds to strict one-to-one concordance; larger *k* quantifies hierarchical nesting where a coarse Louvain community may contain multiple FLCA subthemes.

Bootstrapping Stability

To assess sampling stability, we performed bootstrap resampling with replacement on the core-theme subsample. For each repetition, κ was recomputed and summarized by its mean and 2.5th-97.5th percentile interval. Jensen-Shannon (JS) distance and mean Spearman correlation across resamples were also computed to quantify stability [24-29].

Out-of-Sample Holdout Robustness

To evaluate robustness under dataset shift, we conducted repeated random holdout experiments with a prespecified holdout fraction. On holdout sets, we computed mean Spearman correlation and JS distance between training and holdout rankings to quantify generalization [30,31].

Illustrating TAAA With and Without MP

Textual Terms From Digital Data Assessed Using MP

This text integrates the technical logic of the TAAA with the validation process through MP, supporting both "non-MP" (digit-to-text without true labels) and "MP" (validation against true labels) scenarios to ensure robust bibliometric mapping.

The workflow illustrates the transition in Figure 1, from (1) multisource datasets to (2) the identification of item testlets. (3) The TAAA applies a mode-based function (with tie-breaking rules) to assign a primary person theme to each article (or person). (4) The process concludes with the computation of MP using Cohen kappa [22,23], validating the thematic assignment against true labels to ensure classification accuracy.

Steps for Implementing TAAA via R and a Web-Based Application

For the abstract keyword extraction, the input data came from a CSV file named methodsxabstract.csv containing columns for article title and abstract. In R [16] and the application [24], combined text is stored in df$CombinedText. Abstract keywords are extracted and saved to methodsxabstract_with_keywords_topics.csv.

TAAA Implementation via R and a Web-Based Application

Keywords across multiple columns are provided in top10keywords.csv. Themes are assigned per article using the TAAA model [17,25] and saved sequentially to methodsxabstract_with_keywords_topics.csv. The resulting "theme" variable is used to analyze co-word occurrences, visualizing thematic distributions across articles, countries, and journals (with variables like "theme" and "country" in two columns).

Applications of TAAA for Textual and Numeric Data With MP

The transition from numeric values to article-level (person-level) themes, as shown in part 1 in Figure 1, follows a structured 8-step process:

1. Dichotomization: Convert each numeric item into binary scores using the item-specific mean as a threshold.
2. Tokenization: Transform binary scores into textual tokens by prefixing item labels with "Y" (yes) or "N" (no).

XSL•FO
RenderX

3. Occurrence construction: Retain only "Y-type" tokens to simulate keyword occurrences within each row.
4. Co-word clustering: Apply clustering algorithms to these tokens to derive thematic "cluster leaders" representing coherent testlets across data columns.
5. Person-level assignment: Use the TAAA to map these term-based themes to individual rows (persons), establishing a dominant theme for each entry.
6. External validation (optional): If external reference labels are available, compute MP using Cohen kappa to assess classification accuracy.
7. Web implementation: To enhance user accessibility, the analytical framework [32-34] was deployed as a cloud-based application on Google App Engine (GAE) [35]. This provides a user-friendly interface for researchers to replicate the analysis without requiring local environment configuration, as done with R scripts.
8. Visual interpretation: Analyze the results through an automated HTML report [32,33] featuring Kano diagrams, Sankey plots, volcano plots, and heatmaps.

Data Sources for Application Examples

The application of TAAA to textual entities via the application was conducted with 434 articles published in JMIR Aging from 2020 to 2025. The application of TAAA to numerical entities via the application occurred via virtual data as a test on STEM and ARTS for men and women and as a questionnaire on 2 domains. In addition, the TAAA was applied to Gene Expression Omnibus (GEO) data via the application: A gene expression profile, GSE8401 [36], including 31 primary melanoma and 52 metastatic melanoma (MM) clinical samples, was downloaded from the GEO database [37]. The differentially expressed genes between MM and primary melanoma were assessed using MP.

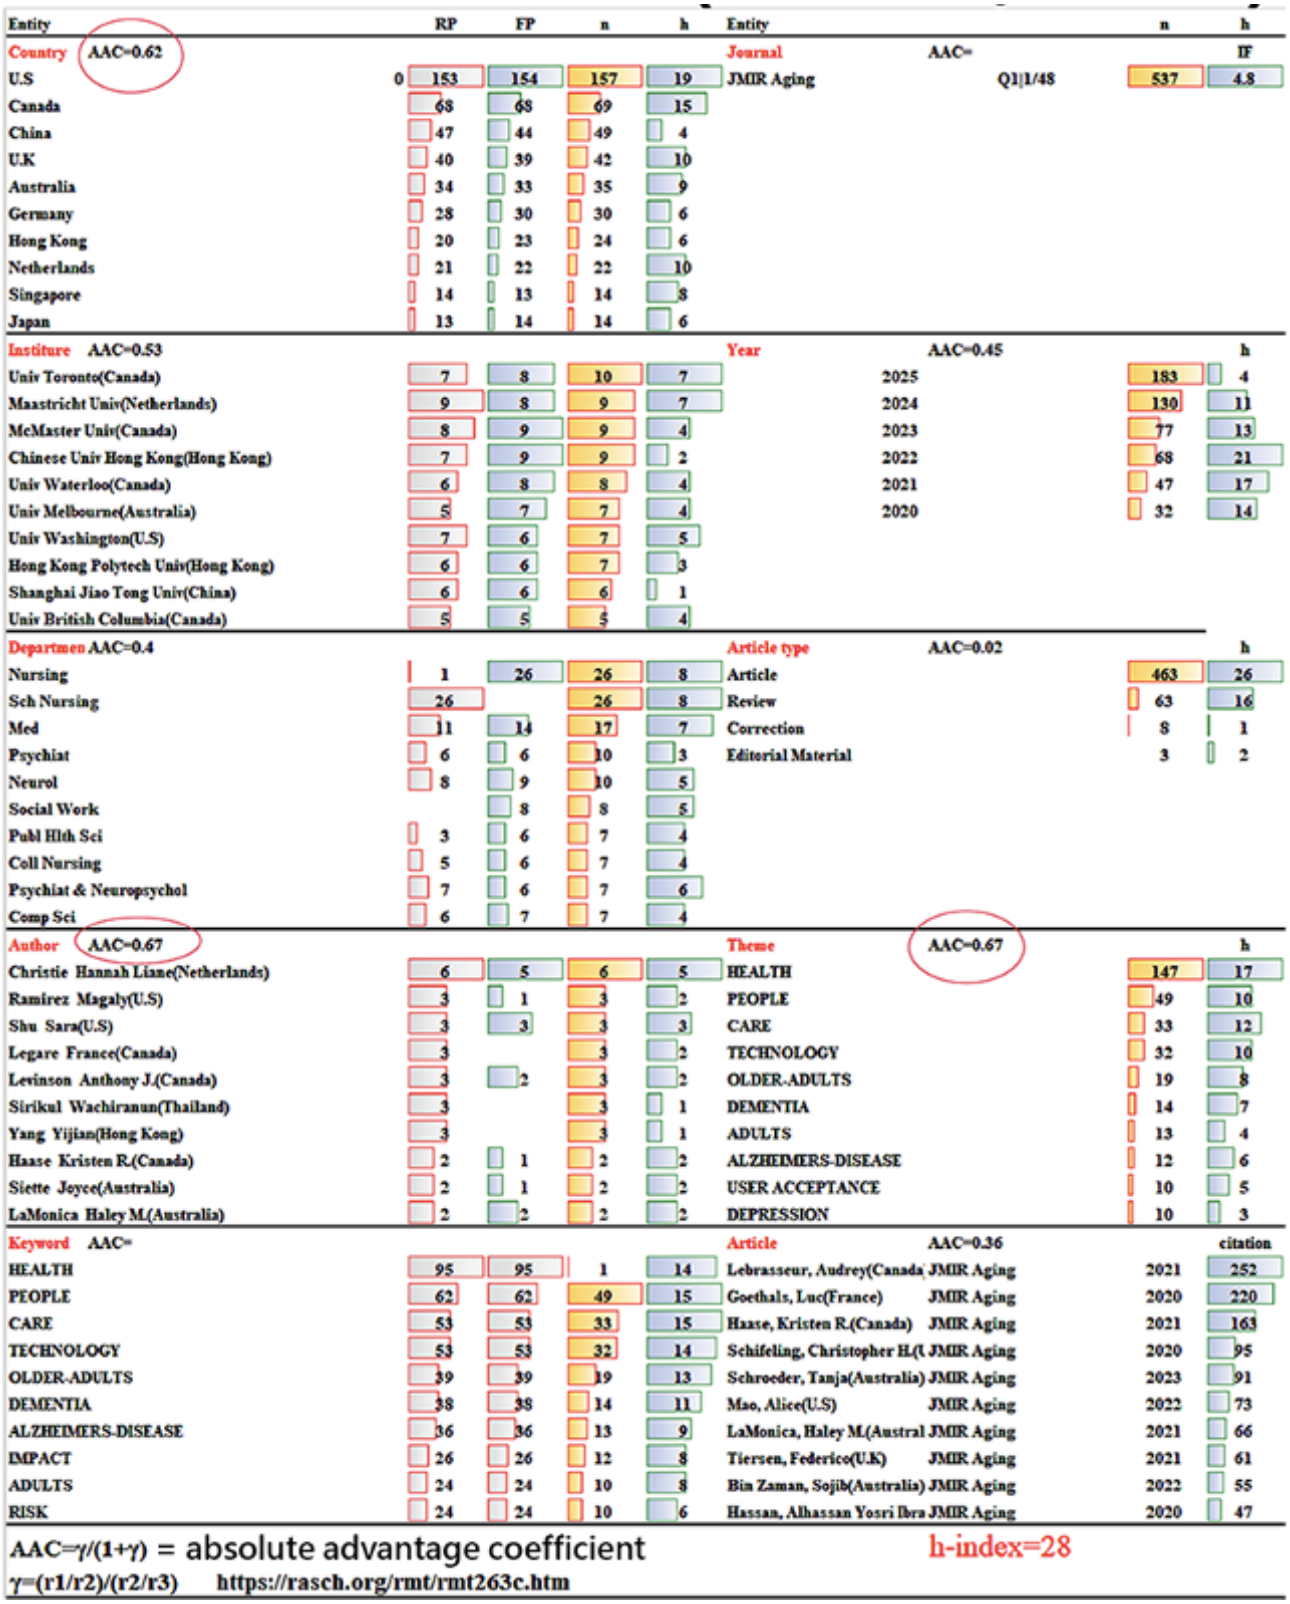
R Packages and Application Used in This Study

All visualizations and data processing were conducted using the R platform [16,17,20,23] or GAE [35]. Kano diagrams were generated in the application or R scripts, with all statistical analyses performed in R version 4.1.3 [13]. Visualizations and results were produced within the RStudio integrated development environment [38]. The way to conduct this study using R scripts is described in Multimedia Appendix 2.

Results

Summary Performance Report for Top 10 Article Elements

Figure 2 presents a comprehensive summary of 434 publications in JMIR Aging (h-index=28 [39]) analyzed across 10 bibliometric dimensions—country, institution, department, year, article type, author, research area, keyword frequency, and citation count.



The United States, Canada, and the United Kingdom led in publication output, while the University of Toronto (Canada) and Maastricht University (the Netherlands) were among the most productive institutions. Nursing and medical departments contributed prominently, with the majority of papers classified as original research articles.

Notably, Hannah Liane Christie (the Netherlands) was the most prolific author (6 articles [40-45]), whereas Audrey Lebrasseur et al (Canada) produced the most-cited study [46], receiving 252 citations for a rapid review on COVID-19's impact on older adults. Core keywords such as HEALTH, PEOPLE, CARE, and TECHNOLOGY reflect the journal's central focus on digital health and aging innovation; see the keyword and theme panels in Figure 2.

Accordingly, this performance overview provides a structural snapshot of JMIR Aging's research landscape, enabling targeted insight into its geographic reach, institutional strengths, and topical emphasis.

XSL•FO
RenderX

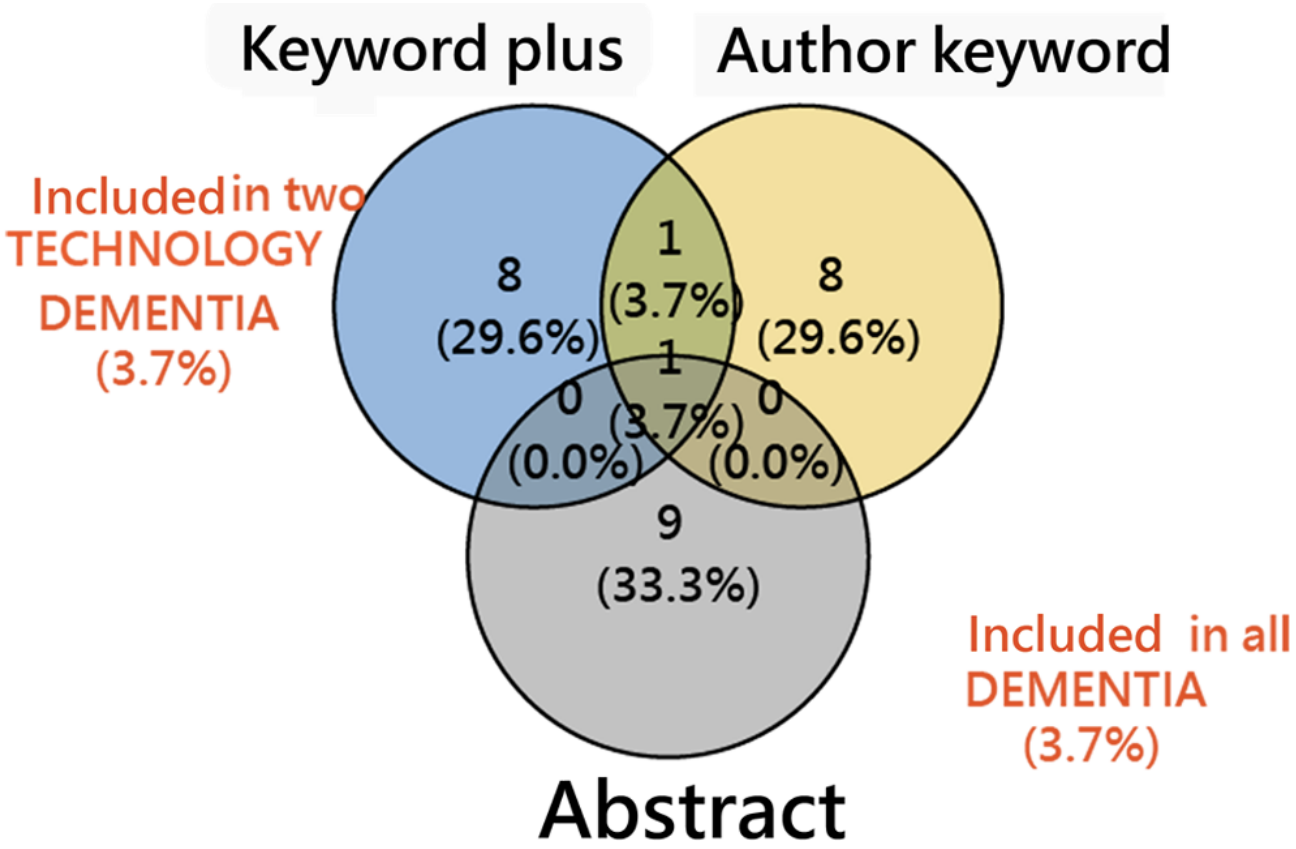
Figure 2. Summary performance report for 10 article metadata categories in JMIR Aging (n=537). FP: first author; RP: first author.

TAAA for Theme Extraction and Implementation

Figure 3 illustrates how the TAAA identified dominant themes across 3 keyword sources: Keywords Plus (external indexing terms): 9 core themes (Figure 3A); author-supplied keywords: 7 core themes representing self-identified research emphases (Figure 3B); and abstract-derived keywords: 9 themes reflecting content-driven topic extraction (Figure 3C).

XSL•FO
RenderX

Figure 3. Core themes extracted from JMIR Aging from 3 keyword sources including (A) Keywords Plus, (B) author-defined keywords (top 7 themes contributing to the h-index), and (C) abstract-derived keywords (top 9 themes contributing to the h-index). DC: dimension coefficient.



XSL•FO
RenderX

Across all 3 scenarios, the top themes were HEALTH (108/282, 39.4%), OLDER ADULTS (140/343, 43.1%), and DEMENTIA (38/158, 25.3%).

To illustrate theme overlap, Figure 4 (Venn diagram) shows that DEMENTIA was the only theme consistently identified in all 3 TAAA runs, underscoring its centrality in the journal's research portfolio.

Hence, the convergence of DEMENTIA across independent keyword sources validates TAAA's reliability in identifying dominant thematic foci and highlights the journal's sustained emphasis on cognitive health in aging research.

Figure 4. Venn diagram showing DEMENTIA as the only theme overlapping across all 3 TAAA approaches.

TAAA for Validation

Subsample Interrater Validation (Core Themes)

Subsample interrater validation on 57 core theme records (20% sampled from 431 articles) showed substantial agreement between TAAA and Reviewer 1 (κ=0.788; 84.2% exact agreement) and moderate to substantial agreement between TAAA and Reviewer 2 (κ=0.672; 75.4% exact agreement). Human-human agreement was moderate (κ=0.597; 68.4% exact agreement), indicating inherent ambiguity in theme boundary decisions.

Misclassifications were concentrated in a small number of adjacent theme pairs, particularly involving the dominant theme (T1) and conceptually related themes (eg, T13/T15), consistent with expected instability in low-prevalence categories (Table 1).

XSL•FO
RenderX

[j]TAAA: Theme Assignment Algorithm in Articles.

When the human-human agreement (κ=0.597) is lower than the TAAA-human agreement (κ=0.788 and 0.672), it leads to several significant implications regarding the reliability and utility of the TAAA algorithm as a "stabilizing force." Although human reviewers may be influenced by subjective interpretation or fatigue, the TAAA applies a consistent, rule-based mode

XSL•FO
RenderX

logic that reduces the "noise" inherent in manual thematic assignment. In bibliometric studies involving hundreds or thousands of articles, manual review is prone to increasing error rates.

Agreement Between FLCA and Louvain

Among 431 records, 373 contained at least one keyword. FLCA yielded 53 themes in the term-membership file, whereas Louvain produced 15 communities on the same mapped keyword graph.

Because the two methods differ in granularity, we evaluated hierarchical concordance by allowing each Louvain community to correspond to its Top-*k* most frequent FLCA subthemes. Agreement increased from 49% (183/373; Top-1) to 65.5% (244/373; Top-2), 77.5% (289/373; Top-3), and 82.5% (308/373; Top-4), indicating that most Louvain communities are unions of a small number of FLCA subthemes. To report a chance-corrected measure at the Louvain granularity (*k*=15), we collapsed FLCA themes to Louvain communities via majority overlap at the term level and computed Cohen κ between the resulting labels, yielding κ=0.399, indicating an upper fair effect (0.21 - 0.40) [24].

Bootstrapping Stability (120 Repetitions)

Across 120 bootstrap resamples, the number of core themes was k=9, and the thematic structure showed high stability (Table 2). The mean JS distance between the bootstrap and reference distributions was 0.057 (SD 0.016), indicating only minor shifts in the theme proportion profile under resampling. The mean Spearman rank correlation was 0.896 (SD 0.071), suggesting that the relative ordering of theme importance was largely preserved across resamples.

Table . Bootstrapping stability and robustness.

Measurement	Repetitions, n	Core themes, k	Holdout fraction	JS[a] distance, mean (SD)	Spearman rank, mean (SD)
Bootstrapping	120	9	—[b]	0.06 (0.02)	0.90 (0.07)
OOL[c] holdout robustness	120	9	0.3	0.12 (0.03)[d]	0.72 (0.13)

[a]JS: Jensen-Shannon.

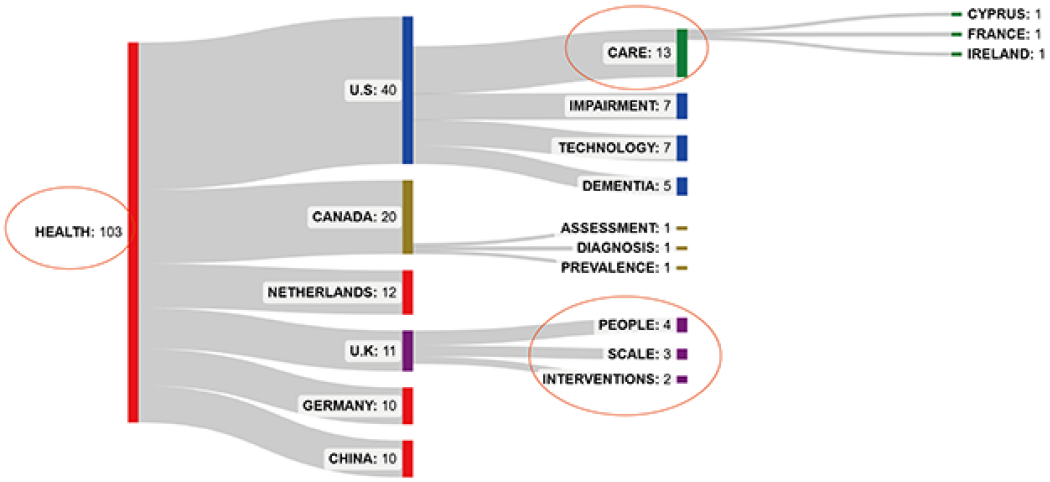
[b]Not applicabe.

[c]OOL: out-of-likelihood.

[d]Train, holdout.

Out-of-Distribution Holdout Robustness (120 Repetitions)

Under 120 repeated holdout (out-of-likelihood/out-of-sample) evaluations with a 30% holdout fraction, the model retained k=9 core themes (Table 2). The mean JS distance between the training and holdout theme distributions was 0.124 (SD 0.034), which is larger than the bootstrap JS distance, reflecting the expected distributional shift induced by data splitting. The mean Spearman correlation between training and holdout rankings was 0.724 (SD 0.127), indicating moderate agreement in theme ordering and suggesting that the primary thematic structure generalizes reasonably well, while lower-prevalence themes are more sensitive to sample partitioning.

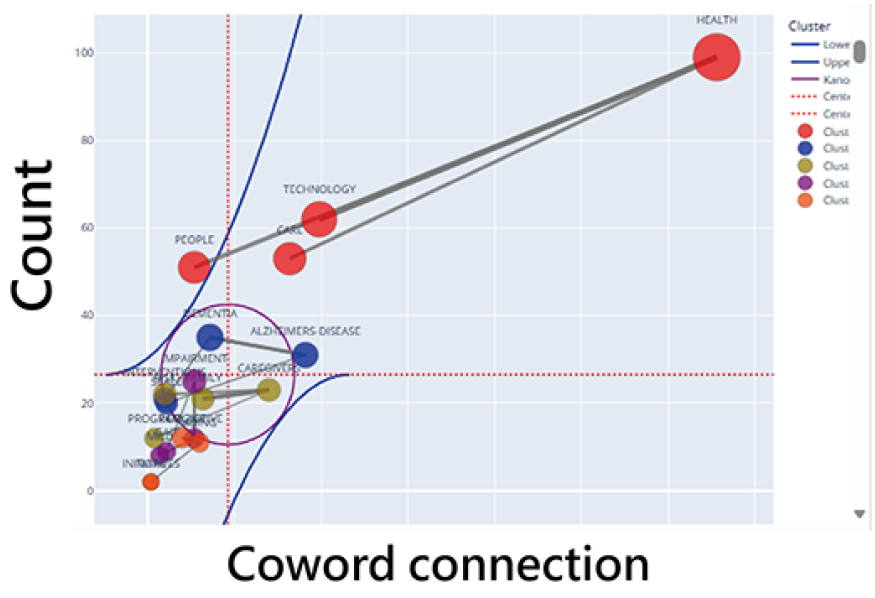


TAAA for Textual Entities via the Application

Figure 5 demonstrates how assigned themes distribute across countries, highlighting geographic research orientations. The United States remained a research leader, followed by Canada and the United Kingdom.

XSL•FO
RenderX

Figure 5. Textual co-word with a new variable of theme: (A) Sankey visualization by country-theme, (B) rectangular data, and (C) create network chart by theme and country via an application [25]. AAC=0.58 <0.7 without dominance role for health=[(99/62)/(62/53)]/(1+[99/62)]/(62/53)]). AAC: absolute advantage coefficient.



(A)

(B)

name	HEALTH	CARE	TECHNOLOGY	DEMENTIA	PEOPLE	RISK	IMPAIRMENT	CAREGIVERS	SCALE	ADULTS
U.S	41	13	7	5	2	2	7	6	2	3

Japan	4	1	2	0	0	1	0	0	0	0
Singapore	4	0	4	0	0	0	0	0	0	0

(C)

DEMENTIA and CARE are closely associated with US authors, whereas ASSESSMENT is linked to Canadian research. SCALE and PEOPLE themes are common in UK-based publications. The Sankey diagram in Figure 5A visualizes these

XSL•FO
RenderX

relationships—flow width represents the proportional connection between countries and their dominant themes.

In Figure 5B, a network chart of country-theme was uploaded by the input form of rectangular data via an application created by our research team [25,34].

Together, these analyses reveal cross-level variation in thematic prominence—DEMENTIA dominates within specific institutions but shares space with broader aging-related themes at the national level, suggesting specialized research clusters driving global impact.

TAAA for Numeric Entities via the Application

Metadata for Publications in JMIR Aging

Dual heatmaps were constructed to examine metadata structure using complementary selection rules: statistical significance (*P* value) and effect magnitude (log10 fold change). Core metaterms were defined as the union of the top 10 up- and downregulated terms under each criterion. These terms were binarized using the mode of term presence > mean across persons and subjected to co-word analysis, followed by FLCA clustering (target_clusters=2).

Resulting term clusters were propagated to publications via TAAA and displayed beneath each heatmap alongside TRUE_LABEL, reflecting a 2-stage publication structure, with contrast themes denoted by social work versus ALZHEIMERS-DISEASE and editorial material versus China.

Although visual correspondence is evident, the modest mapping precision (MP=0.33) indicates residual misalignment between data-driven themes and external labels (Figure 6), suggesting that the thematic transition cannot be strictly partitioned into the periods 2020 - 2022 and 2023 - 2025.

XSL•FO
RenderX

Figure 6. Dual heatmaps for the 66 metaterms in JMIR Aging publications (mapping power [MP]=1.0): (A) heatmap (*P* value–selected) of the top 10 UP + top 10 DOWN metaterms, with increasing *P* values for ALZHEIMERS-DISEASE, Germany, United States, and RISK; (B) heatmap (log10FC-selected) of the top 10 UP + 1op 10 DOWN metaterms, wiith log10FC for China, HongKong, Japan, and RISK; and (C) the probability matrix. TAAA Applied to a Gene Expression Omnibus Data via the Application

Figure 9 demonstrates that applying TAAA to the GEO dataset GSE8401 robustly identifies metastasis-related gene patterns distinguishing MM from primary melanoma. The heatmap (MP: κ=0.90) shows a highly consistent separation of samples, with clear up- and downregulation blocks aligned with clinical status, indicating strong agreement between TAAA-derived themes and true labels.

Paired *t* tests within themes further confirmed the biological relevance: The MM and non-MM were statistically significant between gene testlets (*P*<.001 and *P*=.02).

Figure 9. The selection of significant genes for metastatic melanoma (MM) using differentially expressed genes with mapping power (MP)=0.90 based on a smaller *P* value: (A) heatmap (κ=0.90) and (B) paired *t* tests within True_Label.

(B)

True_Label	n	*F* test	*P* value	eta2	Adjused *P* value
0	31	229.58	<.001	0.88	<.001
1	52	5.88	.02	0.10	.02

Together, these results validate that, under a stringent MP threshold of 0.90, TAAA effectively selects significant differentially expressed genes and yields interpretable, metastasis-specific gene signatures rather than noisy individual genes—doing what a good method should: turning complexity into clarity with statistical poise.

Hypothesis Testing Results

The findings of this study confirmed that that the TAAA can reveal meaningful thematic alignments at the journal, country, and institute levels, supporting deeper insights into scholarly trends and research spots, as shown in Table 3.

XSL•FO

[a]Not applicable.

Table 4 summarizes key conceptual and methodological differences between TAAA and traditional co-word or cluster-based approaches, underscoring TAAA's capacity for article-level theme identification and reproducible bibliometric analysis.

Table . Comparison of Theme Assignment Algorithm for Articles (TAAA) with traditional co-word and theme-assignment methods.

Dimension	Traditional co-word/cluster-based methods	TAAA	Advancement/contribution
Analytical level	Operates at the keyword or cluster level; assigns themes to groups of co-occurring terms	Operates at the article level; assigns a single dominant theme to each article	Enables finer granularity and direct linkage between articles and their thematic focus
Assignment logic	Relies on cluster membership or keyword co-occurrence frequency without article-level aggregation	Uses the statistical mode of clustered keyword assignments within each article to determine its primary theme	Provides a reproducible and deterministic rule for article-level theme labeling
Interpretive output	Generates network maps or clusters without direct theme attribution to individual records	Produces a theme variable for every article, allowing downstream analyses (eg, country, institution, or temporal trends)	Enhances interpretability and enables quantitative comparisons across entities
Reproducibility and transparency	Results vary depending on clustering resolution, software, and visualization parameters.	Fully scripted in R, openly reproducible, with transparent equations and pseudocode (Equation 1)	Improves computational transparency and methodological reproducibility
Scalability and integration	Limited integration with other analytical tools; often visual only	Integrates seamlessly with visualization techniques such as Kano and Sankey diagrams for multidimensional mapping	Supports scalable, automated workflows for journal-, institution-, and country-level analyses

Discussion

Principal Findings

The results indicate that the 3 analytical scenarios identified 9, 7, and 9 core themes from their respective keyword sources, with HEALTH (39.4%), OLDER ADULTS (43.1%), and DEMENTIA (25.3%) emerging as the most prevalent themes. Among these, only DEMENTIA was consistently highlighted across all analyses. The application of dual heatmaps demonstrated the algorithm's capacity for comparative bibliometric mapping in JMIR Aging, with a mapping precision of 0.33 providing quantitative evidence of a 2-stage publication pattern.

These findings support the hypothesis that TAAA effectively assigns a dominant theme to each article using a mode-based approach that aligns with established thematic structures.

- Methodological innovation: Introduces the TAAA, a replicable R-based framework for precise article-level bibliometric mapping
- Multisource validation: Assigns primary themes to 434 JMIR Aging articles using mode-based clustering across 3 distinct keyword sources
- Thematic consistency: Identifies HEALTH, OLDER ADULTS, and DEMENTIA as the dominant research pillars, with dementia showing significant cross-source stability
- Advanced visualization: Uses Kano, Sankey, heatmap, and volcano plots to demonstrate the utility of treating bibliometric metadata with the same rigor as biological "differentially expressed" data

Adding Knowledge to Literature

This study advances bibliometric methodology by introducing the TAAA [17], which systematically assigns dominant themes at the article level using mode-based clustering, improving on

XSL•FO
RenderX

previous techniques [4,5] with R-based implementation [16,17]. Unlike traditional keyword co-occurrence analyses that remain at the cluster level (eg, a study [10] exploring trends and hotspots in research on exercise and Alzheimer's disease), TAAA enables article-level thematic assignment by adding a dedicated theme column to the dataset. This supports more granular analyses of journal focus, research trends, and associations between article entities.

The application and R-based TAAA framework [17,32-34] enhances reproducibility and computational efficiency while enabling seamless integration with visualization tools such as Kano and Sankey diagrams [11,14,15] for clearer thematic mapping with dual heatmaps. Applying TAAA [17,32-34] to JMIR Aging publications demonstrates its practical utility, consistently identifying core themes (eg, DEMENTIA) across multiple keyword sources. Notably, this approach can be applied to other journals to highlight their core themes for readers in future research.

TAAA thus offers a replicable, scalable method for bibliometric studies, supporting country-, institution-, and journal-level analyses that were previously limited by manual theme assignment.

Editorial Application of Abstract-Derived Keywords

In addition to analytical use, the extraction of keywords directly from article abstracts provides a potential editorial application. By comparing abstract-derived keywords with author-supplied keywords and Keywords Plus terms, editors can evaluate the thematic coherence of submitted or published manuscripts. Discrepancies between the automatically derived and author-assigned keywords may indicate whether an article aligns with the journal's primary thematic domains or falls outside its intended scope. Such comparison offers a data-driven mechanism for theme validation, assisting editorial boards with maintaining topical consistency, refining journal aims, and identifying emerging research areas within the publication's portfolio.

Cross-Level Interpretation of the DEMENTIA Theme

The greater prominence of DEMENTIA observed at the institutional level compared with the country level reflects the localized concentration of specialized research centers and collaborative networks focusing on dementia and cognitive aging. Institutions such as the University of Toronto and Harvard Medical School host long-standing dementia research programs that generate high keyword density and thematic coherence within institutional clusters.

At the national level, however, the thematic landscape becomes more diffuse as research activities span multiple subfields of aging and health technology. This pattern suggests that DEMENTIA functions as a core institutional specialization within certain centers of excellence rather than a uniform national research focus, highlighting TAAA's capacity to reveal hierarchical differences in thematic intensity across analytical levels.

Most Cited Article in JMIR Aging

Although Hannah Liane Christie from the Netherlands published the most articles, with 6 publications [24-29] in JMIR Aging, the most highly cited article [46] was authored by Audrey Lebrasseur and colleagues from Canada, with 252 citations. This study with a rapid review synthesizes research on COVID-19's impact on older adults, revealing increased psychological symptoms, ageism, and reduced social interactions. The findings highlight the need for tailored strategies to maintain social ties and address at-risk older adults' specific needs.

Strengths and Implications of This Study

The scalable framework of a reproducible application or R-based TAAA maps co-word clusters to one dominant theme per article using a deterministic mode rule.

Validated mapping via dual heatmaps and MP quantifies alignment with TRUE_LABEL, supporting a stage-like pattern while showing the boundaries are not strictly year-split.

Practical visuals integrating Kano, Sankey/SankeyMATIC, volcano, network, and receiver under the operating curve outputs provide interpretable, actionable bibliometric insights.

Potential Extensions to Other Domains

Beyond bibliometrics, TAAA can be adapted to clinical and other data-intensive settings where subject-level labels must be inferred from multi-item structures rather than directly observed. In clinical research, bifactor or multidomain measures are often reduced to composite scores and evaluated using logistic regression analysis to predict the patient status. TAAA offers a complementary structure-based alternative: It converts item-level patterns into a discrete subject style by assigning the dominant cluster (mode) across a subject's activated features, yielding an interpretable 2-style classification suitable for downstream prediction and stratification.

For example, TAAA can be applied to medication records to derive a patient's dominant treatment pattern (eg, drug class or regimen cluster), supporting analyses of treatment pathways and utilization without requiring explicit brand-company linkage. More broadly, the same framework can harmonize heterogeneous administrative datasets by inferring prevailing categories from fragmented records. These extensions can be implemented using the web-based application [32] provided in this study

Limitations and Suggestions

First, the analysis relied primarily on Keywords Plus from the WoSCC, which may omit domain-specific concepts or vary in granularity compared with controlled vocabularies such as MeSH used in PubMed. Future studies could integrate multiple bibliographic databases and standardized ontologies to improve thematic coverage and semantic precision.

Second, the mode-based theme assignment in TAAA simplifies articles to a single dominant theme, which may underrepresent genuinely multitopic publications. Extensions incorporating weighted frequencies or probabilistic theme assignments could

XSL•FO
RenderX

better capture thematic complexity and are available for further development, as outlined in our GitHub repository.

Third, although abstract- and title-based keyword extraction was automated using R [16] and the application [32], certain preprocessing steps (eg, keyword normalization and cluster interpretation) may still require expert oversight. Greater automation of preprocessing and quality control would further enhance scalability and reproducibility.

Fourth, interrater validation uses two study authors, acknowledges potential expectation bias, and describes blinding procedures more explicitly. Future studies could consider adding more experts to assign themes to articles in comparison withd TAAA.

Finally, validation was conducted using a single journal (JMIR Aging), limiting generalizability. Future work will apply TAAA across multiple journals and domains to more fully assess its robustness, scalability, and cross-disciplinary applicability.

Conclusions

This study introduces the application or R-based TAAA as a systematic approach for assigning dominant themes at the article level. Application to JMIR Aging publications demonstrates that TAAA enhances interpretability and reproducibility while enabling nuanced bibliometric analyses across journals, countries, and institutions. By bridging cluster-level co-word structures with article-level thematic representation, TAAA provides a transparent framework for large-scale thematic mapping. Future work may extend this approach by integrating semantic embeddings or applying the framework to multidisciplinary datasets.

Abstract

Background: As the global population ages, the increasing number of individuals with chronic conditions places a growing burden on family caregivers. Behavioral interventions delivered via application-based platforms, including those on mobile phones, tablets, or the web, have emerged as a powerful tool for enhancing caregiver support.

Objective: This study aims to identify and describe application-based interventions for family caregivers of older adults with chronic conditions, focusing on their designs, features, and impact on caregiver outcomes.

Methods: This review is reported according to the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines. A search of publications from 2007 through December 20, 2022, was conducted across PsycINFO (EBSCO), MEDLINE ALL (Ovid), Embase (Ovid), Web of Science Core Collection (A&HCI, BKCI-SSH, BKCI-S, CCR-EXPANDED, ESCI, IC, CPCI-SSH, CPCI-S, SCI-EXPANDED, and SSCI; Clarivate), ACM Guide to Computing Literature (ACM Digital Library), and Engineering Village (Elsevier) using relevant keywords.

Results: The database search identified 9482 studies, resulting in 290 full-text papers being assessed, and a final 49 studies were included. Forty-four unique applications were identified, demonstrating different designs and features. These studies primarily examined the impact of applications on caregiver well-being, burden, and mental health. While the majority of interventions were perceived as beneficial, several design and research limitations were noted.

Conclusions: While many interventions demonstrate positive effects on caregiver outcomes, there are significant gaps in research design, evaluation, and reporting. Future studies should prioritize greater integration of self-care practices, clarity of intervention components, rigorous adherence to behavioral intervention frameworks, and greater inclusivity in participant samples.

KEYWORDS

aging; mHealth; web application; mobile app; behavioral interventions; mobile health

Introduction

With the aging global population, the increasing number of individuals with chronic health conditions is placing a growing demand on family caregivers for assistance [1,2]. Family caregivers, typically family members or close friends, provide essential care to older adults with chronic conditions, managing activities of daily living and instrumental activities of daily living, including medication management, transportation, and meal preparation [3]. However, caregiver burden often results in negative outcomes such as stress, worse mental health, and reduced well-being [4-6]. Caregivers also face higher risks of social isolation and loneliness, issues that were further exacerbated during the COVID-19 pandemic [7-9]. Despite their central role, caregivers frequently neglect their own health and well-being, underscoring the need for interventions that support both the caregiver and care recipient [10-12].

In this context, behavioral application-based interventions delivered via mobile phones, tablets, or the web have emerged as a powerful tool for enhancing caregiver support. Applications allow caregivers to access support, resources, and health management tools, regardless of the intensity or demands of their caregiving role [13-17]. This flexibility is particularly valuable for caregivers who struggle to seek support due to time

XSL•FO
RenderX

constraints or geographical isolation [18,19]. Tablet, internet, and smartphone use has become prevalent across all age groups, including older adults, many of whom rely on smartphones as their primary or only digital device [20]. The widespread adoption of smartphones and use of web and mobile applications offer unique opportunities to address caregivers' needs in ways that traditional, nonvirtual services cannot [14,21,22]. Behavioral application-based interventions for caregivers could also broaden opportunities to improve psychosocial outcomes, such as reducing stress, improving social connectedness, and promoting well-being [14,23-25].

Despite growing interest in application-based interventions, evidence on their effectiveness and usability remains limited. Many caregivers are older adults themselves, and the usability of these applications is critical, especially for those experiencing age-related changes that affect their interaction with technology [26-28]. As the population of older adults grows, the need for usable, accessible applications to support caregivers in managing their own well-being while caring for others becomes increasingly urgent.

Previous systematic reviews have explored the use of digital health technologies for caregivers, with findings indicating that technology positively enhances self-efficacy, strain, and mastery [24,29,30]. However, many of these reviews focused broadly on mobile interventions [30,31] or specific chronic conditions [14,30], such as dementia or cancer, without thoroughly examining the features (eg, education, stress management, and peer support) that make mobile apps particularly useful or effective for caregivers. Furthermore, past reviews often evaluated existing apps available commercially in app stores (eg, Google Play Store and iOS App Store) rather than in the context of a behavioral intervention study without specificity regarding how these apps influence caregivers' well-being [30,31]. The importance of investigating mechanisms is underscored by the National Institutes of Health (NIH) [32].

This scoping review aims to address these gaps by focusing on application-based interventions for family caregivers of older adults with chronic conditions [33]. It will build upon existing reviews that have explored the broader role of technology in caregiving but have not fully examined application-based behavioral interventions. By summarizing current research on application designs, features, and their impact on caregiver outcomes, the results of this review will inform future application development and research, ultimately aiming to improve the well-being of family caregivers in an aging society.

The primary objective of this scoping review is to identify and describe application-based interventions (web, mobile, and tablet) designed to support family caregivers of older adults with chronic conditions. Specifically, this review will examine the designs (eg, user-centered approach and theory-based) and features (eg, education, stress management, and peer support) of application-based interventions (mobile, web, or tablet) for family caregivers of older adults, as well as their impact on key caregiver outcomes (eg, well-being, social support, and self-efficacy).

Methods

Design

This scoping review is reported using the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines and is guided by the Joanna Briggs Institute methodology [34], which uses the population, concept, and context framework to define the scope of the review, eligibility criteria, and search strategy. The population is family caregivers of individuals with the following chronic diseases identified by the Centers for Disease Control and Prevention (CDC) to be prevalent among older adults in the United States [33]: heart disease, cancer, chronic lung disease, stroke, Alzheimer disease or related dementias (ADRD; including mild cognitive impairment), diabetes, and chronic kidney disease. The concept focuses on application-based interventions, including mobile, web, and tablet applications designed to support caregivers. The context encompasses any care environment or setting in which caregiving takes place, without limitations on geographic region or health care system.

A medical librarian (AH) searched on December 20, 2022, to identify studies focusing on application-based interventions for family caregivers of older adults. The search was conducted in the following databases: PsycINFO (EBSCO), MEDLINE ALL (Ovid), Embase (Ovid), Web of Science Core Collection (Editions=A&HCI, BKCI-SSH, BKCI-S, CCR-EXPANDED, ESCI, IC, CPCI-SSH, CPCI-S, SCI-EXPANDED, SSCI) (Clarivate), ACM Guide to Computing Literature (ACM Digital Library), and Engineering Village (Elsevier). Publication dates ranged from 2007, the year the first iPhone was released, to the date the search was conducted (2022). The search strategy consisted of selecting appropriate keywords such as "family caregiver" and "mhealth," combined with a "double-NOT" strategy to exclude records that were pediatric-only. Search term examples include Medical Subject Headings such as "mobile applications" and "caregivers," and keywords such as "Android," "iPhone," "care partner," and "carer." The full search strategy used for all databases is included in Multimedia Appendix 1. The current review protocol was registered and published on the Open Science Framework [35].

Selection Criteria

Included papers consisted of (1) published and peer-reviewed intervention studies, feasibility studies, pilot studies, randomized clinical trials (RCTs), or clinical trials, with English full texts available; (2) application-based interventions (mobile, tablet, or web) for family caregivers of older adults with one or more of the chronic diseases listed above; (3) applications designed and developed for family caregivers; and (4) papers reporting outcomes (eg, usability and well-being).

Papers were excluded based on the following criteria: (1) the paper is a review, perspective, opinion, conference abstract, commentary, book, book chapter, workshop, presentation, protocol paper, thesis, dissertation, or paper without outcome measures; (2) text-messaging or telephone-based interventions; (3) papers that focused on non-application–based interventions (eg, patient portals, virtual reality [VR], smart home, and wearables); (4) interventions targeting populations other than

XSL•FO
RenderX

caregivers (eg, care recipients and health care professionals); (5) application interventions that used general web platforms accessible by the general population (eg, social media and Zoom [Zoom Video Communications]); (6) studies that used an application prototype (eg, mock-ups) rather than a functional application; (7) interventions consisting solely of internet forums or discussion boards; and (8) studies that did not specify care recipients.

Selection of Studies

All retrieved studies were screened using the Covidence (Veritas Health Innovation Ltd) systematic review software developed by Veritas Health Innovation Ltd. First, duplicate titles and abstracts were identified and removed automatically using Covidence (AH). Then, four researchers (XYL, FF, ESC, and SC) applied the selection criteria and independently screened titles and abstracts. Full texts were then independently screened by 5 researchers (XYL, FF, RZ, KH, and SC) to ensure they met the eligibility criteria. Each title, abstract, and full text was reviewed by 2 researchers, and disagreements were resolved by a third researcher and through consensus meetings. Regular team meetings were conducted throughout the screening process to clarify questions or uncertainties.

Data Extraction and Analysis

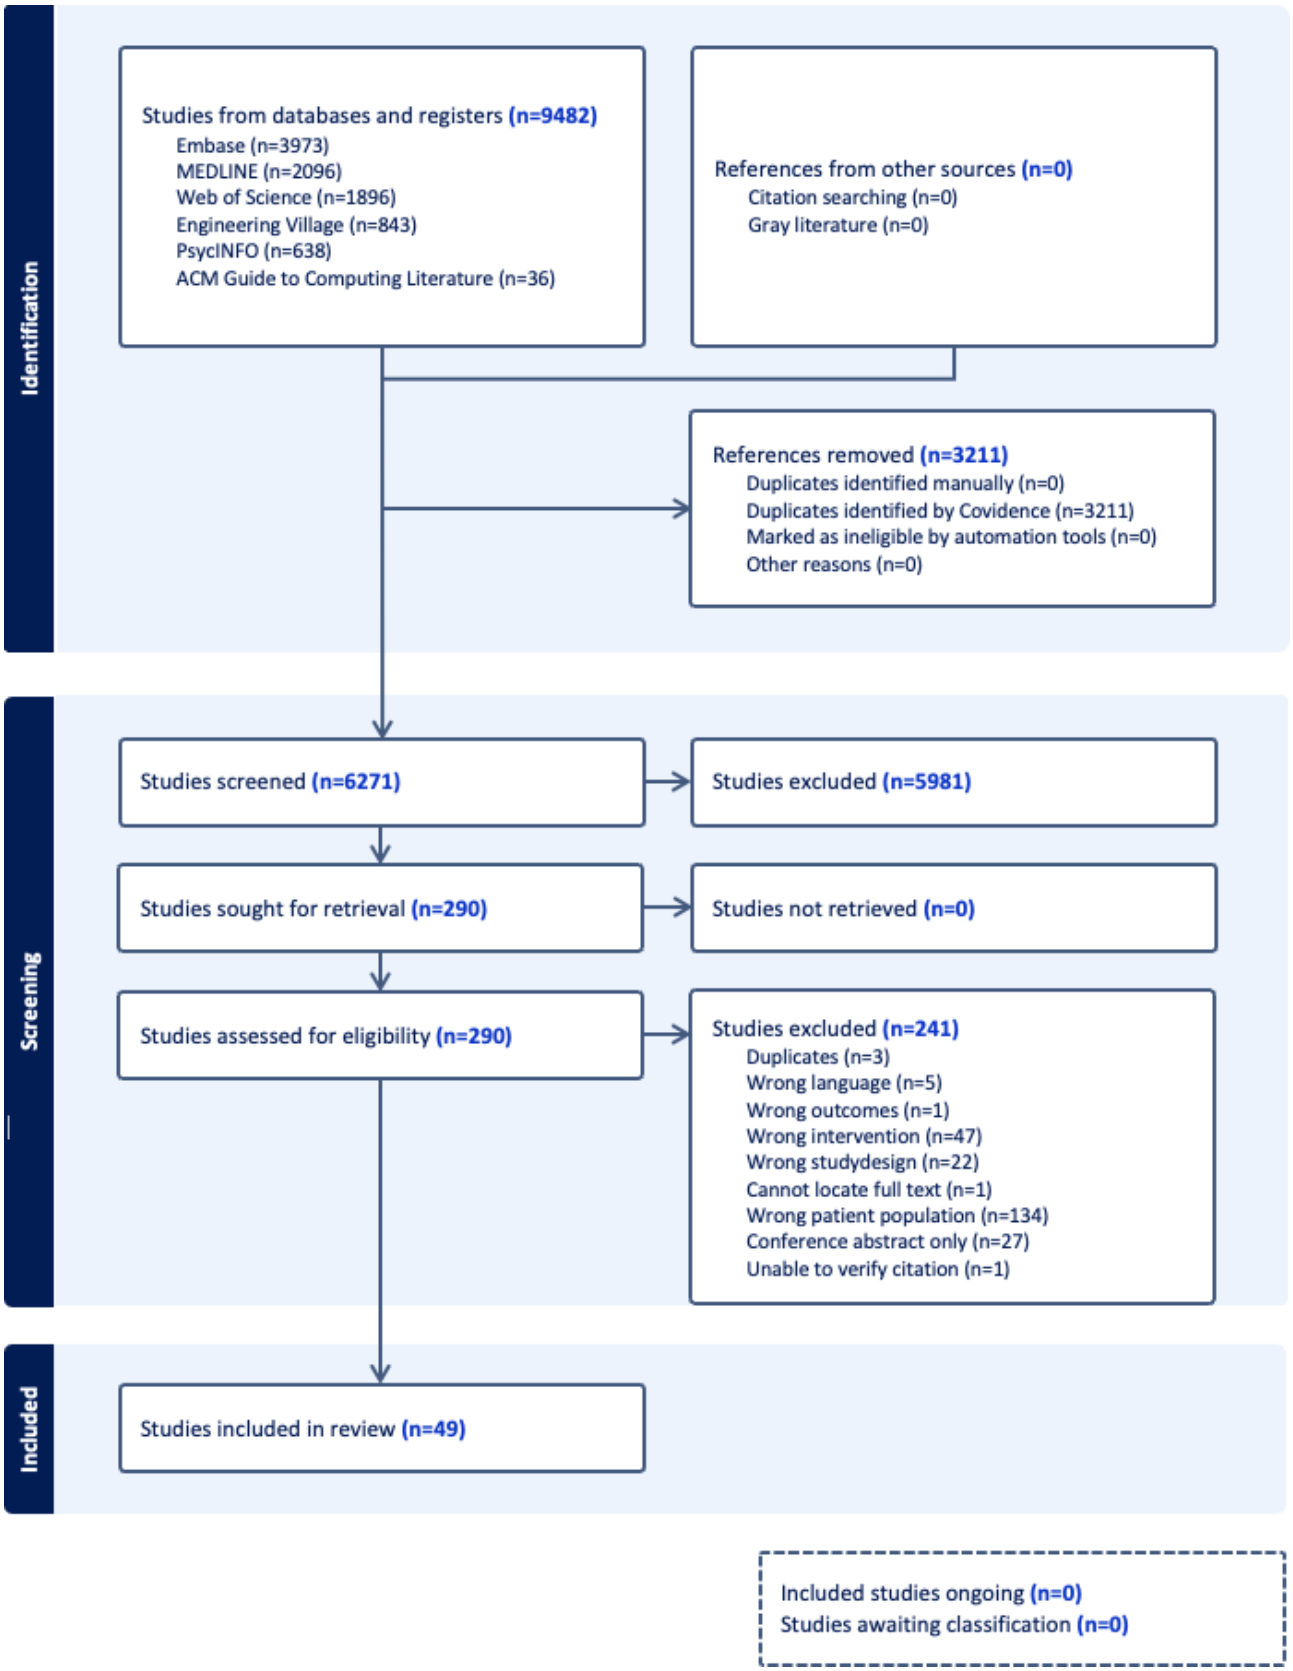
Upon completion of full-text screening, data from included papers were extracted into a predesigned Microsoft Excel spreadsheet. The extracted fields included (1) study information (title, author, DOI, year of publication, and country of origin); (2) research questions and aims; (3) study characteristics (qualitative, quantitative, or mixed methods); (4) participant characteristics (number, condition, inclusion and exclusion criteria, relationship to the care recipient, and demographic characteristics of the caregiver and the care recipient); (5) recruitment strategy (where, how, attrition, and target recruitment goal); (6) intervention (type, duration, participants per condition, setting, treatment fidelity, and frequency of nonapplication components); (7) training (how and who trained participants); (8) application characteristics (type, features, application use frequency, recommended and actual application use, and satisfaction); (9) primary and secondary outcome measures; and (10) quantitative and qualitative results.

Five authors (XYL, FF, ESC, KH, and RZ) independently extracted data from included papers using predefined and standardized templates. The authors extracted and discussed 3 studies together before beginning the data extraction process to ensure proper and standardized extraction. Regular meetings were conducted throughout the extraction process to clarify questions or uncertainties. Moreover, 10% of papers were randomly selected for duplicate extraction to ensure reliability.

After extraction was completed, descriptive quantitative analyses were conducted to summarize the frequency and distribution of application interventions across various caregiver populations, study designs, and outcomes. Thematic analyses were also conducted, in which an initial inductive approach was used to identify themes that were validated and revisited until finalized. All discrepancies were discussed among the authors. The full review process is illustrated in the flowchart in Multimedia Appendix 2.

Ethical Considerations

Ethical approval was not required for this study as it is a scoping review of existing literature and does not involve human participants, animals, or the collection of original primary data.



Results

Characteristics

Figure 1 shows the full PRISMA flow diagram outlining the study selection process. The database search yielded 9482 studies, in which 3211 duplicates were identified and removed, resulting in 6271 studies for screening. A total of 5981 studies were excluded during title and abstract screening, resulting in 290 full-text papers that were assessed for eligibility. Of those, 241 papers were excluded, which resulted in 49 studies included in this review (Figure 1). Studies were published between 2009 and 2022; 55% (27/49) studies were conducted in North America (United States and Canada), 39% (19/49) in Europe (Netherlands, Germany, Italy, Sweden, France, United Kingdom, Austria, Denmark, Poland, and Spain), 4% (2/49) in Asia (China and South Korea), and 2% (1/49) in Australia. The majority of studies (73%, 36/49) targeted family caregivers of people with ADRD, with 12% (6/49) and 8% (4/49) targeting cancer and stroke, respectively. A few studies (6%, 3/49) included family caregivers of older adults with various chronic conditions rather than a single condition (Table 1).

Study and year	Country of origin	Study characteristics	Study design	Study duration	Study setting	Sample size	Met target goal	Attrition rate	Caregiving for what disease	CR[a] demographics	Relationship with CR	CG[b] demographic
Blom et al [38] (2015)	Netherlands	Quantitative	RCT	5 - 6 months	Home	Intervention (n=151) and control (n=100)	NR	Seventy caregivers (28.6%) dropped out before the end of the intervention period: 59 in the experimental group (51 in the first 3 months) and 11 in the comparison group (all between 3 and 6 months).	Dementia	Most persons with dementia were female (60.4%), lived independently (82.9%), and had a mean age of 75.9 (SD 9.4; range 39–93) years. A formal dementia diagnosis was reported for 86.5% of CRs, with AD being the most common diagnosis (74.5%). Slightly more than half (52.4%) received the diagnosis within the previous 2 years. Mean IQ-CODE score was 58.9 (SD 5.75).	Almost all caregivers were spouses (58.4%) or children (in-law; 39.6%).	Predominantly female (69.4%) and living with the CR in the same household (60.4%). Mean age of CG: 61.2 (SD 12.37 years; range 26-87). Most CGs had children (78.8%; mean =2.54, (SD=1.10). All but 2 held Dutch nationality (99.2%). Education level varied from primary school to university, with 47.3% holding a bachelor's degree or higher.

Bodschwinna et al [39] (2022)	Germany	Quantitative	Feasibility	Within 2 months (average intervention duration was 7 weeks, and on average 9.79 days between 2 completed main sessions).	Home	Experimental (PartnerCARE; n=30): guided individually psycho-oncological online intervention delivered on the online platform minddistrict and control (n=30)	Since this was a feasibility study, a formal sample size calculation was not performed. A sample size of 60 participants (30 per group) was the predefined target, based on recommendations for sample sizes in feasibility studies.	The study dropout rate was low (T1: 17% and T2: 29%), and the high intervention completion rate (73.3%) indicates that once participants begin the intervention, they are likely to finish it. This treatment adherence is comparable to other online intervention studies with caregivers, but substantially higher than average intervention adherence in online intervention studies with patients.	Cancer		Supporting partner of patient with cancer. Relationship status: in partnership, 7 (11.9%), and married, 52 (88.1%). Mean relationship duration 18.35 (SD 11.32) years.

Final studies included 21 quantitative, 5 qualitative, and 23 mixed methods studies with various designs: 25 RCTs, 15 feasibility studies, 5 pre-post intervention studies, and 4 usability studies. Intervention durations ranged from 1 session lasting 15 - 30 minutes to 2 years. The majority of interventions were home-based; 5 were delivered virtually, 2 in clinical settings (eg, medical center), and 1 was not reported. A few studies involved interventionists, often clinical psychologists, nurses, or social workers, who received specialized training to deliver the interventions along with an app. About half of all studies (n=27) reported that participants were trained on how to use the app by research assistants or staff via in-person sessions, phone calls, or online methods. Only 20% (10/49) of studies reported fidelity measures, including regular check-ins and adherence assessments to ensure protocol compliance.

Study Participants

Common eligibility criteria across studies included primary caregivers who were adults (typically aged >18 years) caring for a person with dementia or another chronic condition (eg, cancer). Most studies required caregivers to have access to the internet and a device (computer, smartphone, or tablet; n=30). Language proficiency was also a common criterion, with caregivers needing to read and write in the language of the study (n=22), such as English, German, or Chinese. Many studies excluded caregivers with mental health conditions or cognitive impairment (n=11). Recruitment methods varied, with caregivers recruited through health care settings such as memory clinics and hospitals (n=20), community organizations such as Alzheimer's Association and support groups (n=31), online platforms including websites and social media (n=17), and print media such as flyers and newspaper ads (n=18).

Demographic characteristics typically included middle-aged to older adults with a mean age of around 60 years. Caregivers were predominantly female (70% - 80%) and had varied educational backgrounds, with many having at least some college education. Employment status was mixed, with some caregivers employed full-time, part-time, or retired. Care recipients were generally older adults, aged >70 years, with a slight majority being female. The relationship between caregivers and care recipients was primarily spousal or adult children caring for their parents. Sample sizes varied widely, ranging from small pilot studies with about 10 - 30 participants (n=8) to larger trials with >100 participants (n=9). Many studies did not report their target recruitment goals (n=36) or attrition rate (n=22). Among those that reported these outcomes, most met their target recruitment (n=8), whereas some did not (n=5). Attrition rates also varied, with some studies reporting high retention (80% - 90%; n=6) and others reporting significant dropout rates (20% - 30%; n=8) (Table 1).

Application Characteristics

The dataset includes 44 unique applications designed to support caregivers of individuals with various chronic conditions. These applications are categorized as web-based (n=30), mobile (n=12), and tablet (n=2) platforms. The design of these applications often followed adaptations of in-person or previously developed intervention (n=9), a user-centered approach (n=9), and theory-based design (n=3). Other design approaches involve iterative development with user feedback and collaboration with health care professionals (n=3).

The primary functions of these applications include education (n=39), social support (n=19), and self-management tools (n=21). Common components across applications included informational resources (n=39), interactive services such as forums and chat (n=22), and personalized feedback or coaching from researchers or interventionists (eg, coaches and health care professionals; n=10).

Many applications provided educational content for caregivers, including a range of informational resources (n=37) to support chronic condition management and caregiving strategies. Structured modules further enhanced this learning experience by covering caregiving-related topics such as symptom management and communication skills. Practical tools were another important aspect of these applications, with features such as calendars and schedules helping caregivers organize tasks, appointments, and daily activities. Additionally, some applications included resource libraries designed for easy access to papers, videos, and external links for caregiving support.

Interactive services (n=22) were another key feature of these applications, allowing caregivers to connect with others through forums, chat rooms, and social networks. These platforms provided a space for caregivers to share experiences, offer support, and build community. In addition to forums, many applications include private messaging features for more personal communication with other caregivers or health care professionals. Customization and personalization options, including reminder notifications or email alerts, made the applications more responsive to individual caregiver needs.

Support tools in these applications (n=19) often incorporated interventionist-guided approaches to provide step-by-step assistance based on cognitive-behavioral principles or problem-solving techniques. Caregivers also received regular personalized feedback and coaching from interventionists to help monitor progress and adjust strategies as needed. Tracking and monitoring tools were also common (n=21), with applications offering progress tracking features such as daily assessments (eg, ecological momentary assessments) to regularly track mood, stress, and other key metrics.

Only about half of all studies (n=27) reported that participants were trained on how to use the app by research personnel (eg, in-person: n=10, phone calls: n=3, or online: n=6). Participants were typically trained through initial orientation sessions. App use was typically measured through log data (n=24) or self-reported usage (n=5), but many studies did not report app use (n=24). Actual app use during the intervention varied, with

XSL•FO
RenderX

5 studies showing consistent engagement and 11 studies reporting drop-offs in usage over time. Data on user satisfaction were reported in about half of all studies (n=24), with 16 studies reporting moderate to high satisfaction among caregivers.

Intervention Effects on Study Outcomes

Interventions with a comparison group (n=25) followed a waitlist model or received standard care. Control group participants typically had access to basic resources, such as printed materials or standard educational content, but did not receive the more comprehensive features or digital tools provided to the treatment group.

The primary and secondary outcomes across all studies predominantly focused on caregiver well-being and health (eg, depression and stress; n=33), burden (n=16), self-efficacy and competence (n=16), feasibility and acceptability (n=32), social support (n=9), quality of life (n=4), care recipient's symptoms (n=2), coping strategies (n=4), and intervention feedback (n=21).

Overall, the intervention effects on outcomes were generally positive. Many studies reported improvements in primary and secondary outcomes (eg, caregiver well-being, reduced caregiver burden, and enhanced mental health) across time or condition (n=39). For example, caregivers experienced lower levels of depression and anxiety and increased self-efficacy [41]. Usability and acceptability were commonly assessed (n=25), with caregivers often discussing ease of use and satisfaction. Qualitative results showed that a prevalent reason for app usage was the emotional impact of caregiving (n=8), where caregivers shared their experiences of stress, guilt, and isolation. Support and communication also emerged as significant themes regarding why and what caregivers need in terms of support, highlighting the importance of social support networks and effective communication with health care providers. Additional themes included practical caregiving challenges (n=8) and the need for personalized tools (n=2). However, 11 studies reported declining engagement over time, indicating the need for ongoing support and engagement strategies. Moreover, 10 studies showed null effects for outcomes across time or condition, which warrants further discussion (eg, possibility of app content or design failing to meet user needs, inadequate user training, or low engagement) [43,45,57,64,67-69,77,78,84].

Discussion

Principal Findings

This review synthesized 49 studies evaluating application-based interventions for family caregivers of chronically ill older adults (eg, ADRD, cancer, and stroke). These studies primarily examined the impact of applications on outcomes, including caregiver well-being, burden, and mental health. While most interventions were perceived as beneficial for enhancing well-being and social support, several design and research limitations were noted. In the following "Discussion" section, we discuss how these applications support caregivers and identify design and evaluation challenges to guide future research.

Application-Based Intervention Support for Caregivers

The majority of included studies aimed to provide caregivers with education, emotional support, and self-management tools. ADRD caregivers, in particular, benefited from applications that offered resources for managing caregiving tasks and emotional well-being. Caregivers appreciated interventions that enhanced their access to information and social support, especially during stressful caregiving periods. However, some caregivers reported dissatisfaction with applications that were too complex or poorly aligned with their needs, highlighting the importance of user-centered design. In line with broader caregiving research, these findings underscore how psychosocial factors—such as caregivers' perceived social support, resilience, and sense of coherence—shape their ability to benefit from digital tools and influence the extent to which applications can meaningfully support their emotional well-being [22,60,78,84].

For cancer and stroke caregivers, the feedback was similar. Applications focused on information delivery and psychosocial support were generally well received, but challenges arose when the app content was too general or failed to provide disease-specific advice. Across all caregiver groups, there was a demand for more personalized, adaptable interventions that could cater to the evolving needs of caregivers and care recipients as their conditions progressed. These needs are also influenced by well-established psychosocial influences on caregiver stress and coping, including role overload, work-related strain, and the extent to which caregivers have access to emotional and informational resources [39,43,58,76,77,80].

While many interventions aimed to reduce negative emotional states, they did not adequately address broader aspects of well-being, such as promoting caregivers' own self-care practices. Additionally, many interventions focused on reducing stress and burden without a parallel effort to enhance positive emotions or resilience, which could result in caregivers feeling only marginally supported. This gap is notable given evidence that resilience, emotional regulation, and prosocial coping behaviors are key determinants of caregiver health and may moderate the impact of app interventions [24,85]. There is a need for more holistic intervention approaches, promoting not just stress relief but also strategies to enhance self-care, emotional fulfillment, and resilience [25]. This highlights the need for application-based interventions to shift from solely focusing on minimizing negative outcomes to actively promoting well-being. Integrating established psychosocial constructs—and drawing on validated measures such as the Zarit Burden Interview, resilience scales, and sense-of-coherence instruments—may help future app designs more effectively target mechanisms that drive meaningful change for caregivers [5,6,36,38,46,86].

Design and Evaluation Considerations

A significant issue identified in many studies was the lack of clarity regarding which components of multifaceted interventions were responsible for specific outcomes. For instance, some applications aimed to increase both information access and social support, but studies often failed to specify which intervention component influenced outcomes such as

XSL•FO
RenderX

well-being or burden. This lack of specificity makes it challenging to identify the mechanisms through which the app intervention impacts outcomes, a key step in developing targeted behavioral interventions [32].

In some cases, negative or null findings were reported without clear explanations. Exploring potential reasons for these outcomes is crucial, including the possibility of app content or design failing to meet user needs, inadequate user training, or low engagement [29]. Additionally, negative or null findings were frequently underreported, making it challenging to understand why some interventions failed to produce the desired effects, which could be a result of publication bias. Unintended consequences, such as caregivers feeling overwhelmed by app content or difficulty integrating app use into their daily routines, were rarely explored but warrant attention in future studies. Future research should also explore potential unintended consequences or reasons for lack of effects, such as inadequate app design, caregiver disengagement, or issues with the intervention's delivery.

Another issue relates to studies that claimed to use mixed methods designs. While both qualitative and quantitative data were collected, these data were not integrated or triangulated to provide a comprehensive understanding of the intervention's effects, which may limit the study's implications.

Research Considerations

Many studies in this review lacked consistent reporting on key aspects of application-based interventions, such as usage, participant training procedures, and fidelity measures. For instance, of 49 studies, only half (n=27) reported whether participants received any training on using the applications. This omission is particularly problematic given that technology proficiency can vary widely among caregivers, especially older adults. Past research on technology training and proficiency highlights the importance of offering caregivers adequate guidance on digital tools [87], yet many studies failed to measure or report this. Studies that did not measure participants' baseline technology skills may have missed critical factors influencing application engagement and outcomes. Additionally, the lack of data on app satisfaction and usage makes it difficult to assess how well the applications were received and whether caregivers used them as intended. This lack of information limits the ability to assess intervention fidelity (only 20% of studies reported any fidelity measures) and their real-world applicability.

Moreover, adapting in-person behavioral interventions to app formats was common but not always well documented. When delivered via digital platforms, behavioral interventions must adhere to principles such as those outlined in the NIH Stage Model for Behavioral Intervention Development [32], which emphasizes the importance of specifying mechanisms, conducting feasibility studies, and ensuring intervention fidelity. Similarly, recruitment goals and attrition rates were often missing, particularly in feasibility studies and RCTs, which should adhere to standards such as CONSORT (Consolidated Standards of Reporting Trials) for transparent reporting [88]. However, many studies in this review did not clearly align their design with this model, resulting in unclear stages of intervention development and evaluation, where some studies attempted to combine intervention development and RCT phases without clearly defining how these stages were managed.

Limitations of Current Studies

Several limitations were identified. First, sample sizes were small and geographically limited, reducing the generalizability of findings. The studies predominantly involved caregivers from North America and Europe, with minimal representation from Asia and other regions. This limits the cultural generalizability of the findings, as caregiving practices, expectations of family responsibility, and help-seeking behaviors vary across cultural contexts. Additionally, the feasibility and effectiveness of application-based interventions may differ in settings where access to smartphones, internet connectivity, digital literacy, or technological infrastructure is limited [8]. Additionally, marginalized groups and long-distance caregivers were underrepresented, given limited participant diversity in race, ethnicity, and socioeconomic status. Further, many studies did not account for disease stage or care recipient etiologies, which could have provided more nuanced insights into the effectiveness of these applications for different caregiver populations.

Research design weaknesses were also prevalent. Many studies lacked robust control groups, relied on small sample sizes, or used short follow-up periods, limiting the strength and stability of the reported findings. In several studies, the intervention development process was not clearly described (eg, how the app was developed or adapted to digital formats), and reporting was inconsistent regarding levels of rigor, evaluation procedures, and adherence monitoring. These methodological limitations make it difficult to draw firm conclusions about the effectiveness or sustainability of application-based interventions for caregivers. Moreover, few studies examined how or why the interventions had any effects. Mediation or moderation analyses were rarely conducted, making it challenging to identify which components—such as educational content, stress-management tools, peer support features, or mood and symptom tracking—were most influential in improving caregiver outcomes. As a result, the mechanisms of change underlying application-based interventions remain unclear. To advance understanding of how app interventions influence caregiver outcomes, future studies should incorporate mediation and moderation analyses to clarify the mechanisms of change. Such work can help isolate whether specific features drive improvements in caregiver well-being. Finally, many interventions were prototypes or research-only platforms that were not publicly accessible, highlighting challenges related to scalability, implementation, and long-term integration into real-world caregiving contexts.

Limitations of the Current Review

This scoping review has several limitations. First, as a common limitation of scoping reviews [89], we did not include a critical appraisal of the methodological quality or risk of bias in the included studies, which may limit the validity of our findings. Additionally, the database search was conducted in December 2022; thus, any relevant studies published after this date were not included in the screening process. ChatGPT was released in November 2022 and significantly accelerated the development

XSL•FO
RenderX

of artificial intelligence (AI)-based applications. With the increasing interest in AI, future reviews can consider examining the application of AI to promote caregivers' health and well-being. Finally, we did not assess cost-effectiveness or broader health care system implications, which are important considerations for future research.

Conclusions

This review highlights the growing potential of application-based interventions to support family caregivers of older adults, particularly those caring for individuals with ADRD, cancer, and stroke. While many interventions are well-received and demonstrate positive effects on caregiver well-being, there are significant gaps in research design, evaluation, and reporting. Future studies should prioritize greater integration of self-care practices, clarity in intervention components, rigorous adherence to behavioral intervention frameworks, including the NIH Stage Model, and more diverse participant samples. Improved reporting on app usage, satisfaction, and recruitment outcomes is essential for advancing the field and ensuring these digital tools meet the complex needs of caregivers. Moreover, as technology evolves, ongoing research is needed to explore how emerging innovations can further enhance well-being. Addressing these gaps will be crucial for developing effective, scalable, and accessible digital interventions for caregivers across diverse populations.

Acknowledgments

Generative artificial intelligence tools were not used at any stage in the preparation of this manuscript.

Funding

XYL acknowledges support from a National Institute on Aging–funded T32 Training Program in Behavioral Geriatrics (NIA T32 AG049666). FF acknowledges support from the National Institute on Aging of the National Institutes of Health under award numbers K99AG073509 and R00AG073509. ESC acknowledges support from the National Institute on Aging under award number K01AG081540. The funding sources had no involvement other than providing financial support.

Abstract

Background: The risk of falls escalates with advancing age, a consequence of the concomitant degeneration of multiple physiological systems, altered sensory processing capabilities, and reduced postural control. Multisensory integration (MSI) training has been demonstrated to enhance the brain's processing of multisensory information. However, existing studies show considerable variability in intervention duration and training modalities, limiting comparability across studies and contributing to inconsistent findings.

Objective: This study aimed to systematically evaluate the effectiveness of MSI training on postural stability and fall risk in healthy older adults and provide an evidence base for clinical practice.

Methods: Databases including PubMed, Embase, and Cochrane Library were searched by PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines. The methodological quality of the included randomized controlled trials was assessed using the Cochrane risk of bias tool, and publication bias was evaluated through funnel plots. Meta-analyses using R packages quantified effects via standardized mean differences (SMDs) and 95% CIs, with fixed or random effects models selected based on heterogeneity (I^2). Subgroup analyses explored age, intervention duration, and type.

Results: A total of 14 randomized controlled trials were included in the meta-analysis. Results showed that MSI training significantly reduced center of pressure displacement in the anterior-to-posterior displacement (SMD −1.64, 95% CI −2.78 to −0.49, P<.001) and center of pressure displacement in the medio-to-lateral displacement (SMD −1.37, 95% CI −2.68 to −0.07, P<.001). In terms of postural stability, MSI training significantly improved Berg Balance Scale scores (SMD 3.42, 95% CI 2.41 to 4.44, P=.006). In terms of fall risk, MSI training significantly reduced the time to complete the timed up and go test, and intervention type significantly moderated this effect (SMD −1.43, 95% CI −2.36 to −0.50, P<.001). Additionally, MSI training reduced the risk of falls (SMD −1.27, 95% CI −2.03 to −0.52, P<.001).

Conclusions: In conclusion, MSI training is an effective intervention for enhancing static and dynamic postural control and reducing fall risk in healthy older adults, suggesting a beneficial effect on postural stability and fall-related outcomes.

KEYWORDS

multisensory integration training; older adults; postural stability; fall risk; meta-analysis

Introduction

According to the World Health Organization, the risk of falls among older adults increases significantly with age [1], and falls impose substantial societal burdens, both directly and indirectly, including increased demands on family caregiving and health care resources [2]. These events are driven by a combination of age-related physiological decline and underlying pathological factors. It is worth noting that aging is not a single-system degeneration but a complex process of cognitive, musculoskeletal, sensory processing, and other multisystems synergistic decline [3]. On the one hand, sensory-motor system function decreases with aging; on the other hand, aging also leads to changes in the way of processing sensory information in the central nervous system [4-6]. The cognitive demands required to maintain balance during challenging postural tasks

XSL•FO
RenderX

increase in older adults [7-9]. In addition, decreased brain volume and structural changes in the brain, such as gray matter atrophy and decreased white matter integrity, affect the transmission and integration of sensory information in older adults [10,11]. At the same time, changes in neurotransmitter levels interfere with sensory information transmission and processing [12,13]. In particular, functional and connectivity declines in core multisensory brain regions, such as parietal and temporal cortices, reduce multisensory integration in older adults, which in turn affects postural stability and fall risk [8,14,15]. Deficits in postural control are the most important risk factor for falls in older adults, directly weakening the physiological basis for maintaining postural stability and significantly increasing fall risk. Understanding the effects of multisensory integration (MSI) training on postural control is essential to address fall risk and improve quality of life in older adults.

The maintenance of postural stability relies on the dynamic coordination of multisensory integration, in which the brain integrates and assigns weights to visual, vestibular, and somatosensory information in real time [16]. It is important to note that the decline in multisensory integration is not irreversible [17,18], and MSI training is a method to optimize the brain's ability to process multisensory information through targeted interventions. This type of training usually combines visual, vestibular, and somatosensory stimuli to design a variety of tasks [19-21]. Through repeated practice, the nervous system can readjust the weights of different sensory inputs and strengthen the efficiency of integrating sensory information, thus improving postural control and balance stability [22,23]. Studies have shown that MSI training can be beneficial in improving balance function in older adults and can restore sensory integration deficits in patients with neurological impairments [22,23]. Allison et al [24] found that MSI training significantly improved postural stability and fall risk in older adults; however, Dowd et al [25] did not find that MSI training could improve postural stability and fall risk in older adults. Existing studies have found that the length and type of interventions in training programs vary greatly, resulting in limited comparability of results, and their methodological differences may affect the consistency of validation of intervention effects [26-28].

Drawing on previous literature [29-33], when analyzing the effects of interventions targeting memory impairment or balance in older adults, researchers commonly use comparisons based on age stratification, intervention type classification, and intervention duration staging. Combined with regression analysis to examine the influence of these variables on effect sizes, this methodological framework provides a reliable reference for interpreting the heterogeneity observed in this study. Therefore, this study aimed to integrate the existing evidence to quantify the effects of MSI training on postural stability and fall risk in older adults through systematic evaluation and meta-analysis, and to reveal the sources of heterogeneity through subgroup analyses of age, duration of intervention, and intervention type, so as to provide evidence-based medical evidence for the application of MSI training in older adults.

Methods

This systematic review and meta-analysis was conducted in accordance with the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) checklist and registered on PROSPERO on April 1, 2025 (CRD420251023158).

Search Strategy

Two authors (CG and YW) individually conducted a literature retrieval in 5 electronic databases—PubMed, Embase, Cochrane Library, WoS, and Scopus—from the inception of each database up to April 5, 2025, without language restriction. Medical Subject Headings (MeSH) terms or keywords were used during the literature search. The search terms were ("sensory reweight*" OR "sensory recalibrat*" OR "multisensory integrat*" OR "sensory train*") AND ("elderly*" OR "older adult*") AND ("balance" OR "falls" OR "fall risk"), and the detailed search strategy is shown in Multimedia Appendix 1. After the search was completed, all search results were imported into EndNote reference management software (Clarivate) for deduplication, and the reference lists of full-text literature were manually searched to identify studies that were not retrieved through the database search.

Research Inclusion and Exclusion Criteria

The study eligibility criteria are shown in Textbox 1.

XSL•FO
RenderX

Textbox 1. Study eligibility criteria.

Inclusion criteria

- Participants: healthy older adults aged ≥60 years, with no musculoskeletal dysfunction within the past 6 months, no confirmed peripheral somatosensory or vestibular deficits, visual acuity sufficient for daily activities, and a Montreal Cognitive Assessment score ≥26 or a Mini-Mental State Examination score ≥24
- Interventions: the intervention was multisensory integration (MSI) training, defined as any protocol that simultaneously manipulates or stimulates ≥2 sensory modalities (visual, vestibular, and somatosensory) to provoke central sensory integration through conflict or reweighting
- Control group: presence of a healthy control group to establish baseline changes and accurately identify the effects of MSI training
- Outcome measures: the primary outcome was center of pressure (COP) displacement (including anterior-to-posterior and medio-to-lateral displacements). Secondary outcomes included (1) postural stability measures under different test conditions (single-leg standing, 2-legged tandem standing, and 2-legged standing), specifically COP displacement and Berg Balance Scale scores; and (2) fall risk prediction indicators, including direct risk measures (fall risk, times/year) and functional measures (timed up and go test), and total intervention duration (weeks)

Exclusion criteria

- Nonrandomized controlled trials
- Insufficient data for analysis
- Duplicate publications
- Non–peer-reviewed literature
- Serious methodological flaws, defined as a lack of adequate randomization or allocation concealment, intergroup cross-over contamination, use of invalid or noncomparable outcome measures, or dropout rates exceeding 20% without intention-to-treat analysis

The summary of outcome measures is shown in Table 1.

Table . Summary of outcome indicators.

Specific tests		Assessment of indicators
Postural stability test		
	Single-leg standing test	AP[a] displacement[b], ML[c] displacement[d], and BBS[e] score
	2-legged tandem standing test	AP displacement, ML displacement, and BBS score
	2-legged standing test	AP displacement, ML displacement, and BBS score
Fall risk prediction		
	Functional test metrics	TUG[f] time
	Risk prediction indicators	Fall risk (time/year)

[a]AP: anterior-to-posterior.

[b]Center of pressure displacement in the anterior-to-posterior.

[c]ML: medio-to-lateral.

[d]Center of pressure displacement in the medio-to-lateral.

[e]BBS: Berg Balance Scale.

[f]TUG: timed up and go.

Two reviewers independently screened the titles, abstracts, and full texts of the identified studies. Any disagreements were resolved through consultation with a third adjudicator, who made the final determination based on the predefined criteria. Relevant data, including study design, population characteristics, sample size, intervention details, and outcome measures, were extracted into a standardized Microsoft Excel 2024 (Microsoft Corporation) form.

Quality and Risk of Bias Assessment

Quality assessment was performed using the Cochrane risk-of-bias tool (Cochrane), which consists of seven domains: (1) random sequence generation, (2) allocation concealment, (3) blinding of experimental staff, (4) blinding of results staff, (5) data integrity, (6) selective reporting of results, and (7) other sources of bias. For each source of bias, studies were classified as low, high, or unclear (if reporting is insufficient to assess a specific domain) risk. Two independent reviewers (CG and YW) assessed the results. In case of disagreement, differences

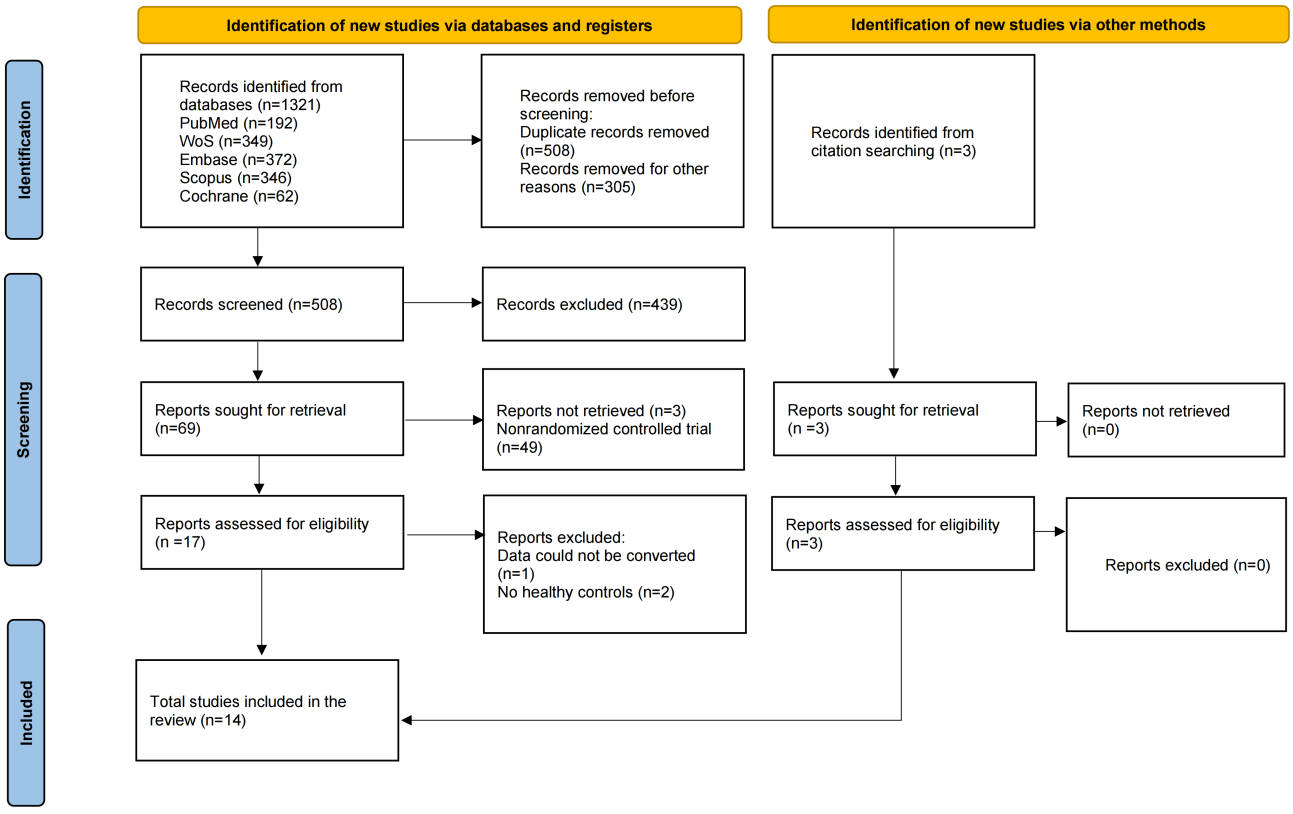
XSL•FO
RenderX

of opinion were discussed and resolved with a third researcher (MX).

Data Extraction

Literature screening and data extraction were carried out using an independent double-blind method. Two researchers, CG and YW, first screened the literature according to the titles and abstracts of the literature, excluded obviously irrelevant studies, then read the full text of the potentially relevant literature, and determined the final selection of the literature according to the inclusion and exclusion criteria. In case of disputes during the screening process, a third researcher (MX) was involved in the discussion and decided. Data extracted included the first author, year of publication, sample size, age of subjects, intervention plan and specific protocol, outcome measures, and major findings. If the original text did not contain the target data or the information was ambiguous, an email was sent to contact the corresponding author for assistance or confirmation.

Statistical Analysis



Meta-analyses were performed using the meta and metafor packages in the statistical software R (version 4.2.0; R Foundation for Statistical Computing). The effect size for continuous outcomes was expressed as the standardized mean difference (SMD), specifically Hedges g to correct for small-sample bias. Effect magnitudes were interpreted using Cohen conventions (0.2=small, 0.5=medium, and ≥0.8=large). This study adopted "95% CI not including zero" as the criterion for determining statistically significant differences between groups. The heterogeneity between studies was assessed by the I^2 statistic. When $I^2 \leq 50\%$, the heterogeneity between studies was considered low, and meta-analysis was conducted using the fixed-effects model; when $I^2 > 50\%$, the heterogeneity between studies was considered high, and meta-analysis was conducted using the random-effects model. Age stratification was based on the age distribution of the study population, dividing participants into 60 to 70 years and ≥70 years groups [34]. Intervention duration was categorized according to the median study period and the stabilization phase of multisensory training effects [35]. Intervention types were classified based on the core modalities (dynamic, static, or combined dynamic-static) used in the included studies, combined with clinical classification standards for balance training. Additionally, regression analysis was conducted to explore key findings of this study. Meta-regression models were fitted within a random-effects framework, and the significance of regression coefficients for each variable was tested to determine whether statistical differences existed in effect sizes between different intervention types. Sensitivity analyses were conducted by excluding the included studies one by one to assess the effect of individual studies on the overall results and to judge the reliability of the results. Funnel plots were used to assess publication bias, and the results were interpreted with caution if publication bias existed, and further unpublished studies were searched or statistically corrected if necessary.

Results

Study Selection and Characteristics

A total of 1321 records were obtained through systematic search of multiple databases. After deleting duplicates, screening titles and abstracts, and reading the full text, 14 studies were finally included. The specific screening process is shown in Figure 1.

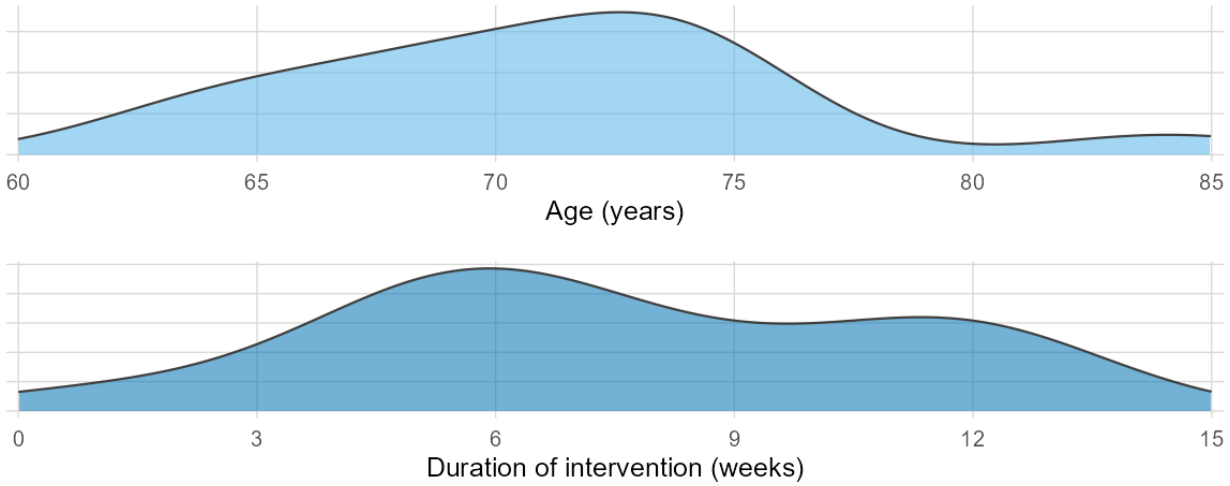


Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flow diagram of the study selection process.

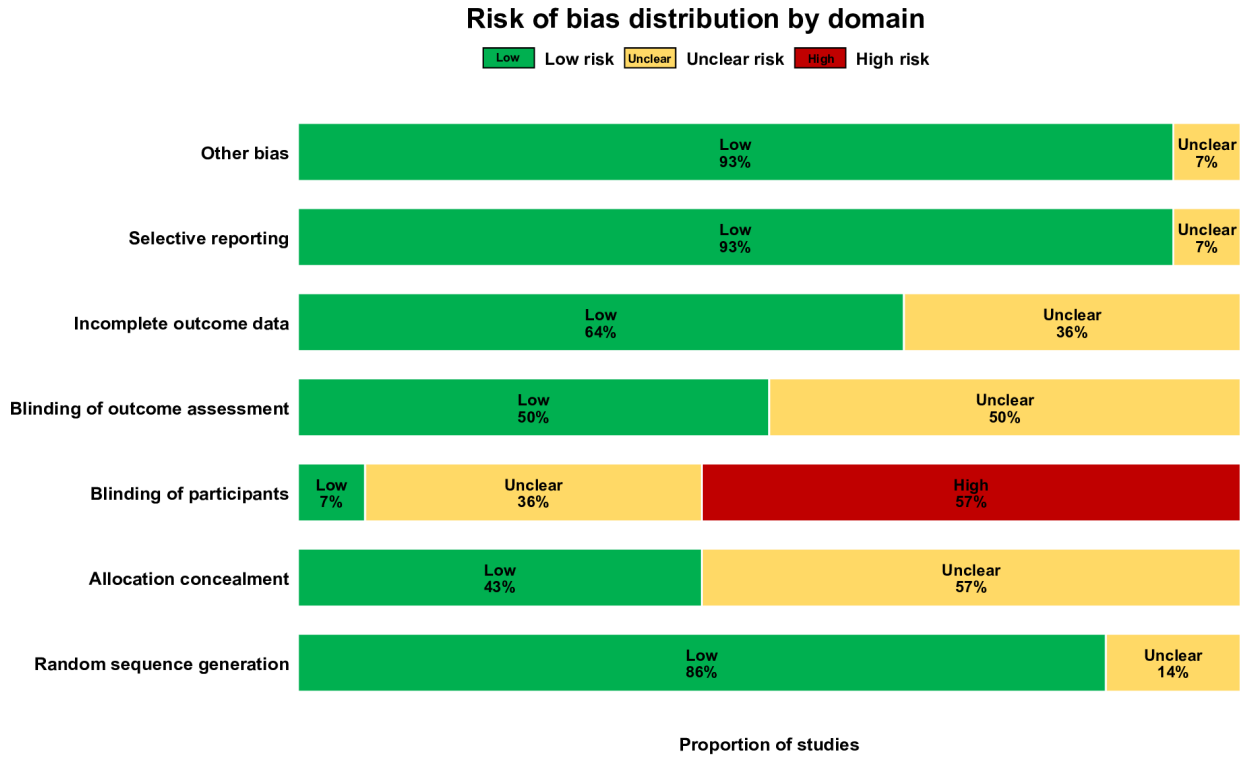
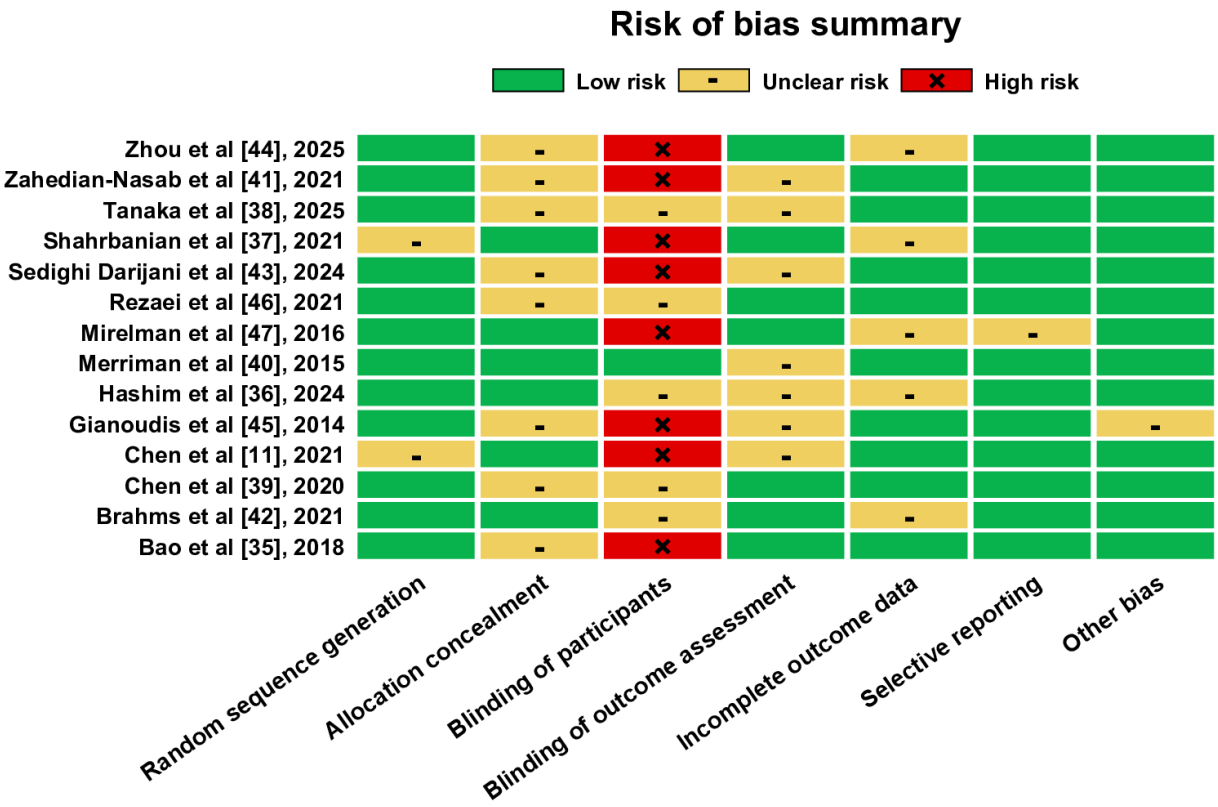
XSL•FO
RenderX



Included studies were published from 2010 to 2025, with a total sample size of 1321 cases, and the type of study was randomized controlled trial. The outcome metrics covered anterior-to-posterior (AP) displacement (5 items) [11,35-38], medio-to-lateral (ML) displacement (4 items) [11,35,36,38], BBS score (3 items) [39-41], TUG (7 items) [35,39,41-45], fall risk (4 items) [37,45-47], and the basic characteristics of each study are shown in Multimedia Appendix 1. Among the included studies, the age of the experimental group was mainly concentrated in 2 intervals, 60 to 70 years and >70 years, and the intervention time was mainly distributed in the period of <6 weeks and >6 weeks. The types of interventions were mainly dynamic balance training, static balance training, and combined dynamic and static balance training, and the distribution is shown in Figure 2.

Figure 2. Distribution maps of age and intervention duration.



Of the 14 included studies, 12 [35,36,38-47] described specific methods of random sequence generation, 6 [11,36,37,40,42,47] described allocation concealment, and 7 [35,37,39,42,44,46,47] were single-blind studies. However, 9 studies [11,35,38-41,43,45,46] reported detachment without specifying the reason, as shown in Figures 3 and 4.

Figure 3. Distribution of risk of bias across assessment domains.

XSL•FO
RenderX

Figure 4. Results of the risk of bias assessment of the included studies.

Main Results

MSI training significantly improved AP displacement (SMD −1.64, 95% CI −2.78 to −0.49; I^2=83%, P<.001), and ML displacement showed a significant reduction (SMD −1.37, 95% CI −2.68 to −0.07; I^2=83%, P<.001). In subgroup analyses, age and intervention duration showed no significant moderating effects on AP or ML displacement. In contrast, the type of intervention significantly moderates AP displacement (P=.009) but not ML displacement. Additionally, we conducted regression analyses using study-level data points to validate these findings and to illustrate the observed distribution of effects across studies. Sensitivity analysis by excluding studies one by one revealed that the pooled effect size of AP displacement fluctuated between −3.41 and −1.45 and that of ML displacement fluctuated between −3.83 and −0.4. All effect sizes after exclusion iterations remained statistically significant (95% CIs did not include 0), indicating that the main results were robust, as shown in Figure 5, Figure 6, Multimedia Appendix 1, and Table 2.

Secondary Results

Effect of MSI Training on Postural Stability in Older Adults

There was low heterogeneity in the studies of BBS scores (SMD 3.42, 95% CI 2.41 to 4.44; I^2=0%, P=.006), suggesting that the MSI training significantly improved BBS scores of the older adults and had reliable effects on the comprehensive quantitative static and dynamic balance enhancement, with a high degree of consistency among different studies. The results of the sensitivity analyses were not stable, and the funnel plot did not show obvious symmetry, suggesting that the results of the studies were influenced by individual studies, as shown in Multimedia Appendix 1 and Table 2.

Effect of MSI Training on Fall Risk in Older Adults

High heterogeneity was present in the studies of time to TUG completion (SMD −1.43, 95% CI −2.36 to −0.50; I^2=89%, P<.001). Subgroup analysis by intervention type was statistically significant (P<.001), and sensitivity analysis results were stable. The funnel plot analysis showed good symmetry, suggesting that the results were relatively reliable. Fall risk–related studies had extremely high heterogeneity (SMD −1.27, 95% CI −2.03 to −0.52; I^2=99%, P<.001). Subgroup analyses by intervention type was significant (P=.001), whereas age and intervention duration were not significant and the results of sensitivity analyses were stable, but the funnel plot showed asymmetry, as shown in Multimedia Appendix 1 and Table 2.

Discussion

This systematic review integrated data from 14 randomized controlled trials and demonstrated that MSI training significantly improved postural stability and reduced fall risk in older adults. Specifically, MSI training led to reductions in AP and ML displacement. However, high heterogeneity was observed in certain outcomes, which may be attributed to methodological variations, participant diversity, and differences in intervention protocols.

Effect of MSI Training on Postural Stability

Although MSI training significantly improved both AP and ML displacements, the high heterogeneity limits the generalizability of these findings. In terms of the intervention protocols, the training methods used in different studies varied greatly. Bao et al [35] used vibro-tactile sensory enhancement interventions, whereas Chen et al [11] used stroboscopic training in balance training; however, meta-regression and subgroup analyses did not identify significant moderating effects of age, intervention duration, or training type on these outcomes. For AP displacement, intervention type showed a significant moderating effect, whereas age and intervention duration did not. For ML displacement, no significant moderating effects were observed, suggesting that other moderating factors (eg, baseline balance ability or cognitive status) may be at play [13,22]. Future studies should standardize intervention protocols to better elucidate the mechanisms by which different training modalities influence balance performance in older adults.

XSL•FO
RenderX

Notably, BBS scores showed consistent improvement with low heterogeneity, indicating that MSI training effectively enhances overall balance control. This aligns with the concept that MSI training promotes central sensory recalibration and optimizes sensorimotor integration. This was attributed to the enhancement of the integration efficiency of the central nervous system by training, which optimized the distribution of sensory weights and thus improved postural control strategies. In a study by Eikema et al [48], it was found that older adults had a more pronounced decline in central sensory integration and a longer effective adaptive world than younger adults when faced with a challenging task. This finding provides an important reference for the development of stratified and individualized interventions in clinical practice based on baseline sensory function and age characteristics of older adults.

Effect of MSI Training on Fall Risk

There is a moderate heterogeneity in the study of the time of completion of the TUG test, and the results of the analysis of the subgroup of the intervention type are significant, which suggests that there is a significant difference in the effects of the different types of interventions on the ability of the older adults to rise and walk, which is clinically important for assessing the effect of training on functional mobility improvement. The results of the subgroup analyses were significant, indicating that the effects of different intervention types on the ability to get up and walk differed significantly, which is clinically important for evaluating the effects of training on the functional mobility of older adults. In addition, the overall heterogeneity of the studies on fall risk was extremely high, and most of the studies had small sample sizes, which resulted in insufficient statistical validity and limited the reliability and extrapolation of the results.

Mechanism of Action of MSI Training

With advancing age, balance and postural control become increasingly vision dependent, as neurodegenerative processes impair vestibular and somatosensory function. Additionally, concomitant neuronal loss and pathway damage further hinder afferent signaling [8,49,50]. MSI training is designed to mitigate these age-related deficits by jointly targeting peripheral sensory function, central integrative efficiency, and neuromuscular coordination [4,51-53]. At the peripheral level, structured visual exercises, such as object recognition under varied illumination and complex backgrounds, have been reported to improve visual acuity and the perception of shape, displacement, and motion [51,52]. Graded vestibular stimuli, including slow head rotations on stable surfaces and gentle tilting or rotation using dedicated apparatus, enhance responsiveness to head and trunk movements [54,55], whereas somatosensory tasks requiring precise limb positioning and force regulation strengthen proprioceptive feedback and movement accuracy [4,53]. These peripheral adaptations are accompanied by central reweighting of multimodal inputs: exposure to diverse sensory environments fosters more efficient integration of visual, vestibular, and somatosensory information [16,51], thereby accelerating postural adjustments and improving stability during dynamic tasks such as walking in simulated complex settings [56-58].

Concurrently, MSI training refines neuromuscular coordination by tightening the coupling between neural commands and muscular execution, manifested as smoother signal transmission, more accurate and rapid muscle responses, and reduced activation latency [56,59-61]. Bugnariu et al [62] reported that older adults exhibited 40 to 60 ms longer electromyographic latencies in the distal-to-proximal activation sequence compared to younger adults. Notably, a single 1-hour MSI session reduced ankle muscle latency by approximately 20 ms, suggesting improved neuromuscular timing [63]. Beyond cortical contributions, MSI training engages the cerebellum, basal ganglia, and other motor control centers: cerebellar metabolic activity increases during training, facilitating consolidation of motor skills, while the basal ganglia modulate initiation and termination of motor programs to enhance movement smoothness and precision [64]. Consistent with this systems-level account, Wang et al [17] reported less adaptive brain connectivity in older vs younger adults and demonstrated that MSI training can augment functional connectivity and neural adaptability, supporting structural and functional central adaptation and establishing a robust neuromodulator network for motor improvement [65]. Taken together, by strengthening sensory inputs, optimizing central integration, and improving neuromuscular coordination, MSI training constitutes a comprehensive and effective approach to enhancing postural stability in older adults, thereby reducing fall risk and improving quality of life [37].

Clinical Significance and Future Prospects of the Study

This study shows that MSI training is important for improving postural stability and reducing fall risk in older adults and provides a theoretical basis and practical guidance for clinical rehabilitation and geriatric care. To enhance the reliability and practicality of the results, future studies should expand the sample size and conduct multicenter studies to include older adults with different health conditions to verify the generalizability of the effect and continue to follow-up and evaluate various indicators to investigate the long-term effect, the best training mode, and the applicability to older adults with different health conditions, and the mechanism of action can be analyzed by combining neuroimaging and muscle electrophysiology techniques. We will continue to follow-up and evaluate various indicators to investigate the long-term effect, the optimal mode, and the applicability to different health conditions of older adults, to provide more accurate and effective interventions.

Comparison With Other Studies

Previous studies [22,66] have confirmed that although single balance or strength training can improve static postural stability, the lack of multisensory conflict simulation makes it difficult to transfer motor adaptations to dynamic multitasking scenarios and fails to effectively reduce the risk of falls. This issue was broken through in 2 systematic review studies [27,28] that used qualitative research to propose that MSI training significantly improves postural control, a finding that is highly compatible with the results of this study.

This study realizes dual innovations at the methodological and outcome levels. In terms of methodology, we broke through the

XSL•FO
RenderX

limitations of previous qualitative studies and adopted a combination of qualitative and quantitative analysis to construct a more rigorous research system by integrating multidimensional data. In contrast to the study by Sápi et al [67], which concluded that MSI training could not improve the COP displacement in the AP direction in older adults, this study, by incorporating the dynamic balance task and revamping the assessment scenarios, confirms that MSI training has a significant improvement in the COP displacement in the AP and ML directions, which is more in line with the real functional needs of older adults.

The innovative value of this study lies in the fact that it is the first quantitative study to systematically demonstrate the effectiveness of MSI training on the optimization of omnidirectional postural control and the reduction of fall risk, which not only provides a quantitative theoretical basis for the prevention of falls in older adults but also has a guiding significance for clinical practice, suggesting that individual functional shortcomings need to be based on individual design of differentiated MSI training programs integrating static and dynamic tasks, so as to accurately improve the motor function and quality of life of older adults. This finding not only provides a quantitative theoretical basis for fall prevention but also guides clinical practice.

Study Quality and Limitations

Several limitations should be considered when interpreting our findings. First, evidence on long-term effectiveness remains limited, as only 3 trials provided follow-up data, and their high heterogeneity precluded meta-analysis. Second, significant methodological and clinical heterogeneity, including variations in randomization, participant characteristics, intervention protocols, and outcome measures, may affect comparability across studies, though we addressed this through random-effects models and subgroup analyses. Third, most trials had small sample sizes, which could overestimate effect sizes and reduce statistical power; sensitivity analyses were performed to ensure robustness. Finally, potential publication bias, as indicated by funnel plot asymmetry, cannot be ruled out despite comprehensive search efforts. Future studies should adopt standardized interventions and assessments, include longer follow-up periods, and explore moderating effects of individual characteristics to strengthen the evidence base for clinical practice.

Conclusion

MSI training can improve postural stability and reduce fall risk in older adults, but we need to conduct long-term follow-up of multicenter and large-sample studies to identify the best intervention mode. Meanwhile, standardization of measurement tools, optimization of intervention protocols, attention to individual differences, and evaluation of long-term effects will help to improve the comparability of studies and provide more accurate guidance for clinical practice.

Abstract

Background: Older adults in rural or underserved settings face persistent access barriers. Digital and remote health interventions may mitigate these gaps.

Objective: The aim of this study is to assess technologies, effectiveness, and implementation challenges of digital or remote health interventions for adults ≥60 years old in rural or underserved contexts.

Methods: A systematic search was conducted in 4 electronic databases, such as PubMed, Scopus, Web of Science, and Embase (inception: April 2025), under dual screening by 2 reviewers. The tool Cochrane Risk of Bias 2.0 was used to assess the risk of bias for randomized trials, and Risk Of Bias In Non-randomized Studies–of Interventions (ROBINS-I) was used for nonrandomized trials. For observational studies, we used the National Institutes of Health quality assessment tool, and a narrative synthesis was performed.

Results: Fourteen studies met the inclusion criteria (randomized and nonrandomized designs; median follow-up ~12 mo). Ten of 14 (71%) reported significant improvements in at least 1 clinical end point (eg, hemoglobin A_{1c}, blood pressure, and weight), 11 of 14 (79%) improved behavioral or psychosocial outcomes, and 5 of 9 (56%) reduced hospitalizations or acute episodes. Risk-of-bias concerns most frequently related to missing data and selective reporting. Digital literacy and broadband access were the most consistent barriers, while multicomponent, nurse-supported models achieved higher adherence. Equity-related dimensions (place, gender, and socioeconomic status) were variably reported, with limited attention to language, cultural tailoring, or social capital. No study included a formal cost-effectiveness analysis.

Conclusions: Digital and remote health interventions can benefit older adults in rural and underserved settings by improving selected clinical and behavioral outcomes. However, heterogeneity, small sample sizes, and the absence of economic evaluations temper certainty. Importantly, gaps in equity reporting and persistent barriers to digital inclusion highlight the need for future trials to integrate PROGRESS-Plus (place of residence, race/ethnicity, occupation, gender, religion, education, socioeconomic status, social capital, plus other context-specific determinants of health equity) dimensions, embed cost-effectiveness assessments, and design interventions that are both sustainable and accessible to the most underserved populations.

KEYWORDS

older adults; rural health; digital health; telemedicine; remote care; underserved populations; health disparities

Introduction

Background

The aging of the global population poses unprecedented challenges for health systems, particularly in rural and underserved communities where access to care remains limited [1]. By 2050, it is projected that 1 in 6 people worldwide will be over the age of 65 years, with a significant proportion residing in rural regions [2]. These populations often face geographic, economic, and infrastructural barriers that impede access to timely and adequate health services [3]. Older adults in these regions experience a disproportionate burden of chronic diseases, such as diabetes, heart failure, and hypertension, as well as age-related cognitive decline and social isolation [4].

Digital and remote health interventions, such as telemedicine, mobile health (mHealth) applications, and remote patient monitoring, offer promising avenues to overcome these barriers [5]. These tools can facilitate timely communication with health care providers, enable continuous monitoring of vital signs, and support behavioral interventions aimed at chronic disease management [6]. The integration of such technologies into clinical practice has accelerated, particularly in response to the COVID-19 pandemic, which highlighted the need for resilient and accessible health systems [7].

In this context, telehealth platforms can strengthen provider-to-provider communication, facilitate referral pathways, and support coordination of care across rural and underserved settings.

Health Care Access Inequities in Rural Aging Populations

Access to health care in rural areas is often hindered by long travel distances, reduced mobility, and limited availability of specialists [8]. These issues are compounded for older adults, who may rely on caregivers or public transportation and experience difficulties navigating health care systems [9]. Studies such as the Informatics for Diabetes Education and Telemedicine (IDEATel) trial have demonstrated that telemedicine interventions can improve glycemic control and cardiovascular risk factors in low-income, underserved older adults [10]. Importantly, this study found that individuals from lower socioeconomic strata benefited as much or more than those from higher income groups, suggesting that tailored interventions can reduce health disparities [11].

Similarly, the Telemedical Interventional Monitoring in Heart Failure 2 (TIM-HF2) trial highlighted the effectiveness of remote patient monitoring in managing heart failure. Adherence to remote monitoring protocols was notably higher in rural residents compared to urban dwellers, especially when interventions were accompanied by patient education and regular contact with health care providers [12]. This suggests that rural patients may value the increased contact and support afforded by digital solutions, particularly when traditional in-person care is less accessible [13-15].

Barriers to Adoption and Usability Concerns

Despite the potential of digital health tools, several challenges persist. Digital literacy remains a significant barrier among older adults, many of whom have limited experience with smartphones, tablets, or web-based applications [16]. Moreover, infrastructural deficits—such as unreliable broadband access—disproportionately affect rural areas and can hinder the consistent use of telehealth platforms [17].

Usability and accessibility of devices also play a critical role in determining intervention success. The adoption of user-friendly interfaces, simplified monitoring equipment, and culturally tailored content can enhance engagement among older users. DiNapoli et al [18] emphasize the importance of addressing age-related cognitive and sensory impairments when designing digital interventions, noting that failure to do so can limit the reach and effectiveness of these programs.

Potential for Social and Behavioral Benefits

Beyond clinical outcomes, digital health interventions may also address broader social determinants of health. Perri et al [19] reported that remote interventions helped reduce social isolation and increased self-efficacy in older adults, fostering a sense of autonomy and connectedness. These psychological and behavioral dimensions are particularly important for rural seniors, who often report higher levels of loneliness and depression compared to their urban counterparts [20].

Rationale for a Systematic Review

Given the rapid expansion of digital health technologies and the pressing needs of aging rural populations, there is an urgent need to synthesize the existing literature to identify effective strategies, common pitfalls, and research gaps. Although some studies have reported promising results, the evidence remains fragmented, and many interventions lack rigorous evaluation. Understanding which approaches work best—and under what conditions—can inform policy decisions and guide the development of inclusive, scalable solutions.

Objective

This review aimed to synthesize evidence on digital and remote health interventions for adults aged ≥60 years in rural or otherwise underserved settings, describing (1) technologies and care models, (2) clinical, behavioral, and service-use outcomes, and (3) implementation barriers/facilitators through an equity lens. The primary analytic perspective was patient-centered, focusing on clinical, behavioral, and usability outcomes among older adults; provider-facing facilitators and system-level factors were considered as complementary.

Methods

Study Design

This systematic review adhered to the PRISMA 2020 [21] (Preferred Reporting Items for Systematic Reviews and Meta-Analyses; CRD420251066174) guidelines and was framed using the PROPS [22] (Population, Remote Health Interventions, Outcomes, Procedures, and Study Design) approach. The PROPS framework provided a structured basis for defining the scope of the review as follows:

- Population: adults aged 60 years or older residing in rural or underserved communities
- Intervention: digital or remote health interventions, including telemedicine, mHealth, wearable devices, and remote monitoring tools
- Outcomes: clinical health parameters (eg, blood pressure and glucose levels), behavioral and psychosocial measures, implementation outcomes (feasibility, adherence, and satisfaction), and digital literacy-related outcomes
- Study design: randomized controlled trials, quasi-experimental studies, prospective and retrospective cohort studies, cross-sectional studies, and mixed methods designs

Eligibility Criteria

We included peer-reviewed papers published in all idioms until April 2025 that reported on digital or remote health interventions targeting adults aged ≥60 years living in rural or underserved settings. Eligible study designs included randomized controlled trials, quasi-experimental studies, cohort studies, cross-sectional studies, and mixed methods evaluations. Interventions had to utilize telemedicine, mHealth, remote monitoring, or other digital health modalities. Studies exclusively focused on urban populations, institutionalized participants, or individuals under the age of 60 years were excluded.

Search Strategy

A comprehensive search was conducted in 4 electronic databases: PubMed, Scopus, Web of Science, and Embase. The search strategy combined Medical Subject Headings and free-text terms related to “older adults,” “digital health,” “telemedicine,” “remote monitoring,” “mobile health,” “rural populations,” and “underserved populations.” Search strings were customized for each database. The last search was conducted in April 2025. Reference lists of included papers and relevant reviews were searched manually for additional eligible studies (Multimedia Appendix 1).

Study Selection

Two independent reviewers (EF and ACG) screened the titles and abstracts using the Rayyan QCRI (Qatar Computing Research Institute) [23] platform. Full texts were retrieved for papers that deemed potentially eligible. Disagreements were resolved through discussion or consultation with a third reviewer (LD). The selection process followed the PRISMA 2020 guidelines [20] (Checklist 1), and a flowchart depicting the number of studies screened, included, and excluded was prepared.

Data Extraction

A standardized extraction form was developed and piloted. Extracted data included author(s), year of publication, country, study design, sample size, mean participant age, intervention characteristics, technology used, health domain targeted, key outcomes, usability measures, digital literacy considerations, implementation strategies, and barriers and facilitators. Intervention types and target health outcomes were categorized following the framework derived from the included studies. One reviewer (ACG) conducted data extraction, and a second reviewer (EF) independently verified the entries.

Risk-of-Bias Assessment

Risk of bias was assessed using the Cochrane RoB 2.0 [24] tool for randomized trials and the ROBINS-I [25] tool for nonrandomized studies. For observational studies, we used the NIH quality assessment tool. Two reviewers conducted the assessments independently and discussed discrepancies to reach consensus. Risk-of-bias results were tabulated, and sensitivity analyses were performed when feasible.

Data Synthesis

Given the heterogeneity of intervention types, outcome measures, and study designs, a narrative synthesis was performed. Studies were grouped according to health conditions targeted (eg, cardiovascular and mental health), types of digital intervention (eg, teleconsultation, mobile app, and remote monitoring), and geographic regions. Themes from qualitative studies were synthesized using thematic analysis and included in cross-cutting narratives. Subgroup comparisons (eg, by rural vs semirural, by intervention duration, or technology type) were conducted where sufficient data were available.

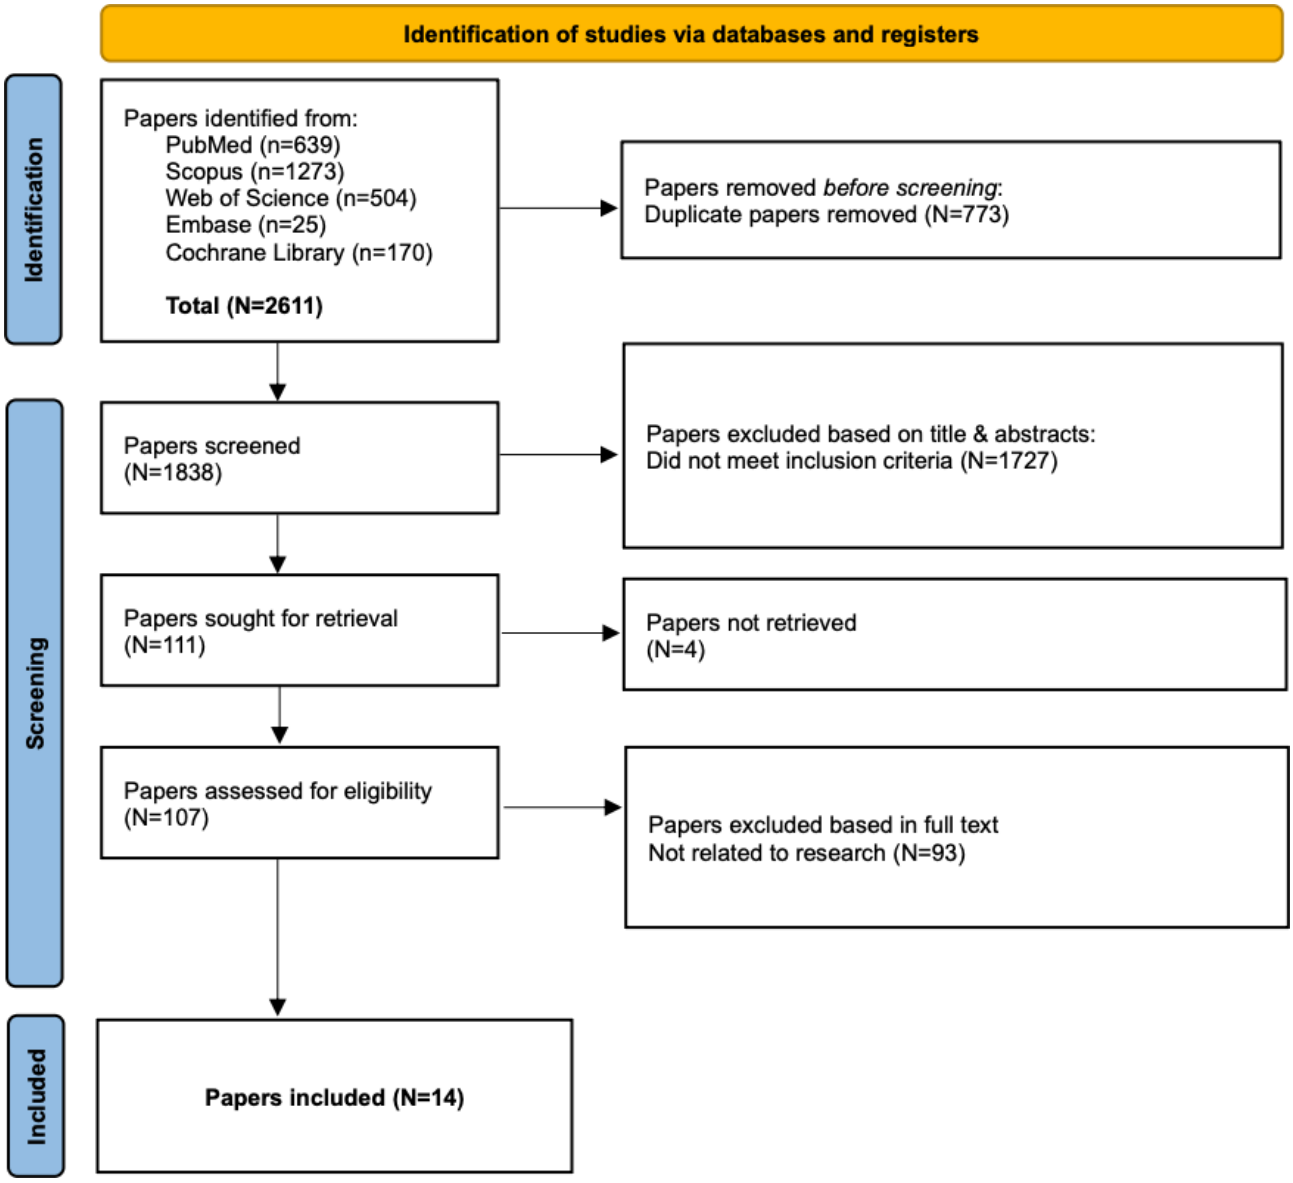
Synthesis Under the PROPS Framework

Aligned with the PROPS framework, the population (P) included older adults in rural or underserved communities. Remote health interventions (R) varied in format but consistently included a digital or telehealth component. Outcomes (O) encompassed clinical parameters, behavioral change, patient-reported satisfaction, and health care utilization. Procedures (P) typically involved remote coaching, telemonitoring, or integrated care coordination. Study design (S) was predominantly randomized or quasi-experimental, ensuring a moderate to high level of evidence.

Ethical Considerations

As this study was based entirely on published literature, no ethical approval was required.

Results



Characteristics of Included Studies

A total of 14 studies met the inclusion criteria and were included in this systematic review (Figure 1). These studies were conducted across diverse settings, including the United States, Canada, Germany, and Australia. The target populations comprised older adults residing in rural or underserved areas and patients with chronic conditions, such as diabetes mellitus, cardiovascular disease, obesity, heart failure, or postsurgical

XSL•FO
RenderX

recovery (Table 1). The majority of the interventions combined digital technologies—such as telemonitoring, phone-based coaching, and web-based rehabilitation—with behavioral, educational, or case management support. Table 1 summarizes the characteristics of included studies, Table 2 details intervention types and digital tools employed, and Table 3 presents the reported outcomes and implementation challenges.

Figure 1. PRISMA 2020 (Preferred Reporting Items for Systematic Reviews and Meta-Analyses 2020) flowchart of study selection process**.** This flow diagram illustrates the identification, screening, eligibility, and inclusion stages of the systematic review. A total of 14 studies met the eligibility criteria and were included in the final synthesis after full-text assessment.

Table . Characteristics of included studies.

Study	Country	Population	Telehealth intervention	Comparator	Main outcomes	Follow-up duration
Barnason et al [16] (2019)	United States	Cardiac patients (post-PCI[a] or CABS[b]), overweight/obese, rural	12-week phone coaching+nurse support	Usual care	Weight loss and self-efficacy	4 and 6 months
DiNapoli et al [18] (2017)	United States	Older adults, low QoL[c], mild cognitive impairment, rural	16 - 20 sessions of phone-delivered CBT[d]	Minimal support control (weekly calls)	Anxiety, depression, and QoL	6 months
Eberly et al [7] (2025)	United States	Heart failure, underserved	Phone-based GDMT[e] titration+blood pressure monitoring	Usual care	GDMT uptake	30 days
Krum et al [26] (2013)	Australia	Heart failure, rural	Phone support+nurse follow-up	Usual care	Hospitalizations and mortality	12 months
Lear et al [3] (2015)	Canada	Cardiac patients, rural and small urban	Web-based rehabilitation platform	Usual care	Exercise capacity and lipid profile	16 months
Perri et al [19] (2019)	United States	Obese adults (528), rural	Telecoaching+tracking	In-person	Weight loss and retention	4, 6, and 12 months
Perri et al [17] (2020)	United States	Obese adults (445), rural	Phone counseling (group/individual)+education	Usual care	Weight loss and maintenance	4, 10, 16, and 22 months
Prescher et al [12] (2023)	Germany	Elderly with HF[f] (1538), rural/urban	Remote monitoring+care coordination	Usual care	Function, QoL, BP[g], ECG[h]	12 months
Russell et al [27] (2011)	United States	Post-knee arthroplasty patients (65), rural	Telemonitoring	Usual care	Function and OA[i] Index	6 weeks
Shea et al [4](2009)	United States	Diabetes (1665), underserved	Telemonitoring+nurse case management	Usual care	HbA_{1c}[j], LDL[k], BP, and satisfaction	5 years
Shea et al [10,28] (2013)	United States	Diabetes, underserved	Telemonitoring+nurse care management	Usual care	HbA_{1c}, SBP[l], and LDL	12 months
Smith et al [29] (2000)	United States	Rural older adults	Telehealth counseling	Not reported	QoL and satisfaction	5 months
West et al [30] (2010)	United States	Diabetes, rural older adults	Telehealth counseling	Usual care	Behavior change	2 - 6 years
Wilson et al [20] (2016)	United States	Smokers, rural	Telemedicine advice	Usual care	Abstinence and self-efficacy	6 months

Table . Effectiveness outcomes by studies.

Study	Clinical outcome	Behavioral outcome	Patient satisfaction	Health care utilization
Barnason et al [16] (2019)	Sustained weight loss	Improved activity and self-efficacy	Moderate satisfaction	Not reported
DiNapoli et al [18] (2017)	No significant clinical change	Improved mood and activation	High satisfaction	Not reported
Eberly et al (2025)	Increased GDMT[a] use	Improved adherence	High protocol adherence	Fewer HF[b] hospitalizations
Krum et al [26] (2013)	Reduced hospitalizations	Not reported	Not reported	Reduced hospitalizations
Lear et al [3] (2015)	Better lipid profile	Not reported	Usability positive	Not reported
Perri et al [19] (2019)	Weight loss	High goal attainment	High satisfaction	Reduced episodes
Perri et al [17] (2020)	Weight loss	Behavior change	High satisfaction	Reduced episodes
Prescher et al [12] (2023)	Cardiac improvements	Improved motivation	High adherence	Lower hospitalization
Russell et al [27] (2011)	Improved OA[c] outcomes	Self-care adherence	High satisfaction	Reduced episodes
Shea et al [4] (2009)	HbA_{1c}[d], BP[e] reduction	Empowerment increased	Positive care perception	Lower rates
Shea et al [10,28] (2013)	HbA_{1c}, SBP[f] reduced	Health management	Not reported	Not reported
Smith et al [29] (2000)	No clinical change	Health awareness	Positive experience	Not reported
West et al [30] (2010)	Improved diabetes control	Goal execution improved	High satisfaction	Not reported
Wilson et al [20] (2016)	Verified smoking cessation	Health awareness	High acceptability	Not reported

[a]GDMT: guideline-directed medical therapy.

[b]HF: heart failure.

[c]OA: osteoarthritis.

[d]HbA_{1c}: glycated hemoglobin.

[e]BP: blood pressure.

[f]SBP: systolic blood pressure.

Table . Clinical recommendations.

Clinical domain	Recommended modality	Target population	Recommendation
Chronic conditions	Multicomponent (coaching+monitoring)	Rural older adults	Integrate digital tools with behavioral support
Diabetes	Telemonitoring+nurse coaching	Rural older adults	Combine remote feedback and coaching
Cardiovascular rehabilitation	Web-based rehabilitation+support	Postcardiac discharge, rural	Use online rehabilitation when in-person is not feasible
Weight management	Behavioral telecoaching	Obese rural adults	Support goals via telecoaching
Mental health	Phone-based behavioral therapy	Rural older adults	Implement CBT[a] remotely

[a]CBT: cognitive behavioral therapy.

Clinical Outcomes (Patient Perspective)

Clinical improvements were reported in most of the included studies. Glycemic control (hemoglobin A_{1c} [HbA_{1c}]), blood pressure, lipid profiles, and weight reduction were the most frequently evaluated parameters. For example, Shea et al [10,28] observed significant reductions in HbA1c and systolic blood pressure following nurse-led telemonitoring interventions in low-income and underserved diabetic populations. Similarly, Wilson et al [20] reported biochemical validation of smoking abstinence in rural participants receiving telemedicine counseling, whereas Perri et al [17,19] demonstrated sustained weight loss in older obese adults receiving telecoaching and tracking interventions for up to 22 months.

In the cardiovascular domain, Lear et al [3] found that a web-based rehabilitation platform improved lipid profiles and exercise capacity, whereas Krum et al [26], Barnason et al [16], and Prescher et al [12] reported fewer heart failure–related hospitalizations and improvements in weight and blood pressure through structured remote follow-up (Table 2). Notably, Eberly et al [7] demonstrated a significant increase in the uptake of

XSL•FO
RenderX

guideline-directed medical therapy for heart failure, supported by remote blood pressure monitoring and medication titration.

Behavioral and Psychosocial Outcomes

Fifteen studies evaluated behavioral and psychosocial variables, including self-efficacy, adherence, physical activity, and mood. DiNapoli et al [18] used cognitive behavioral therapy (CBT) delivered through telephone and observed improvements in mood, patient activation, and decreased depressive symptoms. Barnason et al [16] and Perri et al [17] reported increases in health-related behaviors, such as dietary control, physical activity, and treatment adherence, alongside weight loss outcomes.

Several studies emphasized the role of motivation, activation, and goal setting. For instance, West et al [30] and Smith et al [29] found that behavioral activation and health awareness were significantly improved among older rural adults participating in structured telehealth counseling sessions. Notably, these effects were more pronounced when interventions included personalized coaching and caregiver engagement.

Usability and Satisfaction (Patient-Reported)

Patient satisfaction and usability were assessed in 13 studies. Most interventions received favorable feedback from participants, who cited increased accessibility, reduced need for transportation, and personalized interactions as key benefits. Interventions led by nurses or care coordinators (eg, Shea et al [4], Prescher et al [12], and Smith et al [29]) had especially high ratings. Perri et al [19] reported high retention and satisfaction in group-based telecoaching models, emphasizing the value of social support and continuous feedback.

Although some participants noted challenges, such as intervention length or digital interface complexity, overall engagement and willingness to continue using digital health solutions remained strong across studies (Table 2).

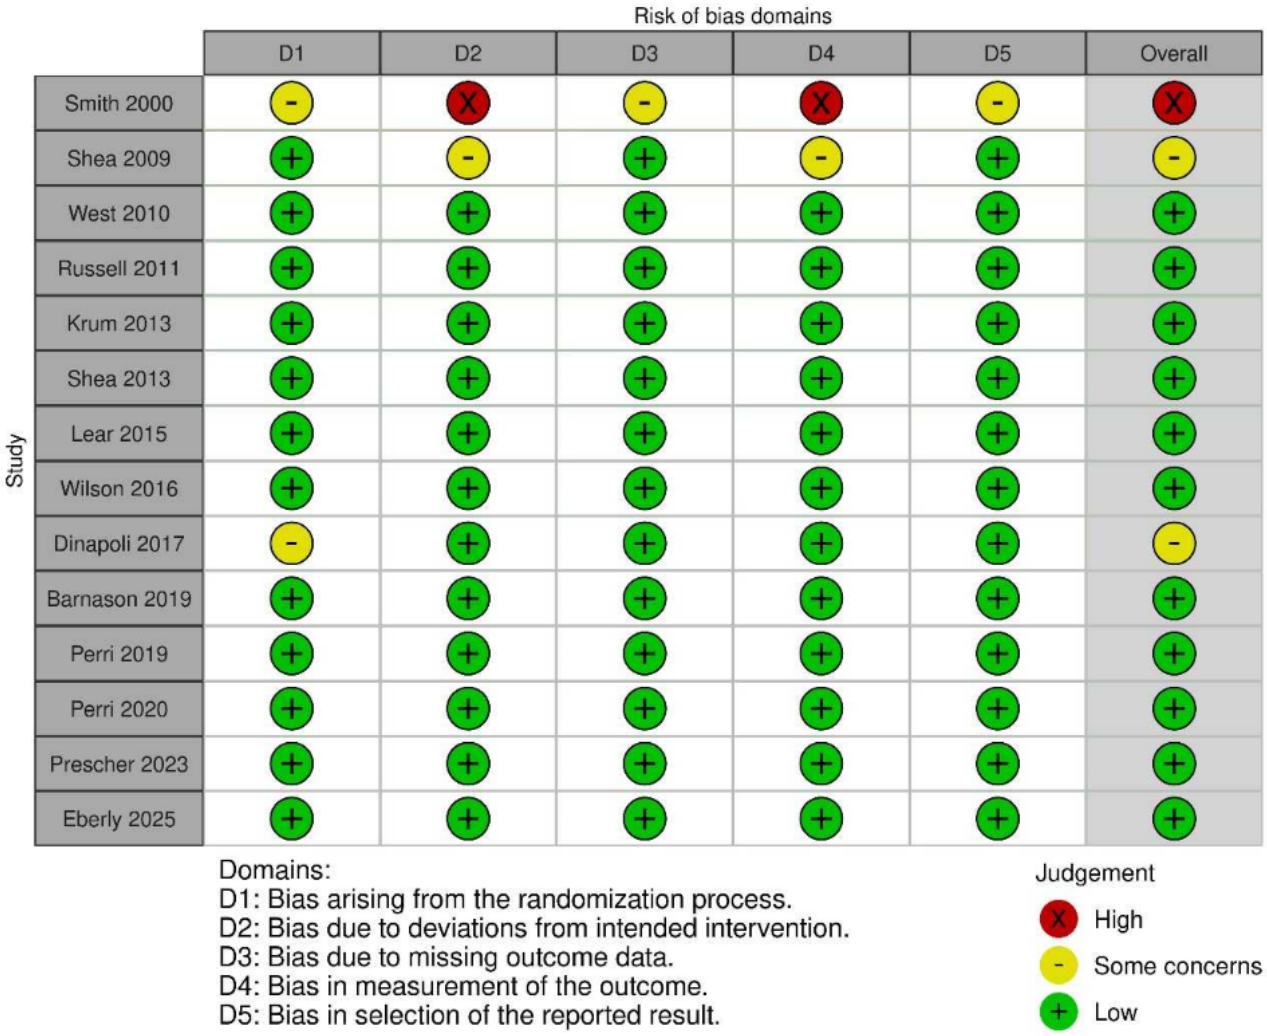
Health Care Utilization and Efficiency

Nine studies reported health care utilization outcomes, including hospital readmissions, acute episode rates, and emergency department visits. Telehealth interventions consistently reduced hospitalization rates in older adults with heart failure or chronic disease, as evidenced in studies by Krum et al [26], Barnason et al [16], and Prescher et al [12]. Shea et al [4] and Perri et al [17] observed reduced acute episodes and improved care coordination through remote monitoring.

While Eberly et al [7] documented fewer cardiac hospitalizations through proactive titration of medications, the majority of studies lacked formal cost-effectiveness analyses. As shown in Table 4, future evaluations must address the economic implications of scaling telehealth models in rural and resource-constrained contexts.

Table . Limitations and research recommendations.

Limitation	Future research action	Justification
Short follow-up	Long-term RCTs[a] (≥12 mo)	Assess sustainability
Small samples	Larger trials with stratification	Avoid type II errors
Lack of cost analysis	Include economic evaluations	Guide policy and budgeting
Limited generalizability	Cultural tailoring across regions	Address population heterogeneity
Inconsistent outcomes	Standardized outcome sets	Enable synthesis
Digital barriers	User-centered design for low literacy	Improve accessibility



[a]RCTs: randomized controlled trials.

Risk of Bias and Study Quality

Figure 2 presents the risk of bias assessment. Using the RoB 2.0 tool, most studies were classified as low risk in randomization, outcome measurement, and reporting domains. However, Smith et al [29] was flagged as high risk due to deviation from protocols and unclear allocation procedures, and DiNapoli et al [18] presented some concerns in the randomization process. Despite these limitations, overall study quality was deemed adequate, with the majority of trials employing rigorous designs and clear outcome reporting.

XSL•FO
RenderX

Figure 2. Risk-of-bias assessment for the 14 included studies. Graphical summary of bias domains assessed using the Cochrane Risk of Bias 2.0 tool. Domains include D1 (randomization process), D2 (deviations from intended intervention), D3 (missing outcome data), D4 (measurement of the outcome), and D5 (selection of reported result). Green (+) indicates low risk, yellow (−) indicates some concerns, and red (×) indicates high risk. Overall risk of bias was low in 12 studies, with two studies (Smith et al [29] and DiNapoli et al [18]) rated as high or having some concerns [3,4,7,10,12,16-20,26,27,29,30].

Implementation Facilitators (Provider Perspective)

Key implementation barriers included limited digital literacy, lack of broadband connectivity, and insufficient cultural adaptation of interventions. Several studies highlighted the importance of preintervention training, simplified user interfaces, and language-appropriate materials. For example, Russell et al [27] and DiNapoli et al [18] integrated patient education modules and caregiver support, which improved both adherence and satisfaction.

Multicomponent interventions—combining synchronous coaching (eg, telephone and video) and asynchronous tracking (eg, mobile apps and remote monitoring)—were associated with greater behavioral change and health gains. Interventions with durations of 6 months or longer demonstrated more durable outcomes. Conversely, short follow-up periods (eg, 30 days in Eberly et al [7]) limited the understanding of long-term sustainability.

Heterogeneity and Feasibility of Meta-Analysis

The feasibility of conducting a meta-analysis was limited by marked heterogeneity across the included studies in terms of populations, intervention modalities, outcome measures, and follow-up durations. Clinical end points ranged from HbA_{1c} and blood pressure to functional capacity and psychological scales, with inconsistent definitions and reporting formats that precluded statistical pooling. Moreover, small sample sizes and diverse study designs further reduced comparability. For these reasons, a narrative synthesis was judged to be the most appropriate approach, allowing results to be interpreted within outcome domains while acknowledging variability in effect sizes and methodological rigor.

Synthesis Approach (PROPS)

Findings were organized according to the PROPS framework, grouping evidence by population characteristics, remote health intervention types, outcomes, and setting or contextual factors.

XSL•FO
RenderX

This approach allowed us to compare heterogeneous studies in a structured manner and highlight converging patterns. For example, in populations with cardiometabolic conditions, telemonitoring combined with nurse support consistently improved HbA_{1c} and blood pressure outcomes, whereas in mental health or behavioral domains, telephone-based CBT and lifestyle coaching showed greater impact on psychological well-being and adherence. Variability across settings, particularly in broadband access and digital literacy, was emphasized as a determinant of intervention success. Narrative weighting of evidence was guided by risk-of-bias judgments, giving higher emphasis to low-risk trials and cautious interpretation of studies with missing data or selective reporting

Equity (PROGRESS-Plus)

Equity-related variables, such as place, gender, and socioeconomic status, were variably reported across studies, while domains, such as religion and social capital, were largely absent. Detailed reporting of each dimension and study is provided in Table S4 in Multimedia Appendix 1.

Summary

Tables 1-4 synthesize the evidence on participants' characteristics, effectiveness, implementation strategies, and limitations. The findings support the potential of digital health interventions to improve health outcomes, reduce hospitalization, and enhance engagement among older adults in rural or underserved settings. However, sustainability, equity, and generalizability remain key areas for further research.

Comprehensive supplementary data provide additional granularity to the synthesized findings. Table S1 in Multimedia Appendix 1 details the complete database search strategy used across PubMed, Scopus, Web of Science, Embase, and Cochrane, confirming methodological transparency and reproducibility. Table S2 in Multimedia Appendix 1 summarizes the direction, magnitude, and certainty of effects for each included study by outcome domain, strengthening the interpretation of clinical and behavioral improvements reported in the main text. Table S3 in Multimedia Appendix 1 presents the frequency distribution of risk-of-bias domains across randomized, nonrandomized, and observational designs, supporting the overall quality assessment discussed earlier. Equity dimensions were systematically mapped in Table S4 in Multimedia Appendix 1, evidencing variable reporting across PROGRESS-Plus (place of residence, race/ethnicity, occupation, gender, religion, education, socioeconomic status, social capital, plus other context-specific determinants of health equity) categories. Table S5 in Multimedia Appendix 1 provides adherence and attrition data, illustrating high engagement rates (>75%) despite common technical barriers, and Table S6 in Multimedia Appendix 1 classifies intervention models by delivery type, clinical applicability, and observed outcomes, emphasizing the comparative advantages of multicomponent, hybrid telehealth formats. Collectively, these supplementary materials reinforce the robustness, contextual diversity, and implementation relevance of the reviewed evidence.

Discussion

Main Findings

This systematic review of 14 studies shows that remote and digital health interventions can significantly improve clinical, behavioral, and satisfaction-related outcomes in older adults living in rural or underserved settings. Telehealth modalities, such as telephone counseling, nurse-led monitoring, and web-based platforms, consistently enhanced chronic disease management, promoted healthier behaviors, and increased accessibility to care. Notable clinical benefits included reductions in HbA_{1c}, blood pressure, and low-density lipoprotein cholesterol in diabetic patients, improved uptake of guideline-directed medical therapy and fewer short-term hospitalizations in heart failure, and better weight loss and retention outcomes in obesity. Behavioral interventions also proved effective, with structured coaching and CBT programs improving patient activation, physical activity, and psychological well-being, highlighting the potential of remote care to address barriers faced by these populations.

Comparison With Prior Work

Our findings align with prior evidence indicating the efficacy of remote interventions in chronic disease management. For instance, Shea et al's [4] work on the IDEATel project has long emphasized the role of telehealth in improving glycemic and blood pressure control in underserved populations. Similarly, Lear et al [3] confirmed the value of web-based platforms in cardiac rehabilitation, echoing the current study's results. However, while prior meta-analyses (eg, Marcolino et al [31]) have generally combined urban and rural populations, this review narrows the focus to older adults in rural or resource-limited settings, highlighting unique challenges and opportunities in this demographic.

Several of the studies in this review support the role of multicomponent telehealth strategies that combine behavioral coaching, self-monitoring tools, and clinical oversight. For example, Prescher et al [12] demonstrated improvements in cardiac functions and reduced hospitalizations when remote monitoring was integrated with coordinated care. This convergence of digital tools and human support appears especially important in rural contexts, where health care infrastructure and workforce shortages often limit access to traditional services [14,32].

Interpretation by Outcome Domains

When interpreting the findings by outcome domains, the evidence suggests that digital and remote health interventions can generate benefits across clinical, behavioral, and health care utilization outcomes, though with varying levels of certainty. Clinical outcomes, such as HbA1c reduction, blood pressure control, and weight loss, were reported in a subset of studies, indicating that structured remote monitoring and nurse-supported programs are particularly effective for cardiometabolic management. Behavioral and psychosocial domains showed improvements in patient activation, medication adherence, and psychological well-being, highlighting the value of tailored telecoaching and CBT-based interventions. In contrast, health

XSL•FO
RenderX

service utilization outcomes, such as reduced hospitalizations or emergency visits, were less consistently observed, likely reflecting short follow-up periods and small sample sizes. Taken together, these results indicate that while the strongest evidence lies in clinical and behavioral benefits, sustained improvements in health care utilization may require longer interventions and broader system-level integration.

Equity Appraisal (PROGRESS-Plus)

Applying the PROGRESS-Plus framework revealed important gaps in how equity dimensions were reported and addressed across the included studies. Most trials provided some data on place of residence, education, or socioeconomic status, but few explicitly measured digital literacy, broadband availability, or cultural and linguistic adaptation of interventions. Gender and age were routinely reported, yet aspects such as occupation, religion, or social capital were rarely considered. Notably, none of the studies systematically evaluated how these factors moderated intervention outcomes, which limits the ability to determine whether digital tools reduced or inadvertently widened disparities. This underreporting underscores the need for future research to integrate equity indicators prospectively into study design and to tailor interventions to the structural barriers and lived experiences of rural and underserved older populations.

Limitations of Included Studies

Despite promising outcomes, limitations in study design, follow-up duration, and reporting hinder the generalizability of findings. As summarized in Table 4, many studies had short follow-up durations (eg, 30 d to 6 mo), which limit our understanding of long-term intervention sustainability. Only a few studies, such as West et al [30] and Shea et al [4], offered follow-up beyond 12 months.

Sample sizes were frequently small or underpowered (eg, Russell et al [27] and Smith et al [29]), increasing susceptibility to type II errors and reducing the robustness of subgroup analyses. The heterogeneity in intervention types and outcome measures also complicates cross-study comparisons. For example, while weight loss and HbA_{1c} were commonly measured, behavioral metrics varied widely and were often self-reported without standardized instruments.

Additionally, economic evaluations were notably absent. None of the included studies systematically reported on cost-effectiveness, despite the critical importance of economic data for policymaking and reimbursement frameworks in telehealth implementation [33,34]. All included studies were conducted in high-income countries; the absence of eligible studies from low- and middle-income countries limits generalizability. We explicitly searched without country restrictions; the lack of low- and middle-income country evidence appears to reflect publication scarcity rather than an a priori exclusion.

Limitations of This Review

This review also has several methodological limitations that should be acknowledged. First, the small and heterogeneous evidence base precluded quantitative pooling and limited the generalizability of conclusions. Second, despite a comprehensive search strategy, we restricted inclusion to peer-reviewed, indexed papers, which may have introduced publication and language bias by excluding gray literature and non-English studies. Third, although dual reviewers independently screened and extracted data, subjective judgments in the narrative synthesis may have influenced the interpretation of findings. Finally, all included studies originated from high-income countries, constraining the applicability of results to low- and middle-income settings where digital and infrastructural barriers may differ substantially.

Barriers to Implementation and Digital Equity

An important contextual finding across studies is the presence of digital and literacy-related barriers among older rural adults [35,36]. Digital literacy was rarely assessed systematically; however, studies like Wilson et al [20] and Smith and Weinert [29] hinted at limited technology familiarity and engagement. Moreover, intervention adherence and satisfaction appeared to be influenced by factors such as perceived complexity, trust in remote systems, and personal contact with health care providers.

These findings echo previous reports emphasizing the need for user-centered, accessible design tailored to the cognitive and sensory needs of older adults. As Barnason et al [16] and DiNapoli et al [18] noted, patient satisfaction and engagement were higher when interventions included regular human interaction, simplified instructions, and consistent technical support.

Implementation Barriers and Health Equity Considerations

The review highlights persistent digital and infrastructural barriers disproportionately affecting older adults in rural or underserved settings [37,38]. Limited broadband access, low digital literacy, and lack of culturally tailored content not only hinder adoption but reinforce existing health inequities [39-41]. These implementation challenges are structurally linked to social determinants of health, such as lower educational attainment and income levels in rural areas [42]. Without addressing these foundational disparities, digital health solutions risk exacerbating rather than alleviating access gaps. Therefore, policy interventions should include investments in digital infrastructure, community-based training, and participatory design processes that reflect local needs [43].

Innovation and Emerging Models

This review highlights not only the effectiveness of established telehealth modalities but also the emergence of hybrid care models and novel delivery platforms tailored to rural aging populations. Notably, interventions incorporating both synchronous (eg, phone-based coaching) and asynchronous (eg, mobile tracking or wearable monitoring) modalities were associated with higher patient engagement and adherence. For instance, the Rural Lifestyle, Exercise, Attitudes, and Relationships Program (LEAP) trial [19] compared group versus individual telecoaching, revealing that group-based formats may enhance social connectedness—a crucial factor for isolated older adults. Similarly, the use of wearable-enabled remote monitoring in heart failure management (eg, TIM-HF2 [12], Hózhó trial [7]) represents a shift toward continuous and passive

XSL•FO
RenderX

data collection, enabling earlier detection of clinical deterioration.

These findings align with a recent framework such as the National Academies of Sciences, Engineering, and Medicine 2022 Digital Health Equity Roadmap, which emphasizes human-centered design, infrastructure co-development, and inclusive implementation pathways to ensure equitable access to digital health. Compared to earlier reviews that emphasized general digital adoption [31], this study foregrounds context-specific innovations, such as culturally adapted content, caregiver-mediated interfaces, and localized broadband workarounds, which offer blueprints for scalable, equitable intervention design in marginalized aging populations.

Implications (Practice or Policy)

To translate the observed benefits of telehealth into routine care, integration into existing primary care models is essential [44]. This requires not only technological interoperability but also alignment with reimbursement policies, provider training, and patient education [45]. Interventions led by nurses or care coordinators demonstrated high satisfaction and adherence, suggesting that a team-based, hybrid care model may offer the most sustainable pathway [46]. Health systems must also establish clear protocols for digital triage, follow-up, and escalation of care to ensure clinical safety [47]. Policymakers should incentivize digital inclusion initiatives and consider telehealth reimbursement parity to support widespread adoption in rural and underserved populations [48]. Distinguishing patient-reported outcomes from provider-facing facilitators clarifies that improvements in usability or adherence reflect patient experiences, whereas professional networking and workflow integration represent implementation considerations at the provider/system level.

Economic Considerations

Although several interventions demonstrated clinical and behavioral benefits, none of the included studies conducted a formal cost-effectiveness analysis. This absence of economic evidence substantially limits the ability of health systems and policymakers to make informed, data-driven decisions regarding large-scale implementation. Without robust cost analyses, it is unclear whether the observed benefits can be achieved sustainably or equitably across diverse settings. Future trials should therefore embed cost-effectiveness and budget impact evaluations alongside clinical outcomes to determine value for money, support reimbursement frameworks, and guide resource allocation in rural and underserved populations.

Risk of Publication and Language Bias

The small number of included studies limited the feasibility of conducting formal statistical assessments of publication bias, such as funnel plots or regression-based tests. With only 14 trials, these methods would be underpowered and potentially misleading. Nevertheless, the predominance of positive findings raises the possibility of small-study effects. In addition, by restricting our search to peer-reviewed and indexed literature, we may have excluded gray literature or non-English studies that could provide null or negative results. These factors suggest that the overall effectiveness of digital health interventions in rural older populations may be somewhat overestimated, and future reviews should seek to mitigate this risk by incorporating broader data sources and multilingual evidence.

Recommendations for Future Research

To advance the field, future studies should prioritize longer follow-up durations to assess the sustainability of clinical and behavioral gains. Large, multicenter trials with stratified randomization would enhance generalizability and allow for meaningful subgroup analysis by age, comorbidity burden, or digital literacy level.

Moreover, standardized outcome reporting is critical. Adopting common core sets of metrics—particularly for behavioral and quality-of-life domains—would enable pooled synthesis and meta-analyses, strengthening the evidence base. Economic evaluations, including cost-effectiveness and budget impact analyses, should also be embedded into study designs.

The implementation of satellite-based internet in geographically remote areas with limited or no connectivity can improve the functionality and accessibility of telehealth platforms and applications, facilitating communication between health care providers and older adult patients. In this context, the limited availability of specialist care in underserved regions may be addressed through the progressive integration of telehealth technologies, expanding access to specialized services for aging populations.

Finally, cultural tailoring and language accessibility should be emphasized in designing telehealth platforms. Rural populations are not homogenous; successful interventions must adapt to the social, linguistic, and infrastructural realities of diverse communities.

Conclusions

Telehealth interventions represent a promising approach to enhancing the health and well-being of older adults in rural and underserved settings. Evidence from 14 studies indicates that remote strategies can contribute to improved management of chronic conditions, support behavioral change, and in some cases, reduce hospitalizations. Yet, important gaps remain regarding cost-effectiveness, outcome standardization, and digital inclusion. Integrating human support with technological solutions appears to enhance adherence and overall effectiveness. Equitable access and long-term sustainability will require greater emphasis on digital literacy, cultural adaptation, and economic feasibility. At present, the lack of formal cost-effectiveness analyses constrains data-driven decisions about large-scale adoption. Future studies should therefore embed economic evaluations and equity considerations to provide the evidence base needed for informed policy and resource allocation in underserved contexts.

Abstract

Background: Older adults face increasing health risks associated with aging and chronic disease; yet, uptake of recommended clinical preventive services remains low. Digital health interventions have the potential to enhance access and engagement, but their effectiveness in older adult populations remains unclear.

Objective: This systematic review aimed to examine the range and types of digital clinical preventive service interventions and assess their impact on preventive care uptake among older adults.

Methods: We conducted a systematic review of peer-reviewed research literature published since 2014. Eligible studies included experimental and quasi-experimental designs evaluating digital interventions targeting community-dwelling adults aged 60 years and older. Interventions focused on high-priority preventive services, including cancer screening and adult immunizations. Data were extracted using a standardized form and synthesized narratively due to heterogeneity in study designs and outcomes.

Results: In total, 24 studies involving over 1.3 million participants from 11 countries were included. Interventions used a range of digital tools, including telephone calls, SMS text messages, patient portals, and video-based education. While some digital and automated interventions demonstrated modest improvements in preventive services uptake, results were mixed. Interventions incorporating personalized elements (eg, tailored telephone counseling or in-person education) were generally more effective than generic, automated communications. Few studies reported on digital literacy support or intervention reach, and engagement with digital platforms was often low.

Conclusions: Digital interventions can support modest improvements in preventive services uptake among older adults, particularly when personalized or combined with human interaction. However, assumptions of digital fluency and limited reporting on engagement constrain generalizability. Future research should prioritize inclusive design, detailed reporting, and strategies that address digital equity to better support older adult populations.

KEYWORDS

older adults; preventive care; digital health; systematic review; screening; vaccination

Introduction

Over the next decade, the percentage of Canadian people aged 65 years and older is projected to increase from 18.5% in 2021 to 22.9% by 2030. Similarly, the proportion of individuals aged 85 years and older is projected to increase from 2.3% in 2021 to 4.6% by 2050 [1]. Accelerated population aging, coupled with increasing chronic disease prevalence, has driven rising health care use and costs [2-5]. For instance, the average per-person health care spending for Canadian people aged 65+ years (US $9260) is 4 times higher than those <65 years (US $2083) [6]. Similarly, older adults in the United States represent 13.5% of the population but account for 45.2% of the top 10% of health care spenders [5]. The trend of population aging and estimates of increased costs highlight the urgent need for approaches that promote healthy aging, reduce chronic disease, and optimize quality of life for older adults.

Engaging older adults to stay current on recommended clinical preventive services is a proactive approach to promote healthy aging. Preventive services comprise activities aimed at disease prevention (eg, immunizations and alcohol or tobacco cessation) and early disease detection (eg, cancer screening, blood glucose, and blood pressure monitoring) [7]. Guidelines for recommended preventive services based on age, gender, and other risk factors have been developed using best evidence for cost-effectiveness and reduced morbidity and mortality [8,9]. However, despite national and provincial preventive services guidelines and recommendations, few older adults are up to

XSL•FO
RenderX

date on all recommended preventive activities. The number of recommended preventive services and their importance increases with age; yet, completion rates are alarmingly low for older adults. According to the British Columbia Cancer Agency, only 52% of women aged 50 - 74 years are screened for breast cancer compared to a target of 70% [10]. A US study estimated a completion rate for all relevant clinical preventive services of only 7.9% for older adults [11].

The rapid development and implementation of digital health services, including preventive services, during and after the COVID-19 pandemic have increased access and convenience [12] but have also had the untoward impact of excluding individuals with limited digital literacy. Although older adults are less frequent users of technology compared to younger age groups [13], evidence indicates that older adults' willingness to engage with digital technologies is growing steadily [14]. However, there remain challenges and barriers for older adults when accessing digital resources and health services (eg, lack of support and poor functionality) [15,16], which contribute to digital inequity and hinder older adult engagement in digital preventive services. Understanding the current state of the science regarding the effectiveness of digital interventions for preventive service uptake in older adults would provide valuable, evidence-based insights to better leverage technology in meeting their needs.

Although systematic reviews have synthesized evidence focused on individual preventive services, such as breast [17] and colon cancer [18] screening, no comprehensive review has been conducted looking specifically at older adults and digital aspects of preventive care services. As such, this review aims to answer this question: What are the range and types of digital clinical preventive services interventions (intervention), and what is their impact on older adults' (population) uptake of clinical preventive services (outcome)?

Methods

Design

This systematic review was designed following the JBI Manual for Evidence Synthesis [19,20] and the Cochrane Handbook for Systematic Reviews of Interventions [21].

Search Strategy

This systematic review captures peer-reviewed research papers addressing digital preventive services uptake targeting older adults. The digital tools considered included telephone (automated or synchronous), text messaging, web-based educational materials or materials delivered via video, or patient portal. The search strategy was developed in consultation with a health sciences librarian (RJ; see Multimedia Appendix 1 for the search strategy from Embase). Search terms were selected based on the review question's main content areas of older adults and clinical preventive services and included a combination of keywords and subject headings. Databases used in the search included MEDLINE, CINAHL, Embase, and PsycINFO. The search strategy was modified only slightly between the databases to incorporate their specific subject headings. Database searches were conducted on December 11, 2023, and updated on July 13, 2025.

Inclusion and Exclusion Criteria

Eligible literature included experimental (eg, randomized controlled trials) and quasi-experimental study designs. Qualitative and observational studies that did not test an intervention were excluded. Studies were included if they addressed preventive services uptake among older adults in response to single (eg, breast cancer screening, colorectal cancer, and blood pressure) or multiple services (eg, blood pressure, cancer screening, and seasonal vaccination). Interventions were limited to high-priority preventive care services based on high clinically preventable burden and established immunization schedules for older adults [8,22]. Preventive care services included 5 related to screening (cardiovascular disease, type 2 diabetes mellitus, hypertension, colorectal cancer, and breast cancer) and 6 related to vaccines (seasonal influenza, pneumococcal polysaccharide, shingles, COVID-19, and tetanus and or diphtheria).

Studies were eligible if they included samples that were primarily community-dwelling older adults. Because some studies did not report disaggregated age and used broad age categories (eg, "older adults" defined as 55+ years), we applied the following rules: studies in which all participants were aged 60 years or older were considered eligible; and if participants younger than 60 years were included, at least 50% of the sample had to be aged 65 years or older. This approach ensured consistency with our focus on older adults while allowing inclusion of studies with varied reporting practices. Studies were excluded if they focused on subpopulations (eg, familial risk and rheumatoid arthritis) or noncommunity-dwelling older adults (eg, long-term care residents) because they do not reflect the asymptomatic population for which preventive services guidelines are designed. Publications were limited to the last 10 years from when the review began to capture current strategies [9,22]. Studies were excluded if they did not report the results of primary research (ie, editorials, letters, search and research protocols, or systematic reviews).

Paper Selection

Two reviewers (LB and MAS) completed abstract screening and full-text screening, blinded to each other's decisions. Search results were added to the abstract management software Covidence for deduplication. A small sample of 10 - 15 records was tested against the stated inclusion and exclusion criteria [23]. The initial test of the screening process involved calibrating agreement, clarifying criteria, and making any necessary modifications before full screening. Following screening calibration, the remaining screening was conducted independently by the 2 reviewers (LB and MAS) [23]. Conflicts were assessed and resolved using consensus by 2 reviewers (LB and MAS). Interrater reliability was calculated using Cohen κ within Covidence software. The Cohen κ for abstract screening was 0.68, indicating substantial agreement [24].

Quality of Evidence

Quality of evidence was assessed using the Cochrane revised tool to assess risk of bias in randomized trials (Risk of Bias 2

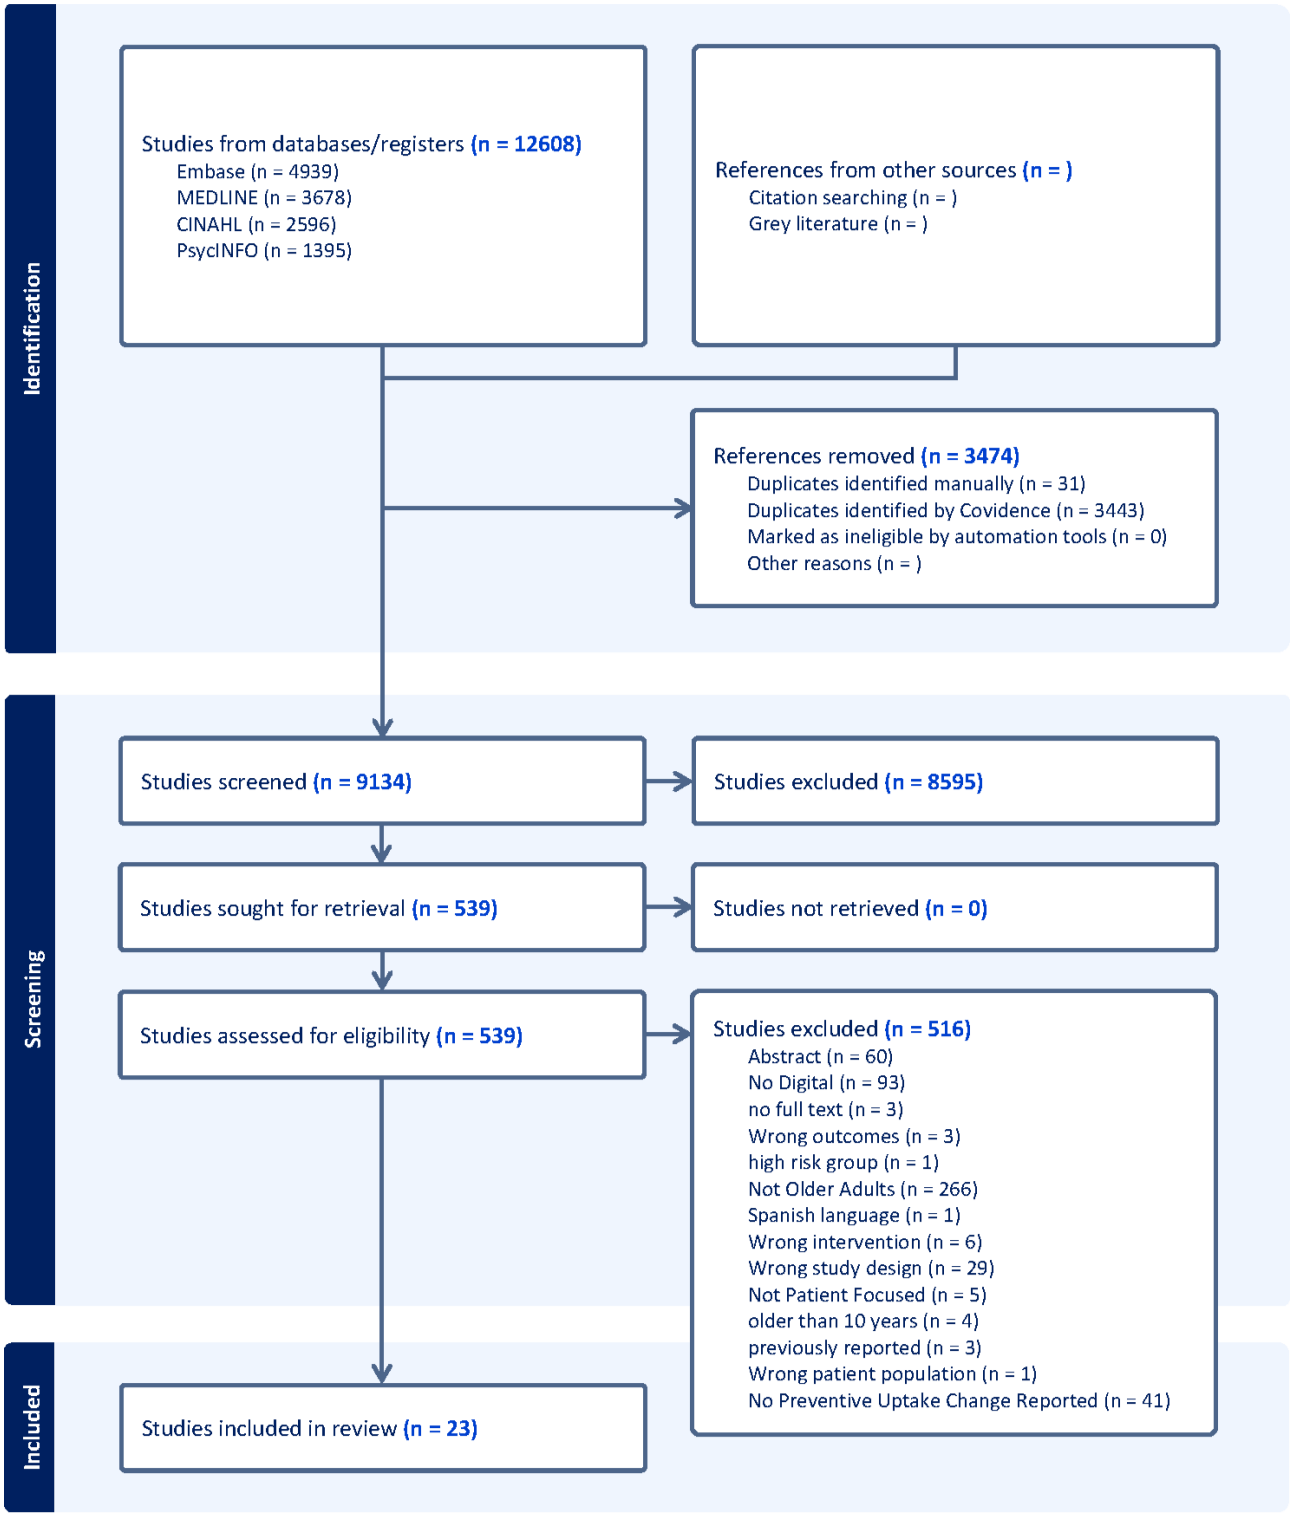
XSL•FO
RenderX

[RoB 2]) [25] and the Risk of Bias in Non-randomized Studies—of Interventions (ROBINS-I) tool [26]. Both tools concentrate on the study's internal validity [25,26]. In both tools, bias refers to a tendency for the results to deviate systematically from what would be expected from a randomized trial, conducted on the same participant group with no flaws in its execution [25,26]. RoB 2 assesses 5 domains of bias: (1) randomization process, (2) deviations from intended interventions, (3) missing data, (4) measurement of outcomes, and (5) selection of reported results [25]. For the RoB 2 assessment, each domain is assigned a risk of bias assessment of low, some concerns, or high risk of bias [25]. ROBINS-I assesses six domains of bias: (1) confounding, (2) selection of participants, (3) classification of interventions, (4) missing data, (5) measurement of outcomes, and (6) selection of reported results [26]. For the ROBINS-I assessment, each domain is assigned a risk of bias assessment of low, moderate, serious, or critical [26]. An overall risk of bias assessment for each paper is then conducted for both RoB 2 and ROBINS-I tools based on the assessment of the domains [25,26]. Risk of bias assessments were conducted by 1 team member and verified by a second reviewer.

Data Extraction and Analysis

Data extraction was conducted using a standardized form. Elements for extraction included study characteristics, study population, intervention characteristics, type of preventive service targeted, single or multiple services, and change in preventive care uptake. Preventive services uptake was defined as the completion of a screening test or immunization, either by self-report, review of medical chart, or insurance claims. Data extraction was conducted by 1 research assistant and confirmed by 2 additional reviewers (MAS and LB).

Data were synthesized using a narrative approach to explore the effectiveness of digital preventive services interventions for older adults. This method was suitable, given the variability in designs and interventions among the studies analyzed [27]. Technology complexity was determined using a researcher-developed scale of low to high based on the degree of interactivity required of older adults to receive the preventive-services intervention [28]. Scale and rating criteria are detailed in Multimedia Appendix 2. The uptake of clinical preventive services was compared across different intervention strategies to identify potential patterns and insights. Data heterogeneity prevented meta-analysis.



Results

Overview

The studies included in this review (n=23) represented 1,205,652 participants from 11 countries: the United States (n=11), Spain (n=3), Hong Kong (n=2), and 1 each from Australia, China, Denmark, France, Israel, Lebanon, and the United Kingdom. Studies were published between 2015 and 2025. A flowchart summarizing the search, screening, and study selection process is included in Figure 1 [29]. Designs included randomized controlled trials (n=20) and quasi-experimental studies (n=3). The majority (n=14) of included studies had a low risk of bias; the remaining had some or unknown risk of bias, but this was not a concern for the conclusions drawn by each study. The preventive services targeted in the interventions included colorectal cancer screening (n=10), influenza vaccination (n=6), breast cancer screening (n=3), pneumococcal vaccination (n=2), combined vaccinations (n=1), and COVID-19 vaccination (n=1; Table 1).

Table . Summary of included papers.

Study	Country	Design	Risk of bias	Sample	Targeted preventive care service	Simple intervention description	Change in preventive service uptake
Basch et al (2015) [30]	United States	RCT[a]	Low	564 participants, average age 57.6 (SD 4) years, 69.3% women, 17.6% White.	CRC[b] screening	• Comparison: CRC print education material • Intervention AD[c]: Comparison+AD • Intervention TTE[d]: Comparison, AD+targeted telephone education	Among those 60 years of age or older, AD plus telephone education group had a higher screening rate than the print group (27.3 vs 7.7%; *P*=.02).
Chan et al (2015) [31]	Hong Kong	RCT	Some concern—lack of detail of concealment	2517 participants aged >65 years, 57.3% women; ethnicity not reported.	Pneumococcal vaccination	• Comparison: Standard of care • Intervention: Education telephone intervention	1325 (53%) participants received the polysaccharide vaccine injection as recorded in the clinical management system—716 (57%) in the intervention group and 609 (48%) in the control group.
Denis et al (2017) [32]	France	RCT (3 arm)	Low	5691 participants, average age 61.2 (SD 6.8) years, 49.4% women; ethnicity not reported.	CRC screening	• Comparison: FOBT[e] kit • Intervention CATI[f]: CATI and FOBT kit • Intervention MI[g]: Motivational telephone interview and FOBT kit	Only 5691 (19.9%) people were actually counseled. There was no difference in completion between the intervention groups taken together and the control group (13.9% vs 13.9%) in intention-to-treat analysis.
Fernández et al (2015) [33]	United States	RCT (3 arm)	Some concern—outcome measure self-reported	656 participants, age 60 to 69 years: 31.8%, age 70+ years: 20.3%, 69.3% women, 100% Hispanic or Latino or Mexican.	CRC screening	• Comparison: No intervention • Intervention SMPI[h]: SMPI with DVD and flipchart • Intervention TIMI[i]: TIMI delivered on tablet computers	In the intention-to-treat analysis, 13.6% in the SMPI group, 10.2% in the TIMI group, and 10.8% in the comparison group completed CRC screening (not statistically significant).

RenderX

Study	Country	Design	Risk of bias	Sample	Targeted preventive care service	Simple intervention description	Change in preventive service uptake
Fleming et al (2018) [34]	United States	Quasi-experimental design	Moderate concern	3415 participants, average age 60.0 (SD 6.3) years, 50.5% women, 32.8% White.	CRC screening	• Comparison: Mass-mailing FIT[j] kit • Intervention phone: Comparison+telephone or recorded message • Intervention in-person: Comparison+one-on-one conversations in clinic	One-on-one conversations either in person (OR[k] 24.63, 95% CI 19.28 - 31.46) or via telephone or recorded message (aOR 14.74, 95% CI 10.96 - 19.82) were more effective for completing the at-home CRC screening than mass mailing before receiving the FIT.
Ghadieh et al (2015) [35]	Lebanon	RCT (6 arm)	Low	350 participants aged 60+ years not receiving the vaccine, 54.9% women; ethnicity 100% Chinese.	Pneumococcal vaccination	• Intervention: Telephone reminder±education • Intervention: Email reminder±education • Intervention: SMS text message reminder±education	Vaccination rates increased to 16.5% in short phone call group, 7.2% in SMS text group, and 5.7% in the email group; from 17.2% to 20.4% in patients older than 65 years.
Hagoel et al (2016) [36]	Israel	RCT	Low	48,091 participants, average age 60.44 (SD=6.04) years, 51.1% women; ethnicity not reported.	CRC screening	• Comparison: No intervention • Intervention interrogative: Interrogative SMS text message reminders±social context • Intervention noninterrogative: Noninterrogative SMS text message reminders±social context	At 6 months, interrogative (9.8%; *P*=.002), interrogative-with-social-context (10.3%; *P*<.001), and noninterrogative-with-social-context (9.6%; *P*<.009) messages had greater uptake compared to no messages in control (8.5%).
Hirst et al (2017) [37]	United Kingdom	RCT	Low		CRC screening		

XSL•FO
RenderX

Study	Country	Design	Risk of bias	Sample	Targeted preventive care service	Simple intervention description	Change in preventive service uptake
				176,231 participants, 43.5% aged 60 - 70+ years, 53% women, 51% White.		• Comparison: Usual care • Intervention: SMS text message reminders	Uptake was 40.5% in the intervention group and 39.9% among controls. Uptake did not differ significantly between groups of older adults (aOR 1.03, 95% CI 0.94 - 1.12; *P*=.56) but did vary for first-time invitees (uptake 40.5% in intervention vs 34.9% in the control group; aOR 1.29, 95% CI 1.04 - 1.58; *P*=.02).
Hurley et al (2018) [38]	United States	Pragmatic RCT	Low	8269 participants, median age 66 years, 52% women; ethnicity not reported.	Influenza or tetanus, diphtheria, acellular pertussis vaccine	• Comparison: Usual care • Intervention: Up to 3 reminders or recalls	The intervention was associated with receipt of any needed vaccine in the adults aged ≥65 years (aOR 1.15, 95% CI 1.02 - 1.30).
Jiang et al (2022) [39]	China	RCT	Low	15,769 total participants, 616 aged 65+ years, 63.3% women; ethnicity not reported.	Influenza vaccination	• Comparison: No intervention • Intervention: Video-led educational intervention	Intervention group more willing to receive influenza vaccination than control group (64.6% vs 51.4%; *P*<.05). Vaccination uptake rate was higher in the intervention group (10.3% vs 3.4% among controls; OR 3.23, 95% CI 1.25 - 8.32; *P*<.001).
Lieu et al (2022) [40]	United States	RCT (3 arm)	Low	8287 participants not receiving the vaccine after prior outreach, average age 72.6 (SD 7) years, 56% women 100% Black or Latino.	COVID-19 vaccinations	• Comparison: Usual care • Intervention: Electronic and/or mail outreach from the provider with or without culturally tailored content	Higher COVID-19 vaccination rates for intervention with cultural content versus usual care (24% vs 21.7%; aHR[m] 1.22, 95% CI 1.09 - 1.37), and for primary care provider outreach without cultural content (23.1% vs 21.7%; aHR 1.17, 95% CI 1.04 - 1.31).

RenderX

Study	Country	Design	Risk of bias	Sample	Targeted preventive care service	Simple intervention description	Change in preventive service uptake
López-Torres Hidalgo et al (2016) [41]	Spain	RCT (4 arm)	Some concern—self-reported outcome	1129 participants, average age 61.4 (SD 6.6) years, 60.1% women; ethnicity not reported.	CRC screening	• Comparison: No intervention • Intervention: Written, telephone, or face-to-face recommendation of CRC screening	Uptake was 15.4% (OR 2.32, 95% CI 1.23 - 4.37) in the written information group, 28.8% (OR 4.38, 95% CI 2.38 - 8.07) in the telephone information group, and 8.1% (OR 1.26, 95% CI 0.59 - 2.68) in the face-to-face group versus 5.9% in the control group.
Luckmann et al (2019) [42]	United States	RCT (3 arm)	Some concern—unclear description of randomization	30,160 participants, 52.3% aged 60 - 84 years, 100% women, 73% White.	Breast cancer screening	• Intervention letter: Reminder letter only • Intervention reminder: Letter plus reminder call • Intervention counseling: 2 letters and tailored education and MI	Over 4 years, mammography adherence was highest with a reminder call (83%) versus counseling (80.8%) or letter only (80.8%), *P*=.03.
Luque Mellado et al (2019) [43]	Spain	Quasi-experimental study	Moderate concern	2343 participants, 53.4% women; age and ethnicity not fully reported.	CRC screening	• Telephone interview	Participation increased with age for both genders (60 - to 64-year group: OR 1.55, 95% CI 1.35 - 1.78 and 64 - to 69-year group: OR 2.07, 95% CI 1.80 - 2.38).
Modin et al (2023) [44]	Denmark	RCT (9 arm; usual care or 9 electronic letters with designs based on behavioral concepts)	Low	964,870 participants, average age 73.1 (SD 6.2) years, 27.4% had CVD[n], 52% women; ethnicity not reported.	Influenza vaccination	• Comparison: Usual care • Intervention arms: 9 different electronic nudges emphasizing the potential cardiovascular benefits of influenza vaccination	

XSL•FO
RenderX

Study	Country	Design	Risk of bias	Sample	Targeted preventive care service	Simple intervention description	Change in preventive service uptake
							Influenza vaccinations were received by 83.1% of participants with CVD versus 79.2% of participants without CVD (*P*<.001). Compared with usual care, a letter intervention increased vaccination rates for those with (absolute difference,+0.60 percentage points; 99.55% CI –0.48 to 1.68) and without CVD (+0.98 percentage points; 99.55% CI 0.27 - 1.70; *P* for interaction .41). Only the repeated letter strategy with a reminder follow-up letter 14 days later was effective in increasing influenza vaccination, irrespective of CVD.
Regan et al (2017) [45]	Australia	RCT	Low	12,354 total participants, 3613 aged 65+ years, 52.6% women, 48.6% non-Indigenous.	Influenza vaccination	• Comparison: No reminder • Intervention: SMS text message reminders	For those ages 65+ years, 20.5% in the intervention group versus 15.8% in the control group were vaccinated (absolute difference +4.7; RR[o] 1.26, 95% CI 1.10 - 1.45; NNT[p] 21).
Sepucha et al (2023) [46]	United States	RCT	Some concern—not all intervention participants received decision coaching	800 participants, average age 60 (SD=8) years, 53% women, 73% White.	CRC screening	• Comparison: Usual care • Intervention: Decision aids for shared decision-making (SDM) and decision coaching	Intervention respondents reported higher SDM scores (mean difference 0.7; 95% CI 0.4 - 0.9; *P*<.001) and less decisional conflict than controls (−21%; 95% CI −35% to −7%; *P*=.003).
Szilagyi et al (2020) [47]	United States	RCT (4 arm)	Low		Influenza vaccination		

XSL•FO
RenderX

Study	Country	Design	Risk of bias	Sample	Targeted preventive care service	Simple intervention description	Change in preventive service uptake
				164,205 participants, 18.7% aged 65+ years, 58% women, 57% White.		• Comparison: No portal reminder • Intervention arms: Patient portal reminders provided one, two, or three times	The adjusted risk ratio for influenza vaccination among individuals aged 65 years and older was 0.97 (95% CI 0.92 - 1.02), with no dose response by number of reminders sent for all age groups.
Szilagyi et al (2022) [48]	United States	RCT (6 arm)	Low	196,486 total participants, 29,795 aged >65 years without diabetes, 58.5% women, 56.9% White.	Influenza vaccination	• Comparison: No messages • Intervention arms: Personalized messages (5 types around loss or gain frame) sent by a health system's patient portal or reminder alone	Influenza vaccination rates for older adults were 55.6% with no statistically different vaccination rates for any study group versus control.
Venishetty et al (2023) [49]	United States	Prospective, pragmatic, two-arm intervention study	Low	344 participants, average age 60.1 (SD 5.5) years, 68% women, 89% White.	CRC screening	• Comparison: Mailed FIT kit and follow-up call • Intervention: Mailed FIT kits with introductory phone calls by a patient navigator or community health worker; there was variability in FIT kits distributed by health clinics	Overall, 25.3% of participants returned the FIT kit. The return rate was higher for the intervention group versus the usual care group (27.8% vs 22.8%; *P*=.003). Participants who received a 1-day sampling kit had a higher return rate (31.3% vs 23.3%).
Vives et al (2024) [50]	Spain	RCT	Low	10,433 participants, average age 60.3 (SD 5.3) years.	Breast cancer screening		

XSL•FO
RenderX

Study	Country	Design	Risk of bias	Sample	Targeted preventive care service	Simple intervention description	Change in preventive service uptake
						• Comparison: Invitation letter+SMS text message reminder • Intervention: SMS text message invitation to mammography with a timed appointment+SMS text message reminder	No difference in the screening participation rate within 12 weeks of the invitation in the SMS text message group (86.6%) and in the letter group (87.3%).
Wang et al (2023) [51]	Hong Kong	RCT	Some concern—self-reported outcome	396 participants, average age 70.2 (SD=4.3) years, 63% women; ethnicity not reported.	Influenza vaccination	• Comparison: Standard online video • Intervention: Chatbot-delivered online intervention tailored to the stage of change once every 2 weeks for 4 sessions	Influenza vaccination rate was higher in the intervention group than the control group at month 6 (50.5% vs 35.3%; *P*=.002).
Wu and Lin (2015) [52]	United States	RCT	Some concern—self-reported outcome	193 participants, 100% women, 100% Chinese American.	Breast cancer screening	• Comparison: Mammography brochure • Intervention: Tailored telephone counseling to personal barriers	For women aged ≥65 years, there was a significant difference in uptake between intervention and control groups (51% vs 25%).

[a]RCT: randomized controlled trial.

Digital tools used included the single or combined use of telephone calls, text messages, patient portal messages, email, and videoconferencing. No studies included a description of digital tool support or training for participants. Under half of the studies (n=9) included a description of the digital intervention's reach (ie, messages opened and calls answered; Table 1).

Range of Interventions

The analysis revealed a wide range of approaches aimed at improving patient engagement and adherence to preventive health screenings and vaccinations. Three main categories of interventions were classified: digital and automated communication, personalized and tailored communication, and in-person interventions supplemented with digital supports.

Digital and Automated Communication Interventions

To increase vaccination and screening rates, 12 studies tested interventions that used automated digital communication tools including electronic health record portal messages, interactive automated calls, automated text messaging, and 1 chatbot-integrated messaging intervention [32,35-38,40,44,45,47,48,50,51]. Across the 12 included trials, most interventions used low-complexity, system-integrated technologies, with a smaller subset relying on simple stand-alone channels (Table 2). Results were mixed, with only 4 interventions demonstrating significant improvements in vaccination or screening rates compared to usual care, as detailed below.

XSL•FO
RenderX

Table . Complexity of technology for digital and automated communication interventions.

Study	Targeted preventive care service	Simple intervention description	Technology	Digital intervention reach	Patient facing complexity
Denis et al (2017) [32]	Colorectal cancer screening	Tailored telephone—computer-assisted counseling or motivational interview	Telephone	33.6% of telephone counseling attempts were technically successful	Low
Ghadieh et al (2015) [35]	Pneumococcal vaccination	Patient reminder system	Telephone, email, or SMS text messages with or without education	2% (121/6,177) SMS transmission failures	Low
Hagoel et al (2016) [36]	Colorectal cancer screening	SMS text message reminders	SMS text messages	Not specified	Low
Hirst et al (2017) [37]	Colorectal cancer screening	Text message reminders	Text message	Mobile phone coverage varied by demographics: 42.7% - 53.3% had registered numbers; 73.4% (1,023/1,393) successfully received text reminders	Low
Hurley et al (2018) [38]	Influenza or tetanus, diphtheria, acellular pertussis vaccine	Centralized reminder or recall	Telephone	Not specified	Low
Lieu et al (2022) [40]	COVID-19 vaccinations	Electronic and/or mail outreach from provider with or without culturally tailored content or usual care	Electronic secure messages	Not specified	Moderate
Modin et al (2023) [44]	Influenza vaccination	Electronic nudges emphasizing potential cardiovascular benefits of influenza vaccination	Electronic letters	Not specified	Low
Regan et al (2017)[45]	Influenza vaccination	SMS text message reminders	SMS text messages	75.5% of eligible patients had mobile phone numbers in the EMR[a]	Low
Szilagyi et al (2020) [47]	Influenza vaccination	Patient portal reminders provided 1, 2, or 3 times or none (control)	Online patient portal messages	52.9% to 58.8% of intervention participants opened at least 1 portal reminder	Moderate
Szilagyi et al (2022) [48]	Influenza vaccination	Personalized messages (5 types around loss or gain frame) sent by a health system's patient portal or reminder alone	Online patient portal messages	Not specified	Moderate
Vives et al (2024) [50]	Breast cancer screening	SMS text message invitation to mammography with a timed appointment	SMS text message	Not specified	Low
Wang et al (2023) [51]	Influenza vaccination	Chatbot-delivered online intervention tailored to the stage of change once every 2 weeks for 4 sessions or standard online video	Chatbot-delivered online intervention	Text messages failed to be delivered to 92 (1.7%) women in intervention	Low

[a]EMR: electronic medical record.

Of the 4 studies aimed at cancer screening, only 1 significantly improved uptake compared to usual care. Hagoel et al [36] conducted a randomized experiment comparing 4 text messages with different theory-based content to no messages (control)

XSL•FO
RenderX

and found that 3 of the 4 messages significantly increased colorectal cancer screening rates compared to the control. Conversely, 2 interventions that used reminders, text messages [37], or phone calls [32], along with mailed Fecal Immunochemical Test (FIT) kits, found no difference in intervention groups compared to usual care (FIT kit plus 1 reminder letter). A breast cancer screening intervention found no difference between text message (intervention) and letter (control) invitations [50].

In 5 studies aimed at increasing seasonal influenza vaccination uptake rates, only marginal increases were observed. Even when increases were observed, absolute increases from baseline for different automated letters were small (0.73 and 0.89 percentage points, respectively) [44]. In the 2 studies examining generic reminders through a patient portal or via text messages, only marginal, nonsignificant increases in vaccination rates were found from baseline [45,47]. Another large-scale study used reminder messages sent through the health system patient portal, tailored to the health belief model loss or gain framework, to promote influenza vaccination uptake [48]. They similarly reported no significant increase in vaccination rates among older adults compared to generic digital reminders [48]. However, in 1 theory-based intervention that used a chatbot to deliver promotional videos corresponding to stages of change theory compared to generic messages, investigators found a significant between-group difference in vaccination rates at 6 months (50% of the intervention group vs 35% of the control group; P=.002) [51].

In total, 3 studies that examined interventions designed to increase the uptake of vaccinations showed small but statistically significant increases. One study compared 3 different reminder modalities to encourage pneumococcal vaccination: a standardized phone call reminder from a nurse, text messaging, or email [35]. Vaccination rates increased from 17.2% to 20.4%, with the largest uptake observed in the phone call group (16.5%), compared to text messaging (7.2%) and email (5.7%) [35]. Hurley et al [38] used a centralized vaccine reminder system for pneumococcal, tetanus, and influenza vaccinations, with the intervention group receiving up to 2 auto-dial phone calls followed by a postcard. Findings showed a significant increase in receiving any of the 3 targeted vaccines in the intervention arm (33.2%) compared with no centralized reminders (29.8%; odds ratio [OR] 1.20, 95% CI 1.06-1.36; P≤.01) [38]. Similarly, receiving either culturally tailored or standard electronic messages from primary care providers modestly increased COVID-19 vaccination uptake compared to no outreach from primary care providers (24% and 23.1% vs 21.7%; P<.01) [40].

Personalized and Tailored Communication Interventions

In total, 7 interventions examined tailored telephone calls to promote preventive services uptake [30,41-43,46,49,52]. Across the 7 interventions, most interventions used low-complexity approaches, primarily relying on manual telephone contact (Table 3). Only 4 of the tailored telephone interventions demonstrated statistically significant improvements in screening rates over usual care.

3 of the studies evaluating tailored or reminder-based interventions found largely nonsignificant improvements in screening uptake overall, though some age-related differences were reported. In one study, investigators used results from a baseline survey on knowledge and barriers to mammography to tailor messages to participants [52]. At the 4-month follow-up, although nonsignificant differences were found among younger participants, older women in the intervention group had significantly higher rates of obtaining a mammogram compared to controls (51% vs 25%) [52]. Luckmann et al [42] compared 2 interventions to a comparison group: a reminder letter with multiple reminder calls or reminder calls with tailored counseling, compared with only a reminder letter. Absolute difference in mammography adherence in the reminder call only intervention group compared to the other arms increased significantly in the 50 to 74 years age range by 3.3% but not in the 75 to 84 years age range [42]. However, the change in mammography adherence from baseline was not significant in either age group for either trial arm [42]. Another intervention to increase colorectal screening compared structured telephone calls after 2 reminder letters to no telephone call [43]. Although overall screening participation was 54.9%, and screening adherence was higher in older age groups than in younger ones (Table 1), there was no between-group difference [43].

Table . Complexity of technology for personalized and tailored communication interventions.

Study	Targeted preventive care service	Simple intervention description	Technology	Digital intervention reach	Patient-facing complexity
Basch et al (2015) [30]	Colorectal cancer (CRC) screening	CRC print education material, academic detailing to primary care providers, and targeted telephone education for patients	Printed brochures +telephone calls (staff-delivered)	Median 5 calls per patient	Low
López-Torres Hidalgo et al (2016) [41]	CRC screening	Written information, telephone call, or face-to-face meeting delivering CRC screening information; control group received no information	Telephone (voice call)	Not specified	Low
Luckmann et al (2019) [42]	Breast cancer screening (mammography)	Call with tailored education and motivational interviewing (MI)	Telephone (voice call)	Only 23.5% of women were reached and accepted MI	Low
Luque Mellado et al (2019) [43]	CRC screening	Structured telephone interview (scripted calls) to nonresponders after first invitation round	Telephone (voice call)	68.8% (1614/2343) contact rate	Low
Sepucha et al (2023) [46]	CRC screening	Telephone decision-coaching call	Telephone (voice call)	54% (214/399) of intervention arm reached by decision coaches	Low
Venishetty et al (2023) [49]	CRC screening	Mailed FIT[a] kits with introductory phone calls by a patient navigator or community health worker; there was variability in FIT kits distributed by health clinics	Telephone	Not specified	Low
Wu and Lin (2015) [52]	Breast cancer screening	Tailored messages to personal barriers	Telephone	Not specified	Low

[a]FIT: Fecal Immunochemical Test.

In contrast to the largely clinically nonsignificant results, 4 of the studies reported significant differences. Basch et al [30] supplemented print education materials with tailored telephone calls aimed at identifying and addressing colorectal screening barriers and encouraging follow-up with a primary care provider. Among those aged 60+ years who had visited a primary care provider during the intervention period, the intervention group was almost 5 times more likely to receive screening compared to print education material alone (36.4% vs 7.7%; χ^2_1=7.3; *P*=.01) [30]. Similarly, Venishetty et al [49] compared usual mailed FIT kits with an introductory phone call from a patient navigator, who introduced them to the program and its contents. The return rate for the usual care plus introductory call arm was significantly higher (27.8%) than that for the usual care arm (22.8%; *P*=.003) [49]. Another intervention on colorectal cancer screening found that a decision worksheet paired with a call from a decision coach significantly improved screening rates [46]. Despite only half (54%) of the intervention group having been reached by the decision coach, the intervention arm had higher screening rates than the control arm (35% vs 23%; *P*<.001) [46]. Another intervention compared written, telephone, and face-to-face tailored communication with a control group to improve colorectal cancer screening [41]. Interestingly, both written information and telephone communication, but not face-to-face communication, showed significantly greater screening uptake compared to the control group (Table 1) [41].

In-Person Interventions Supplemented With Digital Supports

In total, 4 interventions supplemented in-person preventive care education with digital tools [31,33,34,39]. Across these 4 trials, technology use was uniformly simple, with only 2 studies extending into low-moderate complexity (Table 4). In their study, Chan et al [31] found a 3-minute brief health education telephone intervention approximately 1 week before a 3-minute face-to-face health education intervention during participants' medical appointments increased vaccination uptake by 57% compared to the 9% increase for the control group that received standard of care (promotional leaflets and poster displays). A 3-modal intervention study found that compared to mass-mailing, an in-person conversation was the most effective (OR 24.63, 95% CI 19.28 - 31.46), followed by a telephone

XSL•FO
RenderX

one-on-one conversation (OR 14.74, 95% CI 10.96 - 19.82) [34]. A comparison study of a video-based intervention for influenza vaccination supplemented with a 15-minute small group in-person discussion with medical students, delivered in health care centers to older adults, improved vaccination uptake (10.3% increase in the intervention group and 3.4% in the control group; Table 1) [39]. Conversely, a tablet-delivered, tailored interactive multimedia intervention delivered in person by a lay health worker that provided individualized information based on participant responses did not increase colorectal cancer screening uptake compared with a small-media print intervention or no intervention [33].

Table . Complexity of technology for in-person interventions supplemented with digital supports.

Study	Targeted preventive care service	Simple intervention description	Technology	Digital intervention reach	Patient facing complexity
Chan et al (2015) [31]	Pneumococcal vaccination	Brief health-education telephone intervention (3 minutes) delivered by nurses before and during the clinic visit	Telephone (voice call)	Not specified	Low
Fernández et al (2015) [33]	CRC[a] screening	Tailored interactive multimedia intervention delivered on a tablet computer	Tablet-based interactive program	Not specified	Low-moderate
Fleming et al (2018) [34]	CRC screening	One-on-one conversations (in clinic, telephone, or recorded message) to promote FIT[b] completion	Telephone (voice call)	Not specified	Low
Jiang et al (2022) [39]	Influenza vaccination	Video-led educational intervention	Educational video	Not specified	Low

[b]FIT: Fecal Immunochemical Test.

Use of Theory

Of the 23 studies, 9 incorporated theoretical frameworks into their intervention development or design. These studies applied a variety of behavioral theories that focused on intentions, beliefs, motivations, readiness, economics, stages of change, and osteopathic principles. The primary purpose of using theory in the design of interventions was to inform the content and framing of messages (Table 5). Among these studies, 6 of 9 reported significant increases in uptake in the intervention groups, with 3 demonstrating clinically important differences. In contrast, only 4 of 13 atheoretical studies reported a statistically significant increase in preventive care uptake.

XSL•FO
RenderX

Table . Use of theory.

Author (year)	Theory	Theory use	Intervention development description
Fernandez et al (2015) [33]	Fishbein's integrated model of behavior change	Message content and framing	The study used behavioral theory to identify psychosocial factors influencing colorectal cancer (CRC) screening, which were then targeted in intervention, select behavior change methods, and develop tailored messages or content.
Fleming et al (2018) [34]	Osteopathic principles	Intervention delivery	The study applied osteopathic principles by designing the intervention to integrate patients as partners in their own care through one-on-one conversations, education, and motivational strategies.
Hagoel et al (2016) [36]	Question-behavior effect	Message framing	The 4 base intervention messages (reminders for CRC screening) were manipulated in terms of grammatical form (interrogative vs noninterrogative) and social context reference (yes or no).
Lieu et al (2022) [40]	Behavioral science	Message content	Outreach messages were crafted using behavioral science principles, including social proof, loss aversion, and authority figures.
Luckmann et al (2019) [42]	Precaution adoption process model	Message content and framing	The intervention counselors assessed which of the 5 stages of readiness each woman occupied: unaware, decided against, undecided, planning, or scheduled. Based on this, they delivered scripted and tailored education to specifically address her stage and encourage timely mammograms.
Szilagyi et al (2020) [47]	Health belief model	Message content	The development of portal reminder letter content drew on the health belief model to target key psychological drivers of vaccination, used health literacy principles to create accessible messages, applied behavioral economics to enhance motivation, and integrated patient or expert feedback to optimize content.
Szilagyi et al (2022) [48]	Health belief model	Message content and framing	The portal messages were structured following the health belief model, which focuses on individuals' perceptions about health risks (like susceptibility to influenza), perceived benefits of action (vaccination), perceived barriers, and cues to action. Messages were also modeled on precommitment and gain-loss. Precommitment messages asked patients if they planned to get the influenza vaccine, aiming to increase the likelihood of follow-through. Gain-loss messages were crafted to emphasize either the positive outcomes of vaccination (gain frame) or the negative outcomes of not vaccinating (loss frame).

XSL•FO
RenderX

Author (year)	Theory	Theory use	Intervention development description
Wang et al (2023) [51]	Transtheoretical model—stages of change (SOC)	Message content and framing	The intervention started with a chatbot assessment of each participant's stage of change regarding their intentions and plans to receive the vaccine. Participants then received a video tailored to their SOC every 2 weeks for 4 sessions. Their SOC was reassessed each time, allowing the intervention to stay relevant as their readiness evolved.
Wu and Lin (2015) [52]	Health belief model	Message content and framing	The telephone counseling protocol systematically began by assessing each woman's stage of mammography readiness using health belief model constructs (perceived susceptibility, perceived benefits, and perceived barriers), then delivered messages and action steps aligned with her specific needs and beliefs.

Discussion

Principal Findings

Overall, the findings from this review demonstrate that digital interventions for promoting preventive screenings and vaccinations in older adults yield mixed results, with effectiveness varying widely depending on the intervention. While certain strategies showed substantial improvements in uptake, the majority of digital or automated reminders (eg, generic text messages and portal alerts) resulted in only marginal or no increases in screening and vaccination rates.Among the interventions reviewed, those incorporating personalized elements, such as tailored telephone counseling or supplementary in-person education, were consistently more effective than impersonal, automated communications. This suggests that while automation can facilitate uptake, human interaction remains critical for promoting preventive health behaviors in older adults.

Personalization of Digital and Automated Interventions

Digital and automated communication tools, used in nearly half of the studies, can yield statistically significant improvement in uptake of preventive services among older adults. Older adults appear to respond well to generic approaches that notify and send reminders regarding their preventive activities and screenings. However, the effectiveness of simple, generic reminders is generally limited. These outcomes align with earlier systematic reviews and behavior change literature, which also report modest behavior change impacts from brief digital interventions, especially when applied generically to the older adult population [53].

Evidence from this work suggests that interventions incorporating personalized elements, such as tailored telephone counseling or supplementary in-person education, are generally more effective than impersonal, automated communications. This echoes findings from studies on preventive services and digital health adoption, which suggest that human interaction, particularly when delivered by a trusted source, such as a primary care provider, is a critical facilitator of successful behavioral change in older adults [54,55]. The preference for messages from known, trusted sources and for personalized content reflects broader trends in health communication and aligns with user preference studies, which show higher acceptability for content that has a connection to both their care and provider [56,57]. Further, studies have identified the personalization of messages to be an important condition for patient engagement [56,57].

Despite the importance of tailoring interventions to the user's context and to engage them effectively [58], there are challenges related to personnel cost, time, and effort with this approach. However, emerging evidence suggests that artificial intelligence (AI) may offer scalable solutions by automating personalization and tailoring at a scale for low cost [59]. One opportunity, such as AI chatbots, is able to automate interactions while also simulating interactive and empathic dialogue [60,61]. Chatbots trained with motivational interviewing techniques have shown promise in supporting smoking cessation [60,62], addressing vaccine hesitancy [61], and promoting behavior change [63]. However, AI-driven personalization carries important limitations and risks: models can amplify existing biases and worsen inequities if trained on unrepresentative data, produce clinically inaccurate or outdated recommendations without continuous validation, and generate "black box" outputs that are difficult to interpret or explain [64]. Additional research is needed to evaluate the comparative effectiveness, acceptability, and ethical implications of AI-based personalization in diverse populations.

Technology Complexity and Appropriateness

The appropriateness of digital health interventions for older adults is strongly influenced by technology complexity, digital literacy, and the availability of support [65]. While most studies included had low complexity, a consistent limitation across moderately complex digital interventions was the lack of attention to training needs, technical support, or onboarding required for older adults to effectively use digital health platforms such as patient portals, SMS text message reminders,

XSL•FO
RenderX

or email notifications. The assumption of a baseline digital fluency may inadvertently perpetuate ageism and disadvantage those with weaker digital skills, compounding barriers to access and potentially widening health disparities [15]. Studies that evaluated engagement metrics frequently reported low rates of message opening or system use, with only about half of older adult recipients successfully engaging with portal messages or receiving SMS text message reminders, highlighting a significant constraint on the intervention's reach. One recent survey has shown that while many older adults prefer patient portals and email, substantial proportions still rely on traditional methods (hospital websites and telephone calls), with significant numbers excluded by digital-only approaches, especially those aged 75+ years [55]. However, there is an increasing demand for patient portal communication in the population aged 65+ years [66]. This suggests that multimodal, accessible communication is critical for maximizing engagement in older populations.

Use of Theory

Notable in the digital health intervention studies included in this review was the use of theory in intervention design. Approximately half of the included studies explicitly referenced theory, most commonly behavior change, primarily to inform the content and framing of message delivery. While theory use was described in 9 studies, the depth of integration in intervention design is not explicit in all study descriptions. This is similar to critiques raised in a related cardiovascular preventive care research study, where the rigor and depth of theory application were often unclear or inadequately reported, making it difficult to determine whether theory guided the overall intervention architecture or was limited to message wording [67]. This risk of "surface-level" use of theory, where theoretical constructs inform only minor aspects, such as phrasing or framing, rather than the full intervention pathways, has been documented as an ongoing issue in behavioral health research [68,69]. Fewer than half of published behavior change interventions explicitly cite a guiding theory, making it difficult to determine how theory actually contributed to intervention outcomes. The use of theory to guide the studies would have afforded greater explanatory value to the findings, in particular, offering insights into the largely mixed findings that were observed.

Limitations

This review has several limitations that warrant consideration. The diversity of study designs, populations, and intervention types prevented meta-analysis, and findings were instead synthesized narratively. While this approach allowed for exploration of patterns across varied contexts, it limits the ability to quantify pooled effects. Data extraction was conducted by a single reviewer and verified by 2 others, which may introduce bias, as dual independent extraction is considered best practice [21]. Many studies lacked consistent control or comparison groups, and several used complex, multicomponent interventions, making it difficult to isolate the contribution of individual digital modalities. Although all included studies had a mean age of at least 60 years, many were not specifically designed for older adults and also targeted younger age groups. Finally, the review was limited to peer-reviewed, English-language publications, which may have excluded relevant findings from non-English–speaking regions.

Conclusions

While digital communication tools can support modest increases in preventive care uptake among older adults, their effectiveness appears to depend on the degree of personalization. This systematic review's findings highlight that automation alone may be insufficient and that interventions facilitating patient engagement or combining digital outreach with practical supports may be more likely to achieve meaningful improvements in screening and vaccination rates.

Acknowledgments

The authors are grateful for the screening and data extraction support from Sofia Knopf, Mayuran Thavaraj, and Victor Wang. The authors thank Dr. Kristen Haase and Dr. R. Colin Reid for proofreading and editorial review.

Abstract

Background: Falls are prevalent and serious health problems among older adults. Concerns about falling and reduced falls efficacy are common fall-related psychological impairments, representing 2 distinct emotional and cognitive constructs, respectively. The impact of digital-based exercise interventions on these specific constructs remains unclear.

Objective: This systematic review and meta-analysis aimed to synthesize current evidence on digital-based exercise interventions for concerns about falling and falls efficacy among older adults, with a specific focus on determining their differential effects on emotional and cognitive constructs and evaluating their impact on physical performance.

Methods: The PubMed, Web of Science, Cochrane Library, Embase, PsycINFO, CINAHL, CNKI, SinoMed, VIP, and Wanfang databases were systematically searched from their inception dates to May 2025. We searched for published randomized controlled trials on the effects of digital-based interventions on the fear of falling, concerns about falling, and falls efficacy among older adults. The study followed PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines and was performed using Stata 17.0 software (StataCorp LLC).

Results: Eighteen studies involving 2435 participants were included. Meta-analyses revealed significant effects of digital-based exercise interventions on falls efficacy (standardized mean difference 0.70, 95% CI 0.51-0.90; *P*<.001), balance function (mean difference [MD] 4.03, 95% CI 2.57-5.49; *P*<.001), functional mobility (MD −1.65, 95% CI −2.52 to −0.77; *P*<.001), and physical function (MD 0.57, 95% CI 0.12-1.02; *P*=.006) among older adults. However, digital-based exercise interventions had no significant effect on concerns about falling, which is the emotional construct related to falls (standardized MD −0.12, 95% CI −0.28 to 0.05; *P*>.05).

Conclusions: The meta-analysis assessed the efficacy of digital-based exercise interventions on fall-related psychological impairments among older adults and revealed that the effects differed across the constructs. These findings suggest that digital-based exercise interventions have potential benefits for improving falls efficacy and physical performance among older adults compared with controls. However, the effect of digital-based exercise interventions on concerns about falling, which is the emotional construct related to falls, remains uncertain among older adults.

KEYWORDS

digital-based; meta-analysis; older adults; concerns about falling; falls efficacy

Introduction

Falling is a prevalent and serious geriatric problem that affects approximately 52% of older adults worldwide [1,2]. The 2022 World Falls Guidelines recommend incorporating the assessment of concerns about falling into multifactorial risk assessments for fall prevention and management [3]. Such fall-related psychological impairments cannot simply be classified as post-fall syndrome, as they can occur in older adults who have never fallen [4]. Instead, they constitute the central mechanism driving the vicious cycle of falls [5,6]. These psychological impairments not only heighten the risk of physical injuries but also impose a significant psychological burden, manifesting as anxiety, depression, and frailty [7-10], and substantially compromise the overall quality of life of older adults. Moreover, the increased risk of falls and related complications can lead to higher mortality rates in older adults [11]. Effective intervention strategies are urgently needed given these profound implications.

XSL•FO
RenderX

To develop effective interventions, a precise understanding of fall-related psychological impairments is crucial. Common fall-related psychological factors include fear of falling, falls efficacy, concerns about falling, and balance confidence, among others [12-14]. Despite the frequent interchangeable use of these terms, they represent different psychological processes with different predictive values for falls [15]. Fear of falling and concerns about falling are both emotional constructs [16]. The former refers to an individual's emotional response to a real or perceived threat to balance, whereas the latter manifests as a persistent state of worry [17]. On the other hand, falls efficacy and balance confidence are classified as cognitive constructs, primarily referring to an individual's belief in their own ability or confidence in performing activities without falling. Furthermore, balance confidence is closely related to falls efficacy and is regarded as an important dimension of it [18]. Therefore, we use falls efficacy as an umbrella term to encompass the specific construct of balance confidence. This distinction is methodologically and clinically critical because concerns about falling predict future falls, whereas falls efficacy does not [15]. Combining them in meta-analyses dilutes their unique effects and may be a key source of heterogeneity, potentially obscuring the true efficacy of interventions. Distinguishing between them in research is crucial to avoid this bias and to reveal the specific effects of interventions on different constructs.

Owing to rapid advancements, digital technologies have been increasingly applied to exercise and health management for older individuals. Digital technologies are defined as the use of a series of computing platforms, software, internet-connected devices, and sensors for health care and related purposes, including wearable devices, virtual reality (VR), mobile health apps, and web-based communication platforms [19,20]. Digital-based exercise intervention refers to exercise interventions that use digital technologies to prevent, manage, and treat diseases or promote health. While traditional face-to-face interventions, such as group exercise and physical therapy, have demonstrated efficacy in improving physical function [21-23], they present challenges, including temporal and spatial constraints, health care resource disparities, and high costs [19]. Digital-based exercise interventions may offer novel solutions to these limitations through remote accessibility and automated personalization [24].

While several systematic reviews have investigated interventions for concerns about falling or falls efficacy [12,14], important distinctions set our work apart. First, previous reviews, while covering a broad range of interventions, have not provided a dedicated synthesis of digital-based exercise interventions [12-14]. Our review is distinguished by its exclusive focus on digital interventions and the inclusion of trials up to 2025. This is particularly necessary in the rapidly advancing field of digital interventions, such as those based on VR and smartphone apps, ensuring that our synthesis is current and comprehensive. Second, many syntheses of evidence share a methodological limitation in treating the fear of falling, concerns about falling, or falls efficacy as a single, homogeneous construct [25-27]. This approach contributes to significant heterogeneity and inconsistent findings across systematic reviews, as it fails to capture the differential effects of interventions on cognitive and emotional constructs. To address this, our study explicitly distinguishes cognitive constructs, such as falls efficacy, from emotional constructs, such as concerns about falling. This strategy allows us to reveal the specific intervention effects on each construct, thereby advancing the understanding of their distinct mechanisms in digital-based exercise interventions. Finally, while some reviews have focused on adults of broader ages [28-31], our precise targeting of older adults is designed to yield conclusions with greater specificity and clinical applicability for geriatric care.

This systematic review and meta-analysis aimed to (1) provide an updated synthesis of digital-based exercise interventions for concerns about falling and falls efficacy, (2) determine their specific effects on each distinct construct (cognitive and emotional), and (3) evaluate their impact on physical performance.

Methods

The study protocol was registered in PROSPERO (CRD42024567108), and the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines (Checklist 1) were followed [32].

Search Strategy and Study Selection

The PubMed, Web of Science, Cochrane Library, Embase, PsycINFO, CINAHL, CNKI, SinoMed, VIP, and Wanfang databases were systematically searched for relevant publications. The search terms included Medical Subject Headings (MeSH) and free words related to digital-based interventions, older adults, fear of falling, concerns about falling, falls efficacy, and randomized controlled trials (RCTs). The search terms were combined using Boolean operations. There were no restrictions on the language of the publications. The search period ranged from database inception to May 2025 (the specific search strategies are presented in Multimedia Appendix 1).

Study selection and data extraction were performed independently by 2 researchers. All the retrieved studies were imported into EndNote X20 software (Clarivate) for screening, and duplicate studies were automatically removed by the software. The researchers read the titles, abstracts, and full texts of the studies and subsequently removed studies that did not meet the inclusion criteria. After the study selection was completed, two researchers cross-checked the screening results. Any disagreements were resolved through discussion with a third researcher.

Eligibility Criteria

Inclusion Criteria

The inclusion criteria are summarized in Textbox 1.

XSL•FO
RenderX

Textbox 1. Inclusion criteria

- Population: older adults (aged ≥60 y)
- Interventions: participants in the intervention group underwent an exercise intervention that was delivered via digital technologies (wearable devices, exergaming, virtual reality, mobile health apps, and web-based communication platforms).
- Comparison: no digital-based exercise intervention was used in the control group, which included active controls (motor exercise, balance exercise, rehabilitation exercise, and health education) and passive controls (no intervention or maintenance of normal daily living).
- Outcomes**:** studies reporting at least one of the following outcomes.
  - Primary outcome: concerns about falling or falls efficacy included as reported in the original studies, whether as a primary or secondary outcome. Concerns about falling was measured by validated scales (Falls Efficacy Scale–International, Icon-Falls Efficacy Scale, and Short Falls Efficacy Scale). Falls efficacy was measured by validated scales (Falls Efficacy Scale, Activities-Specific Balance Confidence Scale, and Modified Falls Efficacy Scale).
  - Secondary outcome: physical performance included measures of balance (Berg Balance Scale), functional mobility (Timed Up and Go Test), and physical function (Short Physical Performance Battery).
- Study design: randomized controlled trial

Exclusion Criteria

We excluded studies that focused primarily on individuals diagnosed with dementia, duplicate studies, studies with unavailable full texts or important data, meeting abstracts, study protocols, studies without treatment details or primary outcomes, pilot studies, and feasibility trials.

Data Extraction

Two researchers independently extracted data from the complete original studies using a uniform data extraction template. The data extracted included the author's name, country, year of publication, study population, age, sex, sample size, intervention, control, intervention period, duration of intervention, frequency of intervention, outcome indicators, end values in the control and intervention groups, and evaluation tools for the outcome indicators. Any discrepancies between the initial disagreements were first discussed between the 2 researchers until a consensus was reached. If an agreement could not be reached, the disagreement was referred to a third, senior researcher for adjudication and a final decision.

Assessment of the Risk of Bias and Certainty of the Evidence

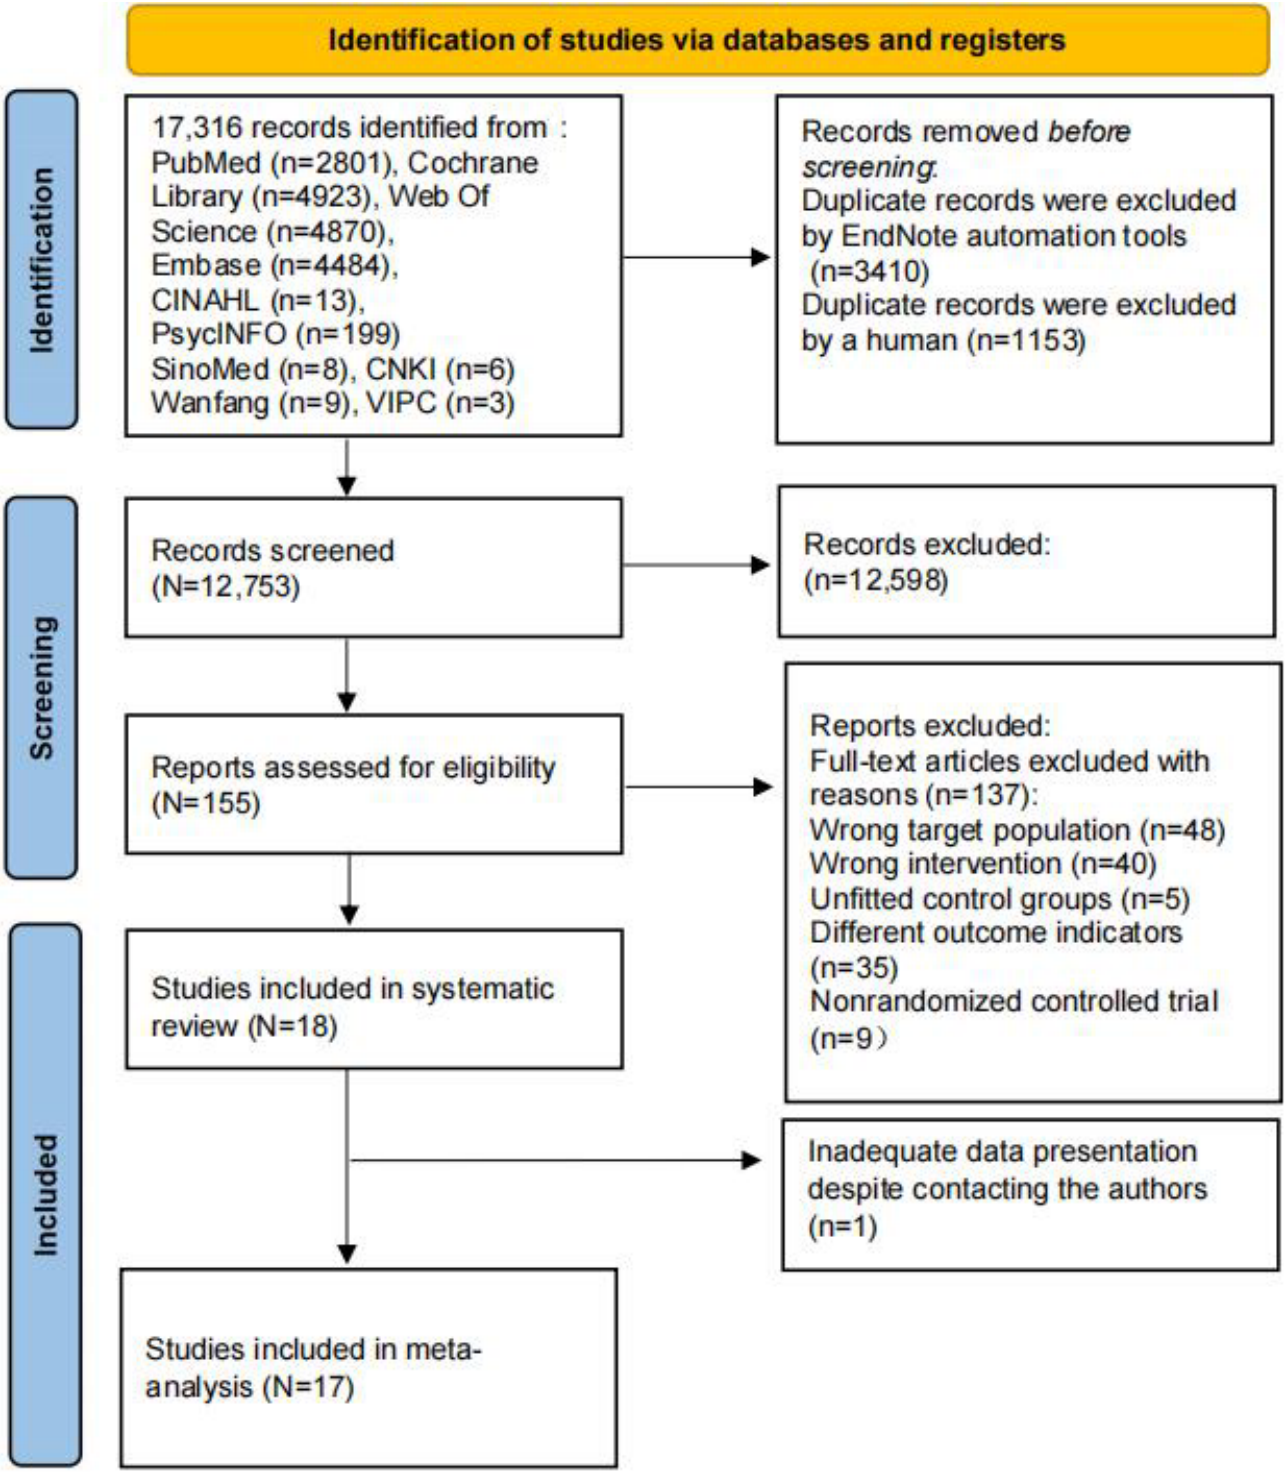
An independent appraisal of the risk of bias for each included study was performed by 2 investigators who used the Cochrane Risk of Bias 2 (RoB2) instrument. The appraisal covered 5 predefined domains: randomization procedure, deviations from intended interventions, missing outcome data, measurement of the outcome, and selection of the reported result. On the basis of the assessments across these domains, the researchers subsequently assigned an overall risk judgment of "low risk," "some concerns," or "high risk" to each included study.

We evaluated the certainty of the evidence using the Grading of Recommendations Assessment, Development, and Evaluation (GRADE) Profiler Guideline Development Tool. In accordance with the GRADE system, the certainty of evidence for each outcome was classified as high, moderate, low, or very low. Any disagreements were referred to a third researcher for adjudication.

Data Analysis

Statistical analysis was conducted using Stata 17.0 (StataCorp LLC). The outcome indicators were continuous variables, and effect sizes were expressed as the means and SDs combined with 95% CIs to report the results of the continuous variable data analysis. For continuous variables, the mean difference (MD) was selected when the same outcome indicator was measured on the same scale; otherwise, the standardized mean difference (SMD) was adopted. Between-group heterogeneity of synthetic effect sizes was tested using the I^2 statistic and P value. Random-effects models were used for the meta-analysis because of anticipated heterogeneity. To further explore the factors influencing the intervention, additional subgroup analyses were performed on the basis of the setting, intervention qualifications, intervention duration, exercise mode, digital platform, duration of the intervention, exposure dosage, and scale-scoring method. Reverse scoring scale–converted data (mean x−1, with the SD unchanged) were included in the analysis alongside positive scoring scale data to improve the accuracy and reliability of the results. For multiarm RCTs, this review included only comparisons that involved an eligible digital-based exercise intervention group and a control group. In the meta-analysis, each trial contributed only one comparison pair to prevent double-counting of control group data. To assess the robustness of the combined effect sizes, sensitivity analyses were performed using a remove-one-article method. For outcomes with data from more than 10 studies, publication bias was assessed via funnel plots [33]. The Egger test [34] and the Begg test [35] were used to further assess publication bias.

Results



Search Results

In total, 17,316 articles were retrieved from 10 databases; 3410 duplicates were removed by EndNote X20 software, and 1153 duplicates were removed manually. A total of 12,598 articles were excluded because their titles and abstracts were not relevant to the aim of the study. After the full texts were reviewed, 137 studies were excluded. Ultimately, 18 studies [36-53] were included in this study. One study [44] was excluded from the quantitative synthesis because of inadequate data presentation

XSL•FO
RenderX

despite contacting the authors. Therefore, 17 studies were included in the meta-analysis (Figure 1).

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flow diagram of the search process.

Characteristics of the Studies

The characteristics of the included studies are presented in Table 1. A total of 2435 older adults were included, with average ages ranging from 67.8 (SD 2.98) to 84.1 (SD 5.5) years. The proportion of women varied between 26.7% and 100%. The publication years ranged from 2013 to 2025. These studies were conducted in the following countries: Australia (n=2) [39,51], China (n=3) [40,42,47], Korea (n=2) [36,53], Switzerland (n=1) [49], Spain (n=2) [41,50], Iran (n=1) [45], Singapore (n=1) [37], Italy (n=1) [38], Türkiye (n=1) [46], the Netherlands (n=1) [48], Pakistan (n=1) [43], Chile (n=1) [52], and Brazil (n=1) [44]. The study settings included a range of environments, such as communities [37,41,46,48,51-53], hospitals [38,39,43,44,47,49,50], and nursing homes or welfare centers [36,40,42,45].

The intervention details of the included studies are presented in Table 2. The interventions were primarily delivered by qualified health care professionals [37-40,42-44,48-50], with

XSL•FO
RenderX

physiotherapists being the most common. In other cases, the delivery was managed by trained nonspecialists [36,41,51,52], including research assistants or physical education instructors. However, the specific qualifications of the interveners were not reported in several trials [45-47,53]. The digital-based exercise modes included balance-dominant balance training [38,41,44,45,48,51]; balance-inclusive multimodal training, which combines balance with one or more forms of resistance or aerobic exercise; and nonbalance training dominated by aerobic exercise [52]. Among these, balance-inclusive multimodal training was the most common. Furthermore, predesigned programs such as Baduanjin [42] and the Otago Exercise Program [47] incorporate various elements, including balance, strength, and flexibility, and are classified as balance-inclusive multimodal training. Exergaming [36-41,43-45,51-53] was the most frequently used digital delivery platform for exercise interventions, followed by computer-based applications [46,47,49,50], while only 2 studies [42,48] used VR to provide a virtual environment for exercise. The duration of individual interventions ranged from 30 to 120 minutes per session. The most frequently implemented duration for a single session was 60 minutes. The frequency of interventions ranged from 1 to 5 times per week, and the most commonly prescribed intervention frequency ranged from 2 to 3 times per week. The duration ranged from 2 weeks to 12 months, and the most common duration was 8 weeks.

The outcomes included concerns about falling, falls efficacy, balance, functional mobility, and physical function. A wide variety of measurement scales have been applied among studies. Nine studies [38,40,41,43,48-52] used the Falls Efficacy Scale–International (FES-I) scale, Short Falls Efficacy Scale, or Iconographical Falls Efficacy Scale, which reflect concerns about falling, and 9 studies [36,37,39,42,44-47,53] used the Activities-Specific Balance Confidence Scale, Falls Efficacy Scale, or Modified Falls Efficacy Scale (MFES), which reflect balance confidence or falls efficacy. Among the included studies, the MFES and Activities-Specific Balance Confidence Scale are positive scoring scales, where higher scores indicate greater falls efficacy. In contrast, the Falls Efficacy Scale is a reverse scoring scale, meaning that higher scores reflect lower falls efficacy. The FES-I, Short Falls Efficacy Scale, and Iconographical Falls Efficacy Scale also follow a positive scoring direction, but in their case, higher scores indicate a greater level of concerns about falling. The Berg Balance Scale [36,38,45,47,52,53], Timed Up and Go Test [36,37,40,43,45,47,49,51-53], and Short Physical Performance Battery [39,46,49-51] were used to evaluate balance, functional mobility, and physical function, respectively. Only 3 out of the 18 (16.7%) included studies [37,43,47] reported concerns about falling or falls efficacy as their primary outcome. Seven (38.9%) studies [39,40,44,48-51] explicitly defined it as a secondary outcome, whereas the remaining studies (44.4%) [36,38,41,42,45,46,52,53] did not clearly distinguish between primary and secondary outcomes in their original texts.

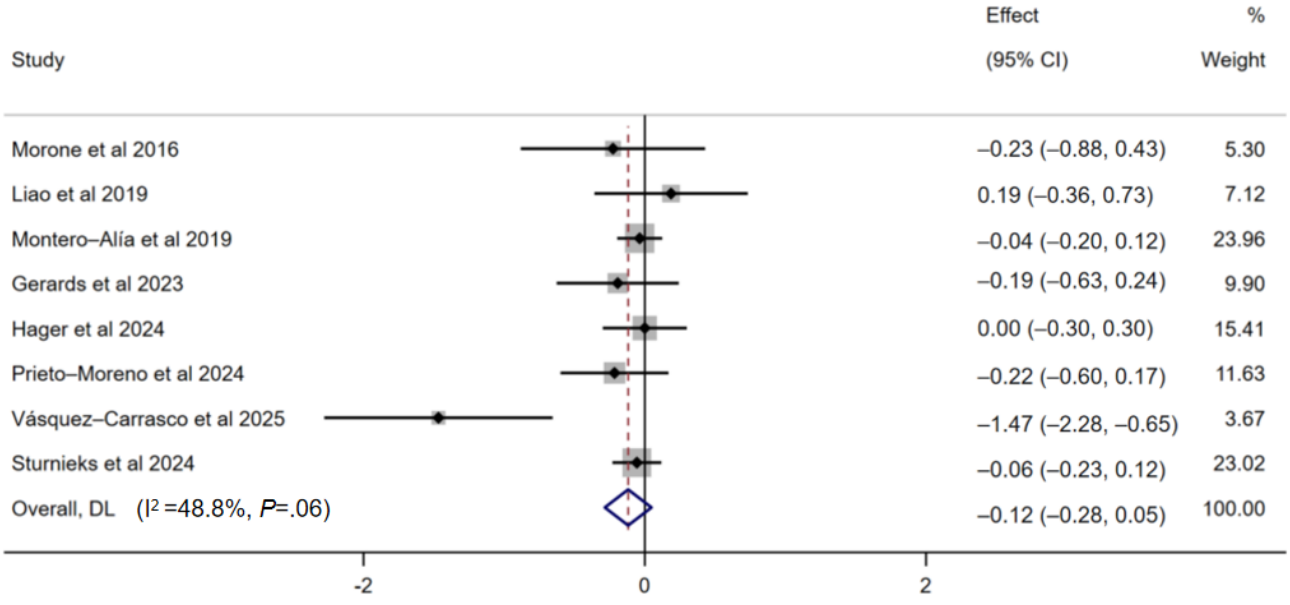
Risk of Bias in RCTs

The risk of bias was assessed for the 18 RCTs included. The majority of studies were judged to have a high risk of bias or to raise some concerns overall. For the domain of the randomization process, the majority of studies were judged to be at low risk of bias. Two studies were rated as having some concerns due to a lack of information on allocation concealment. One study was assessed as being at high risk because significant baseline differences suggested potential problems with the randomization procedure. For deviations from intended interventions, most studies were assessed as high risk or with some concerns, primarily attributed to a lack of blinding for participants and intervention providers. For the domain of outcome measurement, 3 studies were assessed as high risk because blinding of the outcome assessors was not implemented. The risk of bias was assessed as low across all remaining domains (Figure 2).

XSL•FO
RenderX

Figure 2. Risk of bias summary [36-53].

Effectiveness of Interventions



Concerns About Falling

A total of 8 studies evaluated the impact of digital-based exercise interventions on concerns about falling in older adults, involving 758 participants in the intervention groups and 834 in the control groups. The pooled results from 8 studies revealed that digital-based exercise interventions had a significant effect on concerns about falling (SMD −0.12, 95% CI −0.28 to 0.05; P>.05; I^2=48.8%; low certainty of the evidence; Figure 3). None of the subgroup analyses yielded statistically significant results. Although the point estimates varied, none of the tests for subgroup differences were significant (P>.05), with 1 exception: the exercise mode subgroup showed a nominally significant difference (P=.003). However, this finding was driven entirely by a single study in the nonbalance training subgroup, which reported a statistically significant reduction in concerns about falling (SMD −1.47, 95% CI −2.28 to −0.65). When this single

XSL•FO
RenderX

study was excluded, the difference between the remaining exercise mode subgroups was no longer significant (*P*=.86), indicating that the initial subgroup difference was not robust. Therefore, there is no clear evidence to identify which intervention characteristics are most effective for reducing concerns about falling (Table 3).

Figure 3. Forest plot showing the effects of digital-based exercise interventions on concerns about falling (n=8; lower scores indicate greater improvement) [38,40,41,48-52]. Weights are from a random-effects model.

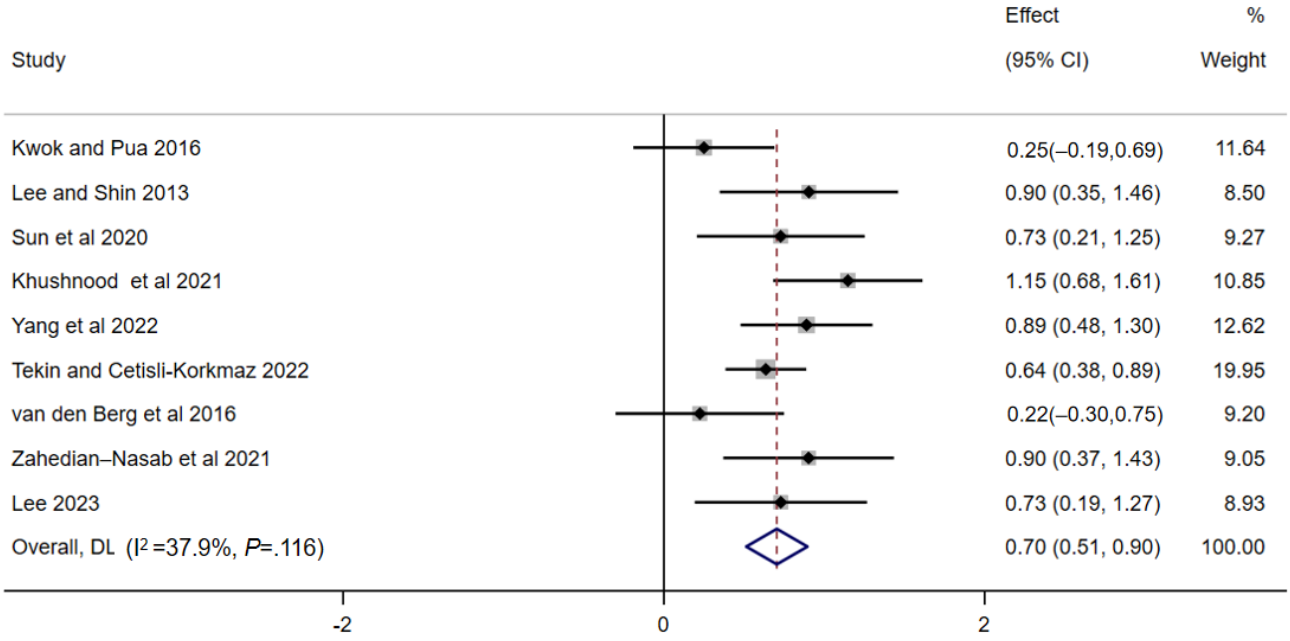
[a]SMD: standardized mean difference.

[b]Not applicable.



[c]VR: virtual reality.

The sensitivity analysis for the cognitive constructs demonstrated that the overall results were robust, as no single study significantly altered the pooled effect estimate. The sensitivity analysis of affect-based constructs revealed that a study by Vásquez-Carrasco et al [52] (SMD −1.47, 95% CI −2.28 to −0.65) was an outlier. After this study was excluded, the intervention effects remained nonsignificant (SMD −0.06, 95% CI −0.16 to 0.04; *P*>.05; I^2=0.0%).

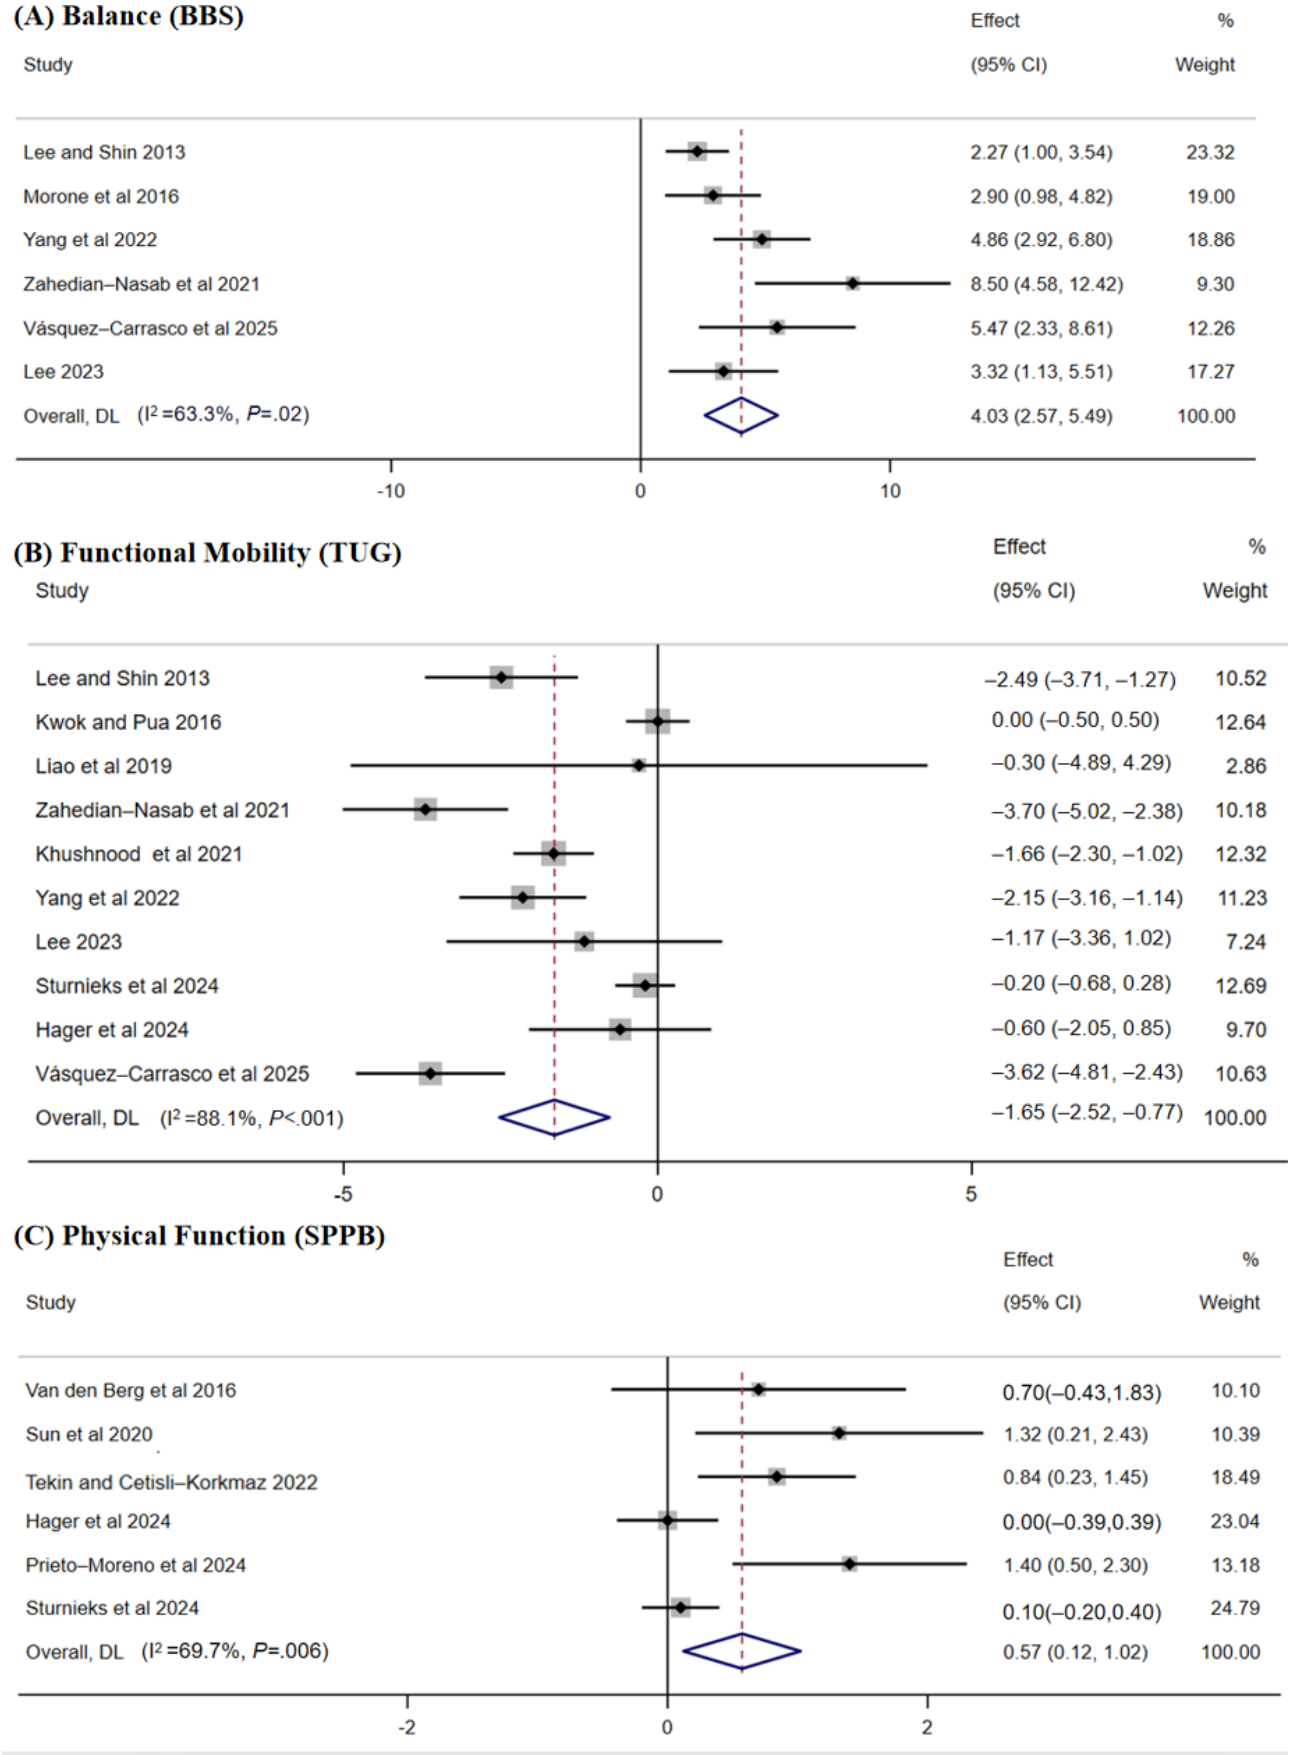
Falls Efficacy

The meta-analysis of 9 studies revealed that digital-based exercise interventions significantly improved falls efficacy among older adults (SMD 0.70, 95% CI 0.51-0.90; *P*<.001; I^2=37.9%; moderate certainty of the evidence; Figure 4). With respect to intervention setting, the effect size was greatest for senior care facilities (SMD 0.84, 95% CI 0.53-1.15), followed by hospitals (SMD 0.77, 95% CI 0.27-1.27), and then community settings (SMD 0.55, 95% CI 0.30-0.80), although the difference between groups was not significant (*P*=.34). With respect to exercise mode, balance training had a greater effect (SMD 0.90, 95% CI 0.37-1.43) than multimodal training did (SMD 0.69, 95% CI 0.48-0.89), but the difference was not statistically significant (*P*=.46). Similarly, a higher exposure dosage was associated with a greater effect, with the >50 times subgroup (SMD 0.83, 95% CI 0.50-1.15) having a greater effect than the <20 times (SMD 0.63, 95% CI 0.16-1.10) and 20 to 50 times (SMD 0.69, 95% CI 0.48-0.90) subgroups did, and there was no significant between-group difference (*P*=.72). With respect to other subgroup variables, including the intervention qualifications, digital platform type, intervention duration, and scale-scoring method, the effect sizes were similar across categories (SMD range 0.56 - 0.90), with no significant differences between the subgroups (all *P*>.05; Table 3).

Figure 4. Forest plot showing the effects of digital-based exercise interventions on falls efficacy (n=9; higher scores indicate greater improvement) [36,37,39,42,43,45-47,53].

XSL•FO
RenderX

The sensitivity analysis for the falls efficacy demonstrated that the overall results were robust, as no single study significantly altered the pooled effect estimate.



Balance (Berg Balance Scale)

The pooled results from 6 studies [36,38,45,47,52,53] revealed a significant effect of digital-based exercise interventions on balance (MD 4.03, 95% CI 2.57-5.49; $P<.001$; $I^2=63.3\%$; moderate certainty of the evidence; Figure 5A). With respect to balance, most subgroups, including the intervention setting, intervention qualifications, exercise mode, and intervention duration showed no significant differences between subgroups ($P>.05$). The only statistically significant subgroup differences were found between the exposure dosage subgroups ($P=.04$). An exposure dosage of less than 20 times (MD 5.43, 95% CI −0.03 to 10.89) had a greater effect than an exposure dosage of more than 50 times (MD 5.03, 95% CI 3.38-6.68) and 20 to 50 times (MD 2.53, 95% CI 1.43-3.63; Table S1 in Multimedia Appendix 1).

Sensitivity analysis revealed that no individual study was able to change the results, but the heterogeneity decreased from 63.3% to 42.6% when Zahedian-Nasab's [45] study was excluded (MD 3.46, 95% CI 2.30-4.61; $P<.001$; $I^2=42.6\%$).

XSL•FO
RenderX

Figure 5. Forest plot showing the effects of digital-based exercise interventions on (A) balance (Berg Balance Scale [BBS]), (B) functional mobility (Timed Up and Go Test [TUG]), and (C) physical function (Short Physical Performance Battery [SPPB]). A lower TUG score indicates a more significant improvement in functional mobility, whereas higher BBS and SPPB scores indicate more significant improvements in balance and physical function, respectively [36-40,42,43,45-47,49-53].

XSL•FO
RenderX

Functional Mobility (Timed Up and Go Test)

In ten studies [36,37,40,43,45,47,49,51-53], researchers reported functional mobility. The meta-analysis indicated a significant effect of digital-based exercise interventions on functional mobility compared with the control group; however, considerable heterogeneity was noted among the included studies (MD −1.65, 95% CI −2.52 to −0.77; *P*<.001; I^2=88.1%; moderate certainty of the evidence; Figure 5B). Subgroup analyses for functional mobility were performed across the intervention setting, exercise mode, the duration of intervention, digital platform, the qualifications of interveners, and exposure dosage. With respect to exercise mode, subgroup differences were initially observed (*P*=.01), with nonbalance training yielding the greatest effect size (MD −3.62, 95% CI −4.81 to −2.43) compared with balance-inclusive multimodal training (MD −1.29, 95% CI −2.22 to −0.37) and balance training (MD −1.89, 95% CI −5.32 to 1.53). However, the significant subgroup difference disappeared (*P*=.74) after the single study of nonbalance training was excluded. With respect to intervention setting, the digital-based exercise intervention delivered in senior care facilities (MD −2.89, 95% CI −4.11 to −1.68) showed a greater improvement effect than that in community settings (MD −1.03, 95% CI −1.20 to 0.07) and hospitals (MD −1.80, 95% CI −2.34 to −1.26), although the difference between groups was not statistically significant (*P*=.08). Interventions lasting less than 12 weeks (MD −2.30, 95% CI −3.33 to −1.28) improved functional mobility more strongly than interventions lasting 12 weeks or more did (MD −1.20, 95% CI −2.28 to −0.11; *P*=.15). For other subgroup variables, including the qualifications of the intervener, digital platform type, and exposure dosage, the effect sizes were similar across categories (MD range: −2.08 to −1.29), with no significant differences between the subgroups (all *P*>.05; Table S1 in Multimedia Appendix 1). Sensitivity analysis revealed that no individual study was able to change the results.

Physical Function (Short Physical Performance Battery)

In 6 studies [39,42,46,49-51], researchers reported the effects of digital-based exercise interventions on physical function. The meta-analysis revealed that digital-based exercise interventions significantly improved physical function among older adults (MD 0.57, 95% CI 0.12-1.02; *P*=.006; I^2=69.7%; moderate certainty of the evidence; Figure 5C). The hospital subgroup had the greatest effect size (MD 1.13, 95% CI 0.42-1.83), which was greater than that of the community subgroup (MD 0.24, 95% CI −0.16 to 0.64; I^2=64.5%; *P*=.060). After the senior care facility subgroup (only 1 study) was excluded, significant between-group differences were observed (*P*=.03). The effect size was greater for the application subgroup (MD 0.67, 95% CI −0.14 to 1.49) than for the exergaming subgroup (MD 0.14, 95% CI −0.16 to 0.44; I^2=81.5%; *P*=.005). However, after excluding the VR subgroup (only 1 study), the difference between groups was no longer statistically significant (*P*=.23). The 20-50 times subgroup yielded the strongest effect (MD 1.02, 95% CI 0.51-1.53), which was superior to that of the >50 times subgroup (MD 0.21, 95% CI −0.22 to 0.64; I^2=59.1%; *P*=.09). After the <20 times subgroup (only 1 study) was excluded, significant between-group differences were observed (*P*=.02). The intervention duration and qualifications of the interveners showed no significant between-group differences (*P*=.43 and *P*=.52, respectively; Table S1 in Multimedia Appendix 1). Sensitivity analysis revealed that no individual study was able to change the results.

Publication Bias

For the outcome of functional mobility, the funnel plot appeared asymmetrical; however, both the Egger test (*P*=.09) and the Begg test (*P*=.53) indicated no statistically significant publication bias (Figure S1 in Multimedia Appendix 1).

Narrative Synthesis

One study [44] was excluded from the quantitative synthesis because of inadequate data presentation, despite attempts to contact the authors. This study revealed that immersive VR-based balance training improved older adults' mobility (Timed Up and Go Test: MD −1.71, 95% CI −2.73 to −0.69) but did not alleviate concerns about falling (FES-I: MD 1.80, 95% CI −2.02 to 5.62), with no significant differences compared with the control group.

Discussion

Effect of Digital-Based Exercise Interventions on Falls Efficacy and Concerns About Falling

The meta-analysis assessed the efficacy of digital-based exercise interventions on concerns about falling and falls efficacy among older adults. Overall, the interventions were effective at improving falls efficacy but not concerns about falling, the emotional construct related to falls. This key distinction suggests that the cognitive and emotional constituents may represent 2 relatively independent intervention targets, requiring distinct strategies to address each effectively.

For falls efficacy, Gao et al [54] reported nonsignificant effects of VR interventions on falls efficacy measured by the MFES in nondisabled older adults. This difference may be because, compared with previous studies, this analysis pooled data from more studies, thus improving the statistical power and stability. The improvement in cognitive constructs through digital-based exercise interventions may be attributed to their ability to provide structured, repetitive exercises and feedback. These findings align with substantial evidence indicating that physical exercise directly enhances physical function and balance [55,56], thereby increasing self-efficacy. This process can be attributed to the underlying neurobiological mechanism: the multisensory stimulation (eg, visual, auditory, and vestibular) provided by digital exercise interventions promotes plasticity in the central nervous system, thereby enhancing the ability of the brain to process sensory information and maintain postural control [57-59]. Consequently, the experience of successfully completing motor challenges, reinforced directly through this neural reshaping, strengthens older adults' balance confidence or falls efficacy. Subgroup analyses explored the potential moderating effects of various intervention characteristics on falls efficacy, and no statistically significant between-group differences were found across all the subgroups, indicating that the improvement effect of digital-based exercise interventions on falls efficacy was consistent across different characteristics. For intervention setting, the effect size was the greatest in senior

XSL•FO
RenderX

care facilities, followed by hospitals and then community settings, which may be attributed to the more standardized implementation and higher participant compliance with interventions in institutional settings. For exercise mode, balance training yielded a slightly better effect than multimodal training, which was consistent with its core mechanism of directly improving postural control ability [60]. The absence of significant differences in the above dimensions might be due to the small sample size of each subgroup and the heterogeneity of intervention protocols across studies. The similar effect sizes across other subgroups, including interveners' qualifications, exposure dosage, and digital platform type, confirmed the robustness of such interventions, providing a reference for their flexible implementation in clinical and community settings.

For concerns about falling, our findings indicate that digital-based exercise interventions did not significantly improve concerns about falling, which is consistent with the findings of Lee et al [28], who used the FES-I. This lack of efficacy may be attributed to 2 primary reasons. First, concerns about falling, as an emotional construct, is fundamentally distinct from the cognitive construct. While a cognitive construct is closely tied to an individual's assessment of their balance capacity and can thus be improved through objective functional gains, the affective construct is characterized by concerns about falling, manifesting as a feeling of dread and apprehension toward situations perceived as threatening to balance [17]. This nonrational emotional response is resistant to standardized interventions that primarily target physical function alone. Second, there is a mismatch in the active components of the existing interventions. The digital interventions included in this analysis were predominantly based on physical training and lacked elements specifically designed to address worrying emotions, making them mechanistically inadequate for directly targeting the core of emotional constructs.

Effect of Digital-Based Exercise Interventions on Physical Performance

The pooled results demonstrated that digital-based exercise interventions significantly improved physical performance, including balance function, functional mobility, and physical function, in older adults. These findings are consistent with previous research. Most digital-based interventions implement structured exercise programs, particularly targeted balance training. These exercises have been proven to enhance lower limb strength, postural stability, and sensorimotor integration, which is the key physiological basis for evaluating balance function and activity ability [55,56]. Systematic exercise also improves the integrated physical capacity needed for daily activities, as reflected in physical function. In addition, digital platforms significantly amplify the effects of these exercises. Exergaming and immersive VR mitigate the monotony of traditional training, substantially increasing motivation, engagement, and adherence [61]. Critically, digital delivery overcomes spatial and temporal barriers, enhancing accessibility and convenience [62,63]. This allows for more frequent and consistent participation, enabling exercise benefits to accumulate fully. Furthermore, the improvement outcomes for both the moderate exposure dosage (20 - 50 times) and the lower dosage (<20 times) were significantly superior to those of the high dosage (>50 times), suggesting that beyond a certain threshold, further increases in exercise volume may not yield additional functional gains and could even diminish effects due to factors such as fatigue or reduced adherence [64].

Strengths and Limitations of the Study

This study has several strengths. First, this study provides the first meta-analytic evidence quantifying the effects of digital-based exercise interventions on both the cognitive and emotional constructs of fall-related psychological impairments among older adults, clearly demonstrating their differential effectiveness. Second, the study was rigorous, using comprehensive terminology and an extensive systematic search strategy. Only reliable evidence from RCTs was included, and registered protocols were adhered to, providing more precise effect estimates.

Moreover, our study has several limitations. First, this study included older adults with different baseline characteristics, and the heterogeneity of the population indicated that many subjects differed in terms of their pathophysiological behaviors and conditions, as well as their comorbidities, all of which may have affected the accuracy of the reported results. Second, most of the original studies included in this review were not designed primarily to improve "concerns about falling" or "falls efficacy," which could lead to an underestimation of the overall effect and an amplification of heterogeneity. The use of self-reported scales to measure fear of falling suggests the possibility of bias and may have led to inaccurate effect size estimates, especially for studies that did not have a blinded assignment to treatment versus control.

Suggestions for Further Research

While the study demonstrates limited efficacy in improving concerns about falling (an emotional construct), it reveals a more positive effect on falls efficacy (a cognitive construct). These differential outcomes underscore the need for more precisely targeted intervention designs in the future. Therefore, clinicians and researchers should select or design digital interventions on the basis of an individual's primary presentation.

To develop these more precisely targeted interventions, future research should prioritize the development of digital programs that integrate evidence-based psychological components, such as cognitive behavioral therapy and mindfulness training, to directly target the core mechanisms of emotional constructs. Future studies should employ more refined research designs to further clarify the specific pathways through which different intervention types (exercise, cognitive, and combined) influence distinct constructs. Furthermore, in terms of outcome assessment, in addition to self-report scales, future studies should explore the use of objective physiological biomarkers or behavioral tasks to more sensitively measure changes in emotional constructs.

Conclusions

The meta-analysis assessed the efficacy of digital-based exercise interventions on fall-related psychological impairments among older adults and revealed that the effects differed across the

XSL•FO
RenderX

constructs. These findings suggest that digital-based exercise interventions have potential benefits for improving falls efficacy and physical performance among older adults compared with controls. However, the effect of digital-based exercise interventions on concerns about falling, which is the emotional construct related to falls, remains uncertain among older adults.

Abstract

Background: Digital exclusion posed a significant challenge, especially in middle-aged and older adults, which affected their health outcomes. However, the evidence regarding the associations of digital exclusion on physical or cognitive function outcomes was controversial, and no systematic review had been performed to synthesize the pooled associations.

Objective: This study aimed to explore the relationship between digital exclusion and physical or cognitive function in middle-aged and older adults.

Methods: We conducted a systematic review and meta-analysis of cohort and cross-sectional studies, including Chinese or English publications retrieved from PubMed, Embase, Web of Science, PsycINFO, Scopus, CNKI, and Wanfang databases up to August 31, 2024. The risk of bias was evaluated using the Newcastle-Ottawa Scale (NOS). The pooled effect size was calculated based on odds ratios (ORs), hazard ratios, risk ratios, and 95% CIs. This study was registered on PROSPERO (CRD42024585459).

Results: Nineteen studies met the inclusion criteria, including 13 cohort studies and 6 cross-sectional studies, which had moderate-to-low risk of bias. The pooled analysis indicated that digital exclusion had prospective associations with decreased basic activities of daily living (incidence rate ratio 1.35, 95% CI 1.12 - 1.64, I^2=94.7%) and instrumental activities of daily living (incidence rate ratio 1.46, 95% CI 1.13 - 1.89, I^2=96.2%), or cross-sectional association with activities of daily living (OR 1.23, 95% CI 0.41 - 3.73, I^2=91%), with no statistical significance in the prospective association with frailty (OR 1.21, 95% CI 0.92 - 1.59, I^2=95.2%). There were prospective associations between digital exclusion and dementia (hazard ratio 1.78, 95% CI 1.43 - 2.22, I^2=0%), decreased Mini-Mental State Examination scores (OR 1.96, 95% CI 1.39 - 2.75, I^2=0%), as well as cross-sectional associations with Mini-Mental State Examination scores (OR 2.90, 95% CI 2.07 - 4.07, I^2=0%), and no statistical significance in the prospective association with cognitive impairment (risk ratio 2.08, 95% CI 0.98 - 4.44, I^2=78.2%).

Conclusions: Our findings indicated the negative associations of digital exclusion with physical and cognitive functions. Future research and clinical practice should consider designing digital interventions and services that match the physical and cognitive capacities and preferences of middle-aged and older adults, thereby improving digital engagement and reducing the harms associated with digital exclusion. Policies should focus on expanding access, reducing financial barriers, and improving digital literacy. However, due to the presence of heterogeneity and publication bias, the results should be interpreted cautiously.

digital exclusion; internet nonuse; physical function; cognitive function; meta-analysis

Introduction

Population aging has become a global concern, posing significant challenges to public health systems and social development [1]. Although aging is an inevitable biological process, a growing body of research has focused on promoting healthy aging, which emphasizes maintaining and improving intrinsic capacity to enhance overall well-being among

XSL•FO
RenderX

middle-aged and older adults [2-4]. The World Health Organization defines healthy aging as "the process of developing and maintaining the functional ability that enables well-being in older age." [5] This functional ability is underpinned by 2 core components: physical and cognitive functions [6]. Physical function provides the strength, balance, and mobility necessary for action, while cognitive function supports the attention, memory, and decision-making needed to guide those actions effectively and safely [7-10]. Preserving both is essential for maintaining independence and preventing disability in later life, and accumulating evidence suggests that midlife might represent a valuable window for earlier monitoring or intervention [11,12].

Rapid digitalization has profoundly transformed the way individuals access information, communicate, and engage with health and social services, such as monitoring age-related diseases and promoting remote health management [13-15]. However, numerous middle-aged and older adults with substantial health care needs are excluded from digital technologies. They are often unwilling or unable to use digital technology critically, which exacerbates the vicious cycle of digital exclusion and health inequalities [16,17]. The prevalence of digital exclusion varies by country and is especially obvious in older adults, accounting for 21.69% in Denmark, 22.61% in the United Kingdom, 60.78% in Mexico, and 97.15% in China [18]. Digital exclusion currently lacks a unified definition and assessment tool. While some studies define it as the ability to send and receive online messages with difficulty [19], it is most commonly defined and measured as self-reported nonuse of the internet [18,20,21].

Growing evidence suggests that digital exclusion is related to adverse health outcomes, such as functional dependence [22], cognitive impairment [18], and psychological distress [23], ultimately elevating the risk of mortality and exacerbating socioeconomic burdens [24]. The evidence on the negative impact of digital exclusion on psychological well-being is particularly well-documented and has been proven to be associated with higher levels of depression [25,26], loneliness [21,27], and social isolation [28,29] in large cohort studies and systematic reviews.

However, evidence regarding the associations of digital exclusion on physical or cognitive function outcomes was controversial, and no systematic review had been performed to synthesize the pooled associations. Several studies analyzed data from 5 nationally representative cohorts conducted in both developed and developing countries. These studies reported that nonuse of the internet was associated with increased risks of cognitive impairment, functional dependence, and frailty [17,18,30]. However, Liu et al [31] found no statistically significant association between internet nonuse and functional disability in China, and García-Esquinas et al [32] observed a similar nonsignificant relationship between nonuse of computers and frailty in European populations. This inconsistency may arise from differences in study populations, definitions of digital exclusion, measurement methods, and sample sizes. To date, no systematic review has comprehensively synthesized the available evidence or assessed the overall magnitude and direction of these associations. A rigorous synthesis is therefore needed to clarify the impact of digital exclusion on functional health, identify potential sources of heterogeneity, and provide an evidence-based foundation for interventions aimed at promoting healthy aging in digitally marginalized populations.

Therefore, this study aims to systematically identify studies regarding the relationship between digital exclusion and physical or cognitive function in middle-aged and older adults, summarize their findings, and assess the certainty of their evidence to provide a comprehensive understanding of the associations.

Methods

Study Design

This review adhered to the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) 2020 statement [33] and was registered on PROSPERO (CRD42024585459; Checklist 1).

Search Strategies

We searched PubMed, Embase, Web of Science, PsycINFO, Scopus, CNKI, and Wanfang databases, from the inception of the databases to August 31, 2024. Only eligible full texts in English or Chinese were considered for review. Two thematic blocks of keywords were used: "Aged" and "Digital exclusion." The search terms were (aged or "middle aged" or "older adult*" or aging or "elder*") AND ("digital exclusion" or "digital inclusion" or "digital divide" or "Internet access" or "Internet use*" or "Internet non-use" or "web usage" or "web use" or "Internet usage" or "digital engagement"). In terms of developing search strategies, we first identified standardized terminology by consulting the Medical Subject Headings (MeSH) database in PubMed. This step ensured the inclusion of entry terms. Subsequently, we examined key published literature to incorporate nonstandardized terms that are conceptually related to digital exclusion, such as "digital divide," "digital inclusion," and "digital engagement" [27,34,35]. The detailed search strategies are shown in Multimedia Appendix 1.

Eligibility Criteria

The inclusion criteria for studies were as follows: (1) middle-aged and older adults as research participants, explicitly aged 45 years and older [36]; (2) digital exclusion was clearly specified as the exposure variable, without redefinition based on dose or frequency; and (3) reporting at least one measure of physical or cognitive function. Specifically, physical function was measured using standardized assessments of functional independence and mobility (eg, activities of daily living [ADLs] and Fried frailty phenotype). Cognitive function was assessed using standardized screening tools (eg, Mini-Mental State Examination [MMSE]) or based on a clinical diagnosis of cognitive impairment or dementia; (4) provision of the odds ratios (ORs), hazard ratios (HRs), risk ratios (RRs), and their corresponding 95% CIs for the associations between digital exclusion and health outcomes; and (5) observational studies.

This study excluded (1) editorials, letters, comments, meeting abstracts, and newspaper articles; (2) studies unable to provide the full text; (3) studies that only reported correlation metrics,

XSL•FO
RenderX

such as Pearson *r* or Spearman ρ, without providing data that could be used to calculate ORs, RRs, HRs, and their 95% CIs; and (4) studies that were not published in English or Chinese.

Study Selection and Data Extraction

Study selection was conducted independently in 2 stages by 2 researchers. A third researcher was invited to resolve the disagreement. Initially, the titles and abstracts of the studies were evaluated in terms of eligibility criteria. In the subsequent stage, full texts of preselected studies were reviewed to confirm their eligibility.

The selected studies were extracted by 2 researchers using a form to extract data on the setting, study design, sample size, basic participant information, digital exclusion assessment tools, categories of digital exclusion, outcome assessment tools, categories of assessment, covariates, and effect sizes of outcomes. Discrepancies between the researchers regarding data extraction were resolved through discussion and consensus with the assistance of a third researcher.

Methodological Quality Assessment

Two researchers independently assessed the methodological quality of each study using the Newcastle-Ottawa Scale (NOS), a quality assessment tool for both cohort and cross-sectional studies [37]. The tool comprises 8 items with a score range of 0‐9 for cohort studies, and 7 items from 0 to 8 for cross-sectional studies [38], as detailed in Multimedia Appendix 2 [17,18,30,32,39-47] and Multimedia Appendix 3 [19,24,31,48-50]. Initially, we conducted a pilot evaluation of 4 articles (2 cohort studies and 2 cross-sectional studies) to standardize the assessment criteria. Discrepancies between the researchers were discussed, and a third researcher was invited to resolve them collectively.

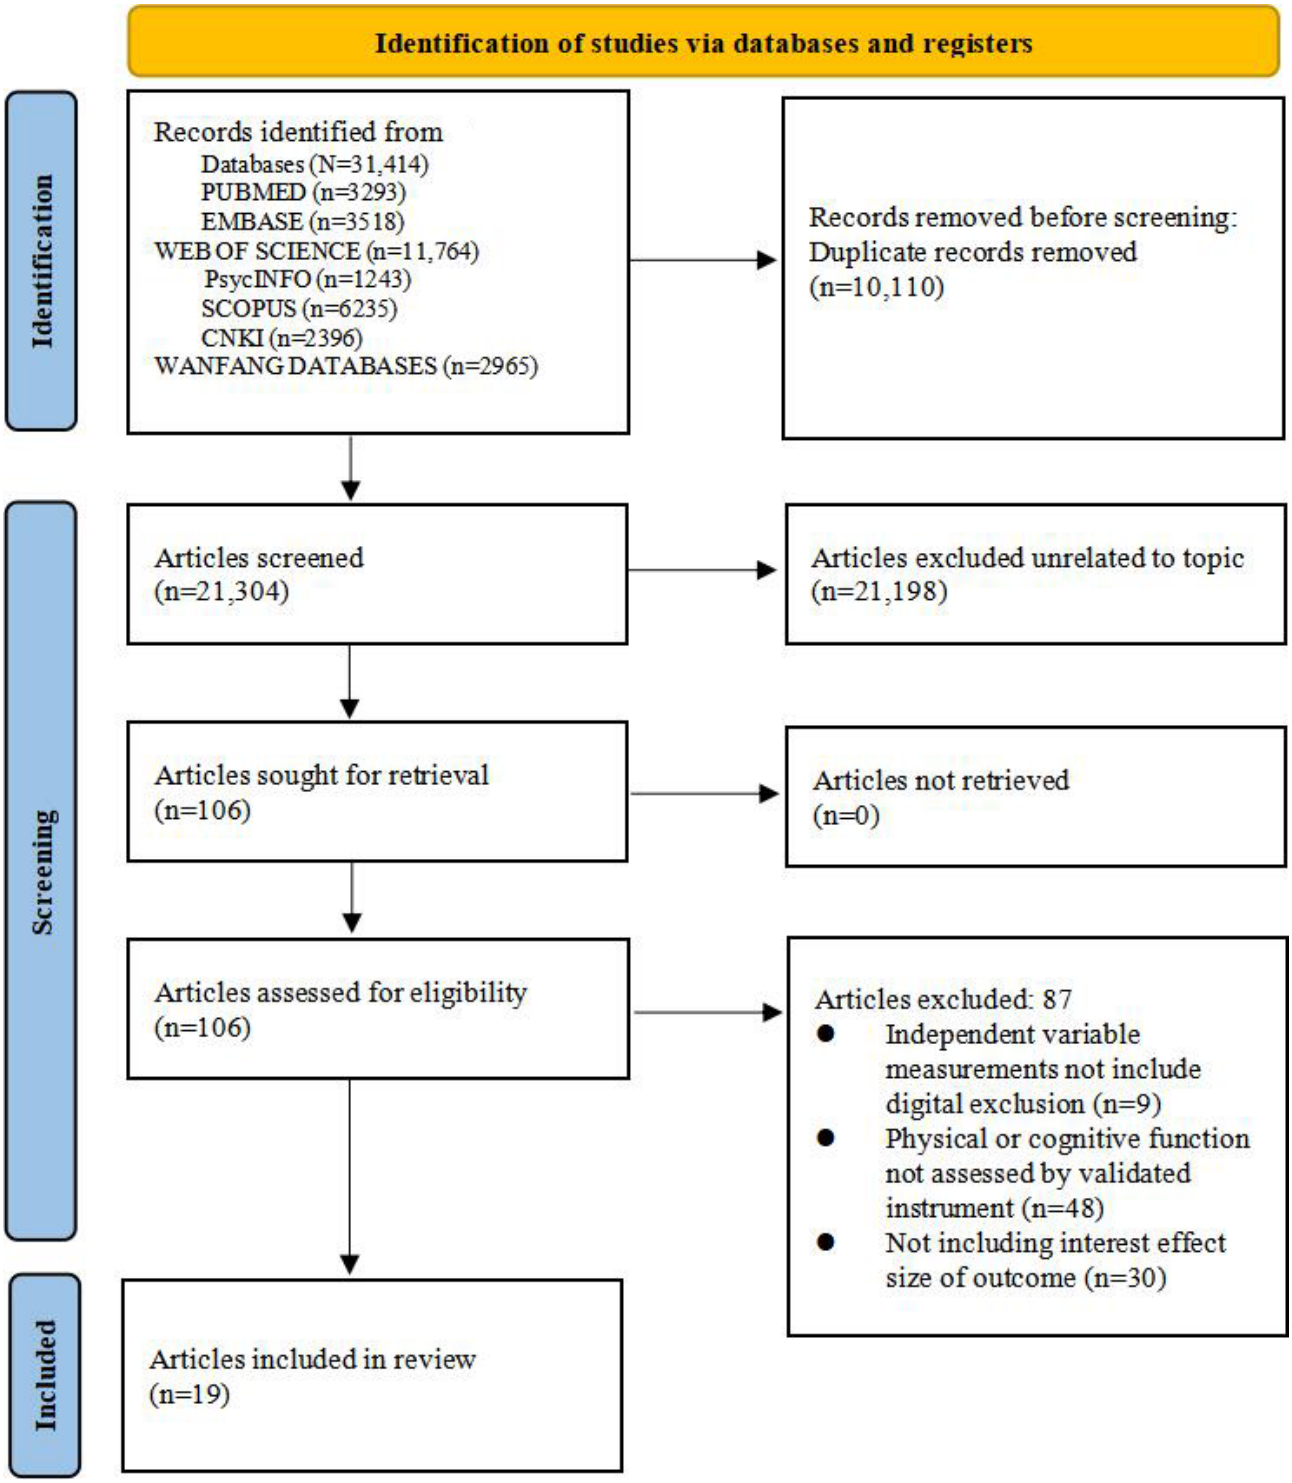
Synthesis and Data Analysis

Descriptive analysis was conducted to summarize the characteristics of the studies. For meta-analysis, the associations between digital exclusion and health outcomes were quantitatively synthesized, and effect sizes were measured using RR, OR, HR, and 95% CIs. Separate meta-analyses were conducted for ORs, RRs, and HRs. Effect sizes adjusted for potential confounders were extracted to ensure comparability across studies, allowing them to be regarded as standardized estimates [51]. When the original studies used "digital exclusion" as the reference group, the reported effect sizes were inverted to represent the impact of digital exclusion versus nonexclusion. This conversion was justified by the mathematical principle that inverting a ratio measure was equivalent to swapping the reference and exposure groups [52]. And all conversions were performed with double-checking for accuracy.

The random-effects model was used if significant heterogeneity (I^2>50% or P<.1) was found among the included studies; otherwise, the fixed-effect model was used. Due to the inclusion of fewer than 10 studies in the meta-analysis, publication bias analysis was not conducted. The meta-analysis and forest plots were performed using R software (R Core Team) with the main package of "*metafor*."

Sensitivity Analysis

Leave-one-out sensitivity analysis was conducted to evaluate the influence of each study on the pooled association estimate. In this procedure, the meta-analysis was repeated multiple times, each time omitting one study and recalculating the pooled association using the remaining studies. When between-study heterogeneity (I^2) exceeded 50%, a random-effects model was applied for the recalculated estimate [53]. Specifically, a study was considered to have a substantial influence if its exclusion caused the new point estimate to fall outside the 95% CI of the original pooled estimate. A study was also deemed influential if the effect size changed noticeably compared to the primary analysis. Noticeable changes were defined as either a reduction of 25‐50 percentage points or a shift from high heterogeneity (I^2>50%) to low or moderate heterogeneity (I^2≤50%) [54-56]. Due to the limited number of available studies, subgroup analysis based on different definitions, frequencies, or ages could not be performed. All results were presented visually using forest plots, along with corresponding CIs. A statistical significance threshold of P<.10 was adopted.



Results

Characteristics of the Studies

A total of 31,414 articles were searched from the databases. After excluding duplicate publications (n=10,110) and ineligible articles (n=21,198), 19 studies were included in this review (Multimedia Appendix 4) [17-19,24,30-32,39-50]. The selection process of the studies was summarized in the PRISMA flow diagram (Figure 1).

XSL•FO
RenderX

Figure 1. The PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flow diagram.

Tables 1 and 2 provide the characteristics of the included cohort and cross-sectional studies, respectively. Three studies focused on middle-aged and older adults aged 45 years or older [24,42,45], while the remaining articles specifically concentrated on older adults aged 60 years or older [17-19,30-32,39-41,43,44,46-50]. Thirteen cohort studies [17,18,30,32,39-47] and 6 cross-sectional studies [19,24,31,48-50] were from different regions, including Spain, England, Japan, the United States, China, Europe, Mexico, Brazil, Sweden, and the Netherlands. These studies were conducted between 2012 and 2024, with the sample sizes ranging from 409 to 155,695. The follow-up duration of the cohort studies ranged from 3 to 17.1 years.

The assessment tools for digital exclusion showed diversity among the included studies. None of the studies used a validated scale; instead, they all used single-item measures to assess digital exclusion. Most studies (n=14) [17,18,24,30,31,39-43,45-48] defined digital exclusion as nonuse of the internet, while other studies defined digital exclusion as nonuse of computers (n=2) [32,44], nonuse of information and communication technology (n=1) [50], nonuse of mobile payment (n=1) [49], and inability to send or receive online messages (n=1) [19].

Seven studies focused exclusively on physical function [17,19,24,30,32,39,50], while 11 examined cognitive function [18,40-49]. Only 1 study assessed both physical and cognitive outcomes [31]. Physical function was assessed by ADLs (n=3) [19,24,30], Frailty index (n=1) [17], and Fried frailty phenotype (n=2) [32,50], with 1 study obtaining physical function outcomes

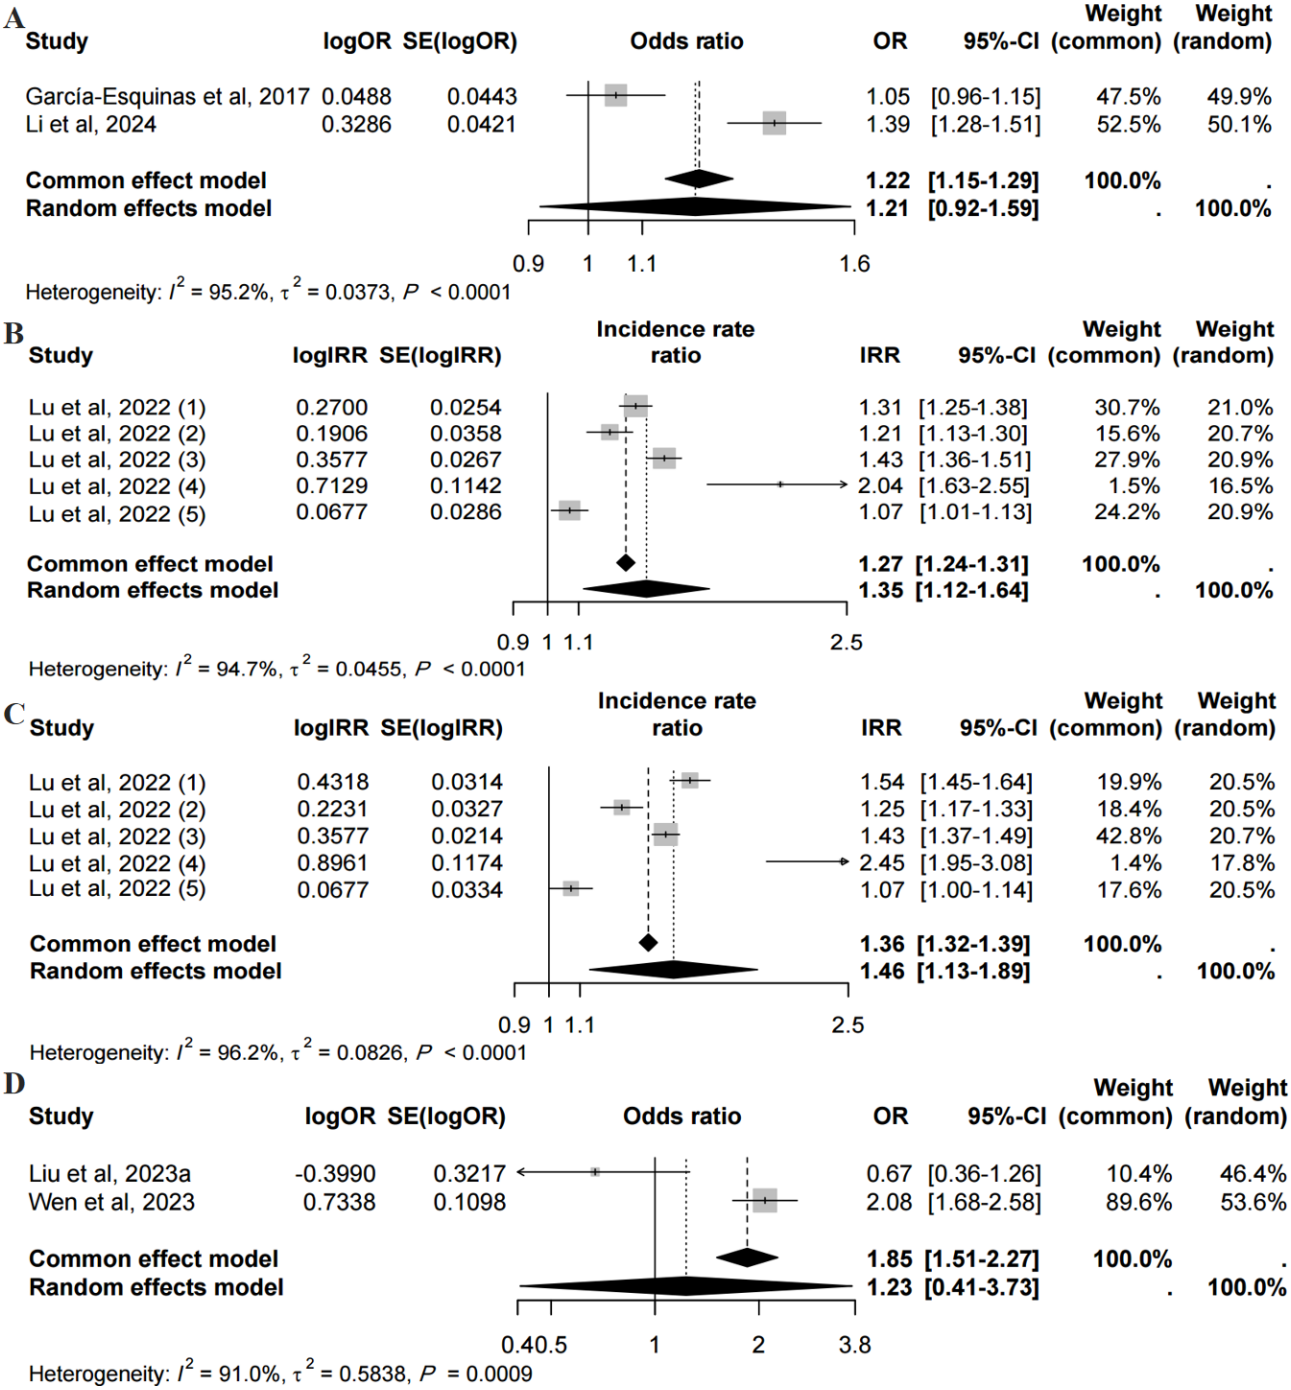
XSL•FO
RenderX

by linking to data from local government systems [39]. The cognitive function was assessed using numerous cognitive tests, including MMSE (n=5) [40,41,47-49], orientation, memory, and executive function tests (n=1) [18], Modified Telephone Interview for Cognitive Status (n=2) [42,43], short-form Informant Questionnaire on Cognitive Decline in the Elderly (IQCODE) questionnaire (n=1) [45], and Brief Community Screening Instrument for Dementia (n=1) [31], with some studies obtaining cognitive function outcomes by linking to data from local government systems.

Risk of Bias Assessment

The overall risk of bias assessment of cohort and cross-sectional studies is shown in Multimedia Appendices 2 and 3.

The overall risk of bias score of cohort studies had a low risk of bias, varying from 7 to 9 points. Regarding the selection bias, all studies included the selection of a nonexposed cohort and the ascertainment of exposure. Similarly, in the comparability and outcome domains, all studies ensured the comparability of cohorts based on design or analysis, assessment of outcomes, and an adequate follow-up period for outcomes to occur. However, 6 studies failed to demonstrate that the outcome of interest was not present at the start of the study [17,18,30,41,43,46], and 4 studies had inadequate cohort follow-up [18,40,41,47].



The overall risk of bias score of cross-sectional studies ranged from 3 to 7 points. All studies clearly stated the study population, had a sample size of more than 300, and assessed the outcome. However, none of the studies reported whether the studied sample had a participation rate of at least 70% (7/10) of the invited individuals.

Association Between Digital Exclusion and Physical Function

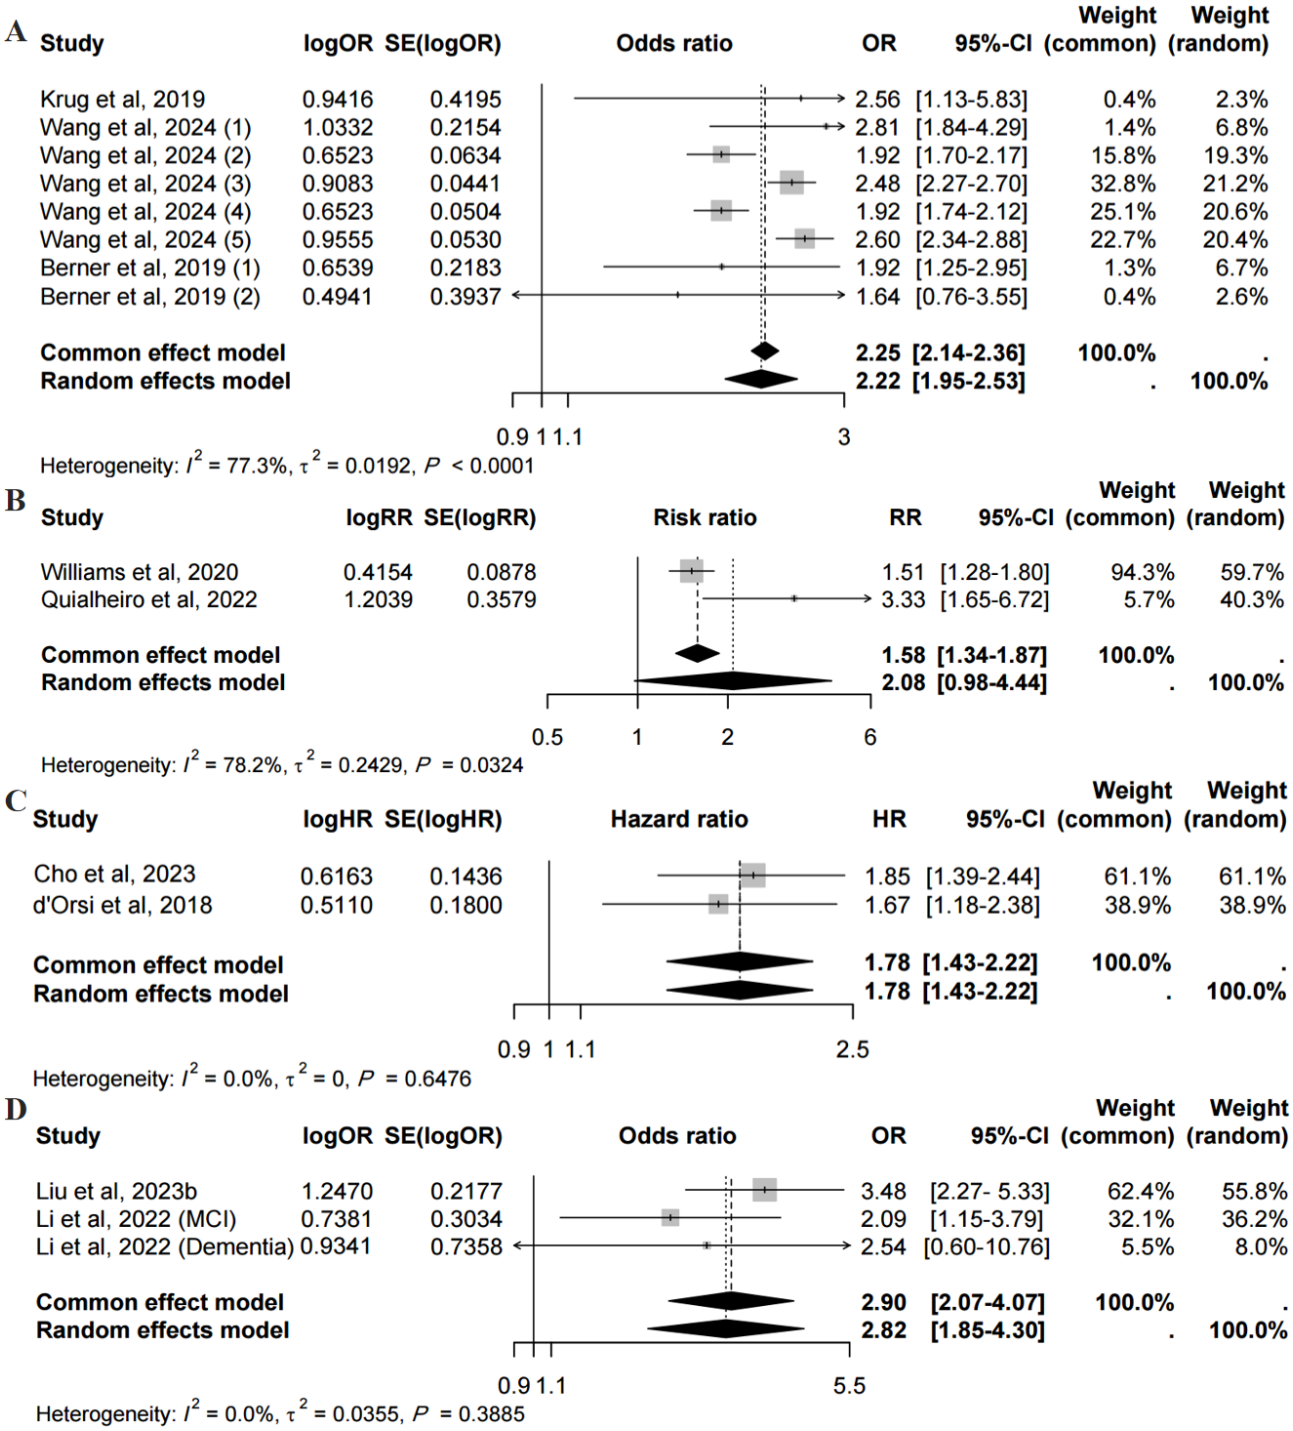
Four studies investigated the prospective association between digital exclusion and frailty, basic activities of daily living (BADLs), instrumental activities of daily living (IADLs), and incident disability [17,30,32,39]. García-Esquinas et al [32] and Li et al [17] investigated the OR value of the association between digital exclusion and frailty. The meta-analysis indicated that there was no statistically significant prospective association between them (OR 1.21, 95% CI 0.92 - 1.59, I^2=95.2%; Figure 2A). Lu et al [30] investigated the incidence rate ratio (IRR) value of the association between digital exclusion and BADLs or IADLs. The pooled associations indicated that digital exclusion was associated with decreased BADLs (IRR=1.35, 95% CI 1.12 - 1.64, I^2=94.7%; Figure 2B) and IADLs (IRR=1.46, 95% CI 1.13 - 1.89, I^2=96.2%; Figure 2C).

XSL•FO
RenderX

Figure 2. Forest plots of prospective and cross-sectional associations between digital exclusion and physical function [17,24,30-32]. (A) The odds ratio value of the prospective association between digital exclusion and frailty. (B) The incidence rate ratio value of the prospective association between digital exclusion and basic activities of daily living. (C) The incidence rate ratio value of the prospective association between digital exclusion and instrumental activities of daily living. (D) The odds ratio value of the cross-sectional association between digital exclusion and activities of daily living. IRR: incidence rate ratio; OR: odds ratio; RR: risk ratio.

Regarding the cross-sectional association, Liu et al [31] and Wen et al [24] analyzed the association between digital exclusion and ADLs. Meta-analysis indicated that there was no significant pooled association between digital exclusion and ADLs (OR 1.23, 95% CI 0.41 - 3.73, I^2=91%; Figure 2D). Tomioka et al [39] found an association between internet use and a lower risk of incident disability. While García-Vigara et al [50] revealed that digital exclusion was associated with a higher risk of frailty.

The pooled analysis indicated that digital exclusion had prospective associations with decreased BADLs and IADLs, no statistical significance in the prospective association with frailty, or cross-sectional association with ADLs.



Association Between Digital Exclusion and Cognitive Function

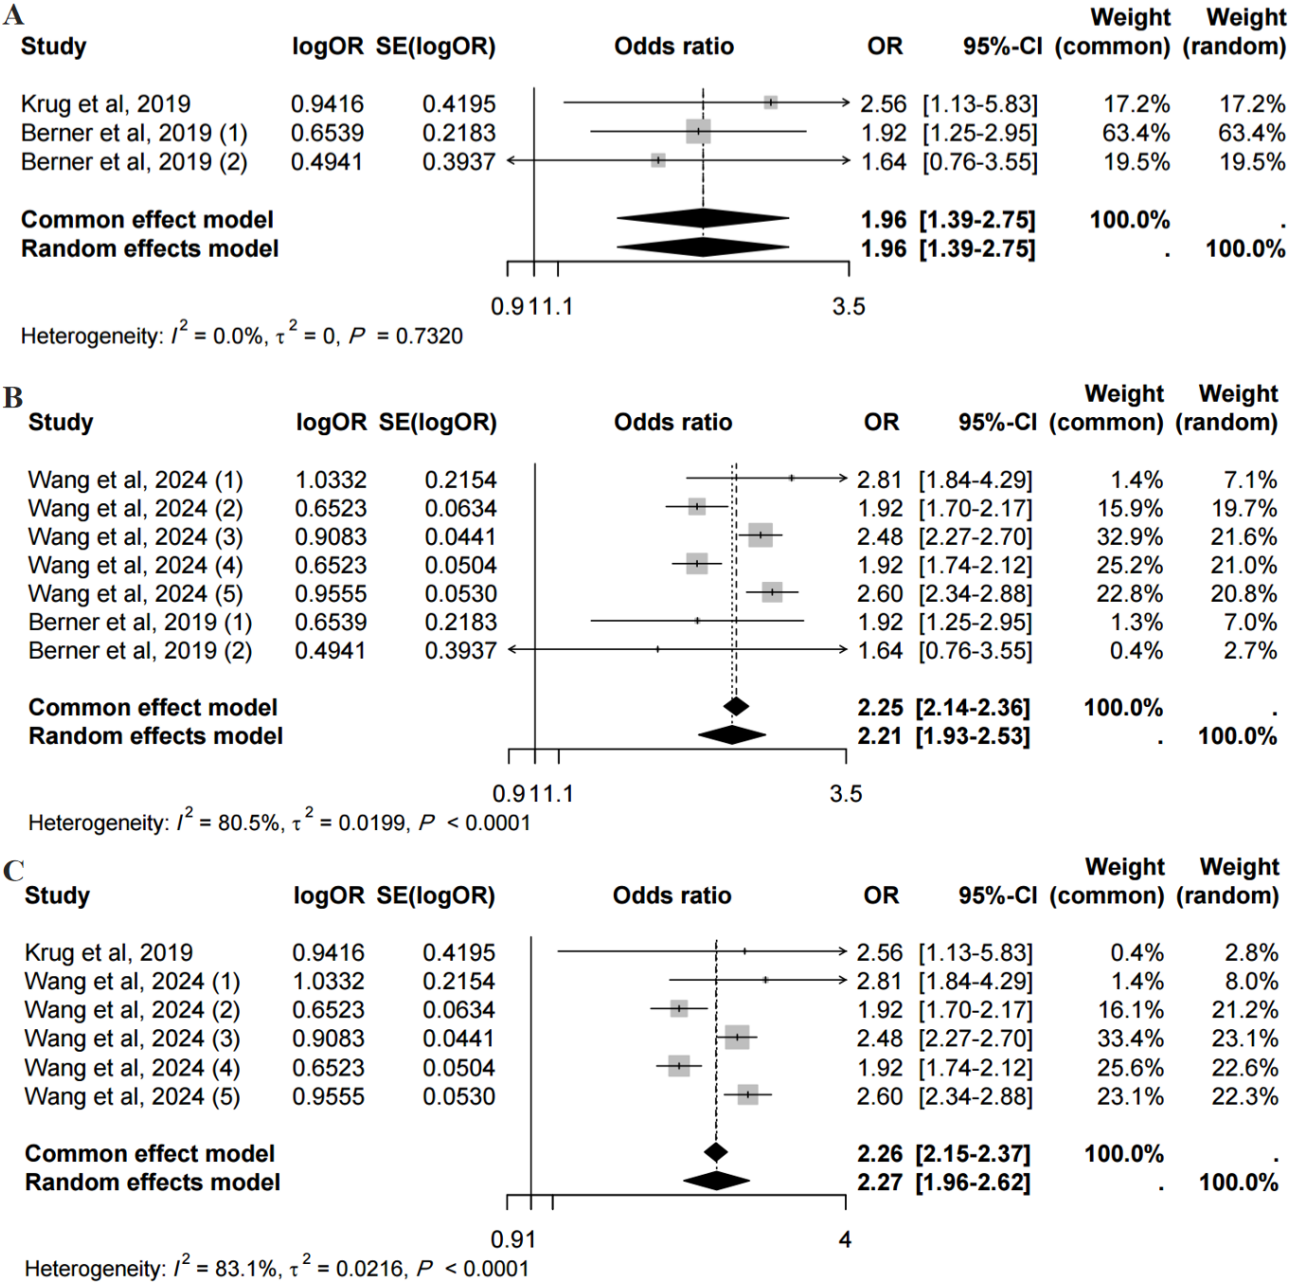
Concerning the cohort studies, Krug et al [40], Berner et al [41], and Wang et al [18] explored the OR value of the association between digital exclusion and decreased cognitive function. Meta-analysis of these cohort studies demonstrated that digital

XSL•FO
RenderX

exclusion was significantly associated with higher odds of decreased cognitive function (OR 2.22, 95% CI 1.95 - 2.53, I^2=77.3%; Figure 3A). Williams et al [43] and Quialheiro et al [47] investigated the relationship between digital exclusion and cognitive impairment. However, meta-analysis of 2 studies [43,47] found no statistically significant association (RR 2.08, 95% CI 0.98 - 4.44, I^2=78.2%; Figure 3B). Cho et al [42] and d'Orsi et al [45] analyzed the HR value of the association between digital exclusion and dementia. Meta-analysis demonstrated a significant association between them (HR 1.78, 95% CI 1.43 - 2.22, I^2=0%; Figure 3C).

Figure 3. Forest plots of cohort and cross-sectional studies on digital exclusion and cognitive function [18,40-43,45,47-49]. (A) The odds ratio value of the prospective association between digital exclusion and cognitive function. (B) The risk ratio value of the prospective association between digital exclusion and cognitive impairment. (C) The hazard ratio value of the prospective association between digital exclusion and dementia. (D) The odds ratio value of the cross-sectional association between digital exclusion and Mini-Mental State Examination scores. HR: hazard ratio; OR: odds ratio; RR: risk ratio.

In terms of the cross-sectional studies, a meta-analysis of 2 studies [48,49] showed that digital exclusion was associated with a decline in MMSE scores (OR 2.90, 95% CI 2.07 - 4.07, I^2=0%; Figure 3D).



XSL•FO
RenderX

There were prospective associations between digital exclusion and dementia and decreased cognitive function, as well as cross-sectional associations with MMSE scores, but no statistically significant prospective association with cognitive impairment.

Sensitivity Analysis

Due to the limited number of studies, sensitivity analysis for the association between digital exclusion and physical function was not performed. In the sensitivity analysis of the prospective association between digital exclusion and cognitive function, a leave-one-out approach was applied, and only minor changes were observed in the results, indicating the robustness of our findings (Figure 4).

Figure 4. Forest plots of cohort studies on digital exclusion and cognitive functioning [18,40,41]. (A) The odds ratio value of the prospective association between digital exclusion and cognitive function, including studies of Krug et al [40] and Berner et al [41]. (B) The odds ratio value of the prospective association between digital exclusion and cognitive function, including studies of Wang et al [18] and Berner et al [41]. (C) The odds ratio value of the prospective association between digital exclusion and cognitive function, including studies of Krug et al [40] and Wang et al [18]. OR: odds ratio.

The sensitivity analysis revealed only minor variations in the results, confirming the stability of our findings, as evidenced by the prospective association between digital exclusion and cognitive function.

Discussion

Summary of Evidence

To the best of our knowledge, this study presents the first systematic review and meta-analysis to comprehensively

XSL•FO
RenderX

evaluate the associations of digital exclusion on both physical and cognitive functions across multiple countries. Synthesizing evidence from 13 cohorts [17,18,30,32,39-47] and 6 cross-sectional studies [19,24,31,48-50], we found that digital exclusion was prospectively associated with declines in IADLs and BADLs, as well as increased risks of incident disability, cognitive impairment, and dementia, and was cross-sectionally related to lower MMSE scores. However, no statistically significant prospective association was observed between digital exclusion and frailty.

Digital Exclusion and Physical Function

Consistent with previous studies [30,39], the meta-analysis identified a negative prospective association between digital exclusion and physical function. Several underlying explanations may account for the associations observed in this study. First, digital exclusion was associated with a minimal chance of using eHealth [57] and limited access to acquire digital preventive and therapeutic health services [58,59]. Second, it might cause a decrease in physical exercise behavior among middle-aged and older adults [60], which can lead to a reduction in skeletal muscle mass, strength, and physical mobility [61], ultimately accelerating the deterioration of physical functions and creating a vicious cycle [62-64]. Additionally, middle-aged and older adults experiencing digital exclusion were prone to dopamine imbalance and induced negative emotions such as loneliness and social isolation [65,66], increasing the risk of incident disability [67].

The associations of digital exclusion on frailty remained debated, and the meta-analysis found no statistically significant prospective association. Frailty is influenced by numerous factors such as age, gender, physiological changes, and other factors [68-70]. Furthermore, the influence of digital exclusion on frailty is likely indirect. It may operate through social isolation, limited access to health information, and reduced physical or cognitive engagement, which accumulate gradually over time [32]. These factors could mask a true association in short-term analyses. In addition, the limited number of studies included in the meta-analysis provided only a modest evidence base. The association between digital exclusion and frailty requires further validation through standardized longitudinal studies with longer follow-up periods and consistent assessments of both digital exclusion and frailty.

Meanwhile, digital exclusion did not demonstrate a cross-sectional association with physical function. One explanation for this inconsistency was the influence of confounding factors. It was also possible that socioeconomic and health-related factors masked the cross-sectional relationship between digital exclusion and physical function. Wen et al [24] reported a cross-sectional association between digital exclusion and physical function without adjusting for confounders [71], whereas Liu et al [31] found no such association after adjustment. In addition, the cross-sectional design was not well-suited to detect the slower impact of digital exclusion on physical function, which emerged gradually through changes in health behaviors and disease management. These findings underscore the need for longitudinal designs to clarify temporal relationships and potential causal pathways.

Digital Exclusion and Cognitive Function

Findings of this study regarding the relationship between digital exclusion and cognitive function broadly aligned with previous research [72-75]. Apart from the aforementioned impact of health care resources and negative psychological emotions, digital exclusion may influence cognitive function through several mechanisms. It not only reduces engagement in cognitively stimulating activities that build cognitive reserve but may also promote negative emotions, which can contribute to neurovascular dysfunction [73,76-78]. Additionally, it is linked to structural brain changes such as reduced volume of the globus pallidus [48].

However, it was noteworthy that no statistical prospective association was observed between digital exclusion and cognitive impairment. This discrepancy could be attributed to several methodological variations across studies. For instance, the studies by Williams et al [43] and Quialheiro et al [47] both investigated populations in the United Kingdom with similar follow-up durations. But the latter had a much smaller sample size (n=594 vs 3937), which could have limited its statistical power and affected the ability to detect significant associations. Furthermore, the 2 studies [43,47] used different assessment tools, which might contribute to the considerable heterogeneity in the meta-analysis.

Dose-Response Relationship and Types of Digital Exclusion

Digital exclusion or excessive internet use both had negative impacts on health outcomes [79-81]. These findings revealed “two sides of the same coin” and emphasized the importance of the frequency of internet use. In terms of the dose-response relationships, previous studies have found an inverted U-shaped association between internet use and cognitive function [42]. In the large-scale prospective cohort study of Cho et al [42], using the internet almost weekly was most beneficial to cognitive function. Additionally, Williams et al [43] and Liao et al [82] have indicated that different types of internet use exert varying impacts on physical and cognitive functions. Previous research showed diverse internet activities benefit cognition more than single ones [83]. However, the optimal types, combinations, and intensity of digital engagement for enhancing physical and cognitive functions in middle-aged and older adults remain unclear. Future research should investigate these factors across different age groups and geographic regions to tailor digital interventions to the needs and capacities of diverse populations.

Different Definitions and Assessment Tools of Digital Exclusion

The prevalence of digital exclusion varies substantially across studies due to differences in national populations, as well as inconsistencies in the definition and assessment tools of digital exclusion among middle-aged and older adults. Some studies had suggested that digital exclusion constituted a part of social exclusion [30], as digital technology marginalized older adults from the digital world [84-86]. It might be associated with a perceived lack of knowledge, inability to access necessary technology and services, and barriers posed by mental health

XSL•FO
RenderX

difficulties [85]. The absence of a unified definition and assessment tool not only reduced the reliability and generalizability of our findings due to high heterogeneity but also hindered the development of effective policies and interventions to address digital exclusion. Future research should focus on establishing a consensus-based conceptual framework and developing rigorously validated assessment instruments of digital exclusion. To ensure global applicability, these tools should be culturally and contextually adaptable, with careful attention to cross-cultural validation that ensures their relevance across diverse populations and settings.

Potential of Assessments Based on Digital Biomarkers

Current assessments of physical and cognitive function in the included studies rely largely on scales that capture activities of daily living, memory, orientation, and related abilities [18,30]. While these tools provide valuable information on functional status, they are largely subjective and may be influenced by self-report bias, assessor variability, or ceiling and floor effects [30,87]. Moreover, evidence directly linking these functional scales to objective biomarkers remains limited. Gotti et al [88] found that inflammatory and immune biomarkers changed significantly after internet-based psychological interventions, demonstrating that digital engagement can trigger measurable biological changes. This evidence presented a promising avenue for exploring underlying health mechanisms through objective biological markers. Advances in digital health further extended this possibility [89]. Chan et al [90] developed Watch Walk wrist-worn algorithms that accurately quantify gait speed [90]. This precision allowed large-scale use and turned routine movements into scalable digital biomarkers. Fan et al [70] demonstrated that integrating wearable gait data with machine learning models can substantially improve frailty prediction [91]. Together, these developments illustrate an emerging capacity to collect continuous or longitudinal data in real-world settings, enabling earlier detection of functional decline and a more nuanced understanding of how digital behaviors may shape health trajectories over time.

Mitigating Digital Exclusion for Middle-Aged and Older Adults

Although growing evidence supports the use of digital technologies to improve physical and cognitive function [92,93], reconciling digital exclusion and digital adoption remains a major challenge. To bridge this divide, it is essential to implement strategies that enhance digital access, strengthen digital literacy, and support digital assimilation [94]. Facilitating the introduction and adoption of user-friendly technologies, particularly those tailored to the needs of older adults, can play a critical role in ensuring equitable digital participation. A growing body of research highlighted co-design as a key approach [95-97]. Chan et al [98] used co-design workshops to involve older adults, health care providers, and community staff in refining a mobile health prototype, ensuring better usability and engagement. Digital navigators can offer literacy training, resolve technical issues, and guide app use, thereby improving technology adoption and integration into care [99]. Beyond design, social support also plays a crucial role. Hänninen et al [100] found that younger family members often act as “warm experts,” offering practical, personalized support that helps older adults manage digital tools with greater confidence.

Limitations and Implications

First, the generalizability of our findings is subject to certain constraints. Our meta-analysis was primarily restricted to studies published in English and Chinese, as these were the languages most accessible to the research team. Under the constraints of time and resources, conducting translations of studies in other languages was not feasible. This limitation may hinder the applicability of the results to regions where other languages are dominant or where cultural and socioeconomic contexts differ significantly. Additionally, the overall number of available studies focusing specifically on digital exclusion remains limited, particularly for middle-aged populations. Most included studies predominantly involved older adults, resulting in inadequate representation of middle-aged cohorts. Due to the limited number of included studies, it is hard to follow different age, sex, education level, income, or rural-urban residence groups to conduct subgroup analyses. This restricts the broader generalization of our conclusions across middle-aged and older adults. Future research should aim to incorporate more diverse geographical and linguistic sources, as well as prioritize well-defined studies involving middle-aged populations, to enhance the generalizability and age-specific understanding of digital exclusion.

Second, our meta-analysis is influenced by the substantial heterogeneity observed in some pooled estimates. This heterogeneity mainly arose from clinical diversity, including variations in population characteristics across different countries and income levels. Methodological diversity also contributed to heterogeneity, including differences in how digital exclusion was assessed across the large cohort studies, restriction to risk-based effect measures, variations in sample sizes, and inconsistent adjustment for covariates. By restricting quantitative synthesis to risk-based effect measures, our findings primarily reflect associations framed within an epidemiological risk perspective and may not fully capture evidence derived from correlation-based analyses using continuous measures. We performed sensitivity analyses to test the robustness of the findings and to identify key sources of heterogeneity. However, the limited number of studies in certain subgroups restricted more detailed investigations. If enough studies are available, conducting a subgroup analysis based on different definitions is informative. In the future, it is necessary to unify the definition of digital exclusion and develop recognized tools for assessment.

Third, the impact of the types and frequency of digital exclusion on physical and cognitive functions could not be explored. Future in-depth research could explore the dose-response relationships of various frequencies and types of digital exclusion on physical and cognitive functions.

Fourth, the exclusion of gray literature might lead to publication bias. It is advisable to search specialized gray literature databases when time, resources, and evidence permit.

Conclusions

Our findings emphasize the negative associations between digital exclusion and physical or cognitive functions. Although our

XSL•FO
RenderX

results do not directly address optimal patterns of digital engagement, it is noted that moderate and diverse digital use may be more beneficial than either nonuse or overuse for maintaining these functions. In clinical practice, integrating digital tools into interventions can support physical and cognitive health when tailored to users' abilities and needs. For policymakers, efforts should focus on expanding internet access, reducing financial barriers, and improving digital literacy through training and awareness programs. For future studies, the need for cautious interpretation and further validation are needed due to variations across studies, assessment tools, and populations.

Abstract

Background: Being socially connected is essential for health and well-being. Nonetheless, many older adults face social isolation, especially in ethnically diverse societies. Digital technologies offer a pragmatic approach to addressing problems with social connectedness; however, a consolidated understanding of their association with social connectedness among ethnic minority older adults remains unaddressed.

Objective: We conducted a systematic review and meta-analysis to investigate the prevalence and utility of digital resources in promoting social connectedness among ethnic minority older adults.

Methods: This systematic review and meta-analysis was guided by the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines. Studies were retrieved from 4 electronic databases. A random-effects meta-analysis was used to estimate the pooled prevalence along with its 95% CI.

Results: Twelve studies were included. The research approaches used by the included studies were as follows: quantitative (n=5), qualitative (n=5), and mixed methods (n=2). Overall, the estimated prevalence of internet use, which was defined as engaging in online activities through digital devices, was 81.8%. Commonly used digital devices were computers (66.7%), smartphones (63.2%), and tablets (29.3%). Sociodemographic, economic, and health-related factors influenced the adoption and use of digital resources among ethnic minority older adults. These older adults relied on digital resources to build meaningful social connections through social participation, maintaining cultural and religious ties, promoting transnational social networks, and fostering their potential for social connectedness. However, digital resources were not always useful for social connectedness and adversely affected in-person contact.

Conclusions: Digital resources can promote social connectedness among ethnic minority older adults by enabling them to maintain their cultural and social values. Cities and regions aiming to promote the social connectedness and well-being of ethnic minority older adults should consider intersectional factors that affect access to digital resources and the sustainable adoption of digital resources.

(JMIR Aging 2026;9:e84962) doi:10.2196/84962

KEYWORDS

digital resources; ethnic minority; older adults; social connectedness

Introduction

There are approximately 5.6 billion internet users worldwide, which accounts for 67.9% of the global population, indicating the fundamental and crucial role of digital resources in the global socioeconomic and developmental milieu [1]. Digital resources encompass any electronic device, tool, system, or equipment that can connect to the internet and generate, store, and/or process data [2,3]. Digitalization and technological advancement are rapidly becoming the mainstay of contemporary communication, education, economic opportunities, and how people interact with their communities, even in low- and middle-income countries [4]. Digital engagements are increasingly underpinning most activities, and this situation also applies to ethnic minority older adults, especially given the myriad sociocultural barriers they face in accessing needed social services and maintaining healthy social connectedness [5]. Social connectedness, the primary focus of this study, is

XSL•FO
RenderX

considered the antonym of loneliness as it involves constructive relationships with others, including groups, communities, and individuals [6]. Thus, it is strongly related to social connections or networks, which represent "the structure, function, and quality of our relationships with others" [7], including family, friends, neighbors, and people within and outside our immediate and external sociophysical environments [6,8]. Such connections are fundamental to individual and social sustainability, resilience, safety, and prosperity, especially among vulnerable people [9].

Older adults, especially those in minority groups, are often vulnerable to social isolation (ie, an object deficit in adequate social connections) and loneliness (ie, psychological pain due to the gap between desired and actual social connections) due to limited opportunities to be socially connected—a situation often compounded by language barriers and economic challenges [7,10,11], which can have a negative impact on their health [12]. It is estimated that one-third of older adults experience some degree of social isolation as their social networks reduce with age [13,14]. This has been attributed to factors such as migration, death, and the age-related functional decline of their usual social connections [10]. Acculturation is the psychological, social, and cultural changes that occur when 2 cultures come in contact [15]. Many migrants, especially those of ethnic minority status, tend to struggle to effectively participate in the traditions, values, and practices of dominant cultures, making them feel a sense of exclusion [16]. A major challenge is often how people from minority backgrounds decide whether to prioritize their heritage or the host culture [16]. Such experience leads to acculturative stress and psychological and emotional strain (eg, language barriers, feelings of being an outsider, experiences of discrimination, and even racism) as people adapt to a different culture [17]. Difficulty in acculturating to a new culture means many ethnic minority people face significant challenges forming meaningful relationships with members of the majority group (ie, social connectedness), something that is likely more abundant among majority populations [18,19]. Likewise, from the perspective of the social identity theory [20], such challenging experiences due to acculturation stress leave questions about how ethnic minority people form or maintain their self-concept relative to the larger population and culture in terms of how they categorize themselves (eg, in terms of race, nationality, and social class), how they identify with the group (ie, the majority group), and how they compare themselves with majority groups and those of similar characteristics as themselves (in-group) [21]. This process of constructing and maintaining social identity can be inimical to the forms of social connections and connectedness available to ethnic minority people, as the formation and maintenance of social relationships are also part of social identity [22].

These challenges with acculturation and social identity make digital tools and resources quintessential to the successful adaptation and social connectedness of ethnic minority people, particularly older adults, as they can provide them with space to reinforce their ethnic and cultural identities and connect with others with similar sociocultural backgrounds and beliefs [3,23]. Digital resources are broadly considered to comprise devices, such as smartphones, computers, tablets, and remote monitoring devices, and the platforms they enable, such as video streaming, messaging app use (eg, WhatsApp and WeChat), online gaming, and social media use (eg, Facebook, TikTok, and Instagram), through the internet [3]. Such resources can promote social connectedness among older adults and reduce loneliness and social isolation [24,25]. For ethnic minority older adults, being in unfamiliar and racially diverse communities reduces their social and cultural capital, leading to limited opportunity for them to generate meaningful social connections, which often affects their well-being adversely [18,26,27]. Despite the benefits and widespread use of digital resources, ethnic minority populations continue to face significant barriers to adopting and utilizing these resources [28]. Identified barriers include limited access to digital technology (eg, the internet), negative attitudes and technology anxiety, data privacy and security concerns, low digital skills, low literacy skills, and unfavorable device and content design [29,30]. These factors align with the Technology Acceptance Model, which argues that factors, including perceived ease of use, perceived usefulness of a technology, attitudes, and intention toward technology use, determine how much a person is willing to accept and adopt different technologies [31,32]. Given these factors, emergent questions include how and to what extent digital tools/platforms serve as mediums for social connections among ethnic minority older adults.

To address such research gaps, some systematic literature reviews have summarized studies on the impact of digital resources on social connectedness among older adults [24,33-36]. However, these studies have mainly focused on older adult populations, leaving a significant knowledge gap regarding specific groups, which complicates efforts to develop inclusive digital strategies, particularly those focused on ethnic minority aging populations, many of whom have difficulty forming social connections [10]. Therefore, this systematic review and meta-analysis seeks to identify the prevalence and utility of digital resources for social connectedness among ethnic minority older adults. The findings from this study can pave the way for well-situated future research and a strengthened knowledge base for responsive policies aimed at promoting social connectedness among ethnic minority older adults to prevent and manage ill-consequences such as social isolation and loneliness.

Methods

Overview

This systematic review was conducted and reported in accordance with the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines [37]. The PRISMA checklist is provided in Checklist 1. It was registered with the International Prospective Register of Systematic Reviews (PROSPERO; CRD420251035114) [38].

Study Selection Criteria

Participants

This systematic review included studies in which some or all study participants were ethnic minority older adults, as defined

XSL•FO
RenderX

in various studies. An ethnic minority group is a group of people who share primarily racial and ethnic identities that differ from the dominant race in a given place. In most places, such people include immigrants (of different races/ethnicities and often different nationalities), indigenous people, people of color, and ethnic groups with characteristics such as different cultures/traditions and languages [27].

Intervention

Studies were included if they (1) explored the use of digital resources for communication or social function among ethnic minority older adults and (2) evaluated the association between the use of digital resources and outcomes related to social connectedness among ethnic minority older adults.

Studies

This systematic review and meta-analysis included primary studies of any design, as well as peer-reviewed journal articles and studies published in English. Editorials, opinion pieces, comments, letters, reviews, and any non–peer-reviewed materials were excluded.

Outcome Measures

The primary outcome of interest was the utility of digital resources for social connectedness. The secondary outcomes were the prevalence of digital resource usage and the factors that influence its use among ethnic minority older adults.

Data Source and Search Strategy

The following electronic databases were searched: PubMed, Web of Science (Core Collection), PsycINFO, and Scopus. Databases were searched between May 2, 2025, and May 4, 2025. Consistent with our consideration of digital resources as electronic devices and their platforms used for social connections, the search strategy included use of a wide range of terms related to the following concepts: electronic devices and platforms (eg, computers, smartphones, tablets, and social media), social connectedness (with related terms such as social network, social connection, social support, social capital, and social interactions), ethnic minority populations (with related terms such as people of color, minority group, human migration, racial minority, aboriginal, and others), and older adults (with related words such as elderly, seniors, and older persons). Detailed information is provided in Table S1 in Multimedia Appendix 1. The expansive search terms enabled the retrieval of comprehensive results of related research. Medical Subject Headings (MeSH), keywords, and free-text terms were combined using “AND” or “OR” Boolean operators. A hand search through Google Scholar and tracing of reference lists of relevant studies were performed to supplement the electronic database search. No geographical restrictions were applied to the search.

Study Selection

Duplicate articles were removed. Two reviewers independently screened the titles and abstracts of articles retrieved by the search to determine their eligibility. Agreement between reviewers during the title and abstract screening was almost perfect (Cohen κ=0.88). A third reviewer resolved any disagreement between the 2 reviewers. Full texts of any potentially relevant articles were obtained and assessed by 2 independent reviewers based on the defined inclusion criteria, with a Cohen κ score of 0.92. Disagreements were resolved by discussion with a third reviewer. The selection process was recorded in detail to produce a PRISMA flow diagram. EndNote (Clarivate) was used to manage the references.

Data Extraction

For studies that fulfilled the inclusion criteria, 2 reviewers independently extracted relevant data. A standard data extraction form was developed. The following data were extracted:

- Study characteristics: authors, year of publication, country, aim, study design, inclusion and exclusion criteria, sample size, gender distribution, and mean (SD) age
- Outcomes/results: type of digital resource, prevalence data, and determinants of digital resource use
- Conclusions: author discussion/conclusions, limitations, funding, and notable conflicts of interest

Study Quality Assessment

Two reviewers assessed the quality of the included studies. Any discrepancies were resolved by discussion. Interrater agreement between the reviewers was excellent, with a Cohen κ score of 0.90. Qualitative and quantitative studies were assessed by using the appropriate Joanna Briggs Institute (JBI) Critical Appraisal Checklist for qualitative research. Consistent with approaches reported in other previous systematic reviews and to facilitate comparison, each item in the appraisal checklist was rated as follows: yes (1 point), no (0 points), and unclear/not applicable (0 points) [39,40]. The sum was divided by the number of items in the appraisal checklist and multiplied by 100 to obtain a percentage. The risk of bias scores were categorized as follows: 80% or more (high quality), 50% - 79% (moderate quality), and below 50% (low quality), as suggested elsewhere [41].

Overall, most of the included studies fulfilled the relevant JBI criteria. Four quantitative studies were rated high quality [42-45]. Similarly, 4 qualitative studies were rated high quality [46-49]. Among the included studies, only 4 reported using a theoretical framework to guide their work [42-44,47].

Details of the quality assessment are provided in Tables S2 and S3 in Multimedia Appendix 1.

Data Analysis

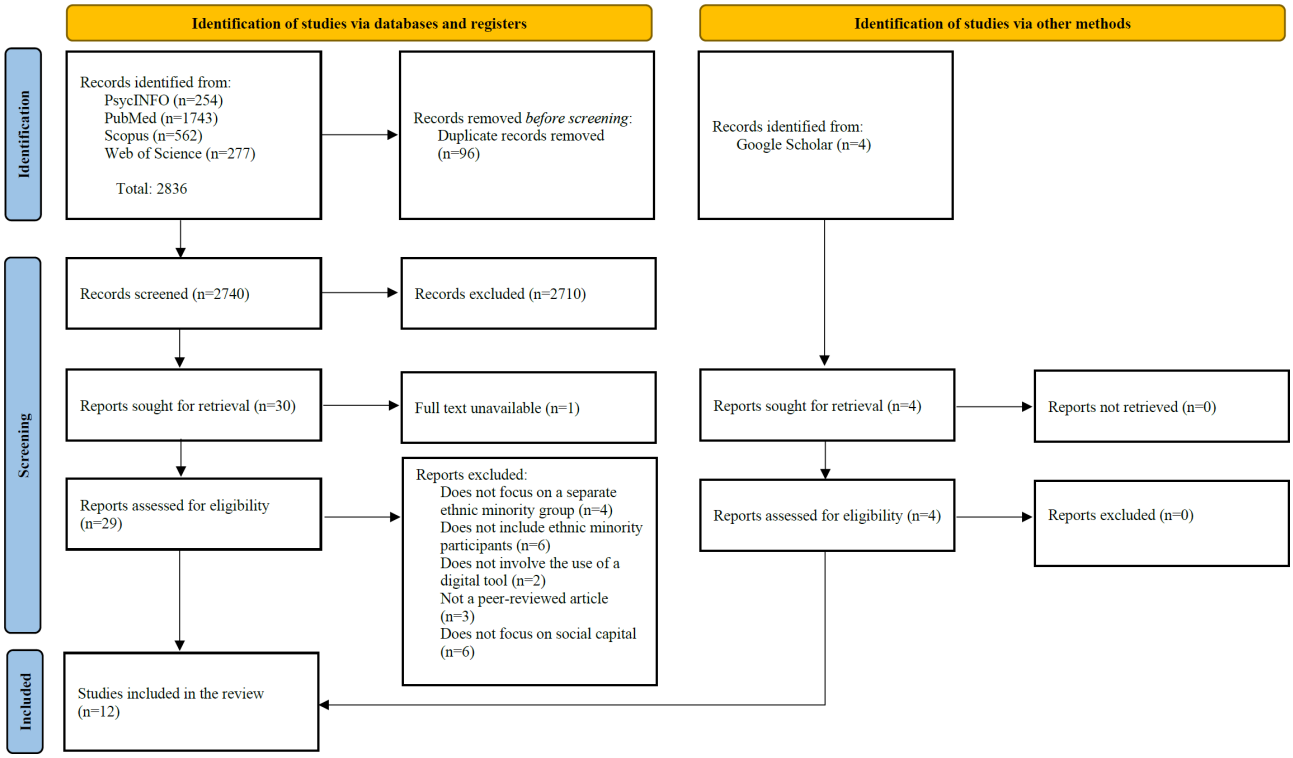
Data were summarized statistically when available, sufficiently similar, and of sufficient quality. The included studies were characterized by the study design and the type of digital resource. Qualitative findings were synthesized thematically following the procedure described by Thomas and Harden [50]. This included (1) free line-by-line coding of the findings of primary studies (eg, identifying prevalence indicators of digital resources and different uses of digital resources for social connections such as religious, cultural, intranational, and cross-national connections), (2) organization of codes into related categories to develop descriptive themes that capture patterns across the included studies (eg, religious and cultural codes were pulled together), and (3) development of higher-order analytical themes (eg, defining and refining categories and names to represent the core idea, such as maintaining cultural and religious connections). The analysis

XSL•FO
RenderX

was mostly deductive, with a focus on addressing the research objectives guided by evidence from the literature on how digital resources affect social connectedness. Two authors led the data analysis, and the other members helped resolve contradictions during the process.

A meta-analysis was conducted on studies that reported quantitative data. A random-effects meta-analysis was used to calculate the pooled data with 95% CIs. The extracted data were used to compute the SE of the prevalence of digital resource usage for each included study, using the equation below, where n represents the sample size and p represents the sample proportion [51].

$$SE=p\times(1-p)n$$



Heterogeneity among studies was estimated using the I^2 index [52], with values categorized as follows: 0%, no heterogeneity; 25% - 50%, low heterogeneity; 51% - 75%, moderate heterogeneity; and >75%, high heterogeneity. Heterogeneity was considered statistically significant at a P value of .05. Forest plots and tables were generated for the visualization of the results. Data were analyzed using Review Manager 5.4 (Cochrane).

Results

Search Results

An initial search of 4 electronic databases yielded 2836 articles, of which 96 duplicates were removed. The remaining articles were screened by title/abstract, and 2710 articles were excluded using the exclusion criteria. Of the remaining 30 articles, 8 met the inclusion criteria. Four additional articles were included through a Google Scholar hand search. Finally, 12 articles were included in this review (Figure 1).

Figure 1. Screening of studies based on the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flow diagram [37].

Characteristics of the Included Studies

Table 1 presents the characteristics of the included studies. The research approaches used by the included studies were as follows: quantitative (n=5) [42-45,53], qualitative (n=5) [46-49,54], and mixed methods (n=2) [55,56]. The included studies were mainly conducted in 4 central countries (United States, n=6; Australia, n=3; Finland, n=1; Israel, n=1), and 1 study was conducted in multiple countries.

Meta-Analysis

Prevalence of Digital Resource Usage Among Ethnic Minority Older Adults

Prevalence of Internet Use Among Ethnic Minority Older Adults

Internet use was defined as engagement in online activities through digital devices. Five studies (1293 participants) reported prevalence data on internet use among ethnic minority older adults [43,44,47,54,55]. The estimated pooled prevalence of internet use was 81.84% (95% CI 71.31 - 92.37). However, the observed between-study heterogeneity was significantly high (I^2=100%; P<.001; Figure 2).

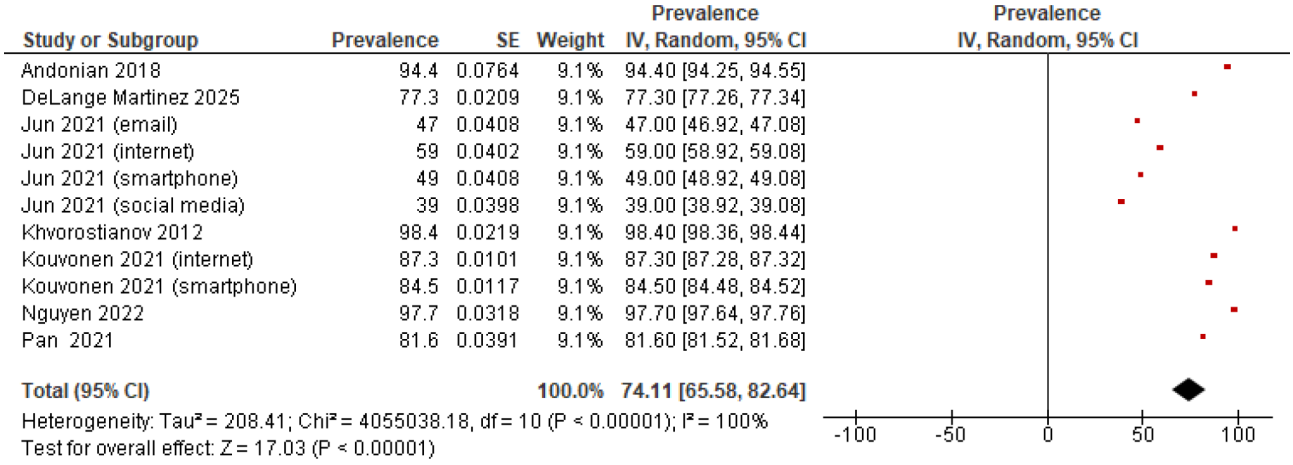

Figure 2. Forest plot of the prevalence of internet use [43,44,47,54,55].

Overall Use of Information and Communication Technology

The overall prevalence of information and communication technology resources that enabled digital engagements was calculated from 7 studies (1794 participants) [42-44,47,53-55]. The overall estimated pooled prevalence was 74.11% (95% CI 65.58 - 82.64). However, a significantly high between-study heterogeneity was observed (I^2=100%; P<.001; Figure 3).

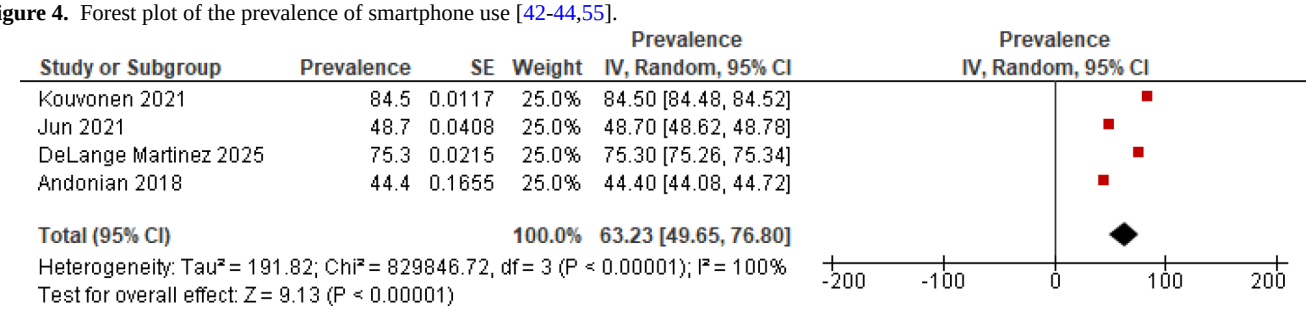

Figure 3. Forest plot of the prevalence of information and communication technology use [42-44,47,53-55].

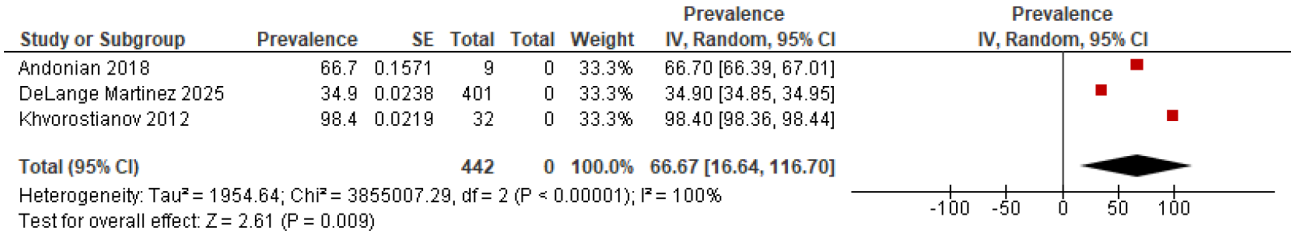
Prevalence of Smartphone Use Among Ethnic Minority Older Adults

Four studies (1525 participants) reported prevalence data on smartphone use among ethnic minority older adults [42-44,55]. The estimated pooled prevalence of smartphone use was 63.23% (95% CI 49.65 - 76.80). However, a significantly high between-study heterogeneity was observed (I^2=100%; P<.001; Figure 4).

Figure 4. Forest plot of the prevalence of smartphone use [42-44,55].



XSL•FO
RenderX

Prevalence of Computer Use Among Ethnic Minority Older Adults

Three studies (442 participants) reported prevalence data on computer use (ie, desktops and laptops) among ethnic minority older adults [42,54,55]. The estimated pooled prevalence of computer use was 66.67% (95% CI 16.64 - 116.70). However, a significantly high between-study heterogeneity was observed (I^2=100%; P<.001; Figure 5).

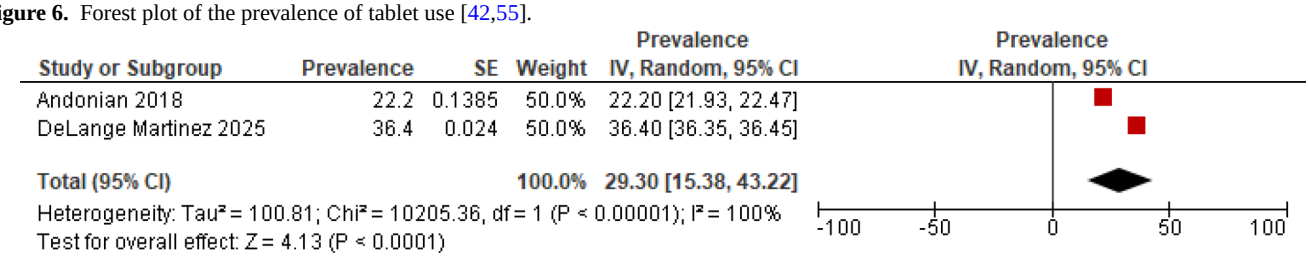


Figure 5. Forest plot of the prevalence of computer use [42,54,55].

Prevalence of Tablet Use Among Ethnic Minority Older Adults

Two studies (410 participants) reported prevalence data on tablet use among ethnic minority older adults [42,55]. The estimated pooled prevalence of tablet use was 29.30% (95% CI 15.38 - 43.22). A significantly high between-study heterogeneity was observed (I^2=100%; P<.001; Figure 6).

Figure 6. Forest plot of the prevalence of tablet use [42,55].

Thematic Synthesis

Thematic synthesis of the extracted data generated the following two major themes: (1) utility of digital resources for social connectedness, and (2) factors that influence the use of digital resources among ethnic minority older adults.

Utility of Digital Resources for Social Connectedness

Overview

The following six subthemes relating to the utility of digital resources for social connectedness were identified: (1) enhancing social integration and participation, (2) maintaining cultural and religious connections, (3) promoting transnational connectedness, (4) fostering intergenerational connectedness, (5) expanding social networks for social connectedness, and (6) downsides of digital resources for social connectedness.

Enhancing Social Integration and Participation

Findings related to digital resources enhancing social integration and participation emerged from quantitative (n=4) [42-44,53], qualitative (n=3) [46,48,49], and mixed methods (n=2) [55,56] studies. It was revealed that platforms, such as social media, enabled ethnic minority older adults to actively participate in social activities, access information and community resources, learn new skills, and interact with community members. For example, a cross-sectional survey of 98 Chinese immigrants in Belgium and the Netherlands found that 81.6% of respondents had more frequent non–in-person contact with kin and nonkin individuals via smartphone-enabled social media to support social participation during the COVID-19 pandemic [53]. Qualitative evidence highlighted the critical role of digital resources in promoting a sense of community belonging among ethnic minority older adults. A study among older adults from non–English-speaking backgrounds living in a residential aged care facility in Western Australia made the following argument [48]:

> *[Touchscreen technology] lifted the mood of the room, transforming it into a livelier space and facilitating a sense of community and shared fellowship among all participants… residents went from being individuals doing nothing to active members of a group, contributing to a sense of belonging.*

Maintaining Cultural and Religious Connections

Evidence on digital resources playing a critical role in maintaining cultural and religious connections among immigrant older adults was drawn from 4 qualitative studies [46-49], 2 quantitative studies [42,45], and 2 mixed methods studies [55,56]. A quasiexperimental study showed that participants who received an internet-based meditation program across various devices demonstrated significantly greater sociocultural adaptation compared with a control group, with effect sizes ranging from 0.55 to 0.87 (P≤.01) [45]. It was observed that digital resources created a convenient virtual space for religious practices, particularly during the COVID-19 pandemic, by connecting the older adults with people of similar faith. In a study of 11 older African immigrants, it was reported that avenues, such as Facebook, created opportunities for social, cultural, and spiritual engagement with others during the pandemic [45]. For instance, a study among older immigrants in Western Australia made the following statement regarding individuals' motivation for participating in the Internet Café community of practice [49]:

XSL•FO
RenderX

> *…desire to connect with the places and memories of their past…on one occasion, the cafe was filled with Irish folk music as a patron played the traditional sounds of his homeland from a website.*

Promoting Transnational Connectedness

Seven studies (4 qualitative studies and 3 quantitative studies) indicated that the availability of digital resources, such as the internet, smartphones, and media, such as video calls or group chats, allowed immigrant older adults to maintain connections with family members and friends across countries [42,45-47,49,53,54]. A cross-sectional survey of 401 older Asian Americans found that 89.2% of respondents agreed that digital resources were useful for engaging family and friends [42]. Khvorostianov et al [54] noted that transnational connections formed through digital resources often led to empowerment and better integration of immigrants into their host societies, including the development of lasting social relationships. It was observed that digital resources played a critical role in facilitating financial transactions, thereby enabling stronger social connectedness through the continuity of transnational caregiving and support. For example, a participant in a qualitative study involving 22 Vietnamese immigrant grandparents made the following statement [47]:

> *[She] maintained daily contact via video phone calls…with her son and grandchildren, as well as a group of Vietnamese close friends…For her mother, she provided transnational care by sending remittances to pay the domestic worker, cover her mother's daily expenses, and purchase nutritional supplements.*

Fostering Intergenerational Connectedness

Findings from 3 qualitative studies [46,49,54] and 2 quantitative studies [43,45] indicated that digital resources fostered intergenerational connections among ethnic minority older adults. Digital resources were important interventions for bonding with grandchildren, facilitating intergenerational language exchange, sharing family history, and mentoring the younger generation. According to Kouvonen et al [43], the frequent use of social media among 631 older immigrants enabled intergenerational interactions. Khvorostianov et al [54] identified that the internet served as a tool that connected grandchildren to their heritage:

> *[We] built a website where we publish articles, memories and documents telling how our relatives were murdered. My grandchildren browse this website too and learn about their family history.*

Expanding Social Networks for Social Connectedness

Evidence from 2 qualitative studies [49,54], 2 quantitative studies [43,44], and 1 mixed methods study [54] indicated that digital resources are critical for expanding the social networks of older adult immigrants. It was reported that internet-enabled computer usage helped ethnic minority older adults engage in social activities that expanded their social participation beyond their immediate environment [55]. Similarly, the use of social media platforms, facilitated by digital tools, supported development and reconnection with past social networks [43,44,49,54,55]. It was revealed that maintaining social networks online helped older adult immigrants cope with distance from family members and friends; thus, it provided physical and emotional support to remain socially connected and alleviate feelings of social isolation [49,54,55]. A study from Australia made the following statement [49]:

> *Improving digital literacy has special implications for the well-being of older migrants because it can enhance their ability to exchange emotional support across distance.*

Downsides of Digital Resources for Social Connectedness

Notwithstanding, having access to digital resources was not always impactful in reducing the outcomes of social connectedness, such as loneliness [53]. Other studies indicated the likelihood that digital resources will reduce human contact, which can worsen quality of life [48]. In the article by Andonian [55], some participants presented instances that can lead to poor social connectedness through physical isolation, such as the following:

> *When I came here, I didn't know anything. Everybody was like running all over the city with, you know [points to smartphone]. What are they doing?! You know, they're not saying "hello" to anybody around them…*

These observations align with others that indicate the limitations of digital resources in promoting social connectedness. For instance, it was found that having a poor health status and being socioeconomically disadvantaged led to less engagement with digital resources, making them less relevant to promoting low social connectedness, as presented in other findings [43,55].

Factors That Influence the Use of Digital Resources Among Ethnic Minority Older Adults

Overview

The systematic review identified sociodemographic, economic, and health-related factors that influence the adoption and use of digital resources among ethnic minority older adults.

Sociodemographic and Economic Factors

Age

Older age was found to be negatively associated with digital resource use [42,43,46,47,49,54,55]. For instance, Kouvonen et al [43] reported that nonuse of the internet and smartphones was prevalent among individuals aged 65 years or older compared to younger age groups (internet nonuse: 97/421, 23.0% vs 40/646, 6.2%; smartphone nonuse: 98/351, 27.9% vs 51/614, 8.3%). Additionally, Nguyen et al [47] found that age was associated with low digital literacy among ethnic minority older adults (Vietnamese Australians). However, they were motivated to learn how to use digital resources due to the social connection opportunities they offered, such as participation in religious events.

Gender

Gender was found to be a predictor of digital resource use among ethnic minority older adults [42,49,54]. DeLange

XSL•FO
RenderX

Martinez et al [42] revealed that female gender was significantly and negatively associated with the use of digital resources and platforms (r=–0.15; *P*=.01). Khvorostianov et al [54] found that older women were more likely to use the internet to develop new professional interests, whereas older men used it to maintain their original professional identity, which helped build their self-confidence as active members of their communities.

Educational Level

Seven studies found that ethnic minority older adults' adoption and use of digital resources were influenced by their levels of education [42-47,54]. DeLange Martinez et al [42] found that older adults with higher educational levels were more likely to utilize digital tools for social connections compared to those with lower educational levels (β=.21; *P*<.001). Nguyen et al [47] stated that Vietnamese migrant grandparents with lower education were less likely to engage with digital resources, with most using them for the first time after their migration. To address disparities in the adoption and use of digital resources, instructions for these resources should be clear and simplified for ethnic minority older adults with limited educational backgrounds to ensure ease of use [45].

Language Proficiency

Few studies stated that language proficiency was related to the adoption and perceived ease of use of digital resources among ethnic minority older adults [42,43]. Kouvonen et al [43] reported that older Russian-speaking immigrants in Finland who had effectively integrated into Finnish society and had strong local language skills were more likely to own a smartphone to access the internet. Linguistic bias in digital resource and application development, which favors English-speaking users, needs to be addressed to facilitate the use of technology among culturally and linguistically diverse older adults [42].

Religion

One study found religion to be associated with the use of digital resources among immigrant South Asian older widows [45]. Pandya [45] identified that an internet-based meditation program was more effective for older Hindu and Buddhist widows than Christian widows because of cultural familiarity with meditation practices.

Economic Status

Economic status was identified as an influential factor in the digital technology used by ethnic minority older adults [43-45,49]. For example, Jun et al [44] reported that Korean immigrant older adults with an annual income greater than US $20,000 were significantly more likely to use digital resources than those in the lower-income group (t_{148}=−4.53; *P*≤.001). The financial cost of digital resources, such as purchasing a smartphone or the monthly cost of internet services, was a significant barrier for low-income older adults, which increased the prevalence of nonuse of digital resources [43].

Health-Related Factors

Physical Health

The physical health of ethnic minority older adults has been identified as a critical factor in the adoption and use of digital resources [43-45,55,56]. Physical health challenges, including decreased vision and coordination, affected the use of digital resources. For example, Kouvonen et al [43] reported that older Russian-speaking immigrants in Finland with poor physical health were 5 times less likely to own and use smartphones compared to those with good physical health (odds ratio [OR] 0.20, 95% CI 0.06 - 0.69; *P*=.006).

Mental Well-Being

Mental health challenges, such as cognitive decline, anxiety, and depression, were identified as critical barriers to the adoption and use of digital resources among ethnic minority older adults [42,43,56]. As observed by Kouvonen et al [43], ethnic minority older adults experiencing depressive symptoms were almost 3 times more likely not to use the internet for messaging or calling compared to those without depressive symptoms (OR 2.68, 95% CI 1.37 - 5.24; *P*=.004).

COVID-19 Restrictions

One study investigated the impact of the COVID-19 pandemic on the adoption and use of digital resources among ethnic minority older adults [53]. Pan et al [53] stated that COVID-19 accelerated the adoption and use of digital resources among older Chinese migrants in Belgium and the Netherlands, with increases of 43.9% and 81.6% in non–in-person contact with family and friends, respectively.

Discussion

Principal Findings and Comparison With Other Studies

Maintaining active social connections is critical to the health and well-being of ethnic minority older adults, as it reduces the risk of social isolation and loneliness [10]. Thus, understanding and promoting the dynamics of social connections among this group of people are important for protecting their health and well-being. The study found significant variation in the prevalence estimates of digital resource use among ethnic minority older adults, with most preferring to use the internet for social connectivity. Overall, the prevalence of information communication technology use was 74.11%, and the estimated prevalence of internet use was 81.8%. Moreover, the values for computers, smartphones, and tablets were 66.7%, 63.2%, and 29.3%, respectively. Internet use ranged from 59.3% among older Korean immigrants in the United States [42] to 98.4% among older Jewish immigrants from the Former Soviet Union in Israel [54]. These findings indicate that while digital engagement for social connection is considerable among ethnic minority older adults, usage disparities exist across ethnic groups [42]. In comparison to studies about older adults generally, which also note a digital divide, these results emphasize the critical role of ethnic and cultural context in shaping digital resource utilization [25,32]. The high prevalence of internet use suggests that targeted digital inclusion strategies could be highly

XSL•FO
RenderX

effective. However, these must be culturally sensitive and address the unique needs and preferences of each ethnic minority group [28,42].

The qualitative synthesis identified two related themes: (1) the utility of digital resources for social connectedness, and (2) the factors that influence their use among ethnic minority older adults. These themes offer insights into the lived experiences of ethnic minority older adults in engaging with digital resources. It was revealed that digital resources function as essential tools for enhancing social integration and participation, maintaining cultural and religious connectedness, promoting transnational connections, and fostering intergenerational connectedness through expanded social networks. These findings suggest that digital resources facilitate access to information and opportunities for ethnic minority older adults to maintain meaningful social relationships with their families who have been left behind in their home countries or have been apart from them while also enabling these older adults to create new social connections to support their well-being [34,36]. From the perspective of social identity theory, digital resources can be instrumental in how ethnic minority populations construct and maintain their self-concepts [21,23]. In this review, such identity construction and maintenance are influenced by digital resources, which bridge geographical boundaries for social connectedness and enable ethnic minority older adults to meet cultural expectations, such as supporting younger generations.

Despite the overall positive aspects of digital resources for social connectedness, this review also points to instances or conditions that make them less relevant or even a causal mechanism for low social connectedness among aging ethnic minority people [53,55]. This finding underscores the importance of physical social connections in fostering social connectedness, as virtual interactions have significant limitations (eg, difficulty in conveying emotions effectively) [56]. These observations mean that the integration of digital resources in promoting social connectedness must be done from a balanced perspective—one that seeks to complement physical interactions with digital resources instead of attempting to entirely replace or overly prioritize the technologies over actual human contact [57]. For ethnic minority older adults, such a balance can be crucial to their acculturation, as found in studies showing that the high prevalence of smartphone use made entry into local cultural dynamics challenging for minority migrant individuals [55,56]. These downsides to digital resources were strongly related to intersectional factors, such as economic status, health status, and others, which require serious attention to enable the sustainable use of technologies in promoting social connectedness, as further elaborated in the following paragraphs.

The systematic review identified several factors that influenced the adoption and use of digital resources among ethnic minority older adults, which were categorized into sociodemographic, economic, and health-related factors. Identified sociodemographic factors included age, gender, educational level, language proficiency, and religion. These factors indicate the intersectional nature of digital engagement among older adults in general, with significant stratification across gender, race/ethnicity, education, and other areas [58]. Considering that many ethnic minority older adults are illiterate (at least in the context of host societies) and have poor language proficiency [26], their use of digital platforms/resources may be weaker than that of ethnic majority older adults in a given place, leading to fewer opportunities to build social connections. At the same time, limitations in language and other intersectional factors can also drive ethnic minority older adults to resort to digital resources [23]. In addition, the results across 7 studies were consistent on the issue that younger ethnic minority individuals were more likely to adopt and use digital resources, which further indicates the significant role of factors, such as educational attainment (mostly higher among young people), in the use of digital resources [42,43,46,47,49,54,55]. However, there was evidence that many ethnic minority older adults were highly motivated to utilize digital resources to stay connected with family and friends [46,47,55], which demonstrates the utility of digital resources for sociocultural adaptation and maintenance of social identity. A previous study has shown that the relationship between age and the adoption of digital resources is mediated by computer self-efficacy, cognitive ability, and computer anxiety [59]. Strong motivation toward digital inclusion can be crucial in cultivating and achieving desirable outcomes that promote social connection through digital means [5].

The review found that the income level of ethnic minority older adults significantly influenced their adoption and use of digital resources. A combination of factors, including high-cost digital resources, limited internet access, and a lack of digital skills, is a key barrier that excludes low-income older adults from accessing and using digital resources. This finding reinforces the theoretical perspectives of the fundamental cause theory, which argues that the health and well-being outcomes of populations are influenced by their access to critical socioeconomic resources [60]. It has been recommended that for ethnic minority older adults to experience the social connection benefits of digital resources, policies and programs cannot solely focus on the technological aspects of their digital inclusion, as economic resources are key to making such programs functional [49].

Furthermore, health-related factors significantly affected the adoption and use of digital resources among ethnic minority older adults. It was recognized that ethnic minority older adults experiencing physical or mental health challenges, such as cognitive decline, depression, anxiety, decreased vision, and coordination, were less likely to own and use digital resources. This is likely because physical and mental health issues can cause disinterest in activities of daily living, in addition to potential compromises to bodily functions needed for digital engagement, such as vision loss [25,28]. Going forward, a deeper understanding of these influential factors is essential for designing and implementing health-appropriate strategies that enable equitable access to digital resources among ethnic minority older adults. Moreover, as with other population groups [61,62], COVID-19 pandemic restrictions, including social distancing measures, led to an increased use of digital resources. Other studies among ethnic minority older adults have found similar results, showing that people used video calls to maintain social connections [63,64]. Thus, experiences during the pandemic can be instructive for incorporating digital tools to

XSL•FO
RenderX

promote social connectedness among minoritized older adults whose sociocultural and adaptation issues weaken their opportunities for lasting social connectedness. Considering the dangers of social isolation as an "epidemic," as observed during the COVID-19 pandemic, can hasten efforts toward integrating vulnerable older adults into social dynamics through digitalization.

Strengths and Limitations

To the best of our knowledge, this is one of the first systematic reviews and meta-analyses to explore the adoption of digital resources to address social connection challenges and the factors influencing their adoption and use among ethnic minority older adults globally. The study followed a rigorous approach to searching relevant articles and extracting and handling data. However, the study has limitations that must be acknowledged when interpreting the findings. First, we limited data extraction to full articles written in English and with full text available, which may have excluded relevant studies. Second, the included studies used different age thresholds to define older adults, including one that recruited participants aged 50 years or older [53]. Divergence in age criteria means that the experiences of older adults across studies are likely to differ, potentially affecting the compatibility of results across the included papers. Third, substantial heterogeneity was detected across the included studies; hence, a random-effects model was applied. Fourth, the lack of information regarding the use of validated instruments in the quantitative studies may have introduced measurement bias. Additionally, it was not possible to infer causal relationships between the use of digital resources and social connectedness because almost all the quantitative studies used cross-sectional designs. Notwithstanding these limitations, this study offers rare, collated evidence on the characteristics and influence of digital resource use among the understudied group of ethnic minority older adults. The evidence offers an opportunity to conduct further empirical studies to better understand ethnic minority older adults' engagement with digital resources and the causal pathways involved.

Conclusion

The findings of this review suggest that digital resources can enhance social connections among older adults from ethnic minority groups. Intersectional factors related to sociodemographic, economic, and health-related aspects are influential in the adoption and use of digital resources by ethnic minority older adults to maintain social connections. Ethnic minority older adults utilize a wide range of digital tools/platforms to enhance their social integration in new or foreign societies, maintain their cultural and religious heritage, and foster intergenerational connections. The findings suggest that access to culturally appropriate and suitable digital resources for ethnic minority older adults with diverse health statuses can enhance social connectedness. While digital resources appear to be positively associated with social connectedness among ethnic minority older adults, future research can extend existing knowledge by examining how these resources may have negative consequences for the extent and nature of the social connections that older ethnic minority people secure. This is in view of some observations that digital resources can discourage in-person contact and may not necessarily be useful for addressing concerns with low social connectedness.

Additionally, it will be instructive to critically examine the diverse social connections formed by these older adults. This is because the types of social networks one possesses determine the nature of the resources embedded in those networks and the impact they will have on various life areas [65]. Moreover, research is needed on how ethnic minority older adults sustain the social connections they form through digital resources compared to those made in person, to advance social sustainability in aging through digital resources. At the same time, in recognition of the limitations and other factors that affect the impact of digital resources on social connectedness in aging societies, research is needed to better understand how various social technologies can be engaged sustainably (eg, effective use over the long term) among aging populations in different places. Finally, longitudinal study designs will be an ideal step toward understanding the stability in the relations between digital resources and social connectedness among older ethnic minority populations.

Funding

The study received funding support from Lingnan University Research Committee, Hong Kong through the Direct Grant Scheme (reference number: DR25E1; principal investigator: PAA).

Abstract

Background: Humanoid robots offer a promising solution to the growing burden of care for older adults. However, existing evidence on their applications for general aging populations remains fragmented and lacks systematic synthesis.

Objective: This scoping review aimed to examine the literature on humanoid robot–assisted support for health care in older adults and identify gaps in the literature to guide future research.

Methods: The methodological framework by Arksey and O'Malley was used to conduct this scoping review. We conducted a comprehensive search in 8 databases, including IEEE Xplore Digital Library, CINAHL, Cochrane Library, EMBASE, PubMed, Scopus, Web of Science, and OpenGrey Repository, covering literature published up to April 30, 2025. The reference lists of key texts were examined, and citation chaining was conducted. Two independent reviewers examined all full articles for fitness with the eligibility criteria and extracted data elements. The study findings were then summarized, coded, and analyzed using the PAGER (Patterns, Advances, Gaps, Evidence for practice, and Research recommendations) framework.

Results: A total of 32,477 articles were retrieved, 59 of which were included in this review. The majority (49/59, 83%) were conducted in real-world settings. Methodologically, 34 studies (34/59, 58%) had small sample sizes (n≤25), with study designs comprising 26 quantitative (26/59, 44%), 22 mixed method (22/59, 37%), and 11 qualitative (11/59, 19%) approaches. Participant characteristics revealed female predominance (>50%) in 32 studies (32/59, 54%), while 27 studies (27/59, 46%) included participants with cognitive impairment. Through PAGER framework analysis, we identified 4 key patterns: (1) effects, perceptions, and experiences of humanoid robots; (2) preferences, expectations, and facilitators for humanoid robots; (3) implementation barriers and challenges; and (4) determinants of user experiences and outcomes.

Conclusions: This scoping review demonstrates the promising yet methodologically constrained potential of humanoid robots in health care for older adults while highlighting key challenges in their practical implementation. Successful integration will require addressing technical limitations, user acceptance barriers, and systemic adoption challenges.

Introduction

Population aging has intensified worldwide, constituting a critical societal challenge. According to the United Nations World Population Prospects 2024 report, the proportion of individuals aged ≥65 years doubled from 5% in 1960 to 10% in 2024, and projections suggest this figure will surpass one-third of the population in the European Union, China, and Japan by 2050 [1]. A study tracking staffing trends since the onset of the COVID-19 pandemic found that 99% of nursing homes and 96% of assisted living facilities in the United States continued to face significant staffing shortages [2]. This study further indicated that 58% of nursing homes were limiting admissions due to lack of staff, with 78% expressing concern that workforce shortages might force them to close [2]. Despite measurable recovery observed in a 2024 follow-up study, employment levels in skilled nursing facilities remained 0.1% below projected benchmarks [3]. Concurrently, informal care systems face growing pressures, with Europe's care burden projected to increase 49.7% by 2050 [4], while caregivers endure physical, emotional, and financial strain [5]. The macroeconomic impact is equally concerning, with each 1% increase in care dependency reducing gross domestic product growth by 0.083%

XSL•FO
RenderX

through workforce attrition [6]. These intersecting crises in both professional and family-based care systems highlight the critical need for innovative support solutions in older adult care.

Humanoid robots present a promising avenue to address these systemic challenges. Since its inception in the 1970s, humanoid robotics has undergone a remarkable evolution, transitioning from rudimentary mechanical mimics to sophisticated platforms capable of complex social interactions [7]. Their anthropomorphic architecture—featuring human-like torsos, limbs, and movement patterns—confers unique advantages in care contexts for older adults. This biomimetic design enhances environmental navigation in human-centric spaces, fosters natural communication through familiar gestural cues, and improves social acceptance compared with nonanthropomorphic alternatives [7]. These attributes make humanoid robots a compelling platform for exploring the integration of physical and psychosocial support in older adult care. Empirical studies have begun to investigate these applications across multiple care domains. For example, the Pepper platform has been evaluated in the domains of cognitive training [8], object transfer [9], and social communication [10]. Similarly, the Nao robot has been studied in contexts such as health education delivery [11] and social interaction therapies [12] for older adults.

The field of robotics and gerontechnology has seen significant growth in research focused on developing care robots to support older adults and their caregivers [13]. Although existing reviews have examined robotic applications in health care, they present several important limitations that warrant addressing to advance the field. First, by conflating anthropomorphic and nonanthropomorphic robotic systems without distinguishing their distinct capabilities [14-16], prior syntheses obscure the unique potential of humanoid forms for fostering natural social engagement—a critical dimension in older adult care. Second, many reviews incorporate heterogeneous populations spanning multiple age groups and health conditions [15], thereby diluting findings that are specifically relevant to the physiological, cognitive, and psychosocial needs of the older adult population. Third, existing analyses often focus narrowly on isolated aspects, such as single-function applications, implementation challenges, or ethical issues in isolation [14,16-18], while neglecting comprehensive, multidimensional assessments of how multifunctional robotic systems operate within integrated older adult care environments. Although a previous scoping review did specifically investigate humanoid robots for older adult care, it was methodologically limited by its narrow search of only 2 databases and inclusion of literature only up to 2019 [19]. These limitations mean the review cannot account for the rapid technological advances and expanded evidence base in humanoid robotics over recent years. Consequently, the current evidence regarding humanoid robot applications for general populations of older adults remains fragmented and lacks an up-to-date, comprehensive synthesis to inform both research and practice.

Given this landscape, we used the scoping review framework of Arksey and O'Malley [20] to systematically map this emerging field. This approach optimally balances methodological rigor with the flexibility needed to (1) characterize current humanoid robot implementations and their care applications and (2) identify critical knowledge gaps requiring prioritized investigation. Our review thus provides both a comprehensive evidence synthesis and a roadmap for future research in this transformative domain.

Methods

Framework

This scoping review used a 5-stage methodological framework proposed by Arksey and O'Malley [20]. Prior to commencement, the study protocol was prospectively registered on the Open Science Framework on May 10, 2025, and is publicly accessible (registration DOI: 10.17605/OSF.IO/P2C8J) [21]. The review adhered strictly to this preregistered protocol without deviation. The conduct and reporting of this review strictly adhered to the PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses Extension for Scoping Reviews) guidelines [22]. The completed PRISMA-ScR checklist is available in Checklist 1.

Identifying the Research Question

This scoping review systematically examined the current evidence regarding the development and implementation of humanoid robots in health care for older adults. To comprehensively map the existing literature, we formulated the following broad yet focused research questions: (1) What types of humanoid robots have been implemented and what specific interventions have been delivered to older adult populations? (2) What is the reported feasibility, preliminary efficacy, and user experience (from older adults and caregivers/staff) associated with these interventions? (3) What critical gaps exist in the current literature that warrant focused attention in future research?

Identifying Relevant Studies

The search strategy was designed to identify both published and unpublished sources, encompassing scientific and gray literature such as conference proceedings. This approach helped mitigate publication bias and capture emerging research, especially in the rapidly evolving field of robotics, where significant findings are often first presented outside traditional journals. An initial exploratory search was conducted in Web of Science to identify relevant articles on the topic. Key terms from the titles, abstracts, and index terms of these articles were extracted to inform the development of a comprehensive search strategy. The search combined robotics-related terms (eg, “humanoid robot,” “social robot,” “robot assist,” “human-robot interaction”) with terms referring to older adults (eg, “aged,” “older,” “elderly,” “geriatric”). A systematic 3-step search approach was used, covering literature published up to April 30, 2025. First, 7 major electronic databases including IEEE Xplore Digital Library, CINAHL, Cochrane Library, EMBASE, PubMed, Scopus, and Web of Science, were searched using predefined keywords and index terms (see Table S1 in Multimedia Appendix 1). Next, gray literature was sourced through the OpenGrey Repository. Finally, reference lists of key publications were examined, and citation chaining was performed to ensure thorough coverage of the relevant literature.

RenderX

Study Selection

The review included original studies in which older adults (defined as individuals aged ≥60 years, aligning with the classification from the World Health Organization [WHO]) received any form of health care support through direct interaction with a physically embodied humanoid robot. We defined a humanoid robot as an autonomous or semi-autonomous machine with human-like morphology (eg, head, torso, arms; bipedal or wheeled mobility) and capable of performing social or physical tasks through human-like modalities such as speech, gesture, or facial expression. Studies that examined perspectives of other stakeholders (eg, care staff, family members, or health care professionals) within the same care context were also included, as these insights contribute to a holistic understanding of implementation and acceptability. For this review, health care is defined according to Merriam-Webster's Dictionary as "efforts made to maintain, restore, or promote someone's physical, mental, or emotional well-being especially when performed by trained and licensed professionals." Our focus within this broad domain is on applications in both clinical settings (eg, hospitals) and long-term social care settings (eg, residential institutions and private homes). All study designs (eg, experimental, observational, qualitative) were considered, and both published and unpublished English-language literature was included without date restrictions. Studies were excluded if they (1) primarily focused on robotic hardware or software development without evaluating a health care application; (2) used nonembodied or simulated representations of robots (eg, video-based or computer-simulated interactions); (3) focused solely on fundamental human-robot interaction mechanisms (eg, laboratory studies of perception or dialogue systems without a health care context or outcome), as these did not address our objective of mapping evidence related to health care support for older adults; or (4) lacked available full text. The study followed a rigorous 4-phase selection process in accordance with PRISMA-ScR guidelines (Figure 1). After initial duplicate removal using EndNote 21 software, 2 independent reviewers conducted title and abstract screening followed by full-text evaluation. Inter-rater agreement was assessed using Cohen kappa, with a value >0.6 considered acceptable. The reviewers then reconciled their findings to ensure comprehensive coverage, with any discrepancies resolved through arbitration by a third reviewer.

XSL•FO
RenderX

Figure 1. Flow diagram of the study retrieval and selection progress.

Charting the Data

We developed a standardized data extraction form aligned with the study objectives to systematically chart key information from included articles. Prior to full implementation, 2 independent reviewers piloted the data collection instrument using the first 5 eligible studies, refining the form through iterative discussion to enhance reliability. Extracted data elements encompassed (1) bibliographic details (authors, publication year, country of origin), (2) study characteristics (research setting, study design, study aims, sampling strategy,

XSL•FO
RenderX

participant demographics), (3) outcome measures, and (4) significant findings. For humanoid robot–assisted health care, we specifically documented (1) core intervention components, (2) program content, and (3) implementation parameters (frequency and duration).

Collating, Summarizing, and Reporting Results

Two independent reviewers conducted parallel analyses to ensure objectivity and minimize bias. Following thorough discussion and reconciliation of findings, the complete research team reviewed and validated the results. Using the PAGER (Patterns, Advances, Gaps, Evidence for practice, and Research recommendations) framework [23], we systematically identified 4 key patterns in the literature, along with their corresponding advances, gaps, practical implications, and future research directions. The PAGER framework is a structured methodological tool specifically designed for analyzing and reporting findings in scoping reviews, enhancing both the clarity and utility of the review output [23]. The acronym encompasses 5 interrelated analytical domains [23]: Patterns (key recurring themes emerging from the literature), Advances (notable developments within the recent evidence base), Gaps (critical limitations or underexplored areas), Evidence for practice (actionable insights for stakeholders), and Research recommendations (concrete suggestions for future research). A foundational step in applying the framework involves creating a patterning chart—a thematic table derived from inductive analysis of included studies—which visually organizes key findings and systematically guides the identification of advances, gaps, and resulting recommendations for research and practice [23].

Results

Study Selection and Characteristics

The study selection process, as depicted in the PRISMA-ScR flow diagram (Figure 1), commenced with the identification of 32,477 records from 8 electronic sources, with 3 additional records obtained from OpenGrey and manual reference searches. Following the removal of 11,716 duplicates using EndNote 21, we conducted initial screening of 20,764 records. Title and abstract review led to the exclusion of 20,588 records that did not satisfy the inclusion criteria. The analysis yielded a Cohen kappa value of 0.88 for inter-rater agreement. Subsequently, 176 full-text articles underwent comprehensive eligibility assessment, culminating in the inclusion of 59 studies for final analysis (see Table S2 in Multimedia Appendix 1).

Table 1 and Tables S3 and S4 in Multimedia Appendix 1 present the key characteristics of the included studies. Publication years spanned from 2012 onward, showing distinct temporal clustering with 10 studies (10/59, 17%) published before 2015, 18 studies (18/59, 31%) published between 2016 and 2020, and 31 studies (31/59, 53%) published after 2020. The publications originated from research teams across multiple regions: Europe (n=20), Asia (n=15), North America (n=7), and Oceania (n=4), with an additional 13 studies representing multinational collaborations. The majority (49/59, 83%) were conducted in real-world settings—defined for this review as environments where care is routinely provided with minimal researcher intervention, as opposed to controlled laboratory or research center environments—while laboratory environments accounted for 10% (6/59), and 5% (3/59) did not specify their location. Across the included studies, participants primarily comprised older adults (59/59, 100%), with a subset also involving informal caregivers (5/59, 9%), formal caregivers (14/59, 24%) and, in 3 studies, individuals categorized as “others.” Methodologically, 34 studies (34/59, 58%) had small sample sizes (n≤25). Among the 59 studies, 26 (44%) adopted a quantitative design, 22 (37%) used a mixed methods approach, and 11 (19%) used qualitative methodologies. Within the quantitative subset, designs varied considerably, encompassing 6 observational (cross-sectional) studies, 4 randomized controlled trials, 5 single-case/within-subjects experimental designs, 7 quasi-experimental (nonrandomized, group-based) studies, and 4 pre-post studies. Participant characteristics revealed female predominance (>50%) in 32 studies (32/59, 54%), while 16 studies (16/59, 27%) omitted gender data. Notably, 27 studies (27/59, 46%) incorporated participants with cognitive impairment.

Description of Humanoid Robot–Assisted Health Care for Older Adults

See Table S5 in Multimedia Appendix 1 for details on humanoid robot–assisted health care interventions. Across the included studies, 25 distinct humanoid robots were used, with Pepper being the most frequently used (n=15), followed by Nao (n=9), TIAGo (n=4), Kabochan (n=3), and Matilda (n=3). The remaining robots were each used in 1 or 2 studies. As detailed in Table 1, the interventions covered 16 key functional domains, with the number of studies per domain ranging from 1 to 23. The most prevalent functions were social interaction (23/59, 39%), cognitive training (15/59, 25%), and physical activity facilitation (11/59, 19%). Among the 59 studies analyzed, 4 did not report intervention duration. Of the remaining 55 studies (55/59, 93%), the majority (30/55, 55%) lasted 1 week or less; 11% (6/55) lasted between 1 week and 4 weeks; and 35% (19/55) extended beyond 4 weeks, including 4 studies (4/55, 7%) that continued for more than 24 weeks.

Patterns of Research Findings

We identified 4 key PAGER patterns of research findings (see Table 2; also see Multimedia Appendix 2 for a detailed analysis of all included studies).

XSL•FO
RenderX

Table . PAGER (Patterns, Advances, Gaps, Evidence for practice, and Research recommendations) framework.

Pattern	Advances	Gaps	Evidence for practice	Research recommendations
Effects, perceptions, and experience of humanoid robots	Preliminary studies indicate the potential of humanoid robots to be effective in care for older adults, with many reporting positive user acceptance and experiences.	Lack of randomized controlled trials, short-duration humanoid robot applications, and small sample sizes and imbalanced population characteristics	Emerging studies indicate that humanoid robots may have the potential to improve cognitive, physical, and psychosocial health in aging populations.	Prioritize conducting rigorously designed randomized controlled trials with larger, more balanced samples to evaluate the clinical effectiveness of longer-term humanoid robot interventions while simultaneously assessing older users' perceptions and experiences.
Preference, expectations, and facilitators for humanoid robots	Heterogeneous and individualized preferences have been observed among older adults regarding humanoid robots' appearance, functionality, and interaction modalities.	Small sample sizes and imbalanced population characteristics	Available findings suggest that involving older adults in the design process to tailor a robot's appearance and functions to individual preferences could enhance its acceptance and utility in care settings.	Use representative sampling strategies and involve cross-disciplinary teams to develop and evaluate personalized robotic interventions, with specific attention to distinguishing between initial novelty effects and sustained engagement over time.
Implementation barriers and challenges	The adoption of humanoid robots in care for older adults may face multifaceted barriers across technological, user-specific, and contextual dimensions.	Lack of multistakeholder perspectives	To facilitate implementation, practice should focus on developing robots with senior-friendly interfaces and complementing their introduction with tailored digital literacy programs for older users and their caregivers.	Adopt a multistakeholder analytical framework, gathering and integrating perspectives from older adults, formal and informal caregivers, health care professionals, policymakers, and technology developers to identify comprehensive implementation strategies.
Determinants of user experiences and outcomes	Available evidence suggests that user experiences and outcomes with humanoid robots may be influenced by user-related factors (eg, demographics, health status, and psychological state) and robot-related characteristics (eg, appearance, personality, and interaction methods).	Small sample sizes and imbalanced population characteristics as well as narrow factor consideration (eg, omitting environmental and contextual variables)	Emerging studies point to the importance of considering user experiences and outcomes as key factors in shaping effective human-robot interactions.	Expand sample sizes and systematically examine a broader range of potential determinants, including environmental (eg, home vs institutional setting) and contextual factors, to better understand what shapes user experience and outcomes.

Effects, Perceptions, and Experience With Humanoid Robots

Research indicates that humanoid robot interventions can yield effects across psychosocial, cognitive, functional, and behavioral domains. A frequently reported psychosocial benefit is enhanced social interaction [8,11,12,25,26,29,37,38,42,43,46,48,51-53,55,58-60,63,71], with associated reductions in loneliness [12,29,37,45]. Improvements in mood and emotional states [8,12,24,25,28,39,42,46,55,59,65,77], alongside decreases in stress, depression, and anxiety [8,12,24,30,39,46,47,58,59,65], have also been observed, although not all studies report significant changes in these areas [58]. In cognitive and functional domains, evidence suggests potential for cognitive stimulation [8,24,29,30,41,46,47,50,55,68,74-77], enhanced task performance [24,41,48,64], and improved limb function [33,56,75]. Regarding health behaviors, some interventions show promise for promoting medication adherence [29,67,70], physical activity [29,31,33,51,56,76], better dietary habits [76], and sleep quality [77]. It is noteworthy that, in specific task-oriented contexts, robotic performance has been perceived as inferior to human care [27]. The sustainability of these positive effects is a critical concern, with evidence pointing to potential attenuation over time [38] or a lack of significant long-term improvement in outcomes such as core dementia symptoms, depression, and quality of life [38,54,58,59].

Perceptions of humanoid robots among older adults and formal oor informal caregivers are heterogeneous, encompassing both positive dimensions and reservations. A substantial body of literature reports favorable perceptions from older adults across multiple dimensions, including acceptability [8,25,26,29,30,38,44-46,49,52,53,60,61,64-66,69-74,76], usability [24,30,38,43,44,50,52,60,69,71], trust [31,64,71,73], satisfaction [11,33,40,43,61], and active or positive attitudes [8,10,24,35,37,43,46,51,55,57,61,65,66,69,72,75,76]. In practice, this manifests as increased user engagement and motivation [8,12,24-26,33,37,39,44,46,48,50,55,58,66,74,76,77] and strengthened perceived social support [59] in some contexts. However, user acceptance is not universal. Some older adults

XSL•FO
RenderX

perceive robots as "too technical" or "lacking a human touch" [51], a challenge exacerbated for those with sensory impairments [51]. Caregiver perceptions are similarly mixed. Although some studies indicated a potential reduction in caregiver workload [51,54,60,76], others report an increased burden due to the need to assist with the technology [46]. Formal caregivers frequently cite practical barriers, including the additional time required for operation, difficulties in workflow integration, and, in some cases, negative attitudes toward the technology's value or appropriateness [51]. Cost-effectiveness is another point of skepticism, raised both by older adults [25] and implicitly within the context of practical implementation challenges.

The lived experience of interacting with these robots underscores several critical considerations. Safety and adverse events, though infrequent, warrant attention. These range from user-expressed safety concerns [57] to documented incidents such as medication errors [38] and adverse psychological reactions leading to study withdrawal [54]. Ethical concerns prominently feature issues of autonomy and privacy, with a noted divergence in emphasis between older adults (prioritizing user control) and caregivers (exercising more caution) [35]. Furthermore, equity and access emerge as significant issues, exemplified by cases where robot design (eg, language support) inadvertently created barriers for participants, highlighting risks of exacerbating the digital divide [46].

Preferences, Expectations, and Facilitators for Humanoid Robots

This synthesis reveals a clear pattern in older adults' preferences for humanoid robots. Older adults show marked preference for humanoid robots' health management functions, especially medication reminders and daily routine notifications [25,43]. Assistive functions like safety monitoring and health reminders consistently receive higher utility ratings than purely social features [45]. At the same time, entertainment-oriented functions such as music playback and memory recall features exhibit high engagement frequency, with studies showing these applications significantly improve mood states and facilitate positive reminiscence [55]. These core functionalities are typically complemented by basic conversational interactions including weather inquiries and casual chats in real-world usage scenarios [37,65].

Beyond functionality, user expectations shape perception and interaction. Users perceive the empathetic version of Ryan robot as more attractive, friendly, and compassionate than its nonempathetic counterpart [39]. Notably, multisensory integration—combining visual, auditory, and tactile stimuli—elicited significantly stronger happiness responses than unimodal (visual-only) or bimodal (visual-auditory) stimulation approaches [28]. Some evidence suggests that older adults may prefer in-person human-robot interaction over remote formats [9]. In studies of walking assistance, participants have been observed to position the robot more as a "navigational guide" rather than a "walking companion" [64]. Regarding humanoid robotic appearance expectations, research indicates older adults expect larger-sized robots [25] but typically reject those taller than themselves [43]. Their appearance expectations encompass a "smiling" and "handsome" design with fluid movements [43], along with friendly aesthetics, strong interactivity, simple operation modes, and integrated verbal-physical interactions [44].

Research documents older adults' functional requests for humanoid robotic systems, which serve as key facilitators for adoption. These emphasize improved interaction quality (enhanced speech clarity, real-time responses, and personality adaptation) [25,31,37], personalized health features (tailored exercise programs and accurate reminders) [38], expanded utility (medication management and emergency services) [37,43], and technical enhancements (advanced voice recognition and adaptive mobility) [55,57]. Although users show interest in customizable cognitive activities and varied applications [65,72], they consistently express reservations about privacy-sensitive functions such as bathing assistance [61].

Implementation Barriers and Challenges

From the machine or technical perspective, limitations manifest across several operational domains. Hardware constraints significantly impair functional capacity, notably in fine motor manipulation [40] and ambulatory assistance [56]. System reliability issues are characterized by intermittent connectivity [43] and unanticipated software termination [26], while interaction protocols demonstrate inadequate natural language processing capabilities [27,49,62]. Sensory apparatuses exhibit suboptimal performance in acoustically challenging environments [55] and human motion detection [43]. User interface implementations frequently present usability barriers, including unintuitive volume modulation controls and instances of erroneous information dissemination (eg, inaccurate meteorological alerts) or unintended nocturnal activation [38]. Crucially, current systems predominantly operate under supervised autonomy paradigms [12], where robots execute predetermined tasks but remain reliant on human oversight and intervention for initiation, safety, and context management rather than achieving genuine operational independence [49].

From the human or user perspective, adoption barriers emerged across 3 principal dimensions. Physical limitations include difficulties engaging with activation protocols [31] and potential safety hazards from unpredicted robotic motions [49]. Psychological factors encompass both initial technophobia [46] and entrenched self-perceptions of digital incompetence [73], necessitating extended skill acquisition periods [47]. Sociocultural concerns involve professional displacement anxieties among care staff [51], diminished interpersonal engagement [73], and surveillance-related ethical dilemmas [49]. Most significantly, prolonged use of these systems may lead to a decline in users' own abilities due to lack of practice and could also undermine the human essence of caregiving [73].

Implementation challenges intersect both perspectives, as even technically proficient systems demand substantial care protocol modifications and extensive personnel training [51], with economic viability assessments challenging the utility of specific design implementations [25].

Determinants of User Experiences and Outcomes

Older adults' experiences and outcomes with humanoid robots are influenced by multiple factors, with significant individual

XSL•FO
RenderX

variations reported across studies. Available findings on demographic characteristics are mixed. For instance, one study suggested that men might be more inclined than women to perceive robots as companions [35], while another found that women exhibited greater cognitive improvement in a specific robot-assisted cognitive training program [47]; however, other research observed no significant gender differences in well-being outcomes [42]. Similarly, although age was not found to significantly affect older adults' attitudes toward robots or their well-being in one study [42], another reported more pronounced cognitive benefits from training among participants aged 75 years and older [47]. Regarding education level, findings present a dual pattern. One study reported that individuals with higher education levels exhibit lower acceptance of robots' social functions [36], whereas a different study found that those with lower education levels showed more significant cognitive improvement in a training context [47]. In terms of health status, some evidence indicates that older adults with less independence in daily living may display greater reliance on robotic assistance [35], and those with higher dependency levels have been associated with moderately reduced well-being scores in one study [42]. Psychological states appear to influence interaction tendencies. For example, one study observed that individuals exhibiting agitation or psychotic symptoms showed stronger engagement willingness than those with depressive or apathetic symptoms [54]; the same study also noted that hearing impairment and sleep deprivation were linked to significantly impaired interaction outcomes [54]. At the interaction design level, findings from a specific study indicated that multimodal (voice-gesture) interaction was most effective at enhancing emotional connection and familiarity [11]. In another study, introverted robot personalities were perceived as more natural in interaction, whereas extroverted robots were considered more entertaining but slightly intrusive [34]. Furthermore, key robot perception dimensions—such as anthropomorphism, animacy, likability, and perceived intelligence—have been found to show significant correlations with functional performance in one study [36].

Discussion

This scoping review provides a systematic examination of humanoid robot–assisted health care support for older adults, analyzing 59 studies that document 25 distinct humanoid robot models currently implemented in both real-world and laboratory settings. Using the PAGER framework as our analytical lens, we identified and organized the extant literature into 4 conceptually distinct patterns. These emergent patterns are detailed in the following sections.

Effects, Perceptions, and Experience With Humanoid Robots

This scoping review aligns with previous findings [19] by demonstrating the multifaceted applications of humanoid robots across various domains of older adult care, encompassing social interaction, cognitive stimulation, physical activity facilitation, and activities of daily living support. Evidence indicates these robotic solutions can successfully promote social interaction, deliver cognitive enrichment, and enhance motor function in older populations. Notably, older adults have demonstrated favorable reception of humanoid robots, expressing positive evaluations of their usability and satisfaction levels while exhibiting constructive attitudes toward this technology. Together, these findings underscore the considerable promise of humanoid robots for innovative implementations in older adult care. Nevertheless, the methodological heterogeneity and specific limitations of the included studies restrict the strength and generalizability of our inferences. In line with existing literature [14], a recurrent methodological limitation across the reviewed literature is the prevalent use of studies with small sample sizes. This issue is frequently compounded by significant gender imbalances, typically skewed toward female participants, and a predominant research focus on older adults with cognitive impairments, potentially limiting the generalizability of findings to the wider, more heterogeneous aging population. Methodologically, the field shows a striking lack of randomized controlled trials—the gold standard for clinical evidence—compounded by typically short intervention durations that fail to capture long-term effects. Additionally, approximately 10% of the included studies were conducted in laboratory settings, which may further restrict the ecological validity and real-world applicability of the reported outcomes. In terms of functionality, current humanoid robot applications remain narrowly focused on cognitive training and social interaction, as confirmed by both our findings and prior research [78]. This limited scope stands in stark contrast to the broader spectrum of care needs documented in the literature [79], which includes essential daily living supports like fall prevention, feeding assistance, toileting, bathing, and position changing. To advance the field, future work should prioritize the development of more versatile robotic systems while conducting rigorous, large-scale multicenter trials with extended observation periods to fully assess the potential of humanoid robots in older adult care settings.

Preference, Expectations, and Facilitators for Humanoid Robots

This scoping review elucidates older adults' preferences and expectations concerning humanoid robots, encompassing functionality, design features, and physical appearance, while also capturing their developmental aspirations for this technology. Our analysis reveals that seniors exhibit complex, multidimensional expectations that are not only highly personalized but also consistently oriented toward robotic systems with expanded capabilities, enhanced stability, sophisticated intelligence, and greater autonomy. These combined demands, which encompass both personalization and high-performance functionality, directly translate into a core technical requirement: Assistive robots must be highly adaptable to diverse home environments and individualized user needs. Achieving this necessary level of adaptability in a cost-effective manner represents a significant technical hurdle requiring advances in sensors, machine learning algorithms, and robotic hardware [80]. However, the current evidence base presents notable methodological constraints. Many included studies have similar methodological limitations as noted in the previous section, particularly regarding sample representativeness. Building upon nursing science's established tradition of

XSL•FO
RenderX

person-centered care [81,82], we propose an integrated development framework that synergizes technological innovation with individualized implementation strategies. This approach necessitates multidisciplinary collaboration among gerontologists, engineers, designers, and health care professionals to advance humanoid robot capabilities, particularly in modular customization, natural interaction algorithms, and reliable multicontext functionality [83]. Parallel to these technical advancements, comprehensive predeployment assessments incorporating detailed geriatric evaluations and user profiling will be essential to ensure optimal alignment between robotic solutions and individual user requirements, thereby maximizing both clinical efficacy and resource efficiency.

Implementation Barriers and Challenges

Similar to prior studies [84,85], we demonstrate that widespread adoption of humanoid robots faces substantial barriers from technical, human, systemic, and sociocultural perspectives. A critical gap in the included literature is its overemphasis on end user experiences while neglecting other essential stakeholders including family caregivers, health care providers, policymakers, and technology developers [18]. This narrow perspective creates an incomplete framework for implementation, which must account for seniors' needs alongside caregiver workflows, institutional policies, and financial sustainability. Furthermore, the implementation context is profoundly shaped by culture-related factors that are often underexamined. These include deeply held social norms regarding the appropriateness of delegating intimate care tasks to machines, varying ethical frameworks across societies for balancing technological efficiency with the preservation of human dignity in care, and differing levels of societal trust in automation. To address these limitations, future research should use a comprehensive approach that engages all relevant stakeholders and explicitly investigates the cultural contexts of deployment settings. For older adult users specifically, implementation strategies should use a phased approach that includes assessing initial perceptions, clarifying concepts, addressing concerns, and demonstrating benefits to enhance acceptance [86]. Structured communication channels and collaborative guideline development can help mitigate risks while fostering stakeholder engagement. From a technical perspective, developing adaptable systems for diverse environments and user needs remains paramount, though cost-effective solutions will require advances in sensors, machine learning, and hardware design. Ethical considerations must go beyond minimum standards, implementing robust data consent protocols that exceed basic International Organization for Standardization requirements [87,88]. Successful implementation further requires addressing affordability to ensure equitable access, developing comprehensive training programs to optimize use, and planning workforce transitions that include retraining opportunities. Culturally appropriate design remains essential for widespread adoption [87]. A successful integration strategy must therefore balance technological innovation with human-centered design and organizational preparedness.

Determinants of User Experiences and Outcomes

Our scoping review reveals that the effectiveness of humanoid robots is determined by both user-related factors (including demographics, health status, and psychological characteristics) and robot-related features (such as appearance, personality traits, and interaction modalities). The studies included in this review exhibit notable methodological constraints, particularly regarding the common issue of limited sample sizes with demographic imbalances and insufficient examination of contextual and environmental variables. Subsequent investigations should prioritize more representative participant cohorts and systematically evaluate the complete spectrum of influential factors to elucidate the key determinants of robot-assisted older adult care. Critically, as emphasized throughout this review, transitioning from standardized implementations to tailored, individualized approaches represents an essential paradigm shift for optimizing humanoid robot integration in older adult health care settings.

Strengths and Limitations

To our knowledge, this represents the most comprehensive and methodologically rigorous scoping review to date examining the applications of humanoid robots in older adult health care. Our study, which was prospectively registered, used the established 5-stage methodological framework by Arksey and O'Malley [20] and adhered to PRISMA-ScR guidelines for transparent reporting. Notwithstanding these strengths, several limitations warrant consideration. First, although our systematic 3-step search strategy identified 59 relevant articles across 7 databases and gray literature sources, we acknowledge the possibility of having missed pertinent studies, particularly those where humanoid robotics applications were not explicitly stated in titles or abstracts. The exclusion of internet searches may have further contributed to this limitation. Second, our English language restriction may have introduced selection bias by excluding potentially relevant non-English publications. Finally, the scope of this review did not encompass certain specialized domains such as robotic surgery or monitoring systems using humanoid platforms.

Implications

This scoping review underscores the considerable promise of humanoid robots in enhancing health care delivery for aging populations, positioning them as a viable solution to mitigate future older adult care challenges. The field has evolved from early locomotion-focused platforms to today's interactive, AI-enhanced systems capable of complex social and assistive functions. Future advancements are expected to encompass greater personalization, multimodal sensing, expanded physical assistance capabilities, and stronger ethical frameworks to support real-world integration [7]. However, the seamless integration of this technology into the daily lives of older adults remains a complex challenge that requires careful consideration. The findings reveal that the needs and expectations of older adults are multifaceted, demanding highly personalized approaches. Successful implementation of humanoid robots in older adult care must extend beyond technological functionality to incorporate the perspectives of all stakeholders—older adults themselves, family members, professional caregivers, health

XSL•FO
RenderX

care staff, institutional leaders, and policymakers. A one-size-fits-all model would be insufficient; instead, adaptable solutions tailored to individual needs are essential to enhance care quality and optimize resource efficiency. However, achieving this personalization at scale necessitates addressing its economic viability. Research and policy must concurrently focus on reducing costs through modular design, scalable software personalization, and innovative funding or reimbursement models to prevent the benefits of personalized robotic care from becoming a privilege of the few. Moreover, the effectiveness of humanoid robots in older adult care is shaped by a dynamic interplay of technological, human, environmental, and ethical factors. Advancing this field requires interdisciplinary collaboration across health sciences, computer science, and engineering, alongside the establishment of standardized frameworks to improve robotic functionality, safety, and autonomy while minimizing risks. Equally critical is the development of older adult–friendly interfaces and targeted training programs to improve digital literacy among older adults. Professional caregivers also need structured instruction to facilitate effective human-robot collaboration in care settings. Simultaneously, ethical concerns—including privacy protection, autonomy preservation, and the establishment of appropriate human-robot boundaries—must be systematically addressed to ensure responsible adoption and sustained trust in robotic care solutions. Although the promise of humanoid robots in older adult care is evident, their long-term viability hinges on addressing these multifaceted challenges through coordinated efforts across technological innovation, user-centered design, workforce training, and ethical governance. Finally, future rigorous randomized controlled trials should prioritize the inclusion of well-defined control groups to precisely isolate the unique effect of humanoid robot interventions. Appropriate control conditions may include, but are not limited to (1) standard care or treatment as usual to establish baseline effectiveness, (2) interventions delivered by human caregivers or companions to benchmark robotic performance against the human touch, and (3) other technological or robotic interfaces (eg, tablet apps, nonhumanoid robots) to distinguish the impact of humanoid form factors and interaction modalities from general technology effects. Such comparisons are essential for determining not just if humanoid robots are effective but also for whom, in what contexts, and relative to what alternatives.

Conclusions

This scoping review systematically mapped the literature on the implementation of humanoid robots in health care settings for older adults, identifying 25 distinct models currently in use. By applying the PAGER framework, the review delineated 4 key thematic patterns within the evidence: (1) effects, perceptions, and experiences; (2) preferences, expectations, and facilitators; (3) implementation barriers and challenges; and (4) determinants of user experiences and outcomes. The available evidence suggests that deployments to date have focused largely on social interaction and cognitive stimulation, with many studies reporting favorable initial user acceptance and experience. Findings also point to individualized user preferences and highlight that adoption is likely influenced by a complex interplay of technical, user-specific, and contextual factors. The analysis underscores persistent evidence gaps—most notably a lack of robust experimental designs, long-term outcome data, and studies conducted in ecologically valid settings with representative populations. Future research should, therefore, prioritize large-scale, real-world trials with diverse older adult populations to evaluate the long-term efficacy and implementation of multifunctional humanoid robots across the full spectrum of care needs. Ultimately, addressing these research gaps will be crucial for overcoming the technical, user-related, and systemic challenges to successful integration.

Abstract

Background: Dementia affects more than 55 million people worldwide, and its progressive cognitive decline creates substantial challenges for intervention testing and real-world implementation. Living Labs (LLs) have become increasingly relevant for piloting interventions in dementia care, offering real-world environments for cocreation and iterative testing. However, operational, ethical, and governance challenges can hinder the effective implementation of dementia-focused initiatives.

Objective: This study aimed to identify and synthesize the facilitators and challenges encountered when piloting dementia-related initiatives within an LL approach.

Methods: A systematic review was conducted in PubMed, Web of Science, Scopus, and EBSCOhost from database inception to January 31, 2024. Studies were eligible if they reported the piloting, implementation, or evaluation of dementia-related initiatives in an LL context. A narrative synthesis was performed using content analysis for initial coding and thematic analysis for theme development. The systematic review was conducted in accordance with PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines.

Results: The 15 included studies were mostly conducted in European countries. Two major themes emerged, namely (1) organizational and operational issues and (2) ethical and legal considerations. Within these, 4 key operational subthemes were identified: engaging people living with dementia (end users), research design and evaluation methods, co-design and testing phases, and LL governance. Ethical and legal considerations covered informed consent procedures and regulatory aspects. Across studies, the most frequently reported facilitators involved familiar environments, stakeholder collaboration, iterative evaluation, and flexible co-design processes. Barriers commonly included fluctuating cognitive symptoms, limited digital literacy, inconsistent stakeholder engagement, time and resource constraints, and fragmented regulatory guidance.

Conclusions: Piloting dementia initiatives in LLs requires methodological adaptability, strong governance structures, and ethical procedures tailored to cognitive impairment. These findings provide actionable guidance for researchers, practitioners, industry partners, and policymakers seeking to develop sustainable, user-centered LLs that support innovation in dementia care.

Introduction

Globally, it is estimated that 55 million people live with dementia, with this number projected to increase to 152 million by 2050 [1]. Dementia is a progressive neurodegenerative disorder that compromises memory, behavior, personality, judgment, attention, spatial awareness, language, abstract thought, and other executive functions [2]. These cognitive impairments significantly reduce individuals' ability to function socially, occupationally, and independently [3]. The growing impact of dementia presents a major public health challenge due to its extensive burden on people living with the disease, families, caregivers, health care professionals, and society as a whole [1,4].

Efforts to improve dementia care have led to the development of innovative approaches that extend beyond traditional clinical and technological interventions. While advances such as artificial intelligence–assisted diagnostics, smart home monitoring, and virtual reality therapies have shown potential, many fail to adequately address the lived experience of people living with dementia [5,6]. This highlights the need for more inclusive, user-centered strategies that embed people living with dementia and their caregivers throughout the innovation process.

In this context, Living Labs (LLs) have emerged as valuable frameworks for cocreating and testing solutions in real-life environments [7]. LLs are user-centered, real-world settings that integrate research and innovation through co-design, iterative testing, and multistakeholder collaboration, following a quadruple-helix approach that connects academia, industry, government, and civil society [8].

Their strength lies in their capacity to foster collaboration between researchers, health care providers, patients, and caregivers, bringing scientific knowledge into everyday practice and allowing continuous feedback loops for refinement and validation [9,10]. However, the application of LLs in dementia care is particularly complex. The multifaceted nature of dementia, ethical considerations related to vulnerable participants, and the logistical and governance demands of maintaining multiactor environments all present significant challenges [10-13].

Previous studies have explored some of these aspects, identifying both enabling and constraining factors in operating LLs in health care. Some of the reported barriers include challenges related to the disease's impact on end users' participation [14,15], such as difficulties in decision-making and evaluation processes [11,12]; securing adequate funding [10]; addressing ethical concerns related to vulnerable populations [16,17]; and managing logistical issues to create realistic yet controlled environments [18]. Conversely, facilitators of successful LLs include strong stakeholder collaboration, robust technological infrastructure, and well-established ethical frameworks [19,20], which enhance the effectiveness and impact of these initiatives. Nonetheless, existing evidence remains fragmented and largely focused on single-case experiences or technological pilots. A comprehensive synthesis of facilitators and barriers specific to dementia-related LLs is still lacking.

Given the increasing prevalence of dementia and the need to optimize innovation processes in real-world contexts, this systematic review aims to identify and synthesize the facilitators and barriers encountered when piloting dementia-related initiatives within an LL framework. By consolidating available evidence, this study seeks to inform the design, implementation, and governance of sustainable, ethically sound, and user-centered LLs that can enhance innovation in dementia care.

Therefore, this review aims to systematically identify and synthesize the facilitators and barriers encountered when piloting dementia-related initiatives within LL environments.

Methods

Search Strategy

A systematic search was conducted in 4 databases for relevant literature: PubMed, Web of Science, Scopus, and EBSCOhost, from database inception to January 31, 2024. Keywords included MeSH (Medical Subject Headings) terms and synonyms as follows: "living lab" AND "dementia" AND "barrier" OR "obstacles" OR "facilitators" OR "enablers." Details of the search strategy, including specific search strings and filters used, are available in Multimedia Appendix 1.

Inclusion and Exclusion Criteria

Studies were included if they met all of the following criteria, namely (1) reporting findings within an LL approach (with consideration for multimethod approaches, user engagement, multistakeholder participation, real-life settings, and cocreation); (2) piloting initiatives related to dementia or cognitive decline; (3) randomized controlled trials, observational studies, qualitative studies, mixed methods studies, intervention studies, implementation science studies, case studies, and systematic reviews or meta-analyses or scoping reviews; and (4) publications written in English, Spanish, or Portuguese.

Studies were excluded if they met any of the following criteria, namely (1) those not addressing the topic of barriers and facilitators of piloting initiatives; (2) those describing or analyzing the technical parameters of a digital solution; (3) those comprising samples with cognitive problems not directly related to dementia or degenerative cognitive impairment (eg, aphasia); and (4) study protocols, theoretical papers, conceptual papers, and position papers.

Study Selection and Data Extraction

After retrieving manuscripts, duplicates were removed using EndNote software (v21; Clarivate Analytics). Subsequently, 2 authors (SA and ND) independently assessed the titles and abstracts of all potentially relevant articles. The full texts of these articles were then meticulously reviewed to determine final eligibility based on predefined inclusion and exclusion criteria. Any discrepancies were resolved through consensus with a third reviewer (TF), who conducted an independent analysis of such manuscripts. Additionally, reference lists of the included articles were screened to identify supplementary relevant studies.

To ensure consistency in data extraction, an Excel spreadsheet (Office 21, v.2405; Microsoft Corporation) was created to

XSL•FO
RenderX

document key study information, including author details, publication year, country, study design, sample size, participant type (eg, people with dementia, professionals, caregivers, and family members), and a brief description of the piloted initiatives. Extracted data also included key facilitators and barriers reported in each study.

Data Synthesis

A narrative synthesis was conducted in accordance with the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) 2020 guidelines. The synthesis followed two sequential analytical stages:

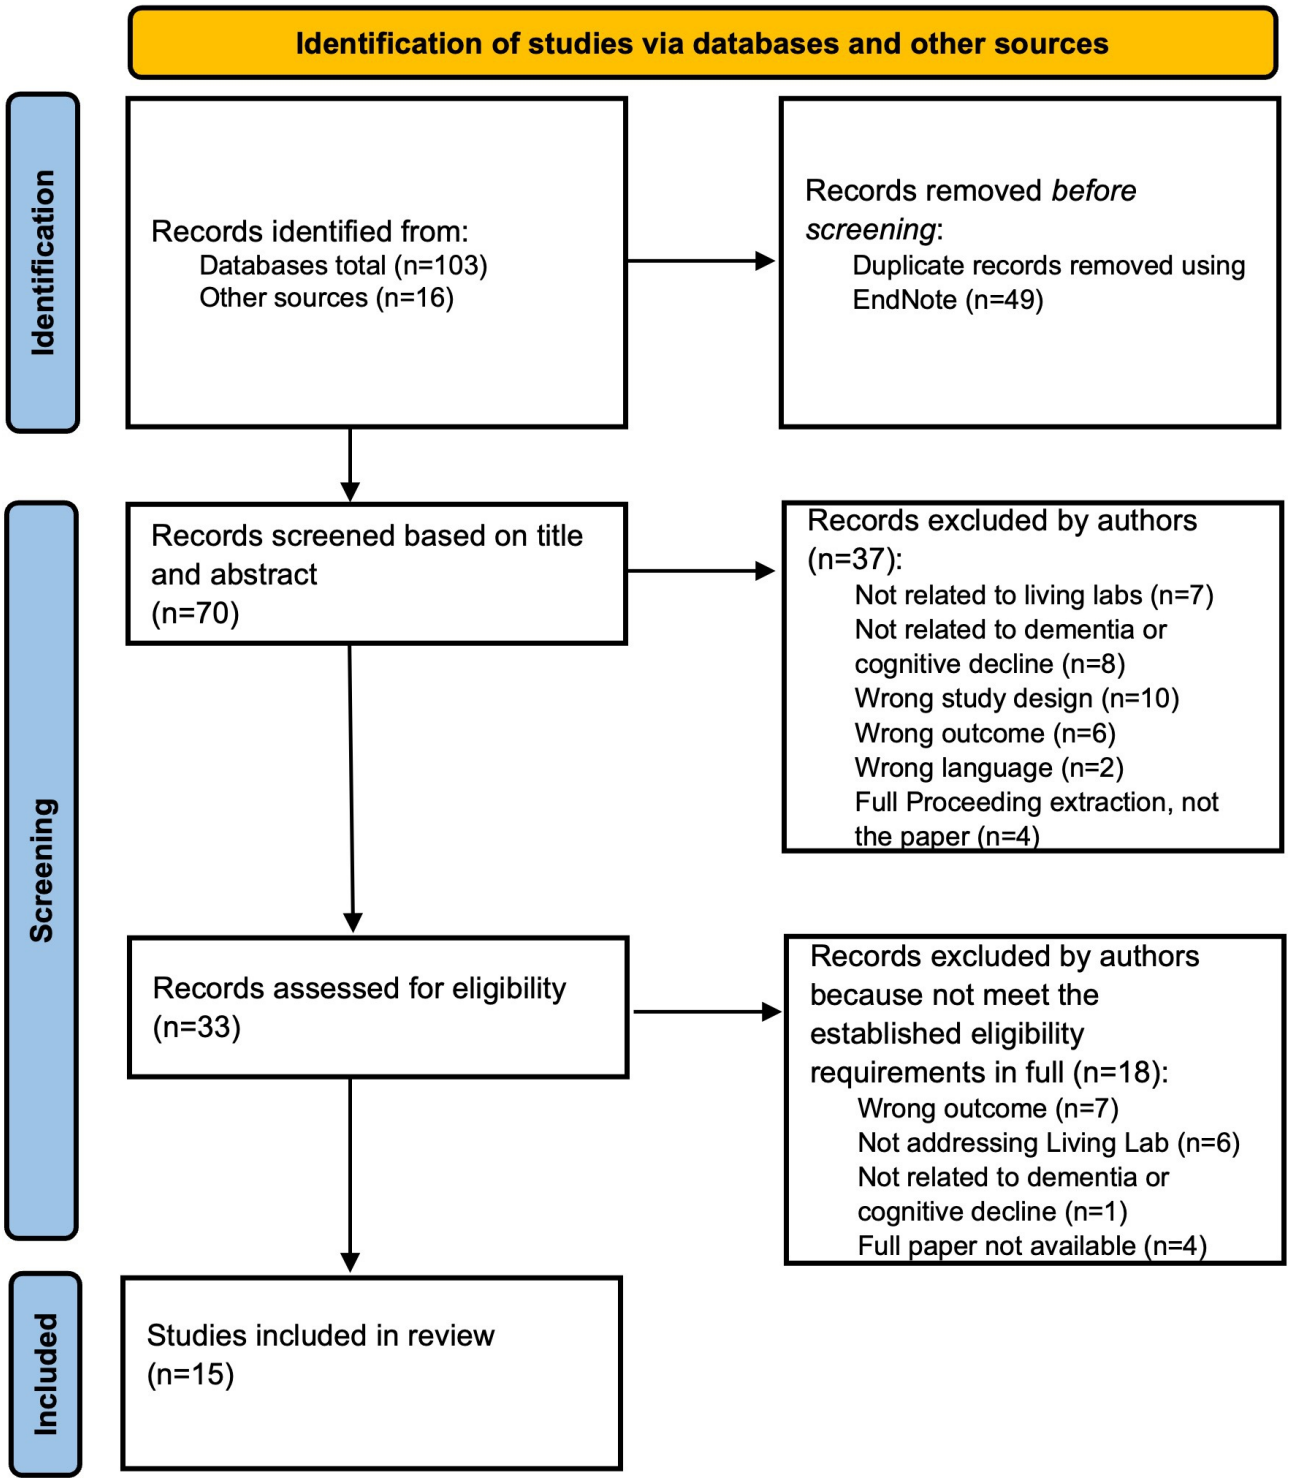
1. Content analysis was first applied to systematically code all reported facilitators and barriers across studies, identifying recurring concepts and relationships.
2. Thematic analysis was subsequently used to cluster and refine these codes into overarching themes and subthemes [21].

Two reviewers (SA and ND) independently performed the coding using NVivo software (v.14.23.3; Lumivero LLC). Regular meetings were held to discuss coding discrepancies and reach consensus, with a third reviewer (TF) available for arbitration when needed.

Following an iterative review of the extracted data and initial coding, two overarching themes were identified: (1) organizational and operational issues and (2) ethical and legal considerations. Each of these themes was further divided into subtopics that encompassed both barriers and facilitators [22]. Themes and subtopics were refined and organized into a final framework of facilitators and barriers.

A formal risk of bias assessment was not conducted, as the included studies primarily focused on methodological and participatory approaches for engaging people living with dementia under an LL approach rather than interventional studies. However, to ensure transparency, a completed PRISMA checklist is provided as supplementary material in Checklist 1. This review was registered in PROSPERO (CDR42024514481).

Results



Overview

The initial search resulted in a total of 119 publications. After duplicate removal and full-text analysis, 15 met the inclusion criteria (Figure 1).

Findings were synthesized narratively through content and thematic analysis, according to the predefined analytical framework. Two overarching themes emerged, which were (1) organizational and operational issues and (2) ethical and legal considerations, each comprising several subthemes that captured both facilitators and barriers. Of the 15 studies [18,23-36], engaging people living with dementia was the most frequently reported subtheme (14 studies) [18,23-31,33-36], followed by research design and evaluation methods (12 studies) [23-31,33-36], co-design and testing phases (12 studies) [23-31,34-36], and LL governance (10 studies) [18,23,26,28-31,33-35].

XSL•FO
RenderX

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flowchart of the included studies.

The studies were mainly qualitative (n=10) [18,23-25,28-32,35] and mixed methods (n=5) [26,27,33,34,36] (Multimedia Appendix 2). The reviewed articles were all from Europe, with the exception of 1 article from Canada, that is, Pigot and Giroux [23]. Facilitators and barriers were presented below by themes and subtopics. Multimedia Appendix 2 provides an overview of the included studies, while Table 1 summarizes facilitators and barriers by theme.

XSL•FO
RenderX

Table . Summary of facilitators and barriers by theme.

Theme	Subthemes	Most frequent facilitators	Most frequent barriers
Organizational and operational issues	• Engaging people living with dementia • Research design and evaluation methods • Co-design and testing phases • Living Lab governance	• Friendly atmosphere, familiar settings, caregiver involvement, and clear communication • Mixed methods approaches, visual aids, iterative feedback, and involvement of key informants • Real-life testing, pilot testing with healthy adults, training sessions, and flexible procedures • Quadruple-helix collaboration, shared vision, transparency, and regular meetings	• Digital literacy limitations, cognitive fluctuations, perceived stigma, and privacy concerns • Low adherence to questionnaires, positive-response bias, inconsistent data, and difficulty demonstrating real-world benefits • Time constraints, technical malfunctions, interruptions, and recruitment difficulties • Funding shortages, administrative burden, communication gaps, and divergent stakeholder priorities
Ethical and legal considerations	• Informed consent procedures • Regulatory aspects	• Rolling consent, adapted forms, and oral and written explanations • Alignment with ethical standards, involvement of gatekeepers, and certification	• Difficulty assessing capacity, limitations of one-time consent, and unclear evidence on audiovisual tools • Fragmented regulations, data-protection challenges, and lack of standardized contracts

Theme 1: Organizational and Operational Issues

Within the theme of organizational and operational aspects, 14 [18,23-31,33-36] out of 15 studies [18,23-36] identified various facilitators and barriers in piloting dementia initiatives using the LL approach. Four subthemes were identified within this theme: engaging people living with dementia, research design and evaluation methods, co-design and testing phases, and LL governance.

Engaging People Living With Dementia (End Users)

Facilitators

Fourteen studies emphasized strategies that promoted meaningful involvement of people living with dementia [18,23-31,33-36]. Common facilitators included a relaxed atmosphere and assisting with transportation [24].

The use of native language, careful pacing of information, and ensuring users were well-informed, using accessible language, were also mentioned [26,27]. Other studies highlighted the importance of a friendly atmosphere (eg, welcome participants with coffee or tea; coffee breaks; and not to dive into the product immediately, but starting by making informal contact first), familiar settings (eg, real-life conditions), and involving familiar people and care professionals to make end users feel safe and understood [18,23,28-31]. Recognizing the real-world benefits of initiatives and managing participants' expectations were described as crucial aspects for fostering engagement [18,27,34]. Another aspect that emerged was the possibility of offering rewards to increase users' willingness to participate in the initiatives [35].

Barriers

Several challenges related to engagement in LL activities were noted in 8 of the reviewed studies [26,28,29,31,34-36]. Some challenges include the participation of users with limited technical skills, which made it harder for them to fully participate. Additionally, not all user suggestions could be implemented due to technical or practical constraints (eg, development stage of the prototype), which sometimes caused frustration or a sense of exclusion because users felt their contributions were not fully considered [31,34]. Furthermore, negative perceptions of the solution, such as seeing it as stigmatizing or too complex to use, can lead to reduced confidence or reluctance to participate, ultimately hindering the engagement of people living with dementia [31,35,36]. Privacy concerns also limited participation, as participants reported reluctance to allow sensor monitoring in private home areas [36]. Other barriers include reluctance to express criticism or fear negative consequences, which can affect their willingness to provide feedback [28].

Research Design and Evaluation Methods

Facilitators

Mixed methods approaches to evaluate studies under an LL framework were endorsed in 12 studies [23-28,30,31,33-36], highlighting its potential to provide a comprehensive understanding of the LL approach, as well as real-world and user experiences. Qualitative methods, such as semistructured interviews and focus groups, effectively captured the experiences of people living with dementia. The use of visual aids, key informants, nonintrusive evaluation instruments [31,33], and postsession reflections [24,31] was recommended to enhance engagement. Additionally, a user-centered research design that emphasizes cocreation and continuous stakeholder

XSL•FO
RenderX

feedback was highlighted in 5 studies [26,28,30,31,33] as essential for developing relevant dementia interventions.

Barriers

Challenges in research design and evaluation methods were noted in 10 [23-25,27,28,30,31,33-35] of the 15 reviewed studies [18,23-36], and included low adherence to questionnaires, bias toward positive feedback, and inconsistent data collection, as well as issues like team changes and lack of diversity among participants that may limit study findings [35]. Other barriers included challenges in demonstrating the real-world benefits of initiatives [28,33,34], and ensuring sustained involvement throughout the project lifecycle [33].

Co-Design and Testing Phases

Facilitators

One widely recognized facilitator, mentioned in 12 [23-31,34-36] out of 15 studies [18,23-36], is the importance of integrating co-design and testing phases into daily activities and real-life settings. Other aspects included clear staff roles and environments tailored to the users' needs, using flexible facilities, nonintrusive methods, and adapting testing conditions for users' difficulties [23,25,26,28-31,34]. Conducting pilots with healthy older adults before involving people living with dementia was suggested as an effective strategy to identify potential issues early and adjust the testing process accordingly [24,30,34], helping to prevent confusion for end users. Implementing training sessions prior to deploying solutions [24,30] was also recognized as a valuable strategy.

Barriers

Challenges related to the co-design and testing phases were noted in 8 studies [23,26,28,30,31,34-36]. These included time constraints, budget limitations, and technical difficulties [26,34,35]. Additionally, the fluctuating symptoms of dementia require highly adaptable solutions, which can be difficult to find [31]. As an example, it was found that users' attention and motor fluctuations affected interaction with digital prototypes, and it was observed that caregivers had to adapt testing sessions daily to participants' cognitive variability [30,31].

Other studies pointed to the difficulties of tests in real-world settings [36], such as interruptions during home interventions, potential performance blur between user and relatives, and conflicts between user and researcher agendas [23].

LL Governance

Facilitators

Governance facilitators were highlighted by 10 studies [23,26,28-31,33-36]. Quadruple helix approach through the collaboration of academia, industry, government, and civil society, nurturing a culture of openness and team belonging, was described as an important aspect to ensure a smooth implementation of the innovation process [23,28,29]. Other facilitators highly mentioned included regular meetings and stakeholders' communication, clearly defined roles, and the development of roadmaps, which contribute to the LL transparency.

Barriers

Governance challenges were identified in 7 studies [18,26,28,31,33-35]. The main identified barriers included funding, time-consuming processes, defining a shared vision among stakeholders, balancing stakeholder interests, maintaining communication across all stakeholders, and managing complex administrative tasks.

Theme 2: Ethical and Legal Considerations

Eight [18,24,26,27,29-32] out of 15 studies [18,23-36] identified ethical and legal facilitators and barriers relevant to a dementia-focused LL approach. These findings were categorized into 2 main topics: informed consent procedures and regulatory aspects. While all studies discussed facilitators and/or barriers related to informed consent procedures, only 4 of them [18,27,29,31] addressed regulatory aspects (refer to Multimedia Appendix 2 for further details).

Informed Consent Procedures

Facilitators

"Process consent" (ie, ongoing seeking permission from participants throughout the study duration) or "rolling consent" (ie, seeking permission from participants as new phases or new activities are introduced) was advocated in 5 [18,26,27,29,32] studies with recommendations to monitor participant reactions and regularly remind them of their option to withdraw [31]. The importance of using both oral and written consent formats was also highlighted [29,32]. Additionally, sending consent forms in advance and assessing participants' capacity to consent were emphasized as key ethical practices [30,32]. Obtaining consent from both people living with dementia and their representatives, using adapted communication strategies, and considering innovative approaches, such as interactive consents (ie, a dynamic and ongoing process of seeking and reaffirming consent from participants) were also noted in some studies [31,32].

Barriers

Challenges related to the obtainment of informed consents were noted in 3 [26,27,32] studies. They include difficulties with one-time consent agreements [26,27] or the complexity of assessing consent capability due to fluctuating cognitive abilities [32]. It was also noted that there is still a lack of evidence that validates the benefits of using audio-visual aids in the consent process [32], which may limit their adoption.

Regulatory Aspects

Facilitators

Regulatory considerations, such as aligning prototypes and research methods with ethical standards and regulatory aspects, were discussed in 2 studies [27,31]. These studies emphasized the involvement of gatekeepers (ie, individuals or organizations who ensure the protection and well-being of people living with dementia, commonly including care institutions, relatives, and health professionals) or regulatory bodies and consistent regulations of recognized authorities (eg, European Network of Living Labs [ENoLL]) to foster collaboration while safeguarding participants' interests.

XSL•FO
RenderX

Barriers

Regulatory barriers were highlighted in 3 studies [18,29,31]. These included fragmented regulations across regions, lack of specific guidelines for cross-country research, absence of standardized contractual models, and challenges in managing sensitive data and intellectual property (mainly due to the collaborative nature and iterative process of LL, which often blurs the lines between roles).

Discussion

Principal Findings

This systematic review identified key facilitators and barriers that influence the successful piloting of dementia initiatives within an LL approach. Two overarching themes emerged, namely "Organizational and Operational Issues" and "Ethical and Legal Considerations," each encompassing a series of recurrent subthemes across the 15 included studies [18,23-36]. Overall, the findings show that LLs hold significant potential to support innovation in dementia care, but their effectiveness depends heavily on adapting methodological, ethical, and governance procedures to the specific needs and vulnerabilities of people living with dementia.

Consistent with previous literature, the studies highlighted that engaging people living with dementia requires approaches that accommodate fluctuating cognitive abilities, promote familiarity, and reduce cognitive burden [19,37,38]. Facilitators such as friendly atmospheres, familiar settings, accessible communication formats, and the involvement of caregivers and professionals emerged as crucial to fostering meaningful engagement. These findings illustrate the inherent complexity of piloting solutions with this population, reinforcing the need for tailored, adaptable, and iterative strategies. They also underscore the importance of ethical awareness and safeguarding the rights and well-being of people living with dementia while ensuring that their perspectives are integrated throughout the co-design process.

Based on the analysis of barriers and facilitators, 3 core aspects emerge as central to understanding the functioning of LLs in dementia care: the target population features, the LL ecosystem**,** and the LL framework gaps.

The Target Population Features

This dimension encompasses the unique needs and challenges faced by people living with dementia, including aspects that influence their participation, engagement, and adherence to the cocreation and testing processes.

The studies showed that users' heterogeneous and fluctuating cognitive symptoms create significant challenges from the earliest stages of the innovation process. These fluctuations affect communication, emotional stability, and the ability to engage with tasks, requiring highly flexible planning and individualized support [39-42].

Aspects related to communication processes (eg, accessible communication, native language, written and oral information, visual aids, regular reminders, and managing information load), flexible and adapted assessment methods and iteration phases, and familiar settings and people, and consistent team members are essential considerations to handle the unpredictable nature of dementia. Addressing these challenges often requires involving proxies (eg, caregivers and relatives), which extends the time needed for the process and may increase communication challenges and stakeholders' differing perspectives. These consequences ultimately influence project governance, sustainability, and the overall pace of development within LLs [38,43,44].

Another key aspect concerns the perceived benefits of the initiatives. Several studies emphasized that people living with dementia and their caregivers are more likely to accept and use a technology or intervention when they perceive clear, immediate value [18,28,31,33,36]. This aligns with previous research that documented that technology is either not accepted at all or is quickly abandoned when users do not perceive an immediate benefit [45-47]. Ensuring simple, intuitive interfaces and avoiding stigmatizing features (eg, making solutions too discreet or discouraging their use within social circles) is therefore essential. Failing to address these factors may lead to user frustration and a refusal to engage or discontinuation of use.

LL Ecosystem

At the ecosystem level, the findings highlight the importance of establishing strong communication flows and working on nurturing the strategic alliances. While the quadruple helix approach provides a solid basis for multiactor collaboration, many studies emphasize the need to expand beyond traditional stakeholders to include society, the media, and local communities [48-52]. This could create more opportunities for digital innovation, diversify funding sources, and contribute to the sustainability of the LL. Sustainability emerged as a recurring challenge, with several studies identifying resource instability and limited long-term planning as barriers to continuity [18,31,33].

Some authors have proposed a "mixed-economy" approach, where both state and private funding support the innovation process in social care [18,45,53]. This approach could be particularly useful in promoting the sustainability of LLs focused on innovation in dementia care.

Another key point is the establishment of a clear goal and shared vision for the LL. The studies reviewed strongly emphasize that LL success requires a clear goal that integrates reliability, real-world benefit, and the well-being of the LL team members. Communication is central to achieving this. It allows collaboration, builds trust, and fosters a sense of belonging. Attention must be given to all stages, from preimplementation, ongoing activities, and postimplementation. Notably, the postimplementation phase appears particularly neglected, with limited evidence on long-term monitoring, communication, and impact assessment (eg, reports, communication, and long-term impact assessment) [54-56]. This gap raises concerns about whether solutions remain relevant and functional after initial deployment, given the progressive nature of dementia [19,43,57].

XSL•FO
RenderX

In dementia care, especially with digital solutions, ongoing monitoring is crucial. Since dementia is a progressive neurodegenerative disorder, adherence to digital solutions will be affected by the disease's progression. Understanding these factors is vital to ensure that digital solutions effectively support the quality of life of people living with dementia and their caregivers, and therefore, should be a central concern of LL activity. Without this focus, LL risks introducing products that do not meet their intended purpose or do not provide real benefit.

LL Framework Gaps

As a relatively new approach, LLs still lack a well-defined regulatory structure. The absence of standardized guidelines leads to inconsistencies across countries and sectors, creating challenges in legal, ethical, and operational domains. This includes heterogeneity in data protection requirements, intellectual property procedures, and ethical oversight mechanisms. The limited dissemination of national dementia strategies, with less than a quarter of countries having them in place, further complicates the development of consistent standards, particularly in these populations [58].

Ethical challenges represent a core concern, particularly regarding informed consent and data protection [16,45,59,60]. Cognitive decline complicates the assessment of consent capacity and increases the need for sensitive, adaptive consent procedures. Innovative approaches such as "rolling consent" or interactive consent forms, ensuring that participants are continuously informed of their rights and can withdraw from studies at any time, fostering trust and ensuring participant safety. Privacy concerns, especially in data-rich environments such as LLs, where monitoring and data collection occur in real-life settings (including homes, hospitals, and nursing homes), further complicate the ethical management of these activities. This complexity underscores the need for robust ethical and legal regulations for dementia-focused LLs.

Mechanisms such as ethical review boards, certification authorities (eg, ENoLL), and standard contractual models can support the establishment of responsible LL operations. Strengthening these structures is critical to fostering trust, enhancing participation, and enabling LLs to function effectively in dementia-focused contexts.

Recommendations for Practice

Based on the results of this study, we have established some recommendations for piloting dementia initiatives (or on cognitive impairment) using an LL approach, providing a practical overview of the findings. The proposed guidelines are organized according to the topics identified in this systematic review (Table 2).

By considering these specific recommendations, LLs can improve their functioning and tackle common challenges in piloting dementia initiatives. Also, these guidelines can contribute to improving practices and to fostering sustainable and efficient innovation processes. By covering a broad range of aspects that include not only user and community involvement, but also research, governance, and ethical and regulatory considerations, these guidelines provide practical guidance for academia (research), policymakers, industry, and health care agents. For example, integrating iterative user feedback and ethical reviews can help tailor initiatives more effectively; furthermore, establishing clear metrics for evaluating the initiatives' impact will be crucial for assessing their effectiveness. At the ultimate end, these guidelines have the potential to enhance the impact of the LL approach in the dementia field, leading to improved health outcomes and quality of life of those affected, ensuring that innovation processes meet users' needs effectively.

XSL•FO
RenderX

Table . Recommendations for operating a dementia Living Lab (based on the categories of results).

Category	Recommendations
Engaging people living with dementia (end users)	• Develop engagement strategies tailored to the characteristics of people living with dementia by focusing on their needs, creating a relaxed atmosphere, using accessible language, and involving close persons, including both relatives and care professionals. • Consider technological difficulties of users, offering simplified digital solutions along with close technical support to enhance usability and acceptability. • Monitor frequently the users' feedback and experience to avoid feelings of frustration and to ensure users feel respected and understood. • Prioritize solutions that respect privacy and avoid being intrusive or stigmatizing. • Keep users well-informed by clearly presenting the potential real-world benefits of the solution, its limitations, and setting realistic expectations.
Evaluation methods	• Privilege mixed methods approaches, particularly semistructured interviews and focus groups, that help people living with dementia to better express their perspectives. • Use alternative communication methods, such as visual aids, and involve close family members or caregivers to enhance communication. • Consider cognitive limitations when selecting tools by using observation and cognitive-specific instruments. • Ensure staff consistency throughout the process and assure appropriate training on evaluation assessments. • Foster friendly and nonintrusive evaluation environments that are flexible and prevent positive biased feedback. • Incorporate a postreflection session to gather more in-depth feedback from users.
Co-design and testing phases	• Integrate co-design and testing phases in real-life settings to make the process more natural and less disruptive. Ensure that testing environments are familiar, avoiding the need for users to adapt to unfamiliar situations. • Conducting pilots with healthy older adults before involving people living with dementia to ensure the prototype functions well and is user-friendly. • Plan the co-design and testing phases with extended time and resources to accommodate potential fluctuations in dementia symptoms. • Consider the technical requirements of the solutions, including font size, format, battery life, menu design, icons, and audio-visual and written content. • Ensure staff consistency and provide appropriate training both for staff and users. • Tailor solutions to users' needs and conduct regular checkpoints to ensure they remain effective.
Research design	• Consider co-creation and exploratory approaches to develop effective solutions for dementia. • Prioritize study designs that use a user-centered approach, combining empirical and naturalistic methods. • Encourage collaboration among stakeholders to create a research design that meets the needs of all partners and maximizes the relevance and impact of the outcomes. • Clearly communicate research procedures to all stakeholders throughout the project lifecycle, especially those with varying levels of involvement, and establish defined research protocols specifically for dementia interventions.

XSL•FO
RenderX

Category	Recommendations
LL[a] governance	• Adopt a quadruple helix approach by involving academia, industry, government, and civil society. • Establish a shared vision early in the project and balance the interests of all stakeholders to ensure smooth implementation. • Foster a sense of team belonging through regular communication, clearly defined roles, and the development of roadmaps. • Implement efficient management and administrative strategies to streamline processes and enhance project execution, while avoiding unnecessary bureaucratic procedures. • Focus on building a broad network of local, national, and international partnerships and seek certification from recognized authorities (eg, ENoLL[b]). • Develop a sustainable business model to secure adequate funding and ensure the long-term sustainability of Living Lab. • Raise awareness of Living Lab initiatives by implementing a robust communication plan that encourages community involvement and engagement. • Consider establishing multidisciplinary boards, including financial, administrative, and scientific experts, to provide comprehensive oversight and guidance. • Integrate a long-term perspective in innovation processes, including postimplementation monitoring. • Regularly report on the impact of Living Lab initiatives, clearly identifying their benefits, with a particular focus on the real-world impact for users.
Informed consent procedures	• Prioritize “process consent” or “rolling consent,” regularly reminding participants of their rights and option to withdraw. Observe any reactions that may indicate reluctance to participate. • Adopt consent-friendly procedures, such as using adapted consent forms and sending informed consent documents in advance for review. • Use both oral and written consent formats, explore innovative methods such as interactive informed consent to enhance engagement. • Consider using tools to assess the capability to consent, and when necessary, obtain consent from both the individual and their representative.
Regulatory aspects	• Involve gatekeepers or regulatory bodies to ensure that research practices adhere to ethical standards and regulatory requirements. • Adopt regulatory procedures by standardizing contractual models and establishing clear guidelines for managing intellectual property and data privacy. • Advocate for enhanced regulatory procedures at both national and international levels to promote harmonized practices and facilitate cross-country activities.

[b]ENoLL: European Network of Living Labs.

Limitations

This systematic review is subject to certain limitations. First, despite a comprehensive search strategy across 4 major databases, relevant studies may have been overlooked due to language restrictions (English, Spanish, and Portuguese), and the still-emerging nature of research on dementia-focused LLs. These factors may have contributed to publication bias and limited the diversity of included contexts.

Another limitation of this study pertains to the thematic analysis of the findings, which is susceptible to the influence of the authors’ backgrounds and understanding of the topic. To strengthen trustworthiness, 2 authors independently coded and discussed emerging categories, and interpretations were refined through consensus and alignment with existing literature and the review’s guiding question.

A formal risk of bias assessment was not conducted, as this review focused on synthesizing facilitators and barriers rather than evaluating intervention effects. While this may limit comparability across studies, a structured appraisal was not applicable given the descriptive and exploratory nature of the evidence. Future reviews should incorporate formal bias assessments when suitable tools for qualitative and mixed methods LL research become available.

Finally, the geographical distribution of the publications is predominantly from European Union countries. Out of 15 studies included [18,23-36], only 1 was outside Europe, which could limit the generalization of the findings and reduce the

XSL•FO
RenderX

applicability of the conclusions to other contexts. Further research is needed to explore how national dementia strategies, funding mechanisms, and societal attitudes influence LL implementation beyond European contexts.

Conclusion

In conclusion, this systematic review identifies key aspects for successfully piloting dementia initiatives within an LL framework. A comprehensive and strategically planned approach is essential to effectively address real-world needs. It encompasses a user-centered design that accounts for the cognitive limitations of people living with dementia and balances the interests of stakeholders. Equally important is the development of robust governance models that foster collaboration, ensure smooth communication, promote extensive networking, and secure consistent and long-term funding, all supported by clear ethical guidelines and regulatory standards. By establishing equilibrium among stakeholders' interests and ensuring adaptability, LLs can serve as effective platforms for driving innovation in dementia care.

Abstract

Background: Despite rising internet use in Canada, older adults continue to face significant barriers in adopting and using digital technologies. Digital literacy among older adults extends beyond technical proficiency, encompassing adaptation to new technologies, overcoming age-related limitations, and addressing socioeconomic disparities. Limited digital skills hinder social participation, access to essential services, and engagement with eHealth technologies, exacerbating disparities in health outcomes.

Objective: This scoping review aimed to identify key barriers to digital literacy among older adults, synthesizing evidence from existing literature to provide a comprehensive understanding of the challenges older adults face in adopting and utilizing digital technologies.

Methods: A systematic search was conducted across the Ovid MEDLINE, PubMed, Web of Science, and EBSCOhost databases to identify studies published in the past 10 years that examined digital literacy barriers among older adults. Data extraction captured population characteristics, study context, research methods, and outcomes, which were thematically analyzed to identify overarching categories and themes.

Results: A total of 22 studies met the inclusion criteria. Most studies used a qualitative design (n=16, 72.72%), with the remaining studies comprising 3 quantitative studies (13.63%) and 3 reviews (13.63%). Seven primary barriers to digital literacy among older adults were identified: (1) health barriers, (2) support networks, (3) convenience and ease of use, (4) knowledge and information, (5) perception barriers, (6) resource barriers, and (7) barriers for special populations. Within these themes, 18 associated categories provided a more detailed understanding of the challenges older adults face in adopting and using digital technologies.

Conclusions: These findings demonstrate that digital literacy challenges among older adults are shaped by interacting individual, social, and contextual factors rather than isolated skill deficits. Barriers often co-occur, with health-related limitations, access to support, technology design, and resource constraints jointly influencing digital engagement. This review highlights the need for integrated and inclusive digital literacy strategies that address compounded barriers and reflect the diverse circumstances of older adults. Future research should focus on establishing consistent definitions of digital literacy, evaluating the long-term impact of digital inclusion initiatives, and addressing the needs of subpopulations experiencing heightened or intersecting barriers.

KEYWORDS

digital literacy; older adults; digital divide; eHealth; internet; technology; digital inclusion

Introduction

Background

Canada, with its diverse and aging population, faces unique challenges and opportunities in promoting digital inclusion for older adults. The older adult population in Canada is expected to grow by 68% between 2017 and 2037; the number of individuals aged 75 and older will double by 2037 [1]. These numbers highlight the urgency of addressing the unique needs and challenges of this population. Despite the high overall internet penetration in the country, a significant digital divide persists among older adults. The term “digital divide” refers to the various social disparities in access to and use of digital tools and services, such as personal computers and smartphones [2].

While digital literacy is essential for everyone in today’s technology-driven world, it is particularly crucial for older adults. The term “digital literacy” encompasses the skills required to use the internet and information and communication

XSL•FO
RenderX

technologies (ICT) effectively, such as computers, smartphones, and social media [2]. For older adults, digital literacy often extends beyond mere technical proficiency. This includes understanding and adapting to new technologies, as well as overcoming barriers related to age-specific physical and cognitive challenges and socioeconomic factors that can limit access to digital tools. Research findings have consistently identified that key barriers to internet use among older adults include age, education, income, and computer-related factors [2,3]. As the digital landscape continues to evolve—marked by the widespread adoption of smartphones, social media, and online services—understanding how digital literacy for older adults is defined and applied across various contexts has become increasingly critical.

In Canada, while internet use among older adults has increased from 32.2% in 2007 to 68.2% in 2016, substantial socioeconomic and access-related disparities persist [4]. Factors, such as preretirement exposure to technology, health status, education, living arrangements, and household income, significantly influence internet use among this demographic. Certain vulnerable populations are disproportionately affected by this digital divide. For example, older adults with higher education levels, better health, and those living with others are more likely to be digitally active, while those with less education, poorer health, and living alone are less likely to use the internet [4]. These disparities highlight the need for targeted digital literacy initiatives tailored to the needs of older adults. Addressing these unique barriers can enhance digital engagement, improve older adults' overall well-being, and enable greater participation in our increasingly digital world.

Benefits and Barriers to Digital Literacy

Achieving digital literacy is vital for social inclusion, accessing information, and managing health care through eHealth technologies [3]. However, older adults often face significant barriers to accessing and using digital technologies. Older adults represent a unique demographic in this regard due to factors such as age-related declines in physical and cognitive abilities, limited prior exposure to technology, and varying levels of education and income [2]. The lack of motivation and the belief that digital technologies are not relevant to their needs can further hinder older adults' engagement with these technologies, particularly in the context of digital literacy acquisition [4].

eHealth, which refers to health-related electronic technologies, particularly the internet, is one area where digital literacy is crucial for older adults [4]. eHealth literacy involves the ability to seek, understand, and apply health information from electronic sources. As more health care services move online, including booking and attending virtual appointments, accessing test results, and managing prescriptions, eHealth is increasingly essential for older adults to maintain autonomy and access necessary care [2]. However, the adoption of eHealth technologies remains low among older adults due to barriers such as design issues, cost, and lack of awareness [5]. A systematic review conducted identified a gap in the literature on eHealth literacy among underserved populations, including older adults [6]. While specific to the United States, this study emphasized the need for targeted research and interventions to improve digital health literacy in these groups.

The advantages of digital literacy for older adults are numerous. With improved digital skills, older adults gain better access to essential information, including health care resources, and can strengthen their social ties, positively influencing their mental and emotional well-being [3]. Additionally, engaging with ICT can stimulate cognition by offering access to games, news, and educational opportunities, which may help delay cognitive decline [3]. By improving digital literacy, age-related disparities can be reduced, fostering connections across diverse groups and promoting knowledge exchange [3]. However, despite these significant benefits, the substantial disparities in digital literacy among older adults in Canada, exacerbated by various demographic factors, highlight an urgent need to systematically explore and identify the most effective strategies and best practices for mitigating these barriers. By doing so, we can ensure that older adults are better equipped to obtain these critical benefits.

Although several reviews have explored older adults' engagement with digital technologies, most have focused on narrow subpopulations or specific digital domains. Prior syntheses have commonly examined digital health adoption, targeted specific older adult groups (eg, those with chronic conditions), or evaluated the impacts and barriers of particular digital literacy interventions, rather than conceptualizing digital literacy as a broader construct [7-10]. For example, Hepburn et al [11] reviewed barriers to digital health technology adoption among older adults with chronic diseases, emphasizing health-related contexts rather than general digital skill acquisition. Similarly, another review focused specifically on older adults' use of eHealth technologies, without addressing the broader range of skills, contexts, and supports that constitute digital literacy more generally [12]. Further research is needed to examine digital literacy as a multidimensional construct. To date, no review has comprehensively synthesized barriers and facilitators to digital literacy among the general older adult population across contexts, underscoring the need for an updated and inclusive scoping review.

Purpose

This scoping review synthesizes existing literature on barriers to digital literacy among older adults and addresses the question: *What are the key challenges and barriers to digital literacy among older adults across different settings?* Framed using the population, concept, and context framework, the population of interest is older adults, the concept is challenges and barriers to digital literacy, and the context includes any relevant setting (eg, community, health care, home). Challenges and barriers were conceptualized broadly to include individual, social, technological, and contextual factors, including health-related considerations where relevant. A scoping review was chosen to map the breadth of existing evidence, identify gaps, and include diverse study designs, which would not be feasible with a systematic or narrative review.

XSL•FO
RenderX

Methods

Overview

This scoping review was conducted and reported in accordance with the PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses extension for Scoping Reviews) guidelines [13]. The PRISMA-ScR guided the review process, including the development of the search strategy, study selection, data charting, and synthesis of results (Checklist 1).

Search Strategy

The search strategy for this scoping review involved a comprehensive and systematic approach to identify relevant studies using multiple databases. A librarian from Queen's University was consulted for this review. The databases used for this review included Ovid MEDLINE, PubMed, Web of Science, and EBSCOhost. The initial search was conducted using Ovid MEDLINE and PubMed databases in June 2024, with an updated search completed in December 2025 of all 4 databases. Search strategies combined controlled vocabulary terms (eg, Medical Subject Headings [MeSH]) and keyword searching, using Boolean operators (AND/OR) to capture concepts related to digital literacy (eg, "digital literacy," "digital divide," "digital inclusion," "computer literacy"), barriers and challenges (eg, "barriers," "challenges"), and the population of interest (eg, "older adults," "seniors"). Search terms were adapted for each database to align with database-specific indexing and syntax (Multimedia Appendix 1). The reference lists of all included studies were also hand-searched to identify additional relevant literature. The review was limited to studies published within the past 10 years (2014 to the date of the search) to ensure relevance to contemporary digital technologies and evolving conceptualizations of digital literacy.

Eligibility Criteria

This review included studies that (1) were conducted in any region, (2) included participants aged 50 years and older, (3) directly or indirectly examined digital literacy (including eHealth digital literacy), explicitly using this term or closely related synonyms, and (4) reported barriers to digital literacy. The age threshold was chosen to ensure that no relevant studies were missed and to align with previous studies that have similarly defined older adults with this age range to capture a broader range of experiences and challenges associated with aging and technology use [14,15].

This scoping review included peer-reviewed studies encompassing qualitative, quantitative, and mixed methods research studies, including systematic reviews, meta-analyses, and scoping reviews. Non–peer-reviewed studies, opinion pieces, and noncredible sources were not considered. Additionally, only studies and documents available in English were included to facilitate accessibility and comprehension.

Study or Source of Evidence Selection

The study selection process used a structured, multistep approach to ensure the inclusion of the most relevant and high-quality studies. All identified documents were imported into Covidence [16]. Duplicates were removed, and titles and abstracts were initially screened by the primary investigator against the predefined inclusion and exclusion criteria. To minimize selection bias, a secondary investigator independently reviewed all titles and abstracts, as well as the full texts of the included and excluded studies, to confirm consistency with the inclusion and exclusion criteria. Discrepancies were resolved through discussion or, if needed, consultation with a third independent investigator. Although formal interrater reliability statistics (eg, Cohen kappa) were not calculated, this double-review and resolution process provided a high degree of interrater reliability and ensured the accuracy and consistency of study selection. The results of this search were recorded using the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flow diagram [17].

Data Extraction

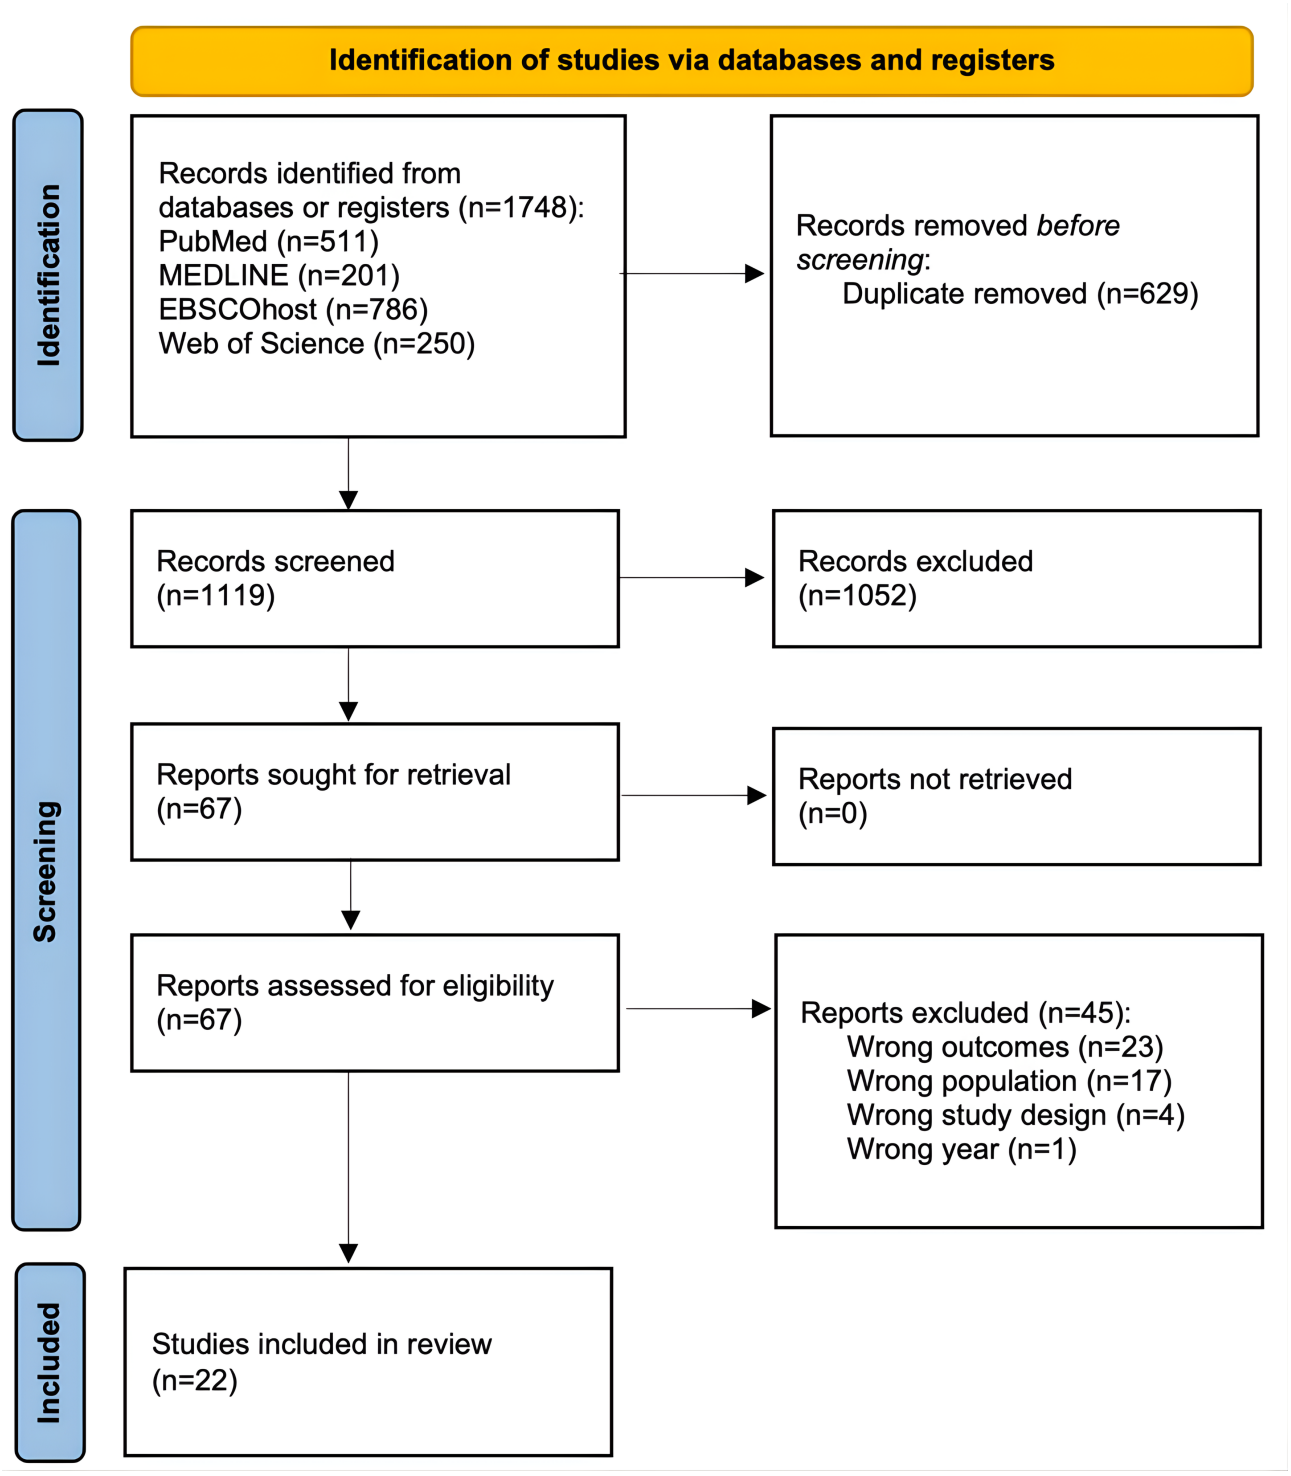
Data extraction was conducted to capture all relevant information from the selected studies. Key details, such as population characteristics (eg, age, gender, socioeconomic status), study context (eg, geographic location, setting), research methods, and outcomes (eg, levels of digital literacy, barriers identified, effectiveness of interventions), were systematically extracted by the primary investigator. A secondary investigator reviewed all extracted information for accuracy. The extracted information was organized into an Excel sheet (2019, version 2407) to facilitate easy comparison and analysis.

Data Analysis and Presentation

The synthesis of the extracted data followed a systematic, iterative process informed by thematic analysis as outlined by Braun and Clarke [18]. Initially, the findings were grouped into categories of statements that reflected similar meanings across studies. These categories were then further analyzed and synthesized into overarching themes representing different types of barriers to digital literacy among older adults. Throughout this process, all decisions regarding category formation, theme development, and coding were documented to maintain an audit trail, ensuring transparency and reproducibility. This approach allowed us to identify 7 key barriers and associated contextual factors, which are presented in a coherent narrative format highlighting the main findings and insights from the review. The methodological quality of the included studies was appraised using the Joanna Briggs Institute (JBI) critical appraisal tools, with the specific checklist applied according to each study's design (eg, qualitative, quantitative, or review). Quality appraisal was conducted to support the interpretation of the findings rather than to exclude studies.

Ethical Considerations

As this study is a scoping review of publicly available literature and does not involve human participants or identifiable data, ethics approval was not required in accordance with the Queen's University Research Ethics Board. An a priori internal protocol was established and used to guide the conduct of this scoping review. In accordance with current methodological guidance (eg, PRISMA-ScR, JBI Manual), prospective registration is not required for scoping reviews. The review was conducted as planned, and no substantive deviations from the internal protocol were made.



XSL•FO
RenderX

Results

Overview

This scoping review resulted in the identification of 1748 studies across 4 primary databases: PubMed (n=511), Ovid MEDLINE (n=201), Web of Science (n=786), and EBSCOhost (n=250). After electronically removing 629 duplicates, 1119 studies were screened against the inclusion and exclusion criteria at the title and abstract level. At this initial screening stage, 1052 studies were excluded. A total of 67 studies were assessed for eligibility through full-text review, leading to the exclusion of 45 studies for the following reasons: wrong outcomes (n=23), wrong population (n=17), wrong study design (n=4), and publication older than 10 years (n=1). Ultimately, 22 studies met the inclusion criteria and were included in the final review. A full outline of the search and selection process is provided in Figure 1.

Figure 1. The PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flow diagram [17].

Study Demographics

Table 1 presents an overview of the characteristics of the studies included in this scoping review, highlighting the year of study publication, the region where the study was conducted, the study design, and the population age characteristics. Half (n=11, 50%) of the studies were recently published between 2022 and 2025. Geographically, the included studies were conducted across diverse global contexts. Four (18.18%) studies were conducted across multiple regions, while 7 (31.81%) studies were classified in the "Other" category, encompassing research conducted in South Korea, Malaysia, Norway, Turkey, Costa Rica, Spain, and China. A majority (n=16, 72.72%) of the studies used a qualitative study design, with 3 quantitative studies (13.63%) and 3 reviews (13.63%). A summary of each study's characteristics is provided in Multimedia Appendix 2 [19-40].

Table . Study demographic information of the included studies (n=22).

Category	Count, n (%)
Year of study publication	
2022 - 2025	11 (50)
2018 - 2021	6 (27.27)
2014 - 2017	5 (22.72)
Region where study was conducted	
Other (ie, South Korea, Malaysia, Norway, Turkey, Costa Rica, Spain, China)	7 (31.81)
Multiple regions or international	4 (18.18)
United States	3 (13.64)
United Kingdom	2 (9.09)
Canada	2 (9.09)
Singapore	2 (9.09)
Australia	2 (9.09)
Study design	
Qualitative	16 (72.72)
Review	3 (13.63)
Quantitative	3 (13.63)

Quality Appraisal

Among the 22 studies included in this review, the overall methodological quality ranged from high to moderate quality, with no studies being excluded on the basis of their quality. Using the appropriate JBI critical appraisal tools [41], 6 studies were appraised as high quality, 12 as moderate quality, and 3 were moderate-unclear quality due to insufficient methodological reporting. The high-quality studies (n=6) were primarily qualitative interview or focus group designs that demonstrated strong alignment between research questions, methodology, and data analysis and reported strategies to enhance rigor, such as multiple coders, audit trails, and triangulation. These studies provided robust, contextually grounded evidence on digital literacy barriers experienced by older adults. The majority (n=13) of studies were appraised as moderate quality, most commonly due to limited reporting of researcher reflexivity, small or context-specific samples, and restricted transferability to more digitally excluded populations. Several review and cross-sectional studies relied on self-reported measures and cross-sectional designs, limiting causal interpretation of identified barriers. Studies rated as moderate-unclear quality (n=3) were retained in the review because these studies still contributed valuable descriptive and contextual insights relevant to understanding barriers among older adults.

Primary Findings

Seven primary barriers of digital literacy among older adults were identified, including health barriers, support networks, convenience and ease of use, knowledge and information, perception barriers, resource barriers, and barriers for special populations. Within these 7 overarching themes, 18 associated categories were identified and provide a more detailed understanding of the specific challenges faced by older adults in adopting and using digital technologies. Consistent with scoping review methodology, the following sections thematically synthesize the 7 identified themes and categories, illustrating the diverse barriers to digital literacy among older adults.

Health Barriers

Health-related barriers are a significant factor impeding older adults' interaction with digital technologies. This theme encompasses 1 category that explores the physical and cognitive challenges faced by older adults when engaging with digital devices.

Evidence from the research shows older adults encounter significant health-related barriers that impede their interaction

XSL•FO
RenderX

with digital technologies. Across studies, age-related physical, sensory, and cognitive changes (eg, vision impairment, reduced dexterity, memory challenges, fatigue, or chronic disease burden) limited older adults' ability to learn, navigate, and sustain use of digital technologies [19-21,29,30,37,38]. In studies focused on digital health and self-management, chronic conditions compounded existing barriers by increasing cognitive load and task complexity, particularly where technologies required ongoing monitoring, interpretation of health information, and sustained engagement over time [24,35,40]. Cognitive impairments, such as memory loss and forgetfulness, were also frequently discussed barriers to digital literacy for older adults [34,35,38,39]. These barriers were frequently described as context-dependent, becoming more pronounced when digital tools were poorly aligned with aging-related needs or fluctuating health conditions, particularly in digital health and accessibility contexts [24,29,30,35,40].

Support Networks

Support networks are essential in shaping older adults' ability to engage with digital technologies. This theme explores 2 key categories: the impact of social support and social influence on digital literacy and technology adoption among older adults. While social support refers to the direct assistance and encouragement provided by family, friends, and community services, social influence encompasses the broader attitudes and behaviors within one's social network that can shape technology use.

The studies reviewed highlight the crucial role that support networks play in helping older adults navigate the digital landscape. However, many older adults lack sufficient social support from family, friends, or community services, which exacerbates their digital literacy challenges [20,21,26,28,32-35,37,39]. Dependence on younger family members for learning new digital skills is not always reliable, as negative interactions, such as lack of patience, can reinforce feelings of inadequacy and discourage use [22,26,33,34,38]. The absence of family or social networks often results in older adults being less likely to adopt internet use [20,21,26,33,34].

Evidence from the reviewed literature shows that social influence is pivotal in the adoption of digital technologies among older adults. Positive or negative attitudes within social networks can impact older adults' engagement with technology [19,24,29,34]. The encouragement or discouragement from family members and peers can either facilitate or hinder the adoption of digital tools [22,28,29,34,35,38].

Convenience and Ease of Use

The convenience and ease of use of digital technologies are crucial factors that determine their adoption and sustained use among older adults. This theme is explored through two key categories: (1) the impact of application interface and design and (2) the challenges posed by continuous technological changes.

The studies reviewed underscore that the design and interface of digital applications are critical determinants of their usability for older adults. Complex interfaces, small font sizes, poor sound quality, and multiple authentication requirements pose significant challenges because they fail to account for the physical and cognitive changes associated with aging, such as declining vision, hearing loss, and reduced memory or cognitive processing speed [22,29,30,35,37,38,40]. Several studies noted that the cumulative burden of multistep processes (ie, repeated logins, verification requirements, and navigating across multiple platforms) further increased cognitive load and reduced sustained engagement among older adults [20,21,25,35,40].

Continuous updates and changes in digital devices and websites create additional hurdles for older adults, causing confusion and a loss of confidence in their ability to use these technologies [29,30,34,37,38]. The constant evolution of technology can be overwhelming and discouraging for older users, leading to reduced engagement.

Knowledge and Information

The ability to effectively use digital technologies is heavily dependent on the knowledge and information available to older adults. This theme examines two key categories: (1) the impact of a lack of digital literacy and skills and (2) the consequences of limited awareness about digital technologies.

Research highlights that a pervasive lack of digital literacy among older adults is a significant barrier to the use of digital technology and services [19,20,22,25,26,33-40]. Many older adults did not grow up with advanced technology, making it challenging for them to acquire new digital skills [19,26,33,34,37,38]. This limited proficiency includes difficulty in navigating digital technologies, a lack of operational or technical knowledge, and minimal exposure to modern digital tools [20,22,27,33,34,37,38]. The general lack of computer proficiency hampers effective use of patient portals and other digital health platforms [25,28,31,35,40].

Many older adults are unaware of available digital technologies, services, and their benefits, which further limits their adoption of these technologies [19,20,27-29,33]. This lack of awareness hinders the effective use of digital health tools for managing health conditions. Beyond operational skills, several studies also reported difficulties appraising the credibility and relevance of online information, particularly in digital health contexts, which hindered confident use of digital services [20,21,25,31,35].

Perception Barriers

Overview

Perceptions and attitudes toward digital technologies play a crucial role in shaping older adults' willingness and ability to adopt and use these tools. This theme encompasses 4 key categories: concerns related to security, privacy, fear, and anxiety; challenges of self-efficacy and motivation; social and psychological barriers; and a preference for traditional methods over digital interactions.

Security, Privacy, Fear, and Anxiety

Concerns about online security and privacy are significant deterrents for older adults when considering the use of digital technology and services. Many older adults fear privacy breaches and distrust digital platforms, which prevent them

XSL•FO
RenderX

from engaging with these technologies [19,21,27,29,32]. This fear is particularly pronounced among rural residents, who express significant worries about breaches of privacy and confidentiality, especially with technologies that monitor daily activities and collect personal data [35]. Beyond privacy concerns, the fear and anxiety older adults experience around technology use often stem from broader security issues. Reports of online scams have heightened these concerns, leading many older adults to avoid digital engagement and digital health services altogether [21,27].

In addition to privacy concerns, older adults often experience anxiety about constant monitoring and the implications of being watched or recorded without consent, further increasing their reluctance to engage with technology [29]. The mistrust of technology, coupled with the complexity of digital tools, exacerbates their anxiety, making digital engagement even more daunting [21,35]. Several studies also reported fear of making irreversible mistakes or damaging devices, which contributed to the avoidance of independent technology use [21,27,32,36,38,39].

Self-Efficacy and Motivation

Low self-efficacy and motivation significantly impact older adults' engagement with digital technologies. Many older adults lack confidence in their ability to use telemedicine and other digital tools due to age-related issues, such as poor eyesight, memory loss, and unfamiliarity with technology [21,23,32,36]. Additionally, older adults' beliefs that they are too old to learn new technologies or that digital tools are unnecessary for daily tasks further hinder their willingness to engage with these tools [23,35]. Internalized age-related stereotypes about technology use further undermined confidence, reinforcing beliefs that digital technologies were better suited to younger generations [19,23,26,34].

Social and Psychological Barriers

The adoption of digital technologies among older adults is often hindered by concerns related to social isolation, stigmatization, and threats to independence. Some older adults fear that reliance on smart technologies could lead to reduced human interaction and increased loneliness, with worries that increased digital interaction might replace physical activity and social engagement [27,29,36]. Additionally, the use of assistive technologies can sometimes lead to stigmatization, as older adults may fear being labeled as dependent or frail, which further discourages their use [29]. Concerns about personal autonomy are also prevalent, with older adults expressing hesitation toward technologies that might impose rigid structures or routines, thereby undermining their sense of independence [29].

Preference for Traditional Methods

Many older adults prefer traditional methods of communication, such as letters and in-person consultations, instead of digital interactions. They value the personal connection and the comprehensiveness of physical examinations, which they believe digital tools cannot replicate [19,29]. The study found a low demand for telemedicine services among rural residents, often due to a preference for face-to-face visits and discomfort with online consultations [29,35].

Resource Barriers

Access to and the affordability of digital technologies are critical challenges that significantly hinder older adults' ability to engage with digital tools. This theme explores 3 key categories: limited access to technology; financial constraints; and the lack of personalized training, all of which contribute to the digital divide among older adults.

Limited access to digital devices and the internet is a significant barrier for many older adults [27,37,39]. This includes issues such as unreliable internet access and lack of necessary equipment, including smartphones or computers [19,20,27,39,40]. Many rural residents particularly struggle with a lack of reliable internet access, which is critical for telemedicine adoption [39]. Not possessing smartphones or having limited access to reliable internet and other digital resources further exacerbates these challenges [20,27]. Residential facilities often lack the necessary infrastructure, hindering older adults' ability to use digital health portals [27].

The affordability of digital devices and internet services is a substantial barrier. Many older adults have limited financial resources to purchase and maintain digital devices or pay for internet access [37,39,40]. The high cost of devices, maintenance, and indirect costs, such as electricity consumption, poses significant obstacles [39,40]. Lower income levels are associated with reduced internet use among older adults [20,21,24,26,40].

The absence of personalized training and ineffective teaching methods further hinder older adults' ability to learn and use digital technologies by failing to accommodate their specific learning needs. Rigid and nontailored instructional approaches can lead to frustration, disengagement, and a lack of confidence, making the learning process overwhelming and exacerbating the digital divide [24,33,38,40].

Barriers for Special Populations

Overview

In addition to the general barriers faced by older adults in adopting digital technologies, certain special populations encounter unique challenges that further complicate their ability to achieve digital literacy. Across studies, barriers affecting special populations were rarely experienced in isolation; instead, they reflected the interaction of health-related, perceptual, usability, and resource constraints, often compounding digital exclusion.

Visually Impaired Older Adults

Visually impaired older adults often lack awareness about the potential of technology to promote independence and reduce loneliness. This lack of awareness limits their engagement with digital tools that could otherwise enhance their quality of life. Additionally, municipalities frequently lack the expertise and capacity to provide adequate training, leaving visually impaired individuals without the necessary skills to use digital technologies effectively [30]. Another significant barrier for visually impaired older adults is the lack of long-term support after initial training. While some may receive training on how to use digital tools, the absence of continuous support,

XSL•FO
RenderX

particularly when faced with technical problems or software updates, can result in the loss of newly acquired skills, thereby hindering sustained technology use [30]. Technological changes present a unique challenge for visually impaired older adults. Learning to use gesture-based interactions and screen readers requires extensive training. Frequent updates and the presence of inaccessible content further complicate the use of digital devices, making it difficult for visually impaired individuals to keep up with technological advancements [30]. These challenges were frequently attributed to inconsistent accessibility standards and design practices, rather than individual limitations, and often resulted in frustration and the abandonment of digital technologies.

Older Adults With Chronic Conditions

Older adults with chronic conditions experienced increased digital literacy barriers due to the combined demands of health self-management and technology use. Studies reported that symptom burden, fatigue, and fluctuating health status increased cognitive load, making it difficult to learn, interpret, and sustain engagement with digital health tools. Technologies requiring frequent monitoring, data interpretation, or consistent interaction were particularly challenging, often leading to reduced confidence and disengagement [24,35,40].

Older Adults With Cancer and Their Caregivers

Both older adults with cancer and their caregivers often lack confidence in their ability to find relevant health information online. This low self-efficacy acts as a barrier to the effective use of digital health tools [34]. Limited familiarity with digital tools and apps is common among older adults with cancer and their caregivers. Additionally, lower levels of education are associated with lower eHealth literacy, making it more challenging for these individuals to engage with digital health resources effectively [31]. The rapid evolution of digital tools creates a barrier for older adults with cancer and their caregivers, who may struggle to keep up with technological changes. This unfamiliarity with new tools can prevent them from fully utilizing digital health resources [31]. Finally, limited access to necessary resources, such as broadband, computers, and other digital devices, particularly in rural areas, further exacerbates the digital divide for older adults with cancer and their caregivers. This geographic disparity highlights the need for targeted interventions to improve digital access and literacy in underserved areas [31].

Culturally and Linguistically Diverse Older Adults

Culturally and linguistically diverse older adults experience distinct digital literacy barriers related to language proficiency, cultural relevance, and reliance on informal support networks. Limited English proficiency and unfamiliarity with technical and health-related terminology restrict the understanding of digital platforms, online instructions, and digital health information, even when access to technology is available [26,28]. These barriers are often compounded by limited access to culturally appropriate training and support, resulting in greater dependence on family members or community intermediaries for navigation and interpretation of digital tools [28]. In some cases, this reliance reduced autonomy and confidence, further discouraging independent technology use. Cultural perceptions of technology, trust, and privacy also shaped engagement, highlighting the need for culturally responsive approaches to digital literacy support [26].

Defining Digital Literacy

In addition to the 7 themes identified in this scoping review, the included studies demonstrated heterogeneous definitions of digital literacy, underscoring the absence of a unified conceptualization in the field. Given this variability, we did not impose a single operational definition for the purposes of synthesis. Instead, we documented and compared the range of conceptualizations described in the included studies to accurately reflect the existing heterogeneity in the literature. Aslan et al [19] define digital literacy as the ability to find, evaluate, and communicate information using information and communication technologies, emphasizing the core skills necessary for effective information management. Kebede et al [20] offer a comprehensive framework, outlining digital literacy as comprising 5 key indicators: information and data literacy, communication and collaboration, digital content creation, safety, and problem-solving. This structured approach reflected the multidimensional nature of digital literacy. Chee [27] focuses on the practical application, defining digital literacy as the ability to use devices and online platforms, which highlights the functional aspect of digital literacy. Finally, Baek et al [22] define digital literacy as the ability to use and understand information obtained from various digital devices, stressing the significance of comprehension within the digital literacy framework.

Discussion

Principal Findings

This scoping review identified 7 interrelated domains of barriers to digital literacy among older adults: health barriers, support networks, convenience and ease of use, knowledge and information, perception barriers, resource barriers, and barriers for special populations. Together, these themes capture a broad range of challenges, such as physical and cognitive impairments, lack of social support, complex app interfaces, limited digital literacy, security concerns, financial constraints, and a preference for traditional methods of communication. These findings highlight the intricate and multifaceted nature of the digital divide among older adults.

While digital literacy and technology adoption barriers have often been reported separately, recognizing their complex interplay is crucial. Prior research has often examined digital literacy barriers in isolation, focusing separately on technology adoption, access, or specific older adult populations [7-12]. This synthesis suggests that older adults frequently encounter multiple barriers simultaneously, aligning with ecological and life-course perspectives on technology use in later life. This pattern is consistent with ecological and life-course models of aging and technology use, which emphasize how individual, social, and environmental factors interact over time to shape engagement with digital technologies in later life [42-44]. Many of these barriers do not exist in isolation; rather, they often work together to create compounded difficulties for older adults. For instance,

XSL•FO
RenderX

limited access to technology can exacerbate feelings of anxiety and insecurity, while financial constraints may prevent access to personalized training that could alleviate these concerns [20,21]. Similarly, social isolation may intensify the impact of low self-efficacy, leading to a reluctance to engage with digital tools [24,30,38]. An example of this interplay can be seen in how physical barriers, such as poor motor skills or visual impairments, can exacerbate challenges related to convenience and ease of use [30,31,42,43]. Complex interfaces or small font sizes can make digital devices particularly difficult for those with physical limitations, further discouraging use [23,30,31,43,45]. Therefore, it is important to view digital literacy barriers holistically, understanding that older adults often experience multiple, interconnected challenges that influence their ability to use and benefit from digital technologies. Addressing these barriers effectively requires an integrated approach that considers the full spectrum of factors influencing digital literacy.

These findings extend the literature on digital literacy among older adults by synthesizing a wide range of reported barriers and demonstrating how they cluster across multiple domains, including resource constraints, perceptions of technology, and social and psychological factors. Rather than occurring in isolation, barriers were frequently described as interconnected, with multiple challenges shaping older adults' experiences of digital engagement. This synthesis supports a more nuanced understanding of digital literacy that moves beyond single-factor explanations and highlights the cumulative and interacting nature of barriers encountered in later life.

In relation to eHealth technologies, the findings highlight how barriers commonly associated with eHealth literacy, such as design complexity, cost, and limited awareness, are frequently described alongside broader influences, including social support and perceptions of technology [5,19-21,39]. This pattern suggests that challenges related to eHealth engagement are embedded within wider digital literacy contexts rather than being solely attributable to individual skill deficits. Consistent with broader eHealth literacy literature [ie, 45,46], these findings suggest that engagement with digital health technologies is shaped by intersecting usability, access, and psychosocial factors rather than individual competence alone. Taken together, these observations point to the importance of considering multiple, interacting factors when examining eHealth literacy among older adults.

Defining Digital Literacy

Despite the increasing recognition of digital literacy as a critical competency for older adults, this review identified substantial variability in how digital literacy is defined and operationalized across studies. Definitions ranged from basic functional skills to more comprehensive frameworks encompassing information evaluation, communication, safety, and problem-solving. This heterogeneity complicates cross-study comparison and limits the development of targeted interventions.

Consistent with prior work, including the review by Oh et al [47], many commonly used measurement tools emphasize narrow aspects of digital literacy while overlooking broader competencies such as digital content creation and online safety. Although frameworks, such as the digital competence model, propose multidimensional conceptualizations, few studies apply these comprehensively in research with older adults. The lack of comprehensive assessment tools limits the ability to accurately evaluate digital literacy and develop targeted interventions.

The absence of a universally accepted definition of digital literacy complicates research efforts and impacts how digital literacy is assessed across studies. Varying definitions contribute to fragmented approaches, with some emphasizing technical proficiency, while others incorporate cognitive and social dimensions. This inconsistency leads to measurement gaps, as most widely used tools fail to capture the full scope of digital skills needed for meaningful engagement with technology. For instance, while some assessments, such as the Mobile Device Proficiency Questionnaire, evaluate all 5 digital competence competencies, many omit crucial aspects, such as digital content creation and online safety [47]. Without a standardized framework, it is difficult to compare findings across studies or develop interventions that effectively address older adults' digital literacy needs [47].

Future Directions

To address conceptual variability in the literature, future research would benefit from explicitly defining how digital literacy is conceptualized within the context of older adulthood or, at minimum, clearly acknowledging heterogeneity in existing definitions when designing studies. Greater conceptual clarity, supported by the development and adoption of standardized and validated measurement frameworks, would enhance the comparability and coherence of findings across studies. Establishing a shared foundation for defining and measuring digital literacy would also strengthen policy and practice efforts by ensuring that digital inclusion initiatives align with the real-world needs of older adults [47].

Future research should prioritize the development and evaluation of tailored interventions that address the specific barriers identified in this review [25,37]. Longitudinal studies are needed to assess the sustained impact of digital literacy programs on older adults' quality of life and health outcomes. Interdisciplinary research that integrates gerontology, technology design, and education can offer a more comprehensive approach to enhancing digital literacy among older adults. Collaboration with community organizations, policymakers, and technology developers will be essential in designing and implementing effective, scalable interventions.

Additionally, researchers should examine the barriers faced by specialized populations, such as older adults with visual impairments, chronic conditions, and those from rural or low-income backgrounds. These groups encounter unique challenges that often amplify difficulties in engaging with digital technologies. For instance, older adults with visual impairments struggle with the lack of accessible content and frequent technological changes, which can render screen readers and gesture-based interactions ineffective without extensive training [31]. Addressing these specialized needs through inclusive technology design and tailored interventions is crucial to ensure

XSL•FO
RenderX

that all older adults can achieve digital literacy and benefit from technological advancements.

This review highlights the need for multifaceted interventions that simultaneously address the interconnected barriers older adults face [20,21,25,30]. Future studies should explore approaches that integrate digital literacy training with accessible and affordable technology solutions. Additionally, research should evaluate the effectiveness of personalized and community-based approaches to digital literacy, particularly those that involve collaboration with educators, social workers, and family members. Investigating these strategies will provide evidence-based recommendations for scalable interventions that not only improve digital literacy among older adults but also enhance their overall quality of life.

Practical Implications

The findings of the scoping review have several practical implications for policymakers, practitioners, and technology developers. By highlighting the interconnected nature of digital literacy barriers, this review can support the development and funding of comprehensive interventions that address multiple challenges simultaneously, rather than focusing on isolated barriers. Policymakers should consider creating and funding programs that increase the accessibility and affordability of digital devices and internet services for older adults. Consistent with the findings of this review, affordability remains a significant barrier, with many older adults unable to purchase or maintain digital devices or pay for reliable internet access [20,21,25,27,45]. Addressing cost-related barriers is a necessary foundation for improving digital participation among older adults, particularly those living on fixed or limited incomes.

Practitioners can leverage insights from this review to design and implement community-based digital literacy programs that address the diverse and intersecting needs of older adults. The results highlight the importance of personalized, ongoing, and confidence-building approaches to training, particularly for individuals with limited prior exposure to digital technologies or reduced self-efficacy [25,37].

Technology developers play a critical role in reducing digital exclusion by prioritizing user-centered designs that accommodate age-related sensory, cognitive, and motor changes. The findings emphasize the need for intuitive interfaces, simplified navigation, and accessible design features, such as readable text, clear audio, and reduced cognitive load [23,30,31]. In addition, providing continuous education, guidance, and support related to technological updates can help older adults maintain confidence and sustained engagement, particularly as frequent changes were shown to undermine usability and self-efficacy [21,30,31,38]. By implementing these coordinated strategies, policymakers, practitioners, and technology developers can work together to address the multifaceted barriers identified in this review and support more equitable digital participation among older adults.

Limitations

Several limitations of the scoping review should be acknowledged. First, the exclusion of non-English studies and older publications may have limited the scope of insights into global digital literacy barriers among older adults. However, this decision was made to ensure consistency in data interpretation and to focus on more recent studies that reflect the rapidly evolving digital landscape. Additionally, this review focused solely on the experiences of older adults, excluding perspectives from individuals who play a key role in digital literacy education, such as tutors, librarians, and other educators. This approach was chosen to center firsthand accounts of the barriers faced by older adults. While the perspectives of educators and other stakeholders are undoubtedly valuable, the scope of this review was intentionally narrowed to prioritize firsthand accounts from the target population. As such, future research should consider incorporating educators' insights to provide a more comprehensive understanding of the barriers to digital literacy among older adults, ultimately informing more effective, tailored interventions.

Conclusion

The scoping review provides a comprehensive synthesis of the key barriers to digital literacy among older adults, highlighting the intricate and multifaceted nature of these challenges. The review identified 7 primary themes (ie, health barriers, support networks, convenience and ease of use, knowledge and information, perception barriers, resource barriers, and barriers for special populations) that collectively shape the digital experiences of older adults. These barriers often interact, potentially increasing the challenges older adults face in engaging with digital technologies. These findings suggest that engagement with digital technologies is shaped by a complex interplay of individual, social, and contextual factors. Future work could explore strategies that address these barriers while considering diverse abilities, levels of support, and contextual constraints. Additionally, research would benefit from greater consistency in defining digital literacy and examining how multifaceted approaches may support digital participation among subpopulations facing heightened barriers.

Abstract

Background: Older adults often face mobility challenges and usability barriers when navigating transportation options due to age-related physical, cognitive, and sensory changes. While transportation planning e-tools can support their independence, most are not designed for their specific needs. There is a lack of comprehensive, age-friendly usability design principles tailored to this context.

Objective: This study aims to identify, synthesize, and prioritize the most relevant age-friendly usability design principles and guidelines for developing transportation planning e-tools that are tailored to the needs of older adults.

Methods: A scoping review was conducted following the Arksey and O'Malley methodological framework, enhanced by guidance from the Joanna Briggs Institute and reported according to the PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses Extension for Scoping Reviews) standards. The literature search was performed across the following six scientific databases: MEDLINE (PubMed and National Center for Biotechnology Information), AgeLine (EBSCOhost), Cochrane Library (Wiley Online Library), Scopus (Elsevier), IEEE Xplore, and TRID (Transportation Research Board), and was supplemented by gray literature identified through Google Scholar and Google Search, covering the period from January 2013 to April 2025. To guide the analysis, 4 foundational usability frameworks by Nielsen; Shneiderman and Plaisant; Gerhardt-Powals; and Weinschenk and Barker were used to inductively derive generic principles that structured the classification of age-friendly guidelines. This process resulted in the organization of extracted guidelines into 10 core usability principles. The analytic hierarchy process was applied by a single expert to rank the principles based on expert pairwise comparisons and their frequency of reference in literature.

Results: The study identified 31 relevant studies. From these, 500 age-friendly guidelines were refined into 68 actionable guidelines across 10 usability principles: visual clarity, structure and navigation, ease of use, information, minimizing memory load, feedback, accessibility, consistency, simplicity, and control. The analytic hierarchy process ranked visual clarity (36.4%), structure and navigation (22.1%), and ease of use (12.5%) as the top 3 age-friendly design priorities.

Conclusions: This study offers an evidence-based foundation for developing transportation planning e-tools that promote older adults' autonomy and digital inclusion, with prioritized guidelines applicable to transportation planning e-tools and to the broader field of age-friendly digital design. Ongoing updates and active user involvement are essential to ensure their sustained usability and long-term relevance.

Introduction

Background

As people age, they often encounter mobility-related difficulties, which can significantly impact their ability to engage in society [1]. These difficulties can make everyday activities, such as attending medical appointments or participating in social and recreational events, increasingly challenging [2]. Reduced physical capacity, changes in vision [3] and balance [4], as well as the onset of chronic illnesses [4], contribute to these mobility issues. As a result, many older adults find it difficult to maintain the independence and social connections that are crucial to their overall well-being [5]. Addressing these challenges requires a comprehensive approach, including accessible transportation options that help older adults remain active and engaged in their

XSL•FO
RenderX

daily lives, despite steep hills and heavy snowfall, which are common in Nordic countries like Canada.

In the province of Quebec (Canada), data from 2019 show that approximately 64% of older adults drive and 23% travel as passengers, while about 9% use taxis, adapted transport, or public transit, and only 3% rely on walking, cycling, or mobility devices. Men were more likely than women to drive (80% vs 50%), while women more often traveled as passengers (35% vs 10%) and used taxis, paratransit, or public transit more frequently (12% vs 7%) [6]. Although only a small proportion of older adults use public or shared transportation, studies indicate that this limited use does not necessarily reflect a lack of interest but rather barriers such as safety concerns, difficulties accessing clear travel information, and a lack of confidence or comfort when using available options like buses—often due to fears of becoming disoriented or encountering unwanted social interactions [7,8].

To mitigate these challenges, there is a growing need for transportation planning e-tools that can assist older adults in accessing reliable information about their travel options. E-tools (eg, route-planning systems) could help drivers feel safer by avoiding hazardous routes, such as steep hills or poorly lit roads, particularly in challenging conditions [9]. However, engaging with such digital tools often proves difficult for this population. Age-related changes such as reduced visual sensitivity [10] can make it hard to accurately select interactive elements, thereby disrupting the overall trip-planning experience [11]. In addition, cognitive factors, such as reduced attention, can make it more difficult to navigate digital interfaces [12]. Consequently, the design of transportation planning e-tools must consider both the functional changes associated with aging and the diversity in digital competencies among older adults [13]. It is therefore essential to adapt these tools, particularly their interfaces, to better meet the needs of older adults.

Given the notable lack of studies specifically focused on developing and evaluating transport planning interfaces tailored to the needs and preferences of older adults through a participatory design approach [14], it becomes increasingly important to identify comprehensive age-friendly design principles and usability guidelines. While a number of design frameworks exist for general usability [15], few explicitly address the cognitive, physical, and perceptual changes associated with aging [16,17]. Without clear, context-specific design guidance, there is a risk that digital solutions will continue to fall short of accessibility and usability standards for this population. A systematic synthesis of existing guidelines is relevant to ensure that future e-tool interfaces are not only inclusive but also practical, empowering older adults to confidently plan and manage their trips. It is therefore essential to fill the gap by identifying, consolidating, and prioritizing existing age-friendly usability design principles to inform the development of transportation planning e-tools that are both effective and attuned to the diverse capabilities of older users.

Objective

This study aims to identify, synthesize, and prioritize the most relevant age-friendly usability design principles and guidelines for developing transportation planning e-tools that are tailored to the needs of older adults.

Methods

Study Design

This scoping review was conducted using the methodological framework proposed by Arksey and O'Malley [18], which includes five stages: (1) identifying the research question; (2) identifying relevant sources; (3) selecting studies; (4) charting the data; and (5) collating, summarizing, and reporting the results. Methodological guidance from the Joanna Briggs Institute was also integrated to enhance the rigor of the review. The reporting process adheres to the PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses Extension for Scoping Reviews) guidelines (Checklist 1) [19]. In the second phase, the analytic hierarchy process (AHP) [20] was used to prioritize the age-friendly usability design principles identified through the scoping review.

Scoping Review: Identifying the Research Question

The study is guided by the following research question: What are the most relevant age-friendly usability design principles and guidelines for developing transportation planning e-tools tailored to the needs of older adults? This question was structured using the population, concept, and context (PCC) framework, where the population is older adults, the concept focuses on age-friendly usability design principles and guidelines, and the context involves the development of transportation planning e-tools.

Identifying the Relevant Sources

This stage consisted of searching scientific and gray literature published in English from January 2013 to May 2023, with an updated search conducted twice, in April 2024 and April 2025. This timeframe was selected to capture the most recent decade of research on age-friendly usability guidelines and transportation planning e-tools, reflecting rapid advances in digital technologies. The search was performed across six (6) scientific databases: MEDLINE (PubMed and National Center for Biotechnology Information), AgeLine (EBSCOhost), Cochrane Library (Wiley Online Library), Scopus (Elsevier), IEEE Xplore, and TRID (Transportation Research Board). To supplement the scientific literature, gray literature was identified through Google Scholar and Google Search, with the first 50 results from each platform screened for inclusion to ensure relevance and manageability.

The development of the search strategy followed a systematic and collaborative approach. Initially, authors compiled a list of relevant databases and preliminary keywords based on the study objectives. This preliminary version was then critically reviewed by a professional librarian, who contributed methodological expertise throughout the process. His recommendations were informed by the PRESS (Peer Review of Electronic Search Strategies) 2015 guidelines [21], leading to substantial improvements in keyword formulation, the use of Boolean operators, and the integration of controlled vocabulary terms. To improve the effectiveness of the search strategy, the professional librarian suggested running preliminary tests to

XSL•FO
RenderX

evaluate how well the selected terms captured relevant studies. Based on the outcomes, he recommended several refinements. For example, the terms “Graphical User Interface” and “GUI” were added to ensure that studies using different terminology could be retrieved. These adjustments aimed to reduce the number of irrelevant results and to ensure that key studies were not overlooked.

Controlled vocabulary, such as Medical Subject Headings terms in PubMed, was mapped and complemented by a tailored list of free-text terms to reflect diverse indexing practices and author phrasing across databases. After executing the search, the results were imported into Zotero (Corporation for Digital Scholarship) for reference management. Initial deduplication was performed using Zotero’s automated function, followed by a thorough manual screening by the first author (SBG) to remove any remaining duplicate records. The final search strategy, including both controlled vocabulary and keywords, is presented in Table 1.

Table . Keywords and concepts.

Concepts	Keywords	Controlled vocabulary (by database)
Aging	“Older adult” OR “Old people” OR “Elderly” OR “Senior” OR “Aging” OR “Normal aging” OR “Frailty” OR “Aged” OR Old*	• MEDLINE or Cochrane Library: aged (MeSH[a]) • AgeLine: aged, older adults • TRID: elderly persons (thesaurus)
E-tool	“Website” OR “Application” OR “E-tool” OR “Web application” OR “App” OR “Web”	• MEDLINE or Cochrane Library: mobile applications (MeSH) • IEEE Xplore: software applications (IEEE thesaurus) • TRID: websites (TRID thesaurus)
Guideline	“Design principles” OR “Web design principle” OR “Design guideline” OR “Web design guideline” OR “Usability guideline” OR “User interface design guideline” OR “UI design guideline” OR “User experience design guideline” OR “UX design guideline” OR “GUI” OR “Graphical user interface”	• MEDLINE or Cochrane Library: user-computer interface (MeSH) and guidelines as topic (MeSH) • AgeLine: human-computer interaction and usability engineering • TRID: Human factors engineering
Transport	“transport* OR “public transport*” OR mobility* OR travel OR “public transit” OR “active transport*” OR “alternative transport” OR paratransit OR bus* OR carpool*	• MEDLINE or Cochrane Library: transportation (MeSH) • AgeLine: transportation • TRID: transit, mobility, and public transportation

[a]MeSH: medical subject headings.

Selecting the Studies

To be eligible for inclusion, sources needed to address usability guidelines specifically aimed at older adults.

Sources were excluded if they met any of the following criteria: (1) written in a language other than English and (2) focused on e-tools other than websites or apps.

The first author (SBG) conducted the initial screening of all identified sources based on titles and abstracts, followed by a full-text review to assess their eligibility. To mitigate potential bias and strengthen the reliability of the process, 20% of the study selection was independently reviewed and validated by a co-author (VP). Specifically, the co-author independently reviewed 20% of the records retained after the title and abstract screening stage, as well as 20% of the studies assessed at the full-text eligibility stage, to verify inclusion decisions and ensure consistency.

Charting the Data

To chart the data, 4 pioneering sets of general usability guidelines were selected: Nielsen [15], Shneiderman and Plaisant [22], Gerhardt-Powals [23], and Weinschenk and Barker [24]. These foundational works have stood the test of time, are widely cited in the fields of human-computer interaction and user experience, and have been extensively validated across diverse domains and user groups. Each set offers a distinct yet complementary perspective on usability: Nielsen outlined 10 usability heuristics, Shneiderman and Plaisant introduced 8 golden rules of interface design, Gerhardt-Powals proposed 10 cognitive principles for interface development, and Weinschenk and Barker organized their recommendations into 11 thematic categories. It is important to note that these frameworks were identified before screening relevant studies and were not part of the scoping review dataset. Rather, they were used to develop an initial analytical framework (charting form) to guide the systematic extraction and categorization of age-friendly usability guidelines from included studies. This approach ensured that the analysis was structured, consistent, and comprehensive, while preventing selection bias.

To develop the charting form, the first author (SBG) thematically analyzed the 4 pioneering sets of selected general usability guidelines using the Braun and Clarke [25] inductive thematic analysis approach. Guidelines from key authors were compiled into a cross-table and grouped into broader categories

XSL•FO
RenderX

based on emerging patterns. Redundant or overlapping items were removed or integrated to ensure clarity and uniqueness. These refined categories were then defined as 10 core usability principles associated with 19 generic usability guidelines (Table 2).

Table . Interface design principles with associated generic guidelines.

Principles and guidelines	Shneiderman	Nielsen	Weinschenk and Barker	Gerhardt‐Powals
Feedback				
Informative feedback	✓	✓	✓	
Confirmation of the actions that are done successfully	✓		✓	✓
Let users be aware of results			✓	
Consistency				
Present new information in familiar frameworks and structure				✓
Consistency in using familiar icons and colors	✓	✓		✓
Minimizing the memory load				
Memory load avoidance	✓	✓		✓
Avoid changes in familiar behavior to speed up the action of the experienced users	✓			
Simplicity				
Simple error message (not codes)	✓	✓	✓	
Simple and relevant information (eliminate unnecessary information to reduce the use of the resource in multitasks)		✓		✓
Simple layout			✓	✓
Accessibility				
Consider user profile in design (eg, digital literacy)	✓	✓		
Flexibility in providing information for a wide range of users with different cognitive abilities, in different tasks, for both experienced and novice users		✓		✓
Structure and navigation				
Error prevention by implying target limitation (eg, do not allow the user to enter numeric characters in alphabetic fields)	✓	✓	✓	
Data grouping				✓
Control				
Ability to control by undo, redo, or exit	✓	✓	✓	
Command and control model to let users know how they should answer the questions and enter the information			✓	
Ease of use				
Easy to access help and support		✓		✓
Visual clarity				
Use graphics as much as possible instead of text				✓
Information				
Use names that are conceptually related to function				✓

RenderX

Subsequently, a structured Microsoft Excel grid was developed to chart the sources identified through this scoping review. In this grid, source characteristics (including publication year and study context), e-tool types, and age-friendly guidelines, categorized according to usability principles derived from the 4 pioneering general usability frameworks mentioned earlier, were captured. Similar to the generic usability design guidelines, the Braun and Clarke [25] thematic analysis framework was used. Since the generic usability guidelines served as the foundation for developing age-friendly usability guidelines, a deductive approach was chosen. In this context, all the identified guidelines were compiled into a cross-table. This process involved reading through the guidelines to understand their content and context, ensuring that each entry was accurately represented in a table. In the next step, each guideline was labeled with a principle that best represented its content, facilitating the organization of the guidelines into manageable pieces for further analysis. Subsequently, guidelines with the same labels were grouped together. The labeled guidelines were then reviewed and refined to ensure accurate clustering. Redundant guidelines within each group were identified and removed to simplify the dataset. Additionally, similar guidelines were integrated to reduce overlap and ensure that each guideline was distinct and relevant. Finally, the process concluded with final reporting. This process resulted in a clear and distinct set of guidelines.

Collecting, Summarizing, and Reporting Results

A combination of descriptive-analytical methods and thematic analysis [25] was applied to examine all data categories, including source characteristics, e-tool types, and age-friendly guidelines. The findings were then synthesized and interpreted to map the most relevant age-friendly usability design guidelines for creating transportation planning e-tools tailored to older adults' needs, categorized in the 10 core usability principles previously defined.

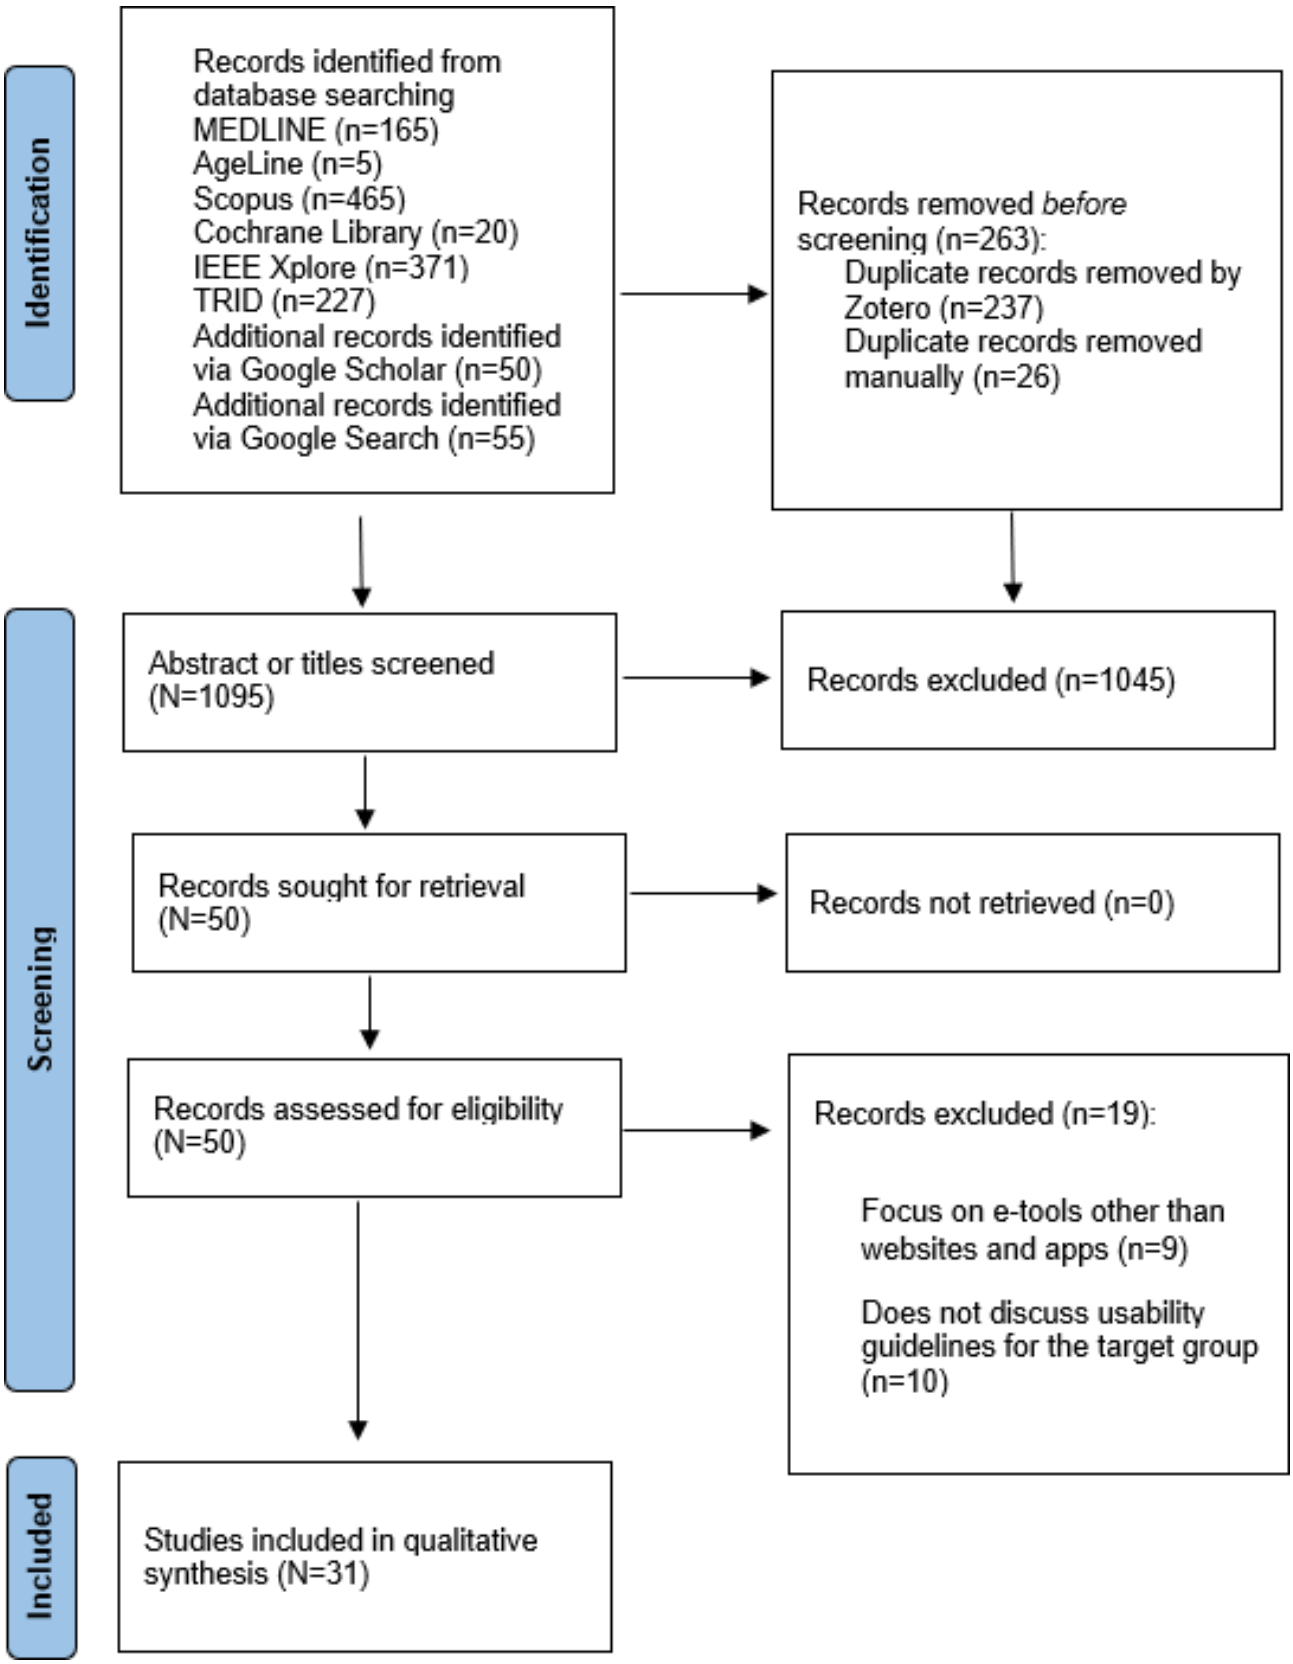
Prioritization Using the AHP

To prioritize the age-friendly design principles identified through the scoping review, the AHP [20] was used. This method enables prioritization through pairwise comparisons, relying on expert judgment to establish a structured hierarchy of priorities [20]. A key advantage of AHP is its systematic approach to comparing and ranking alternatives or criteria [26]. To guide the pairwise comparisons, the Saaty's [20] fundamental scale of relative importance was used. This scale assigns numeric values to verbal judgments: 1 for equally important, 3 for moderately important, 5 for strongly important, 7 for very strongly important, and 9 for extremely important. The even numbers 2, 4, 6, and 8 serve as intermediate values between these main levels.

To validate the results of the AHP, the consistency ratio (CR) is calculated using the formula CR=CI/RI, where the consistency index (CI), derived from pairwise comparisons, is measured using the following formula and then compared with the corresponding random index (RI).

$$CI=\lambda max-nn-1$$

In this study, the AHP Online System (AHP-OS), developed by Goepel [27], was used by the first author (SBG), who has extensive experience in human-centered design and usability evaluation, to conduct pairwise comparisons of each design principle. The software aggregated these comparisons and calculated normalized priority weights. Principles with higher frequencies in the scoping review were considered more influential and were assigned higher relative importance values on the Saaty fundamental scale (eg, "moderately" to "very strongly" more important) compared with less frequently cited principles. This approach ensured that the prioritization systematically reflected both the literature evidence and expert judgment. Using this method facilitated decision-making by quantifying expert input, producing a consistent ranking of the most critical age-friendly usability design principles, and resolving conflicts between design criteria.



Results

Scoping Review

A total of 1358 sources were initially identified through database searches and gray literature. After removing duplicates, 1095 unique sources remained. Following the screening of titles and abstracts, 50 sources were retained. Of these, 19 did not meet the inclusion and exclusion criteria, leaving 31 sources for full-text analysis (Figure 1).

XSL•FO
RenderX

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) 2020 flow diagram detailing the process of literature search, screening, and selection.

Characteristic of Sources

Out of the 31 sources (Table 3), 26 (83.9%) clearly indicated the publication year, ranging from 2001 to 2024 [28-53]. Most (n=24, 77.4% publications) guidelines were published between 2015 and 2024 [28-30,32-44,46-53], with a peak in 2023 (n=5, 16.1% publications) [29,39,41,44,49].

[a]Data not available.

[b]UX: user experience.

[c]UI: user interface.

Of the 31 sources, 11 (35.5%) specified the context of the study. Most of these contexts were related to health, representing 16.1% of the total sources [42-44,46,49]. Other identified contexts included tourism [52], communication [53], gaming [31,32], public service [29], and religion [28].

The majority of sources (n=17, 55%) focused on age-friendly usability guidelines related to developing apps, reflecting the

XSL•FO
RenderX

growing use of smartphones and mobile technology among older adults [28-32,37-39,43,44,46-51,53]. Five (16.1%) sources focused on guidelines for developing websites [34,35,42,45,52], and 3 (9.6%) sources covered both websites and apps [54-56]. Additionally, 6 (19.3%) sources did not indicate the type of e-tool [33,36,40,41,57,58].

A total of 500 guidelines were identified. Among them, visual clarity accounted for 26.6% (133 guidelines) and had the highest frequency of referral, while consistency, simplicity, and control each represented 5% (25 guidelines) and had the lowest frequency of referral. For more detailed information on the frequency of referral for each principle, see Table 4.

Table . Frequency of referral to guidelines associated with each principle.

Principles	Frequency of referral, n (%)
Visual clarity	133 (26.6)
Structure and navigation	82 (16.4)
Ease of use	63 (12.6)
Information	48 (9.6)
Minimizing the memory load	39 (7.8)
Feedback	31 (6.2)
Accessibility	29 (5.8)
Consistency	25 (5)
Simplicity	25 (5)
Control	25 (5)

After removing or integrating redundant or overlapping items to ensure clarity, 74 age-friendly usability design guidelines were identified and categorized under 10 core principles derived from general usability guidelines. The next step involved combining the guidelines identified through the generic usability design guidelines (19 guidelines) with the age-friendly usability design guidelines (74 guidelines), resulting in a total of 93 guidelines. In this process, the guidelines related to each principle were reviewed together, redundant guidelines were removed, and similar ones were combined to reduce overlap. The goal was to ensure that only the most relevant and unique guidelines were retained. As a result, from the initial 93 guidelines, 68 were finalized and categorized into the 10 design principles. Table 5 presents the final set of age-friendly usability design guidelines categorized into 10 core principles.

RenderX

Table . Age-friendly usability design principles and guidelines.

Principles and guidelines	Relevant studies
Feedback	
Provide informative feedback by showing clicked links, task status, waiting periods, and error messages with resolution steps.	[15,22-24,29,34,35,38,39,41,48,49,54,57]
Request confirmation before performing actions that could cause significant changes or data loss, and confirm successful actions	[29,33,36,38,41,48]
Consistency	
	[15,22,23,33-35,38,40,42,43,45,47,57]
Maintain consistency in design elements across pages and screens such as by using familiar icons, input formats, colors, menu hierarchy, and so on.	
Present information clearly by using familiar frameworks and structures, and apply consistent navigation patterns and layouts.	[23,29,38,39,49,50,57]
Underline text only when it is a link.	[58]
Minimizing the memory load	
Present 1 task or process at a time.	[15,22,23,29,34-36,39,47]
Avoid complex dynamic input fields that require multiple gestures or the use of both hands.	[29,42,55]
Eliminate unnecessary or repetitive actions.	[29,38]
Limit the number of key functions on the home screen to 12 or fewer for tablets and 6 or fewer for smartphones.	[38,41,43,46,49,52]
Avoid changes in familiar behavior to speed up the actions of experienced users.	[22,34,35]
Use images, videos, or audio to complement text information.	[38,45]
Minimize time-sensitive content and provide options to adjust or extend time limits if necessary.	[34,35,38,39,41,42,56]
Simplicity	
Simplify data entry processes	[38,43]
Use simple and easy-to-understand graphics.	[43,48,52,55]
Ensure simplicity, clarity, and consistency in screen layout, navigation, and terminology.	[15,23,24,32,34,35,38,39,48,55]
Provide simple error messages (not codes).	[15,22,24,33,36,38,41]
Accessibility	
Consider user profiles in design such as their digital literacy, and visual and cognitive impairment.	[15,22-24,34,38,43,45,47,52]
Ensure button accessibility with a universal approach, accommodating left-handed users.	[34]
Use icons alongside text labels.	[34,38]
Include alternative data entry methods for users unable to use the primary method.	[34,35]
Ensure the app interface adapts to device rotation and user attempts to enlarge screen content.	[29]
Provide content in various multimedia formats, such as text, videos, pictures, and audio.	[30,31,34,35,38,47]
Structure and navigation	
Avoid requiring users to double-click or drag to interact with the page.	[34,36,41,45,50]
Offer both click-to-zoom and 2-finger zoom gestures.	[37,47,48]
Minimize data entry steps to ideally fewer than 3.	[43,52]
Provide help tutorials or brief animated instructions.	[29,33-35,38,46,47,52]
Clearly indicate touchable or clickable elements.	[34,35,39,47,56]
Position key elements (eg, buttons and information) at the center of the screen.	[31,34,35,38,39,41,47,48]
Guide users with systematic navigation to indicate their location and the next step.	[29,34,38,39,41-43,45,52]
Provide a virtual keyboard for numerical or alphabetical entry.	[15,22,24,38]
Use a short, simple, and static pull-down menu.	[34,38,45,48]
Include spell check for errors.	[38]

XSL•FO
RenderX

Principles and guidelines	Relevant studies
Maintain hierarchy in feedback, navigation, visual design, and data grouping.	[23,34,35,38,42,47,57]
Avoid using scroll bars, especially horizontally.	[34,35,38,45,48]
Position search tools at the top right.	[34]
Control	
Provide zoom-in ability up to 200%.	[33,38,47]
Consider the home menu as a safe return point.	[31,34,35,43]
Ability to control requests by undoing, redoing, and exiting.	[15,22,24,31,33,36,38,45,57]
Avoid disappearing messages; let users close them manually.	[36]
Offer adjustable text sizes, color schemes, and contrast to enable personalization of the user experience.	[35,38,42]
Ease of use	
Enable a function to remember usernames and passwords.	[34]
Make account creation optional for users.	[34]
Incorporate autosave features whenever possible.	[43,46]
Provide support for both orientations.	[47,57]
Include automatic data entry (eg, time and date) to reduce data entry time and keyboard use.	[29,31,35,38,39,47]
Ensure easy access to help and support.	[15,23,29,35,36,39,41,43,53,55]
Consider target touch areas of at least 9 x 9 mm, with a minimum of 8 dp of inactive space between them.	[30-34,37-39,41-43,47,48,50,54,55,58]
Visual clarity	
Avoid using fluorescent colors and colors with minimal contrast, such as green and red; yellow and blue; or green and blue.	[29,34,35,38,42,43,45,52,54]
Avoid using all capital letters words.	[34,38,45]
Consider 3:1 and 4:1 color contrast ratio for text and large text respectively.	[29,30,34,36,38-40,42,43,48,49,54,55]
Adjust the contrast range between 1.7 and 3.0.	[30,34]
Use blue, red, and magenta as the link colors on a white background due to their high visibility.	[34,36,38,43,45]
Use brightness levels of 75% and 50%.	[34,51]
Use font sizes of 12 point to 14 point for body text and 16 point for titles.	[28,33-35,38-40,43-45,47,48,50-53,55,58]
Use sans serif fonts like Arial, Helvetica, and Tahoma.	[29,34,38,45,51,54,55]
Avoid justified alignment, unfilled text, text shadows, large blocks of italic or bold text, and underlined text.	[38,42,45,54]
Maintain line spacing between 1.5 to 2.	[38,45]
Consider using bold typefaces for emphasis.	[28,38,45,54]
Avoid complex and distracting elements such as animations, blinking text, patterned backgrounds, pure white backgrounds, pure black text on white backgrounds, and transparent menus.	[23,34,38,39,42,44,45,51,57]
Information	
The website should not include pop-up messages or advertisements.	[52]
Avoid unclear or ambiguous language.	[31,33,35,38,39,41,42,45,49,52]
Do not use abbreviations or symbols.	[38]
Ensure each page has a clear and descriptive title.	[38]
Avoid using Roman numerals.	[38]
Use short sentences (less than 70 characters per line) and paragraphs (each focusing on a single idea) and avoid hyphenating words at the end of lines.	[38,39,45,54]
Highlight important information for better visibility.	[34,38]
Use active voice to enhance clarity.	[38,45]

Principles and guidelines	Relevant studies
Use names that are conceptually related to function.	[23,34,35,38,42,52,53]

Analytic Hierarchy Process

AHP was used to assess the relative importance of the 10 identified age-friendly usability design principles. This prioritization was based on expert judgment (SBG) and the frequency of references found in the scoping review. For example, visual clarity had the highest frequency of 133 (26.6%) references, whereas control had 25 (5%) references. During pairwise comparisons, this difference guided the assignment of the Saaty scale values: visual clarity was often judged as "strongly" or "very strongly" more important than principles with lower frequencies. The results indicated that visual clarity, structure and navigation, and ease of use were the most critical principles for the development of transportation planning e-tools tailored to older adults.

The CR, which measures the reliability of pairwise comparisons, was calculated at 7.5%, remaining below the acceptable threshold of 0.10 (10%) as recommended by Saaty [20]. The AHP decision matrix is presented in Multimedia Appendix 1.

According to the results, visual clarity was ranked as the highest priority, receiving 36.4% of the total weight. This indicates that guidelines associated with visual clarity should take precedence, particularly in cases where they may conflict with other guidelines or functional aspects of e-tool development. Structure and navigation and ease of use were ranked second and third, with priority weights of 22.1% and 12.5%, respectively. A complete ranking of the principles and their corresponding weights is presented in Table 6.

Table . List of principles sorted by their rank and the percentage of their priority.

Principles	Rank	Priority, %
Visual clarity	1	36.4
Structure and navigation	2	22.1
Ease of use	3	12.5
Information	4	10.5
Minimizing the memory load	5	6.3
Feedback	6	3.8
Accessibility	7	2.8
Consistency	8	2.1
Simplicity	9	1.9
Control	10	1.8

Discussion

Principal Findings

This study aimed to identify, synthesize, and prioritize age-friendly usability design principles and guidelines for transportation planning e-tools tailored to the needs of older adults. Through a comprehensive scoping review and the application of the AHP, the study provides a structured, evidence-based framework to guide the design of inclusive digital transport tools. The synthesis of existing usability guidelines identified 68 clear and actionable recommendations, which were categorized under 10 core design principles. Among these, visual clarity, structure and navigation, and ease of use emerged as the highest priorities for enhancing the usability and comfort of digital tools for this population.

In general, our results highlighted the effectiveness of these generic usability guidelines in categorizing design principles tailored to specific user groups, particularly older adults. As Ahmad et al [59] pointed out, these generic usability guidelines function as essential rules of thumb that all user interface designers should follow. Although general guidelines are widely applicable, there is significant value in customizing them to meet the specific needs of older adults when developing age-friendly e-tools. Through actionable recommendations, this customization enhances the usability and adaptability of such e-tools. This perspective aligns with Patsoule and Koutsabasis [60], who argued that identifying and validating a set of principles and guidelines for web design specifically for older adults improves the adaptability of an e-tool to their needs and preferences.

More specifically, our results revealed that the principle of visual clarity was ranked as the highest priority, followed by structure and navigation and ease of use, which were ranked second and third, respectively. This underscores the critical importance of visual clarity in designing e-tools for older adults, particularly for travel planning, which is inherently complex and involves managing multiple types of information such as destinations, schedules, and personal preferences. A clear and intuitive interface reduces cognitive load, making tasks more manageable and less stressful, thereby improving usability and encouraging long-term adoption among older adults [61]. In support of these findings, Patsoule and Koutsabasis [60] highlighted "Visibility" and "Ease of Understanding" as the top 2 principles in age-friendly heuristics for redesigning websites for older adults.

XSL•FO
RenderX

Their research aligns with the prioritization identified through the AHP methodology, further validating the emphasis on visual clarity, structure and navigation, and ease of use. These principles are vital in ensuring that older adults can effectively use e-tools without confusion or frustration.

Structure and navigation, ranked second (22.1%), further emphasizes the importance of logical content organization and user orientation within interfaces. Well-defined pathways, minimized data entry steps, and effective wayfinding features are essential to mitigate disorientation and cognitive overload [12,62]. Similarly, the third-ranked principle, ease of use (12.5%), points to the necessity of designing interfaces that are both intuitive and forgiving, offering support mechanisms such as autofill, orientation flexibility, and minimal setup requirements. At the other end of the spectrum, principles such as Control, Simplicity, and Consistency received the lowest prioritization. While their lower scores suggest they may not be as immediately critical as visual clarity or navigability, they remain essential for ensuring a robust and holistic user experience. To support this, Nahm et al [63] highlighted that "simple design with clear instructions" was a key preference among older adults, in contrast to design elements that rely on complex navigation or ambiguous features.

Given the dynamic nature of technology and the evolving needs of older adults, it is crucial to continuously refine and expand age-friendly usability design principles and guidelines. Nurgalieva et al [64] highlight that while many such guidelines exist, their adoption is often limited without ongoing efforts to make them more accessible, organized, and actionable. Furthermore, a recent systematic review of mobile app design for older adults emphasizes the importance of iterative, user-centered design, including feedback loops, adaptation to emerging devices, and integration of new accessibility features, to ensure that e-tools remain intuitive, usable, and relevant over time [65].

Limitations

Although the study highlights the most relevant age-friendly usability design principles and guidelines for transportation planning e-tools, certain limitations should be acknowledged. First, the protocol for the scoping review was not registered in advance. Although the review followed established methodological frameworks and incorporated rigorous processes for data collection and analysis, the absence of a registered protocol may limit the transparency and reproducibility of the review process. To mitigate this limitation, steps were taken to enhance transparency and minimize bias: a second reviewer validated 20% of the study selection and data extraction, the search strategy was fully documented, and a professional librarian reviewed and refined the search approach. Notably, the methodology did not include the consultation step recommended by Levac et al [66], which is often used to enhance the relevance and applicability of findings through stakeholder engagement. Nevertheless, the results of this study were extensively applied in the Mobilaînés project [67] to support the co-design and development of an age-friendly transportation planning e-tool. The implementation of this innovative e-tool helped validate the practical value and effectiveness of the guidelines identified through the scoping review in addressing the digital accessibility needs of older adults. Second, although the data selection and extraction processes were confirmed by co-authors, study screening was performed by the first author. The validation process, while helpful, might not have fully addressed all possible sources of subjective influence. Future research could benefit from involving multiple reviewers in the data extraction and study selection stages, thereby providing a more balanced perspective and reducing the risk of individual biases affecting the outcomes. Third, the current study relied on a single expert for the AHP analysis, which may limit the generalizability and robustness of the prioritization results. To reduce this limitation, frequency data from the scoping review were integrated into the pairwise comparisons to provide a more objective basis alongside expert judgment, thereby helping to reduce potential bias. Nevertheless, involving multiple experts in future AHP analyses could further strengthen the validity of the findings. Incorporating diverse viewpoints and ensuring thorough cross-checking of the data would enhance the robustness and credibility of the review results. Fourth, it is possible that some articles were not retrieved, due to the selected keywords and lack of consideration for gray literature. Although the database searches included a broad range of academic publication types (eg, journal articles, conference papers, and proceedings), many age-friendly usability guidelines and design frameworks are disseminated through gray literature such as institutional reports, professional guidelines, and practitioner-oriented documents, which are not consistently indexed in bibliographic databases. To ensure comprehensive coverage, Google Scholar and Google Search were therefore used to identify gray literature, with the first 50 results from each platform screened to balance systematic coverage with feasibility. This complementary approach strengthened the inclusiveness of the review while acknowledging the inherent limitations of gray literature searching. Finally, while the search strategy may not have captured every possible variation in spelling, pluralization, or word order, the integration of standardized indexing terms (eg, MeSH) and a wide range of keyword formats enhanced the comprehensiveness of the literature search (Multimedia Appendix 2). The review and input from the professional librarian also played a key role in ensuring methodological soundness and adherence to systematic review guidelines.

Conclusions

This study offers valuable insights into the design of transportation planning e-tools tailored to the needs of older adults, providing a robust foundation for the development of accessible and user-friendly digital interfaces. Indeed, the insights generated from this research are highly transferable, offering valuable contributions not only to transportation e-tools but also potentially to other apps and websites that support the autonomy and social participation of older adults. Continued refinement of these guidelines, through iterative updates and the active involvement of older users in the design process, will be crucial to ensure their long-term relevance and impact.

Acknowledgments

The authors gratefully acknowledge librarian Miguel Escobar for his invaluable contribution in reviewing and enhancing our search strategy to ensure its accuracy and comprehensiveness and Hélène Pigot for her insightful guidance and support throughout the study. The authors used the generative artificial intelligence tool ChatGPT (OpenAI) for copyediting and language refinement during manuscript preparation.

Funding

This study is financially supported by the Fonds de recherche du Québec–Santé (2020-VILL279242) and Bourse pour les nouveaux étudiants de 3e cycles du Centre de recherche sur le vieillissement, Sherbrooke.

Data Availability

All data generated or analyzed during this study are included in this published article and its supplementary files.

Authors' Contributions

SBG and VP were responsible for the conceptualization of this study. VP secured funding and provided overall supervision of the research project. SBG conducted the database and web searches for this scoping review, under the guidance of VP and MG. Screening of publications, data extraction, and data analysis were performed by SBG and subsequently validated by VP. SBG drafted the initial manuscript, which was reviewed and revised by VP and MG. All authors read and approved the final version of the manuscript.

Abstract

Background: The daily use of digital technologies is transforming the day-to-day lives of older adults. Among these technologies, artificial intelligence–enabled smart glasses have recently emerged, which allow constant interaction with the device itself and with the environment. They are designed to be used for multitasking, including options such as being able to take photographs and/or videos; record immersive audio; make calls; and share multimedia content through voice commands, touch, or blink detection.

Objective: The aim of this study was to map the existing evidence and gain insight into the effectiveness and potential benefits of artificial intelligence–enabled smart glasses in promoting active living in old age.

Methods: A scoping review was performed following the PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses extension for Scoping Reviews) statement by consulting the PubMed, Scopus, and Web of Science databases using a search strategy and syntax (“smart glasses” AND (“older adult” OR elderly OR aging) AND health). The review process was conducted through the Covidence online platform, and the final review protocol was prospectively registered in the Open Science Framework. Both the research question and eligibility criteria were based on the population, concept, and context framework for scoping reviews.

Results: From a total of 58 papers identified, 6 (10.3%) studies were finally included (2 pilot studies, 2 technological development studies with experimental validation of a prototype, 1 mixed methods feasibility trial, and 1 survey) published between 2015 and 2023 after eliminating duplications and screening titles, abstracts, and keywords. The results suggest that the use of artificial intelligence–enabled smart glasses may contribute to improving the quality of life, independence, autonomy, motor functions, and social interactions of older adults.

Conclusions: Because of the novelty of this type of digital technology, there is very little research on this topic at present. Moreover, the adoption and implementation of artificial intelligence–enabled smart glasses are conditioned by hindering factors such as data protection, the high price, and the lack of compatibility with conventional prescription glasses, as well as the lack of evaluation of their effectiveness, usability, and acceptance.

(JMIR Aging 2026;9:e81157) doi:10.2196/81157

KEYWORDS

smart glasses; artificial intelligence; AI; older adults; well-being; active aging

Introduction

The aging of populations worldwide raises important questions for health systems and social policies. In this context, the promotion of active aging, understood as older people’s ability to adapt and function in their daily environment [1-3], has become a priority to improve the quality of life of older adults in terms of health, participation, and safety. Given the decline in physical and cognitive functioning with advancing age, coupled with demographic shifts toward an increasingly aging society, it is essential to contribute to improving the well-being of this population [4]. Emerging digital technologies offer new opportunities to support these objectives [5]. These technologies, which include information and communications technologies, websites, cloud computing, big data, 3D printing, social networks, software, mobile devices, robots, and artificial intelligence (AI), enable immediate access to and transmission of information. Additionally, they enable communication in multiple formats over telecommunication networks anytime and anywhere, interconnection between devices, and automation [6-9].

AI-enabled smart glasses have recently stood out among these technologies [10]. These are wearable devices designed for multitasking use, integrating advanced technologies such as displays, cameras, internet connectivity, and AI to offer additional functions beyond those of traditional glasses (eg,

XSL•FO
RenderX

take photos, record audio and immersive videos, listen to music, make and receive calls, and share multimedia content) [11-13]. These devices can be controlled by users through voice commands, touch, or physical inputs such as blink detection.

The most advanced AI-enabled smart glasses use this technology to process and analyze data in real time, enhancing the user experience by interacting with the environment in the most efficient and enriching way [13]. Due to their technological features, AI-enabled smart glasses promise to help older adults gain higher daily functional autonomy for active aging by providing feedback, personalized assistance, and training, such as in taking medication, getting dressed, learning to eat more healthful food, or exercising [14-16]. Moreover, this technology takes advantage of the fact that older adults often wear traditional glasses [17].

While the potential of AI-enabled smart glasses has been studied in the area of health training [18,19], at the professional level [12,20-22], and as an assistive technology to support functional diversity [13,23,24], as well as in younger populations [4,25], research on their use in active living in old age, as a training resource, and/or in the promotion of the well-being of older adults is scarce. For this reason, a scoping review was carried out as it is appropriate for identifying key concepts that underpin a given field of research, as well as clarifying the definitions and/or conceptual boundaries of a topic [26-29].

The main objectives of this study were to map the available evidence and identify gaps in the existing research, as well as to examine the effectiveness and possible benefits of AI-enabled smart glasses in promoting active aging in older adults. We explore their potential impact and provide an overview of them, as well as clarify key concepts related to their use in fundamental areas such as autonomy, well-being, and social participation, while also identifying barriers that affect both the implementation and adoption of these devices.

Methods

Study Design

A scoping review was performed in accordance with the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) statement [30], consistent with the standards and the updated and extended checklist for scoping reviews, PRISMA-ScR (PRISMA extension for Scoping Reviews) [31]. Similarly, relevant recommendations to ensure the thoroughness and quality of the process were taken into account in the different phases and drafting of this scoping review [29].

The final review protocol was prospectively filed with the Open Science Framework on April 16, 2025 [32], and is publicly accessible.

Databases and Search Strategies

In March 2025, a total of 3 databases of high scientific impact, relevance, completeness, and functionality for research were consulted, with one of them specific to the health field given the nature of the study: PubMed, Scopus, and Web of Science. Two phases were determined to establish the search strategy. First, as phase 1, an iterative premapping was carried out in the 3 databases, combining terms such as “artificial intelligence glasses,” “well-being,” and “benefits” with those referring to older adults (“older adult,” “elderly,” and “aging”) to unify the keywords used in the first studies found and, in this way, be able to establish a subsequent search strategy that was as operational as possible. Thus, a network of co-occurring keywords was generated using the data visualization and analysis software VOSviewer (version 1.6.20; Centre for Science and Technology Studies, Leiden University) from a total of 10 preliminary documents: 2 (20%) from PubMed, 6 (60%) from Scopus, and 2 (20%) from Web of Science.

Then, as phase 2, based on the keywords co-occurring in the preliminary documents, it was decided to use and combine the following terms with the Boolean operators “AND” and “OR” using the following search strategy: (“smart glasses” AND (“older adult” OR elderly OR aging) AND health). In this way, where appropriate, words were combined to reflect the syntax and search parameters common to all 3 databases. In addition, it should be noted that the number of records generated did not vary when truncation was used in the term “health*.”

Selection Criteria and Participant Demographics

The research questions were formulated based on the stated objectives and according to the eligibility criteria, as follows: (1) what scientific evidence exists and what knowledge gaps can be identified on the use of AI-enabled smart glasses in promoting active aging in older adults? (2) What is the effectiveness of AI-enabled smart glasses and what potential benefits do they offer in the promotion of active aging in older adults? (3) What barriers or factors reported in the literature may hinder both the implementation and adoption of AI-enabled smart glasses in older adults for the promotion of active aging?

As shown in Table 1, the population, concept, and context framework was used in this scoping review. It is a structure that streamlines the approach and definition of inclusion criteria in scoping reviews [29].

XSL•FO
RenderX

Table . Details of the population, concept, and context (PCC) framework and eligibility criteria.

PCC domain	Description
Population	Older people, ie, those aged >65 years, following the definition of the World Health Organization [33], and older adults who live in nursing homes or residences
Concept	Use of AI[a]-enabled smart glasses by older adults and their effectiveness and possible benefits in the promotion of active aging; AI-enabled smart glasses similar to Ray-Ban Meta, Solos AirGo Vision, Halliday glasses, Microsoft HoloLens 2, Google Glass, or Epson Moverio BT-300, among others; and wearable assistive technology devices with built-in AI and/or AI-automated mechanisms for older adults
Context	Use of AI-enabled smart glasses in daily life; for self-management of health; for educational purposes; in improving cognitive aspects, autonomy, and quality of life; as a means of leisure for interactive entertainment and/or social connections in one's own home, in residences, or in health care settings; and consideration of barriers to implementation and/or adoption, such as technological availability, levels of digital literacy, technological accessibility, and factors inherent to socioeconomic and cultural conditions

[a]AI: artificial intelligence.

As this is a particularly recent topic and the use of this type of technology is on the rise, it was decided not to consider any exclusion criteria related to the type of document, year, area, and language, among others, so as not to discard related studies. The only exclusion criterion taken into account was that the studies should not be focused on conventional augmented or virtual reality glasses without built-in AI and/or capabilities that use AI through their software.

Data Collection Procedures

To approach the review process, the online platform Covidence (Veritas Health Innovation) was used, which facilitates and optimizes the conduct of this type of study (eg, import of references, screening of records, blind review, data extraction, and risk of bias assessment). Two reviewers independently and blindly carried out the entire review process on this platform based on the proposed eligibility criteria, justifying and recording the reasons for exclusion. Any discrepancies during the selection of studies were discussed and resolved through consensus.

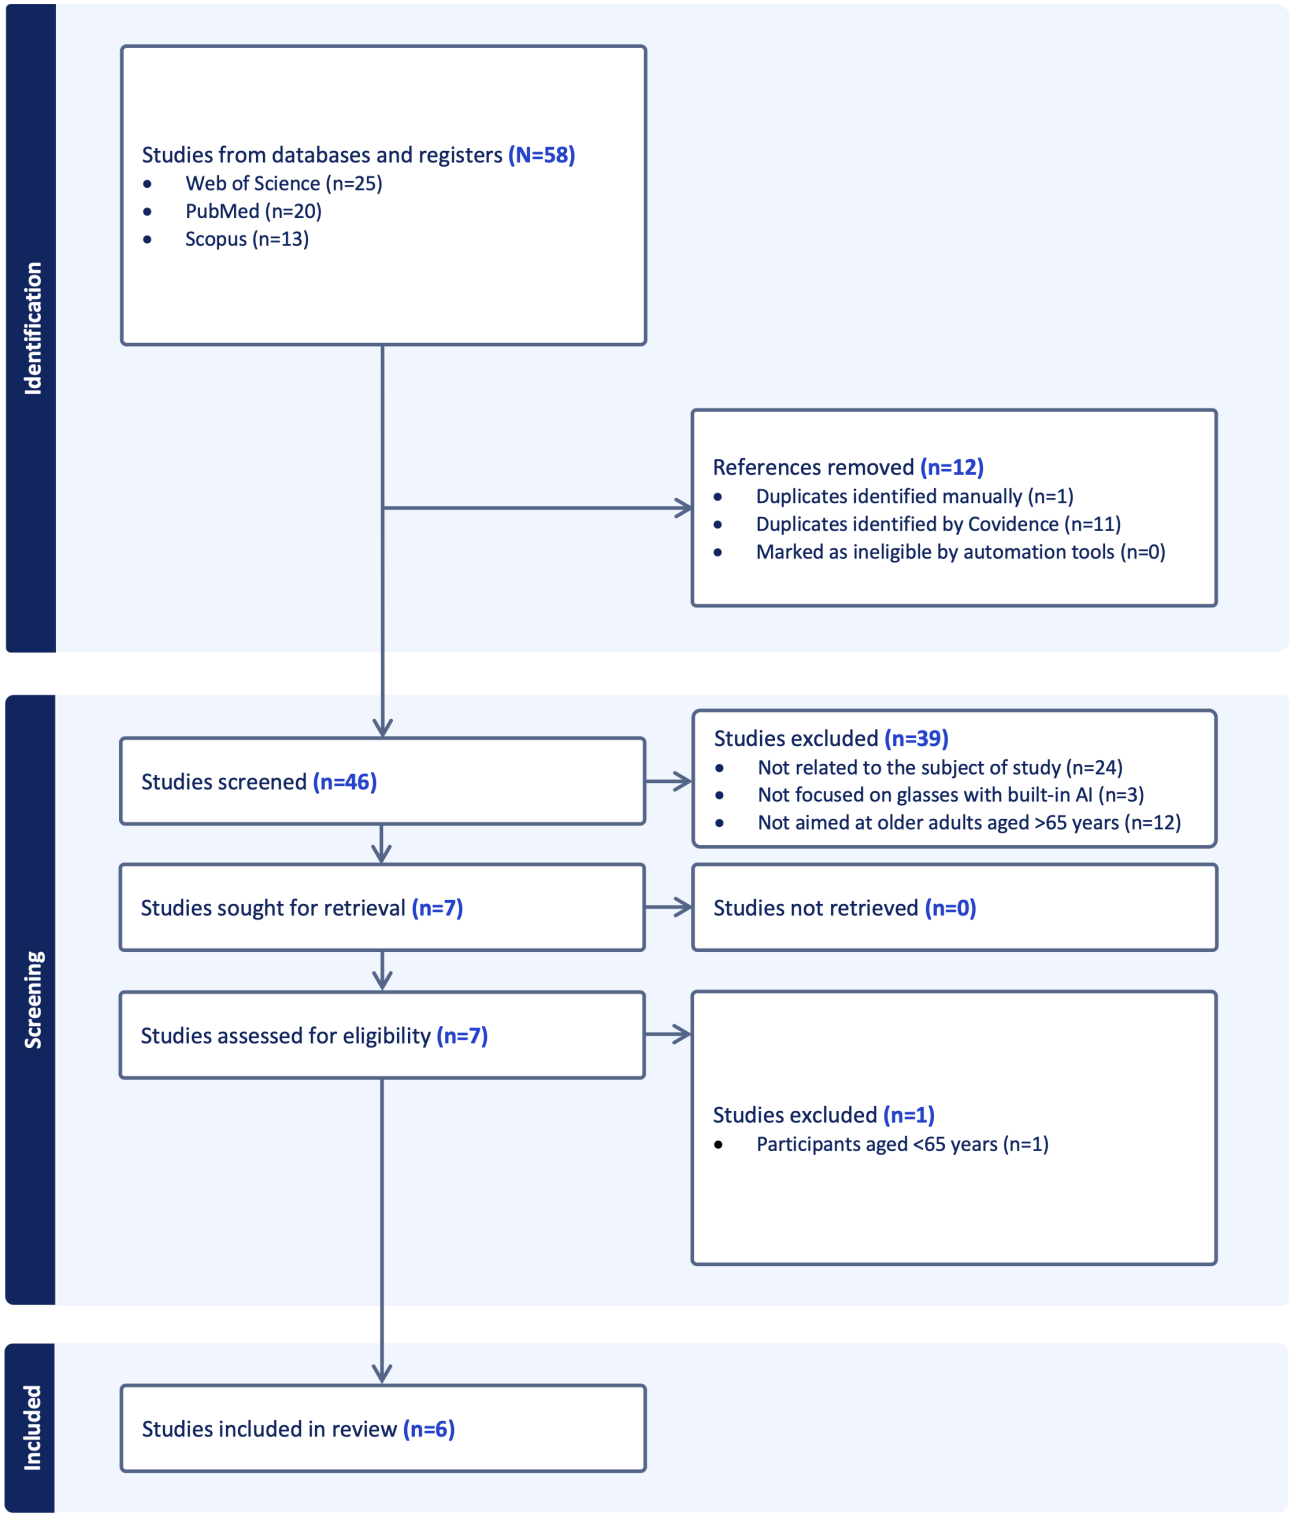
Data extraction, focused on identifying, organizing, and compiling the most relevant information related to the main objective of this review, was carried out in an exhaustive manner, including all the findings reported in the selected studies, to guarantee a rigorous and coherent analysis in accordance with the available evidence. The extracted data included the following details: (1) author and year of publication, (2) title, (3) type of document, (4) country of origin, (5) objective, (6) methodology, (7) sample, (8) type of AI-enabled smart glasses used and/or analyzed, and (9) main results.

Data Analysis

After finalizing the data extraction process, the key findings obtained from the selected studies were summarized and presented in an evidence synthesis table (Multimedia Appendix 1 [14-16,23,34,35]).

In addition to examining the effectiveness and potential benefits of this type of technology in active living in old age, some barriers were detected that affect both the implementation and the adoption of AI-enabled smart glasses in this sector of the population. Furthermore, the gaps found in scientific literature regarding interventions based on these digital technologies were also synthesized, leading to the elaboration of a detailed summary of the objectives and findings of this study.

Results



Inclusion of Studies

Of a total of 58 records, 12 (20.7%) duplicate documents were eliminated. Subsequently, the remaining 79.3% (46/58) of the results were screened by analyzing the titles, abstracts, and keywords. Of these 46 papers, 39 (84.8%) were excluded because they were not related to the topic under study, not focused on AI-enabled smart glasses, and/or not targeted at adults older than 65 years. Therefore, 7 studies were reviewed in full. Of the 7 studies analyzed in full, 1 paper was excluded because it was not aimed at older adults and did not consider age (>65 years) among the participants.

As shown in Figure 1 (flowchart adapted from the PRISMA-ScR guidelines) and Table 2, 6 studies were included in this scoping review.

Table . Summary of the included studies on artificial intelligence (AI)–enabled smart glasses for older adults.

Study	Sample	Glasses or device	Study design	Outcomes
Muema et al [14]	Older adults with cognitive impairment (not specified)	Microsoft HoloLens 2	Experimental integration study	Improved independence and autonomy via companion robot–AI-enabled smart glasses integration and enhanced emotion recognition
Tunur et al [15]	7 older adults with Parkinson disease	Google Glass	Mixed methods feasibility study	Safe and acceptable, improvements in motor function, and positive participant satisfaction
Zhao et al [16]	62 older adults with Parkinson disease	AI-enabled smart glasses (general)	Online survey	Positive attitudes toward adoption and perceived usefulness for daily activity support and self-confidence
Moshtael et al [23]	23 older adults with macular disease	Epson Moverio BT-200	Pilot quantitative study	Increased reading speed and satisfaction with personalized text display
Wang et al [34]	50 older adults	Epson Moverio BT-300	Experimental prototype study	Accurate facial recognition, improved text readability, and voice command control validated
Chang et al [35]	5 older adults	Jorjin J7EF AR smart glasses	Pilot quantitative study	Improved exercise adherence and recovery rates and AI-enabled smart glasses feasible for home-based fitness promotion

Demographics of the Included Studies

Half of the papers were published in 2020 [15,23,34], with the publication period starting in 2015, when the first of the eligible studies was published [16], and including 2022 [14] and 2023 [35]. The studies were conducted in 5 different locations: Canada [14], the United States [15], the Netherlands [16], the United Kingdom [23], and Taiwan [34,35].

Designs of Included Studies

Five of the 6 studies used a quantitative methodology [14,16,23,34,35], and 1 study adopted a mixed methods approach [15]. This was a single-group feasibility pilot test where previously validated questionnaires and standardized scales were administered, as well as semistructured interviews. Three studies used an experimental-technological perspective [14,34,35]. The use of surveys [16] or the application of standardized tests [23] as instruments and techniques for data collection was also highlighted.

Selection Criteria and Participant Demographics

Sample size varied significantly in all the studies, ranging from 5 [35] to 62 [16]. Only 1 study did not specify the sample size, although it referred to older adults with reported cognitive impairment [14]. In 3 of the 6 studies, gender was specified, with predominantly female participants in 2 studies [15,23] and male participants in 1 study [16]. These 3 studies also reported the age of the participants, with an average of 69 years [15], 66 years [16], and 81 years [23]. Regarding place of residence, the home or residential centers were the norm in 3 studies [14-16], with residence in rural areas being relevant in 1 study [35]. Two studies omitted data on place of residence [23,34]. The diagnosis of an illness was an eligibility criterion in 3 studies, specifically Parkinson disease [15,16] and macular degeneration with oculomotor deficits [23]. No study detailed data on the occupation, educational level, or degree of digital literacy and technological training of the participants.

A wide variety of AI-enabled smart glasses were considered in the different studies, highlighting Microsoft HoloLens 2 [14], Google Glass [15], Epson Moverio BT-200 [23], Epson Moverio BT-300 [34], and Jorjin J7EF AR smart glasses [35]. Only 1 study addressed this type of technology in a generalized manner without specifying the model of glasses [16]. In addition to AI-enabled smart glasses, in the included studies, other technologies and devices were used, such as intelligent robots and virtual assistants [14], tablets and smartphones [16], cloud computing [34], and a portable Android device that performs real-time data processing (eg, image analysis or posture calculation) to send information to the glasses while the user moves or exercises [35].

The promotion of autonomy and the improvement of motor functions were the most noteworthy benefits as AI-enabled smart glasses can provide visual support or auditory cues by overlaying information in real time [14-16]. Similarly, benefits for physical health were evidenced through a more active lifestyle and increased mobility of the participants [15,35], as well as positive results in social interactions [14]. Another benefit identified was the improvement in reading performance and text readability due to the dynamization and personalization via AI-enabled smart glasses [23,34].

The main barriers or hindering factors that were identified in the results of the studies included sociocontextual, distinguishing

XSL•FO
RenderX

privacy issues and network vulnerabilities [14] or the high cost of the devices [15,16]. In terms of the inherent factors of the technology itself, such as its design and technical characteristics, some glasses may be inconvenient to use for this sector of the population due to the reduced size of the displays or a limited audio volume [15], as well as the possible absence of blue light filters in some displays [16]. An internal barrier was the lack of evaluations of the usability and acceptance of these technologies among older adults [14].

Discussion

Principal Findings

Preliminary findings suggest improvements in quality of life, independence, motor function, and social relationships among older adults resulting from the use of AI-enabled smart glasses. In terms of quality of life and overall well-being, aspects such as lack of social connections, independent living, or decreased mobility of older adults are some of the current concerns in this population. AI-enabled smart glasses have emerged as digital enabling technologies to alleviate these issues.

This scoping review contributes to scientific literature by mapping the available evidence on this type of technology and identifying indicators of effectiveness and potential benefits in promoting active aging. As this is an emerging technology with a marked innovative character, there are currently very few studies on it. Therefore, the contribution of this scoping review, from a holistic point of view, is even more significant. AI-enabled smart glasses facilitated independence, functional autonomy, and improvement of motor skills in the context of active and healthy aging [14-16]. These benefits were produced because these portable devices contribute to more conscious decision-making and greater confidence in the actions performed, as well as improvements in motor performance skills such as coordination, posture, and balance. For these reasons, AI-enabled smart glasses have the potential to empower older adults in the performance of their daily tasks and routines [16,34].

In addition, the implementation of AI-enabled smart glasses in this sector of the population produced an increase in daily physical activity levels due to the ubiquitous nature of this type of technology [15,35]. In other studies, links were found between the adoption of AI-enabled smart glasses and improvements in social connections through home automation [14]. It has also been demonstrated that AI-enabled smart glasses facilitate reading in real time [34]. In this sense, these technologies could offer alternatives for entertainment and personal enjoyment [15].

It was also shown that the use of AI-enabled smart glasses minimized symptoms of diseases such as Parkinson disease or macular degeneration [15,16,23]. All this translates into a significant increase in well-being and quality of life through daily assistive devices [14,16,35].

However, some hindering factors and/or barriers were identified regarding both the adoption and implementation of these wearable devices among older adults. First, more research is needed to guarantee aspects related to the safety, effectiveness, usability, and social acceptance of AI-enabled smart glasses regarding active living in old age [16].

Second, it is important that AI-enabled smart glasses are compatible with the prescription glasses worn by older adults, are easy to use, include a simple and natural interface, and recognize broad gestures rather than overly precise keystrokes. All these features would facilitate navigation [16].

The use of displays without blue light filters in this type of technology could alter quality of sleep and circadian rhythm. In fact, prolonged use of AI-enabled smart glasses may cause a feeling of visual fatigue or mild dizziness [15].

Furthermore, the efficient use of these digital technologies still needs to address the limited digital literacy of many older people [36,37]. In other words, the lack of technological skills and basic competencies in the use of electronic devices and digital tools is a limiting factor in the adoption of these devices and autonomous and independent management [38-40], showing the need to promote training strategies for digital learning and empowerment in older adults.

Limitations and Future Research

Although only 6 studies fulfilled the inclusion criteria following an exhaustive search that identified 58 documents, we consider that this scoping review is both relevant and valid, given that the subject of study (AI-enabled smart glasses) represents an emerging technology. Consequently, it is to be expected that scientific literature in this area remains limited or is still in the early stages of development. This review mapped the current state of knowledge and identified gaps in the literature, offering a meaningful and relevant preliminary overview that is consistent with the objectives of a scoping review. However, publication bias, methodological heterogeneity, sample size constraints, the instruments used, and the limited availability of rigorous conceptual frameworks, together with inherent language restrictions, made it difficult to establish relationships among the included studies. Therefore, further empirical research with more rigorous methods and periodic reviews is suggested as the scientific output grows and new AI-enabled smart glasses become commercially available.

Conclusions

The available studies included in this scoping review suggest that AI-enabled smart glasses enable improvements in the quality of life of older adults, especially in capabilities and skills such as independence, autonomy, and motor function. Preliminary evidence also indicates higher levels of physical activity and increased social interactions through the use of AI-enabled smart glasses. Although these portable devices could offer a more inclusive and accessible digital future by potentially delaying the effects of aging and contributing to active living in old age, these results should be interpreted cautiously given the limited number of studies and methodological heterogeneity.

This scoping review used a synthesis of evidence to clarify the state of the art and expand existing knowledge on the role of these digital technologies in promoting active aging, in addition to identifying gaps in research that serve as a basis for future studies. It is necessary to explore more deeply the potential

XSL•FO
RenderX

mechanisms underlying aging delay through this type of digital technology, which requires research with larger samples and longitudinal designs. Moreover, successful implementation and adoption require addressing digital literacy and ongoing training in technological skills among this population segment, as well as addressing challenges related to data protection, usability, acceptance, efficiency, and technical complexity.

Abstract

Background: Population aging poses significant public health challenges. Older adults often face multimorbidity, functional decline, and diminished quality of life. While physical activity can mitigate these effects, adherence remains low. Immersive virtual reality (IVR) has emerged as a promising, engaging tool to promote physical and cognitive health in this population.

Objective: The review aims to evaluate the effectiveness of IVR interventions lasting 4 weeks or more on quality of life, physical activity, pain, perceived effort, and adverse events in older adults.

Methods: A systematic review and meta-analysis were conducted following PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) and Cochrane guidelines. Literature was searched across PubMed, Web of Science, PEDro, and Scopus, as well as sources of gray literature. Eligible studies included randomized controlled trials involving participants aged >60 years, using IVR via head-mounted display. Outcomes assessed included quality of life, physical activity, pain, perceived effort, and adverse events. Risk of bias and evidence certainty were assessed using Risk of Bias 2.0 and GRADE (Grades of Recommendation Assessment Development and Evaluation), respectively.

Results: A total of 14 studies with 839 participants were included in the qualitative synthesis, of which 8 were eligible for quantitative meta-analysis. The pooled analysis showed a statistically significant moderate effect of IVR on quality of life (standardized mean difference [SMD]=0.48, 95% CI 0.1-0.8; *P*=.007), particularly in interventions lasting 10 to 12 weeks or involving more than 600 minutes of exposure. For physical activity, no significant differences were found between IVR and control groups (SMD=–0.2, 95% CI –0.7 to 0.4; *P*=.50). Evidence for secondary outcomes (pain, perceived exertion, and adverse events) was limited and largely qualitative, with inconsistent findings. Pain outcomes, assessed in 2 studies, indicated reductions in the IVR group, especially when multimodal approaches were used. Perceived effort was not systematically measured. Adverse events were generally mild, with cybersickness being the most reported issue.

Conclusions: IVR interventions of 4 weeks or more appear to moderately improve quality of life in older adults, especially those with clinical vulnerabilities or in institutional settings. Although effects on physical activity were not significant, trends suggest potential with appropriate program design. Preliminary findings support IVR's use in pain reduction, particularly when incorporating emotional and multisensory elements. The low incidence of adverse events suggests good tolerability. Overall, IVR is a promising and safe tool to support healthy aging, though further high-quality studies are needed to confirm these findings and assess long-term outcomes.

Introduction

By 2030, the population of adults aged ≥65 years is expected to reach 994 million (12% worldwide), intensifying pressures on public-health systems [1]. From a biological perspective, aging is defined as a complex and progressive process that affects multiple systems, leading to a decline in functional capacity and increased vulnerability to various pathologies [2]. Aging is often accompanied by impairments such as loss of muscle strength, cognitive decline, and a heightened risk of falls and disability, all of which negatively impact the autonomy and quality of life of older adults [2-4].

In this context, it is crucial to identify effective strategies that support health and well-being in later life, with physical activity being one of the fundamental pillars for promoting healthy aging [5]. In older adults, physical activity is associated with better physical function, preservation of cognition, and enhanced quality of life. It is also linked to lower disability in activities of daily living, fewer falls, and a reduced risk of neurodegenerative diseases such as dementia [6-9]. Moreover, it has been linked to decreased mortality rates, and it is a leading modifiable determinant of healthy aging with a dose–response association to all-cause and cardiovascular mortality in older adults [10,11]. However, despite the available evidence, the proportion of older adults who meet physical activity recommendations remains suboptimal [11]. Several factors contribute to this, including lack of awareness of the benefits, fear of pain or falling, low motivation, and environmental barriers [12].

In this regard, immersive virtual reality (IVR) emerges as a potential nonpharmacological therapeutic alternative. Through 3D-simulated environments experienced via devices known as head-mounted displays, IVR offers an immersive experience in which users can interact with the virtual environment [13]. IVR's sensorimotor immersion and playful elements may support engagement with physical activity, but current evidence is exploratory and based on a small feasibility trial [14]. Because IVR may enhance motivation and engagement, it is clinically and pragmatically important to test whether multiweek IVR programs can change physical activity behavior. Accordingly, our protocol designated physical activity as a coprimary outcome [15]. Additionally, its design allows for the adjustment of difficulty levels, making it a customizable alternative [16,17]—a feature considered essential in exercise prescription [18].

On the other hand, IVR has also proven useful in interventions aimed at cognitive stimulation and reminiscence, thereby expanding its range of applications in the context of active aging [19,20].

Currently, evidence suggests that IVR may benefit balance, mobility, cognition, and psychological well-being. However, some trials have reported mixed or modest effects [20-23]. These findings highlight the need for standardized outcome measures and adequately dosed programs in future research. These interventions have been implemented in both healthy individuals [21,24] and those with chronic medical conditions [22] or mild cognitive impairment [20]. However, existing reviews often involve short intervention periods [25]. This limits the ability to observe sustained long-term effects and may inflate immediate benefits [15,21]. Therefore, the focus is placed on programs delivered over periods that map onto the recall horizons of core quality-of-life instruments, a window that also coincides with the early emergence of neural and motor adaptations in response to training [26-30]. Trials in older adults have reported measurable gains over such intervals—cognition, balance, and functional outcomes [31-34]. Importantly, centering analyses on these exposure windows reduces the susceptibility of very brief interventions to novelty and Hawthorne effects [35]. In line with the World Health Organization's (WHO) healthy aging agenda, which prioritizes functional capacity and well-being as central goals in aging societies, we selected quality of life and physical activity as primary outcomes. These measures are patient-centered indicators of healthy aging and modifiable behavior, making them particularly relevant assessment criteria [36].

Prior reviews in older adults have primarily established that virtual reality (VR) is acceptable and feasible, while noting that evidence for effectiveness remains limited [15]. Other syntheses have focused on exergames and outcomes such as balance in long-term care facilities, aggregating heterogeneous exposure durations and without a prespecified minimum dose [37]. More recent randomized controlled trial (RCT)-only reviews of head-mounted display VR suggest benefits for physical activity and broader well-being, but do not isolate ≥4-week programs as an a priori inclusion criterion [38]. To our knowledge, no systematic review has focused exclusively on IVR interventions in older adults with a minimum duration of ≥4 weeks as an a priori inclusion criterion.

The objective of this systematic review and meta-analysis is to evaluate the effectiveness of IVR interventions lasting 4 weeks or more on the quality of life, physical activity, pain, perceived effort, and adverse events in older adults.

Methods

The protocol for this systematic review and meta-analysis was registered in the International Prospective Register of Systematic Reviews (CRD420251019170). It was conducted following the recommendations of the Cochrane Collaboration and the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines (Checklist 1) [39]

Search Strategy

A bibliographic search was completed between March 15, 2025, and June 15, 2025, in all the following databases: PubMed, Web of Science, PEDro, and Scopus. Additionally, we systematically searched for gray literature. This included searches in ClinicalTrials.gov, the WHO International Clinical Trials Registry Platform, ProQuest Dissertations & Theses Global, and medRxiv. Search strategies used are available in Multimedia Appendix 1 [14,18,24,29,40-53].

We also carried out a "snowball" search to identify additional studies by searching the reference lists of publications eligible for full-text review.

XSL•FO
RenderX

Inclusion and Exclusion Criteria

Inclusion criteria were defined according to the PICOS (population, intervention, comparison, outcome, study design) framework: (1) we included studies only if all participants were aged ≥60 years at baseline; (2) IVR intervention, alone or combined with other therapies, lasting 4 weeks or more; (3) the comparison group can be control, placebo, or another type of intervention; (4) outcome measures related to physical activity, quality of life, pain intensity, perceived effort, and adverse events; and (5) randomized controlled trials (RCTs), crossover clinical trials, and randomized mixed methods studies.

Exclusion criteria were: (1) studies with participants aged under 60 years, although the average age is 60 years or older; and (2) studies whose intervention is defined as immersive but does not use the head-mounted display.

No language restrictions were applied while searching.

Study Selection

Once the research question was defined, studies were identified and screened accordingly. Following the search strategy, all references were imported into Rayyan (Rayyan Systems Inc) to exclude duplicate studies [54].

Two independent researchers (IT-C and JB-A) conducted the study selection based on the predefined inclusion and exclusion criteria. In cases of disagreement, a third researcher (HB-A) was consulted to resolve discrepancies and reach a consensus.

Data Extraction

First, two researchers (IT-C and JB-A) independently extracted key information from the included studies. In case of discrepancies, a third researcher was consulted to resolve disagreements. The extracted data included: first author and year of publication, country, study design, sample size, age, diagnosis, setting, type of intervention of the groups, hardware and software of VR used, time of intervention (total amount of time in h, session time, frequency, and number of wk), outcomes, and follow-up period.

In the second phase, quantitative data for both primary and secondary outcomes were extracted. For the primary outcomes—physical activity and quality of life—as well as for the secondary outcomes of pain, perceived effort, and adverse events, mean and SD values were collected. When studies reported both change scores and final values, the final values were prioritized for analysis. When information regarding any of the above was unclear, we contacted authors of the reports to provide further details.

If data were only available in graphs, the graph digitization software GraphGrabber 2.0.2 (Quintessa Ltd) was used for extraction [55].

Risk of Bias

The methodological quality of the included studies was independently assessed by 2 researchers using the Cochrane Risk of Bias 2.0 tool for both parallel and crossover designs [56]. In instances where discrepancies arose between the two primary researchers, a third independent researcher was consulted to resolve disagreements. This tool evaluates the risk of bias across 5 domains: randomization process, missing outcome data, measurement of outcomes, selection of reported results, and deviations from intended interventions.

In addition, selective reporting will be judged by comparing published outcomes with registered protocols when available.

Main Outcomes

The primary outcomes of this study were quality of life and physical activity. Any objective or self-reported measure of these outcomes was considered eligible for inclusion, provided the instruments used demonstrated evidence of validity and reliability. No restrictions were placed on the number or timing of assessment time points (eg, baseline, postintervention, and follow-up).

The secondary outcomes included pain intensity, perceived effort, and adverse events. The same eligibility and selection criteria were applied, with preference given to the numeric rating scale (NRS) and visual analog scale (VAS) for pain intensity [57].

Statistical Analysis

A meta-analysis was conducted to estimate the overall effect of IVR interventions on quality of life and physical activity levels in older adults. As the included studies used different scales to assess these outcomes, the standardized mean difference (SMD) was used as the effect size measure. In all cases, higher scores indicated better outcomes, except for the study by Rodríguez-Fuentes et al [43], which used the Parkinson Disease Questionnaire (PDQ-39) scale, where lower scores reflect a better quality of life.

All hypothesis tests were 2-tailed, with statistical significance set at α=.05. Effect estimates are reported with 95% CIs. The inverse variance method was applied using a random-effects model, considering the expected clinical and methodological heterogeneity among studies. For each outcome, 95% CI were calculated, and a significance level of P<.05 was established. The magnitude of the effect was interpreted according to the Cohen criteria: small effect (SMD approximately 0.2), moderate (approximately 0.5), and large (≥0.8).

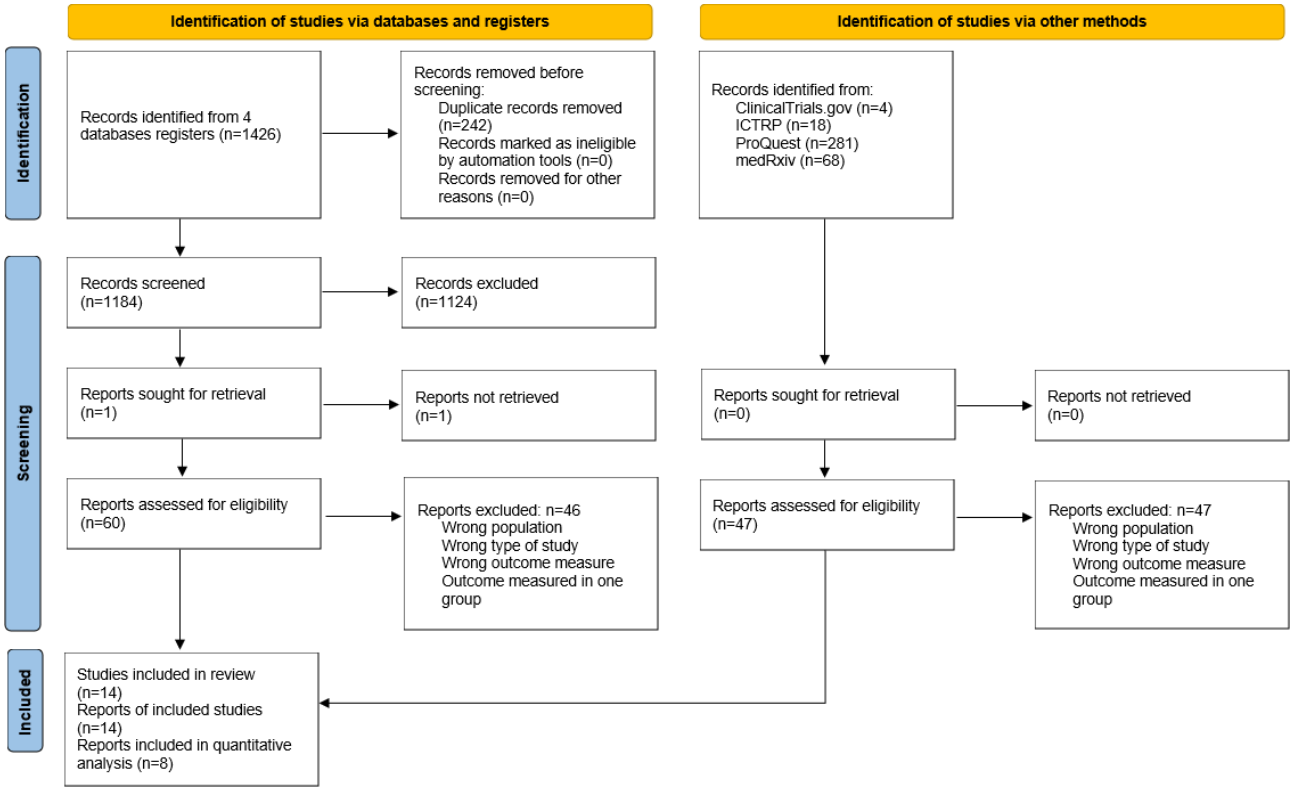
Statistical heterogeneity was assessed using the chi-square test, the ^{2} estimate, and the I^2 statistic. Heterogeneity was established as low for I^2=25%, moderate for I^2=50%, and high for I^2=75%. Subgroup analyses were conducted based on type of control group (active vs passive), intervention duration in weeks (6 - 8wk vs 10 - 12 wk), and total exposure time (180 - 480 min vs 600 - 1800 min). In addition, a sensitivity analysis was conducted by sequentially excluding each individual study to assess its impact on the overall effect size and heterogeneity.

All statistical analyses were performed using Review Manager (RevMan) version 5.4.1. The certainty of the evidence will be assessed using the GRADE (Grades of Recommendation Assessment Development and Evaluation) approach [58].

Deviations From Protocol

Several deviations from the International Prospective Register of Systematic Reviews protocol occurred. The mental component of the 12-item Short Form Survey (SF-12) was not

XSL•FO
RenderX



analyzed to avoid conceptual overlap (Multimedia Appendix 1 [14,18,24,29,40-53]). Publication bias assessment was planned but not performed due to <10 studies per outcome (Multimedia Appendix 1 [14,18,24,29,40-53]). When required, means and SDs were estimated from median (IQR) following validated procedures (Multimedia Appendix 1 [14,18,24,29,40-53]). Subgroup analyses were restricted to comparator type, intervention duration, and total exposure; definitions and limitations are detailed in Multimedia Appendix 1 [14,18,24,29,40-53].

Results

Study Selection

The selection process is illustrated in the PRISMA 2020 flow diagram (Figure 1) in this review.

Figure 1. Flow diagram in this review. ICTRP: International Clinical Trials Registry Platform.

We found 1426 records in database searching. After duplicate removal, we screened 1184 records, from which we reviewed 60 full-text documents. Later, we searched documents that cited any of the initially included studies as well as the references of the initially included studies. However, no extra studies that fulfilled the inclusion criteria were found in these searches.

Ultimately, 14 trials met the inclusion criteria and were included in the systematic review. Of these, 8 studies were included in the meta-analysis. The remaining 6 studies were excluded from the quantitative synthesis because they did not report outcome measures corresponding to the primary endpoints analyzed in the meta-analysis (ie, quality of life or physical activity).

Study Characteristics

This systematic review included 14 RCTs published between 2021 and 2025 [14,19,25,43-53], with a total of 839 older adults and sample sizes ranging from 9 to 293 participants. While most studies included older adults without specific diagnoses [14,19,25,44,45], others focused on populations with cognitive impairment or frailty [46-48,50], balance and mobility issues [51], Parkinson disease [43], knee osteoarthritis [53], chronic low back pain [52], or individuals with joint arthroplasty [49].

Regarding settings, 10 studies were conducted in community centers or nursing homes [19,43-48,50-52], 3 in laboratory conditions [44,52], and 2 at home [14,53].

Most studies focused on physical activity delivered via VR, using environments that required movement [14,44,51]. In some cases, VR-based physical activity was combined with usual care or conventional rehabilitation, such as occupational therapy or kinesiotherapy [45,49]. Other interventions emphasized cognitive training delivered via VR [46], sometimes including underdesk ergometers for simultaneous stimulation [47,48]. Some protocols included education sessions, followed by structured VR-based exercise programs [25,53].

A few studies explored more therapeutic applications of VR, such as immersive reminiscence therapy [19], or multimodal pain management programs that integrated psychoeducation and movement therapy [52]. One study used VR to simulate daily living environments, aiming to promote autonomy in participants with cognitive frailty [50].

Control conditions varied: some used usual care [19,45,47,50], others applied active comparators such as conventional rehabilitation or group-based exercise [14,43,48,49,51-53] and a few used no-intervention or educational controls [25,44,46].

XSL•FO
RenderX

Session durations typically ranged from 15 to 60 minutes, with frequencies varying from 1 to 5 times per week over periods from 4 to 12 weeks. The longest interventions, by Lo et al [53] and Rodríguez-Fuentes et al [43], lasted 12 weeks.

Detailed tables summarizing the characteristics of each included study are provided in Table 1 (study characteristics) and Table 2 (intervention characteristics). In addition, detailed specifications of software, hardware, and outcome instruments are provided in Multimedia Appendix 1 [14,18,24,29,40-53].

Main Outcomes

Quality of Life

Among all 6 studies assessed quality of life using various validated tools such as EuroQol VAS [44,53], SF-12 [45,50], World Health Organization Quality of Life Scale Brief Version (WHOQOL-BREF) [43,46] and PDQ-39 [46,50].

Overall, 5 studies reported improvements in quality of life following IVR interventions. Chiu et al [46] and Zheng et al [50] found the most notable effects, with WHOQOL-BREF scores nearly doubling and significant gains in SF-12 mental health, respectively. Only Barsasella et al [44] found no overall differences in EuroQol 5D-3L scores between groups, though improvements were noted in specific domains such as pain and anxiety.

Physical Activity

Among all 3 studies assessed physical activity using both self-report and objective measures (eg, Yale Physical Activity Survey, Garmin Vivosmart 4, and ActivPAL accelerometry) [14,25,53].

Drazich et al [24] observed modest gains in vigorous activity within the VR group, despite stable weekly activity levels. Kershner et al [14] reported greater gains in steps and vigorous activity for the video conference group, though the VR group improved more in functional capacity. Lo et al [53] found slightly higher metabolic equivalent of tasks in the VR group, but without significant differences.

Intensity of Pain

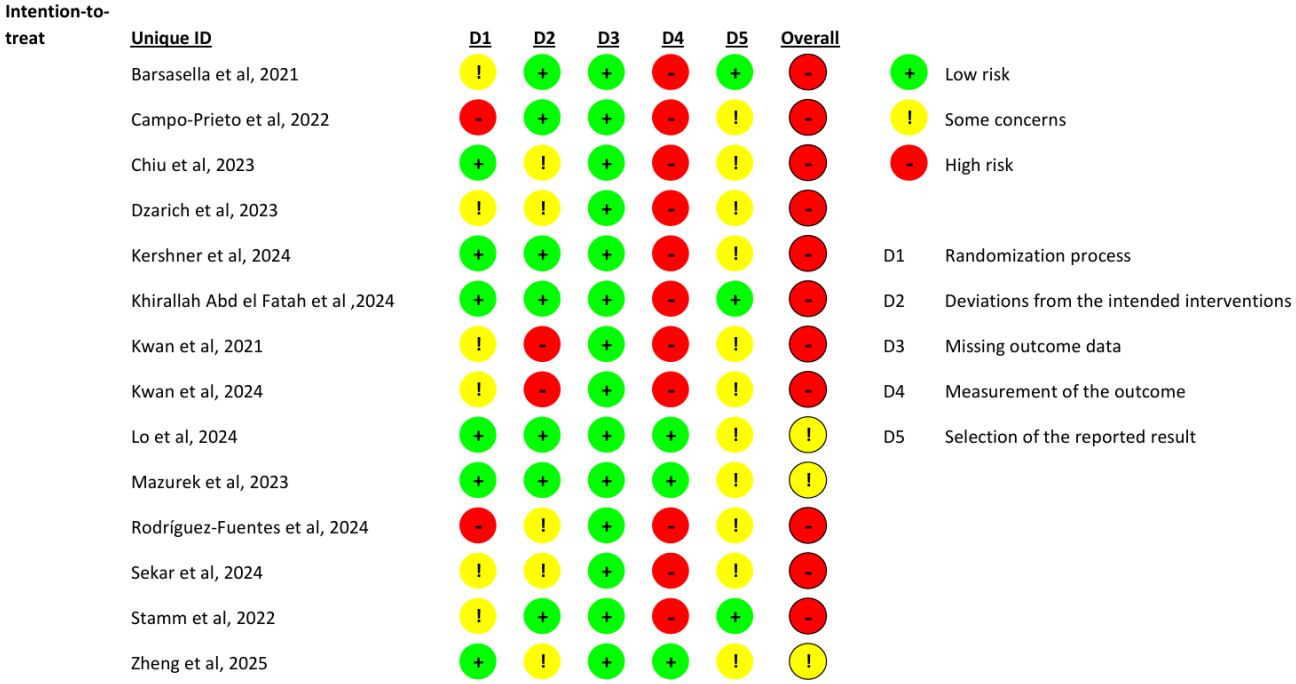
Out of all 2 studies addressed pain. Lo et al [53] used the NRS and Western Ontario and McMaster Universities Osteoarthritis Index subscale in patients with osteoarthritis, showing reductions in both scores within the VR group (NRS: 5.93-4.78; Western Ontario and McMaster Universities Osteoarthritis Index: 189.5-160.2), with minimal changes in controls. However, these differences did not reach statistical significance when comparing IVR to control, suggesting no conclusive effect attributable to the intervention. Mazurek et al [49] reported a significant drop in VAS scores in the VR group (5.27-0.88), exceeding improvements in the control group.

Perceived Effort

None of the included studies systematically assessed perceived effort using validated tools such as the Borg rating of perceived exertion scale or comparable measures.

Adverse Events

Adverse events were reported in 7 of the included studies, focusing on cybersickness [14,19,25,45,47,48,53]. Overall, most studies reported minimal or mild adverse events. In the pilot study of Kwan et al [47,48], 1 participant in the VR group withdrew early due to persistent symptoms of cybersickness, while the RCT reported low incidence rates (0.7%-3%) across 293 participants. Kershner et al [14] observed mild symptoms present in some participants. Lo et al [53] found that 5 out of 15 participants in the VR group reported mild adverse events such as dizziness or visual fatigue, though these did not result in discontinuation.



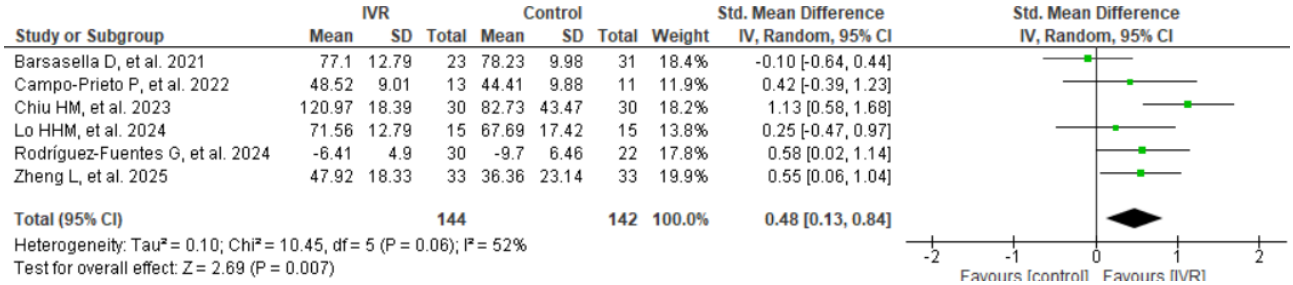
Risk of Bias in Studies

Most studies were judged to be at high risk of bias, except for 3 studies that showed a moderate risk [49,50,53]. All studies demonstrated low risk in domain 3 (missing outcome data). In domain 4 (measurement of the outcome), all but 3 studies were rated as high risk [49,50,53]. In domain 5 (selection of the reported result), 3 studies were rated as low risk, while the remaining studies were judged to have unclear risk.

As shown in Figure 2, the agreement rate achieved between the 2 researchers who completed risk of bias assessment was 81.43%. In case of disagreement, a third researcher resolved it.

XSL•FO
RenderX

Figure 2. Risk of bias [14,18,24,43-53].



Results of Syntheses

Quality of Life

As shown in Figure 3 (effect of IVR on quality of life), a total of 6 RCTs including 286 participants (IVR group: n=144; control group: n=142) were synthesized to examine the effect of IVR interventions on quality of life in older adults. The meta-analysis yielded a statistically significant moderate effect in favor of IVR compared to control conditions (SMD=0.48, 95% CI 0.1-0.8; *P*=.007). Heterogeneity was moderate (I^2=52%; *P*=.06; ^{2}=0.10), indicating some variability across studies.

Figure 3. Effect of immersive virtual reality (IVR) on quality of life [43-46,50,53].

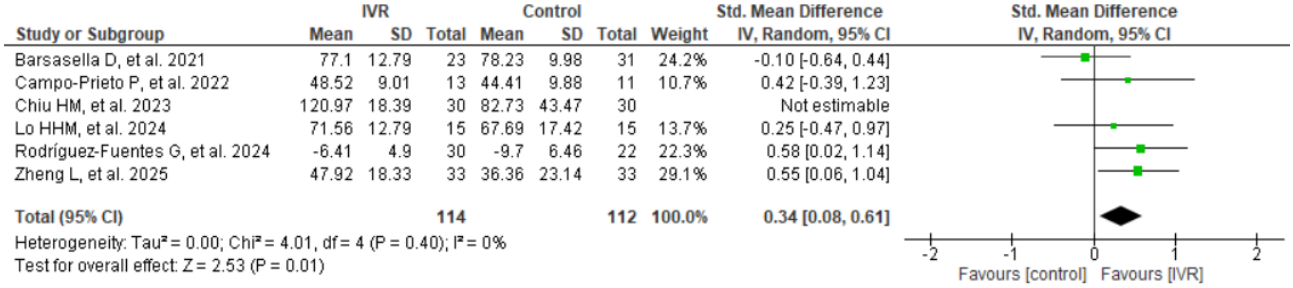
As shown in Table 3 subgroup analyses were performed to explore the potential influence of comparator type, intervention duration in weeks, and total intervention time in minutes.

XSL•FO
RenderX

Table . Subgroup analysis.

Subgroup	Studies, n	Participants, n	Random-effects model		Heterogeneity I^{2b} (%)	Between subgroups difference	
			SMD[a] (95% CI)	*P* value		Chi-square (*df*)	*P* value
Comparator type						0.02 (1)	.89
Passive control	4	110	0.50 (−0.04 to 1.04)	.07	71		
Active control	2	82	0.48 (0.12 to 0.84)	.05	0		
Weeks of intervention						0.00 (1)	.97
6 - 8	2	120	0.51 (−0.69 to 1.72)	.40	90		
10 - 12	4	172	0.48 (0.18 to 0.79)	.002	0		
Minutes of intervention						0.00 (1)	.99
180 - 480	3	138	0.49 (−0.31 to 1.28)	.23	80		
600 - 1800	3	286	0.49 (0.13 to 0.84)	.003	0		

[a]SMD: standardized mean difference.



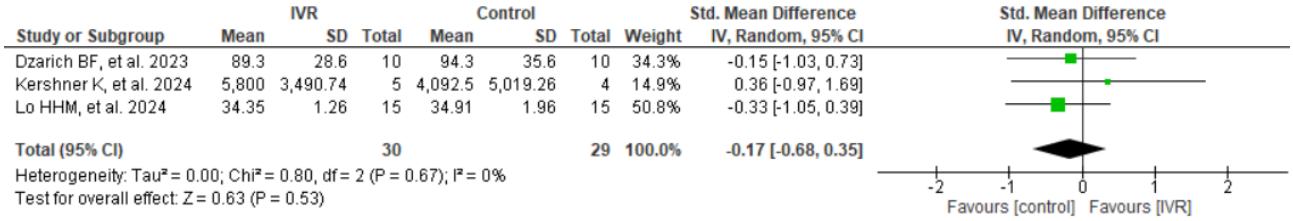
[b]I^2: inconsistency index.

Within-subgroup analyses showed statistically significant effects in some conditions. For instance, a significant effect was observed in the subgroup receiving 600 - 1800 minutes of intervention (SMD=0.49, 95% CI 0.13-0.84; *P*=.003), in contrast to the nonsignificant effect in the 180 - 480 minutes group. Similarly, the 10 - 12 week intervention subgroup showed a statistically significant moderate effect (SMD=0.48, 95% CI 0.18-0.79; *P*=.002), while the 6 - 8 week group did not (*P*=.40).

Regarding comparator type, significant effects were observed in the active control group (*P*=.05), but not in the passive control group (*P*=.07). However, despite these within-subgroup differences, the overall between-subgroup comparisons were not statistically significant for any of the 3 variables assessed: comparator type (*P*=.89), duration in weeks (*P*=.97), or total minutes of intervention (*P*=.99). These findings suggest that while effect sizes may vary descriptively across subgroups, such differences are not supported statistically.

As shown in Figure 4 (sensitivity analysis of IVR effects on quality of life), a sensitivity analysis was conducted excluding the study by Chiu et al [46], which presented the largest effect size (SMD=1.1). When this study was removed, the overall effect in favor of IVR remained statistically significant (SMD=0.3, 95% CI 0.08-0.6; *P*=.01), although the magnitude of the effect was reduced. Notably, heterogeneity was eliminated (I^2=0%; ^{2}=0.00), suggesting that this study contributed substantially to the observed heterogeneity in the main analysis.

Figure 4. Sensitivity analysis of IVR effects on quality of life. IVR: immersive virtual reality [43-46,50,53].



Physical Activity

Among all 3 RCTs involving a total of 59 participants (IVR group: n=30; control group: n=29), IVR was assessed on physical activity in older adults. The meta-analysis revealed no statistically significant difference between groups (SMD=−0.2, 95% CI −0.7 to 0.4; *P*=.50).

As shown in Figure 5 (effect of IVR on physical activity), heterogeneity among studies was minimal (I^2=0%; *P*=.70; ^{2}=0.00), indicating high consistency in the direction and magnitude of effects across studies. Due to the small number of studies, no subgroup or sensitivity analyses were performed for this outcome.

XSL•FO
RenderX

Figure 5. Effect of immersive virtual reality (IVR) on physical activity [14,24,53].

Certainty of Evidence

As shown in Figure 6 (assessment of evidence according to GRADE), the certainty of the evidence for the outcome quality of life was rated as low. Downgrading was applied due to very serious concerns related to the risk of bias. For the outcome of physical activity, the certainty of the evidence was rated as very low. Downgrading was applied due to serious risk of bias, very serious imprecision, and strong suspicion of publication bias.

Figure 6. Assessment of evidence according to GRADE (Grades of Recommendation Assessment Development and Evaluation). IVR: immersive virtual reality; SMD: standardized mean difference. *Out of 6 studies, 4 contributing to this outcome were judged to have high risk of bias, particularly due to issues in the randomization process, deviations from intended interventions, and selective reporting. The remaining 2 had some concerns. **Out of the 3 studies, 2 were judged to have high risk of bias, particularly in randomization and outcome assessment. The overall certainty was downgraded due to methodological limitations. ***The CI was wide and included both meaningful benefit and harm. The small sample size and lack of statistical significance led to downgrading by 2 levels. ****Only 3 studies were included in the meta-analysis for physical activity, which prevents formal assessment of publication bias. Due to the small number of trials and likelihood of selective reporting, strong suspicion of publication bias was considered.

Certainty assessment						N of patients		Effect		Certainty
N of studies	Study design	Risk of bias	Inconsistency	Imprecision	Other considerations	IVR	Control group	Relative (95% CI)	Absolute (95% CI)	
Quality of life										
6	Randomized trials	Very serious*	Not serious	Not serious	None	144	142	-	SMD 0.48 higher (0.13 higher to 0.84 higher)	Low*

3	Randomized trials	Serious**	Not serious	Very serious***	Publication vias strongly suspected****	30	29	-	SMD 0.17 lower (0.68 lower to 0.35 higher)	Very low*,**,***,****

Discussion

Principal Findings

To our knowledge, this review is the first to focus exclusively on IVR interventions in older adults with a minimum duration of ≥4 weeks as a predefined inclusion criterion. The findings reveal a statistically significant moderate effect of IVR on quality of life, especially in individuals with clinical vulnerability or living in institutional settings. In contrast, no significant effects were observed for physical activity, and the direction of the results across included studies was inconsistent. Although some isolated findings indicated minor improvements in specific physical activity parameters, these were not replicated across trials and were derived from interventions of limited intensity or duration. As such, current evidence does not support definitive conclusions regarding the impact of IVR on physical activity, though it highlights important considerations for future program design. On the other hand, given the limited number of studies and heterogeneous measurement, secondary outcomes (pain, perceived exertion, and adverse events) could not be robustly quantified. We retained these outcomes because they were prespecified in our protocol and are clinically salient, but current evidence is insufficient to support firm conclusions. Additionally, preliminary results indicate potential benefits for pain reduction, and IVR was well tolerated, with low incidence of mild adverse events.

Quality of Life

Our findings suggest a moderate, statistically significant improvement in quality of life with IVR versus control; however, the certainty of evidence is low due to risk of bias. The observed effect size—approaching the 0.5 threshold commonly regarded as clinically meaningful in geriatric interventions—suggests a relevant improvement in this population. The psychological sense of presence elicited by IVR may diminish the perception of aversive stimuli such as pain or anxiety and promote emotional regulation, intrinsic motivation, and well-being [59,60].

Notably, the most pronounced benefits were evident among older adults with clinical diagnoses, indicating efficacy in individuals with functional vulnerabilities. This observation is consistent with previous research reporting cognitive gains in populations with mild cognitive impairment [61]. Moreover, interventions implemented in residential or institutional environments tended to yield more consistent and favorable outcomes. In support of this, Li et al [62] reported that IVR experiences in nursing homes enhanced not only well-being and social engagement but were also perceived as meaningful and motivating by participants.

Regarding intervention characteristics, programs incorporating cognitive or functional components generated more substantial improvements than those centered exclusively on physical exercise. This may reflect the inherently multidimensional nature

XSL•FO
RenderX

of quality of life, which integrates cognitive, emotional, and social dimensions in addition to physical health [63].

In terms of duration, longer interventions (10 - 12 wk or exceeding 600 min) could be associated with more reliable improvements in quality of life. This finding is aligned with results from Vasodi et al [64], who reported that extended IVR programs led to better outcomes in older adults' mood and well-being, potentially due to increased engagement, gradual adaptation, and the consolidation of behavioral changes over time.

Physical Activity

The effectiveness of IVR in promoting physical activity among older adults appears to be highly contingent on intervention design; however, in our review, the evidence is very uncertain. The meta-analysis included only 3 randomized trials and showed no statistically significant differences between IVR and control groups, with inconsistent directions of effect across studies. Coupled with the very low certainty of evidence, small total sample size, and wide confidence intervals, these findings should be interpreted as hypothesis-generating rather than decision-informing. These findings align with previous evidence suggesting that brief, lab-based programs are generally insufficient to generate sustained behavioral change. For instance, studies by Lo et al [53] and Drazich et al [24] reported only modest or transient increases in activity, likely due to seated, low-intensity exercises and short durations. In contrast, research in younger adults shows IVR can elicit greater physiological responses—such as increased oxygen consumption and enjoyment—when compared to traditional 2D formats, likely due to enhanced emotional engagement [65].

The success of longer, home-based interventions like those reported by Dinet and Nouchi [66] may reflect the critical importance of habit formation and environmental integration, which require extended exposure periods and real-world application contexts. However, such outcomes seem contingent on the intervention's ability to integrate into daily routines, adapt to user capacity, and sustain motivation over time.

A further limitation is the reliance on self-reported physical activity measures, which are subject to bias. Future research should use wearable devices with validated protocols for objective monitoring. Overall, IVR can support physical activity, but only if programs are engaging, adaptable, and promote long-term autonomous use.

Intensity of Pain

The effects of IVR on pain intensity in older adults show heterogeneous results, probably conditioned by the design of the interventions and the characteristics of the participants. In the pilot study by Lo et al [53] with older people with knee osteoarthritis, the differences in pain intensity did not reach statistical significance compared to the control group, which may be attributed to the limited format of the intervention, focusing exclusively on strength without aerobic elements or relevant visual distracters.

In contrast, the study by Mazurek et al [49] shows more robust results: after 8 sessions of IVR with psychotherapeutic approach and immersive relaxation, a significant reduction in pain was observed, with a significant difference compared to the control group. This effect could be explained by the inclusion of psychological components, such as attentional distraction, emotional reinforcement, and the use of therapeutic metaphors, which have been associated with a downward modulation of pain in previous neurobiological studies [67,68].

Additional studies reinforce this approach. Li et al [69] observed a significant reduction in chronic low back pain in older adults after 8 weeks of IVR combined with functional exercise, highlighting increased adherence and reduced analgesic use in the IVR group. Taken together, the evidence suggests that IVR may be effective in reducing pain in older adults, especially when applied with a multisensory, emotional, and adaptive approach.

Adverse Events

The results of this review suggest that IVR is generally well tolerated by older adults, with a low incidence of adverse events, mainly related to mild symptoms of cybersickness (dizziness, nausea, and visual fatigue). Studies such as those by Campo-Prieto et al [45], Drazich et al [24], or Khirallah et al [18] reported no adverse events, while others, such as Lo et al [53], did observe mild symptoms in one third of participants, with no related dropouts. In Kwan et al [47,48], one withdrawal due to persistent cybersickness was reported, but in their later study, with a larger sample size, the incidence was low (0.7% - 3%). These findings are consistent with previous reviews. Weech et al [70], in a systematic review, identified that symptoms of cybersickness are common in immersive environments, but their severity tends to be mild and dependent on factors such as content type, duration of exposure, and individual characteristics. Stanney et al [71] emphasized the importance of individualized visor fit, especially interpupillary distance, noting that poor fit significantly increases discomfort, especially in women.

Overall, the evidence suggests good overall tolerability, although not without some episodes.

Clinical Implications

The findings suggest that IVR may be a valuable clinical tool to enhance the quality of life in older adults, particularly those with functional limitations or in institutional settings. Given the predominance of high risk of bias across several trials and low to very low certainty by GRADE, the pooled effects should be interpreted as signals of possible benefit, not as precise estimates for clinical decision-making.

Interventions combining cognitive, physical, and motivational elements show greater effectiveness. Although physical activity outcomes were not significant, appropriate program design appears crucial for adherence. Preliminary evidence also supports IVR's use in pain management, especially with emotionally engaging approaches. Its low rate of adverse events indicates good tolerability. With proper device adjustment and supervision, IVR can be progressively integrated into geriatric rehabilitation across various care environments.

XSL•FO
RenderX

From a policy perspective, our findings align with the UN Decade of Healthy Aging, particularly its priority on maintaining functional ability and person-centered care. IVR could act as an engagement-enhancing tool when embedded within routine health and social care services [72]. Operationally, its integration should be guided by WHO's integrated care for older people pathways in primary and community care and adhere to the principles of the Global Strategy on Digital Health—namely interoperability, equity, and evidence-based implementation [72].

Limitations

This systematic review and meta-analysis present several limitations related to its design and execution. First, although the search strategy was comprehensive and included 4 major databases, relevant studies indexed in other sources may have been missed. However, no language restrictions were applied, which mitigates selection bias. Second, the number of studies eligible for inclusion in the meta-analysis was limited, particularly for some outcomes such as physical activity and pain, reducing the statistical power and precision of the effect estimates. Additionally, due to the low number of included trials per outcome (n<10), we could not perform funnel plots or the Egger test to formally assess publication bias. Third, the heterogeneity in outcome measurement instruments and reporting formats across studies made it necessary to apply specific criteria for data inclusion, such as prioritizing final values over change scores and estimating means and SD when only medians and interquartile ranges were reported. These decisions, although methodologically justified, may introduce some degree of imprecision. Finally, some planned subgroup analyses could not be conducted due to insufficient data availability. While sensitivity analyses were performed where possible, the overall ability to explore sources of heterogeneity was limited.

A wide range of instruments was used to assess quality of life and physical activity (SF-12, EuroQol-5 Dimensions, WHOQOL-BREF, PDQ-39, accelerometers, and self-report surveys). While we synthesized conceptually similar constructs, instrument heterogeneity reduces scale-specific interpretability and likely contributed to between-study variance.

Future RCTs should address current evidence gaps by prioritizing: (1) the use of standardized and psychometrically validated outcome measures, particularly for physical activity and perceived effort; (2) objective monitoring of physical activity levels through wearable devices to reduce reliance on self-report; (3) long-term follow-up assessments to determine the durability of IVR effects on quality of life and functional outcomes; and (4) cost-effectiveness analyses to evaluate the feasibility of implementing IVR programs in real-world geriatric care settings; and (5) future studies should focus on the analysis of contextual factors—such as delivery model (standalone IVR vs adjunct), supervision intensity, and care setting—as potential effect modifiers. In addition, the main bias in the review was due to the unblinding of assessors and nonregistered protocols; therefore, future studies should (1) blind outcome assessors, and (2) prospectively register protocols with a prespecified analysis plan to prevent selective reporting.

Conclusions

IVR interventions lasting 4 weeks or more appear to moderately improve quality of life in older adults, especially those with clinical vulnerability or living in institutional settings. In contrast, no significant effects were observed for physical activity, and available evidence does not support a consistent trend in favor of IVR. Further research is needed to determine whether specific program designs could enhance its impact in this domain. Pain, perceived effort, and adverse events are included as secondary outcomes, but the evidence is sparse and largely qualitative. Policies and previous research also support the potential of IVR in reducing pain, particularly when using multisensory and emotionally engaging approaches, although the certainty of evidence is low to very low according to GRADE; therefore, these findings should be interpreted with caution. Overall, IVR is well tolerated and shows promise as a safe, adaptable, and motivating tool to support healthy aging, warranting further research in diverse settings.

Funding

This research received no external funding. Part of JBA's and ITC's salaries were financed by the European Social Fund Plus.

Abstract

Background: Digital health tools are increasingly vital in rural health care due to widespread hospital closures and the rapid adoption of telehealth during the COVID-19 pandemic. Rural older adults, a uniquely vulnerable population, face barriers to accessing these tools due to rurality and usability challenges. Although a growing body of literature examines the acceptability and usability of digital tools among rural older adults, no study has synthesized this research to establish best practices.

Objective: This study aims to review existing literature on digital health tools for rural older adults, highlighting key lessons learned about their acceptability and identifying strategies to improve usability for this population.

Methods: Following the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines, this study reviewed literature that investigated the role of digital health tools on the health outcomes of rural older adults (ie, at least 60 years old). The literature was retrieved from 5 electronic databases through June 2023. This study and all reviewed literature were conducted in the United States. Guided by a systematic process, 2 reviewers assessed relevant articles for eligibility, analyzed data, and extracted relevant content. The extracted findings were organized according to the evidence-based technology acceptance model, which assesses the acceptability of a technology by its usefulness, ease of use, and intention to use.

Results: The preliminary title review produced 7728 results, and 38 eligible manuscripts were included in the final review. Studies included both rural older adults and providers of rural older adults as participants. Digital health tools included, but were not limited to, videoconferencing, phone calls, telehealth monitoring, telemedicine appointments, and computer-based interventions. Findings on the usefulness of digital health tools by rural older adults were mixed. While digital health tools were useful for overcoming barriers to accessing care, these tools were less useful for rural older adults with limited digital literacy. Additionally, some studies described that the technology was easy but difficult to use when faced with environmental barriers, equipment issues, and discomfort with the technology. Rural older adults often reported an intention to use the technology after the study. Yet, on a few occasions, participants who preferred in-person care visits or did not have buy-in on the technology reported no intention to use the technology again.

Conclusions: Our review highlights that rural older adults and their providers generally view digital health tools as acceptable for delivering care and, in some cases, as a viable alternative to in-person clinic visits. While certain barriers impacted the acceptance of these tools among rural older adults, many of these challenges were not directly linked to their age or rural location; thus, they are potentially applicable to urban older adults.

KEYWORDS

health services; older adult; rural health; digital health; social determinants of health

Introduction

Digital health tools facilitate communication between patients and health care providers and offer access to resources. These tools encompass a range of technologies, including mobile health apps, electronic health records, wearable devices, and telehealth services. Social distancing mandates related to COVID-19 facilitated increased funding to support improved access to broadband internet and the rapid uptake of digital health tools [1]. To increase digital tool access and use by rural residents, in the spring of 2022, the US Department of Health and Human Services announced a US $16.3 million expansion to telehealth care in the Title X Family Planning Program [2]. Thus, rural health care professionals and systems were able to integrate digital tool uptake in their care rapidly [3]. Telehealth uptake in health clinics and hospitals increased by 154% in March 2020 compared with March 2019 [4]. For many rural patients, digital health tools are an essential component of their health care management and will likely remain important for timely and continuous rural care coordination [1].

Rural older adults represent a vulnerable population at the intersection of aging and rural residency, facing well-documented yet preventable challenges in accessing health care [5]. Rural residents are rapidly aging in place. For instance, 25% of older adults live in a rural or small town, and this is expected to rise to 33% by 2030 [6]. Additionally, for many rural older adults, care management is complex, confusing, and further challenged by coordination between distant health care facilities [7]. Since 2010, over 160 rural hospitals have permanently closed their doors, reducing access to inpatient care, which is critical for improving rural community health [8]. Therefore, aging rural populations will increasingly experience limited access to specialty care and poorer health outcomes [9].

Digital health tools can potentially overcome care coordination challenges for rural older adults. Once rural older adults engage with digital health tools, they often find their experience satisfactory and, at times, comparable to in-person visits [10]. Rural older adults evaluated web-based consultations conducted by service providers with high efficiency and satisfaction scores [11]. Once older adults understand the technology, they often find it an acceptable mode of care when punctuated by in-person visits.

Despite high levels of satisfaction with digital tools by rural older adults, compared with urban older adults, this vulnerable population has reduced telehealth use [12,13]. Also, although rural residents are willing to adopt digital health tools [14,15], studies show that rural older adults report slower telehealth uptake than younger rural adults [16,17]. This is partially due to barriers that make using digital health tools difficult for rural older adults. Some of these barriers include technical literacy, lack of technical support, cost, ownership of technology, and visual acuity [13]. In a systematic review including rural adults aged 55 years and older who have used telehealth, older adults reported a willingness to learn how to use various digital tools, but 30% felt too inexperienced with technology to use them [18]. Similarly, in a sample of Medicare enrollees, rural cancer survivors had a significantly lower predicted probability of internet use for patient-provider communication when compared with urban cancer survivors with Medicare (28% vs 46%) [19]. Importantly, not all rural older adults will find digital health tools to be a favorable health care management tool. Yet, funding to increase broadband access and the threat of widening rural medical deserts will facilitate continued telehealth uptake of digital tools by health care systems, thereby reinforcing the increased uptake of digital health tools by rural older adults. Increasing the acceptability of digital health tools and reducing barriers to their uptake for rural older adults are essential for providing health care to rural older adults.

Given the rapid acceleration of digital health tools by rural health care providers, rural older adults find digital health tools helpful. Still, rural older adults have reduced uptake of these technologies compared with both urban older adults and younger rural adults. With the increasing use of digital health tools, understanding their acceptability among rural older adults is crucial for ensuring this vulnerable population stays engaged in their care management and coordination as reliance on these tools continues to grow. Details about the rural older adults' digital health tool acceptability and usage can inform tool intervention design, implementation, and evaluation. Existing research summarizes the effectiveness of services such as telehealth among older adults, but strategies to improve rural older adults' usage of digital health tools are limited [18]. Therefore, this study will systematically review the existing literature in the United States on rural adults' acceptability of digital health tools and assess lessons learned on digital health tool usage among rural older adults.

Methods

Study Design

The study was analyzed and reported in accordance with the Cochrane systematic review guidelines and the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) 2020 guidelines (Multimedia Appendix 1) [20,21].

Search Strategy and Data Sources/Protocol Registration

A trained librarian conducted searches in MEDLINE (Ovid), Cochrane Database of Systematic Reviews (Wiley), Embase (Elsevier), CINAHL (EBSCO), and PsycINFO (EBSCO) databases. This search included articles published in English through June 5, 2023. Keywords and subject headings related to the following topics were used to identify possible articles: rural residents, older adults, the use of

XSL•FO
RenderX

technology-enhanced tools to navigate telehealth, and acceptability. See the supplementary materials for the complete search strategy. Following, we searched the references of eligible articles for additional relevant articles. The protocol was registered post hoc in the International Prospective Register of Systematic Reviews (PROSPERO CRD42021287924).

All articles eligible for data extraction underwent title and abstract review, and full-text review by a pair of reviewers. Reviewers independently assessed the articles based on the eligibility criteria (see below) using standardized procedures in the systematic review software Covidence (Covidence systematic review software, Melbourne, Victoria, Australia). A pair of reviewers discussed and resolved conflicts in weekly meetings. Each article was assessed for quality by 2 reviewers. Extracted content and Quality Assessments were reported using Microsoft Excel and Covidence.

Eligibility Criteria

We included research articles of investigations conducted in the United States that assessed a digital health tool's ability to connect patients with providers, where at least 25% of the sample population identified as rural, and at least 25% of the sample identified as at least 60 years old. Articles were excluded if they were a review (eg, systematic or scoping), withdrawn, a conference proceeding, an abstract, or a dissertation. We also excluded articles published before 1999, as we deemed that the technology or lessons learned from the technology over 25 years ago were antiquated.

Data Extraction

Paired reviewers conducted consensus meetings to agree upon the rationale for data extraction content and synthesize the results. Table 1 displays the extraction content. In short, paired reviewers reported each article's title, first author, and year of publication. The outcome variables collected from each study included the participants' age (average or mean), study design, and type of digital health tool technology (eg, videoconference or wearables). Following the technology acceptance model (TAM), we extracted data related to the core TAM domains: perceived usefulness, perceived ease of use, and intention to use [22]. The perceived usefulness domain describes how much technology improves a patient's performance. Perceived ease of use is the effort required to use the technology. Last, intention to use refers to a patient's willingness to use the technology. Given that we aim to synthesize acceptability and lessons learned, our analysis did not assess the effect of the outcomes. This systematic review did not need an exploration of heterogeneity or a sensitivity analysis.

XSL•FO

Table 1. Summary of findings.

Study	Population characteristics		Study design	Technology	Usefulness	Ease of use	Intention to use
	Age	Rural					
Anderson et al [23]	Mean age 61 years	Community-based outpatient clinics in rural Southeast Texas	Qualitative	Videoconferencing	• It was accessible. • Videoconferencing was convenient and reduced transportation issues.	• Participants reported that there was too much information covered in the 2 self-management classes and that 2.5 hours was too long for a single videoconferencing session. • Clinicians reported that they had no time to assist when technology problems occurred. • Clinicians reported that there was only limited clinic space to hold videoconferencing sessions.	• Not applicable.
Barton et al [24]	28.5% of the sample is 60 years or older	67.3% of the sample is from rural Colorado	Cross-sectional	Phone call, videoconference	• Providers reported that ease of access to patient records, scheduling follow-up visits, and timely follow-ups were all better accomplished during digital visits than office visits (2-4.5× higher, all P<.001).	• Not applicable.	• Patients who did not engage in telehealth listed "preference to seeing the provider in person" and "telehealth not being an option" as reasons.
Bernacchi et al [25]	Mean age 60.2 years	Rural dwelling residents from Southeast US	Mixed methods	Videoconferencing	• Access to an oncology nurse during COVID-19 increased rural cancer patients' access to care, information, and education. • Participants gave unfavorable scores to questions that asked about the use of the technology. For example, the lowest scoring items were "my health is better than it was before I used the technology" (—X = 3, SD = 0.89).	• Participants struggled with connecting to appointments due to a lack of equipment or discomfort with digital technology. • Three participants with insufficient broadband used nearby telehealth satellite sites at local clinics or hospitals. • Participants often relied on family members for connection due to limited internet experience or poor broadband signals.	• Participants were committed to overcoming barriers in order to speak with their nurse.

XSL•FO
RenderX

Study	Population characteristics		Study design	Technology	Usefulness	Ease of use	Intention to use
	Age	Rural					
Bonsignore et al [26]	Mean age 72 years	Rural counties in Western North Carolina	Mixed methods	Telemonitoring	• TapCloud increased patient-provider relationship, accessibility to clinicians, increased response times, improved efficiency, and made medications more accessible. • Accessibility to a provider increased comfort, along with communication and preemptive management of problems.	• TapCloud's facilitation of direct, efficient contact with patients made it easy to use. • Patients and caregivers were particularly enthusiastic about how easy medication refills are with TapCloud. • Patients and caregivers find the TapCloud application intuitive, easy to use, and not time-intensive.	• Once coached on using the application, patients readily adopted the technology and often felt a sense of accomplishment in doing so.
Browning et al [27]	Mean age 81 years	Residents of rural Southwest Virginia	Retrospective quality improvement case series	Phone-based telehealth monitoring	• Participants felt nurses had better accessibility to vitals (88.9%). • 90% felt a better connection with their doctor.	• 77.8% found telehealth easy to use.	• Not applicable.
Collie et al [28]	Mean age 60.7 (SD 9.24) years	Resident of Intermountain region of Northeastern California	Pretest-posttest	Videoconferencing	• Not applicable.	• Participants adapted quickly to videoconferencing and reported no communication difficulties. • The facilitator faced challenges due to time lags and poor lighting.	• All said they would recommend it to other women with breast cancer.
Cummings et al [29]	Mean age 52.8 (SD 16.2) years	Rural counties in eastern North Carolina	Descriptive	Nonmydriatic retinal imaging telemedicine system	• 85% of images were "good or fair" when examined by a retinal specialist. • Retinal specialists reported "very certain or certain" in 84% of diagnoses.	• 96.3% of the participants were "very comfortable" or "comfortable" with the portable camera.	• Not applicable.
DeHart et al [30]	41.2% of the sample is 55 years or older	Rural resident from South-Eastern State	Mixed methods	Web and mobile-based telehealth with remote monitoring	• The application effects were seen through the increased coordination across agencies, technology fit with intraoffice demands, growing practice through engagement, flexible delivery, reduced provider travel, geographic access, reduced patient transport, saving time/visits for patients, reduced costs, and fewer challenges to sustainability.		• The most common patient-level challenge reported by providers was a lack of buy-in to use the service consistently.

XSL•FO
RenderX

Study	Population characteristics		Study design	Technology	Usefulness	Ease of use	Intention to use
	Age	Rural					
						• Telehealth had organizational technology and space challenges. • Patient skills and comfort were a challenge. • Provider knowledge and skills were a challenge. • Rural patients struggled with technology access, often due to a lack of broadband technology in homes, but also due to technology skills for aging populations and those with less education.	
Demaerschalk et al [31]	Mean age 66.3 (SD 13.5) years	Patients at rural medical centers, more than 185 miles from a primary stroke center	Randomized control trial	Telestroke	• Results indicate effectiveness in the organization and structure of stroke telemedicine networks for extending stroke care in rural communities.	• Technical problems were noted in 20 of 27 (74%) of telemedicine consultations and in 0 of 27 telephone consultations. However, none of the issues kept the patient from being cared for.	• Not applicable.
Depatie and Bigbee [26]	Senior living facility serving adults aged 60 years or older	Rural northern California senior centers	Descriptive mixed methods	Mobile health technology		• Participants' comfort level with using email or the Internet to communicate with a health care provider was evenly split.	• Responses to interest in incorporating technology into daily life for health tracking and communication with a health care professional indicated that 33% had no interest, 23% were somewhat interested, and 13% indicated that they already used this technology.

XSL•FO
RenderX

Study	Population characteristics		Study design	Technology	Usefulness	Ease of use	Intention to use
	Age	Rural					
					• 67% felt it was moderately important for the technology to monitor their health, but do not feel comfortable sharing with their provider. • 53% felt it was somewhat or extremely important to monitor their health and were comfortable sharing information with their provider. • 46% felt it was somewhat or extremely important to monitor their health as well as share information over the internet with their health care provider. • 44% indicated it was moderately, somewhat, or extremely important to use mobile health technology in combination with in-home nurse visits. • 40% felt it was somewhat or extremely important to connect patient education and support groups online. • 77% felt health technology had a clear benefit on their health.		
DeVido et al [32]	Mean age 54 (SD 19.4) years	Providers at a rural population-serving hospital	Case report	Telepsychiatry	• Telepsychiatry is capable of responding to many consultation questions in a hospital setting. • Cognitive test items were collected reliably using a camera function that interpreted physical images. • Telemedicine gave valuable clinical data regarding psychotic symptoms. • Telepsychiatry was applicable in accessing a diverse range of patients. • Communication between the resource nurse and referring physician was aided through telemedicine.	• Technological challenges included getting the cameras and software to operate reliably. • An ongoing challenge was the integrity of the image and audio. • Audio feed was compromised by Wi-Fi connectivity problems.	• Not applicable.

XSL•FO
RenderX

Study	Population characteristics		Study design	Technology	Usefulness	Ease of use	Intention to use
	Age	Rural					
Donahue et al [33]	Mean age 57.9 (SD 12.4) years	Rural North Carolina county	Cohort	Phone-based digital health care	• 84% of participants set a goal and reached at least one goal due to digital health technology.	• Not applicable.	• Providers expressed interest in continuing the phone coaching program with their participants, if resources were available. • 96% would recommend phone coaching to others. • 58% of participants remained engaged with phone coaching over the 12-month period (missed fewer than 3 consecutive monthly calls), 17% were less engaged (received at least one call), and 25% were not engaged.
Finley et al [34]	82% of the sample is 65 years or older	Three rural outpatient telehealth clinics, or one urban outpatient clinic in Arizona	Mixed methods	Telecardiology	• Patients perceived service as competent and began to see benefits in accessibility, reduced transportation, and general timesaving.	• Not applicable.	• When compared with the telehealth group, in-person participants more frequently expressed concerns about technology, about care not being face-to-face, and made more negative statements about quality. • Rural participants held the most positive attitudes toward telehealth, while suburban participants held the least positive attitudes toward telehealth.
Geller et al [35]	54.6% of the sample is 61 years or older	Patients and their providers from rural practices in Vermont	Quasi-experimental	Computer-based interactive interventions			• Not applicable.

XSL•FO
RenderX

Study	Population characteristics		Study design	Technology	Usefulness	Ease of use	Intention to use
	Age	Rural					
					• Preliminary evidence that the technology could educate patients about screening. • Technology promoted patient-provider discussion, provider recommendations, and positive patient intentions to get a screening.	• Digitally everyone found the program easy to use. • Older participants and less educated participants found the sound (reading the information and questions on each screen) helpful compared with the younger and more educated participants.	
Gutierrez et al [36]	Mean age 65.2 years	Patients from a VA[a] hospital in rural Wisconsin	Mixed methods	Telehospitalist	• Communication benefits • Telehospitalists reported confidence that the diagnosis accuracy and quality were that of in-person. • Patient satisfaction showed improvement in care coordination (18%; P=.02).	• Connectivity problems were prevalent, although most providers were able to resort to a backup plan. • Internet connectivity was inconsistent, leading to disruption in video communications. • It was easy to contact bedside providers/telehospitalist: 100% telehospitalist, 42.9% physicians, 10% nurses, and 22.2% other staff.	• Not applicable.
Hatch et al [37]	47.4% of the sample is 65 years or older	33.1% of the sample resided in a rural area	Descriptive cross-sectional cohort	Telehealth	• Not applicable.	• Older and low-education patients are less familiar with the required technology and experience some technological limitations.	• Not applicable.
Hicks et al [38]	Mean age 68.9 years	Residents in rural midwestern state	Experimental	Telemonitoring	• 78.3% indicated that the use of telehealth technology improved their care. • 78.3% indicated it was very convenient. • 95.7% of the respondents indicated that the telehealth technology affected their relationship with their nurses positively.	• 95.7% indicated it was very easy to communicate with the agency personnel using the equipment. • 95.7% of the respondents indicated that the telehealth technology was very easy to use. • 87.0% indicated that the telehealth technology worked very well.	• 91.3% of the respondents indicated definitely and 8.7% indicated maybe when asked if they would use the digital health technology again.
Holloway et al [39]	Mean age 61.3 (SD 11.6) years	Residents in rural Montana	Pretest-posttest	PRISM[b] digital health care videoconferencing			• Not applicable.

XSL•FO
RenderX

Study	Population characteristics		Study design	Technology	Usefulness	Ease of use	Intention to use
	Age	Rural					
					• Patients learned to work with the technology, enabling them to interact effectively with patients at other sites. • Participants felt that the ability to participate in a team approach to diabetes management without traveling was beneficial. • Compared with baseline, patients reported improvements in diabetes care of 30-200% 1 year after the intervention.	• Scheduling was a difficult and time-consuming task. • Staff members easily learned to use telehealth technology. • In most cases, patients were able to learn manual skills using telehealth technology. • 99% felt the technology picture and sound were clear. • 100% of patients felt comfortable learning health information using this technology and said they understood the information as if it were imparted in person.	
Khairat et al [40]	Mean age 77.8 years	66.7% of the sample resided in rural North Carolina	Cross-sectional	Videoconferencing follow-up care	• Geriatric patients did not have trouble using digital health tools. • Telemedicine platforms improve primary care by allowing providers to follow-up with their geriatric patients at a time and place that is most convenient for both groups.	• Not applicable.	• Not applicable.
Kulcsar et al [41]	Mean age 60.3 (SD 16.1) years	The majority of patients resided in rural New Hampshire or rural Vermont	Cross-sectional quality improvement	Telerheumatology	• Providers reported that 19% of the patient visits seen via Telerheumatology were inappropriate for the telemedicine visit type due to poor understanding of symptoms, symptom complexity, and the limited ability to perform a physical examination. • 81% of patients rated that they were comfortable with the provider's ability to examine them, thought the provider spent an adequate amount of time with them, and made an accurate diagnosis of their condition.	• 94% of patients felt that each individual member of the staff made check-in easy, was friendly, and competent with the videoconferencing equipment. • An area of greatest dissatisfaction for patients stemmed from problems with scheduling appointments (usually follow-up).	• About half (53%) of the patients either agreed or strongly agreed that they would like to be seen via telerheumatology again if given the option.

	Age	Rural					
Liu et al [42]	Mean age 67 years	Patients from a clinic in rural Wisconsin		Teleophthalmology	• Teleophthalmology was often preferred by patients because it was more comfortable than traditional eye examinations, since pharmacological pupil dilation was usually not needed. • Teleophthalmology is effective for increasing diabetic eye screening rates in rural populations.	• Tele-ophthalmology offered convenience through same-day scheduling, proximity to the patient's primary care provider, and short wait times. • Patients appreciated the quick, easy, and painless nature of tele-ophthalmology compared with traditional, in-person eye examinations.	• Participants reported being unaware of tele-ophthalmology prior to the study.
Locke et al [43]	Mean age 69.2 years	Residents of rural zip codes defined by the United States Census Bureau	Retrospective	Home computer video health technology	• 96% of participants preferred video telehealth rather than traditional training visits at the medical center. • 76% of participants would not have gotten additional inhaler training if not for the telehealth. • The telehealth inhaler training delivered via internet video telehealth demonstrated an improvement in technique overall. • The main benefits, as listed by participants of the program, were convenience, time-saving, and decreased travel expenses. • Inhaler training delivered via video telehealth by a pharmacist was well received. • The CHAT inhaler training program provided an alternative to in-person visits for rural patients with transportation burdens.	• Among 93 home telehealth program enrollees, 19 (20%) faced technical issues with the computer or video software that prevented participation. • A quarter of participants reported frequent technical problems, consistent with pharmacists noting issues in 149 (63%) of scheduled visits, and 19 visits (13%) were postponed or partially completed due to unresolved technical issues. • Common issues included patient errors or confusion (41% of visits) with the video telehealth program, particularly with logging into the Jabber program and basic computer skills, along with 11% experiencing computer/software issues and 25% having audio/video troubles. • Despite these challenges, over 90% of participants found the equipment easy to set up and appreciated the benefits of convenience, decreased travel time and expenses, and increased privacy.	• A majority (96%) preferred home video telehealth for inhaler training compared with going to the medical center for in-person training.

Quality Appraisal

The quality assessments were achieved through critical appraisal tools used in Joanna Briggs Institute Systematic Reviews [59] and the McGill Mixed Methods Appraisal Tool Version 2018 [60]. Two reviewers assessed the quality of each included article represented in the extracted data. Weekly meetings were held to discuss conflicts. Studies with a quality score of less than 50% were not included in the analysis, indicating evidence of reporting bias.

Results

Overview of Reviewed Studies

Figure 1 provides a summary of the selection process and illustrates our systematic review of the literature. The preliminary title review produced 7728 results, out of which 7616 underwent the abstract review, and 511 completed the full-text review. Following the assessment, 16 studies were excluded because they scored less than 50% of the total possible score for each respective quality test. Our final review included 39 studies.

XSL•FO
RenderX

Figure 1. PRISMA flow diagram.

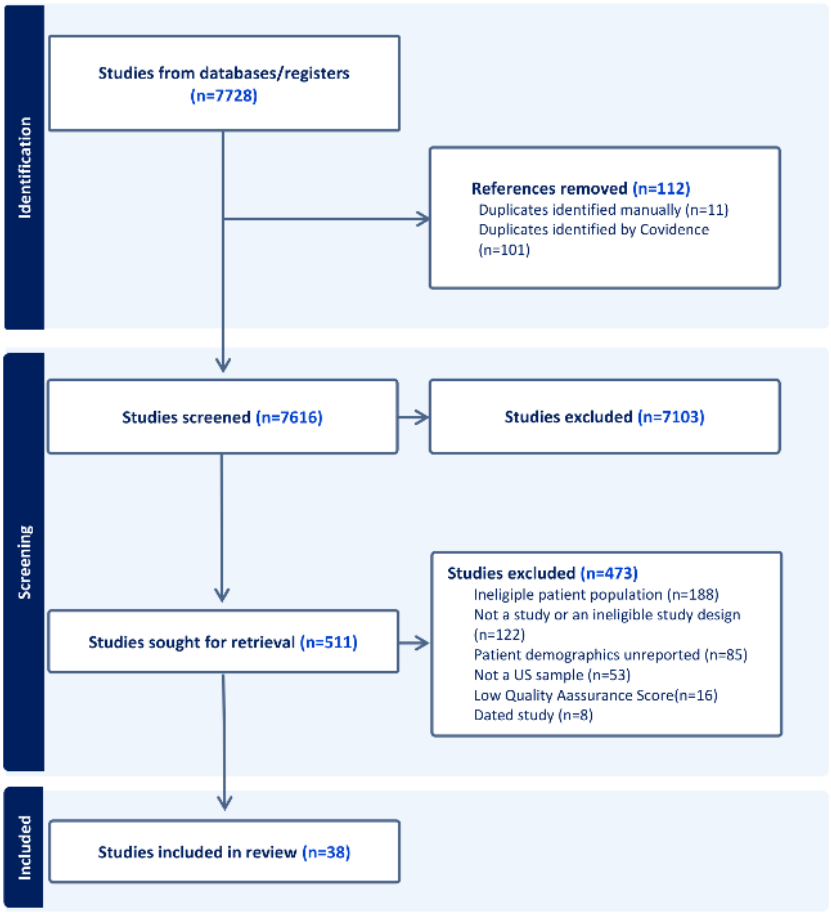

Table 1 details our data extraction, elucidating article information according to the first author and publication date, study population age, study design, technology used, and TAM domains. Since 25% of the population had to be at least 60 years old for eligibility, it is important to highlight that studies reported the mean age, included samples exclusively of older adults (eg, Medicare enrollees), and provided the percentage of participants within specific age ranges. The study design of eligible studies was cross-sectional (n=8), qualitative (n=7), and mixed methods (n=11). We will detail lessons learned from the eligible studies according to the TAM domains below.

Technology Usefulness

Digital health tools were useful for connecting patients to providers [25,26,35,38,54,61], assisting participants with improving health outcomes and care management [25,31,38-43,47-49,51-54,57,61], and reducing transportation burdens [17,23,30,34,43,47-50,53,55]. Uniquely, Anderson et al [23] reported on the role of telehealth videoconferencing in strengthening patients' social and peer connections. Providers also considered that digital health tools were useful for care management [24,29,32,36,40,49] and communicating with other providers [30,32,47]. Although the respective technology was considered useful, multiple studies reported that rural older adults needed additional supports to facilitate the usefulness of the technology, including behavioral goal setting [57] and assistive devices [49].

Despite the reported usefulness of digital health tools, some studies also reported that they were less than useful. Bernacchi et al [25] revealed that digital health technology was less useful for participants with limited experience with digital technology. Similarly, according to Kulcsar et al [41], nearly one in 5 patients scheduled for a telerheumatology visit was deemed unsuitable due to poor symptom understanding, symptom complexity, and the limitations of conducting a physical examination remotely.

Ease of Use

Articles that addressed the digital health tools' ease of use described the tools as uncomplicated [48], requiring an adequate amount of training to use [62], easy to access health information [39,44], easier than an in-person examination [42], easy to communicate with a health care professional [36,38,61], and intuitive [26]. Hybrid models that provided supplemental real-time instruction with the technology improved the ease of use [41,50]. Importantly, some digital health tools were easier to use than others. For example, Schooley et al [49] assessed that mental health evaluations via email and telephone were challenging because of barriers to observing nonverbal cues, yet were easier to accomplish via a videoconference. Additionally, Geller et al [35] reported that audio features improved the ease of using a computer-based intervention for older adults. Providers also reported that digital health tools improved the ease of managing appointments [24,45], accessing and reviewing patient records [24,45], and contacting patients [26]. Weiner et al [55] reported that a low "no-show" rate (3%)

XSL•FO
RenderX

evidenced the ease of using videoconferencing visits. Locke et al [43] reported that 90% of the providers reported that the technology was easy to use, despite the fact that more than half of the providers reported issues with scheduling, and 41% reported that patients were confused about using the technology.

Commonly, studies have reported on the challenges of using technology. Digital health tools were more complicated to use when faced with environmental barriers (eg, poor lighting) [23,28], technical or equipment issues [17,25,30-32,36,43,51,53,56], discomfort with the technology [17,25,30,56], reduced access to adequate internet [30,32,36,51], and distrust in the technology [17]. DeHart et al [30] and Hatch et al [37] observed a positive relationship between education levels and ease of use, which was particularly challenging for older adults with low levels of education. Although many studies reported the challenges of using digital tool technology, West et al [57] reported that supplemental instructions were critical for overcoming usage barriers.

Intention to Use the Technology

Most commonly, participants reported an intent to use the digital health tool technology through sustained use poststudy [34,38,41,47,51,53], future referrals or recommendations [28], high levels of digital tool uptake [43,50,55,58], and evidence of improved care management [25,43,47,50]. For example, Locke et al [43] reported that 96% of the participants preferred home video telehealth inhaler training rather than going to the clinic for in-person training. Bernacchi et al [25] detailed another example of intention to use videoconferencing technology through the patient's commitment to contact their health care provider despite challenges with equipment and broadband. Strowd et al [51] and Finley et al [34] reported that rural residents were more likely to consider telehealth in the future compared with urban residents. A study indicated that participants were more likely to continue with specific delivery modes of digital health tools, such as telephones, rather than web-based options [49].

When participants did not intend to use the digital health tool technology, it was often due to a preference for in-person visits [24,34,44,45,53,56] or a lack of buy-in about the technology [30,42]. Additionally, 2 studies identified age associations with intentions to use digital health tools. Older adults had reduced intentions of continuing their care digitally [49,51].

Discussion

Principal Findings

This review aimed to assess lessons learned about the acceptability of digital health tools among rural older adults. Following a systematic review approach, we organized our findings according to the TAM, focusing on the usefulness, ease of use, and intention to use digital health tools of rural older adults. The domains of the TAM aim to detail predictors of potential acceptance or rejection of the technology. Our findings revealed that digital health tools were, in most cases, useful for care management, reducing transportation burdens, and improving patient-provider communication. Two articles reported that digital health tools were less useful when the technology was misaligned with the participant's digital skills level or when the technology was unsuitable for the given care visit types. Several articles highlighted the ease of use of digital health tools for rural older adults, describing them as uncomplicated, intuitive, and effective for connecting with health care providers. Most articles that discussed the ease of using digital health tools focused on the ease of specific features of the tool (eg, audio capabilities) or the type of technology (eg, telephone vs digital). However, digital health tools were more difficult to use due to technical or equipment issues, discomfort with the technology, and limited access to broadband internet. Last, the findings on rural older adults' intention to use digital health tools were robust, as evidenced by participants' preference to continue using the technology after the study concluded and improved health outcomes. Comparatively, participants did not intend to use the digital health tools when they preferred an in-person visit or when they were not sold on the benefits of the digital health tool. Together, the TAM domains reveal that rural older adults and their providers largely consider digital health tools as acceptable modes of receiving care and, at times, a suitable alternative to in-person clinic visits. Despite barriers that reduced rural older adults' acceptance of digital health tools, many of these barriers were not associated with their age or rural residence.

Technology Usefulness: Lessons Learned

Digital health tools are useful for accessing health care and care management, but their effectiveness in improving health outcomes in older adults is mixed. Our review highlights that digital health tools were useful for mitigating burdens related to accessing health care and care management for both providers and patients. Articles reported that useful care management needs included scheduling, accessing health records, and patient-provider communication. The positive findings on remote care management and usefulness are specific to this review, and it is important to note that the effectiveness of remote care management and monitoring on health outcomes is mixed. In a review of remote care management of depression and anxiety in older adults, the findings on psychiatric outcomes were mixed, and no studies demonstrated a statistically significant effect of remote care management on health care use or cost [63]. Another review of mobile integrated health interventions for older adults revealed that these interventions reduced emergency department call volume and transports [64]. Thus signaling that digital health tools were useful for care management during emergency health events.

To build on this body of evidence, our review uniquely emphasizes the usefulness of digital/remote care management for rural older adults—a population that has complex care needs but often resides in a medically underserved area with reduced access to broadband internet and technology literacy programming. However, future systematic and meta-reviews are needed to assess the effectiveness of digital health tools with care management features on health outcomes and costs for rural older adults.

Ease of Use: Lessons Learned

Easy-to-use technology is associated with improved health outcomes; however, the design of technology may not be

XSL•FO
RenderX

sufficient, and external support (eg, timely technical assistance) may be necessary. According to the TAM, digital tools that are perceived to be easy to use are more likely to be accepted by the intended audience. Based on this review, rural older adults and their providers frequently highlighted user-friendly features of the tools that improved ease of use. However, there was strong evidence that external factors—such as technical issues, equipment limitations, and discomfort with the technology—hindered usability. There is a positive relationship between the health of older adults, their social connectedness, access to high-quality health care resources, and the perceived ease of use of digital health tools [46,65]. Notably, this evidence signals that technology design alone does not improve the ease of using digital health tools. Specifically for older adults, in-person synchronous technical assistance, access to remote technical assistance, and early interventions from hospital administrators are reported facilitators for increasing the ease of use of digital health tools [15,25,29]. Overall, this evidence underscores the need for additional resources and external support to enhance the perceived ease of using digital health tools for rural older adults.

Intention to Use the Technology: Lessons Learned

Despite design flaws or technical difficulties, rural older adults generally intended to continue using technology beyond the observed period. Factors such as the preference for in-person care and a lack of buy-in about the technology influenced the participants' intent to use digital health tools. Yet, our findings revealed that participants described an intention to use digital health tools despite also reporting that the technology was not always useful or easy to use [25,34,41,43]. In a similar study on patient portal use by older adults, challenges were noted with log-ins and the user interface design, such as color and font [62]. Despite these issues, older adults expressed an intention to continue using the portals due to their other beneficial features. In summary, in light of the barriers to ease of use and usefulness, rural older adults often overcame them to continue using digital health tools [25].

Additional Considerations for Digital Tool Acceptability

In synthesizing lessons learned, our review identified several phenomena, not salient enough to categorize as a lesson, but worthy of continued discussion. Namely, our review reveals both differences and commonalities in user behavior and preferences between older adults in rural and urban areas. As reduced access to broadband internet is a common barrier for rural residents, this was not the most reported impediment to digital tool acceptability in this review, as expected. According to the Federal Communications Commission's data reported in 2021, 23%-50% of rural residents had poor access to broadband internet [66]. The rather limited mention of challenges associated with rural internet connectivity, in this review, is inconsistent with the existing literature, which indicates that poor internet connection is a key barrier to digital tool use acceptability for rural residents [15]. Also notable is that multiple studies reported a measure of digital tool acceptance among rural residents compared with urban residents. For example, Finley et al [34] reported urban-rural differences in intention to use, indicating that rural patients, compared with urban and suburban patients, had more favorable attitudes toward telecardiology. This higher acceptance of digital health tools by rural patients likely punctuates the growing reliance on and acceptance of digital health tools in the wake of dwindling local health care resources and rising health care costs. While these findings suggest that rural and urban residents share common barriers to technology acceptability, our conclusions do not suggest that "one-size-fits-all" interventions should be considered. Rather, additional qualitative examinations on the rural-urban differences in attitudes toward digital health tools and the acceptability of these tools are warranted.

This review synthesized a diverse representation of technology modes (eg, videoconference or phone call), highlighting the robust intervention designs implemented in rural settings. These findings strengthen the evidence base on digital tool acceptability among rural patients, with all modes being reported as acceptable. Yet, important distinctions emerged across the reported technology modes, making salient conclusions about the most acceptable modes speculative. For example, both Anderson et al [23] and Svistova et al [17] used videoconferencing; however, Anderson et al [23] employed a Veterans Affairs-supported platform, and Svistova et al [17] used Zoom. The journal articles provided limited details regarding platform-distinctive features, though such distinctions could plausibly impact acceptability and usability very differently. In the current review, technology modes were extracted as they were identified in the original article to ensure transparency. A more detailed analysis of the technology's distinctive features and their impact on acceptability warrants further investigation.

The data collected for this study includes both pre– and post–COVID-19 pandemic publications, which provide key insights into how rural older adults' acceptance of digital health tools evolved, resulting from the rapid uptake of telehealth due to COVID-19 precautions. Many of the studies that were published prior to the COVID-19 pandemic often emphasize the same sentiment of the digital divide between younger and older generations. The existing literature evidences that the pandemic exacerbated this divide, as prepandemic older adults were less likely to benefit from technological innovations [67]. Specifically, pre- and early-pandemic trends indicated that age and rural zip codes were inversely related to continuous digital tool use [68]. Multiple studies from our review that were published prepandemic identified that younger participants were more likely to engage in digital tool technologies [49,56]. Yet, in a peripandemic investigation, Bernacchi et al [25] describe that videoconferencing with a nurse increased access to care for older rural cancer patients. Similarly, postpandemic, individuals older than 65 years used telemedicine over 3 times more when compared with prepandemic, further emphasizing this technological shift [19].

The findings of this review have practice and research implications. To improve practice, our findings suggest that health care providers adopt hybrid care models—combining both digital and in-person visits. It is essential for providers to emphasize the benefits of digital health tools, such as reducing travel burdens and offering greater convenience

XSL•FO
RenderX

[30,39,43,47,49,50,53]. Additionally, future research should include interventions aimed at increasing technology literacy among rural older adults and provide additional synchronous and asynchronous supports to help rural older adults better understand the technology [17,25,30-32,36,37,51,56,57]. For caregivers who support rural older adults, digital health tools have the potential to reduce caregiving burdens. Tools such as remote monitoring enable doctors and nurses to keep patient health under observation while the patient remains in the comfort of their home [30,38,54]. This technology could reduce the burden on caregivers and limit accidents. Last, it is our hope that these findings will influence policy that increases funding for the development of digital health tools that can decrease health disparities within rural older adult populations.

Limitations

This study has several strengths and limitations. The synthesis of our findings was guided by the core domains of the TAM [69]. Previous studies have reported that the Perceived Usefulness, Perceived Ease of Use, and Intention to Use domains are important for determining user acceptability. They are the core of all TAM models used across the literature, thus chosen for this study. Yet, additional domains and extensions have been added over time, including the "Attitudes Toward Using" domain [70,71]. Although our synthesis is limited to conclusions derived from the core domains, these domains provide sufficient information to inform our overall aim of assessing user acceptability. Additionally, a trained librarian conducted a data search of publicly available databases (eg, PubMed). Despite our comprehensive search conducted by a trained librarian, some relevant studies may have been missed due to factors such as publication dates postreview, non–English language restrictions, or potential oversight in keyword selection. It is important to note that participants in health outcomes research are often younger than 65, have higher household incomes, greater technological literacy, and are more likely to reside in urban areas [27,33,72]. Therefore, our review's focus on rural older adults and digital tool use may highlight a potential participant bias in our sample, limiting the generalizability of our findings to the broader rural older adult population. As with all scholarly reviews, researcher bias could have impacted the results. However, because multiple reviewers assessed each manuscript and attended consensus meetings for each manuscript, this bias was reduced.

Conclusion

This study aimed to systematically review articles that incorporated digital health tools used by rural older adults in order to assess their acceptability and usage of the tools. Following the TAM, we highlighted the usefulness, ease of use, and intention to use digital health tools. In summary, digital health tools were valuable for rural older adults with complex care needs, helping mitigate access barriers and support care management tasks like scheduling and patient-provider communication. While rural older adults and providers found the tools user-friendly, external factors such as technical issues and equipment limitations impeded usability, signaling the need for additional support and resources. Despite challenges with ease of use, rural older adults expressed an intention to continue using digital health tools, recognizing their overall benefits in managing care, especially in underserved areas. As medical deserts widen in rural communities, and in response to the rapid uptake of telemedicine due to COVID-19 precautions, digital health tool reliance is likely to grow for rural residents. Understanding what this uniquely vulnerable population views as acceptable and what facilitates their uptake of digital health tools is critical for addressing health disparities and bridging the digital divide in rural communities.

Funding

MWL and ZMS were supported by a grant from the National Cancer Institute (Grant Number: K01CA262342). MWL is also supported by a Northwestern University Clinical and Translational Sciences Institute grant (Grant Numbers: NUCATS; UL1TR001422, Principal Investigator: Richard D'Aquilla), an Institutional Research Grant (IRG-21-144-27) from the American Cancer Society (Principal Investigator: Leonidas Platanias), and funds from the Northwestern University Center for Community Health (grant number: not applicable). Opinions and comments expressed in this paper belong to the authors and do not necessarily reflect those of the National Institutes of Health.

Authors' Contributions

ZMS was responsible for formal analysis, methodology, project administration, visualization, writing the original draft, and reviewing and editing subsequent drafts. EQ was responsible for the formal analysis, writing the original draft, and reviewing and editing subsequent drafts. JP was responsible for writing the original draft and reviewing and editing subsequent drafts.

Conflicts of Interest

None declared.

Abstract

Background: Exercise has a positive impact on the health of older adults. However, due to physical conditions, psychological factors, and external environment constraints, older adults still face significant challenges in maintaining exercise. Exercise adherence is relatively low. Extended reality (XR) technology offers new ways for older adults to exercise and improve their adherence. Existing research mainly focuses on short-term effects, paying insufficient attention to maintaining long-term engagement and establishing effective incentive mechanisms. By introducing service design methods, user experience, stakeholder collaboration, and adherence support can be better integrated at different stages of exercise intervention, thereby enhancing the willingness and enthusiasm of older adults to continue to participate in exercise.

Objective: This review aims to evaluate how XR-based exercise interventions targeting populations with a mean age of older than 50 years integrate service design strategies to enhance exercise adherence and to identify critical gaps in their long-term application.

Methods: A systematic review was conducted across PubMed, Scopus, Web of Science, CINAHL, PsycINFO, and ACM Digital Library (January 2020-July 2025). Eligible studies (1) used XR to support exercise or rehabilitation, (2) included participants with a mean age of older than 50 years, (3) reported at least one service design activity, and (4) provided adherence-related outcomes. Dual independent screening and structured data extraction were performed.

Results: A total of 9 studies (242 participants) met the inclusion criteria. Most applied participatory, co-design, or user-centered design with iterative prototyping, but few advanced to full implementation or applied a complete service design cycle. The user experience was generally positive, but evaluations were primarily based on self-reports with limited objective tracking. Although exercise adherence was generally high in most studies (80%-100%), this assessment was primarily based on attendance-related indicators. There was a lack of consistency in how adherence was defined across studies, and no unified measure of exercise adherence was established. Exercise frequency, duration, and attendance were commonly reported, whereas exercise intensity and accuracy were often overlooked. Existing evaluations also lacked long-term tracking of exercise adherence. Regarding intervention delivery settings, most studies were conducted in laboratories, hospitals, and care facilities. Few studies investigated implementation in community settings, which made XR interventions difficult to adapt to the real-world conditions faced by older adults in their daily lives and hindered their promotion and application to a broader community population.

Conclusions: Current XR exercise interventions for older adults show promising short-term adherence but rarely embed service design continuity or comprehensive adherence monitoring. The combination of structured service design processes with standardized and multidimensional adherence indicators can provide strong support for participants to continue engaging in XR exercise projects. When implemented in community settings, these interventions can enhance scalability and better support an age-friendly XR exercise system.

Introduction

As life expectancy increases, the older population has grown rapidly, and chronic disease prevalence has risen. Many older adults live with long-term conditions such as cardiovascular disease [1], type 2 diabetes [2], obesity [3], arthritis [4], and dementia [5]. The growing number of such cases is already putting pressure on health care systems globally [6,7]. For example, health care costs for frail older adults range from US $2540 to US $221,400 per person annually [8]. In Singapore, the societal cost associated with multimorbid older adults amounts to US $11,970 per person per year [9]. In Europe and North America, health care expenditures for older adults with multimorbidity are likewise considerable. For example, among older patients with heart failure and diabetes, annual hospital care spending was estimated at approximately US $10,956 per person in England and US $30,877 per person in the United States [10]. Regular exercise helps older adults maintain their health and reduces a variety of age-related problems, such as cardiovascular disease [11,12], decreased musculoskeletal strength [13], risk of falls [14], and psychological distress [15]. Despite the clear benefits of exercise, older adults generally lack the ability to continue exercising [16]. For example, the adherence rate in an aerobic exercise group of older adults averaged only 49.7% [17], while a 6-month intervention reported a 35% dropout rate among participants aged 65 to 74 years [18].

Older adults face numerous barriers to exercise, including physical fatigue and pain [19,20], psychological concerns and low confidence [21,22], and unsafe or unsuitable spaces in their communities [16,23]. Lack of sustained support and encouragement also makes it difficult for many older adults to maintain long-term exercise [19]. These issues suggest that more flexible interventions that can adapt to individual needs are needed to help older adults cope with physical, psychological, and environmental challenges.

To address these challenges, technologies such as virtual reality (VR), augmented reality (AR), and mixed reality (MR), collectively referred to as extended reality (XR) technology, have been proposed as a potential means of increasing the frequency and accessibility of physical activity among older adults. XR interventions also contain key features such as immersive environments, real-time interactive feedback, and gamification [24-26]. Some studies have reported that VR helps older adults better control blood sugar, improve motor function, and enhance emotional health [25,27,28]. In addition, studies have shown that group activities based on VR decrease loneliness among older adults and increase their enthusiasm and initiative for exercise [29,30]. AR and MR applications support mobility and balance training and are particularly suitable for older adults in institutional care [31,32]. Even though these results are encouraging, most XR-based exercise programs are short-term. Their main goal is to test the usability of the technology, rather than exploring how to sustain long-term behavioral changes [33,34]. Current XR device designs often overlook the needs of older users, leading many to experience difficulties and frustration. Interfaces may be too complex, visuals too intense, or the space required may exceed what their home can provide [35-38].

Since most XR interventions lack long-term planning, service design has gained attention as a way to build more sustainable solutions. It provides a flexible framework to connect user needs, coordinate stakeholders, and maintain consistent experiences over time [39,40]. User journey mapping [41,42], service blueprints [43], and co-creation methods [44] offer ways to identify behavioral touchpoints, track drop-off moments, and target interventions towards a dynamic user experience (UX). However, in many XR exercise studies, service design approaches are often applied in the early design or prototyping stages and rarely receive ongoing support during implementation and evaluation [45,46]. As a result, UXs become fragmented, and behavioral insights are not fully leveraged across the intervention process.

This review responds to existing gaps by taking a service design perspective to explore XR-based physical activity programs for older adults. Adherence is not treated as a fixed individual outcome, but as a dynamic process influenced by ongoing design efforts, emotional involvement, and multisystem collaboration [40,47]. This review adopts the TiSDD (This is Service Design Doing) framework [40] to analyze how service design methods contribute to each phase of XR interventions. The framework includes a 4-stage process covering research, ideation, prototyping, and implementation. Drawing on insights from participatory methods, user-centered design, and health service research, this review examines how sustained adherence is supported and identifies challenges arising from fragmented services. It further informs the development of XR interventions that are attuned to both the needs of older adults and the full exercise engagement cycle.

This review focuses on three core questions:

1. What kinds of service design strategies have been used in XR-based exercise programs for older adults?
2. In what ways are these tools applied to support continuity and improve the user experience throughout the intervention process?
3. What types of adherence outcomes have been observed in these interventions?

Methods

Study Design

This study conducted a systematic review to synthesize diverse research, focusing on how XR-based exercise interventions for older adults can address exercise adherence through service design strategies. This review followed the transparent, structured process of the PRISMA (Preferred Reporting Items

XSL•FO
RenderX

for Systematic Reviews and Meta-Analyses) guidelines (Multimedia Appendix 1) [48] to ensure reproducibility and methodological rigor.

Eligibility Criteria

Studies were included if they met all of the following criteria: (1) they enrolled participants with a mean age of older than 50 years—this standard is based on the World Health Organization's definition of older people in resource-limited settings, where life expectancy is generally shorter [49]; (2) they focused on XR-based interventions involving physical activity, exercise, or rehabilitation; (3) they reported the use of at least one service design method (eg, personas, cocreation, user journey mapping, user-centered design, or participatory design) during the development or implementation of the intervention; (4) they reported outcome data related to exercise adherence, including at least one of the following dimensions: frequency, duration, intensity, or accuracy of exercise performance; and (5) they used or proposed quantitative, qualitative, or mixed method evaluation strategies, with evidence of feasibility, usability, or preliminary outcomes.

Studies were excluded if they met any of the following conditions: (1) they focused solely on cognitive training or entertainment without an exercise component; (2) they did not include older adults as the primary target population; or (3) they were editorials, commentaries, opinion pieces, or lacked sufficient methodological detail or relevance to the research question.

Information Sources and Search Strategy

A structured search was conducted across 6 academic databases: PubMed, Scopus, Web of Science, CINAHL, PsycINFO, and the ACM Digital Library. The search strategy combined Boolean operators and thematic clusters covering: XR technologies ("virtual reality" OR "augmented reality" OR "mixed reality" OR "extended reality" OR "immersive technology"), service design methods ("service design" OR "user journey" OR "journey mapping" OR "experience map" OR "co-design" OR "participatory design" OR "user-centered design" OR "human-centered design"), and the target population and activity ("older adult" OR "elderly" OR "geriatric" AND "exercise" OR "physical activity" OR "rehabilitation"). Searches were limited to peer-reviewed papers published in English between January 2020 and July 2025. Full-text availability was required for eligibility assessment and data extraction; records for which the full text could not be accessed were excluded at the screening stage. Gray literature sources and trial registries were not systematically searched, as this review focused on peer-reviewed studies that provided sufficient methodological detail on service design activities and XR intervention implementation. The full database-specific search strategies are detailed in Multimedia Appendix 2.

Study Selection

All retrieved records were imported into a Zotero library (version 7.0.24; Corporation for Digital Scholarship), and duplicates were removed. Two independent reviewers (JN and SW) screened the titles, abstracts, and full texts of the remaining papers against the predefined inclusion and exclusion criteria. Discrepancies were resolved through discussion; if consensus could not be reached, a third reviewer (YY) was consulted.

Data Extraction and Management

Data extraction was performed using a standardized Microsoft Excel 2021 spreadsheet to ensure consistency across studies. Two reviewers independently extracted data on study characteristics, service design strategies, UX, and adherence outcomes. Discrepancies were resolved through discussion until consensus was reached. To classify the application stages of service design strategies, this study adopted the TiSDD framework [40]. Table 1 summarizes the definitions and typical activities of each stage, which served as the reference for coding service design applications in the included studies.

Table 1. Service Design Stages Defined by the TiSDD (This is Service Design Doing) framework.

Stage	Description	Typical activities
Research	Understanding users, behaviors, and context	Ethnography, interviews, observation, participatory workshops, and data analysis
Ideation	Generating, refining, and prioritizing concepts	Brainstorming, clustering, voting, and decision matrices
Prototyping	Developing and testing service concepts	Storyboarding, role-playing, mock-ups, and digital/physical prototypes
Implementation	Deploying and managing interventions	Change management, technical development, training, and monitoring

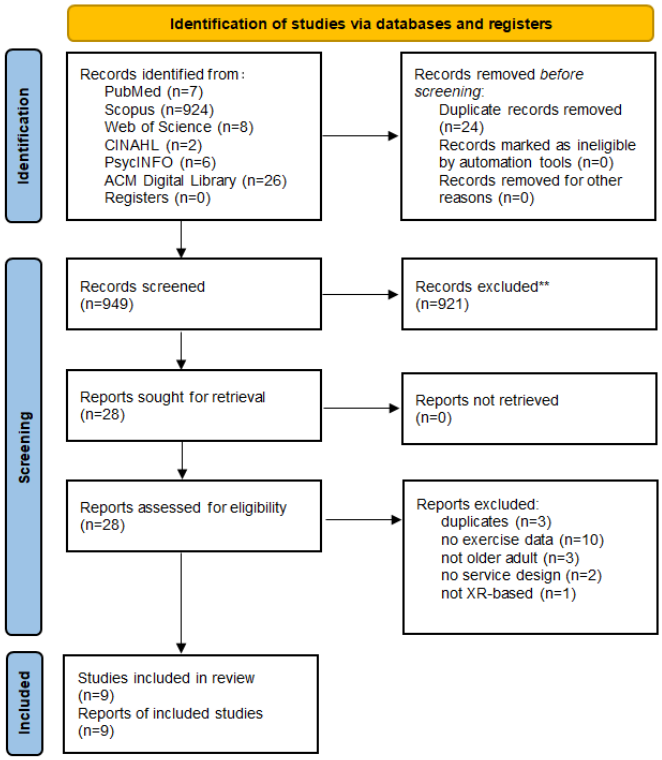
Data Synthesis

Data synthesis was organized around 3 research questions and divided into 4 sections, including study characteristics, service design outcomes, UX outcomes, and adherence outcomes. This thematic framework enabled a narrative synthesis that examined how service design tools were used, how they supported continuity and UX, and what types of adherence outcomes were reported.

Quality Assessment

To assess the quality of the studies, critical appraisal was conducted using the Mixed Methods Appraisal Tool (MMAT; version 2018; McGill University) [50]. The MMAT is a specially designed tool that can be used to assess the quality of different types of studies in the same review, including qualitative, quantitative, and mixed methods studies. The quality of all studies was assessed by the first reviewer (JN) and checked for accuracy by 2 other authors (YY and SW). In line with

XSL•FO
RenderX



MMAT guidance, the tool was not used to score or exclude studies, but to support the interpretation of the findings [50].

Results

Sample

The total number of identified records was 973. After duplicates were removed, 949 records remained, and these were screened for title and abstract relevance. The number of excluded studies after title and abstract screening was 921. The full texts of the remaining 28 papers were read and analyzed, of which 19 were excluded due to factors such as the absence of exercise-related data, duplication, non–older adult populations, lack of service design elements, or lack of XR-based interventions. As a result, 9 studies were included in the final review (Figure 1).

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) 2020 flow diagram of the study selection process.

Study Characteristics

This review included 9 studies published between 2020 and 2025, conducted across 9 countries: Italy, Portugal, the Netherlands, the United Kingdom, Germany, Spain, Canada, Cyprus, and China. Of the 9 studies, 67% (6/9) were mixed methods designs [51-56], 11% (1/9) was a mixed methods study with an embedded randomized controlled trial [57], 11% (1/9) was a quasi-randomized controlled trial [58], and 11% (1/9) was a nonrandomized quantitative study [59]. A total of 242 participants were involved across all studies, with sample sizes ranging from 6 to 75. The mean age of participants ranged from 52.8 to 86.8 years. A total of 89% (8/9) included both male and female participants [51-54,56-59], while 11% (1/9) did not report gender information [55].

All 100% (9/9) studies used VR as the XR modality [51-59]. A total of 67% (6/9) of studies reported specific XR headset models [51-53,55,56,58], while 33% (3/9) did not specify the hardware used [54,57,59]. A total of 78% (7/9) of studies described the XR interaction modality [51,52,54-58], whereas 22% (2/9) did not report interaction details [53,59]. A total of 100% (9/9) of studies reported some form of XR supervision and support during intervention delivery [51-59]. A total of 33% (3/9) of studies reported information on XR cybersickness or tolerability [51,54,55], while 67% (6/9) did not report tolerability-related data [52,53,56-59].

Exercise types included 44% (4/9) upper limb rehabilitation interventions [51,52,55,56], 22% (2/9) gait or balance training [54,58], 11% (1/9) lower limb training [57], 11% (1/9) adapted physical activity [59], and 11% (1/9) multidomain physical-cognitive rehabilitation [53].

Intervention settings included 44% (4/9) hospital-based studies [51-53,57], 11% (1/9) university or research laboratory [58], 11% (1/9) biomedical research institute [54], 11% (1/9) long-term care residence [56], and 11% (1/9) home-based environment [55], 11% (1/9) study used a mixed-setting intervention across nursing homes, hospitals, and home environments [59] (Table 2).

[a]XR: extended reality.

[b]F: female.

[c]M: male.

[d]VR: virtual reality.

[e]Quasi-RCT: quasi–randomized controlled trial.

[f]RCT: randomized controlled trial.

Quality Assessment of the Studies Included

Based on the MMAT assessment, the overall methodological quality of the included studies was acceptable.

Most studies demonstrated adequate quality across their respective methodological domains. The qualitative components generally met MMAT criteria, showing appropriate study design, data collection, and coherence between data, analysis, and interpretation.

Among quantitative studies, one randomized controlled trial met all MMAT criteria. Several nonrandomized studies showed limitations related to confounding, as confounders were not clearly accounted for in the study design or analysis.

Most mixed methods studies provided a clear rationale for using a mixed methods design and demonstrated integration between qualitative and quantitative components. However, some studies showed limited methodological transparency, reflected by “can’t tell” ratings on selected MMAT criteria.

No studies were excluded on the basis of quality appraisal. Detailed MMAT ratings for each study are provided in Multimedia Appendix 3 [51-59].

Service Design Outcomes

Service Design Tools and Strategies

Across the 9 included studies, service design strategies were predominantly grounded in participatory, co-design, and user-centered approaches. A total of 4 (44%) studies applied participatory design [52,56,57,59], 2 (22%) studies adopted co-design [51,53], 1 (11%) study used collaborative design [58], 1 (11%) study adopted user-centered design [54], and 1 (11%) study explicitly combined participatory and user-centered methods [55].

Stakeholder involvement demonstrated a multistakeholder pattern in most cases. All studies (9/9, 100%) involved older adults [51-59], 8 (89%) studies engaged rehabilitation professionals such as physical therapists, rehabilitation physicians, or kinesiologists [52-59]. Five (56%) studies involved technical and design experts [51,52,54,55,58], 4 (44%) studies included medical staff such as physicians, nurses, or paramedical professionals [51,53,54,59], and 1 (11%) studies engaged caregivers or community staff [59]. In total, 7 (78%) studies incorporated 3 or more stakeholder groups [51-55,58,59], reflecting a predominant emphasis on collaborative development across clinical, technical, and end user perspectives (Table 3).

XSL•FO
RenderX

Table 3. Service design tools and applications across service stages.

Author (year)	Service design strategy	Stakeholder groups involved	Application stage (TiSDD[a] model: research/ideation/prototyping/implementation)	Service design activities and functions
De Luca et al [59], (2025)	Participatory design	Older adults, caregivers, therapists, communities, and clinicians.	Research + Prototyping: Participatory design was used to engage older adults, caregivers, therapists, and other stakeholders to identify user needs and define goals (Research), iteratively refined the system prototype based on user feedback during development (Prototyping).	Service design activities structured adapted physical activity services for older adults in nursing homes and home settings by defining service workflows and delivery scenarios, positioning the VR[b] system as part of an integrated service rather than a standalone technology.
Sweeney et al [53], (2025)	Cocreation	Older adults with stroke, physicians, nurses, and therapists.	Implementation: The intervention was deployed, managed, and monitored in a real-world hospital ward environment.	Service design activities structured a multitechnology, group-based rehabilitation exercise service within an acute stroke unit by configuring service workflows, defining staff and patient roles, and integrating multiple rehabilitation technologies into a supervised group delivery model.
Ciemer et al [58], (2025)	Collaborative	Older adults, expert groups from the domains of Human Movement Science, Experience Design, and Game Design.	Research + Prototyping: User needs were identified through involvement of target users (Research), and the EXploVR prototype was developed and iteratively tested by a multidisciplinary team together with older adults (Prototyping).	Service design activities structured EXploVR as a supervised, community-oriented fall-prevention service by defining training workflows, staff roles, spatial and safety arrangements, and designing the intervention to support relevance to daily-life mobility and participation for older adults.
Bosch-Barceló et al [54], (2024)	User-centered design	Older adults with Parkinson disease, physiotherapists, nurses, and computing scientists.	Research + Prototyping + Implementation: Initial user needs were collected through feedback and expert interviews (Research), software was developed and validated using the Scrum method (Prototyping), and implementing the intervention in a real world setting and collecting feedback (Implementation).	Service design activities structured a supervised, technology-supported gait rehabilitation service by defining session workflows, physiotherapists and patient roles, safety arrangements, and progression rules, integrating a gamified VR environment into routine physiotherapy-led delivery.
Mehrabi et al [55], (2022)	Participatory and user-centered design	Older adults with no or mild cognitive impairment, exercise professionals, game designers, engineers from human factors and assistive technology fields, and a local VR studio.	Research + Prototyping: An extensive user-centered and participatory design process was applied, involving stakeholders including older adults, exercise professionals, game designers, and assistive technology experts (Research). The system was iteratively refined based on user feedback (Prototyping). The paper did not detail each phase separately.	Service design activities structured a remotely delivered home-based VR exercise service by defining session workflows, participant and staff roles, and remote onboarding and support procedures, enabling older adults to safely engage in a 6-week exergame intervention outside clinical settings.
Matsangidou et al [51], (2022)	Co-design	Older adults with dementia, medical and paramedical staff, Human-Computer Interaction (HCI) in health care experts.	Research + Ideation + Prototyping: Needs and barriers were identified through focus groups (Research), followed by concept generation and prioritization through workshops and brainstorming sessions (Ideation), and then rapid prototyping and testing with user feedback (Prototyping).	Service design activities structured a supervised VR-based physical training service for people living with dementia by defining session workflows, therapist-patient roles, safety and calibration procedures, and integrating VR into routine care delivery within a restricted hospital environment.
Matsangidou et al [52], (2023)	Participatory design	Older adults with dementia, physiotherapist, human-computer interaction (HCI) researcher.	Prototyping: The intervention applied the RITE rapid prototyping method, using observation notes and semistructured interviews to iteratively refine the system (Prototyping).	Service design activities structured a personalized, therapist-supported VR rehabilitation service for seated upper-body physical training for people living with dementia, by defining calibration-based exercise workflows, therapist monitoring roles, and adaptive feedback mechanisms to support safe and independent task execution in clinical settings.

XSL•FO
RenderX

Author (year)	Service design strategy	Stakeholder groups involved	Application stage (TiSDD[a] model: research/ideation/prototyping/implementation)	Service design activities and functions
Eisapour et al [56], (2020)	Participatory design	Older adults with dementia, exercise therapists, and kinesiologists.	Research + Prototyping: User needs were gathered through focus groups and observations (Research), and the prototypes were refined iteratively based on user feedback (Prototyping).	Service design activities structured dementia-friendly VR exercise delivery by co-designing with therapists and people living with dementia, iteratively refining 2 VR exercise environments, and embedding safety and accessibility supports (eg, audio guidance and individualized calibration) for seated upper-body training in long-term care.
Xu et al [57], (2021)	Participatory design	Older adults with stroke, physical therapists, and rehabilitation physicians.	Research + Prototyping + Implementation: Design inputs were collected from stroke patients, therapists, and physicians (Research); the game prototype was refined based on feedback to improve usability (Prototyping); and the final version was tested in a hospital rehabilitation ward with evaluations from multiple stakeholder perspectives (Implementation).	Service design activities structured a therapist-supervised VR service for poststroke lower-limb rehabilitation by translating stepping- and gait-training protocols into adjustable Stomp-Joy–based game tasks, and embedding role-based clinical workflows for session prescription, progression control, and safety supervision.

[a]TiSDD: This is Service Design Doing.

[b]VR: virtual reality.

Application Across Service Stages

The coverage of service design stages demonstrated apparent variation (Table 3). Seven of 9 (78%) studies applied the Research stage, identifying user needs and design elements through interviews, focus groups, or on-site observations [51,54-59]. One (11%) study addressed the Ideation stage, using workshops and brainstorming sessions to generate and prioritize concepts [51]. Eight (89%) studies engaged in the Prototyping stage, improving the usability and interaction experience of the system through rapid prototyping or RITE methods [51,52,54-59]. Three (33%) studies entered the implementation stage, deploying and managing the system in hospital, biomedical research, or rehabilitation ward settings [53,54,57].

Regarding stage coverage, 2 (22%) studies were single-stage [52,53] and focused exclusively on Implementation or Prototyping. A total of 7 (78%) studies were multistage, involving 2 or more phases [51,54-59]. Among these, 4 (44%) studies adopted a 2-stage process from the Research to Prototyping stage, enabling user needs to be identified and rapidly translated into iterative prototypes [55,56,58,59]. Two (22%) studies implemented a 3-stage combination of Research, Prototyping, and Implementation [54,57], 1 (11%) followed a 3-stage process covering the sequence of Research, Ideation, and Prototyping [51]. Notably, no study completed all 4 stages of the TiSDD model.

Across the included studies, service design activities were primarily used to configure how XR interventions functioned as services in real-world care contexts. Specifically, service design activities [51-59] were used to (1) define service workflows and delivery scenarios, (2) clarify roles and responsibilities of patients, therapists, and staff, and (3) integrate XR systems into existing rehabilitation, care, or home service structures (Table 3).

User Experience Outcomes

The included studies evaluated UX using 5 methods. Five of the 9 (56%) of studies used standardized usability questionnaires, such as System Usability Scale, The Single Ease Question, Simulator Sickness Questionnaire, Questionnaire for User Interaction Satisfaction, and NATU Quest (Assistive Technology Usability Questionnaire for people with Neurological diseases), to assess system usability and task difficulty [51,52,54,55,59]. Five of the 9 (56%) studies evaluated emotional and immersive experience through tools like Flow Short Scale, Physical Activity Enjoyment Scale, Exergame Enjoyment Questionnaire, Physical Activity Affect Scale, Visual Analogue Scale, Observed Emotion Rating Scale, and Slater-Usoh-Steed Questionnaire [51,52,55,56,58]. Two of the 9 (22%) studies captured motivation and engagement using the intrinsic motivation inventory and a 4-point engagement scale [56,57]. Two of the 9 (22%) of studies examined self-efficacy and safety perceptions using tools such as ABC-6/8, the Bandura scale, and custom safety items [55,58]. Six of the 9 (67%) studies used qualitative feedback methods, including interviews and open-ended forms [52-57].

Participants generally reported a positive UX. Five of the 9 (56%) studies reported that interventions were enjoyable and immersive, with participants frequently highlighting high levels of engagement and emotional benefits [51,52,54,56,58]. Three of the 9 (33%) of studies indicated perceived usefulness and value for rehabilitation, with self-report measures reflecting strong motivation and recognition of exercise benefits [55,57,59]. Two of the 9 (22%) studies included feedback from clinical staff who found the interventions both feasible and encouraging [53,57]. They highlighted outcomes such as increased patient confidence, improved mood, and reduced staff workload. However, 33% (3/9) of studies also pointed to negative aspects, including fatigue, discomfort from wearing head-mounted displays, and a decrease in enjoyment during cognitively demanding or extended sessions [51,54,57] (Table 4).

Table 4. User experience (UX) outcomes.

Author (year)	UX measurement method	UX feedback
De Luca et al [59], (2025)	QUIS7[a]-based questionnaire (5-point Likert)	76.7% (58/75) reported positive experience, 68.5% (51/75) were satisfied, 65.8% (49/75) found it useful.
Sweeney et al [53], (2025)	Staff interviews (qualitative)	Clinical staff considered the intervention acceptable, reporting that it improved patients' confidence, mood, and motivation for rehabilitation, while also alleviating staff workload.
Ciemer et al [58], (2025)	FKS[b], PACES-S[c], EEQ[d], ABC-6/8[e], custom questions on confidence	High levels of enjoyment (FKS, PACES, EEQ scores high and stable); participants reported the training as enjoyable, immersive, meaningful, and safe, with reduced fear of falling.
Bosch-Barceló et al [54], (2024)	SUS[f], NATU Quest[g], SSQ[h], user feedback	High satisfaction reported. participants preferred natural environments (countryside, forest), found the experience pleasant and immersive, and appreciated the dog design as reassuring and the environments as realistic. Some participants noted that fog and high speeds reduced enjoyment. Although they reported fatigue, the system was generally acceptable and motivating.
Mehrabi et al [55], (2022)	Ad hoc usability and game UX questionnaire, 5-point pictorial Likert enjoyment scale, PAAS[i], Bandura self-efficacy scale, semi-structured interviews	Positive UX: high satisfaction, usability, and immersion; high enjoyment (Likert); interviews show game is engaging and feasible; PAAS indicates positive emotions; self-efficacy supports future exercise intention.
Matsangidou et al [51], (2022)	OERS[j], VAS[k], VRSQ[l], SUS, SEQ[m]	FIVR[n] significantly increased positive affect (higher OERS scores), reduced sadness and anxiety; patients reported the training to be more enjoyable, immersive, and emotionally positive; SIVR[o] was better than conventional training but less effective than FIVR; some patients remained sensitive to wearing the HMD[p].
Matsangidou et al [52], (2023)	SUS, SEQ, OERS, VAS, task performance, and interviews	In the final prototype, significant improvements were observed in presence and usability (with SUS and SEQ scores significantly increased); participants showed increased positive emotions (pleasure) and reduced negative emotions (such as sadness, anxiety, anger); observation notes and interviews indicated that VR training elicited feelings of enjoyment, interest, and self-identification (eg, perceiving the training as more relevant to their personal context and natural to perform).
Eisapour et al [56], (2020)	Daily and weekly questionnaires (5-point Likert), 4-point engagement scale, interviews, open-ended feedback, and expert reviews.	Participants generally reported enjoying the VR experience, finding it relaxing and enjoyable, with high immersion, comfort, and usability; some expressed a preference for more challenging tasks or more variety rather than repeating the same movement.
Xu et al [57], (2021)	IMI[q] questionnaire (5 dimensions), semistructured interviews	Patients reported high scores in interest/enjoyment, perceived competence, and value/usefulness on the IMI questionnaire, indicating high engagement and perceived benefits of the game. However, it was noted that interest may decline with long-term use and that the system lacked a recording mechanism. Both patients and clinicians considered the experience pleasant and motivating.

Exercise Adherence Outcomes

This review analyzed exercise adherence outcomes reported across the included studies. Given the heterogeneity in adherence definitions and measurement approaches, no conversion or standardization of adherence metrics was performed. Instead, adherence outcomes were synthesized by grouping indicators according to their underlying behavioral constructs, allowing comparison within similar categories while highlighting dimensions that remain underevaluated.

Attendance-based adherence indicators were the most consistently reported. Five of the 9 (56%) studies reported attendance-related indicators, including completion and dropout rates, with completion rates ranging from 80% to 100% and dropout rates varying between 2% and 13% [53,55-58]. In this review, references to “high adherence” were primarily derived from attendance-related indicators, as these were the most frequently and consistently reported measures across studies.

Performance-based adherence indicators were reported less consistently and captured different aspects of task execution and progression. Four of the 9 (44%) of studies monitored exercise accuracy, including task precision, movement quality, and success rates through in-game metrics or trajectory tracking systems [51,52,54,56]. Furthermore, 33% (3/9) of studies discussed performance progression across sessions, including observed improvements or declines in task success rates and response times [52-54].

Self-reported adherence indicators were the least frequently reported. One of the 9 (11%) studies assessed self-reported perceptions of adherence, with 65.8% (49/75) of participants indicating that the system supported their physical activity routines [59].

Across the 4 core adherence components synthesized in this review, including frequency, duration, intensity, and accuracy [60]. Seven of the 9 (78%) of studies clearly defined exercise frequency [51,52,54-58]. Furthermore, 89% (8/9) of studies reported the duration of exercise, including both session length and program length [51-58]. Three of the 9 (33%) studies addressed exercise intensity [55,56,59]. Four of the 9 (44%) of studies captured the accuracy of exercise performance [51,52,54,56]. None of the studies included long-term follow-up to assess sustained exercise adherence.

No studies were excluded from the review due to unclear adherence reporting; however, the variability and incompleteness of adherence measures limited cross-study comparability and constrained conclusions regarding long-term adherence (Table 5).

XSL•FO
RenderX

Table 5. Exercise adherence outcomes.

Author (year)	Exercise protocol (planned dose)	Exercise adherence indicators	Exercise adherence results	Follow-up
De Luca et al [59], (2025)	6-week program	IPAQ-SF MET[a] value (quantitative), IPAQ-SF[b] activity level classification (inactive/active), self-reported improvement in physical activity adherence.	No significant improvement in overall physical activity levels; 9% (7/75) of participants improved from inactive to sufficiently active; 65.8% (49/75) agreed and 9.6% (7/75) strongly agreed that VR2Care improved adherence to physical activity.	Not reported
Sweeney et al [53], (2025)	Duration not specified	Session attendance, training duration, task completion rate, performance progression.	On average, each patient completed 9.1 sessions (SD 7.4) during hospitalization, with a total rehabilitation time of 508.4 minutes (SD 521.2) and an average of 52.0 minutes per session (SD 15.7). Patients achieved an additional 52 minutes of rehabilitation per day prior to discharge. Dropout rate was low (1/60, 2%).	Not reported
Ciemer et al [58], (2025)	3-week program; 2 sessions per week; 60 minutes per session; total of 6 sessions	Adherence was tracked through an attendance log recorded at each session.	A total of 32 participants completed the study, with 16 in the intervention group and 16 in the control group. A total of 6 participants dropped out during the study (intervention group: n=4; control group: n=2), resulting in an overall dropout rate of only 13% (4/32).	Not reported
Bosch-Barceló et al [54], (2024)	3 sessions; 1 session per week; each session included treadmill warm-up and 4 bouts of gait training with rest intervals; total session duration approximately 20-21 minutes	Obstacle avoidance performance (success rate in each bout across 3 different difficulty environments).	Obstacle avoidance performance improved during the training phases, with better performance after familiarization on Day 1; performance slightly decreased on Days 2 and 3 as difficulty increased, but overall remained satisfactory.	Not reported
Mehrabi et al [55], (2022)	6 weeks; 3 sessions per week; 15-20 minutes per session	Session adherence rate; gameplay metrics.	The authors anticipated an adherence rate of ≥80%. Gameplay performance metrics were automatically recorded to assess participation.	Not reported
Matsangidou et al [51], (2022)	3 experimental sessions; each lasting approximately 30 minutes	Task accuracy (number of correctly performed repetitions out of 10), task independence (number of therapist interventions required), completion time (seconds), movement quality (match with baseline movements).	Under the FIVR[c] system, patients demonstrated higher task accuracy, greater independence, and better movement quality; the time required for simple movements (Side Arm Raise) was shorter, and although the time for complex movements (Overhead Press) was longer, accuracy improved.	Not reported
Matsangidou et al [52], (2023)	3 iterations of RITE[d] testing; each iteration approximately 30 minutes, including up to 20 minutes of VR[e] exposure	Task completion rate, task independence score, execution time, movement trajectory error.	Over the 3 prototype iterations, task completion and independence significantly improved, execution time decreased, and movement trajectories became closer to the target, indicating progressively improved exercise adherence.	Not reported
Eisapour et al [56], (2020)	3-week program; 5 sessions per week; ≈20 minutes per session	Completion rate (whether all exercises were completed), range of motion (reach), movement distance, velocity.	All participants completed all scheduled VR exercise sessions (6/6, 100% completion); exercise performance (range of motion, distance, velocity) was comparable to therapist-led exercise, with no significant differences; participants perceived VR exercise workload as adequate and comparable to therapist-led sessions.	Not reported
Xu et al [57], (2021)	2-week program; 5 sessions per week; VR training (30 minutes) combined with conventional physical therapy; total of 10 sessions	Intervention attendance/dropout rate; number of completed sessions during the intervention period.	Of the 24 participants, 2 withdrew—one due to a fall during training, without injury, and one for personal reasons.	Not reported

Discussion

Principal Results

This review synthesized evidence from 9 XR-based exercise interventions targeting older adults and revealed a field that was promising yet constrained by structural and methodological limitations. Most studies grounded their service design strategies in participatory, co-design, and user-centered approaches [51-57,59], frequently combined with iterative prototyping [51,54-59]. However, service design processes were often incomplete, with most studies concentrating on early research and prototyping stages, showing limited engagement in ideation [51] and progression to implementation. Only 3 studies progressed to the Implementation stage [53,54,57]. Although multiple stakeholders were involved and participatory principles were widely adopted, their contributions were largely confined to early-stage design decisions and usability refinement, rather than extended to shaping long-term service integration or delivery models. This uneven coverage across service stages constrained the translation of interventions into sustained service offerings. When interpreted through behavior change frameworks such as Capability, Opportunity, Motivation–Behavior [61] and behavior change techniques [62], the limited continuity of service design across later stages helps explain why sustained exercise behavior was rarely examined. While early-stage co-design and prototyping supported initial engagement and motivation, fewer interventions addressed opportunity-related factors, such as integration into everyday contexts, reinforcement strategies, and long-term support mechanisms, which are essential for maintaining behavior over time.

UX outcomes were generally positive. Participants reported pleasant experiences, high levels of immersion, and increased motivation in questionnaires, usability evaluations, and interviews. However, some studies also noted negative adverse effects, such as fatigue, headset discomfort, and decreased enjoyment during challenging or long tasks [51,54,57]. Overall, most evaluations relied on subjective reports, with limited use of objective measures, such as physiological or behavioral data. This reliance on self-reported short-term experience indicators limits the extent to which positive UX can be interpreted as evidence of sustained engagement. While enjoyment and immersion appear effective in supporting initial participation, the lack of longitudinal and objective measures constrains understanding of how these experiences translate into continued exercise behavior over time.

Most studies reported high levels of exercise adherence, though inconsistently across dimensions, despite the use of a 4D adherence framework [60] in our synthesis; few studies comprehensively reported across all dimensions. Frequency and duration were the most reported measures of exercise adherence; however, few studies compared them with established exercise guidelines. Most studies conducted minimal monitoring of exercise intensity, and only 1 applied validated physiological measurement. While some VR systems included metrics related to movement accuracy, the studies did not integrate these metrics into the formal outcome framework for exercise adherence. This fragmentation of adherence dimensions impeded cross-study comparison and masked the contribution of specific design features to behavioral engagement. Most studies assessed exercise adherence using non-standardized, short-term measures. Attendance and task completion were the most commonly used surrogate measures of adherence; some studies also reported adherence through in-game performance metrics, performance progression over time, or self-reported perceptions of adherence, but none adopted a standardized long-term assessment framework. As a result, the consistently high adherence rates reported across studies should be interpreted cautiously, as they primarily reflect short-term participation rather than sustained exercise continuity. The absence of standardized, multidimensional, and longitudinal adherence assessments limits insight into whether engagement persisted beyond the intervention period.

Notably, 8 studies conducted interventions in hospital, laboratory, or long-term care settings [51-54,56-59], and 1 study conducted its intervention at home [55], with no studies implementing community-based deployment, highlighting a critical gap for real-world scalability. The traditional health management model mainly relied on hospital or home-centered interventions, and the increasing demand for population aging and chronic disease management posed greater challenges to this model [63-65]. In contrast, community-based health management was considered a sustainable strategy that could provide convenient, long-term services and promote healthy behaviors among older adults [66,67]. Community and group-based programs provide social interaction, emotional support, and a sense of belonging, which reduce isolation and strengthen psychological stability [16,22]. Community XR interventions also faced some challenges in resource sharing and management. Community-based XR exercise often requires multiple participants to share equipment, space, and network resources. However, most community spaces lacked the specialized infrastructure necessary to support immersive exercise programs, including adequate physical space, stable power supply, network connectivity, and safety facilities [68]. This created unresolved issues such as shared use time arrangements, equipment maintenance, and technical assistance training for community staff [68,69]. For community XR projects to be truly implemented, they also need the support of policies and management mechanisms [70]. For example, by optimizing community resource allocation and conducting technical personnel training, practical problems such as equipment sharing and insufficient infrastructure can be addressed [71].

The dominance of controlled environments in the reviewed studies, therefore, limits the interpretation of continuity and scalability outcomes. While such settings support feasibility testing and supervised delivery, they do not reflect the operational conditions under which older adults engage in exercise in everyday community contexts, making it difficult to assess whether XR-based interventions can be sustained beyond experimental or clinical settings.

XSL•FO
RenderX

Comparison With Prior Work

The findings of this study aligned with broader existing evidence. With the application of technology-assisted interventions in the field of rehabilitation and exercise for older adults, participatory methods and user-centered design principles were gradually integrated into the entire process of intervention development [72,73]. This trend also appeared in VR rehabilitation and digital health projects, where researchers generally emphasized the widespread application of participatory design and rapid prototyping design [35]. However, our synthesis identified a critical difference: early creative ideation and comprehensive multi-stage service design remained underused. Most studies adopted fragmented design processes without forming a closed loop between service design and adherence monitoring, which limited the ability to anticipate long-term engagement barriers and optimize real-world implementation.

Several studies confirmed that immersive VR interventions provided positive feedback to older adults, including heightened feelings of pleasure, increased willingness to participate in activities, and improved emotional well-being [74,75]. However, some studies reported side effects, such as fatigue, mild physical discomfort, or sensitivity to the headset after the intervention [76,77].

High short-term adherence appeared consistent with prior findings on gamified VR engagement [26,78]. However, this adherence pattern likely resulted from 2 limitations: first, the intervention duration was insufficient, and second, the adherence assessment did not form a standardized indicator, but rather participants achieved a real and sustained change in behavior. In interdisciplinary research practice, standardized compliance assessment played a crucial role. It bridged definitional gaps across disciplines, enabled unified evaluation criteria, and offered standardized measurement tools for longitudinal tracking [60,79]. Furthermore, due to the lack of follow-up data, researchers could not determine whether such adherence persisted beyond the short term [80].

However, a critical underexplored dimension in prior work and our synthesis concerned the setting of implementation. Existing research suggested that implementing XR intervention in community settings could support social interaction, emotional regulation, and behavioral improvement [81-83]. However, most studies focused on hospitals, laboratories, and care facilities. This narrow setting focus weakened the ecological validity of research findings and hindered a comprehensive evaluation of the long-term sustainability of interventions. Integrating XR into community programs could have improved accessibility, peer support, and emotional connection; however, this remained an overlooked area in current research.

Limitations and Future Research

This review had some limitations. First, the number of studies included in the analysis was relatively small, and the sample size of most individual studies was also small. More importantly, the studies showed pronounced heterogeneity in design, baseline characteristics of participants, and intervention implementation processes. These differences not only reduced the statistical power of the overall analysis but also limited the generalizability of the research conclusions. In addition, restricting inclusion to studies with accessible full texts may have excluded relevant work based on access rather than content, introducing potential selection bias; gray literature and trial registries were not systematically searched, which may have resulted in the omission of unpublished or ongoing studies. Second, none of the included studies established longitudinal follow-up links, which made it impossible to determine whether the short-term participation adherence translated into long-term behavioral change or functional improvement. Third, regarding intervention settings, most studies focused on hospitals, care facilities, or laboratory environments. In contrast, empirical evidence from community or home settings remained relatively limited, which also weakened the applicability of the findings to real-life scenarios. Finally, although this review adopted an XR-oriented scope, all included studies used VR interventions, reflecting the current concentration of evidence rather than an intentional focus on VR, and exploration of AR or MR modes remained relatively limited. Studies applying AR or MR technologies were identified in the broader literature and have demonstrated positive physical or cognitive outcomes among older adults [84,85]; however, these approaches have not yet been systematically examined within service design-oriented frameworks. The limitations of this technology exploration made it difficult to reveal the comparative advantages of different XR methods in terms of accessibility, usability, and situational adaptability, which affected the comprehensive understanding of the overall application value of XR technology.

To address the shortcomings of current research, future studies should adopt standardized, multidimensional adherence assessment metrics [60]. By establishing unified assessment dimensions and criteria, these metrics could resolve inconsistencies caused by variations in measurement and provide a stable foundation for long-term follow-up studies. Exploration of community-based interventions should be strengthened, with designs that closely mirror real-world exercise environments to address contextual barriers to adaptation effectively. Furthermore, service design tools such as user journey maps should be incorporated into the intervention process, leveraging their visualization capabilities to identify potential dropout risk points at each stage of the intervention, providing a concrete reference for iterative optimization of intervention plans. In parallel, multimodal tracking systems should be developed that integrate physiological data collected by wearable devices, participant behavioral logs, and in-game performance metrics. These systems should generate adaptive feedback to provide participants with more personalized support for interventions. Finally, future research should expand its technological scope by exploring AR and MR modalities and evaluating their potential for more inclusive and ecologically valid exercise interventions.

Conclusions

This review systematically evaluated how XR-based exercise interventions for older adults incorporated service design strategies to support exercise adherence. Although participatory design and gamified VR experiences have been widely used in related research, most studies have remained fragmented and

XSL•FO
RenderX

short-term. There were clear deficiencies in both the systematic integration of multistage service design processes and the effective incorporation of standardized compliance frameworks; a comprehensive research practice system had not yet been established. Research findings indicated generally high levels of exercise adherence; however, conclusions varied across studies, and few focused on the intensity of adherence, long-term maintenance, or the ecological validity of the findings. Further analysis from the perspectives of intervention setting and technology application revealed that most existing interventions focused on hospital or laboratory settings, whereas the exploration of community settings, as well as the development of other XR modalities such as AR and MR, was relatively limited. To address this gap, future XR intervention research should integrate structured service design tools throughout the intervention lifecycle, develop standardized adherence metrics, establish multidimensional adherence tracking mechanisms, and extend deployment to real-life settings. By promoting synergy among behavioral engagement, service continuity, and situational adaptability, the effectiveness of XR intervention in helping older adults build sustainable exercise habits, while also providing an empirical reference for the innovative development of inclusive digital health services.

Abstract

Background: Social isolation is a prevalent issue among older people in long-term care facilities (LTCFs), with profound negative impacts on their quality of life and mental health. However, the authentic experiences and underlying mechanisms of social isolation among older people in LTCFs remain understudied. A nuanced understanding of these experiences is essential for designing targeted nursing interventions.

Objective: This study aimed to systematically review and synthesize qualitative evidence to explore the experiences of social isolation among older adults in LTCFs and analyze them in terms of causes, mechanisms, outcomes, and strategies.

Methods: A systematic review and qualitative meta-synthesis were conducted. We searched PubMed, Web of Science, Embase, PsycInfo, Cochrane Library, CINAHL, Scopus, Chinese Biomedical Literature Database, CNKI, Wanfang Data, and Weipu (VIP) with no restriction on the start year, up to February 2025. Two reviewers (WL and ZM) independently screened studies, extracted data using a Microsoft Excel spreadsheet, and assessed study quality with the Joanna Briggs Institute Critical Appraisal Checklist for Qualitative Research. Qualitative data synthesis was performed following Thomas and Harden’s thematic and content analysis method, including line-by-line coding of participant quotes, organizing codes into descriptive themes, and developing analytical themes.

Results: A total of 4856 papers were retrieved through systematic searches, and 14 qualitative studies met the inclusion criteria. Four overarching analytical themes were identified: (1) root cause: person-environment mismatch (encompassing 4 interrelated dimensions: imbalance between declining individual capacity and insufficient environmental support, negative self-perception paired with inadequate positive environmental feedback, personal biases conflicting with homogeneous institutional social ecology, and disrupted social roles due to rigid institutional management); (2) overt behavioral patterns: proactive isolation, defensive isolation, and adaptive isolation; (3) inner emotional experiences: feelings of confinement, sorrow, and weariness; and (4) strategies for restoring person-environment match: active engagement in interaction, rational acceptance of coexistence, and passive avoidance and withdrawal. Notably, person-environment mismatch was confirmed as the core mechanism driving the onset and persistence of social isolation in this population.

Conclusions: Person-environment mismatch is the fundamental driver of social isolation among older adults in LTCFs. Interventions should prioritize restoring person-environment alignment—including optimizing physical environments, reconstructing supportive social environments, and enhancing psychological empowerment. Future studies should focus on developing tools to quantify person-environment matching degrees in LTCFs and conduct longitudinal evaluations of targeted interventions to further reduce social isolation and promote active social participation among older people.

Introduction

Population aging is an increasingly prominent global issue, with projections indicating that the number of adults aged 65 years and older will exceed 1.6 billion by 2050—more than double the current figure [1]. Against the backdrop of increasingly declining birth rates and an aging population, faced with practical challenges including family downsizing, regional separation, and a scarcity of community care resources, long-term care (LTC) is in high demand among older people. Given these circumstances, more families are choosing to place older relatives in long-term care facilities (LTCFs). The core mission of LTCFs is to support older adults in maintaining maximum independence, rather than providing services that replace their existing or potential abilities, undermine functional capacity, and increase care dependency [2]. Nevertheless, despite providing essential safety guarantees and professional care services, the inherent institutional attributes of LTCFs—marked by standardized structured environments, rigid administrative regulations, and centralized care protocols—may unintentionally exacerbate the risk of social isolation among older people [3]. To contextualize the focus of this study, a clear distinction is drawn between social isolation and loneliness: social isolation denotes an objective lack of meaningful social contacts and high-quality interpersonal relationships, while loneliness refers to a subjective emotional response to unmet interpersonal needs [4-6].

Social isolation represents a significant potential risk faced by older adults in LTCFs of older people care [7]. Evidence suggests that LTCFs do not adequately provide comprehensive care services suited to the diverse requirements of older people [8]. In LTCFs, tight space-time management standards restrict the timing, place, and manner of older individuals' daily activities. Due to understaffing and severe workloads, caregiving staff devotes the majority of their time and energy to satisfying older people's fundamental physical requirements [9], such as aid with daily living and medical care. In such settings, compared to those living in the community and at home, older people in LTCFs often lack meaningful social engagement, adequate sensory stimulation, and positive interpersonal relationships, and thus experience a far higher rate of social isolation [10,11]. A number of studies have shown that the social network of older people, as an important social resource, is closely related to their health and quality of life [12,13]. Older people in LTCFs who experience social isolation face an increased risk of mortality, higher morbidity, depression, and cognitive decline, and they are also more prone to physical pain and psychological distress [14]. Meanwhile, the deterioration in physical function makes older people in LTCFs more worried, worsens social isolation [15], and develops a vicious cycle, which may lead to a greater burden of institutional care and have negative societal impacts.

In actuality, for older people facing the risk of reduced social networks and increased social isolation, increasing social integration of older people is of vital importance, as it could alleviate the devastating sense of isolation and loneliness from LTC nursing and improve the quality of life of older people [16]. Despite decades of research on social isolation, most studies on social isolation of older people have focused primarily on community-dwelling older adults [17]. However, social isolation among older people in institutionalized care settings may differ significantly from that of older people living in communities in terms of mechanisms, manifestations, and effects [18]. Due to factors such as traditional cultural beliefs and weakened social functions of older people, with the aim of not burdening their children and reducing family burden, they may hide their emotional needs to some extent after entering in LTCFs, resulting in hidden and difficult to dynamically identify symptoms of social isolation. At the same time, due to management needs, LTCFs may encounter stricter institutional rules, limited environmental support, and reduced social network relationships [19]. Because of this group's unique physical functions, cognitive status, and social roles, the complexity of personal and environmental circumstances increases their risk of social isolation, making it more difficult to overcome through regular social support networks. However, older people living in the community could usually keep certain social roles and engage in specific social activities to interact with the outside world through their existing relatives, colleagues, and neighbors [20]. As a result, moving the study focus to older people in LTCFs could improve their quality of life, lower medical expenditures, and lessen the burden of social care for older adults [21]. This not only broadens the situational relevance of social isolation theory but also provides a practical foundation for creating more tailored intervention tactics.

Given the institutional characteristics of LTCFs and the objective nature of residents' social isolation, the person-environment fit (P-E fit) theory provides the core theoretical framework for explaining the underlying mechanisms of this phenomenon [22]. This theory focuses on the dynamic interaction between individuals and their environments, stressing that the alignment between personal needs or attributes and environmental resources or provisions determines adaptive outcomes [23]. Specifically, when older people's core needs (autonomy, social engagement, and dignity) match LTCFs' resources, norms, and support, they tend to maintain active social participation and well-being. Conversely, standardized care norms may suppress social initiative, and insufficient interaction opportunities fail to meet diverse needs. Such a mismatch may further induce psychological distress or physical health decline. From the P-E fit perspective, LTCF residents' social isolation can thus be viewed as a negative outcome of the imbalance between older people's personal resources and the environmental resources provided by the institution. However, this research offers a limited understanding of how older adults in LTCFs experience social isolation while neglecting older adults' subjective experiences of this mismatch. Key questions remain: How do LTCF environments reshape residents' social experiences? How do they make sense of, interpret, and respond to this sense of "isolation"? Answering

XSL•FO
RenderX

these requires targeted qualitative exploration—laying the foundation for this study.

Based on the results of systematic sorting and comparison, this study opted to use qualitative meta-synthesis as the research approach [24]: (1) social isolation among LTCF residents differs in its nature and manifestations from that among community-dwelling older people; it differs significantly in formation mechanisms, manifestations, and influencing variables. Through rigorous literature screening and quality assessment, qualitative meta-synthesis can not only systematically integrate scattered findings from existing qualitative research and connect fragmented evidence (environmental constraints, personal perceptions, and interaction patterns) but also reveal the unique formation mechanism of social isolation among LTCF-dwelling older adults via "reinterpretation" and "theoretical synthesis," thereby better addressing the uniqueness and innovation of this study [25]. (2) This study uses the P-E fit hypothesis to explain how environmental-person mismatch in LTCFs causes social isolation among older adults. Most current qualitative research focuses on 1-sided influencing factors, while qualitative meta-synthesis can identify qualitative evidence of "individual—environment—interaction" in existing studies, revise and refine the P-E fit theory framework for closed settings, and clarify the key mechanisms of social isolation in LTCFs and the specific forms of "mismatch" [26]. The need to deepen the P-E fit theory arises from the fundamental differences between LTCF residents and community-dwelling older adults [27]. Qualitative meta-synthesis could strengthen this theory to explain the formation mechanism of social isolation in LTCFs and potential solutions, thus promoting a systematic understanding of the phenomenon.

This review aimed to identify the experiences of social isolation among older people in LTCFs and analyze them in terms of causes, mechanisms, emotional experiences, and coping strategies. The findings of this study will inform the design and implementation of targeted interventions to alleviate social isolation and improve the well-being of this population.

Methods

Overview

We conducted a systematic review and qualitative meta-synthesis (PROSPERO CRD42024591240) and report the findings in accordance with the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) (Multimedia Appendix 1) [28] and the ENTREQ (Enhancing Transparency in Reporting the Synthesis of Qualitative Research) statement [29] (Multimedia Appendix 2). We chose this study approach because qualitative meta-synthesis is useful for generating theoretical and conceptual knowledge, informing therapeutic interventions and research programs, and improving the clarity, comprehensiveness, and transparency of qualitative systematic reviews [30].

Search Strategy

We conducted a comprehensive electronic search of English and Chinese databases, including PubMed, Web of Science, Embase, PsycInfo, the Cochrane Library, CINAHL, Scopus, the Chinese Biomedical Literature Database, CNKI, Wanfang Data, and Weipu (VIP). The search included qualitative studies exploring social isolation experiences among older adults receiving LTC, with no start date restriction and a cutoff date of February 2025. According to the PICOS (population, intervention, context, outcome, study design) framework recommended by the Joanna Briggs Institute (JBI) Centre for Evidence-Based Healthcare in Australia, 4 key concepts were used: older adults, social isolation, LTC, and qualitative research. A comprehensive search was conducted for each concept using a combination of MeSH terms and free-text keywords. A backward citation search was also performed for all identified studies. For detailed examples of our search strategy, see Multimedia Appendix 3.

Inclusion and Exclusion Criteria

The PICOS model recommended by the JBI Evidence-Based Healthcare Center in Australia was used to determine the inclusion and exclusion criteria for the study. The inclusion criteria were as follows: (1) population (P): older people aged 60 years and older who are receiving LTC; (2) intervention (I): the causes and lived experiences related to social isolation among older adults receiving LTC; (3) context (C): residential facilities providing LTC for individuals who require assistance with daily living activities and have specific health and care needs, such as nursing homes or integrated medical and nursing care facilities; (4) outcome (O): the manifestations, impacts, and coping strategies of social isolation; and (5) study design (S): qualitative research or mixed method studies (only the qualitative component was included), using methodologies such as phenomenology, grounded theory, or ethnography.

The exclusion criteria were as follows: (1) studies where social isolation was not the primary research phenomenon but only a subtheme; (2) social isolation caused by lockdowns or isolation measures during the COVID-19 pandemic; (3) literature not available in English or Chinese; (4) full texts not accessible; (5) duplicate publications or studies with incomplete data; and (6) conference abstracts, commentaries, or reviews.

Study Selection and Data Extraction

Search results were entered into EndNote (version 8; Clarivate Analytics), then exported to Covidence after duplicates were removed. Five reviewers (WL, ZM, WT, YS, and YZ) independently screened titles and abstracts, with full-text reviews conducted in duplicate (2 reviewers [WL and ZM] per paper) to identify eligible studies. Eligible data were retrieved and entered into a Microsoft Excel spreadsheet, which included (1) general study and sample characteristics, (2) methodology, (3) participant quotes, and (4) themes and findings. Throughout, conflicts were settled through discussion and judgment by a third reviewer (YZ).

Appraisal of Methodological Quality

The JBI Critical Appraisal Checklist for Qualitative Research, with 10 items, guided the evaluation of the quality of the included publications [31]. Each publication was examined by 2 researchers (WT and YS) who worked separately. Disagreements were also resolved through discussion and further

XSL•FO
RenderX

evaluation. Inclusion needed a specified minimum of "yes" in 6 domains. All included studies clearly outlined their objectives and provided a thorough explanation of how the research was conducted in alignment with these objectives. Two studies reported all items recommended by the JBI-Qualitative Assessment and Review Instrument tool.

Data Synthesis

This study adopts a systematic review and thematic synthesis approach focusing on qualitative research. In the case of mixed method studies, only the qualitative data were included for analysis and integration to maintain methodological coherence. This study followed the three-stage thematic synthesis process proposed by Thomas and Harden [25]: (1) line-by-line coding of relevant texts: all descriptions related to the social isolation phenomenon among older people in LTCFs were compiled and coded; (2) organization of codes into descriptive themes: new descriptive themes were created by comparing the data from the first phase (eg, boredom and rational acceptance of coexistence), with connections clarified, similar themes merged, and grouped coding applied; and (3) development of analytical themes: the descriptive themes from the previous stage were re-examined, and similar descriptive themes were classified into a comprehensive outcome (the analytical themes included causes, manifestations, feelings, and coping strategies of social isolation). The synthesis analysis was conducted by 2 researchers (YS and YB), with a third experienced independent reviewer (GX) coordinating the thematic analysis. The entire research team carefully reviewed the data analysis process to ensure consistency in the interpretation of results and adequacy of the analytical themes.

Rigor, Trustworthiness, and Reflexivity

Rigor

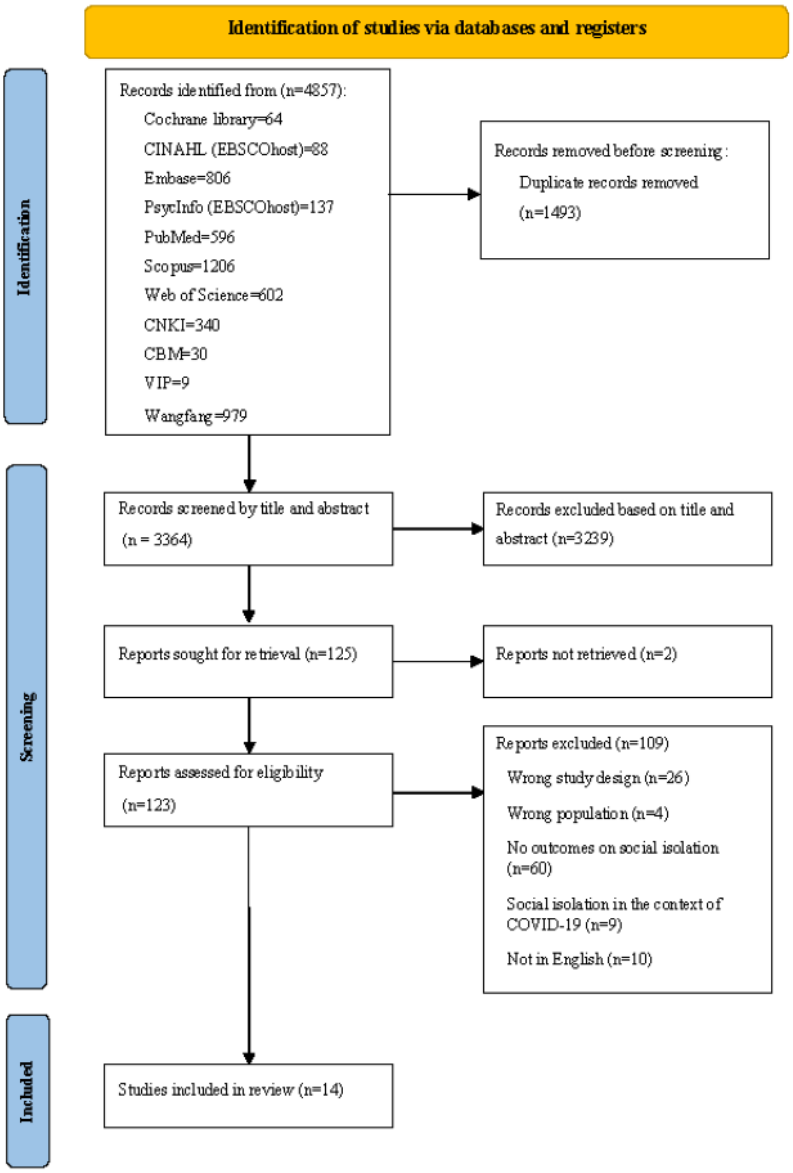
This study used a comprehensive search strategy across 11 databases, rigorous quality appraisal using JBI criteria, and consistent data analysis following Thomas and Harden's [25] 3-stage thematic synthesis. Two researchers (WL and ZM) independently conducted screening, data extraction, and coding, with disagreements resolved through discussion and third-reviewer (YZ) adjudication, and the entire research team reviewed the coding and theme development process to ensure consistency and adequacy of the synthesized results.

Trustworthiness

Drawing on Lincoln and Guba's [32,33] criteria for establishing trustworthiness in qualitative research, we implemented four strategies: (1) credibility: prioritizing participants' direct quotes over authors' interpretations to ensure that findings authentically represent older adults' experiences. Member checking was indirectly achieved by verifying that the synthesized themes were consistent with the original findings of the included studies, with the research team discussing and confirming the alignment between coded data and thematic interpretations; (2) transferability: providing thick descriptions of study contexts (settings, participant characteristics, and care environments) to enable readers to assess applicability to other LTCF settings; (3) dependability: maintaining an audit trail documenting all analytical decisions, data extraction spreadsheets, coding frameworks, and theme development processes; this trail enables other researchers to replicate the study process and verify the consistency of the results; and (4) confirmability: 2 independent researchers (WL and WT) performed data extraction and coding, with a third reviewer (YS) resolving discrepancies to reduce bias. Thematic synthesis was guided by the P-E fit theory, and the research team repeatedly compared synthesized themes with original data to ensure that conclusions were data-driven rather than based on prior assumptions.

Reflexivity

The research team comprised nursing and psychology researchers with diverse backgrounds in geriatric care, institutional management, and qualitative methods. Acknowledging that team members' clinical experiences and cultural contexts (Chinese health care settings) might introduce bias, we implemented three reflexive practices [34]: (1) maintaining a reflexive journal to document preconceptions and analytical decisions, with explicit documentation during thematic synthesis of instances where personal experiences or disciplinary backgrounds could influence interpretation; (2) conducting peer debriefing with external qualitative experts not involved in data analysis—an independent researcher specializing in social isolation reviewed the final thematic framework, providing feedback on potential biases to ensure that findings were objective and data-grounded; and (3) explicitly bracketing prior assumptions during coding via iterative comparison of codes against raw data. While 2 cofirst authors (WL and ZM) led data analysis, multidisciplinary perspectives from psychology and the older people care management team members counterbalanced individual interpretations.



Results

Overview

A total of 4856 studies were identified via systematic database and hand searches. Of these, 123 underwent full-text review, and 14 qualitative studies involving 210 older people were ultimately included in the meta-synthesis. The screening process is shown in Figure 1. The studies (2006-2023) were conducted in various regions, including China (n=7), the United Kingdom (n=3), Ireland (n=1), New Zealand (n=1), Australia (n=1), and Finland (n=1). The research settings included nursing homes, social welfare institutions, and hospitals. In studies that clearly report the sex of participants, 94 female of 148 (64%) participants were included, with a relatively lower proportion of male participants. However, the study analyses were based on the entire study population of older people. In total, 6 studies reported the duration of LTC, with a minimum duration of 10 weeks, while the remaining studies did not provide information on the length of care. A variety of qualitative methodologies were used, with mixed methods designs being the most common, with data collection methods primarily relying on semistructured interviews and participant observation. The main findings of this review are presented in Table 1.

Quality Assessment

According to the JBI criteria, all studies, except for 1, described at least 7 of the key items. All studies followed strict qualitative research methodologies and designs. Except for 4 studies, the remaining studies provided detailed statements of participants' results. In total, 5 studies did not explicitly report whether appropriate institutional ethics approval had been obtained. Only 3 studies addressed the influence of the researcher on the research or the impact of the research on the researcher (Table 2), indicating a potential bias in the findings.

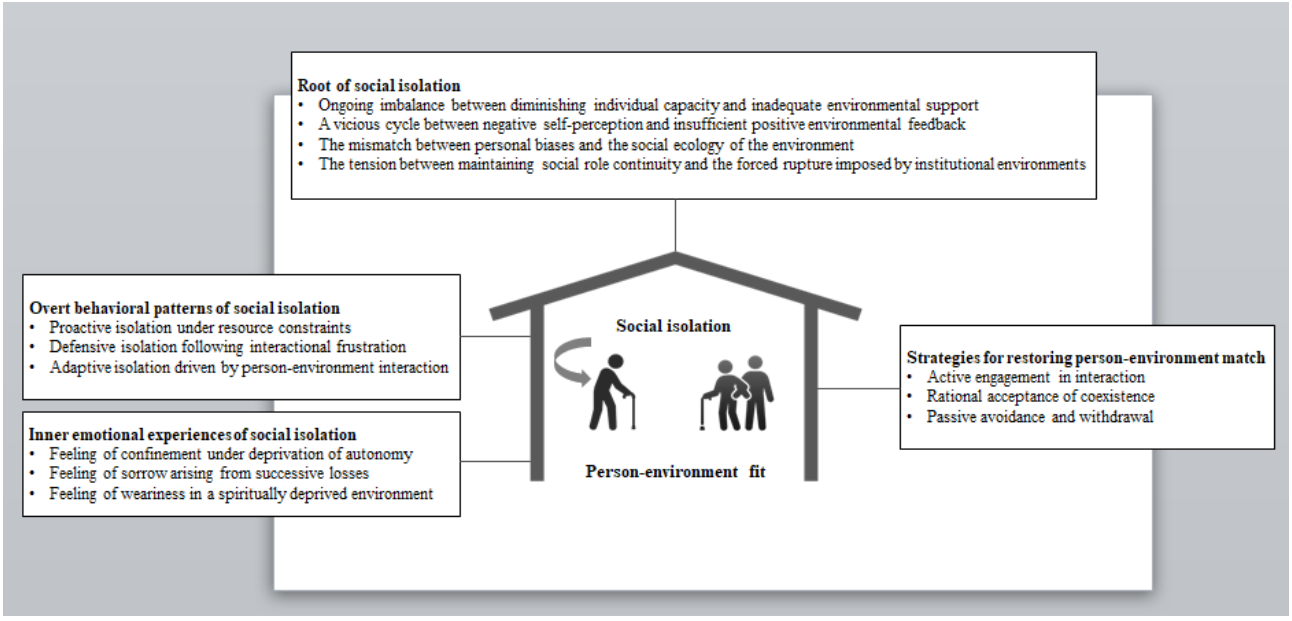
(10) Do the conclusions drawn in the research report flow from the analysis, or interpretation, of the data?



Main Findings of the Meta-Synthesis

Overview

This study generated 4 main themes (roots, manifestations, emotional experiences, and coping strategies of social isolation among older adults) and 13 subthemes.

The research team and qualified interpreters reviewed the identified themes to ensure alignment with the original authors' intended interpretations, thereby enhancing the accuracy of thematic analysis across all included studies. These themes effectively reflect the social isolation experiences and perceptions of older people in LTCFs. Figure 2 shows the examination of each theme.

Figure 2. Thematic overview diagram.

XSL•FO
RenderX

Theme 1: Person-Environment Mismatch as the Root of Social Isolation

Ongoing Imbalance Between Diminishing Individual Capacity and Inadequate Environmental Support

With advancing age, individuals experience a gradual decline in physiological functioning accompanied by a marked increase in the prevalence of chronic diseases. Older adults living in LTCFs frequently experience ongoing declines in mobility and capacity for independent daily living [49]. However, many LTC settings remain inadequate in providing supportive features—such as accessible infrastructure, mobility assistance, and functional spatial layout—thus failing to effectively offset the decline in residents' functional capacity. This insufficiency of environmental support diminishes older adults' autonomy and opportunities for external engagement, constraining their social participation and ultimately resulting in social isolation driven by the combined effects of functional decline and environmental misfit.

> *As I age and my health deteriorates, I need daily medication and injections. Over the past month, I have been receiving injections continuously and taking numerous pills each day. I truly have no desire to go out, nor is it physically feasible for me. Instead, I am just lying in bed* [48]
>
> *I used to be able to walk and visit friends, but now with this illness (diabetes) and my gout, along with foot sores, I can't walk anymore. I can only sit or lie down, and I can't go anywhere* [46]

A Vicious Cycle Between Negative Self-Perception and Insufficient Positive Environmental Feedback

Older adults living in institutional settings are susceptible to negative psychological states—including stigma, self-directed ageism, and feelings of guilt—triggered by aging and illness. In contrast, LTC environments generally provide far fewer affirming social interactions and psychological support than community contexts enriched by family and neighborhood ties, leaving older adults' negative self-perceptions insufficiently mitigated or corrected. Over time, these enduring negative self-perceptions lead older adults to withdraw from social engagement due to fear of being judged or misunderstood, thereby further limiting their access to positive environmental experiences. As a result, a self-perpetuating vicious cycle develops, in which negative self-cognition and insufficient positive feedback from the environment continuously reinforce each other.

> *If you go out by [accessible taxi] ... you wonder if they're gonna turn up* [38]
>
> *With this illness (diabetes), my savings and pension have been spent entirely on medication. Even going out to socialize incurs costs. Sometimes my children help out a little, but I feel embarrassed to ask for support; I don't want to be a burden to them* [46]

The Mismatch Between Personal Biases and the Social Ecology of the Environment

After entering LTCFs, older adults often form social circles based on individual differences such as personal values, behavioral patterns, and past experiences. For example, some may instinctively distance themselves from peers with highly stigmatized illnesses and choose to interact only with those who are moderately impaired or still self-sufficient. Institutional environments often fail to provide diverse and flexible social groups; thus, the avoidance strategies individuals adopt to maintain self-identity become barriers to rebuilding their social networks.

> *These severely disabled older people individuals should not have been placed on our floor. They are entirely dependent on the caregivers for mobility, and their temperaments are often volatile, leaving the area unclean. We do not want to live on the same floor with them* [39]
>
> *I don't want to go out. Those people lack manners. I went to college and used to be a Chinese teacher, so I can't communicate clearly with them. Take my neighbor, for example—she's practically crazy. She insults others and calls me names, saying I'm an introverted bore. She mocks my education, but her cultural level is far below mine. I refuse to share a room with her or interact with them* [47]
>
> *people don't want to socialise with frail people* [43]

The Tension Between Maintaining Social Role Continuity and the Forced Rupture Imposed by Institutional Environments

Moving into an institutional setting imposes an abrupt and involuntary disruption on older adults' established social functions and living contexts. Yet, the enclosed structure of LTC settings, the task-driven nature of care practices (focused on physical tasks rather than emotional connection), and the rigidity of institutional management collectively hinder the smooth transition and continuity of older adults' social roles. These conditions expedite the erosion of their social identity and emotional support, ultimately exacerbating social isolation.

> *There's nobody to talk to (...) no normal people, just the tea lady and the kitchen staff* [47]
>
> *I've been thinking about my friend who lives near Cuihu, but now that I'm living in this facility, I can't go out. Oh well, I'm fine here (telling myself that). It's probably best not to meet up anyway* [47]
>
> *I used to want to chat, so I would wait for the caregiver to come at mealtime just to say a few words. But she was always busy, rushing to feed me and then move on to the others. Gradually, I stopped trying to talk* [40]

Theme 2: Overt Behavioral Patterns of Social Isolation in the Context of Person-Environment Mismatch

Proactive Isolation Under Resource Constraints

Such isolation behaviors constitute a deliberate avoidance strategy adopted by older adults following an evaluation of their

XSL•FO
RenderX

functional restrictions and the physical or supportive barriers within institutional environments [50]. Although these older adults often desire social participation, when they perceive that environmental supports (such as hearing aids, barrier-free facilities, or accessible activity spaces) are inadequate to compensate for physical deterioration, they reasonably foresee possible frustration or risk during social engagement. Consequently, in order to prevent possible communication barriers, physical strain, or unsafe conditions, they opt to limit or withdraw from social engagement. This behavior reflects a rational, cost-benefit–driven decision aimed at minimizing the adverse outcomes that may result from social interaction.

> *I do want to talk to someone, but my health and other conditions don't allow it. Sometimes my spouse takes me out on a tricycle, but it still feels difficult to make friends or have a conversation* [46]
>
> *It's not that I don't want to go out and talk to people—it's just that I'm too deaf. Even if someone tries to speak to me, they'd have to shout, and I still might not catch what they're saying. So, I just stay in my room by myself* [40]

Defensive Isolation Following Interactional Frustration

This pattern of behavior arises from repeated negative interpersonal interactions experienced in institutional contexts. When older adults face frequent rejection or misunderstanding during social interactions, they are likely to develop a consistent pattern of negative attribution, placing the cause on others or on an unsupportive environment. As a defensive strategy, individuals deliberately retreat from social settings to shield themselves from additional interpersonal hurt and emotional pain. While this behavior offers short-term self-protection, in the long run, it depletes social capital and entrenches the individual's isolation.

> *Ask for help and you're turned down. That hurts ... It's not worth the aggravation ... I don't want to ask anybody for anything, nothing ... I don't want another knock-back* [38]
>
> *And they don't speak to me and I don't speak to them. We are like bits of kids, oh dear God. To think that I have come to this* [37]

Adaptive Isolation Driven by Person-Environment Interaction

Certain older adults demonstrate reduced intrinsic motivation for social interaction, influenced by personality characteristics or life stage factors. At the same time, the social activities offered by institutional environments tend to be limited in variety, depth, and attractiveness, thus insufficient to foster residents' motivation to engage. In this context, a passive equilibrium emerges between the individual's limited social needs and the environment's equally limited social offerings. Older adults' seeming acceptance of solitude is not only a manifestation of personal preference but also a consequence of the environment's insufficient provision of meaningful social engagement: "[Being alone] doesn't bother me anymore" [38].

Theme 3: Inner Emotional Experiences of Social Isolation in the Context of Person-Environment Mismatch

Feeling of Confinement Under Deprivation of Autonomy

The feeling of confinement arises from the tension between the individual's desire for autonomy and the physical as well as administrative constraints of institutional settings. As older adults' physical abilities deteriorate with age and illness, institutional environments often intensify restrictions through closed spatial layouts, rigid outing regulations, and standardized routines, resulting in a pronounced sense of being trapped within specific areas (eg, a room, a floor, or the entire facility). The confinement experience goes beyond physical restriction. It reflects a profound psychological response to the institutionalized deprivation of personal autonomy and indicates a severe loss of one's sense of control over the environment.

> *I just feel cut off from the outside world that's all ... I don't feel I have contact with the outside world at all* [36]
>
> *you can get in alright but you can't get out* [35]

Feeling of Sorrow Arising From Successive Losses

With the progression of aging and chronic illness, residents in LTCFs tend to endure a wider spectrum of losses than their peers, including diminished bodily autonomy, bereavement of close companions, separation from a spouse, and disruption of familiar environments. When faced with the loss of youth, vitality, and beloved relationships, certain older adults sink into a pervasive sorrow from ongoing losses, leading to an increasingly pessimistic outlook on life. During this journey marked by continual loss, some older people become absorbed in nostalgic recollections, rendering them more susceptible to distress and emotional isolation.

> *more of a torment I think ... That is the thing that gets me I start talking like this and then it goes out of my head. I have a hell of a job to get it back. It is awful really* [35]
>
> *All my family's gone. I had to accept that. You see other people coming in with families. It does hurt. But you move on. You just move on, say, "Well, they're lucky. Their family and that are still alive"* [42]
>
> *[My friend] who takes me shopping had been away, so I hadn't been out for quite some time* [38]

Feeling of Weariness in a Spiritually Deprived Environment

Some older persons in LTCFs find life tedious and uninspiring. On the one hand, their daily routines are dictated by established care processes, leaving little possibility for autonomy or personal choice, resulting in a lack of novelty and variation in their lives. On the other hand, the restricted range of activities available in LTCFs frequently fails to meet their different interests, leading people to believe that life is dull and lifeless. This lack of mental stimulation can quickly lead to boredom, exacerbating their feelings of loneliness and isolation. The absence of cognitive stimulation can readily induce fatigue and exacerbate their social isolation.

XSL•FO
RenderX

> *There's really nothing going on; I just can't do anything all day, and I feel a sense of emptiness inside* [48]
>
> *life is people; we need to belong; we need to talk, we old lonely men (...) we see each other every day, but we don't talk, we don't even know what to do* [42]

Theme 4: Strategies for Restoring Person-Environment Match to Alleviate Social Isolation

Active Engagement in Interaction

Some older people deal with social isolation by actively engaging in social activities and socializing with others. By expanding their exposure to the outside world, such as participating in group activities or attending institutions for older adults, they might form new relationships or pursue personal hobbies, re-establish social links with the outside world, and gain a sense of belonging and importance.

> *The nursing home has provided us with a sound system specifically for square dancing after dinner. Essentially, as long as one can walk, everyone comes together daily to enjoy dancing* [41]
>
> *if you don't participate you can be left out and feel isolated, so I participate in some of the things* [42]
>
> *It's nice to sit with the nurses and talk and laugh about things with them when they are not busy working* [44]

Rational Acceptance of Coexistence

Another group of older people copes by rationally accepting the institutional context and adjusting their mindsets to achieve inner balance, a strategy closely tied to the LTCF-specific experience of "relocating from family to institutional care." Over time, they seek inner peace by changing their mindset and progressively adjusting to live in harmony with their caregivers and cohabitants. This logical acceptance keeps individuals from experiencing more psychological distress, even though they still feel alienated from the outside world.

> *Now that the children have to work and take care of their own kids, they are under a lot of pressure and don't have time to look after us. That's why we've come here. We have to adapt to this environment, take care of ourselves, and avoid getting sick so we don't add to our children's burdens* [39]
>
> *Good child, I'm old now, and I'm stuck here. My spouse passed away early. My health isn't good; I have high blood pressure and have been on medication for a long time. I just don't have the energy to be around those lively people. Right now, I'm just taking it one day at a time and not thinking too much about it* [48]

Passive Avoidance and Withdrawal

Some older people adopt passive coping behaviors in response to LTCF-related social barriers, forming a maladaptive cycle of isolation. This coping strategy involves passive avoidance and withdrawal from social interactions among older people. Due to the fixed, inflexible schedules and routines in LTCF, residents' personalized social needs often cannot be met. In response, some older people choose to withdraw from institutional social activities, avoid social environments, and reduce interaction with others as a form of passive coping. Long-term avoidance may harm their psychological and physical health, making them feel even more alone. Over time, this creates a vicious cycle, in which older people retreat for extended periods of time, no longer seeking opportunities to contact with the outside world, and may even acquire suicidal ideation.

> *Well I just can't be bothered ... I just don't want to make the effort. I mean, I don't get up very early in the mornings ... When I feel lonely I don't want to do anything ... [I've] just lost interest* [38]

Discussion

Principal Findings

This synthesis identifies person-environment mismatch (encompassing 4 interrelated dimensions: functional decline vs insufficient environmental support, negative self-perception vs feedback deficit, personal bias vs homogeneous institutional ecology, and role disruption vs rigid management) as the core mechanism driving social isolation of older people in LTCFs. This mismatch manifests in 3 behavioral patterns (proactive, defensive, and adaptive isolation) and 3 emotional states (confinement, sorrow, and weariness), with residents adopting active engagement, rational acceptance, or passive withdrawal as coping strategies. Notably, LTCF residents' social isolation is a unique, institution-specific phenomenon (not an extension of community-dwelling), and interventions should prioritize restoring person-environment congruence—providing targeted guidance for optimizing institutional care, strengthening social support, and fostering active social participation among older people in LTCFs.

Core Mechanism Elaboration: Person-Environment Mismatch as the Root Cause of Social Isolation Among Older People in LTCFs

This study confirms that person-environment mismatch is the core driver of social isolation among older adults in LTCFs, validating the P-E fit theory and extending its utility to institutional older people care via empirical evidence. These 4 interrelated dimensions of this mismatch collectively contribute to social isolation, with synergistic rather than independent effects. First, the gap between declining physical capacity (eg, mobility loss from diabetes or gout) and insufficient environmental support (eg, lack of barrier-free facilities) forms a "functional restriction→participation barrier" loop. This finding is consistent with previous research linking environmental inadequacy to social withdrawal [51] and further highlights that this issue is persistent in LTCFs, where impaired mobility often confines residents to their beds. Second, negative self-perceptions—fueled by financial strain (eg, pensions spent on medication) or distrust in external support (eg, worries about accessible taxis)—are not mitigated by LTCFs' weak emotional feedback. Unlike community settings with family ties, this gap exacerbates self-directed ageism and active avoidance [46], and this study adds that such cycles are more intractable in closed

XSL•FO
RenderX

institutions. Third, personal biases (based on education or health status) collide with LTCFs' homogeneous social ecology. While Zhang et al [52] noted institutional homogeneity limits adaptation, this study further finds that the absence of flexible social groupings turns preferences (eg, avoiding severely disabled peers) into long-term isolation. Fourth, closed management and task-oriented care disrupt social roles (eg, losing "friend" or "teacher" identities), eroding emotional anchors. Consistent with the findings of Huang et al [53] on role disruption and isolation, this study highlights that LTCFs' lack of role-transition support accelerates this erosion. Together, these dimensions reveal that person-environment mismatch in LTCFs is a cumulative, interactive process—each dimension reinforces the others—making isolation more deeply rooted than in community or home settings.

Analysis of 3D Environmental Conflicts: Reflections on Person-Environment Mismatch

Overview

Drawing on the study's empirical findings, environmental conflicts in LTCFs can be categorized into 3 dimensions: physical, social, and psychological. Each dimension reflects specific manifestations of person-environment mismatch and deepens social isolation, consistent with the multidimensional environmental framework of Smith et al [54]. At the same time, this study found that the social isolation performance of older persons in LTCFs could be classified as "proactive," "defensive," and "adaptive," which is consistent with previous research findings [46,52].

Physical Environment Versus Physiological Needs: Aggravating "Sense of Confinement" and "Proactive Isolation"

Conflicts here stem from LTCFs' failure to align spatial-temporal arrangements with the declining physical capacity of older people. First, rigid time management (eg, unified meal or rest times) creates "flattened time," contradicting residents' need for autonomy. This exacerbates meaninglessness and passive isolation [51], and our results add that such rigidity leaves no room for adapting to individual energy levels (eg, residents too fatigued from medication to participate in scheduled activities). Second, insufficient barrier-free facilities (eg, lack of walking aids) trap mobility-impaired residents—our cases show that those with foot injuries or gout cannot reach activity areas, reinforcing physical confinement [52]. Third, closed spatial layouts sever external connections; residents unable to meet friends outside (as in our results) rely solely on internal resources, and when these are scarce, isolation deepens.

Social Environment Versus Social Needs: Triggering "Loneliness" and "Defensive Isolation"

This dimension's core issue is the mismatch between homogeneous social services and diverse individual needs. First, unified care (eg, passive waiting for meals or bathing) ignores social preferences—extroverts need group interactions, while introverts need one-on-one chats. We have a former Chinese teacher who is unable to communicate with peers with lower cultural levels, and this case illustrates this point [47]; this mismatch increases withdrawal. Second, caregivers prioritize tasks over emotional support; our results show that residents wanting to chat during meals are rushed, leading to "defensive isolation" (eg, no longer initiating interactions) [53-56]. Third, tense peer relationships—driven by health discrimination (eg, avoiding severely disabled peers)—undermine belonging. Our cases of residents refusing roommates who insult them reflect this, aligning with the observation of Nielson et al [43] of peer exclusion worsening isolation. Additionally, this study also believes that some older people may find it difficult to express their feelings of social isolation. This can make it difficult for caregivers to understand and sympathize with older people because of limitations and a lack of knowledge about the level of expertise of caregivers.

Psychological Environment Versus Psychological Resilience: Strengthening "Sense of Powerlessness" and "Adaptive Isolation"

Imbalances here lie in LTCFs' failure to support older people's mental coping with isolation. First, caregivers lack psychological skills to recognize loneliness or anxiety; uniformity of feeling among people remains impossible, and this study summarizes these themes as "active participation in interactions," "rational acceptance of coexistence," and "passive avoidance and withdrawal." Some older people stop expressing feelings when unheard, fostering powerlessness [57,58]. Second, monotonous activities (eg, repetitive handicrafts) fail to meet self-worth needs; older people in previous research have described "empty lives," leading to "adaptive isolation" (accepting loneliness) [59-62]. Third, static assessments ignore changing needs of older people (eg, hearing loss requiring hearing aids leads to a sense of powerlessness in expressing needs), and this static care deepens passive withdrawal.

Practical Implications: Person-Environment Matching-Based Interventions for Social Isolation

Overview

Guided by the study's core findings—effective coping strategies (eg, active participation and rational acceptance) and 3D environmental conflicts—interventions should focus on "repairing person-environment mismatch." Targeted, actionable measures are proposed across physical, social, and psychological dimensions to facilitate older adults' transition from "passive restriction" to "active adaptation," aligning with P-E fit theory's intervention orientation [23].

Optimizing the Physical Environment: Enhancing "Adaptability" to Reduce Physical Barriers to Socialization

Implement Flexible Time Management

Referring to older adults' need to "arrange activities independently" in the results, LTCFs should allow older adults to choose meal and rest times within a certain range (eg, "providing 2 meal periods in the morning and evening") [44]. Posters listing daily flexible slots should be displayed in residential wings. LTCFs could increase participation in 2 or more weekly timed activities (eg, 15:00 calligraphy and 17:30 group walks). This reduces the sense of meaninglessness caused

XSL•FO
RenderX

by "flattened time"—consistent with the "temporal autonomy" intervention [63].

Construct Semiopen Spatial Layouts

Within closed management, facilities can establish weekly outing schedules (eg, community park visits on Wednesday mornings and friend visits on Friday afternoons), with 1 staff member assigned to every 6 residents. On a monthly basis, facilities can invite 2 to 3 community volunteers (eg, retired teachers and craftsmen) to hold on-site interactive activities such as paper-cutting workshops [64]. These practices help older people reconnect with the outside world and reduce their sense of isolation from external society.

Reconstructing the Social Environment: Strengthening "Supportiveness" to Improve the Quality of Social Interaction

Transform Caregiver Role Positioning

LTCFs should strengthen training for caregivers in psychological support skills, transforming them from "task executors" to "social facilitators." For example, caregivers should "take the initiative to chat with older people during meals and listen to their feelings," integrating social support for older people into daily nursing work: nursing staff actively care about the older people's mood and feelings during meal delivery or daily patrols, communicate for about 5 minutes each time, and record their social and reaction situations in nursing records. This reduces the occurrence of "defensive isolation"—aligning with the view of Caspar and O'Rourke [65].

Foster an Inclusive Peer Atmosphere

Through "collective ice-breaking activities" and "peer mutual aid programs" [66] (eg, "pairing 1 high-functioning resident with 1 severely disabled resident for 30-minute daily interactions"), it breaks the prejudice of "unwillingness to live with severely disabled peers" and reconstructs positive peer relationships and eliminates "health discrimination."

Improving the Psychological Environment: Enhancing "Empowerment" to Boost Individual Coping Resilience

Strengthen Collaborative Support Between Families and LTCFs

Facilities can organize monthly "family activity days" (eg, parent-child tea parties on the second Sunday of each month) and provide free video call stations [67]. Staff can assist residents who are not familiar with digital devices, and each resident can make three 15-minute video calls per week. In addition, facilities can share "resident social progress reports" with family members quarterly to encourage family involvement in social goal-setting.

Establish a Dynamic Psychological Assessment Mechanism

LTCFs should regularly assess older adults' psychological states (eg, "loneliness level, social willingness") and changing needs (eg, "hearing loss requiring hearing aids"). Timely adjustments to intervention strategies can prevent "passive withdrawal due to unrecognized needs"—consistent with the proposal of Davies et al [68] for "dynamic monitoring to match psychological needs."

To ensure implementation, establish a three-tier oversight system: (1) micro: caregivers track daily intervention adherence via logs, (2) meso: LTCF managers conduct monthly spot checks (eg, verifying flexible meal times), and (3) macro: collaborate with local aging agencies to audit quarterly and provide funding for barrier-free renovations. This system ensures that interventions translate from policy to practice, driving residents' shift to active adaptation.

Strengths and Limitations

The strengths of this qualitative systematic study and meta-synthesis include a good grasp of older people's social isolation experiences. All relevant studies were identified using a careful search approach. However, unavoidable heterogeneity exists due to cross-national variations in LTCF resident characteristics and the care services provided. Factors including the sex and health status of the study population, the quality of care provided by caregivers, and the care environment quality may all influence how older people perceive their living environment. A key limitation is the uneven sex distribution among participants in the included studies, with most reporting a higher proportion of the female population. This sex imbalance may have influenced the salience of specific thematic findings. Future qualitative studies should aim for more balanced sex recruitment to capture sex-specific experiences of social isolation. At the same time, it is important to note that although many of the included studies were conducted from a Chinese perspective, several others originated from different countries. Cultural variations in older adults' perceptions of social isolation may additionally introduce bias into the interpretation of study findings.

Conclusions

This qualitative meta-synthesis explores social isolation experiences among older people in LTCFs and analyzes the underlying causes, behavioral manifestations, emotional experiences, and coping strategies associated with this phenomenon. Although this study describes social isolation experiences across both agentic and structural dimensions, most participants perceived social isolation as an individual challenge shaped by the interaction between their internal perceptions and the external institutional environment. As such, older people had to deal with these experiences using the social and individual strategies they had developed [69].

Additionally, there is a need to continue exploring the role of caregivers and other aged care staff in the prevention and management of social isolation of older people in LTCFs. Focusing on the needs of older people in LTCFs, through environmental transformation, relationship reconstruction, and dignity empowerment, the symbiotic relationship between humans and the environment can be reconstructed. Future research should further explore the quantification of person-environment matching in LTCFs—including the development of valid assessment tools—to enable more targeted interventions for social isolation.

Abstract

Background: Falls are a major contributor to injury, disability, and mortality among older adults worldwide. Digital health–based e-counseling has emerged as a scalable strategy to support fall prevention by addressing physical, behavioral, and cognitive risk factors.

Objective: This scoping review aimed to map the scope, characteristics, and outcomes of e-counseling interventions for fall prevention among adults aged 60 years or older.

Methods: Guided by Arksey and O'Malley's framework and reported in accordance with PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses Extension for Scoping Reviews), we searched PubMed, ScienceDirect, CINAHL, and ProQuest for studies published between January 2019 and May 2025. Eligible studies evaluated digital or telehealth-based counseling interventions for fall prevention. Data were synthesized descriptively, and methodological quality was appraised using the Mixed Methods Appraisal Tool.

Results: A total of 13 studies were included, comprising randomized controlled trials, feasibility studies, qualitative research, and retrospective cohorts conducted across Asia, Europe, and North America. e-Counseling modalities included virtual reality, mobile health application, teleconsultations, and wearable-triggered feedback systems. Reported outcomes included reductions in fall incidence ranging from 15% to 90.9%, improvements in balance and mobility, increased fall risk awareness, and enhanced self-efficacy. Interventions incorporating cultural tailoring and digital literacy support demonstrated higher engagement and adherence.

Conclusions: e-Counseling appears to be a promising and scalable approach for fall prevention in older adults, with benefits across physical and behavioral domains. Future research should focus on long-term effectiveness, equitable access in low- and middle-income settings, and integration into routine health care systems.

(JMIR Aging 2026;9:e78444) doi:10.2196/78444

KEYWORDS

e-counseling; fall prevention; older adults; digital health; telehealth; scoping review

Introduction

The rapid aging of the global population is transforming societal structures and health care demands worldwide. The global population aged 60 years and older is expected to double, reaching 2.1 billion by 2050, with 16% of the world's population being 60 years or older by 2050 [1]. In Indonesia, 26 million people are aged 60 years and older, accounting for 9.8% of the total population [2]. The population of older adults is expected to reach 48 million by 2045, accounting for 15% of the total population [3]. This significant growth in the older adult population underscores the increasing demographic importance of this age group and the urgent need for attention to their needs and health challenges.

XSL•FO
RenderX

Falls are one of the leading causes of morbidity and mortality among older adults, often resulting in severe physical injuries, psychological distress, and increased health care costs [4]. Globally, it is estimated that 646,000 older adults die from falls each year, making it the second leading cause of accidental deaths worldwide [4]. In the United States, about 36 million falls are reported among older adults each year, leading to more than 32,000 fatalities [5]. In Indonesia, falls are also a major health issue, with approximately 23% of older adults experiencing at least 1 fall annually, contributing to significant morbidity and health care costs [6,7]. Contributing factors to the increased risk of falls include age-related physical decline, such as decreased muscle strength and balance, as well as chronic health conditions such as arthritis, visual impairments, and cognitive decline [8,9]. Furthermore, polypharmacy, or the use of multiple medications, can increase the likelihood of dizziness and instability, further elevating the risk of falls [10,11]. These alarming statistics underscore the urgent need for targeted interventions to prevent falls and promote the overall health and safety of the older adult population.

Falls among older adults have significant physical, emotional, and economic consequences, making them a critical public health concern. Physically, falls are the leading cause of injury and injury-related mortality in this demographic, accounting for approximately 646,000 deaths globally each year [4]. Survivors often experience serious injuries, including fractures and head trauma experience, leading to long-term disabilities and increased dependence on caregivers [12,13]. Emotionally, many older adults develop a fear of falling again, which can result in reduced physical activity, social isolation, and a diminished quality of life [14]. Economically, falls impose a substantial burden on health care systems, with US medical costs for fall-related injuries exceeding US $50 billion annually [5]. This financial strain affects not only individuals but also families and health care resources, highlighting the urgent need for effective fall prevention strategies to mitigate these impacts [15,16].

Various preventive measures have been implemented to address this critical issue. Traditional strategies, such as balance and strength training interventions, have shown effectiveness in reducing fall risk by improving physical capabilities [17]. Home safety assessments and modifications, including removing tripping hazards and improving lighting, are also essential strategies [18]. Additionally, community-based interventions that combine education and physical activity, such as Tai Chi classes, have been proven to enhance balance and reduce falls among older adults [19]. However, these interventions are not always accessible, particularly for older adults with mobility limitations or those living in rural and underserved areas [18]. In response, digital health innovations, particularly e-counseling, have emerged as promising tools for delivering tailored fall prevention strategies in a more scalable and accessible format.

In this context, e-counseling refers to digitally delivered, personalized counseling provided via telehealth platforms, mobile applications, or online systems to support behavior change e-counseling refers to digitally delivered, personalized counseling provided via telehealth platforms, mobile application, or online systems to support health behavior change. In fall prevention, e-counseling facilitates individualized goal setting, progress monitoring, and behavioral coaching grounded in self-efficacy theory [20]. Evidence suggests that e-counseling can improve fall risk awareness, adherence to preventive behaviors, and engagement in balance and mobility exercises [21,22]. By overcoming barriers related to mobility, distance, and resource constraints, e-counseling offers a scalable alternative to traditional in-person interventions. However, evidence remains fragmented regarding long-term sustainability, effectiveness across diverse populations, and integration into existing health care systems, highlighting the need for a comprehensive scoping review [23-26].

Despite its growing application, the evidence base on e-counseling for fall prevention in older adults remains fragmented [27]. Prior reviews have largely focused on in-person interventions or general eHealth approaches, with limited synthesis specifically addressing e-counseling modalities and outcomes. Additionally, there is a paucity of evidence on how these interventions are tailored for diverse populations, integrated into clinical practice, and sustained over time. Given these gaps, a scoping review is warranted to map the scope, characteristics, and outcomes of existing e-counseling interventions aimed at fall prevention among older adults. Therefore, this scoping review aims to (1) map the types and delivery modes of e-counseling interventions for fall prevention; (2) summarize reported physical, cognitive, and behavioral outcomes; and (3) identify research gaps to inform future intervention development and implementation.

Methods

Study Design

This study employed the methodological framework established by Arksey and O'Malley for conducting a scoping review [28] used, which consisted of 5 essential steps. First, the research question was clearly and objectively identified. Second, relevant articles were selected to ensure the study's focus. Third, related literature was extracted from the identified articles for further analysis. Fourth, the data collected from these sources were organized, summarized, and analyzed. Finally, the findings were reported, as outlined in the framework [28]. The review also adhered to the PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses Extension for Scoping Reviews) checklist to ensure comprehensive and replicable reporting [29].

Research Question and Framework

The review was guided by the population, concept, and context framework: population—older adults aged ≥60 years at risk of falls; concept—e-counseling interventions for fall prevention, including digital, telehealth, or app-based personalized counseling; and context—health care or community-based settings where digital interventions are implemented. The central research question was as follows: *What is the current scope of evidence regarding the use of e-counseling to prevent falls in older adults?*

XSL•FO
RenderX

Eligibility Criteria

Studies were included if they met the following criteria: (1) population—participants aged 60 years or older with a focus on fall prevention; (2) intervention—e-counseling interventions delivered through telehealth platforms, mobile application, video consultations, or other digital formats; (3) outcomes—reports on fall rates, balance, mobility, adherence, or related physical and cognitive outcomes; (4) study types—peer-reviewed empirical studies (quantitative, qualitative, or mixed methods), including randomized controlled trials (RCTs), quasi-experimental studies, longitudinal studies, and cohort studies; (5) timeframe—published between January 1, 2019, and May 31, 2025; and (6) language—English. Studies were excluded if they focused solely on in-person counseling, targeted populations other than older adults, or lacked full-text availability.

Information Sources and Search Strategy

Literature searches for this study were conducted using PubMed, ScienceDirect, CINAHL, and ProQuest in May 2025. The search strategy was designed to provide a comprehensive overview of e-counseling interventions for fall prevention among older adults. Keywords were aligned with Medical Subject Headings (MeSH) and incorporated Boolean operators “OR” and “AND” to refine the search results. The specific keywords used included “e-counseling,” “fall prevention,” “older adults” OR “elderly,” “telehealth” OR “digital counseling.” This systematic approach ensured that relevant literature was thoroughly explored to inform the study’s objectives.

Identification and Selection of Literature

The literature search was conducted independently through trusted databases. The retrieved articles were then analyzed, with differences and duplicates being removed. The process of searching for and selecting articles was illustrated using the PRISMA-ScR flowchart [30].

Data Extraction

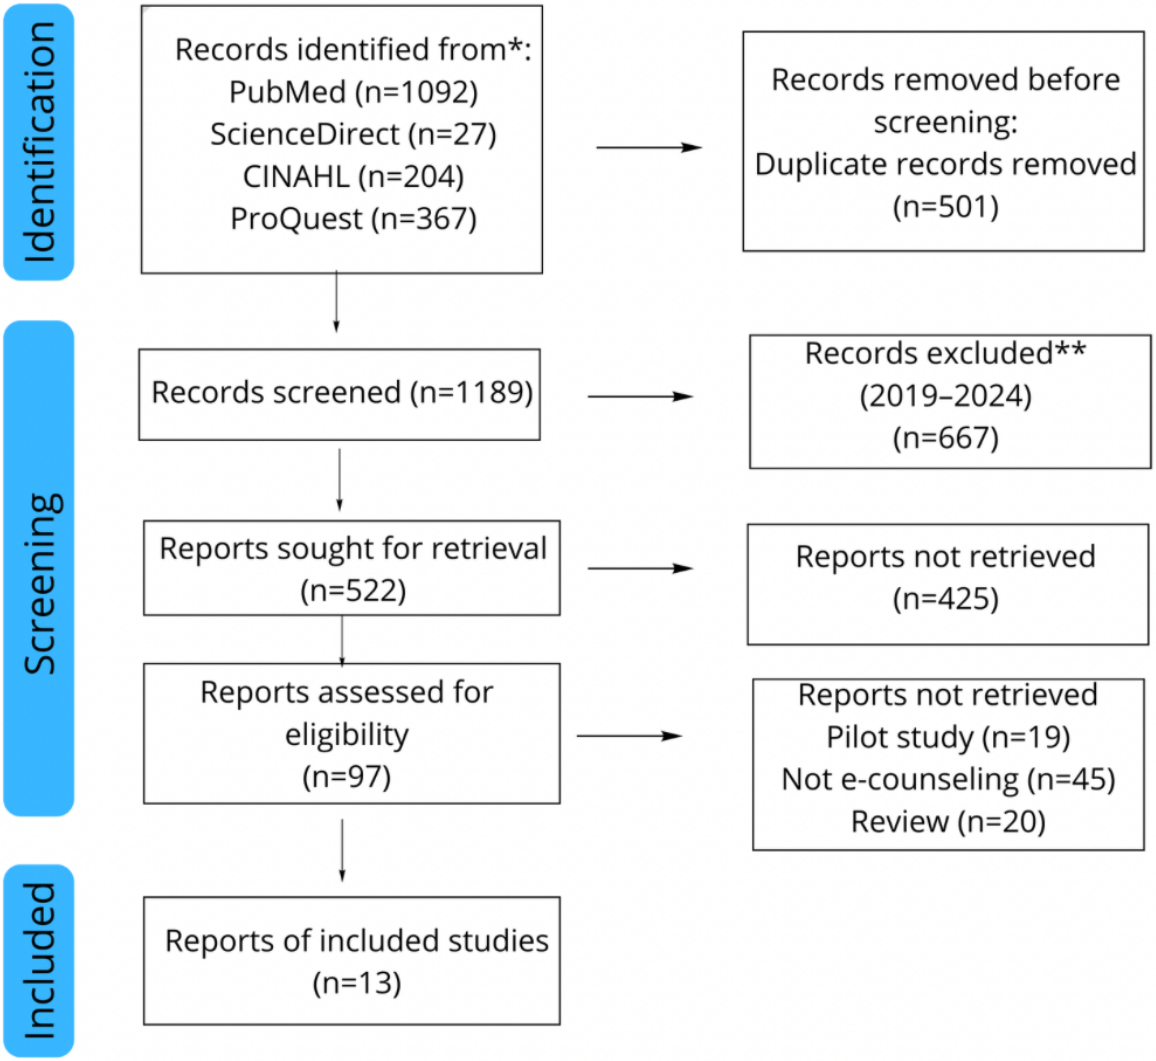
Data were collected and organized in Microsoft Word in the form of a table containing several components: article title, authors, publication year, research objectives, study design, study location, type and delivery mode of e-counseling intervention, technologies or platforms used, fall-related outcomes (eg, fall rates, balance, and mobility), cognitive or behavioral outcomes (eg, adherence and self-efficacy), and key findings. Two reviewers performed data extraction independently to ensure consistency and accuracy.

Quality Appraisal

While scoping reviews do not typically require formal quality evaluation, this review incorporated a structured assessment to better understand the methodological soundness of the included studies. To achieve this, each study was appraised using the 2018 version of the Mixed Methods Appraisal Tool (MMAT), with consideration given to its specific research design. Two independent reviewers conducted the appraisal, examining elements such as the clarity of the research aim, the suitability of the chosen methods, the completeness of reported outcomes, and potential sources of bias. Importantly, this evaluation was not used to determine study inclusion or exclusion but served to enhance the interpretation of findings and highlight methodological gaps that could guide future investigations.

Data Synthesis and Analysis

A descriptive and thematic synthesis approach was applied. Data were first categorized based on study design, intervention type, and outcome domains. Themes were then identified around the delivery formats (eg, telehealth and mobile apps), effectiveness (eg, fall reduction and mobility improvement), and implementation factors (eg, adherence and accessibility). Findings were summarized narratively, supported by tabulated evidence to illustrate patterns, strengths, and gaps.



Results

Search Results

The flow of study selection is outlined through the PRISMA-ScR flow diagram, detailing each phase of the review process. An initial search across PubMed, ScienceDirect, CINAHL, and ProQuest yielded 1690 records. After eliminating 501 (29.6%) duplicates, 1189 (70.4%) titles and abstracts were screened. The remaining 97 articles underwent full-text review. During this phase, 84 studies (86.6%) were excluded: 19 (22.6%) were pilot trials, 45 (53.6%) did not involve e-counseling, and 20 (23.8%) were review papers. In the end, 13 studies (13.4%) were included in the final analysis. The study selection process is presented in the PRISMA-ScR flowchart (Figure 1; [30,31]).

XSL•FO

Figure 1. PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses Extension for Scoping Reviews) flow diagram illustrating the study selection process for this scoping review. n indicates the number of records at each stage, and N indicates the total number of records identified. The figure is adapted from Moher et al [31]).

Findings

Characteristics of Included Studies

The included studies demonstrated a diverse range of research designs. RCTs [32,33] offered strong empirical evidence on intervention effectiveness. Pilot and feasibility studies [34,35] assessed initial usability and participant acceptance. Qualitative designs [36,37] provided insight into user perceptions, while retrospective cohort analyses [38,39] and observational designs [40] reflected real-world outcomes. Thiamwong et al [41] applied a cluster RCT to evaluate community-based peer-led interventions. The geographical distribution of the studies reflects global interest in digital fall prevention. Studies were conducted in Asia (Hong Kong, Thailand, and Indonesia), Europe (Germany and the United Kingdom), and North America (the United States). This variety shows the adaptability of e-counseling across different health care systems and cultural contexts.

Delivery modes ranged from immersive virtual reality (VR) [32], app-based learning modules [42], and artificial intelligence (AI)–assisted mobile health (mHealth) apps [39] to telehealth-facilitated interventions [33,43]. Peer-supported and community-led interventions [41] and hybrid models that transitioned from in-person to digital [34] highlight the flexibility of intervention formats. Wearable-triggered interventions, such as sensor belts [44], were also represented. The platforms used included tablet application [40], full-immersion VR systems [32], wearable smart belts [44], and wrist-worn fitness trackers [36]. mHealth application [39] and telehealth delivery models [43] were common. Digital literacy training [34] was crucial in improving accessibility among older adults.

Quality Appraisal Results

The pilot RCTs by Ip et al [32] and Arena et al [33] met most MMAT criteria, demonstrating well-defined aims, suitable randomization methods, and consistent outcome measures. Both studies had clear intervention protocols and provided sufficient follow-up data, although sample sizes were relatively small, limiting generalizability.

Dajpratham et al [38] and Alves et al [39], using retrospective designs, demonstrated strong documentation of real-world outcomes and substantial sample sizes. However, their reliance

XSL•FO
RenderX

on previously collected data posed risks of selection and reporting biases, particularly in the absence of control groups or standardized assessment timelines. Community-based interventions such as those conducted by Nazhira et al [42] and Thiamwong et al [41] provided robust insights into localized fall prevention strategies. While their designs were appropriate for evaluating feasibility and community relevance, some limitations were noted in participant blinding and long-term outcome measurement.

Feasibility and observational studies by Hladek et al [34], Jacobson et al [35], and Bajdek et al [40] generally adhered to MMAT standards, showing clearly defined objectives and consistent methods. However, several studies lacked comprehensive reporting on confounding variables and did not always include detailed rationales for sample size selection.

Qualitative studies, including those by Ojo et al [36] and Tang et al [37], scored highly on relevance and depth of data interpretation, effectively capturing user experiences and motivational factors. Nevertheless, transparency regarding coding frameworks and researcher reflexivity was limited in some cases.

The intervention led by Ritchey [43], though pilot in scope, aligned with MMAT criteria for interventional research, showcasing clear protocols and outcome metrics. Similarly, the real-world adaptive study by Kinosian and Stefanacci [44] demonstrated a high degree of ecological validity and intervention relevance, though it lacked some methodological transparency in data analysis.

Key Findings

Across the included studies, several consistent patterns emerged. First, e-counseling interventions were delivered through diverse digital modalities, including VR, mobile application, telehealth sessions, and wearable-based feedback systems [32]. Despite this variation, effectiveness did not appear to depend solely on technology type. Instead, interventions that incorporated personalized feedback, cultural tailoring, and usability support demonstrated higher engagement and adherence [43]. Second, most studies reported improvements in balance, mobility, and fall-related outcomes, with reported reductions in fall incidence ranging from 15% to 90.9% [39]. Third, behavioral and psychological outcomes—such as increased self-efficacy, confidence, and fall risk awareness—were commonly reported, particularly in interventions that emphasized goal tracking and continuous monitoring. Barriers to implementation included limited digital literacy, unequal access to technology, and resource constraints, especially in underserved populations [44].

Positive effects of these interventions were noted across a range of outcomes, particularly those related to fall risk. Improvements were frequently reported in participants' mobility, balance, and overall fall incidence. For example, the use of VR led to significant gains in both physical coordination and cognitive functioning [32]. Similarly, tools that used AI to assess fall risk enabled more accurate predictions and preventive action [39]. Interventions delivered through peer coaching and app-based platforms demonstrated measurable reductions in fall risk and improvements in physical capability [33,41]. Notably, the remarkable 90.9% reduction in hip fractures reported with the Tango Belt (ActiveProtective Technologies, Inc) highlighted the value of wearable, sensor-based protective devices.

Beyond physical outcomes, psychological and behavioral effects were also evident. Several studies recorded notable increases in participants' confidence in managing fall risk, better executive functioning, and improved knowledge of fall prevention techniques. Interventions that focused on building digital skills and promoting access, especially among vulnerable groups, also led to increased confidence and social connectedness [34]. Key to behavior change was the use of individualized feedback and goal tracking features, which fostered greater involvement and sustained commitment from users. The success of these interventions was also closely tied to how well they were implemented. User satisfaction and acceptance were higher in studies that emphasized intuitive design and meaningful interaction. At the same time, disparities in digital access, technological literacy, and economic resources emerged as ongoing barriers to equal adoption. These challenges point to the need for thoughtful planning when considering how such interventions might be scaled and integrated more broadly. The characteristics of the included studies are summarized in Table 1.

XSL•FO

Table 1. Characteristics of the studies and summary of the findings (N=13).

Authors and publication year	Study design	Study location	Type and delivery mode of e-counseling	Technologies or platforms used	Fall-related outcomes	Cognitive or behavioral outcomes	Key findings
Ip et al [32], 2025	Pilot RCT[a]	Community setting, Hong Kong	VR[b] game-based interactive training	Full-immersive VR system	Mobility, balance, walk speed	Executive function, fall efficacy	Greater cognitive-motor improvement vs non-VR group
Dajpratham et al [38], 2025	Retrospective cohort study	Thailand	Personalized digital fall risk assessment	Clinical + digital tools	Fall rate, balance (Timed Up and Go, 30-s chair stand)	Medication adherence	Falls reduced from 80% to 27.4%; sedatives increased risk
Nazhira et al [42], 2025	Community intervention	Indonesia	Video-based balance training	Digital instructional videos	Balance improvement	Knowledge gain	Improved balance and daily confidence
Alves et al [39], 2024	Retrospective real-world analysis	Germany	AI[c]-assisted risk feedback	Longitudinal INdividualized Digital Evaluation of Risk and Aging mHealth[d] app	Fall incidence (6–24 months)	Risk awareness, engagement	Fall Risk Score predicts falls; supports stratified care
Bajdek et al [40], 2024	Observational study	United States	Digital exercise + cognitive assessment	Tablet-based app	Exercise adherence	Cognition, tech readiness	High adherence improves cognition
Ritchey et al [43], 2024	Interventional Veterans Affairs pilot)	United States	Virtual exercise + education	Telehealth platform	Balance, sit-to-stand	Fall self-efficacy	High feasibility and independence
Kinosian et al [44], 2024	Adaptive cohort	United States	Wearable protection system	Tango Belt	90.9% reduction in hip fractures	Adherence	Effective injury prevention
Ojo et al [36], 2024	Qualitative PEER[e] follow-up)	United States	Wearable engagement intervention	Fitbit	Increased physical activity	Motivation	Real-time feedback improves adherence
Tang et al [37], 2024	Qualitative study	United Kingdom	Digital instructional app	Keep On Keep Up (Chinese)	Balance awareness	Engagement, usability	Cultural tailoring improves uptake
Thiamwong et al [41], 2024	Cluster Randomized Controlled Trial	United States	Peer-led digital coaching	BTrackS	Reduced fall risk behavior	Perception, adherence	Effective in low-income groups
Hladek et al [34], 2023	Feasibility study	United States	Hybrid digital transition	Digital literacy + device training	Not directly measured	Confidence, inclusion	Improves access and digital skills
Arena et al [33], 2021	Randomized Controlled Trial	United States	HOP-UP-PT program[f]	In-person + phone	Reduced fall risk	Mobility confidence	Effective home-based intervention
Jacobson et al [35], 2021	Feasibility study	United States	Digital coaching	Online modules	Feasibility outcomes	Usability, acceptance	Scalable and acceptable

[a]RCT: randomized controlled trial.

[b]VR: virtual reality.

[c]AI: artificial intelligence.

[d]mHealth: mobile health.

[e]PEER: Participant Engagement and Empowerment Resources

[f]HOP-UP-PT program: Home-based Older Persons Upstreaming Prevention–Physical Therapy.

Discussion

Principal Findings

This scoping review demonstrates that e-counseling interventions offer meaningful benefits for fall prevention among older adults, with consistent improvements observed in physical outcomes, behavioral engagement, and fall risk awareness across diverse settings.

The study findings demonstrate that e-counseling offers substantial potential in addressing the multifaceted issue of fall prevention among older adults. The diverse modalities used, ranging from VR training to mHealth application and wearable technologies, demonstrate adaptability to various settings and

XSL•FO
RenderX

populations. Notably, the integration of culturally tailored content and user-friendly interfaces appears to enhance engagement and adherence, which are critical factors in the success of fall prevention interventions.

The observed benefits align with prior research indicating that digital interventions can effectively reduce fall incidence and improve balance and mobility. For instance, a previous study demonstrated that e-counseling interventions, whether delivered via telehealth, video consultations, or mobile apps, address many of these barriers by improving accessibility and allowing older adults to engage in fall prevention strategies from the comfort of their homes [45]. However, earlier reviews often focused on in-person interventions, such as group exercise interventions, home visits, or physical therapy, to address fall risk in older adults [46]. Moreover, earlier reviews highlighted issues with adherence, often related to the logistical difficulties of attending in-person sessions consistently [18]. Previous reviews had not emphasized the role of digital tools as strongly, as the technological infrastructure and adoption among older adults were not as widespread [47]. With the increased availability and acceptance of technology, recent studies have shown that digital platforms can provide continuous monitoring and personalized interventions, a feature that was less prominent in earlier studies that focused on more generalized group interventions.

Additionally, previous reviews noted a lack of sustained follow-up, with many interventions being short term and failing to assess the long-term sustainability of fall prevention strategies [48]. Recent findings show that e-counseling, through regular follow-ups and remote monitoring, enhances adherence and promotes long-term engagement in fall prevention activities [49]. This continuous interaction is a marked improvement over older models, which often relied on intermittent or in-person check-ins. Another critical advancement in recent studies is the inclusion of cognitive training and the exploration of how e-counseling can improve not only physical outcomes such as balance and mobility but also cognitive function [50]. Earlier reviews primarily focused on physical outcomes, leaving cognitive aspects underexplored. Recent studies have demonstrated that e-counseling can provide a holistic approach by incorporating both physical and cognitive training into fall prevention strategies, offering a more comprehensive intervention [25]. In summary, compared to previous reviews, the recent findings reflect significant advancements in accessibility, adherence, and the integration of personalized care through digital tools, positioning e-counseling as a scalable and effective intervention for fall prevention among older adults.

Despite the promising findings from existing studies, several research gaps remain in the field of e-counseling for fall prevention among older adults. First, although prior studies demonstrate improvements in knowledge, confidence, and adherence to safety measures, evidence on long-term effects on fall rates and overall health outcomes remains limited. Second, most studies focus on specific populations or geographic regions, limiting generalizability to more diverse groups of older adults with varying health statuses and cultural contexts. Third, the impact of different e-counseling modalities (eg, video calls vs SMS text messaging) on engagement and effectiveness remains underexplored. Finally, although some studies report reductions in fall-related anxiety and increases in physical activity, further research is needed to determine how e-counseling can be integrated into broader health care systems and coordinated with in-person care to support comprehensive fall prevention strategies. Addressing these gaps may enhance the effectiveness and applicability of e-counseling interventions for older adults [24,51].

A multidisciplinary home-based telehealth intervention has also been shown to be feasible and effective in reducing fall risk among older adults, highlighting the importance of integrated and technology-supported approaches in fall prevention programs [52].

Clinical Implications

The results underscore the potential of e-counseling as an integral component of fall prevention interventions in clinical practice. Health care providers should consider integrating e-counseling interventions into routine care for older adults, particularly those facing mobility challenges or residing in remote areas where access to in-person services is limited. By leveraging digital tools, clinicians can offer personalized care plans that adapt to each individual's needs, enhancing adherence to recommended exercises and preventive measures. Moreover, the observed improvements in balance, mobility, and cognitive function suggest that e-counseling not only reduces fall incidence but also contributes to the overall well-being of older adults. Clinicians should be proactive in promoting e-counseling options as part of comprehensive fall prevention strategies, particularly in light of the growing acceptance of telehealth among older populations. Additionally, the role of regular follow-ups and continuous monitoring emphasizes the need for a structured approach to e-counseling. Health care professionals should prioritize ongoing engagement with patients through scheduled virtual check-ins, ensuring that individuals remain motivated and accountable in their fall prevention efforts. This ongoing support can foster greater confidence and satisfaction, leading to more effective long-term outcomes.

Limitations

Several limitations must be acknowledged. First, the eligibility criteria restricted the inclusion of articles to those published in English and within the last 5 years (2019-2025), potentially excluding relevant studies in other languages or earlier research that could provide valuable insights into e-counseling for fall prevention among older adults. Additionally, the selection of articles was based on predefined criteria, which could introduce selection bias; focusing on specific databases may have led to the omission of studies published elsewhere or gray literature, affecting the review's comprehensiveness. Furthermore, the included studies varied in their designs, methodologies, and outcome measures, complicating the synthesis of findings and limiting the ability to draw definitive conclusions regarding the effectiveness of e-counseling interventions.

Conclusions

This scoping review shows that e-counseling represents a promising and scalable approach to fall prevention among older adults, particularly when interventions are personalized,

XSL•FO
RenderX

culturally appropriate, and supported by ongoing monitoring. These findings can inform the development of integrated digital fall prevention strategies within health care systems and support policy initiatives aimed at promoting healthy aging. Future studies should prioritize long-term effectiveness, equitable access in low- and middle-income settings, and sustainable integration into routine care.

Abstract

Background: Sedentary behavior (SB) is a critical, modifiable risk factor for adverse health outcomes. Evidence suggests that SB is higher among individuals with cognitive impairment relative to their cognitively healthy peers. However, the nature and extent of SB across cognitive impairments remains unclear, largely due to the reliance on self-report data and the lack of synthesized evidence from more accurate methodology, such as wearable devices. Wearable device–based methodologies offer a reliable means of capturing SB in real-world settings, circumventing the recall bias inherent to self-report methods. Continuous remote monitoring of SB, via wearable devices, may provide nuanced insights important for understanding SB's contribution to cognitive impairment and health consequences.

Objective: This review aims to synthesize evidence on the volume, patterns, and variability of SB across cognitive impairment and critically appraise the wearable device–based methodology used to capture SB in this population.

Methods: Following PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines, we searched 5 databases (Embase, MEDLINE, PsycInfo, Scopus, and Web of Science) up to January 2025 for peer-reviewed English-language studies using wearable devices to measure SB in community-dwelling or aged residential care residents aged 50 years or older with cognitive impairment (PROSPERO: CRD42024616523). Study quality was assessed using an adapted version of the National Institute of Health Quality Assessment Tool for Observational Cohort and Cross-Sectional Studies. Data were extracted on SB outcomes (eg, volume, pattern, and variability) and methodological characteristics (eg, device type, placement, SB classification/processing, and its corresponding validation).

Results: From 2824 screened records, 17 studies (2016-2025) were included. Most studies (n=11, 65%) were of "good" quality (scoring ≥5 on bias assessment). Synthesis revealed inconsistent evidence for differences in SB volume across cognitive impairment. However, individuals with dementia consistently exhibited a unique SB pattern, engaging in significantly fewer but longer sedentary bouts than other forms of cognitive impairment and cognitively intact controls. All (n=17, 100%) studies used volume metrics to describe SB, followed by pattern metrics (n=7, 41%); only 1 study reported on SB variability. Methodological appraisal found significant heterogeneity: 13 different device models across 6 body placements were used. Most studies quantified SB using count-based thresholds (counts per minute), which were largely unvalidated in cognitively impaired or older adult populations.

Conclusions: This review found that participants with dementia consistently exhibited a unique pattern of SB compared to other forms of cognitive impairment and healthy controls, while evidence for differences in SB volume was inconsistent. This may

XSL•FO
RenderX

indicate that differences in SB volume are not inherent to dementia pathology but may be mediated by other factors, such as neuropsychiatric symptoms or environmental influences. Furthermore, methodological heterogeneity and unvalidated thresholds were observed throughout the review, highlighting a need for standardized protocols to enhance the validity and clinical applicability of future research.

KEYWORDS

cognitive impairment; dementia; mild cognitive impairment; sedentary behavior; systematic review; wearable technology

Introduction

Dementia is a leading global cause of disability and dependency, affecting 55 million people worldwide, a figure projected to double by 2050 [1,2]. Dementia is an umbrella term for multiple progressive neurological diseases that impact cognitive function, leading to significant impairments in functional abilities [2]. However, subtle changes in cognition often occur years before dementia diagnosis. Mild cognitive impairment (MCI) is a transition state between healthy cognitive aging and dementia, wherein cognitive performance is below the expected level for age and education level but does not interfere with independence [3,4]. Approximately 5%-15% of individuals with MCI progress to dementia each year, making it a significant risk factor [5]. Identifying modifiable lifestyle behaviors across cognitive impairment (including MCI and dementia) is therefore a critical public health priority, essential for prolonging cognitive health and reducing escalating health care expenditures [6-9].

Sedentary behavior (SB) is recognized as a distinct, modifiable risk factor for cognitive decline [7,10-12]. Although lifestyle interventions have historically targeted physical activity (PA) to promote healthy cognitive aging [13,14], emerging evidence clarifies that PA and SB are not merely opposite ends of a single continuum: individuals may meet PA guidelines yet still accumulate prolonged sedentary time that exacerbates cognitive decline [12,15-17]. This distinction carries particular significance for people with cognitive impairment (ie, MCI or dementia), who often face barriers such as executive dysfunction, apathy, and caregiver dependence that hinder active lifestyles and promote greater engagement in SB [18-21].

SB is defined as any sitting, reclining, or lying behavior, while awake, characterized by an energy expenditure ≤1.5 metabolic equivalent tasks (METs) [22-24], or any “nonupright” activity [24]. A growing body of evidence indicates that people with cognitive impairment engage in significantly more SB compared with their cognitively healthy counterparts [25]. This is quantitatively demonstrated by studies reporting that those with cognitive impairment spend up to 80% (9.7 hours) of their day sedentary [26-28], in contrast to 55% (7.7 hours) reported in the general older adult literature [29]. These quantitative findings are corroborated by qualitative evidence where 1 study found nursing home residents with cognitive impairment spend a large proportion of their day “doing nothing,” resulting in boredom, frustration, and hopelessness [30]. Collectively, these patterns underscore a critical target for intervention. First, excessive sedentary time is independently linked to exacerbated cognitive decline [15,25,27]. Second, the high volume of SB can worsen psychological symptoms commonly experienced in this population, including apathy, depression, and anxiety, thereby further diminishing overall quality of life [31-33]. This can also create an indirect pathway whereby increased SB exacerbates psychological symptoms, which in turn reduce PA engagement, forming a self-reinforcing cycle of SB [21]. Although differences in PA have been observed across cognitive impairment subtypes (eg, MCI and dementia) and severity levels (eg, mild, moderate, and severe) [34,35], it remains unclear whether SB varies similarly. The current evidence base is limited and methodologically heterogeneous [36,37]. Consequently, the precise nature and extent of SB across cognitive impairments remains inconclusive.

Accurately measuring SB is a critical first step toward developing interventions for individuals with cognitive impairment to reduce the associated health risks. The primary assessment methods offer a trade-off between context and precision. Self-report tools (eg, questionnaires) are popular for their practicality and ability to identify activity types but are undermined by recall bias and inaccuracy, which may be exacerbated by cognitive impairment [38-41]. In contrast, device-based measures are often regarded as the “gold standard” for assessing SB volume and pattern [40,42] and are recommended for assessing SB in people with cognitive impairment in free-living environments [40,41,43]. Unlike self-report tools, device-based methods enable detailed analyses of sedentary patterns, making them particularly valuable for detecting subtle behavioral changes over time and well-suited for research aiming to understand the nuanced relationship between SB and cognitive impairment [44,45]. As such, they offer a promising avenue to accurately capture SB in real-world settings with minimal participant burden [37].

Device-based methods can encompass a wide range of technologies, from smart-home systems (eg, indoor positioning systems [46]) to wearable devices (eg, accelerometers [47]). Smart-home technology can capture accurate contextual SB data in an unobtrusive manner [48]; however, it is often constrained to the home environment and requires complex infrastructure and data processing [46,48]. In contrast, wearable devices can capture SB data with high precision at a reduced cost [49]. Crucially, their ability to measure SB in free-living environments, beyond the home, provides the ecological validity necessary to understand SB patterns across all daily contexts in people with cognitive impairment [50].

Despite their advantages, wearable-based methodologies are marked by considerable heterogeneity in the SB literature

XSL•FO
RenderX

[15,51]. Wearable devices primarily assess SB through 2 approaches: by quantifying a lack of movement using accelerometer cut points or detecting body posture [52]. Although posture-based measurement is considered the most accurate method for identifying SB [22,43,52,53], much of the existing literature relies on cut-point thresholds (counts per minute [CPM]). These thresholds vary substantially across studies and can produce markedly different SB estimates [54]. Beyond threshold selection, a growing body of evidence indicates that SB estimates are also influenced by broader methodological factors, including device brand (eg, activPAL and Axivity), body placement (eg, thigh or wrist), and the metrics used to characterize SB (eg, sedentary time and bout length) [44,55-60]. Such methodological inconsistencies and lack of standardization may bias estimates of SB and complicate comparisons across studies. However, whether these methodological variations influence SB estimates in populations with cognitive impairment is yet to be synthesized.

This systematic review aims to synthesize the existing evidence on SB volume, patterns, and variability (fluctuation of SB) and to critically appraise the wearable technology methods and metrics used. By identifying and analyzing the key sources of methodological variation, this work seeks to promote more standardized and appropriate measurement approaches. Addressing these methodological challenges is a critical prerequisite for advancing SB research and translating findings into practical health benefits for populations with cognitive impairment.

Methods

Search Strategy

This review was preregistered on PROSPERO (CRD42024616523) and designed in accordance with the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) [61]. PRISMA 2020 checklist is available in Multimedia Appendix 1. Five databases were used for this search: Embase, MEDLINE, PsycInfo, Scopus, and Web of Science. The search criteria were restricted to studies conducted up to the date of the most recent search (January 2025), with no lower date limit. Keywords relevant to cognitive impairment, wearable digital technology, and SB formed a search string (Multimedia Appendix 2).

Selection Criteria

Articles were screened in accordance with the most generally adopted definitions of SB: any sitting, reclining, or lying behavior, while awake, characterized by an energy expenditure ≤1.5 METs [22-24] or any nonupright activity [24].

Inclusion and Exclusion Criteria

Articles were included if they were (1) peer reviewed; (2) published in the English language before 2025; (3) conducted within community-dwelling or aged residential care settings, including supportive living, assisted living, residential aged care, nursing homes, and care homes; (4) investigated individuals with MCI or dementia, inclusive of all subtypes to capture the full breadth of cognitive impairment presentations [62-65]; (5) involved participant samples with a mean age of ≥50 years to ensure the inclusion of MCI and young-onset dementia [62,63,66,67]; (6) reported SB metrics measured through quantitative wearable devices (eg, accelerometry); and (7) defined SB either in accordance with the established consensus definitions or through an alternative but clearly articulated and appropriate definition.

Articles were excluded if they were (1) published in a language other than English; (2) conducted in acute, in-patient hospital, or palliative care settings (as inactivity in these environments is often medically mandated and does not represent an individual's usual, volitional behavior [68,69]); (3) focused solely on PA or sleep-related metrics; (4) assessed SB through subjective self-report measures without the inclusion of quantitative wearable-derived data; (5) involved children, adolescents, or adults without cognitive impairments, including those with subjective cognitive impairment; (6) included mixed populations without disaggregated SB data for individuals with cognitive impairment; or (7) were not primary research articles such as conference abstracts, conference proceedings, posters, study protocols, letters to the editor, reviews, meta-analyses, or gray literature.

Data Extraction

All titles, abstracts, and full texts were independently screened by 2 reviewers (JLW and CH) using Rayyan software developed by Ouzzani et al [70]. Any disagreements were settled by a third reviewer (RMA).

Author JLW created data extraction forms using Excel (Microsoft Corp) and refined them in collaboration with 2 other authors (CH and RMA). One author (JLW) independently extracted data from all eligible articles, and the extracted data were verified by author CH.

The key measures of interest were: (1) study design, (2) participant characteristics and study setting, (3) stage of cognitive impairment (ie, MCI and mild, moderate, or severe dementia) and diagnostic criteria applied, (4) measure of outcome (SB), and (5) comparisons between groups (healthy controls or other forms of cognitive impairment). For outcome measures (SB), we extracted the (1) SB metrics and their values (eg, volume, pattern, and variability metrics); (2) method of assessment (eg, accelerometry); (3) definition of measurement (eg, body posture or cut-point thresholds); (4) device name and manufacturer; (5) data collection procedure (eg, device placement and length of assessment); (6) previously established validity and reliability of SB classification (eg, validation of cut point); and (7) data processing algorithms used to derive SB outcomes, including the classification approach (eg, cut-point–based or posture-based), algorithm source (eg, academic or proprietary), and evidence of algorithm validation.

Assessment of Study Quality

The quality of study articles was assessed using an adapted version of the National Institute of Health Quality Assessment Tool for Observational Cohort and Cross-sectional Studies [71]. This adapted version has previously been used in similar reviews [72]. Study quality was assessed based on 7 questions, which can be found in Multimedia Appendix 3.

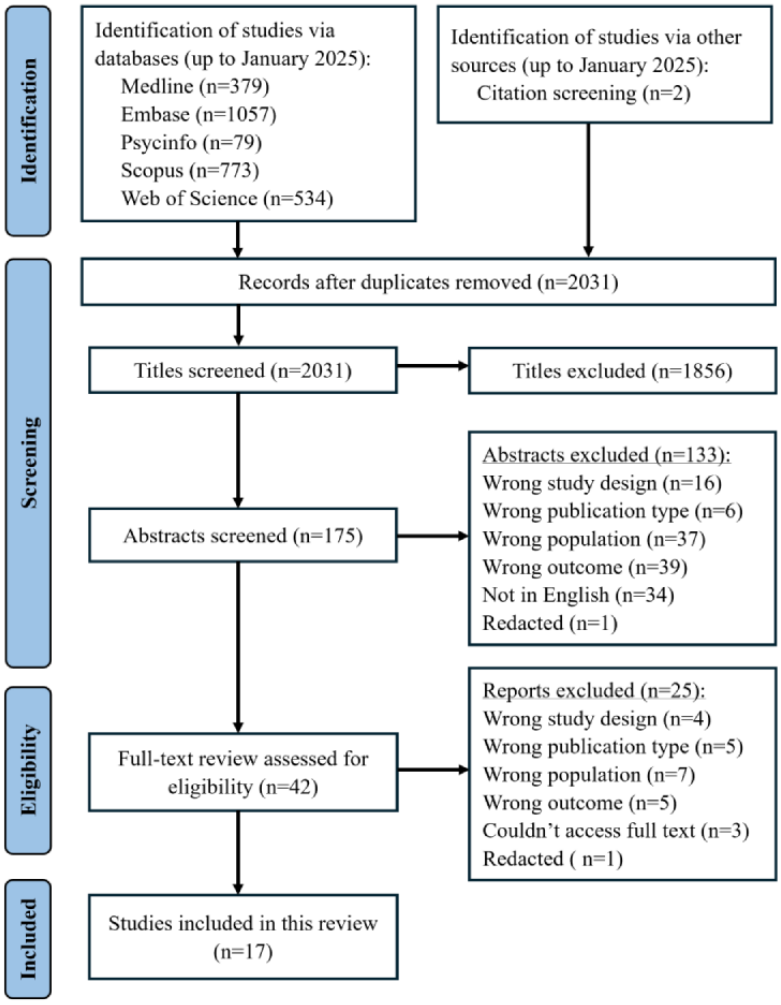
XSL•FO
RenderX

Two raters (JLW and CH) independently assessed the quality of the studies and reached consensus through discussion; average scores determined the overall quality of each study. A binary system was used to rate the studies (1=yes and 0=no), which enabled a summed score out of 7 to aid in determining the overall quality of each study (rated good: scores 5-7, moderate: scores 3-4, or poor: scores 0-2).

Data Synthesis

Narrative data synthesis was applied to summarize and integrate findings across the studies. Reflecting this systematic review's aims, results were grouped by (1) synthesis of reported SB outcomes in people with cognitive impairment, considering disease severity and subtype; and (2) wearable technology methods and metrics used to measure SB, including device type and placement, characterization of SB, and processing techniques and validity. Due to heterogeneity in the data, meta-analysis was infeasible.

To support the interpretation of data and provide consistency across the literature, we categorized wearable technology metrics of SB into volumes, patterns, and variability of behavior. These categories were theoretically derived, drawing on established concepts in SB and PA literature [24,72-74], and were operationalized before the final data synthesis to ensure consistent classification of metrics across all included studies. Volume refers to the amount of time spent in SB during a specified period (eg, per day or full assessment period), expressed either as an absolute value (minutes or hours) or as a relative value (percentage of time) [22]. Where necessary, time-based data were converted to a common unit (eg, minutes) to ensure consistency in aggregation and comparison. Pattern explains the way sedentary time is accumulated, including the number and duration of SB bouts, the interruptions in SB, and the distribution of SB throughout the day [24]. Variability refers to the intraindividual fluctuations or day-to-day changes in sedentary time and captures how consistently (or inconsistently) a person engages in SB across different days or within various segments of the day (eg, morning vs evening) [75]. The categorization of metrics was performed by the primary researcher (JLW) and reviewed by all authors. Any amendments were discussed collaboratively, and all revisions were agreed upon by consensus.



Results

Search Yield

Figure 1 describes the results of the search strategy for articles investigating SB using wearable digital technology in people with cognitive impairment. The search was conducted between November 2024 and January 2025 and initially yielded 2822 articles; 2 additional studies were identified through citation screening. Our final systematic review included 17 articles, all of which were published between 2016 and 2025.

RenderX

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flow diagram demonstrating the search yield for this systematic review.

Study Characteristics

Table 1 contains information relating to all the study characteristics. Studies took place in Germany (3/17, 18%), the Netherlands (3/17, 18%), the United States of America (3/17, 18%), Australia (2/17, 12%), Canada (2/17, 12%), Hong Kong (1/17, 6%), Japan (1/17, 6%), Norway (1/17, 6%), and Portugal (1/17, 6%). The sample size of participants with cognitive impairment ranged between 8 and 539 across all studies, with a mean age range of 68-91.7 years. Regarding participants with cognitive impairment, 59% (10/17) of studies reported ≥50% of participants as female. A total of 3 (18%) studies reported the ethnicity of participants with cognitive impairment, whereby more than 87% of the participants were White. Most studies were cross-sectional (14/17, 82%), the remaining studies (3/17, 18%) used baseline data from randomized controlled trials or intervention studies; there were no longitudinal observational studies. Of the 17 studies, 11 included only community-dwelling participants, 3 included only institutionalized participants, and 3 included a mix of both (Figure 2 [76-92]).

[h]RDC: regular day care.

[i]MoCA: Montreal Cognitive Assessment.

[j]VM: vector magnitude.

XSL•FO
RenderX

Figure 2. Overview of cognitive impairment categorization, study population, and control group comparisons for all studies included in this review. FDC: farm-based dementia care; MCI: mild cognitive impairment; MoCA: Montreal Cognitive Assessment; PDD: Parkinson disease dementia; RDC: regular day care.

Levels of cognitive impairment described across the 17 studies included MCI (n=5, 25%), unspecified severity of dementia (n=4, 20%), unspecified level of cognitive impairment (n=3, 15%), mild-moderate dementia (n=2, 10%), mild-severe dementia (n=2, 10%), mix of MCI and dementia (n=2, 10%), probable MCI (n=1, 5%), and mild dementia (n=1, 5%) (Figure 2).

For the purposes of this review, cognitive impairment was categorized into 3 broader cohorts: MCI (n=6), dementia (n=11), and mixed cognitive impairment (n=5), spanning the 17 studies. Mixed cognitive impairment refers to cohorts that have been identified as cognitively impaired with no specific diagnosis or mixed groups of dementia and MCI. Overall, 12 studies (71%) included comparisons to controls, resulting in 16 control cohorts corresponding to the dementia (n=7), MCI (n=4), and mixed cognitive impairment (n=5) cohorts (Figure 2).

A total of 8 (47%) studies specified dementia disease subtypes, of which 88% (n=7) included participants with Alzheimer disease (AD) [77,80,85,87,91-93]; 25% (n=2) reported participants with MCI/dementia due to Parkinson disease [79,91]; 25% (n=2) involved participants with vascular dementia or mixed dementia [91,93]; and 13% (n=1) included participants with frontotemporal dementia, dementia with Lewy bodies, or Korsakoff syndrome [91]. Additionally, 15 (88%) studies explicitly described procedures to characterize cognitive impairment (eg, clinician review and cognitive score thresholds), and 80% (n=12) of these used validated diagnostic criteria.

Quality Assessment

Mostly, studies were of adequate quality, with 65% (11/17) being rated as “good” and 35% (6/17) being rated as “moderate.” No studies were rated “poor.” The most common reasons for reduced study quality were a lack of sample size justification (n=15) (Multimedia Appendix 3).

Aim 1: Volume Patterns and Variability of SB in People With Cognitive Impairment

Overview

A summary of extracted outcomes (metrics reported by ≥2 studies) is provided in Table 1, with all metric definitions and prevalence detailed in Table 2. A comprehensive narrative synthesis of all extracted outcomes is provided in Multimedia Appendix 4.

XSL•FO
RenderX

Table 2. Prevalence and descriptions of SB[a] metrics captured in this review.

SB metric	Frequency, n (%)	Description
Volume		
Volume of SB	17 (100)	Time spent in SB for a specified time frame (eg, per day/per week) expressed as an absolute value (hours/minutes/seconds) or relative value (percentage of time)
SB time	10 (59)	Amount of time (hours/minutes/seconds) spent in SB over a specified period (eg, per day/week)
SB proportion	10 (59)	Percentage (%) of time spent in SB over a specified period (eg, per day/week)
Lying time	2 (12)	The length of time spent in sedentary lying (hours/minutes/seconds)
Sitting time	2 (12)	The length of time spent in sedentary sitting (hours/minutes/seconds)
Inactive time	1 (6)	The length of time spent inactive (sum of lying and sitting time) (hours/minutes/seconds)
Lying proportion	1 (6)	Relative percentage of time spent in sedentary lying
Sitting proportion	1 (6)	Relative percentage of time spent in sedentary sitting (%)
SB proportion (METs[b])	1 (6)	Relative percentage of time spent with intensity levels of ≤1.5 METs (%)
Pattern		
Pattern of SB	7 (41)	The number of sessions and distributions of sedentary activity over a specified period (eg, per day/week)
SB bouts (≥30 minutes)	4 (53)	The number of sedentary bouts lasting over 30 minutes, continuously
SB bouts	3 (18)	The number of sedentary bouts accumulated over a specified time (eg, per day/week)
Mean SB bout length	3 (18)	The average length of time spent in a singular sedentary bout
SB interruptions	1 (6)	The count of nonsedentary bouts that occur between two sedentary bouts
SB bouts (≥60 minutes)	1 (6)	The number of sedentary bouts lasting over 60 minutes, continuously
Hourly SB distribution	1 (6)	The extent to which an individual's SB differs across hours of the day
Variability		
Variability of SB	1 (6)	Fluctuations in sedentary time or patterns across a specified time (eg, day-to-day) within individuals or groups over time
Day-to-day variability	1 (6)	The extent to which an individual's SB differs across multiple days

[a]SB: sedentary behavior.

[b]METs: metabolic equivalent tasks.

Volume

All 17 studies used volume metrics to describe SB in individuals with cognitive impairment. Nine studies (53%; 10 cohorts) reported SB time per day: 4 in dementia (5 cohorts; ranging from 510 to 1038 minutes per day) [80,88,91,93], 2 in MCI (ranging from 626.9 to 637 minutes per day) [78,84], and 3 in mixed cognitive impairment (ranging from 476.2 to 1203 minutes per day) [77,86,90]. A total of 3 out of 4 dementia studies considered control group comparisons [80,91,93]; only 1 study [91] reported significantly higher SB time in institutionalized participants with dementia per day relative to both community-dwelling participants with dementia (P<.05) and healthy controls (P<.001), while the remaining 2 dementia studies reported no significant differences in SB time per day [80,93]. In MCI, neither of the 2 studies performed comparative analyses with control groups. For mixed cognitive impairment, all 3 studies considered control comparisons; only 1 study reported significantly higher SB in those with unspecified cognitive impairment (P<.01) [90], with the others reporting no significant differences [77,86]. Additionally, 1 study [87] reported SB time per week in mixed cognitive impairment (142.7 hours per week) and found no significant differences when compared with controls.

Nine studies (53%; 12 cohorts) reported SB as a percentage of the day: 5 in dementia (ranging from 57% to 89% per day) [79,85,88,92,93], 5 in MCI (ranging from 43.55% to 78% per day) [78,79,81,85,89], and 2 in mixed cognitive impairment (ranging from 57.8% to 87.2% per day) [85,86]. Among dementia studies, 4 included control comparisons [79,85,92,93], 2 reported statistically higher SB proportion (P<.05) [85,93], while the others found no significant differences [79,92]. Contrastingly, 4 of 5 MCI studies [79,81,85,89] and both mixed cognitive impairment studies considered group comparisons with controls, reporting no statistically significant differences. Additionally, 1 study [82] reported SB as a percentage of the week in 2 dementia cohorts (ranging from 39.7% to 43.51% per week), without comparison with healthy controls.

Two studies [76,84] assessed SB as sitting and lying minutes per day, respectively, 1 in dementia [76] (sitting: 678 minutes; lying: 546 minutes) and 1 in MCI [84] (sitting: 558 minutes;

XSL•FO
RenderX

lying: 21 minutes). Neither incorporated control comparisons, and no studies in mixed cognitive impairment reported this metric.

Finally, 1 study [79] assessed SB in people with dementia and MCI compared with cognitively intact controls using 3 volume metrics. First, it measured the proportion of time spent at ≤1.5 METs, finding that participants with dementia were sedentary for 89% of the day, compared with 84% for those with MCI. However, these differences were not statistically significant, either between MCI and dementia (P=.92) or between dementia and cognitively intact controls (P=.64). Second, the study reported the proportion of time spent lying and sitting. The MCI group spent the largest proportion of their day lying (42%), followed by sitting (34%), whereas the group with dementia spent more time sitting (42%) than lying (40%). However, no statistical comparisons were reported for this postural data, and these metrics were not assessed in mixed cognitive impairment groups.

Pattern

Seven studies (41%) used pattern metrics to describe SB in individuals with cognitive impairment. Four studies (57%; 6 cohorts) reported the number of prolonged (≥30 minutes) SB bouts per day: 2 in dementia (ranging from 2.3 to 4.1 bouts per day) [85,93], 3 in MCI (ranging from 3.5 to 5 bouts per day) [81,84,85], and 1 in mixed cognitive impairment (3.3 bouts per day) [85]. In dementia, both studies considered comparisons with controls [85,93]; 1 reported a significantly higher number of prolonged bouts compared with healthy controls, MCI, and mixed cognitive impairment groups (P<.05) [85], while the other found no significant differences [93]. In MCI, 2 of the 3 studies conducted comparative analyses with controls [81,85], with one reporting significantly more prolonged bouts than healthy controls (P<.05) [81] and the other finding no significant difference [85]. For mixed cognitive impairment, the single study found no statistically significant differences compared with controls [85].

Three studies (43%; 6 cohorts) reported average SB bout length: 3 in dementia (ranging from 474 to 1098 seconds) [79,85,93], 2 in MCI (ranging from 378 to 515 seconds) [79,85], and 1 in mixed cognitive impairment (390 seconds) [85]. All studies considered comparisons with control groups. All 3 dementia studies reported significantly longer bout durations compared with healthy controls (P<.05); 1 study further reported that this difference remained significant when compared to both MCI and mixed cognitive impairment groups [85]. In contrast, studies of MCI and mixed cognitive impairment found no significant differences in average bout length vs controls.

Two studies (43%; 5 cohorts) reported the number of SB bouts per day: 2 in dementia (ranging from 86.1 to 97.0 bouts per day) [79,85], 2 in MCI (ranging from 89.4 to 129.0 bouts per day) [79,85], and 1 in mixed cognitive impairment (91.4 bouts per day) [85]. All studies conducted comparative analyses with controls. For participants with dementia, both studies reported significantly fewer SB bouts compared with healthy controls (P<.05); 1 study further noted this finding remained significant when compared with a group with mixed cognitive impairment, but not MCI [85]. In contrast, studies of MCI and mixed cognitive impairment found no significant differences in this metric compared with controls. Additionally, 1 study reported the number of sitting bouts per week in mixed cognitive impairment (MCI and AD) [87], reporting 681.5 sitting bouts per week, with no significant differences compared with controls.

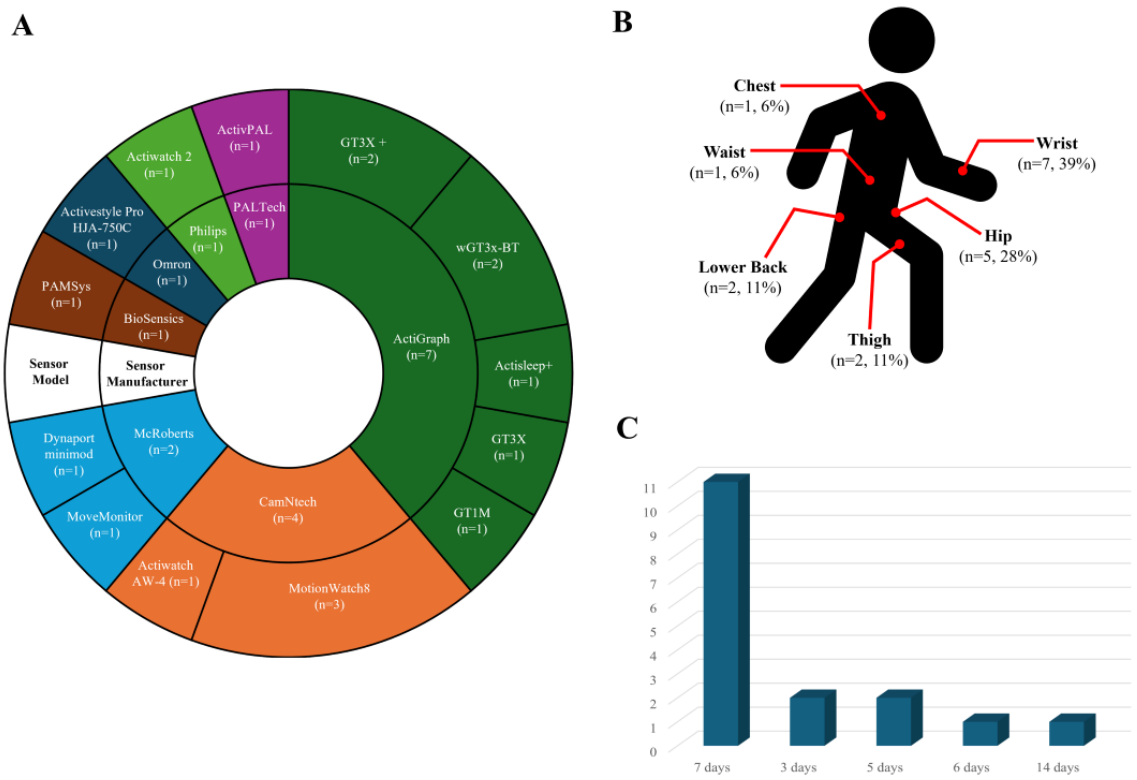
One study [93] compared daily sedentary interruptions between participants with dementia and healthy controls. Although the group with dementia averaged 27.2 interruptions per day, this difference was not statistically significant (P=.20). This metric was not assessed in participants with MCI or mixed cognitive impairment.

Another study [84] quantified the daily number of sedentary bouts exceeding 60 minutes in individuals with MCI, finding an average of 1 bout per day. However, this study did not consider control group comparisons, and this metric was not assessed in groups with dementia or mixed cognitive impairment.

Finally, 1 study [86] reported the hourly distribution of SB and found participants with unspecified cognitive impairment spent significantly more time sedentary, compared with healthy controls, during the hours of 7 AM to 11 AM, 1 PM, and 4 PM. This metric was not assessed in participants with dementia or MCI.

Variability

One study [76] reported day-to-day variability of participants with dementia, where they found SB parameters demonstrated consistently low day-to-day variability between Friday and Saturday and Saturday and Sunday (intraclass correlation coefficients ranging from 0.82 to 0.85), indicating minimal influence from day-specific or contextual factors. This metric was not assessed in participants with MCI or mixed cognitive impairment.



Aim 2: Wearable Digital Methods and Metrics Used to Measure SB in People With Cognitive Impairment

Overview

All studies (100%) used accelerometer-based wearable devices to measure SB in people with cognitive impairment. Across the 17 studies, 13 different device models were used across 7 different manufacturing brands (Figure 3A). The most common manufacturing brand reported was ActiGraph, with 41% (7/17) of studies using 5 different ActiGraph models to measure SB. However, the MotionWatch8 (CamNtech Ltd) was the most used wearable device across the studies (3/17, 18%). Six different body placements were used for devices, the most common placement being the wrist (7/17, 39%) (Figure 3B). Five different assessment periods were reported by studies; most study protocols (11/17, 65%) requested participants to wear the devices for 7 days (Figure 3C).

XSL•FO
RenderX

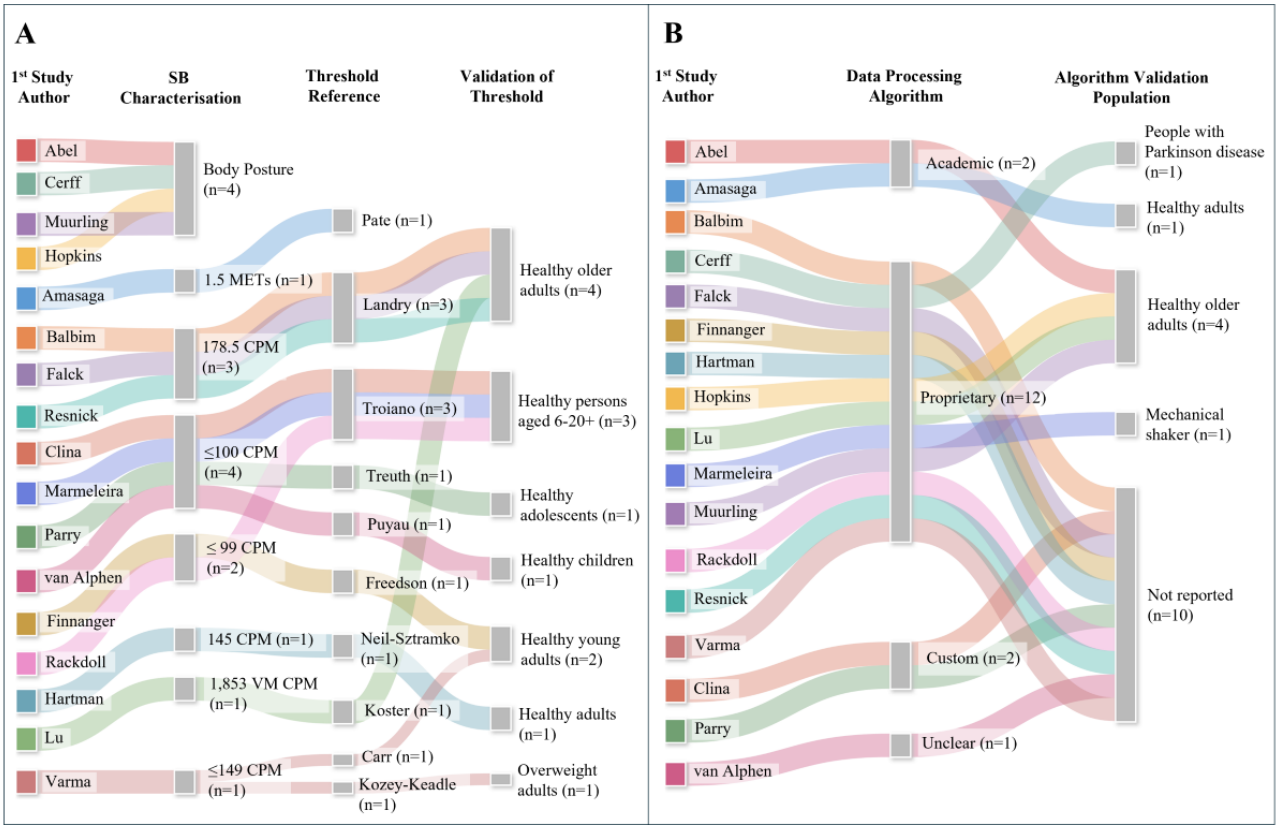
Figure 3. Methods and protocols used across studies included in this review. (A) Digital devices used to capture sedentary behavior (SB) metrics categorized by sensor type and manufacturer, (B) prevalence of placements of wearable devices on the body, and (C) prevalence of SB collection time periods.

Data Loss and Wear Compliance

Thirteen (76%) papers reported reasons for data loss, including insufficient data collection (n=11, 92%; <3 days [82,85,86]; <4 days [87,88]; <5 days [78]; <6 days [93]; <6 consecutive days [91]; <80% daily wear time [79]; <10 hours daily [84]; <10 hours on at least 3 days including 1 weekend day [80]), technical issues (n=6, 46% [87-91,93]), removal or refusal to wear devices (n=3, 23%; wrist [90,91]; lower-back [87]), lost devices (n=2, 17% [87,91]), forgetting to wear the device (n=1, 8% [87]), and organizational issues (n=1, 8% [91]).

Nonwear Identification and Wear Time Criteria

Eleven studies (65%) explicitly reported identifying nonwear in their analyses, either by specifying the criteria used (eg, zero accelerometer counts for a specified period, n=8 [77,80,81,85,86,88,90,92]) or by referencing nonwear algorithms (n=3 [79,82,87]). The remaining studies either did not report (n=4 [76,84,89,91]) or explicitly did not perform (n=2 [78,93]) nonwear identification. Fourteen studies (82%) established thresholds to determine data validity. The minimum required days for inclusion ranged from 3 to 6 days (n=11), and the minimum required wear per day ranged from 8 to 24 hours (n=11) (Multimedia Appendix 4).



SB Quantification and Algorithm Validation

All studies (100%) reported their quantification of SB. A total of 4 (24%) classified SB using body posture [76,79,84,87], and 1 study (6%) classified SB as ≤1.5 METs [77]. A total of 71% (12/17) used CPM thresholds to classify SB.

In these cases, the thresholds were supported by references to validation studies conducted in 7 distinct populations (Figure 4A [76-92]). Furthermore, 16 (94%) studies described the data processing algorithms used to extract SB outcomes, 12 (75%) used proprietary algorithms provided by the manufacturer, 2 (13%) adopted academic algorithms provided from previous research, and 2 (13%) used custom-developed algorithms. Further, 7 (44%) studies explicitly reported the validation of the algorithms to extract SB outcomes (Figure 4B).

XSL•FO
RenderX

Figure 4. Variability in sedentary behavior (SB) characterization, thresholds, and processing across all studies (n=17). (A) Approaches to SB characterization, adopted thresholds, and validation of thresholds. (B) Data processing algorithms used to process SB with corresponding validation populations. CPM: counts per minute; METs: metabolic equivalent tasks; VM: vector magnitude.

Influence of Methodological Approaches on SB Estimates

The choice of classification approach appeared to influence the types of metrics reported across the included studies. Studies using posture-based classification were more likely to report pattern-related metrics (3/4, 75%) compared with those using CPM thresholds (4/12, 33%). The MET-based study did not report any pattern-related metrics. Day-to-day variability was the least frequently captured dimension, reported in only 1 study [76], which used a posture-based approach. The specific parameters used by each study are detailed in Multimedia Appendix 5, and definitions for all identified metrics are provided in Table 2. As SB volume was the only outcome reported by all studies, it was used to examine how methodological choices shaped the resulting estimates. Volume metrics reported by at least 2 studies are synthesized below and in Table 1, with a complete overview provided in Multimedia Appendix 4.

Device Placement

All CPM-based studies (n=12) applied devices on the wrist (n=7 [78,81,82,85,90,91,93]) or hip (n=5 [80,86,88,89,92]). Wrist-worn SB time ranged from 510 to 1203 minutes per day (n=4 [78,83,90,91]), and the proportion ranged from 43.55% to 63.2% per day (n=4 [78,81,83,85]). Hip-worn SB time ranged from 565.6 to 622.2 minutes per day (n=3 [80,86,88]), and proportion ranged from 60.94% to 87.2% per day (n=4 [86,88,89,92]). Posture-based studies (n=4) applied devices on the lower back (n=2 [79,87]), thigh (n=1 [84]), or chest (n=1 [76]). Lower-back placement produced sedentary proportions of 78% to 89% per day [79]. Thigh placement reported 637 minutes of SB time per day [84], while chest reported 1224 minutes per day [76]. The single MET-based study (n=1 [77]) used a waist-mounted device and reported 476.2 minutes of SB time per day.

Classification Approach

Among the studies adopting the lowest cut-point thresholds of ≤99-100 CPM, SB time per day ranged from 565.6 to 1038 minutes (n=4 [80,86,88,91]), while SB proportion per day ranged from 72% to 87.2% (n=3 [86,88,89]). In studies adopting mid-range thresholds of ≤145-149 CPM, SB proportion ranged from 57% to 60.94% (n=2 [92,93]). For those using a higher threshold of ≤178.5 CPM, SB time per day ranged from 626.9 to 1203 minutes (n=2 [78,90]), with SB proportion per day ranging between 43.55% and 61.65% (n=2 [78,81]).

Posture-based studies generally provided more granular data than threshold-based methods. Two such studies reported daily SB time (637-1224 minutes per day) and further distinguished between sitting (558-678 minutes per day) and lying time (21-546 minutes per day) [76,84]. Additionally, a study using body-posture classification estimated the proportion of SB spent at ≤1.5 METs to be between 84% and 89% per day [79]. The single MET-based study estimated SB time ≤1.5 METs (476.2 minutes per day) [77].

Denominator Choice in Proportion Calculations

Of the 10 studies that quantified SB proportion, a total of 6 [82,85,86,88,92,93] calculated proportion relative to wear or

XSL•FO
RenderX

wake time, and 4 [78,79,81,89] calculated proportion relative to a full day (24 hours). Specifically, within CPM-based studies, using wear or wake time as a denominator yielded higher SB proportions (range: 57%-87.2%) compared to those calculated relative to a 24-hour day (range: 43.55%-72%).

Algorithm Type

Of the 12 studies (16 cohorts) using proprietary algorithms, 8 reported SB proportion per day [78,79,81,85,86,89,92,93] (11 cohorts; range: 43.55%-89%), and 5 reported SB time [78,83,84,86,90] (range: 510-1203 minutes per day). Both studies using academic algorithms [76,77] reported SB time (range: 476.2-1224 minutes per day). The 2 studies using custom algorithms [80,88] also reported SB time (range: 565.6-622.2 minutes per day). No clear patterns emerged across algorithm types, as estimates overlapped considerably.

Discussion

Overview

This systematic review is the first to characterize SB across cognitive impairments (ie, MCI and dementia) and critically appraise the wearable digital methods used to measure it. A key finding is that while total SB volume did not consistently differ between those who are cognitively impaired and controls, their pattern appeared to. Specifically, individuals with dementia exhibited significantly fewer but longer sedentary bouts. However, this review also highlights significant methodological inconsistencies in how SB is measured. Variations in device type and placement, wear-time protocols, cut-point thresholds, proportion denominators, and reported outcomes limit cross-study comparisons and, consequently, our understanding of SB and its influencing factors.

Impact of Cognitive Impairment and Disease Subtype on SB

To reflect Aim 1, this review suggests that the relationship between cognitive impairment and SB may be characterized less by a simple increase in volume and more by a potential shift in pattern. The available evidence indicates that people with dementia tend to exhibit longer and fewer sedentary bouts compared with those with MCI and cognitively intact controls [79,85,93], a profile that could be indicative of more prolonged, uninterrupted SB, which is often considered the most hazardous type [94]. However, no longitudinal research was identified in the review, meaning we cannot ascertain how SB patterns change with disease progression or if it predicts worse outcomes. Furthermore, our synthesis points to a nuanced conclusion: a significantly greater volume of SB does not appear to be a consistent hallmark of cognitive impairment. Among the 12 studies (comprising 18 cohorts) that considered control comparisons, only 4 identified a significant increase in SB volume [85,90,91,93]. Of these, 3 (75%) were specific to dementia cohorts, while 1 pertained to a group with mixed cognitive impairment. The existing self-report literature, which focuses on physical inactivity, provides a relevant context for interpreting the current findings on SB. Studies have found that physical inactivity is not directly associated with lower global cognition in community-dwelling adults with dementia [95-100]. Instead, inactivity appears to be more closely linked to other factors, including depression, a history of falls, fewer waking hours, and environmental barriers [95,99-102]. This suggests that cognitive impairment may not inevitably lead to pervasive inactivity, which may also extend to SB, pointing to the influence of other mediating factors.

The apparent discrepancy between inconsistent volume and consistent pattern findings may be explained by neuropsychiatric symptoms and their interaction with the environment, rather than the disease pathology itself. For instance, apathy, a prevalent symptom in dementia, varies significantly between individuals and may manifest not as a greater total sedentary time, but as a reduced frequency of interruption, leading to the observed pattern of prolonged bouts [32,103]. This perspective is supported by Alonzo's [104] theory, which posits that the impact of an illness emerges from its interaction with the individual's environment. In this view, symptoms like apathy and disorientation interact with environmental contexts (eg, institutional settings and lack of stimulation) to promote sedentariness. Qualitative evidence corroborates this mechanism, identifying symptoms such as exhaustion and disorientation as common barriers to activity [103]. Therefore, future qualitative research is warranted to further elucidate the lived experience of sedentariness in this population.

It is important to note, however, that this interpretation is constrained by the methodological limitations identified in this review. The widespread use of wrist-worn devices and unvalidated cut points [37,105] is likely to impair the detection of short, nonpostural movements that break up sedentary time. Therefore, the current evidence base may underestimate the true extent of sedentary patterns in cognitive impairment, and the potential role of symptoms warrants further investigation with more precise and standardized measurement tools.

Furthermore, the generalizability of these findings across dementia subtypes remains uncertain. The available evidence is predominantly derived from cohorts with Alzheimer disease (88% of studies that reported dementia subtypes). Other dementia subtypes were included but not analyzed separately [91,93], preventing insights into how their unique symptomatic profiles might influence distinct SB patterns [106,107]. The current literature's focus on Alzheimer disease underscores a significant evidence gap regarding SB in non- Alzheimer disease dementias, which future research should devote attention to.

Current Approaches for Wearable Digital Methods and Metrics for Characterizing SB in People With Cognitive Impairment

Aligned with Aim 2, key findings in this review indicate that, in keeping with existing literature [108], studies quantified SB through 2 distinct methods: identifying body posture or applying cut-point thresholds. These approaches also shape the type of outcomes that can be derived; posture-based methods more readily capture pattern-related metrics (eg, bouts and breaks), whereas cut-point threshold approaches primarily quantify overall sedentary volume. This methodological divergence is compounded by differences in device placement and detection mechanisms. For posture-based measurements, thigh-worn

XSL•FO
RenderX

devices struggle to distinguish sitting from lying [43], while lower-back devices struggle to distinguish sitting from standing [109]. In contrast, cut-point thresholds do not distinguish between postures and are highly sensitive to nonambulatory arm movements. Consequently, wrist-worn devices may misclassify sedentary fidgeting as nonsedentary time [110,111].

This pattern is reflected in the findings of the present review: trunk placements (eg, hip, lower back, and waist) generally reported higher and more stable estimates of SB time and proportion, whereas wrist-worn devices produced the lowest SB proportions and the greatest variability in SB time. However, these differences may also be partially explained by how SB is characterized, as wrist-worn studies demonstrated greater variability in cut-point thresholds compared with more standardized placements such as the hip. Collectively, these findings suggest that differences in SB estimates may be driven less by device placement alone and more by underlying methodological choices (eg, CPM thresholds), which reflect differing conceptualizations of SB.

The CPM approach was the most common method adopted to measure SB in cognitive impairment, with 71% (12/17) of studies using this method. The CPM approach is widely used in SB research [112] and functions as a proxy measure for energy expenditure (METs) [40], aligning with the standard SB definition of ≤1.5 METs. However, its application is highly inconsistent; 6 different CPM thresholds were identified in this review, none of which were validated in cognitively impaired populations. Although 2 thresholds (178.5 CPM [78,81,90] and 1853 vector magnitude CPM [85]) were validated in healthy older adults, the remainder lacked validation in any older population, significantly undermining the validity and comparability of findings.

The consequences of this inconsistency were most apparent in estimates of sedentary proportion. Unlike the broader literature, where lower cut points typically yield lower sedentary estimates [43,113], studies in this review using lower thresholds (≤99–100 CPM) reported the highest sedentary proportions, whereas higher thresholds (≤178.5 CPM) produced lower estimates. This inverse pattern suggests that lower cut points validated in younger populations may overestimate sedentary time when applied to older adults with cognitive impairment, while thresholds derived from older populations may provide more accurate estimates. These trends were not observed for absolute sedentary time (minutes per day) or by algorithm type (proprietary, academic, and custom), indicating that proportional differences may instead reflect denominator choice. Studies using waking or wear-time denominators reported higher sedentary proportions than those using a 24-hour denominator, as excluding sleep and nonwear reduces the denominator and inflates the proportion of time classified as sedentary. This aligns with methodological evidence demonstrating that accelerometer processing decisions, including wear-time definitions, substantially influence sedentary estimates and complicate comparisons across studies [114-117]. Together, inconsistencies in cut-point selection and denominator choice limit comparability across studies and hinder evidence synthesis.

While less common, posture-based methods (used by 24% of studies) offer a more direct assessment of SB. This approach circumvents the need for population-specific energy expenditure validation and may offer more accurate detection of SB [24,43]. Matthews et al [29] have called for such objective definitions to incorporate posture, arguing that energy-based criteria alone may not fully capture the nature of SB. However, this method introduces a different set of limitations; crucially, it cannot estimate METs and is therefore limited to classifying posture rather than intensity [118]. This is a significant constraint, as it diverges from the consensus energy-based definition of SB (≤1.5 METs). Therefore, the definition provided by Chastin and Granat [24] (“any nonupright activity”) may offer a practical alternative. Thus, the choice of method to measure SB presents a fundamental trade-off: prioritizing conceptual alignment with the energy-based definition of SB, often via CPM, at the potential cost of measurement accuracy (due to the current lack of validated CPM thresholds), or opting for the practical accuracy of a posture-based definition (“any nonupright activity”) that may neglect the MET component of SB.

It is important to recognize that SB, like all behaviors, is multifaceted and challenging to fully capture with a single measurement [38]. Therefore, future research should carefully consider the limitations of existing measurement tools and select those best aligned with specific research objectives and target populations. Crucially, measures must adhere to core principles of good measurement: demonstrating reliability, validity, population specificity, and sensitivity to change [119,120]. By emphasizing such criteria, researchers can enhance the accuracy and relevance of SB assessment, particularly in populations with unique physiological profiles such as cognitive impairment.

Recommendations

To aid future research and advance the field, we propose a set of recommendations to guide more meaningful and standardized approaches to measuring SB in people with cognitive impairment (Textbox 1).

XSL•FO
RenderX

Textbox 1. Recommendations for standardizing sedentary behavior measurement in cognitive impairment research.

Recommendations

- Validate cut-point thresholds and/or body posture algorithms in older adults, or populations with cognitive impairment, where possible, ensuring they account for functional limitations and typical behavioral patterns for their application in people with cognitive impairment.
- Standardize the reporting of sedentary proportion. To support cross-study comparability, researchers should either:
  - Report sedentary proportion using a fixed 24-hour denominator.
  - If reporting proportion relative to a non–24-hour specified period (eg, wear or wake time), also report the absolute sedentary time (eg, total minutes per day) to allow readers and future analyses to calculate proportions using their preferred denominator.
- Establish minimum reporting standards for sedentary behavior methodology. Studies should explicitly report device model and placement, cut-point threshold, and validation source, denominator used for proportional estimates, wear-time criteria, and sleep inclusion/exclusion status.
- Develop and adopt a core set of outcomes for sedentary behavior research in cognitive impairment, including key metrics, such as total sedentary time, number of prolonged bouts, and mean bout length, to enable cross-study comparison.

Strengths and Limitations

This review has several strengths. It is the first to systematically examine the wearable digital technology methods and metrics used to assess SB in individuals with cognitive impairment, offering a comprehensive overview of current practices and highlighting key methodological inconsistencies. The study also extends its scope to consider the influence of cognitive impairment severity and disease subtype on SB, which has received limited attention in previous research. A rigorous search strategy, transparent inclusion criteria, and quality appraisal of included studies further strengthen the reliability of the findings.

However, this review's findings are subject to important limitations. The categorization of SB into volume, pattern, and variability, while necessary for synthesis and aligned with existing frameworks [72,121], may not capture all relevant dimensions of SB. Furthermore, the deliberate exclusion of home-based technologies, though methodologically justified by their current lack of standardized validation and restricted ecological scope [48,122], delimits the evidentiary basis exclusively to wearable-derived data. Consequently, the conclusions presented here should be interpreted within the context of these methodological boundaries.

Conclusions

This review establishes that while preliminary evidence suggests that SB patterns differ across cognitive impairment, differences in SB volume are not consistently observed. Furthermore, the increasing use of wearable technology to assess SB in cognitive impairment is hampered by significant methodological heterogeneity and a critical lack of population-specific validation. This heterogeneity underscores the critical need for a consistent methodology to advance the field and establish robust, reproducible evidence on the role of SB in cognitive impairment.

The NIHR Newcastle BRC is a partnership between Newcastle Hospitals National Health Service (NHS) Foundation Trust, Newcastle University, and Cumbria, Northumberland and Tyne and Wear NHS Foundation Trust, and is funded by the NIHR. Authors JLW, SDD, AJY, and RMA are supported by the NIHR Newcastle BRC.

The views expressed in this publication are those of the authors and not necessarily those of the NIHR, NHS, or the UK Department of Health and Social Care. The funders had no role in the design of the study or the preparation of this manuscript.

Data Availability

All data generated or analyzed during this study are included in this published article and its Multimedia Appendices 1-5. All articles included in the review are publicly available online. The complete search strategy, including the search strings used for each database, is provided in Multimedia Appendices 1-5 to facilitate reproducibility.

Funding

SDD and CH were supported by the Innovative Medicines Initiative 2 Joint Undertaking (IMI2 JU) project IDEA-FAST (grant agreement 853981). SDD and CH were supported by the UK Research and Innovation (UKRI) Engineering and Physical Sciences Research Council (EPSRC) (grant reference EP/X031012/1 and grant reference EP/X036146/1). RMA received funding from the NIHR (NIHR 301677) and the NIHR Three Schools Dementia Career Development Award (NIHR-SSCR-DP-CDA30). AJY has received research support from the NIHR Newcastle BRC, Dunhill Medical Trust, EU IMI, NIHR, Parkinson's UK, Michael J Fox Foundation, Weston Brain Institute, Lewy Body Society, Intercept Pharmaceuticals, and Electrocore, and has received

XSL•FO
RenderX

funding and/or honoraria from Britannia, UCB, AbbVie, GSK, Teva-Lundbeck, GE Healthcare, and Genus for attending or speaking at educational events.

Authors' Contributions

Conceptualization: JLW, RMA
Data curation: JLW
Formal analysis: JLW, CH
Funding acquisition: RMA
Investigation: JLW, CH, RMA
Methodology: JLW, RSF, RMA
Supervision: CH, SDD, AJY, RMA
Validation: JLW, CH, RMA
Visualization: JLW
Writing – original draft: JLW
Writing – review & editing: JLW, CH, RSF, SDD, AJY, RMA

Conflicts of Interest

SDD is a shareholder of Enoda Health Ltd. This shareholding did not have any relationship with the work in this paper.

Abstract

Background: Physical and cognitive function, both of which decline with aging, are significantly interrelated. Although numerous studies have investigated the effect of physical exercise on cognitive function, relatively few have examined the impact of pure cognitive training on physical performance.

Objective: This review aimed to summarize the effects of pure cognitive training on balance and mobility in older adults.

Methods: Electronic databases (PubMed, Embase, CINAHL, and PsycInfo) were searched in February 2025. Randomized controlled trials that investigated the effect of pure cognitive training on balance and mobility in older adults were included. Pure cognitive training refers to a strictly nonphysical approach involving guided practice on a standardized set of cognitive tasks aimed at optimizing cognitive functioning. For the outcomes, balance performance focused on standing balance tests and comprehensive balance assessment scales. Mobility performance primarily focused on gait speed under a single-task condition (ie, walking only), gait speed under a dual-task condition (ie, conducting cognitive tasks while walking), and the Timed Up and Go test. The Physiotherapy Evidence Database (PEDro) scale was used to evaluate methodological quality. The level of evidence for the available outcomes was rated using the Grading of Recommendations Assessment, Development, and Evaluation (GRADE) system. Meta-analyses and sensitivity analyses of studies with high methodological quality were performed if 3 or more studies were obtained.

Results: Fourteen studies were eventually included. The methodological qualities of 8 (57%) studies were rated as good, while those of 6 (43%) studies were rated as fair. A meta-analysis of studies with high methodological quality showed that pure cognitive training has a significant effect on cognitive-motor dual-task gait speed (standardized mean difference [SMD] 0.39, 95% CI 0.04-0.75; n=376 participants; moderate-quality evidence) but not single-task gait speed (SMD 0.12, 95% CI −0.05 to 0.30; n=506 participants; moderate-quality evidence). No significant improvements were found in functional mobility (SMD 0.29, 95% CI −0.60 to 1.18; n=566 participants; low-quality evidence) or balance (SMD 0.18, 95% CI −0.34 to 0.69; n=139 participants; very low-quality evidence).

Conclusions: Cognitive training does not improve balance or mobility under single-task conditions but does improve walking speed under cognitive-motor dual-task conditions in older adults. A cognitive training protocol targeting executive function, consisting of 40- to 60-minute sessions conducted 2 to 3 times per week over a period of 8 to 10 weeks, has been shown to be effective.

Introduction

Aging is associated with a decline in functional capacity, which could be attributed to decreased physical and cognitive functions. Existing evidence has demonstrated that physical and cognitive functions are closely interrelated. For instance, faster gait speed is positively correlated with better memory, executive function, and overall cognitive abilities [1]. Greater gait variability is independently linked to poorer cognitive performance among older adults regardless of age [2,3]. Higher cognitive function scores, as assessed by the Mini-Mental State Examination (MMSE), independently predicted better performance in functional mobility, independent of age and other clinical factors [4,5], while mild cognitive impairment (MCI) was found to affect specific gait parameters and functional mobility performance [6].

In terms of causality, substantial research has been conducted to evaluate the effect of physical exercise on cognitive functions. One systematic review found that physical exercise reduces global cognitive decline and improves working memory in individuals with MCI or dementia [7]. Another demonstrated that physical exercise enhances cognitive function across older adults with different levels of cognitive performance, ranging from intact cognition to MCI and dementia [8]. The improvement in cognitive function following physical exercise could be attributed to the increased cerebral perfusion and cardiac output during exercise [8]. Furthermore, physical exercise was found to stimulate the secretion of brain-derived neurotrophic factor (BDNF) in the hippocampi, increase the production of myokines such as irisin and insulin-like growth factor-1 (IGF-1), and reduce the accumulation and aggregation of β-amyloid in the brain [9-12]. These physiological changes provide a foundation for cognitive performance. Collectively, these findings underscore the pivotal role of regular physical activity in preserving cognitive functions in older adults.

On the other hand, research has shown that cognitive processing plays an important role in physical functions, particularly gait and balance. Walking requires motor planning and visuospatial perception, which involve executive function, perceptual-motor function, and visual attention [13]. A progressive decline in frontal cognitive functions, such as that seen in Alzheimer disease, may cause concomitant disorganization of the neural networks that control locomotion, leading to impaired gait performance [13,14]. Similarly, balance is closely related to executive function, mental flexibility, and response inhibition. It has been reported that older adults with balance issues performed worse on tasks requiring mental flexibility and response inhibition [15]. Therefore, there has been an increasing interest in the potential of cognitive training to improve physical function. A recent meta-analysis concluded that sequential programs combining cognitive training and exercise effectively enhance both cognitive and physical functions in healthy older adults. However, this review was unable to isolate the specific impact of cognitive training on physical function [16].

To date, a systematic review published in 2018 [17] evaluated the effect of cognitive training without a physical exercise component on physical function. It revealed that cognitive training can improve gait performance under complex task conditions but not under single-task conditions. On the basis of these findings, investigating the effect of pure cognitive training on mobility and balance, alongside gait, would offer a more comprehensive view of its impact on physical function, given that both domains are closely linked to cognition [1,18]. Furthermore, with new studies published in the past few years [19,20], it is timely to consolidate the latest evidence on the effects of cognitive training on physical function in older adults.

Therefore, this systematic review aims to isolate and evaluate the impacts of single-task cognitive training targeting any cognitive function, including computerized cognitive training (CCT) [21], video games, and cognitive remediation, on mobility and balance outcomes in older adults. The findings will provide an updated understanding of the relationship between cognitive training and physical outcomes.

Methods

Data Sources and Searches

A systematic review was conducted to investigate the effects of cognitive training on the mobility and balance of healthy older adults. The PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guideline was followed [22]. Searches were performed in 4 electronic databases (PubMed, Embase, CINAHL, and PsycInfo). The initial search was performed on September 8, 2022, and the final search was done on February 7, 2025. The population, intervention, comparison, outcome, and study design (PICOS) framework was followed for the search strategy. The keywords used in the different databases are shown in Multimedia Appendix 1. The protocol for this systematic review was registered with PROSPERO prior to data analysis (CRD42023401100) [23].

Study Selection

Search records were screened based on their titles and abstracts to exclude irrelevant articles. The full texts of the remaining articles were reviewed based on the PICOS framework, including the following components: participants (people aged ≥65 years), intervention (pure cognitive training), comparison (usual care or health education), outcome (physical performance), and study design (randomized controlled trial [RCT]). Therefore, this review included studies that (1) recruited older adults aged ≥65 years; (2) provided pure cognitive training as a strictly nonphysical approach involving guided practice on a standardized set of cognitive tasks aimed at optimizing cognitive functioning or slowing brain aging [24,25]; (3) included a comparison group receiving no cognitive training; (4) assessed outcomes related to balance, mobility, or gait under single-task conditions, which refer to the execution of a motor task in isolation, and cognitive-motor dual-task conditions, which involve the simultaneous execution of a primary motor

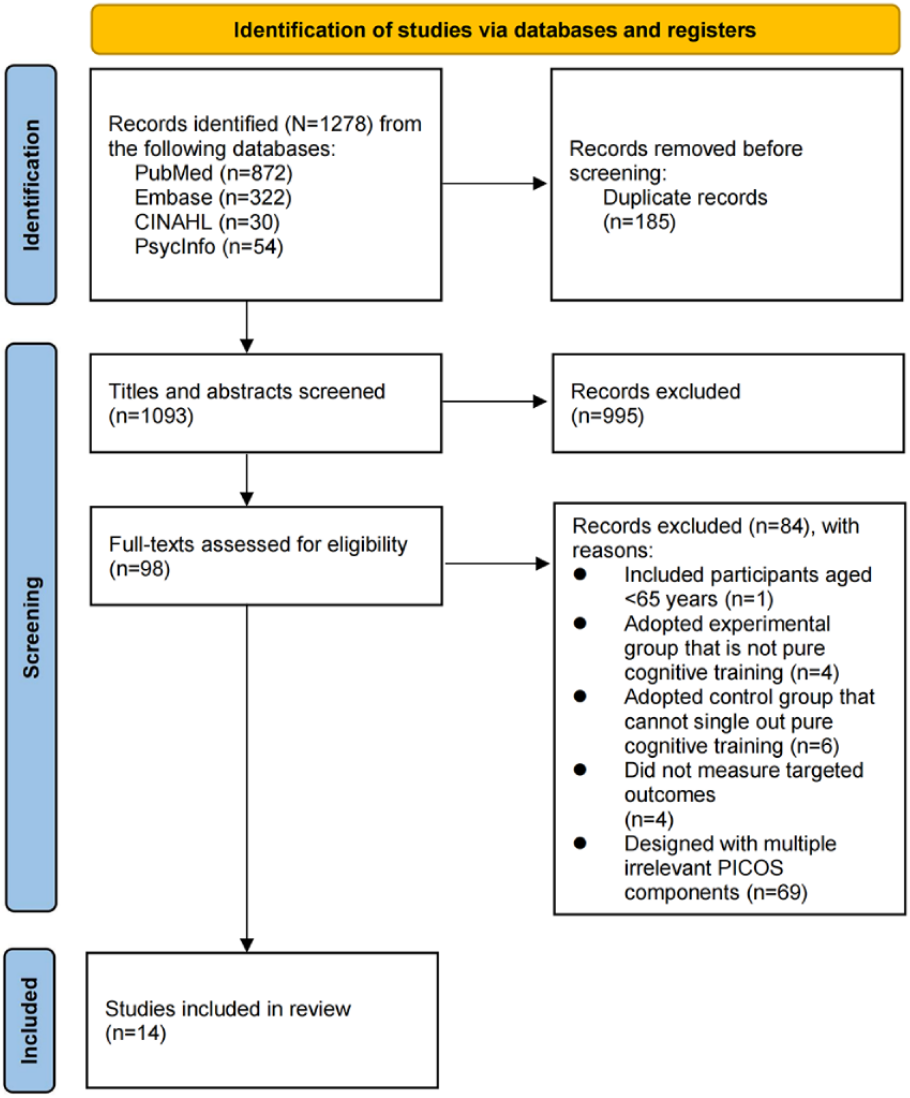
XSL•FO
RenderX

task alongside a concurrent cognitive task; and (5) used a RCT study design. Studies were excluded if they (1) included participants with cognitive impairments (eg, dementia or MCI) or neurological diseases known to impair gait (eg, Parkinson disease and stroke) or (2) applied only cognitive-motor dual-task interventions, preventing the specific effects of cognitive training from being isolated.

Methodological Quality Assessment and Quality of Evidence

The Physiotherapy Evidence Database (PEDro) scale was used to assess the methodological quality of each selected study [26]. The PEDro scale is a formally validated instrument with established reliability and validity for quantifying the methodological quality of RCTs. For articles that were not available on the PEDro website, they were rated independently by 2 of our team members using the PEDro criteria. A higher PEDro score indicates better methodological quality. The studies were then classified as excellent, good, or fair according to their PEDro score (9-10="excellent," 6-8="good," and 4-5="fair"). The quality of evidence for the outcomes was rated using the Grading of Recommendations Assessment, Development and Evaluation (GRADE) approach [27-30]. The downgrade and upgrade criteria of GRADE are listed in Multimedia Appendix 2.

Data Analysis



The effects of cognitive training on the outcomes of interest were categorized into mobility and balance. Meta-analysis was performed if ≥3 studies of similar outcomes were obtained. Random-effects models were used for all meta-analyses to address heterogeneity across studies. The standardized mean difference (SMD) and 95% CI were computed and presented in forest plots (Review Manager version 5.4.1; Cochrane Collaboration). A *P* value of ≤.05 was considered statistically significant. The I^2 index was used to test the heterogeneity of the included studies in each meta-analysis. A separate meta-analysis including studies with high methodological quality (PEDro score ≥6) was performed to avoid contamination of the results by low-quality studies. For meta-analyses with moderate to high heterogeneity (I^2>50%), subgroup analyses were performed if all subgroups could include at least 2 studies [31]. Publication bias was statistically assessed using the Egger regression asymmetry test to detect potential asymmetries in the evidence base if there were >10 studies included in the meta-analysis [32]. A *P* value <.10 on the Egger regression asymmetry test indicated the presence of publication bias [33]. The Egger regression method is a statistical tool used in meta-analyses to detect publication bias by assessing whether smaller studies with less significant findings are underrepresented in the published literature. When publication bias was detected, a trim and fill analysis was conducted to impute the findings of potentially unpublished studies and assess the robustness of the results. Narrative analyses were performed for outcomes for which meta-analyses could not be performed.

Results

Our search yielded a total of 1278 records. Ultimately, 14 (1%) trials [19,20,34-45] with a total of 898 participants met the eligibility criteria and were included in this systematic review (Figure 1).

Study Characteristics

The characteristics of the included studies are summarized in Table 1. The sample size ranged from 20 to 238, with the mean age of participants ranging from 66.2 (SD 7.1) to 85.7 (SD 5.4) years. Most studies recruited community-dwelling individuals. One study included nursing home residents [42]. One study included only male participants [35]. The details of each study are listed in Multimedia Appendices 3 and 4 [1-14].

[a]N/A: not applicable.

[b]CCT: computerized cognitive training.

[c]The percentages sum to more than 100% as individual studies may report multiple outcomes.

Intervention Protocols

A total of 71% (10/14) studies used CCT as the intervention [19,20,35-38,40,41,43,44], while 4 (29%) used noncomputerized training [34,39,42,45]. Studies that adopted CCT used training programs designed to improve executive function, which include Mindfit (CogniFit Inc), CogniFit Program (CogniFit Ltd), and other self-designed programs. Noncomputerized training included therapist-led visual attention training [34], attentional capacity and working memory training [39,42], and board game–based cognitive training [45]. The duration of the training programs ranged from 3 weeks to 12 months. Most interventions were conducted 1 to 3 times per week, with each session lasting between 20 and 120 minutes. One study [19] involved self-directed home-based training, in which participants completed flexible sessions at their own pace, averaging 120 to 150 minutes of training per week.

Methodological Quality and Quality of Evidence

Among the 14 included studies, 8 (57%) [19,20,34,38-40,43,44] were rated as good (PEDro score 6-8) and 6 (43%) [35-37,41,42,45] were rated as fair (PEDro score 4-5). The PEDro score of each article is outlined in Multimedia Appendix 5 [1-14]. The quality of evidence for outcomes rated using GRADE is listed in Table 2. The quality of evidence for gait speed under single-task and cognitive-motor dual-task conditions

XSL•FO
RenderX

was rated as moderate. The quality of evidence for functional mobility and balance was rated as low and very low, respectively.

Table 2. Grade of Recommendations Assessment, Development, and Evaluation (GRADE) assessment of the quality of evidence[a].

Outcomes	Risk of bias[b]	Inconsistency	Indirectness	Imprecision	Publication bias	Large effect	Plausible confounding	Dose response gradient	GRADE quality	Effect size (95% CI)
Gait speed	0	0	0	−1[c]	0	0	0	0	Moderate	0.19 (−0.00 to 0.38)
Gait speed (high-quality studies)	0	0	0	−1[c]	0	0	0	0	Moderate	0.12 (−0.05 to 0.30)
Dual-task gait speed	0	0	0	−1[c]	0	0	0	0	Moderate	0.26 (0.03 to 0.49)
Dual-task gait speed (high-quality studies)	0	0	0	−1[c]	0	0	0	0	Moderate	0.39 (0.04 to 0.75)
Functional mobility	0	−1[d]	0	−1[c]	0	0	0	0	Low	0.29 (−0.60 to 1.18)
Balance scale	−1[e]	0	0	−2[b]	0	0	0	0	Very low	0.18 (−0.34 to 0.69)

[a]0 indicates that no serious limitations were identified in that domain; therefore, no downgrading was applied. Negative values (−1 or −2) indicate downgrading of the quality of evidence due to identified limitations (eg, imprecision or inconsistency).

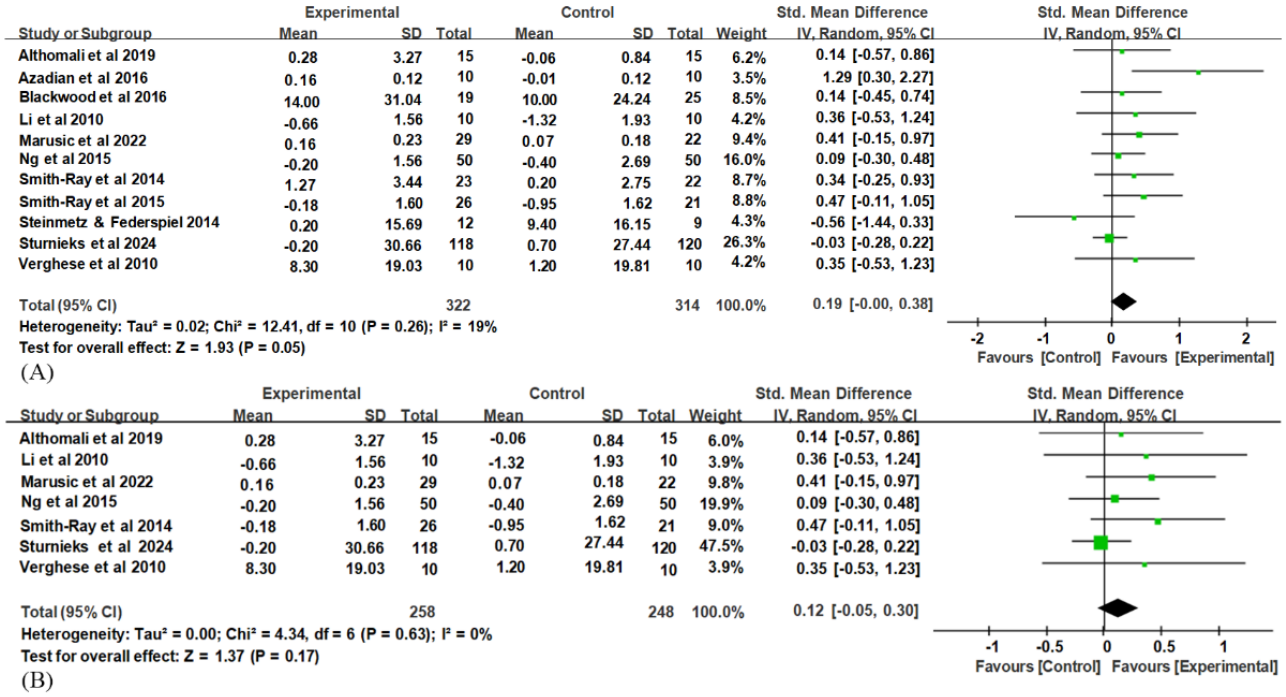
[b]The *P* value of the Egger regression asymmetry test is less than 0.1.

[c]The number of participants included in the primary meta-analysis was <400, and the 95% CI spanned the appreciable harm or benefit thresholds.

[d]Heterogeneity I^2 larger than 50% in the meta-analysis.

[e]More than 50% of the participants included in the primary analysis from trials with a Physiotherapy Evidence Database score of <6.

Mobility



Fourteen studies [19,20,34-36,38-44,46,47] investigated the effect of cognitive training on mobility-related outcomes.

Single-Task Gait Speed

Of the 14 studies, 13 (93%) [19,34-36,38-44,46,47] investigated the effects of cognitive training on gait speed. Meta-analysis showed that cognitive training significantly increased single-task gait speed (SMD 0.19, 95% CI −0.00 to −0.38; Z=1.93; P=.05; I^2=19%; n=636 participants; moderate-quality evidence; Figure 2A). The Egger regression asymmetry test indicated no evidence of publication bias (P=.35). Yet, the result turned nonsignificant in the sensitivity analysis that included only studies with high methodological quality (SMD 0.12, 95% CI −0.05 to −0.30; Z=1.37; P=.17; I^2=0%; n=506 participants; moderate-quality evidence; Figure 2B) [19,34,38,39,41,43,44].

XSL•FO
RenderX

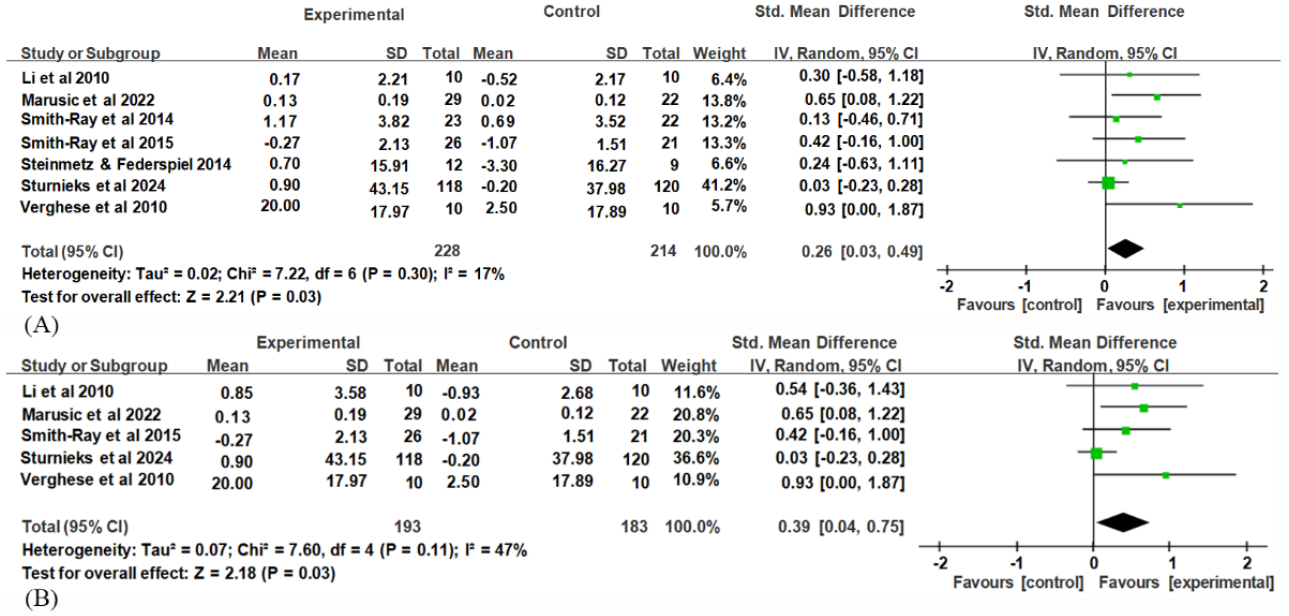


Figure 2. Gait speed. (A) Meta-analysis including all studies that reported gait speed outcomes and (B) meta-analysis including only studies rated as having high methodological quality.

Cognitive-Motor Dual-Task Gait Speed

A total of 50% (7/14) studies [19,38,40-44] investigated the effects of cognitive training on cognitive-motor dual-task gait speed. Meta-analysis showed that cognitive training significantly increased cognitive-motor dual-task gait speed (SMD 0.26, 95% CI 0.03 to −0.49; Z=2.21; P=.03; I^2=17%; n=442 participants; moderate-quality evidence; Figure 3A). The results remained significant in the sensitivity analysis that included only studies with high methodological quality (PEDro score ≥6; SMD 0.39, 95% CI 0.04 to −0.75; Z=2.18; P=.03; I^2=47%; n=376 participants; moderate-quality evidence; Figure 3B) [19,38,40,43,44].

Figure 3. Cognitive-motor dual-task gait speed. (A) Meta-analysis including all studies that reported cognitive-motor dual-task gait speed outcomes and (B) meta-analysis including only studies rated as having high methodological quality.

Functional Mobility

A total of 43% (6/14) studies [19,20,34,36,40,45] investigated functional mobility using the Timed Up and Go (TUG) test as an outcome measure. Meta-analysis showed that cognitive training had no significant effect in improving functional mobility (mean difference [MD] 0.29, 95% CI −0.60 to −1.18; Z=0.63; P=.53; I^2=77%; n=566 participants; low-quality evidence; Multimedia Appendix 6).

XSL•FO
RenderX

To delineate the contributing factor to the largest heterogeneity, subgroup analyses were conducted based on the methodological quality of the trials, the type of training (CCT vs non-CCT), total training hours of the program, individual training duration, and the baseline mean age of the participants. Nevertheless, the largest I^2 value ranged from 79% to 88% in all subgroup clusters. No clear contributing factor to the high heterogeneity could be identified. The results remained nonsignificant in all subgroup analyses (Multimedia Appendix 7).

Additionally, 7% (1/14) study reported no significant effect on dual-task TUG test (P=.53) [34].

Other Mobility Parameters

Only 7%(1/14) study [35] reported gait parameters other than gait speed, including stride and step length, stride duration, step, single-support duration, and double-support duration during single-task walking, and gait asymmetry during single-task and dual-task walking. Meta-analysis was not appropriate because of the insufficient number of studies. This study reported statistically significant improvements (P<.05) in some gait parameters and a significant decrease in gait asymmetry in the cognitive training group compared with the control group. Detailed results are presented in Multimedia Appendix 4.

Balance Performance

The effect of cognitive training on balance was evaluated in 5 studies [20,34,37,41,45].

Balance Scales

Of the 14 included studies, 2 (14%) used the Berg Balance Scale (BBS) and 1 (7%) used the Mini-Balance Evaluation Systems Test (Mini-BESTest) [34,41,45]. The 2 scales were combined in a meta-analysis. No significant effect was found in the cognitive training group compared with the control group (SMD 0.18, 95% CI −0.34 to −0.69; Z=0.67; P=.50; I^2=56%; n=139 participants; very-low–quality evidence; Multimedia Appendix 8). Despite the high heterogeneity, no subgroup analysis could be performed as there were only 3 studies in the meta-analysis. Any grouping would result in at least 1 subgroup containing only 1 study.

Static Balance

Only 21% (3/14) studies [20,34,37] reported static balance with contrasting results. The tests were carried out under either eyes-open [34] or eyes-closed [20,37] conditions. Althomali et al [34] reported that cognitive training had no significant effect on the duration of single-leg standing under eyes-open conditions relative to the control group (P=.56). Liu et al [20] reported that cognitive training led to a significant increase in the duration of single-leg standing under eyes-closed conditions when compared with the control group (P=.005). Hou et al [37] reported only a combined result of the one-leg stance test (OLST) and the TUG test, prohibiting the isolation of the balance outcome for analysis.

Discussion

Principal Findings

Our systematic review summarized the effects of cognitive training on mobility and balance in older adults. Overall, our meta-analysis showed that cognitive training significantly enhanced cognitive-motor dual-task gait speed (P=.03) and marginally improved single-task gait speed (P=.05). However, the results for single-task gait speed turned nonsignificant in the sensitivity analyses that included only studies with high methodological quality. No significant improvement was found in functional mobility or balance outcomes following cognitive training.

Effectiveness of Cognitive Training on Mobility and Balance Outcomes

Overview

Our meta-analysis revealed the effect of cognitive training on balance and mobility performance under different cognitive loads. According to the dual-task paradigm [48], single-task walking, functional mobility tests (ie, TUG test), and balance assessment tests (ie, BBS, Mini-BESTest, and OLST) were considered tasks with a low cognitive load, while cognitive-motor dual-task walking was considered a task with a high cognitive load [49]. Thus, results consolidated in this review suggest that cognitive training could improve only tasks with a high cognitive load and not those with a low cognitive load.

Effectiveness of Cognitive Training on Tasks With a High Cognitive Load

One of the possible explanations for this finding is the central capacity sharing model [50]. Cognitive-motor dual-task walking has been described as involving 2 simultaneous tasks (walking and a cognitive task) that interfere with each other and compete for cognitive resources. It has been stated that when attentional resources are limited in capacity, at least one of the tasks may deteriorate in performance. Among the 7 studies reporting cognitive-motor dual-task gait speed outcomes, 4 (57%) [38,40-42] did not assess changes in cognitive performance, 2 (29%) reported no significant change in cognitive function [19,43], and 1 (14%) demonstrated enhanced executive function [44]. Additionally, within the studies [43,44] with a significant improvement in dual-task gait speed, 1 (50%) study showed an improvement in cognitive function [44]. These findings suggest that the observed improvements in gait performance might stem from (1) enhanced cognitive capacity; (2) improved automaticity in performing cognitive tasks [51], allowing more cognitive resources to be allocated to walking, thereby enhancing physical performance without sacrificing cognitive performance; or (3) a mix of both. As we see no deterioration in cognitive performance from the available data, the improved dual-task walking speed would not be the result of a pure reallocation of existing cognitive resources, which would consequently reduce the resources available for concurrent cognitive tasks and potentially diminish cognitive performance [52]. More data are required to confirm our postulation.

XSL•FO
RenderX

Effectiveness of Tasks With a Low Cognitive Load

Our results suggest that cognitive training does not improve physical function directly, as seen in the lack of significant changes in outcomes for tasks that require a low cognitive load. Although our overall meta-analysis found a significant improvement in single-task gait speed (P=.05), the analysis of studies with high methodological quality did not show a significant improvement. This discrepancy may be attributed to a few factors: the stricter methodological standards of high-quality studies, which likely reduced the potential for overestimated effects, and the lower heterogeneity (I^2=0%) in the analysis of high-quality studies, suggesting more consistent and reliable findings. Meanwhile, studies in the high-quality group generally included larger sample sizes than those of lower quality (506 participants in the high-quality group vs 130 participants in the low-quality group). Notably, 1 large RCT (n=238 participants) reported no significant between-group improvements in single-task gait speed [19]. In contrast, the only study that reported a significant improvement in single-task gait speed had a small sample size, with only 10 participants in each group [35]. Additionally, this study included only male participants and focused on individuals with potential balance impairments, as indicated by a BBS score <52 and/or a self-selected gait speed of ≤1.1 m/s on the 10-meter walk test. These findings suggest that cognitive training may not significantly improve single-task gait speed in relatively healthy older adults.

Nevertheless, our review identified consistent results across outcomes involving low cognitive load, including functional mobility and balance measured using the TUG test, BBS, and Mini-BESTest, with no significant changes observed. We hypothesize that older adults, in general, have sufficient cognitive resources available for less cognitively challenging tasks. Consequently, the central capacity sharing model does not apply [50], which might explain the nonsignificant effect of cognitive training on tasks with a low cognitive load.

Conceptual and Mechanistic Interpretation

The pattern of benefit observed in this review can be interpreted within contemporary motor control theory. Healthy adult walking is partly automatic, meaning that steady-state gait can be regulated with limited executive attention, whereas aging and dual-task demands shift gait toward more deliberate, executive control [53,54]. From this perspective, pure cognitive training would not be expected to substantially alter well-practiced single-task walking or simple balance tasks in cognitively intact older adults, as these tasks may already be supported by sufficient automatic sensorimotor control. Its effect is more likely to appear during cognitive-motor dual-task walking, where cognitive resources are invoked, and training-related improvements in attention, inhibition, working memory, or task switching may reduce competition between cognitive and locomotor processes. This also aligns with the near- vs far-transfer framework [55,56]: improvement in dual-task gait speed reflects near transfer, given its shared executive-control demands with cognitive training, while the lack of effects on single-task gait speed, mobility, and balance is consistent with limited far transfer to outcomes with lower cognitive load.

Neurophysiologically, this interpretation is consistent with evidence that dual-task walking engages frontal cortical systems. Functional near-infrared spectroscopy (fNIRS) studies show that walking while talking in older adults is associated with prefrontal cortical activation, supporting the view that attentional and executive-control networks contribute to gait when task demands increase [57]. Systematic neurophysiological evidence also indicates that cognitive-motor interference involves distributed cortical resource allocation rather than a single gait-specific locus [58]. Therefore, the significant improvement in dual-task gait speed found in this review may reflect more efficient frontal compensation or cognitive resource allocation during cognitively demanding walking, although the included trials were not designed to directly test these neural mechanisms. Future trials should combine gait outcomes with neurophysiological measures, such as fNIRS or electroencephalogram (EEG), to determine whether behavioral gains correspond to reduced or more targeted prefrontal recruitment during dual-task gait.

Effective Training Protocol

As the meta-analysis revealed that pure cognitive training significantly improves only cognitive-motor dual-task gait speed, it is more pertinent to focus on the training protocols that could lead to an improvement in cognitive-motor dual-task gait speed.

Among the studies analyzed for dual-task gait speed with high methodological quality, all used CCT aimed at improving executive function. The training sessions lasted for 40 to 60 minutes, with 2 to 3 sessions per week, for a range of 8 to 10 weeks. After further analysis, we found no difference in training protocols between studies that reported significant improvements [43,44] and those that reported nonsignificant improvements [19,38,40].

Clinical Significance

This review demonstrated that pure cognitive training significantly improves cognitive-motor dual-task walking speed. Nevertheless, this review provides no direct evidence on whether the small-to-moderate effect size found on dual-task walking speed is clinically important. To contextualize the improvement in dual-task gait speed, a sensitivity analysis, including only studies using the same unit of measurement, was conducted to obtain the MD for comparison with the minimal detectable change (MDC) or minimal clinically important difference (MCID).

Pure cognitive training increased dual-task gait speed by 8.83 cm/s (MD 8.83, 95% CI 0.32-17.34; experimental n=157 participants: control n=152 participants; I^2=44%; P=.04; 3 trials of good methodological quality). This improvement falls within the ranges of MDC (5-10 cm/s) [59,60] and MCID (8-20 cm/s) [61,62] reported for various older populations. Therefore, a firm quantitative conclusion about its clinical significance cannot be drawn. Nevertheless, this improvement might be valuable as cognitive-motor dual-task walking speed is a critical predictor of falls, frailty, disability, and mortality [63].

XSL•FO
RenderX

In particular, the improvement in cognitive-motor dual-task gait speed may be relevant to fall prevention because walking in real-world situations often involves distractions, such as texting while walking [64]. Cognitive-motor dual-task gait speed reflects the ability to maintain walking performance under divided-attention conditions that commonly occur in daily life. A systematic review and meta-analysis reported that slower gait speed under both single- and dual-task conditions can differentiate fallers from nonfallers among older adults, supporting dual-task gait speed as a marker of fall risk [65]. More specifically, in a prospective cohort of 646 community-dwelling older adults, poorer walking-while-talking speed predicted incident falls after adjustment for normal walking velocity and other confounders. Conversely, participants in the fastest 14% of the walking-while-talking speed distribution had a significantly lower risk of incident falls than the remaining 86% of the cohort [66]. Therefore, the gain in cognitive-motor dual-task gait speed may indicate a greater capacity to walk safely while attention is divided between concurrent tasks.

However, pure cognitive training did not appear to improve physical performance directly in older adults. This could be attributed to the low cognitive requirement of simple balance and general mobility tasks among healthier older adults. It should be noted that the cognitive load of the same task could be different in older adults with different abilities. We observed a trend that studies that included older adults with poorer physical function [20,35,40,45], or included more difficult balance tasks (ie, single-leg standing with eyes closed) [20], tended to report significant improvements. Results might differ if more challenging balance tasks were involved or if participants were older adults with known physical or cognitive impairments.

Limitations

For the 5 trials that included balance outcomes, only 3 types of outcomes (BBS, Mini-BESTest, and OLST) were used. The insufficient diversity in balance outcomes prevents a comprehensive analysis of balance performances, thereby restricting the ability to evaluate the relationship between cognitive training and balance.

This meta-analysis primarily used gait speed and cognitive-motor dual-task gait speed as indicators of gait performance. However, gait performance should not be determined solely by gait velocity. Other gait parameters, such as spatiotemporal measures, can also be an important determining factor of gait performance. Yet, the effects of cognitive training on the spatiotemporal aspects of gait were not examined because of the limited number of studies available. Thus, future investigations are needed to explore the relationship between cognitive training and various spatiotemporal gait characteristics under single-task conditions among healthy older adults.

As this study included only cognitively intact older adults without any diseases affecting gait, the findings may not be generalizable to those with cognitive impairments or gait-related health conditions. Additionally, the cognitive training in most included studies focused primarily on enhancing executive function without targeting other cognitive domains.

Furthermore, for the meta-analysis with high heterogeneity (functional mobility), metaregression analysis was not performed as the meta-analysis included only 6 studies, falling short of the recommended minimum of 10 studies required for a metaregression model [32].

Conclusions

Cognitive training, aimed at improving executive function and lasting for 40 to 60 minutes per session, 2 to 3 sessions per week, over 8 to 10 weeks, improves cognitive-motor dual-task walking speed in older adults. However, cognitive training could not improve single-task mobility or balance performance in cognitively intact older adults.

Abstract

Though exergames attract considerable research interest as tools for preserving cognitive function in older adults, a decade of meta-analytic evidence reveals a persistent gap between theoretical promise and empirical demonstration: exergames rarely outperform conventional motor-cognitive training and do not generate the sustained engagement that preventive benefit requires. These results reflect limitations that are structural: the field focused predominantly on clinical populations rather than primary prevention; training concepts borrowed from rehabilitation protocols rather than grounded in the specific neuroplastic mechanisms of the exergaming medium; and virtual environments that are digitally sophisticated but culturally and esthetically neutral, systematically excluding the stimulation that converging evidence from neuroaesthetics, cultural epidemiology, and narrative neuroscience identifies as a core active ingredient of brain health promotion. To address these limitations simultaneously, this viewpoint introduces Motor-Cognitive Active Gamified Immersive Cultural (MAGIC) exergames, defined as "virtual reality solutions in which motor-cognitive interactions are embedded in artistic content, cultural heritage, or historically situated narrative to exploit optimal neurobiological substrates of the intervention." Drawing on an integrated theoretical framework, we develop mutually reinforcing mechanistic pillars: multimodal sensorimotor engagement within ecologically valid immersive environments; semantic and narrative activation of memory systems; emotional and autobiographical resonance as a dopaminergic driver of learning consolidation and sustained participation; and the re-engineering of physical effort evaluation from aversive to appetitive through aesthetic pleasure and narrative absorption. A fundamental implication is that in MAGIC exergames, motivation is not engineered through gamification mechanics—it is released by the intrinsic value of inhabiting a culturally meaningful world. We further argue MAGIC exergames correspond to a specific use that is, Cultural Snacking, which consists of the serialization of MAGIC content into brief, narratively open daily episodes of 5 to 10 minutes, designed for 3 to 5 daily consumptions across varied contexts. This dosing architecture is compatible with the motivational profile of healthy older adults who do not identify as patients or trainees. The paper opens perspectives with a design and research agenda structured around three priorities: characterizing MAGIC exergames by the type of motor-cognitive interactions they deliver rather than by the technology platform; conducting mechanistic neuroimaging investigations targeting the specific biomarkers of neuroplastic benefit that creative cultural engagement is expected to produce; and building the intersectoral innovation ecosystem that brings cultural institutions, digital health teams, and older adults together as co-designers. Without waiting for MAGIC-specific trials, we invite the digital medicine, public health, and silver economy communities to recognize that museums, heritage sites, and cultural institutions are potentially the most ecologically valid, intrinsically motivating, and cost-effective substrates for a new generation of brain health exergames that are as meaningful as they are effective. The scientific, institutional, and economic conditions for this convergence already exist.

Exergames, Brain Health, and Cognition: A Promising Yet Unfulfilled Agenda

As populations age at unprecedented rates, primary prevention of cognitive decline and neurocognitive disorders has become a strategic priority of public health systems worldwide, with the aim of preserving the brain health of healthy older adults before clinical thresholds are reached [1]. Older adults are acutely aware of the prospect of cognitive decline, but evidence-based options available to them remain largely confined to aerobic and muscular exercise programs [2], that many people find insufficiently motivating to sustain. This

XSL•FO
RenderX

adherence problem is structural. Devices developed within a clinical or rehabilitation context benefit from externally supported adherence: medical prescription, professional supervision, a therapeutic framework, and an explicit recovery goal collectively sustain engagement, so that motivation does not need to be intrinsically generated by the intervention itself. This support structure is absent in primary prevention. Among healthy individuals who present no symptoms, face no institutional obligation, and answer to no supervisor, adherence can rest on nothing but intrinsic interest in the activity. This contextual shift is fundamental, and it constitutes, we argue, the central justification for the Motor-Cognitive Active Gamified Immersive Cultural (MAGIC) framework developed in this paper: designing a desirable, culturally meaningful environment that fits naturally into daily life is not a cosmetic optimization of an exergame intervention—it is the condition of its preventive effectiveness.

Over the past decade, exergames—that is, virtual reality solutions that combine physical activity with cognitive challenge within a gamified interface—have been considered as a promising solution for preventing, delaying, or compensating (at least partially) brain alterations and decrease in cognitive performance. By simultaneously delivering cardiovascular effort (endurance), complex goal-oriented movements, and cognitive stimulation in gamified virtual environments, they should, in theory, be more motivating and produce synergistic neuroplastic effects superior to single-domain interventions. Meta-analyses and systematic reviews have reported benefits in executive function, memory, and processing speed [3-5], yet a more rigorous reading of the cumulative evidence reveals a persistent gap between theoretical promise and empirical demonstration [6-9]. For instance, the first and most influential meta-analysis in the field, Stanmore et al [4], reported a moderate positive effect of exergames on global cognition, yet no evidence was found that exergames outperform cognitively demanding control conditions. Subsequent analyses have extended and deepened this assessment. Sokolov et al [7] found no significant advantage of exergames over conventional exercise for cognitive outcomes when head-to-head comparisons were made under controlled conditions, challenging the central claim that the combination of physical and cognitive stimulation in a gamified interface produces synergistic neuroplastic effects. Generally, the meta-analytic literature on exergames and cognition displays a pattern that is characteristic of confirmation bias: effect sizes consistently diminish as methodological rigor increases, and the findings most frequently cited as proof of concept contain, upon closer reading, the seeds of more uncertain conclusions. This conclusion is compounded by a well-documented publication bias, that is, selective reporting of positive findings; once publication bias is corrected for, the apparent cognitive benefits are substantially attenuated [6].

However, despite these conclusions, the field is maintaining a firm optimism about the cognitive benefits of exergaming [10,11], which is a direct consequence of the belief in the magical power of technology and the “product-first” approach, testing specific commercial platforms designed for entertainment as if the product itself were the intervention, rather than characterizing the type of combined training delivered. In a systematic review specifically designed to characterize the type of combined training delivered by exergames, Torre and Temprado [9] identified that the overwhelming majority of exergame studies do not characterize and control for the actual training content delivered, regardless of the technological interface. By misidentifying the exergame as the unit of analysis rather than the training program it supported, the field has systematically generated a literature too heterogeneous to be informative and too methodologically flawed to support causal inference. This failure has limited the understanding of the mechanisms engaged to enhance brain plasticity and cognitive performance in durable and transferable ways [12,13], so that whether and how exergames can be meaningfully improved remains an open question.

How Can Exergames Better Enhance Brain Health and Cognition in Older Adults?

The design logic of exergames required to better enhance brain health and cognition should overcome the limitations that have constrained exergame research in the discovery of effective neuroplastic principles. Four design recommendations follow directly from this diagnosis. First, new exergames should not limit themselves to a curative objective. Instead, the entire design logic—environments, task demands, and motivational architectures—should be structured for the primary prevention of cognitive decline in cognitively healthy older adults, that is, to preserve and enrich capacities rather than to remediate clinical deficits. This reorientation implies a fundamentally different user model, in which the older adult is not a patient to be treated but a capable individual whose neuroplastic resources are to be maintained and deepened through intrinsically motivating engagement. Throughout this paper, “cognitively healthy older adults” refers operationally to community-dwelling individuals, typically aged 65 to 85 years, without a diagnosed neurocognitive disorder and retaining full autonomy in activities of daily living; this population is distinct from, and considerably larger than, the clinical or prefrail populations that conventional exergame research has predominantly targeted. Specifying outcomes of interest for this population is less straightforward than in rehabilitation, where the therapeutic target and a success criterion can be defined a priori. In primary prevention, the relevant question is not whether performance improves in absolute terms but whether decline relative to an expected age-matched trajectory is slowed or arrested over a multiyear horizon, evaluated against domain-specific cognitive measures and, where available, neuroimaging-derived markers of functional brain aging. We return to this question of outcome specification in the research agenda below. Second, future exergames should be grounded in theoretically specified training concepts that exploit what is genuinely specific to the exergaming medium. Rather than developing motor-cognitive, physical-cognitive, or multidomain training concepts validated against neuroplastic mechanisms, the field has oscillated between 2 equally under-specified approaches: the gamification of existing rehabilitation protocols, principally to increase patient motivation [14], and the adoption of commercial

XSL•FO
RenderX

entertainment exergames [15,16]. However, neither approach deeply addresses the questions that a principled exergaming intervention must answer first: what type of movement, what cognitive demand, and what interaction between the two is neurobiologically productive? A related and underappreciated gap concerns the minimum intensity of physical effort, or alternatively the minimum complexity of motor movements, required to exploit facilitation-guidance mechanisms, which remains poorly specified [17,18]. Indeed, the field has largely imported conventional physical activity recommendation logic without questioning whether this dosing architecture is either optimal or realistic for cognitively healthy older adults whose motivational profile and daily routines are poorly served by the scheduled session model. Third, exergame research should capitalize more systematically on the video game literature, which has accumulated robust evidence that regular practice of action video games produces measurable and transferable benefits on attention, processing speed, executive function, and visuo-spatial cognition. This is a body of evidence that health-oriented exergame researchers have systematically ignored, though it provides both a source of theoretical insight into the mechanisms of game-based cognitive enhancement and a design benchmark against which the specific added value of physical and motor engagement in exergames could be rigorously evaluated. Ignoring it has left the field unable to answer a fundamental question: what does motor engagement specifically contribute, over and above the cognitive stimulation that commercial video games already provide? This question is not merely theoretical. Regularly engaging a cognitive process to maintain or strengthen it is also, at least implicitly, the logic underlying cognitive or "brain" training, whose promises and limitations are well-known regarding generalization of training-related benefits beyond the trained task [19,20]. In the present paper, we posit a new framework relative to this corpus: where brain training relies on the repeated, isolated engagement of a single trained process, MAGIC exergames hypothesize that benefit arises from the simultaneous, multisystem engagement of sensorimotor, semantic, and emotion-valuation networks within a single ecologically valid task. Whether this multisystem engagement yields more generalizable benefit than single-process training remains to be established and constitutes one of the central empirical questions this paper's research agenda is designed to address. Fourth, new exergames should actively exploit the neuroplastic potential of rich cultural, narrative, and autobiographically resonant content rather than designing virtual environments that mimic superficially senior-friendly aesthetics while remaining culturally neutral. The neuro-aesthetic evidence demonstrates that genuine aesthetic and cultural experiences simultaneously recruit sensorimotor, emotion-valuation, and meaning-knowledge neural systems in a configuration that no purposive cognitive task can replicate [21]. The brain clock framework shows that creative engagement delays brain aging in domain-independent ways [22], and the cultural epidemiology literature documents that regular cultural participation predicts slower cognitive decline across decades of longitudinal follow-up [23]. We hypothesize that embedding motor-cognitive training within culturally meaningful, esthetically rich, and narratively coherent environments is more than a cosmetic design choice; it constitutes one of the most promising design decisions available, pending dedicated empirical validation. Since no available exergame considers all these blind spots simultaneously, the principles that make exergaming effective to deliver on its neuroplastic promise remain poorly understood. Thus, the question arises of whether a fundamentally different approach to designing new exergames might succeed where most of the existing ones did not.

Recently, a recommended direction has been to move "beyond just-for-fun exergames" [24], to adopt rigorous step-by-step design processes [25,26], and a logic grounded in scientifically validated training concepts to target the specific mechanisms that underlie, combined training effects [8,13,24]. Though this approach represents a step forward relative to purely entertainment-driven exergames, it often results in libraries of motor-cognitive exercises that mimic therapeutic protocols, simply apply recommendations for conventional physical activity programs, and whose motivational appeal rests almost entirely on the thin scaffolding of gamification. Moreover, the "beyond just for fun approach" converges on the dominance of the facilitation-guidance model of brain-body interaction, either in its neurobiological formulation [27,28] or its more recent motor-cognitive variant that is, the Adaptive Capacity Model (ACM) [29]. Though very heuristic, this model is incomplete since it frames the body as a vehicle for stimulating brain plasticity rather than as the primary site of intelligent engagement with a meaningful world. Also, it considers cognitive training tasks as inputs to be optimized rather than as dimensions of a richer, culturally embedded experience. To address this issue, the present Viewpoint paper introduces a new category of preventive digital intervention and develops the theoretical and empirical foundations for a research and design agenda of these new digital brain-health solutions targeting healthy older adults.

A New Theoretical Foundation: MAGIC Exergames

The three structural blind spots identified above point toward a category of preventive digital interventions that: (1) target cognitively healthy older adults, (2) are grounded in a principled understanding of neuroplastic mechanisms rather than in the replication of existing exercise protocols, and (3) place culturally rich, esthetically meaningful, and narratively immersive content at the center of the experience. We propose to call this category MAGIC exergames and define it as: "a virtual reality solution in which brain-mind-body interactions are included in artistic content, cultural heritage, or historically situated narrative, to exploit the neurobiological, psychological and emotional mechanisms involved in problem-solving under changing conditions and constraints." The theoretical orientation underlying MAGIC exergames draws on two converging frameworks. The first is Bardy Human Movement Intelligence (HMI) [30], and the second is the theory of cognizant action developed by Araújo et al [31] within the Ecological Dynamics tradition [32]. Both frameworks share the common premise that movement is not a delivery mechanism for neuroplastic stimulation that ultimately enhances decomposed and isolated

XSL•FO
RenderX

cognitive processes, but the medium through which biological, psychological, emotional, and sensorimotor processes are integrated in a high-order dialogue between brain, body, and environment. In this view, cognition does not follow from movement; it is expressed through it. This perspective extends the ACM [29], which accounts for the neurocognitive and physiological bases of the relationships between physical activity, complex motor skills, brain plasticity, and cognition. Where the ACM grounds the benefits of motor-cognitive training in evolutionary neuroscience, HMI and Ecological Dynamics frameworks extend this foundation by incorporating the esthetic, cultural, social, and technological dimensions of the environments in which motor behavior takes place [30]. In doing so, a conceptual continuity is established between multidomain training [9], grounded in the evolutionary neuroscience model, and the richer theoretical architecture required to account for goal-directed movement in informationally dense, culturally and aesthetically meaningful environments. This reframing implies that cognition is inherently embodied, situationally grounded, culturally shaped, and inseparable from the emotional and aesthetic dimensions of the environment in which it unfolds—conditions that generic exergame environments, culturally neutral by design, systematically fail to provide. Applied to the exergame context, this suggests that the design of MAGIC exergames must immerse both the cognitive functions to train and the physical exercises to gamify within the richness and meaning of the environment itself: its affordances, its narrative coherence, its aesthetic resonance, and its capacity to invite the kind of fully embodied, intrinsically motivated engagement from which neuroplastic change most reliably emerges. This is precisely what MAGIC exergames are specifically designed to instantiate: the conservation of intentionality in informationally rich and culturally meaningful environments by coupled perception and action.

MAGIC Exergames: Design Considerations

The theoretical framework developed above has direct implications for the design of exergames that go beyond the standard recommendations of exercise and medical science to converge toward the capacity of arts, cultural, and creative engagement to prevent ill health, promote well-being, and support cognitive resilience across the lifespan [33,34]. MAGIC exergames instantiate this notion by making the cultural experience a neurobiological and motivational substrate of brain health prevention. Below, we present the different mechanistic pillars of the MAGIC exergames (Figure 1) and different design principles that make them genuinely distinct from both conventional exergames and existing immersive cultural experiences (Table 1). This distinction matters because cultural content could plausibly act through 2 nonequivalent pathways. The first is a neurobiological one: authentic aesthetic experience is hypothesized to jointly recruit sensorimotor, emotion-valuation, and meaning-knowledge systems in a configuration that purposive cognitive tasks and culturally neutral gamified environments do not reproduce. The second is purely motivational: cultural framing functions as a sophisticated wrapper that overrides the automatic cost evaluation described by the Theory of Effort Minimization in Physical Activity (TEMPA) without engaging any neural mechanism beyond those already recruited by the underlying motor-cognitive task. We hold that MAGIC exergames are designed to engage both pathways simultaneously and that their distinctiveness as a category, rather than a culturally themed variant of existing exergaming, rests on this dual and synergistic engagement. Thus, cultural content is not merely dressing applied over a validated cognitive-motor task to make it more palatable, but is hypothesized to codetermine, jointly with the motor-cognitive interaction itself, the neuroplastic outcome. This is a testable claim, and we return to it in the research agenda below.

Figure 1. The 4 mechanistic pillars of Motor-Cognitive Active Gamified Immersive Cultural (MAGIC) exergames and their convergence toward the preservation of cognitive function in healthy older adults. Pillar 1 (multimodal sensorimotor engagement) draws on the Adaptive Capacity Model and the Human Movement Intelligence framework to specify the types of motor-cognitive interactions most productive for neuroplasticity. Pillar 2 (semantic and narrative activation) engages episodic and semantic memory systems through culturally coherent narrative environments. Pillar 3 (emotional and autobiographical resonance) exploits dopaminergic reinforcement via personally meaningful cultural content. Pillar 4 (motivational architecture) operates through intrinsic motivation and the Theory of Effort Minimization in Physical Activity (TEMPA) bypass, operationalized as Cultural Snacking—brief, narratively open episodes designed for multiple daily consumptions. Together, these 4 pillars converge to support the preservation of cognitive function in healthy older adults through sustained, intrinsically motivated cultural immersion.

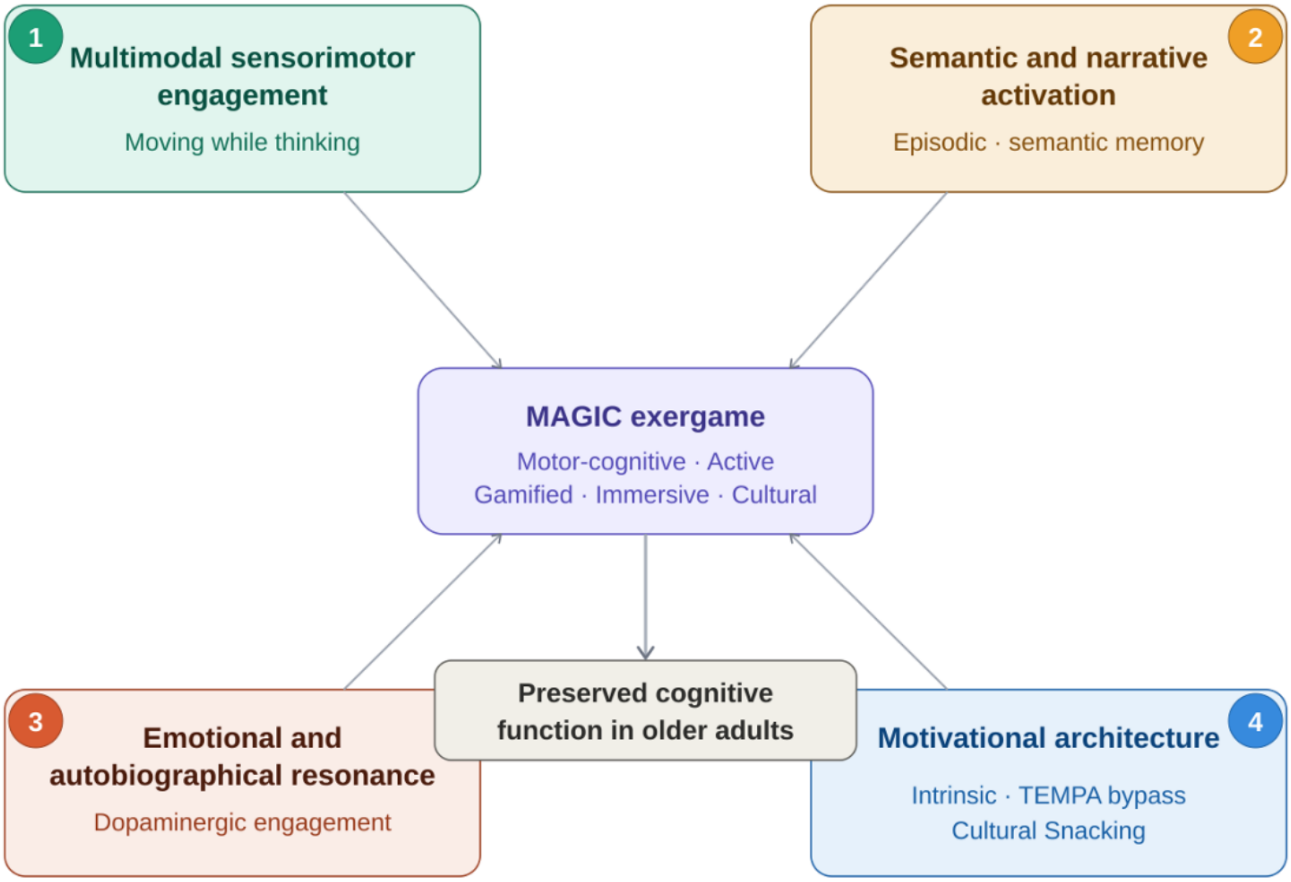

Table . Examples of Motor-Cognitive Active Gamified Immersive Cultural (MAGIC) interactions across the 3 engagement pathways, specified by the type of motor-cognitive interaction they deliver rather than by platform[a].

Engagement pathway	Example MAGIC interaction	Underlying motor-cognitive demand (HMI[b] framework)
Acti-gaming (curiosity-driven)	Wandering a reconstructed 1920s street market to locate a specific vendor's stall, identified only by a half-remembered visual cue from an earlier episode	Incidental locomotion and visual search under low cognitive load; episodic memory retrieval cued by environmental context
Exergaming proper (sustained return)	Restoring a damaged fresco panel by reproducing, with the hand controller, the gesture sequence of the original painter as revealed progressively across sessions	Bimanual coordination and motor sequence learning, with progressive task complexity invisibly tied to narrative deepening across sessions
Exergame-based training (explicit improvement goal)	Guiding a historical figure safely across a collapsing archive under time pressure, requiring rapid target pointing while withholding response to decoy objects	Speed-accuracy constrained pointing (Fitts-type) combined with response inhibition under time pressure—a moving-while-thinking architecture (stop-signal paradigm)

[a]Engagement pathways follow the motivational taxonomy proposed by Manser et al [24]. The HMI framework [31] specifies motor-cognitive demands in terms of perception-action coupling within a structured task environment rather than as isolated cognitive processes. All three examples can be delivered on the same platform (eg, a recumbent-bike exergame with a head-mounted display); the pathway distinction is motivational and design-level, not technological.

[b]HMI: Human Movement Intelligence.

Multimodal Sensorimotor Engagement and Immersive Presence

In the theoretical framework of MAGIC exergames, neuroplastic change emerges from the continuous, adaptive negotiation between a moving body and an informationally rich environment. High-fidelity immersive environments in three-dimensional virtual reality recruit a broader and more ecologically valid range of sensorimotor processes than two-dimensional screen-based exergames. Therefore, the sense of presence becomes a central mechanism that simultaneously engages proprioceptive, vestibular, and peripersonal space systems, creating the conditions for motor-cognitive interaction at a scale that flat-screen interfaces cannot achieve. Moreover, when cultural content structures the immersive environment, guiding participants through a virtual reconstruction of a heritage site, animating historical artifacts, and embedding movement cues within a narrative, the sensorimotor engagement acquires the additional quality of contextual relevance. Actions have meaning within the story: the player does not feel they move to fulfill a training prescription but to navigate a world through goal-directed behaviors whose significance is immediately legible. Such an engagement of motor-cognitive interactions moves beyond classical dual-task paradigms toward what Herold et al [35] term "Moving while Thinking" situations, in which cognitive tasks are incorporated into motor tasks rather than added alongside them. This configuration has been identified as particularly effective for enhancing adaptive behavior in informationally rich environments [17]. This pursuit of a high information rate must be reconciled with the fall risk inherent to physically engaged movement in immersive three-dimensional environments, a concern of particular relevance for healthy older adults. MAGIC design addresses this concern at the hardware and interaction level rather than by reducing informational richness: motor-cognitive bricks involving locomotion or high force production are preferentially delivered in seated or semireclined configurations (as in the recumbent-bike Silver Explorer prototype discussed below), and mixed reality passthrough, rather than fully occluded VR, is favored for daily domestic use because it preserves the user's perceptual awareness of the surrounding physical space throughout the experience. The cascade of formats discussed later in this paper, from supervised location-based installations to lightweight passthrough mixed reality for daily use, is itself a safety architecture as much as an accessibility one.

Semantic, Narrative, and Motor-Cognitive Engagement

In MAGIC exergames, participants navigating a virtual heritage site are not performing a motor task and a cognitive task in parallel; instead, they are inhabiting a world whose exploration is simultaneously sensorimotor, semantic, episodic, and aesthetic. These multimodal, semantically dense, and motor-cognitively demanding environments are lacking in most available exergames, which are focused on gamified exercise libraries rather than meaningful cultural worlds. Several studies have demonstrated that most brain structures vulnerable to aging are those recruited when older adults navigate a culturally rich, narratively coherent environment, which continuously engages episodic memory (recognizing historical objects), semantic memory (retrieving contextual knowledge), spatial navigation (orienting within an immersive scene), and prospective cognition (anticipating what comes next in the narrative) [36,37]. Recently, Coronel-Oliveros et al [22] published the first large-scale demonstration of the link between creative engagement and measurable protection of brain health through delaying functional aging of the involved cerebral networks. It should be noted that Coronel-Oliveros et al [22] documented a dose-dependent effect of active creative practice and expertise (dance, music, visual arts) rather than receptive exposure to a predesigned cultural environment. However, neurobiological evidence for receptive cultural engagement specifically comes from the epidemiological literature. For instance, Tymoszuk et al [38] showed that sustained, repeated engagement with theater, concerts, and museums was associated with improvements in well-being. Moreover, Fancourt et al [39], using epigenetic clocks in 3556 adults from a nationally representative UK cohort, provided the first biological evidence that arts and cultural engagement, including both participatory and receptive activities (attending performances, visiting heritage sites, reading, making music), is associated with a 2% to 4% slower pace of biological aging, in a dose-dependent fashion comparable in magnitude to physical activity. These studies directly support the hypothesis that receptive cultural immersion, of the kind delivered by MAGIC exergames, engages neurobiological mechanisms productive for healthy aging, independently of active creative practice. The ACM provides the complementary neurobiological rationale to the potential benefits of narrative, culturally, and esthetically rich environments for brain and cognition. It proposes that the simultaneous engagement of complex motor skills, physical activity, and higher-order cognitive functions in adaptive, goal-directed motor behavior activates neuroplastic mechanisms more effectively than either domain alone. Based on this model, motor-cognitive exergaming, in which complex motor sequences are simultaneously combined with incorporated cognitive demands (moving while thinking), is hypothesized to produce superior cognitive benefits to either physical-cognitive dual-task arrangements or single-domain training, even when the intensity of physical activity is low [9,17,35].

Emotional and Autobiographical Resonance

Cultural content anchored in the biographical and historical world of current older adults carries a neurobiological asset that purposive exergames entirely lack, that is, autobiographical resonance. Music from one's youth, heritage sites from one's region, artworks of personal significance—these stimuli engage the emotional-valuation system with an intensity that generic game content cannot match. According to the triad model proposed by Chatterjee and Vartanian [19], aesthetic experience simultaneously activates sensorimotor, emotion-valuation, and meaning-knowledge neural systems. Moreover, the physiological and affective "chills" triggered by music or visual art are presumably associated with dopaminergic [36], creating a

XSL•FO
RenderX

pleasure signal that the TEMPA framework identifies as the most powerful predictor of motivation and sustained participation [37]. This emotional engagement consolidates learning, potentiates synaptic plasticity, and biases future behavior toward re-engagement. A MAGIC exergame that generates genuine aesthetic emotion is assumed to create, with each session, an automatic motivational trace that draws older adults to a self-reinforcing dynamic that gamified training protocols have consistently failed to produce.

Pleasure, Effort Minimization, and Motivational Architecture

Designing for sustained engagement in MAGIC exergames therefore requires a motivational framework that operates simultaneously at 2 levels: the reflective level of conscious goal pursuit and the automatic, prereflective level that determines whether physical activity is initiated at all. The integration of these 2 frameworks yields the motivational architecture that MAGIC exergames require, in consistency with the classification of exergaming motivational dynamics proposed by Manser et al [24]. Self-Determination Theory [40], applied to MAGIC exergames, generates useful design principles—player choice to support autonomy, adaptive difficulty to support competence, cooperative or social modes to support relatedness—which are associated with higher deliberative engagement and internalization of motivation [24]. The relatedness dimension deserves further development than the present model currently affords, since the MAGIC framework as developed above focuses primarily on the individual's interaction with the cultural environment, while social engagement is independently established as protective against cognitive decline. Plausible avenues for incorporating a social dimension without displacing the individually paced, narratively open structure of Cultural Snacking include asynchronous shared exploration of the same cultural world, in which players leave discoverable traces or annotations for others who visit later, and noncompetitive collaborative narrative milestones reached jointly across a small group's cumulative individual sessions. These remain design proposals rather than validated mechanisms and are noted here as a direction for future elaboration of the model. However, this framework, which operates exclusively within the reflective motivational system, cannot account for the automatic barrier that precedes deliberate engagement. This limitation is addressed by the TEMPA [41,42], which demonstrates that movement-related cues are automatically processed as costly, that is, as an aversive signal that the brain evaluates and acts upon before any deliberate motivational reasoning is engaged. Exergames whose training logic is perceptually transparent are particularly vulnerable to TEMPA dynamics. Cultural immersion offers a fundamentally different architecture in this respect: a senior navigating a virtual heritage site is not experiencing effort; they are living an adventure. In the vocabulary of Csikszentmihalyi's flow theory [43], the challenge-skill balance is naturally calibrated by the cultural content itself, and the loss of self-consciousness that characterizes flow is precisely the condition under which automatic effort minimization is most effectively suspended. Converging evidence confirms that pleasure experienced during physical activity, not in anticipation, not afterward, is the strongest predictor of long-term adherence [41] and that individualized prescriptions targeting moment-to-moment affective valence generate higher adherence rates than standard prescriptions at 8-week follow-up [42]. In the language of TEMPA, cultural immersion does not merely motivate; it restructures the automatic cost-benefit calculation that determines whether the activity happens at all.

Thus, MAGIC exergames are distinct from conventional approaches to exergames in which motivation is engineered through gamification, considered as an extrinsic incentive architecture superimposed upon a training activity to make it more tolerable. In MAGIC exergames, gamification is not the solution to the motivational problem. Instead, the cultural experience, the narrative world, the aesthetic resonance, and the autobiographical significance of the content generate intrinsic motivation that requires no external scaffolding, because inhabiting a world that matters is already what the player desires.

The heterogeneity of motivational profiles among healthy older adults requires that this integrated framework be operationalized across three distinct engagement pathways, each corresponding to a different relationship between the player and exergaming, and each instantiating a different mode of engagement [22] (see Table 1). The first pathway concerns players motivated primarily by the intrinsic pleasure of cultural exploration and narrative discovery, rather than by any explicit improvement goal. Unlike in conventional exergames, where gamification mechanics (points, rewards, levels) provide the motivational scaffold, in MAGIC exergames the cultural experience constitutes the primary motivational substrate. Accordingly, engagement corresponds to *acti-gaming* [24], that is, occasional, curiosity-driven interaction in which physical and cognitive activity is a natural consequence of cultural immersion rather than a deliberate training investment. The design priority for this pathway is brief, narratively open episodes that generate voluntary return through incompleteness and aesthetic resonance rather than through reward accumulation. Attention is absorbed by the cultural world, and the physical activity embedded within it is experienced not as effort but as the natural condition of inhabiting an experience the player actively desires. The second pathway concerns players who return regularly not to improve but to sustain their capacities through the pleasure of cultural immersion, which could be termed "cultural discovering while exercising." Here the distinction from classical exergames is sharp: the player is not returning because a gamification system incentivizes them to do so, but because an unresolved narrative, an esthetically compelling environment, or an autobiographically resonant cultural world draws them back intrinsically. Their engagement corresponds to *exergaming proper*. Because these players are not motivated by explicit progress, failure must be rare and brief, and progression must remain invisible as training load, experienced instead as deepening cultural and aesthetic richness. The design priority is narrative coherence and continuity across sessions. The cultural world must persist, evolve subtly between episodes, and generate the sense that something awaits one's return. The third pathway concerns players who are explicitly motivated by improvement of

XSL•FO
RenderX

functional capacities and who seek in the MAGIC exergame an opportunity in this respect. Even for these players, the MAGIC framework proposes that the challenge structure be embedded within the cultural narrative rather than superimposed upon it as an explicit training layer. Challenges are presented as culturally situated opportunities that require precise motor sequences, demand spatial navigation under cognitive load, or call for sustained attentional engagement, so that the training logic remains legible to those who seek it while remaining transparent to those who do not. Their engagement corresponds to *exergame-based training* [22]. For these players, gamification mechanics may play a supporting role, but the primary motivational substrate remains the cultural experience and the narrative world—with gamification serving as a complementary layer rather than the foundational architecture.

Rethinking the Use of Exergames: Density, Intensity, and Cultural Snacking

To ensure their effectiveness in preserving brain health and cognition, a critical design challenge for MAGIC exergames concerns the translation of principles of exercise sciences into a format compatible with the lived reality of healthy older adults. Sustained neuroplastic benefit requires repetition, progressive challenge, and sufficient accumulated volume. Immersive cultural experiences are usually delivered as location-based events, typically designed as singular, unrepeatable events. Therefore, the question is how to make exergame formats more culturally appealing and how to reconceive the architecture of engagement itself. Two converging bodies of evidence may help to reframe this. First, Herold et al [44] demonstrated that the standard Frequency, Intensity, Time, Type framework is insufficient to characterize the dose-response relationship between physical activity and brain health, and that *density*—the temporal distribution of activity bouts across the day—must be treated as an independent and potentially decisive variable. Second, the exercise snacking literature shows that brief, intermittent bouts of physical and cognitive activity distributed across the day produce cognitive benefits at least comparable to, and in some respects superior to, equivalent continuous volumes, with an optimal accumulated daily duration of approximately 90 minutes best achieved through multiple short bouts rather than extended single sessions. These findings are directly transformative for MAGIC design. Rather than architecting sessions around conventional exercise prescriptions, MAGIC exergames should be conceived as high-density, narratively serialized micro-episodes whose temporal distribution and cultural continuity across the day become active design variables.

Regarding intensity, the conventional assumption that brain plasticity and cognitive benefits require moderate-to-vigorous aerobic effort is substantially qualified when movement occurs in informationally rich environments with complex motor-cognitive demands. Carrubba et al [17] demonstrated that even moderate- or low-intensity physical activity produces neuroplastic effects comparable to high-intensity training when embedded in rich environments, because it is the continuous adaptive negotiation between a moving body and a demanding environment, not cardiovascular intensity per se, that drives the neuroplastic response. What MAGIC exergames require is not a high heart rate but a high information rate. This opens MAGIC to the full spectrum of mobility and fitness levels characteristic of healthy older adults, without requiring the aerobic effort that purposive exergames demand and that TEMPA dynamics make so difficult to sustain. The design principle that synthesizes both insights is what we term *Cultural Snacking*, which consists of the serialization of MAGIC content into autonomous episodes of 5 to 10 minutes, each complete in itself yet narratively open, designed for 3 to 5 daily consumptions across varied contexts—home, residential facility, hotel, workplace—with or without full VR immersion. The mechanism of re-engagement in Cultural Snacking is categorically different from the gamification logic that underlies conventional exergame design. In gamified exergames, re-engagement is engineered through extrinsic incentive structures—point accumulation, streak rewards, leaderboard positioning, unlockable content—that create artificial obligations to return. Cultural Snacking operates on an entirely different motivational logic. Re-engagement is driven by narrative incompleteness and aesthetic absorption to continue a story that matters to players—a heritage site not yet fully explored, a historical figure whose motives remain unresolved, a cultural object whose significance has only been partially revealed. This is intrinsic motivation in its purest form; it requires no external scaffolding because the activity itself is the reward. It is precisely the motivation that cultural content is uniquely positioned to generate in an older adult population for whom personal history, aesthetic experience, and cultural resonance carry a depth of meaning that points, badges, and leaderboards cannot replicate. Critically, progression in Cultural Snacking does not occur through the explicit escalation of cognitive task difficulty. Instead, progression operates entirely through the gradual modification of environmental constraints, in the spirit of ecological dynamics: richer spatial configurations, more ambiguous cultural affordances, temporally more demanding motor-cognitive sequences, as the narrative world deepens across episodes. This progression is invisible as training load but experienced as increasing narrative and aesthetic richness. The player does not feel themselves becoming more capable—they feel the world becoming more meaningful. The neuroplastic benefit and the cultural experience are not merely adjacent: they are constitutive of each other. Between episodes, the cultural world persists and subtly evolves, generating the sense that something awaits one's return. In the framework of TEMPA, this mechanism is hypothesized to convert the automatic cost evaluation of physical effort into an automatic invitation. A legitimate concern is whether the repeated transition between daily activities and an immersive device, several times a day, would itself impose a cognitive and logistical load that conflicts with the effort-minimization principle the model otherwise seeks to exploit. We argue that this friction is directly addressed by the choice of delivery hardware rather than by the Cultural Snacking architecture itself: next-generation standalone mixed reality headsets require no external computer or cabling, start through a single gesture, and, in passthrough mode, do not require play-space recalibration between sessions. This remains a design hypothesis rather than an established finding, and we return to it in the

XSL•FO
RenderX

research agenda below, where repeated-engagement friction is identified as a measurable outcome in its own right [44]. The exercise snacking evidence [45] and the Cultural Snacking model establish that MAGIC exergames are not merely more engaging than conventional exergames—they are more neuroplastically effective and more motivationally coherent.

Conclusion and Perspectives

Based on underwhelming research on the hypothesized superiority over conventional alternatives. This Viewpoint paper recommends adopting a fundamentally different conceptual approach to designing MAGIC exergames: (1) targeting cognitively healthy older adults as the primary prevention population, (2) grounding their design in the neurobiological logic of HMI and Ecological Dynamics, and (3) placing culturally meaningful, aesthetically rich, and autobiographically resonant content at the center of the intervention. Moreover, the mechanistic pillars of MAGIC exergames developed in the present paper converge on a single design principle that inverts the classic logic of exergame design by assuming that in MAGIC exergames, pleasure is not a reward added to a training protocol: it is the training protocol. A practical challenge that this approach must confront is scalability: content that is culturally rich and personally meaningful risks becoming prohibitively costly to produce across different regions, languages, and population subgroups if each MAGIC environment is built as a bespoke production. Two factors are likely to mitigate this constraint. First, the motor-cognitive bricks specified by the combined-training taxonomy are largely reusable across narrative settings, so that production cost concentrates in environmental and narrative content rather than in the validated interaction mechanics themselves. Second, partnerships with heritage and cultural institutions, which already hold digitized or digitizable collections, offer a route to amortizing content production beyond what a single research or commercial actor could sustain alone. Whether this is sufficient to keep MAGIC content affordable at population scale remains an open empirical and economic question.

Practically, MAGIC exergames could be conceived as a system of complementary formats—from location-based event to the domestic sphere, organized along the reality-virtuality continuum, each optimal for a different use context, immersion depth, and accessibility level, yet all anchored in the same narrative and cultural world. Large-scale projection environments without headsets offer high aesthetic immersion with zero technological barrier, making them ideal for weekly location-based MAGIC sessions. Augmented reality on tablets and smartphones provides a zero-barrier entry point for the shortest micro-snacks integrated into daily life. Mixed reality passthrough devices represent the most promising format for daily domestic Cultural Snacking: immersive enough to sustain narrative engagement, safe enough to eliminate fall risk, and sufficiently lightweight for repeated daily use. This cascade architecture resolves simultaneously the cybersickness problem, the repetition problem by providing lightweight formats compatible with Cultural Snacking, and the accessibility problem by allowing older adults of very different technological comfort levels to enter the same cultural world through different doors. An advanced existing proof-of-concept for this convergence is *Submersive* (Austin, Texas; projected opening 2027), which is explicitly positioned at the intersection of immersive art, neuroaesthetics, and therapeutic wellness, while integrating wearable biometric sensors to measure in real time how immersive artistic environments affect the human body and brain, feeding data back into iterative space design. *Submersive* thus illustrates, as a project still under development rather than as established evidence, the convergence this paper advocates: a private operator from the entertainment world deliberately integrating the conceptual tools of neuroaesthetics and health research to transform a cultural experience into a wellness intervention. Should it open as planned and meet its stated design objectives, Submersive would provide further commercial validation of this convergence; at present, however, it remains a projected outcome rather than a demonstrated one, a distinction this paper is careful to maintain given its own critique, in earlier sections, of unrealistic optimism in the exergaming field.

What it still lacks to constitute the full MAGIC model is an explicit research agenda. This could be structured around three main recommendations. First, future studies must abandon the "technology-first approach" to characterize MAGIC exergames by the type of combined motor-cognitive interactions they deliver—specifying the physical intensity, motor challenge, cognitive load, and cultural content richness as independent and measurable variables. This requires the development of a dedicated taxonomy that incorporates dimensions of narrative coherence, aesthetic richness, and autobiographical resonance as primary design variables. Second, mechanistic investigations are needed, including neuroimaging to identify longitudinally sensitive biomarkers of preventive efficacy and neuroplastic change that creative cultural engagement is expected to produce. Third, comparative designs with active control groups—conventional exergames, standard combined training, and real-world cultural engagement—with adequate follow-up periods are necessary to establish both the superiority and the persistence of MAGIC-induced benefits. Concrete, measurable outcomes that would distinguish a MAGIC intervention from a standard multidomain exergame in a controlled trial should include functional brain-age indices derived from network-level connectivity measures, of the kind reported by Coronel-Oliveros et al [22]. For instance, electroencephalographic comparison between a MAGIC condition and a content-matched "library" condition presenting the identical cognitive-motor bricks without narrative or cultural framing could isolate the neurophysiological contribution of cultural embedding; spontaneous re-engagement rate could serve as a behavioral proxy for intrinsic adherence, which directly distinguishes the MAGIC motivational model from approaches reliant on extrinsic gamification incentives. These outcomes should also be tracked against the logistical-friction hypothesis raised above regarding repeated daily device use.

The future development of MAGIC exergames requires an intersectoral and multidisciplinary innovation ecosystem. The raw material of MAGIC resides in cultural institutions, while the neurobiological and design knowledge required to translate this content into effective interventions resides in digital health

XSL•FO
RenderX

research teams. Bringing these 2 communities into structured co-design programs, with older adults as co-designers, is the essential first institutional step. Indeed, location-based immersive cultural experiences, which already attract a predominantly senior audience, represent a natural entry point for proof-of-concept studies, combining high-quality cultural content with physical engagement in ecologically valid, nonclinical settings. Thus, without waiting for MAGIC-specific trials, we invite the digital medicine, public health, and silver economy communities to recognize that cultural and artistic content is potentially the most ecologically valid, intrinsically motivating, and cost-effective setting for a new generation of immersive exergaming interventions that are as meaningful as they are effective in enhancing brain health, cognition, and well-being. The scientific, institutional, and economic conditions for this convergence already exist.

Abstract

Leprosy is endemic in many low-income countries, affecting mainly the poorest communities. The disease can lead to sensorimotor functional losses that can predispose patients to reduced independence. In older adults, these losses associated with leprosy are added to those already resulting from natural aging and associated comorbidities, which can contribute to the clinical picture of frailty syndrome in these older adults. Early detection of frailty can reduce several serious consequences for these individuals, preventing loss of quality of life and financial costs to patients and the health care system. Sensors built into smartphones have been proposed as low-cost, and highly sensitive tools for detecting motor loss and could help monitor the risk of some frailty features in older people affected by leprosy.

Introduction

Population aging affects all countries today. While high-income nations have already plateaued, transitional and low-income countries are still undergoing the process [1]. Aging causes physiological and structural changes, resulting in some degree of loss of function and independence [2]. Additionally, various diseases can result in physical impairment in old people [3].

In certain circumstances, older adults may experience physical, psychological, and social challenges that reduce their ability to tolerate stressors and cause a cumulative decline in organic functions, making them susceptible to falls and potential negative consequences, including death [4]. The term used to describe this geriatric condition is frailty or frailty syndrome, which is characterized by three of five phenotypes: weakness, low level of physical activity, unintentional weight loss, slow gait speed, and exhaustion [5].

Transitional countries, such as Brazil and India have an impoverished population affected by numerous endemic diseases. Although frailty syndrome may be common in these populations, it is largely unrelated to these endemic diseases. However, leprosy can be a significant comorbidity factor, which, when combined with frailty, can greatly increase the risk of physical disabilities [6].

In regions in which leprosy is endemic, balance control and mobility are not adequately assessed in primary care services due to the high cost and limited availability of gold-standard assessment tools, which are primarily found in research or referral centers. Evaluation of balance or mobility is often conducted through the use of scales or low-cost clinical tests, which may lack the sensitivity necessary to identify early fall risks [7-9]. New options using portable digital technologies have been suggested and validated for conducting this kind of motor evaluation [10,11].

In this context, we suggest discussing the significance of evaluating frailty syndrome in older people with leprosy as a crucial public health policy. Additionally, we propose smartphones as a digital health intervention that could improve the monitoring of the risk of falls in the overlooked population of older adults with leprosy.

The Assessment of Frailty in Leprosy

Leprosy, caused by the bacterium *Mycobacterium leprae*, or less frequently by the *Mycobacterium lepromatosis*, is an

XSL•FO
RenderX

infectious disease that can result in neuropathies compromising proper somatosensory, visual, and vestibular system functioning, as well as muscle strength [12-14]. Although these functions are altered, balance assessment is not included in the standardized protocols established by the World Health Organization (WHO) [15], which serves as the foundation for national protocols in countries like Brazil.

The WHO disability grading system recommends assessing tactile sensitivity, muscle strength, and vision [15]. However, despite vision, somesthesia, and muscular activity contributing to balance control, individualized assessment of each of these functions does not provide a comprehensive understanding of balance control. Furthermore, evaluations of the vestibular system or other somatosensory modalities including temperature, pain, and proprioception, are not considered. It is crucial to note that there is no direct evaluation of mobility or balance in patients with leprosy.

Considering the widespread lack of assessment for both balance and mobility in patients with leprosy of all age groups, the issue becomes particularly concerning in older adults [6]. This population already experiences natural functional declines that are associated with physiological aging, as well as other comorbidities that are more prevalent as individuals age. These comorbidities, such as diabetes, hypertension, and osteoporosis, add to the functional impairment experienced by older adults.

Assessing frailty in older individuals with leprosy holds paramount importance for several reasons. The identification of frailty in older adults with leprosy would enable the timely detection of potential complications (increased risk of disability, delayed wound healing and ulcer development, increased falls, psychological complications, reduce quality of life, etc), facilitate physical and psychological interventions during milder clinical conditions, and provide health managers with valuable insights, thereby contributing to the formulation of new health policies and health care measures [16,17].

Since frailty specifically causes a decrease in muscle mass and strength, which can significantly affect balance control and mobility in older adults with leprosy, monitoring these functions may aid health managers in identifying those who may be at the risk of developing frailty syndrome.

Tracking Frailty Using Smartphones

There is a growing interest in using smartphones to track frailty in older adult populations, and several studies have explored their potential. Most of the apps used to track fragility used applications with forms to be filled with clinical descriptions of the patients following the criteria to classify the Fried's frailty phenotype [18,19]. Other apps have validated the use of sensors from smartphones (cameras and/or inertial sensors) to quantify functional activities that would be associated with the features of fragility [20,21].

Evaluation of Movement as a Potential Indicator of Functional Losses Related to Frailty

The high cost and limited accessibility of gold-standard movement analysis methods, like force platforms, electromyography, and video capture systems, pose significant barriers among poorer populations. These instruments require highly sensitive sensors and robust construction to ensure accuracy and regular, specialized calibration to maintain reliability, and are accompanied by advanced analytics software, thereby adding to the overall cost. These systems often require controlled environments, reliable power supplies, and ample physical space, which may be unavailable in resource-limited areas. Skilled professionals are necessary to operate and interpret the data from these systems, but such expertise is often lacking in underserved regions. These are often only found in specialized research laboratories, hospitals, or sports centers, limiting access for general populations.

However, smartphones with a multitude of built-in sensors have recently emerged, offering validated low-cost alternatives for a range of motor tests. These devices have the potential to provide high-precision assessments in primary care settings [22].

Specifically, for the evaluation of balance control and mobility, various proposals have demonstrated that the inertial sensors, namely the accelerometer and gyroscope, present in smartphones can extract numerous characteristics that describe these functions [23-25].

For static balance assessment, accelerations in the anteroposterior and mediolateral axes can be used to quantify body oscillations in the time domain and time frequencies. These measurements are comparable to those obtained with force platforms [10]. In the case of dynamic balance assessment, inertial sensors have been used during tests like the sit-to-stand test, which introduce various additional variables beyond the number of sit-and-stand cycles performed within a specific time, as is customary in clinical testing [26]. The assessment of mobility via the Timed Up and Go test solely relies on the time it takes to perform [27]. However, the addition of a smartphone to the test can provide measurements of acceleration during the process of getting up and down from a chair, as well as the time taken to walk to and from the chair, and the angular velocity of turns taken during the test [28].

In addition to balance and mobility tests, performing other motor tests on smartphones can also be of interest for evaluating patients with leprosy. The Finger Tapping Test and reaction time test, which indirectly indicate nerve conduction time, can provide valuable information, as nerve conduction time may be delayed in patients with leprosy [29,30].

Factors to Be Considered When Introducing a Smartphone to Monitor

XSL•FO
RenderX

Motor Functionality in Older People With Leprosy

Many experts discussing the implementation of smartphones in health care may initially assume that the proposal involves using the patient's smartphone to acquire all biological signals. However, for digital health interventions, such as motor assessment of patients with leprosy, it is recommended to use smartphones provided by the health care service. Some issues to consider would be the following: (1) the service can ensure that the device meets the necessary technical requirements and is compatible with the software; (2) few studies have evaluated the reliability of measurements using smartphones in unsupervised motor tests; (3) self-tests using smartphones may not be suitable for potentially fragile patients, as some tests (balance and mobility) require trained personnel to be present to prevent falls; and (4) accessing patient history data for evaluation purposes would be decentralized and challenging for managers. The latter is also a factor that does not indicate that the health care professional's smartphone should be used.

Few smartphone apps include more than one motor test. Most of the apps validated in the literature are still experimental and not available in virtual app stores. Some of the available apps provide files with time series of sensor recordings for offline analyses using computational routines. Furthermore, applications that report the values of the extracted characteristics do not provide normative reference values for interpreting those measurements. Therefore, before any intervention, it is necessary to have a plan for processing and storing the data so that the intervention is not frustrating.

While smartphone-based movement analysis apps offer great promise, these interventions are not without significant challenges. Addressing cost, privacy, digital literacy, regulatory, and systemic barriers will be critical for successful implementation, particularly in low- and middle-income countries (LMICs) and older populations. A well-rounded strategy involving stakeholder collaboration, robust funding mechanisms, and tailored solutions can help overcome these obstacles, ensuring that these tools fulfill their potential for equitable health care delivery.

While smartphones are more affordable than gold-standard equipment, they may still be expensive for underfunded health systems or patients in LMICs. Bulk purchases by governments or institutions might reduce costs, but initial investments could strain already limited budgets. Beyond initial procurement, ongoing costs for repairs, software updates, and network connectivity could be prohibitive. Health systems in LMICs often struggle with basic infrastructure issues (eg, lack of clean water and staff shortages). Allocating resources to digital health tools could be viewed as a lower priority compared to addressing these fundamental needs. Investing in smartphone-based interventions might divert funds from critical areas like vaccine programs, malnutrition initiatives, or essential drug supplies. Governments and stakeholders would need to weigh the benefits of early diagnosis and monitoring of movement disorders against these other pressing needs. Another possibility is looking for other mechanisms for funding such as partnerships with nonprofits or nongovernmental organizations focused on health equity, international aid or grants from organizations like the WHO or international foundations (such as the Gates Foundation), and public-private collaborations where technology companies subsidize costs for social impact.

Storing sensitive health data on cloud servers could expose patients to risks of data breaches or misuse. Many LMICs lack robust data protection laws, creating additional vulnerabilities. Some strategies can be applied to mitigate these vulnerabilities such as the use of encryption for data storage and transmission, storage of data locally on the device where feasible, minimization of cloud reliance, and development and enforcement of clear, transparent privacy policies, thereby ensuring compliance with international standards like General Data Protection Regulation where applicable. Patients need to understand how their data will be used and stored. Consent processes must be clear, culturally appropriate, and account for varying levels of digital literacy.

Many older adults, especially those in LMICs, may lack digital literacy (familiarity with smartphones), have physical barriers (poor vision, tremors, or limited dexterity), distrust in technology, or fear of making mistakes, which might discourage adoption. Developers should consider assistive technologies, such as voice commands or larger, high-contrast displays, and simplified user app interfaces; stakeholders should consider training and support programs for the patients, although they might add to implementation complexity.

The regulatory requirements for medical devices and health apps vary significantly among countries. In LMICs, regulatory frameworks for digital health tools may be underdeveloped or nonexistent. In contrast, high-income countries might impose rigorous standards, thus delaying deployment. Early engagement of local regulatory bodies is necessary to clarify requirements and ensure compliance. Some cultures may have reservations about adopting digital health tools due to mistrust of external technology or ethical concerns. Tailored community engagement and education are crucial.

Despite these challenges, we believe that the introduction of a smartphone for motor assessment as part of a digital health intervention holds potential benefits for all stakeholders involved in caring for patients with leprosy. Health professionals would be able to access objective data on various functional abilities for comparative assessment of therapy effectiveness. Health managers could offer personalized services based on functional characteristics of patient demand and plan health policies tailored to the population served by the service. Patients stand to benefit from enhanced health monitoring, as explained above.

Abstract

The aging population presents a pressing challenge for health care systems, necessitating effective strategies to address the complex needs of older adults. The Veterans Health Administration in the Department of Veterans Affairs (VA), the largest integrated health care system in the United States, has embraced the Age-Friendly Health Systems (AFHS) initiative from the Institute for Healthcare Improvement to ensure safe and high-quality care for older veterans. In AFHS, health care providers consistently use the evidence-based 4Ms framework (what matters, medication, mentation, and mobility) to deliver comprehensive care for older adults in all care settings. This viewpoint paper explores the potential of artificial intelligence (AI) to enhance the evidence-based implementation of the AFHS 4Ms framework in the VA to provide optimal care for older adults. By leveraging AI technologies, such as natural language processing, machine learning, large language models, clinical decision support, and data analytics, this viewpoint examines the opportunities and challenges of using AI to support the 4Ms domains in a large, integrated health care system. Furthermore, it discusses the potential benefits of integrating AI-driven decision support systems and predictive analytics to personalize care, reduce polypharmacy and potentially inappropriate medications, enhance cognitive and mood assessments, and better identify mobility issues and interventions. By examining the intersection of AI and age-friendly care in the VA, this viewpoint highlights the transformative potential of AI to expand 4Ms care and improve the experience of providers and older adults across diverse health care settings.

(JMIR Aging 2026;9:e75686) doi:10.2196/75686

KEYWORDS

age-friendly health systems; 4Ms framework; aging; artificial intelligence; technology; older adults; geriatrics; Veterans Health Administration

Introduction

The United States is experiencing a significant demographic shift, characterized by a rapidly aging population. By 2050, an estimated 82 million individuals will be aged 65 years or older [1]. The Veterans Health Administration in the Department of Veterans Affairs (VA) is the largest integrated health care system in the United States, and a significant number of older veterans are enrolled in health care provided by the VA [2]. An estimated 30% of adults aged 65 years or older could benefit from specialized care from geriatricians; however, there continues to be a scarcity of trained geriatricians despite innovative solutions to meet the rising demands within the geriatric workforce [3]. To meet the increasingly complex care needs of the growing older veteran population, the VA joined the Age-Friendly Health Systems (AFHS) movement in March 2020 [4]. The AFHS initiative within the VA continues to build on decades of evidence-based care and innovation in geriatrics, which aligns with the 4Ms framework (what matters, medication, mentation, and mobility) [5] and supports the VA's goal of becoming a high reliability organization [4,6-8].

As efforts to train health care professionals to optimize a geriatric-friendly workforce continue, artificial intelligence (AI) can be leveraged to supplement these efforts and support the

XSL•FO
RenderX

geriatric workforce in providing high-quality care to older adults with multiple chronic conditions.

The VA as an Age-Friendly Health System

The AFHS framework emphasizes developing and aligning care plans for older adults to meet the goals that matter most to them. AFHS was established in 2017 by the John A. Hartford Foundation and the Institute for Healthcare Improvement (IHI) in collaboration with the American Hospital Association and the Catholic Health Association of the United States. This initiative promotes a comprehensive framework known as the 4Ms, which focuses care on the "what matters" element to the patient and on assessing medication, mentation, and mobility to ensure evidence-based and reliable care for older adults [7,8].

The VA has made important strides in adopting the 4Ms on an enterprise scale. As of July 2025, the VA has implemented AFHS in 455 clinical sites, with all sites receiving Level 1 Participation in AFHS recognition from the IHI [9]. Level 1 recognition means that the clinical site has described how the 4Ms will be put into practice. Of these sites, 297 have achieved Level 2 Committed to Care Excellence recognition from the IHI. Level 2 recognition means that the clinical site has tracked and shared the number of older adults reached with the 4Ms over at least 3 months and has described how the 4Ms will be sustained in practice. The implementation and spread of AFHS in the VA has reached 164 Veteran Affairs Medical Centers nationwide.

The central focus of the AFHS movement is to prioritize "what matters" to older adults—the first "M"—placing their specific health outcome goals and care preferences at the forefront across all care settings. The VA has developed several ways, through different programs, to elicit this information, such as the Whole Health Mission, Aspiration, Purpose inquiry; the Patient Priorities Care survey; and the Well-Being Signs tool. These tools are accessible through an age-friendly 4Ms template and can be viewed, if previously populated, when the template is opened. Health care providers looking to readily view this information to position the visit in what matters to the patient must open the template. Currently, no function exists to easily elicit from the chart what a veteran's health priorities may be if the template wasn't previously used.

The second "M"—"what medication"—emphasizes limiting the use of high-risk medications and dose adjustments when a high-risk medication is essential to achieve what matters to older adults. Within the VA, there is active groundwork to support safer medication use: VIONE (Vital, Important, Optional, Not indicated), a nationwide deprescribing program with dashboards and risk tools embedded in the electronic health record (EHR), has been disseminated across more than 130 medical centers and supports pharmacist-led deprescribing [10]. VA informatics efforts have also applied natural language processing (NLP) to prescribing problems and are advancing AI- and machine learning (ML)-enabled decision support as part of a learning health system strategy [11]. Software built into the EHR notifies providers of medication interactions; however, currently, systems to review medications using Beer's criteria (which identify medications potentially inappropriate for older adults) or to alert health care providers to medication-disease interactions (eg, anticholinergic medications in patients with cognitive impairment) are not standard and require the expertise of geriatric-trained providers and pharmacists.

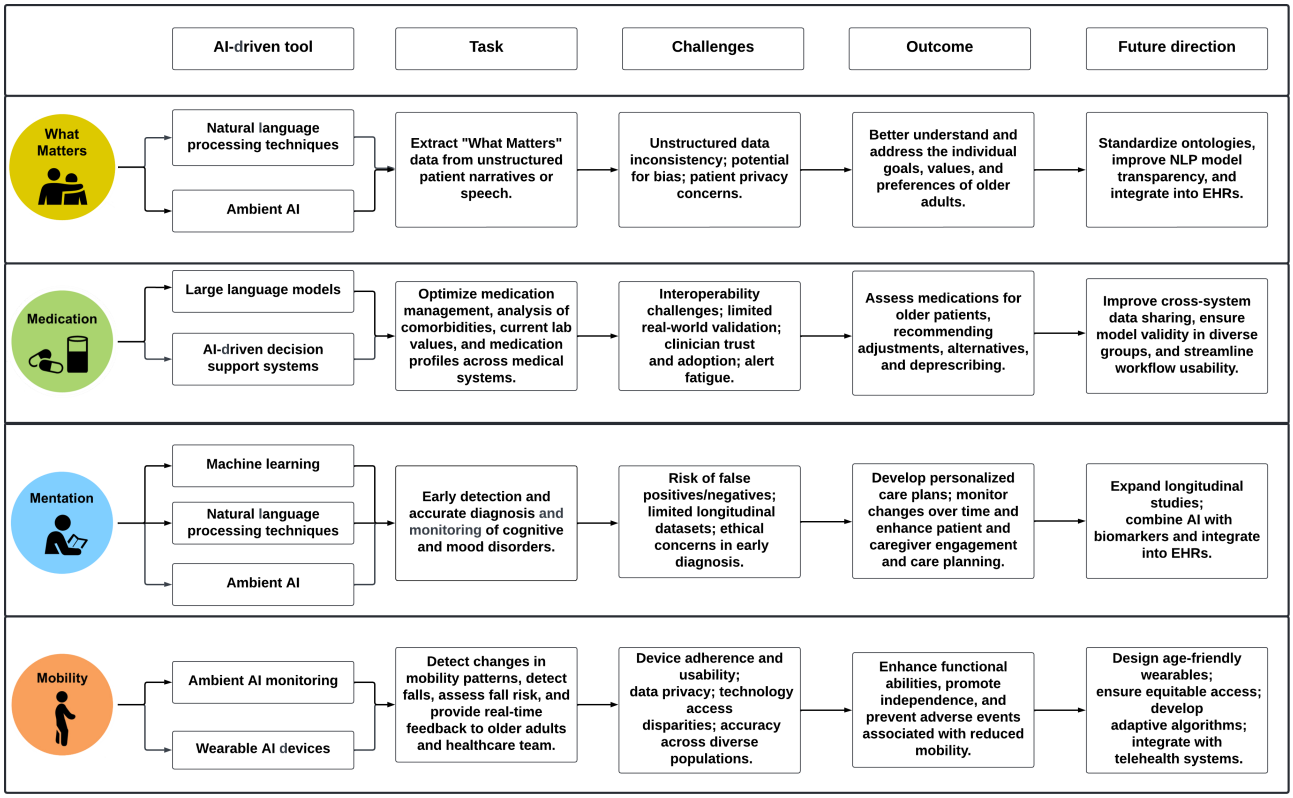
The third "M"—"what mentation"—concentrates on preventing, identifying, treating, and managing conditions such as dementia, depression, and delirium across care settings. Current use of the AFHS template with embedded cognitive and mood screening tools has improved access to these evidence-based assessments. Implementation, although progressing, faces challenges related to time and documentation constraints. Although there is a program for mental health clinicians to initiate and review mental health assessments (Mental Health Assistant), there is no repository within the EHR to easily view past screening results and actions; the AFHS template must be opened. Unless a veteran presents for cognitive evaluation to a mental health or geriatric specialist, the current system relies on individual providers to determine the best time to screen for cognitive impairment, often after warning signs for dementia are exhibited. Electronic frailty indices, based on predictive models such as the VA Frailty Index and the Care Assessment Needs score, exist within the VA system [12]; however, they are not used in clinical settings to identify patients at risk of cognitive decline.

The final "M"—"what mobility"—promotes mobility evaluation to encourage older adults to safely engage in daily physical activity to maintain function and pursue what matters to them. Current use of the AFHS template using embedded mobility screening tools prompts health care providers to perform either a history or physical examination-based screen. Real-time remote monitoring of gait or fall risk for ambulatory care patients is not yet part of routine care, and other potential predictors, such as the Care Assessment Needs score, do not correlate well with physical functioning [13].

Individually, each "M" has the potential to improve health outcomes, reduce low-quality services, and increase the use of cost-effective interventions. Introducing the 4Ms approach as part of AFHS improves care for older veterans [4]. To promote the AFHS 4Ms approach and offer better care to the older population, the VA must leverage all tools, including the potentially transformative use of appropriate AI techniques.

AI is a rapidly developing technology that encompasses various fields of knowledge and uses a wide range of techniques. Its primary goal is to simulate and extend human intelligence through machines [14]. Within the field of AI, research areas include expert systems, ML, robotics, decision support systems, and pattern recognition. There are many potential applications of AI in health care for older adults, such as clinical decision support (CDS) systems, robotics for physical rehab and physiotherapy exercises, NLP and speech analysis, medical imaging and video processing, wearable devices and signal processing from digital watches that track health data, and using ML for targeted drug therapy [15,16].

XSL•FO
RenderX



AI has already demonstrated its potential in geriatric care by addressing challenges such as caregiver shortages and resource disparities. Researchers increasingly believe that AI may further enhance the well-being of older adults by redistributing health care resources, including nursing and other professional support. Numerous studies have explored the application of AI in geriatric care, focusing on areas such as Alzheimer disease care, disease recognition, and medication reminders [17].

Our viewpoint is that appropriate use of AI could better use and integrate the 4Ms across the VA. The implementation and sustainment of 4Ms care require scalable and efficient strategies to deliver equitable, evidence-based care to reach all older adults. We propose leveraging AI technologies, such as NLP, ML, ambient AI, CDS, and data analytics to support the AFHS movement. This manuscript delves into the opportunities and challenges in using AI to support the 4Ms domains within the VA system.

Use of AI for 4M-Based Care at the VA

Although AI is rapidly advancing, its application to AFHS and the 4Ms framework has not been systematically characterized. To date, no research has comprehensively assessed the scope, trends, effectiveness, or gaps in AI-driven approaches to AFHS within the VA. This lack of synthesis represents a barrier to advancing implementation and scaling of age-friendly care. By leveraging AI methods such as NLP, ML, predictive modeling, and advanced data analytics, with emerging opportunities in deep learning and large language models (LLMs), there is significant potential to transform large volumes of unstructured and structured clinical data into actionable insights that enhance evidence-based, person-centered care for older veterans within the 4Ms framework. Figure 1 describes the proposed use of AI for age-friendly 4Ms-based care.

Figure 1. Proposed use of artificial intelligence (AI) for age-friendly 4Ms-based care. EHR: electronic health record; NLP: natural language processing.

What Matters

Using AI in health care for older adults can expand the available tools to improve care delivery and assist health care professionals in personalizing medicine for this population. Implementing AI within the context of AFHS, with a focus on what matters to the older adult, may enable more efficient development of care plans that are both personalized and optimized. The AFHS 4Ms framework represents a paradigm shift in the care of older adults by emphasizing alignment of clinical practice guidelines with patients' health goals and lifestyle preferences.

Extraction and compilation of EHR data across health care systems regarding patients' priorities and goals remain challenging. AI tools such as NLP and ML can support clinical decision-making by identifying and synthesizing these priorities, thereby assisting clinical teams in formulating care plans centered on what matters to older adults. NLP, a branch of AI, enables computers to understand, extract, and analyze information from human language in clinical text and documentation. These techniques can extract insights from unstructured patient narratives, including documentation of goals, life-sustaining treatment, and advance care planning, to provide clinicians with a clearer understanding of patients' values and preferences.

Recent work in this area has demonstrated promising applications. For example, Gleason et al [18] developed a rule-based NLP system to classify patient portal messages from

older adults by the 4Ms domains (including the "what matters" domain) and achieved an area under the curve of 0.90 in identifying messages sent by care partners [18]. Similarly, Min et al [19] developed an NLP algorithm to automatically capture daily care experience preferences from narrative data, demonstrating how AI can operationalize the "what matters" domain at scale [19].

Beyond text-based extraction, emerging technologies such as ambient AI (ambient scribing) can capture and synthesize clinical discussions in real time, including conversations around "what matters," to further support AFHS [20]. Integrating these AI-enabled insights into clinical workflows can promote more patient-centered care, facilitate shared decision-making, and improve patient satisfaction.

While some scholars caution that reliance on AI-driven clinical decision algorithms could risk a return to paternalistic models of care, AFHS emphasis on the "what matters" domain provides an important safeguard. By ensuring that AI tools are designed and implemented with patient priorities at the center, AFHS can help expand personalized medicine for older adults in a manner that enhances, rather than replaces, the patient voice.

Medications

In the "medication" domain, AI-enabled CDS can help optimize pharmacotherapy for older adults by screening for high-risk prescribing, drug-drug interactions, renal-dose mismatches, and deprescribing opportunities at the point of care. Contemporary reviews show that ML models can predict adverse drug events from EHR data and that CDS interventions in older populations improve medication safety and deprescribing outcomes [21]. Emerging LLM applications extend this capability. LLMs are advanced AI systems trained on large-scale text data to understand and generate human language. The term "large" refers to the size of the datasets that assist in learning patterns in language. The term "language" reflects the model's ability to understand, summarize, translate, and code text. The term "model" refers to the computational system that learns patterns in data to generate predictions or output. A 2025 scoping review mapped how generative AI and LLMs mitigate medication-related harm across the medication-use process [22] and a cohort study published in *JMIR Aging* demonstrates that an LLM-based pipeline can identify deprescribing opportunities for older adults, while also noting limits in complex clinical scenarios [23].

Modernization of medication reconciliation workflows highlights progress and remaining integration gaps that AI-driven CDS can address. These developments indicate that AI, including NLP, ML, and LLMs, may be potentially used to augment medication safety across the AFHS framework by surfacing risks, proposing safer alternatives and dose adjustments, and flagging candidates for deprescribing—particularly when embedded in workflows and paired with pharmacist and clinician review.

Mentation

AI also holds promise in the "mentation" domain, where timely identification and management of cognitive and mood disorders are critical. ML approaches trained on large datasets can aid early detection and differential diagnosis of cognitive impairment (eg, Alzheimer disease and mild cognitive impairment). NLP applied to clinical notes improves delirium ascertainment that is often undercoded in structured data [24]. In addition, prototype ambient and patient-facing systems such as the SeVA prototype system use artificial emotional intelligence with chatbot-based monitoring and 2 mobile apps to provide timely checks and health status recording; early deployments report feasibility for detecting delirium and supporting nursing workflows [25]. Similarly, a recent study demonstrated the feasibility of using ML to analyze Wi-Fi–based motion sensor data to predict depression among older adults [26]. Together, these AI methods can synthesize cognitive testing, narrative documentation, and real-time signals to inform personalized care plans and track changes over time.

Mobility

AI can strengthen the "mobility" domain by continuously detecting changes in gait and activity, assessing fall risk, and triggering timely interventions. Ambient and wearable sensing, ranging from step counters and actigraphy to contactless in-home systems, can monitor mobility patterns and surface deviations that matter clinically. In real-world living settings for older people, an AI video–based fall detection system reduced time on the ground and accelerated staff response after unwitnessed falls, demonstrating an actionable feedback loop to care teams [27].

In-home smart apartment platforms have similarly generated automated health alerts from passive sensors to notify clinicians of mobility and health changes, supporting earlier evaluation and intervention [28]. Contactless radio frequency sensing has enabled continuous home-based monitoring of gait speed and impairment (eg, in Parkinson disease), offering a path to track functional decline between visits [29].

Complementary evidence from reviews shows that ambient assisted-living and remote passive-sensing technologies can detect falls, changes in activities of daily living, and health status shifts, informing prevention and individualized mobility care plans [30].

The 4Ms as an Integrated Set

We propose implementing an integrated AI approach to the 4Ms. A prompted LLM extraction service will harvest 4Ms signals from structured and free-text EHR sources and patient messages ("what matters" domain preferences, high-risk medications, cognitive or behavioral changes, and falls or balance changes), building on evidence that LLMs can detect postoperative falls from clinical narratives [31]. A VA chat generative pretrained transformer chart reviewer will then compile the 4Ms into a provenance-linked 4Ms summary card, using structured data fields where permissible, and surface care gaps—such as missing goals-of-care documentation, high-risk prescribing, delirium language, or gait decline—as team-routable alerts. To ease documentation burden, ambient AI–assisted drafting and smart templates will prepopulate 4Ms documentation, supported by a previsit 4Ms gaps checklist and 2-click insertion into EHR notes. Success metrics could include

XSL•FO
RenderX

entity-level F_1-scores of at least 0.80 for key 4Ms concepts, note-level recall of at least 0.90 for any 4Ms signal, a 25% or greater reduction in documentation time, a 20% or greater increase in 4Ms completeness, improved usability scores, and demonstrable gains in goal-concordant care and time to action on fall risk and high-risk medications.

Barriers and Challenges to Integrating AI Into AFHS and EHRs

There are numerous challenges to integrating AI into health care for older adults. One consideration is the potential degradation of face-to-face human contact with clinicians and health care professionals resulting from the implementation of these technologies. This could lead to fewer routine caregiver interactions and increased social isolation [15]. Another challenge, as previous studies have demonstrated, is that wearable devices in long-term care environments can be uncomfortable and the sensors may disturb sleep [32]. Considerations such as these must be at the forefront of discussions regarding AI implementation in the care of older adults.

While AI has the potential to support health care professionals in the provision of high-quality health care services for older adults, numerous concerns have been raised in research studies, including bias in AI algorithms, which have the potential to precipitate existing disparities in access to health care resources, and concerns about patient privacy in the setting of possible cybersecurity threats [15].

Implementing AI within the VA to support the evidence-based AFHS 4Ms framework presents multiple challenges and barriers. One major challenge is integrating AI with existing EHRs. EHRs are often complex and fragmented across various platforms, necessitating sophisticated data harmonization strategies to enable AI-driven insights without compromising data integrity [33]. Furthermore, ethical considerations are paramount, as AI systems must ensure patient privacy and confidentiality, consistent with HIPAA (Health Insurance Portability and Accountability Act) regulations, while also being transparent in decision-making processes to gain stakeholders' trust [34]. The health system culture may pose another barrier, as clinicians may resist adopting AI tools due to perceived threats to clinical autonomy, potential disruptions to established workflows, and the learning curve associated with new technologies [35]. Addressing these issues requires a comprehensive strategy that aligns technological advancements with ethical standards and cultural readiness, involving stakeholders at all levels of the VA.

While the integration of AI into AFHS care within the VA presents exciting opportunities that may improve patient experience and allow older people to age in place and live in their homes longer, and decrease cognitive burden on clinicians and health care professionals, several challenges must be addressed. These include ensuring data privacy and security, data harmonization within the EHR, addressing potential biases in AI algorithms, and fostering user acceptance and trust in AI-powered systems. Overcoming these challenges requires interdisciplinary collaboration among health care professionals, data scientists, engineers, and policymakers supporting the AFHS to provide optimal personalized health care to older adults.

By applying a scientific lens to the intersection of AI and age-friendly care, this viewpoint paper has explored the transformative potential of AI in enhancing evidence-based implementation of the 4Ms framework. It highlights the opportunities and challenges in leveraging AI technologies to personalize care, improve medication management, enhance cognitive and mood assessments, and optimize mobility interventions for older adults across diverse health care settings. The findings of this study have implications for health care policymakers, administrators, and researchers seeking to maximize the benefits of AI in delivering high-quality, person-centered care for older adults.

Conclusion

This viewpoint paper addresses the urgent need to develop effective strategies for the use of AI to enhance evidence-based implementation of the AFHS framework within the VA as a model for AI integration in a large, integrated health care system. AI tools such as NLP, ML, and data analytics can be leveraged to support effective implementation of 4Ms-based care across the VA health care system. Integrating AI-driven decision support systems and predictive analytics can personalize care, reduce polypharmacy, improve cognitive and mood assessments, and identify mobility issues more effectively. This viewpoint highlights the transformative potential of AI in expanding care for older adults by creating easier and more effective ways to implement 4Ms care, potentially improving outcomes and experience for older adults across the VA. Embracing AI in AFHS holds promise for enhancing care quality, optimizing resources, and improving well-being. Further research and collaboration are needed to fully harness AI's potential in age-friendly care, leading to effective and person-centered health care solutions globally.

Abstract

Background: Postoperative delirium (POD) is a common and severe complication in older adult patients with hip fracture, yet its pathogenesis remains unclear.

Objective: This study aimed to develop a predictive model for POD following hemiarthroplasty in older adult patients by integrating high-throughput targeted metabolomics and machine learning.

Methods: In this prospective multicenter cohort study, 260 older adult patients undergoing hemiarthroplasty for hip fracture were enrolled. Preoperative serum samples were analyzed via high-throughput targeted metabolomics. Differential metabolites were screened using random forest (RF) and least absolute shrinkage and selection operator regression. Predictive models were constructed using gradient boosting, logistic regression, and RF, with performance evaluated using receiver operating characteristic curves and the area under these curves (area under the receiver operating characteristic curve [AUC]).

Results: Absolute quantification of 201 metabolites revealed 41 (20.4%) significantly differentially expressed metabolites. RF and least absolute shrinkage and selection operator regression identified 16 candidate biomarkers. The logistic regression model demonstrated optimal performance, achieving an AUC of 0.855 (95% CI 0.800 - 0.910) in the overall cohort. Upon 7:3 partitioning into training and test sets, the model maintained robust predictive accuracy, with AUCs of 0.844 and 0.856, respectively.

Conclusions: Integration of preoperative metabolomics and machine learning enabled accurate prediction of POD in older adult patients with hip fracture, facilitating personalized risk stratification and tailored clinical management.

KEYWORDS

high-throughput targeted metabolomics; machine learning; prediction and prevention; postoperative delirium; older adult surgical patients

Introduction

Postoperative delirium (POD) is a common and severe neuropsychiatric syndrome affecting 10% to 50% of older adult surgical patients, particularly within the first 48 hours postoperatively. Characterized by acute fluctuations in attention, cognitive impairment, and altered consciousness, POD significantly prolongs intensive care unit stays, increases hospitalization costs, and elevates mortality rates [1]. Long-term consequences include persistent cognitive decline and an

XSL•FO
RenderX

elevated risk of dementia [2,3]. The pathogenesis of POD remains elusive, with hypotheses spanning neuroinflammation, neurotransmitter imbalances, metabolic dysregulation, and sleep-wake cycle disruptions [4]. Notably, preoperative cognitive impairment, advanced age, and perioperative stressors such as surgery duration and blood transfusions have been identified as independent risk factors [5,6]. Given the global aging population and rising surgical demand, there is an urgent need for early diagnostic tools and preventive strategies to mitigate POD's clinical and economic burdens.

Current diagnostic approaches rely heavily on clinical observation, which lacks sensitivity and specificity, particularly in the early stages of POD [7]. While metabolic dysregulation has emerged as a key feature of POD, traditional biomarkers lack predictive power. Metabolomics—a systems biology approach analyzing small-molecule metabolites—offers unprecedented opportunities to elucidate underlying pathophysiological pathways [8]. For instance, our preliminary studies revealed significant disturbances in polyunsaturated fatty acids, energy metabolism, oxidative stress, and amino acid imbalances in postoperative patients [9,10]. Furthermore, systemic inflammation markers (eg, interleukin-6 and C-reactive protein) and β-amyloid peptides correlated with POD onset in vulnerable populations [11]. However, existing research has yet to integrate high-throughput targeted metabolomics with artificial intelligence to develop predictive models capable of identifying at-risk individuals preoperatively [12].

Surgery-induced systemic inflammation is a core driver of POD, wherein metabolites act as dual-effect mediators—either amplifying inflammation or providing neuroprotection. Proinflammatory lipid mediators derived from arachidonic acid, such as prostaglandin E2, can directly damage hippocampal synapses [13,14], whereas preoperative deficiencies in gut microbiota–derived short-chain fatty acids such as propionate impair the suppression of neuroinflammation via the nuclear factor kappa-light-chain-enhancer of activated B cell pathway [15]. Concurrently, imbalances in neurotransmitter systems significantly contribute to cognitive dysfunction. Inadequate availability of choline, a precursor for acetylcholine synthesis, combined with metabolic alterations in γ-aminobutyric acid precursors such as L-serine, exacerbates postoperative neuropsychiatric symptoms [13]. Furthermore, the age-related decline in cerebral metabolic reserve predisposes older adult patients to neuronal energy failure under surgical stress. Disruptions in the tricarboxylic acid (TCA) cycle lead to lactate accumulation, and deficiencies in branched-chain amino acids—key substrates for neuronal energy metabolism—compromise neurotrophic support, establishing a pathological cycle of "energy substrate exhaustion–metabolic waste accumulation" [16]. These mechanisms underscore the value of metabolites as "molecular sensors" in POD pathophysiology, providing a theoretical foundation for our targeted metabolomics approach focused on inflammation, neurotransmission, and energy metabolism.

Building on prior work characterizing metabolic disturbances in geriatric perioperative patients [17-19], this study represents a paradigm shift by integrating high-throughput targeted metabolomics with machine learning to develop a clinically actionable prediction model for POD in older adult patients undergoing hip hemiarthroplasty. Unlike conventional approaches that rely on single biomarkers or broad genomic frameworks [19,20], our targeted metabolomics platform enables high quantitative accuracy and reproducibility, thereby facilitating clinical translation [21-23]. By moving beyond traditional physiological parameters and leveraging machine learning to integrate multiple metabolite markers, we aim to overcome the limitations of single-biomarker strategies and conventional statistical models.

Therefore, the primary objective of this multicenter prospective cohort study was to identify preoperative serum metabolite signatures associated with POD by using high-throughput targeted metabolomics. Furthermore, we sought to develop and validate a machine learning–based predictive model that integrates these metabolite biomarkers to enable early risk stratification and individualized prevention of POD in older adult surgical patients. This integrative approach not only aims to advance the mechanistic understanding of POD but also holds potential for clinical implementation in perioperative care.

Methods

Study Design

This prospective observational multicenter cohort study was conducted from June 2021 to January 2024, with patient recruitment from June 2021 to December 2023 and follow-up completion in January 2024. In this study, 586 older adult patients (aged ≥60 years) scheduled for hemiarthroplasty due to hip fractures were initially enrolled. Inclusion criteria were age of 60 years or above and undergoing total hip replacement under uniform general anesthesia. Exclusion criteria were American Society of Anesthesiologists physical status classification of grade III or higher, Mini-Mental State Examination (MMSE) score below 23, history of central nervous system (CNS) disorders or psychiatric diseases, current use of sedatives or antidepressants, preoperative biochemical abnormalities indicating renal dysfunction or active hepatic disease, preexisting diabetes mellitus, history of neurosurgical or cardiac surgery, refusal to complete study protocols or inability to comprehend the study language, severe auditory or visual impairment, illiteracy, Parkinson disease, and alcohol or substance dependence. All baseline data (demographics and clinical characteristics), preoperative serum samples, and postoperative outcomes (POD incidence and cognitive function) were collected prospectively according to a predefined protocol without retrospective data retrieval.

Ethical Considerations

All experimental procedures in this study were approved by the Ethics Committee of the Sixth People's Hospital Affiliated to Shanghai Jiao Tong University School of Medicine (approval number 2021-YS-237). The study was conducted in accordance with the Declaration of Helsinki. Written informed consent was obtained from each participant or their legally authorized representative prior to enrollment. To protect participant privacy and confidentiality, all personal identifiers were removed, and data were anonymized prior to analysis. Access to study data was restricted to authorized research personnel only. No

XSL•FO
RenderX

financial compensation was provided to participants. All study procedures in this research have been registered at the Chinese Clinical Trial Registry [24] with the registration number ChiCTR-CPC-15006141.

Dietary Management

All patients in the experimental group received a light diet preoperatively. Semiliquid feeding was initiated 6 hours after general anesthesia, followed by a gradual transition to a light regular diet.

Anesthetic Protocol

Patients underwent standardized general anesthesia for hemiarthroplasty. Premedication included intramuscular midazolam (3 mg). Anesthesia induction was performed with intravenous fentanyl (0.1 mg), propofol (1.5 mg/kg), and vecuronium (0.1 mg/kg). Maintenance anesthesia was administered via a semiclosed circuit system using sevoflurane (1‐1.5 maximum allowable concentration) and oxygen (1 L/min). Continuous intraoperative monitoring included pulse oximetry, invasive arterial blood pressure waveform, end-tidal partial pressure of carbon dioxide, and 3-lead electrocardiography.

Surgical Procedure

Hemiarthroplasty involved replacement of the fractured femoral head with a metallic prosthesis and insertion of a metal stem into the femoral shaft to enhance implant stability.

Biospecimen Collection

Preoperative blood samples were collected on the day of the surgery prior to entering the operating room. Postoperative samples were obtained immediately upon transfer from the postanesthesia care unit. Serum was cryopreserved for subsequent high-throughput targeted metabolomics profiling.

POD Diagnosis

Among the 260 enrolled patients undergoing total hip replacement, POD was assessed twice daily (8 AM to 8 PM on postoperative days 1‐3) using the Confusion Assessment Method (CAM) [25,26] as recommended by the *Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition*. Diagnostic criteria were (1) acute onset with fluctuating symptoms, (2) inattention, (3) disorganized thinking, and (4) altered consciousness. POD was confirmed if criteria 1 and 2 were present along with either criterion 3 or 4. Patients were categorized into POD and non-POD groups.

The CAM (POD diagnosis) was conducted by research nurses certified in the CAM scale. Before study initiation, all involved nurses completed certified training for the Chinese version of the CAM scale (certificate numbers archived). The assessment results were reviewed, and the POD diagnosis was confirmed by the designated psychiatrists (see the Perioperative Cognitive Assessment section), thereby avoiding potential bias from nurses' subjective judgments.

Clinical Data Collection

Baseline demographic data, anesthesia- and surgery-related parameters, and other clinical variables were systematically documented. Clinical data collection was performed by research coordinators. Each center designated 1 coordinator (with a master's degree or higher in nursing or a related field) responsible for recording baseline characteristics (age, sex, and BMI) and surgical and anesthesia parameters (operation duration and anesthesia duration). Data entry was monitored weekly by a clinical research associate who spot-checked 20% of cases to ensure accuracy.

Observer Selection and Training for Clinical Assessments

CAM Assessors (Research Nurses)

All nurses completed standardized training on the Chinese CAM version led by psychiatrists and obtained certification through theoretical and practical examinations to ensure accurate identification of core delirium symptoms. Only certified nurses participated.

MMSE Assessors (Psychiatrists)

Each center designated 1 psychiatrist with 5 years or more of geriatric neuropsychological experience to conduct all MMSE evaluations, minimizing interassessor variability and ensuring consistent scoring practices.

High-Throughput Targeted Metabolomics Platform

Serum samples were analyzed using the Q300 metabolite assay kit (Metabo-Profile) [27]. Sample processing, including protein precipitation and derivatization, was automated on an Eppendorf epMotion workstation. Metabolite separation and detection were performed using ultrahigh-performance liquid chromatography (UPLC) coupled with tandem mass spectrometry (ACQUITY UPLC Xevo TQ-S system; Waters). The detailed sample preparation protocol and complete UPLC coupled with tandem mass spectrometry parameters are provided in Multimedia Appendix 1. Raw data processing, including peak integration and metabolite quantification, was conducted using the QuanMET software (version 2.0; Metabo-Profile). Quality control (QC) samples were analyzed intermittently to ensure analytical consistency.

Standardization Measures: Ensuring Data Consistency Through Training and Reliability Checks

To avoid multicenter data bias, the following standardization measures were implemented before and during the study.

Unified Training

Specific training sessions were conducted, covering (1) interpretation of the methods and inclusion and exclusion criteria (eg, American Society of Anesthesiologists grade determination standards and MMSE scoring details), (2) demonstration of scale administration procedures (eg, step-by-step demonstration of the Chinese MMSE and CAM), and (3) case exercises (all involved health care professionals [including research nurses and psychiatrists] practiced independent scoring, followed by group review of discrepancies to unify judgment standards).

Platform Standardization

Metabolomics analysis was performed by Metabo-Profile. All samples were preprocessed according to a unified workflow

XSL•FO
RenderX

(High-Throughput Targeted Metabolomics Platform section). One QC sample was inserted every 12 samples to ensure interbatch consistency of the assay results (coefficient of variation<30%).

Blinding Design: Assessors Were Double Blinded to Metabolomics Results to Avoid Diagnostic Bias

To prevent knowledge of metabolomics results from influencing cognitive assessments or POD diagnosis, this study used an assessor-analyst double-blinding design.

Assessor Blinding

The psychiatrists and research nurses responsible for MMSE and CAM assessments were only aware of the patients' clinical information (eg, age and surgery type) and were completely unaware of the patients' preoperative serum metabolomics results (eg, differential metabolite levels and whether they belonged to a potential high-risk POD group). Metabolomics testing was performed by an independent laboratory. The test results were provided only to the statistical analyst after all cognitive assessments were completed and POD diagnoses were finalized. Only then were the metabolomics data and clinical outcomes merged for model building and analysis.

Statistical Analyst Blinding

Before modeling, the statistical analyst received only anonymized metabolomics data (patient IDs replaced with random numbers) and anonymized clinical outcomes (1=POD; 0=non-POD). The analyst was unaware of the patients' specific clinical information to avoid subjective selection of feature variables.

Machine Learning Model Development

Hyperparameter Tuning

Model hyperparameters were optimized via 7-fold cross-validation with grid search. Least absolute shrinkage and selection operator (LASSO) regression (λ) was tuned using 10-fold cross-validation (log(λ): −10 to 2). Random forest (RF) used 500 trees with mtry tuned among {2,9,16}. Gradient boosting (Extreme Gradient Boosting) was optimized for tree number (50-150), depth (1-5), learning rate (0.01-0.1), and minimum node size (minimum number of observations in the trees' terminal nodes: 1-5). Logistic regression (LR) required no tuning.

Class Imbalance Handling

Overview

The POD-to–non-POD ratio was approximately 1:3.6. We used the area under the receiver operating characteristic (ROC) curve (AUC) as the primary metric due to its robustness to class imbalance. The test set achieved an AUC for the precision-recall (PR) curve of 0.966, confirming good minority-class identification.

Model Calibration

Calibration plots showed good agreement between predicted probabilities and observed outcomes for the final LR model.

Software

Analysis used R (version 4.3.2; R Foundation for Statistical Computing) with *caret* (version 6.0-94) for model training and tuning and *ggplot2* (version 3.5.0) for visualization.

Comprehensive Model Evaluation

The model's performance was comprehensively evaluated beyond discrimination. The overall model performance was quantified using the Brier score. Calibration was assessed visually using calibration plots and numerically by calculating the calibration in the large (intercept) and calibration slope. The clinical utility of the model was evaluated using decision curve analysis, which quantifies the net benefit across a range of probability thresholds. Given the class imbalance (POD prevalence of approximately 21.5%), PR curves and the average precision (AP) score were also analyzed alongside ROC curves to provide a more informative assessment of the model's performance in identifying the minority class (POD).

Statistical Analysis

Overview

Demographic and surgical data were analyzed using SPSS (version 26.0; IBM Corp). For continuous variables, normality was assessed via the Kolmogorov-Smirnov test; normally distributed data were analyzed via one-way ANOVA, and nonnormally distributed data were analyzed via the Kruskal-Wallis *H* test. For categorical variables, group differences were evaluated using the chi-square test (significance threshold: $P<.05$).

Metabolomics data underwent multivariate and univariate analyses on the iMAP platform (version 1.0; Metabo-Profile). For multivariate analysis, principal component analysis for dimensionality reduction and outlier detection was conducted, with partial least squares discriminant analysis and orthogonal partial least squares discriminant analysis to maximize intergroup discrimination (threshold: Variable Importance in Projection>1.0). For univariate analysis, differential metabolites were screened via 2-tailed *t* test and Mann-Whitney *U* test (threshold: $P<.05$).

RF and LASSO regression identified potential biomarkers [28]. The predictive performance of biomarkers was evaluated using gradient boosting, LR, and RF models, with ROC and PR curves generated to assess diagnostic accuracy.

A nested cross-validation approach was used to mitigate overfitting and robustly assess model generalizability. The cohort (N=260) was initially randomly split into a training set (70%; n=182) and a hold-out test set (30%; n=78). Model development and hyperparameter tuning were confined strictly to the training set using 7-fold cross-validation. In this inner loop, the training set was partitioned into 7 folds; the model was iteratively trained on 6 folds and validated on the remaining fold. The model with the best average performance across the 7 folds (LR) was retrained on the entire training set, and its final performance was evaluated on the independent test set. This strategy prevents information leakage and ensures an unbiased performance estimate.

XSL•FO
RenderX

The final analytical cohort comprised 260 patients, including 56 (21.5%) with POD. For the development of the machine learning model using the 16 selected metabolites, the event per variable (EPV) ratio was 56/16 = 3.5. While an EPV of 10 is often recommended for ideal stability in predictive modeling, an EPV greater than 3 is generally considered acceptable in exploratory biomarker discovery studies, particularly in fields such as metabolomics where prior data are limited [29]. Furthermore, the obtained AUC of 0.855 with a 95% CI of 0.800 to 0.910 indicates a reasonably precise estimate of the model's discriminative ability. This precision, evidenced by the CI width, supports the adequacy of the sample size for the primary objective of model development and initial internal validation within this cohort.

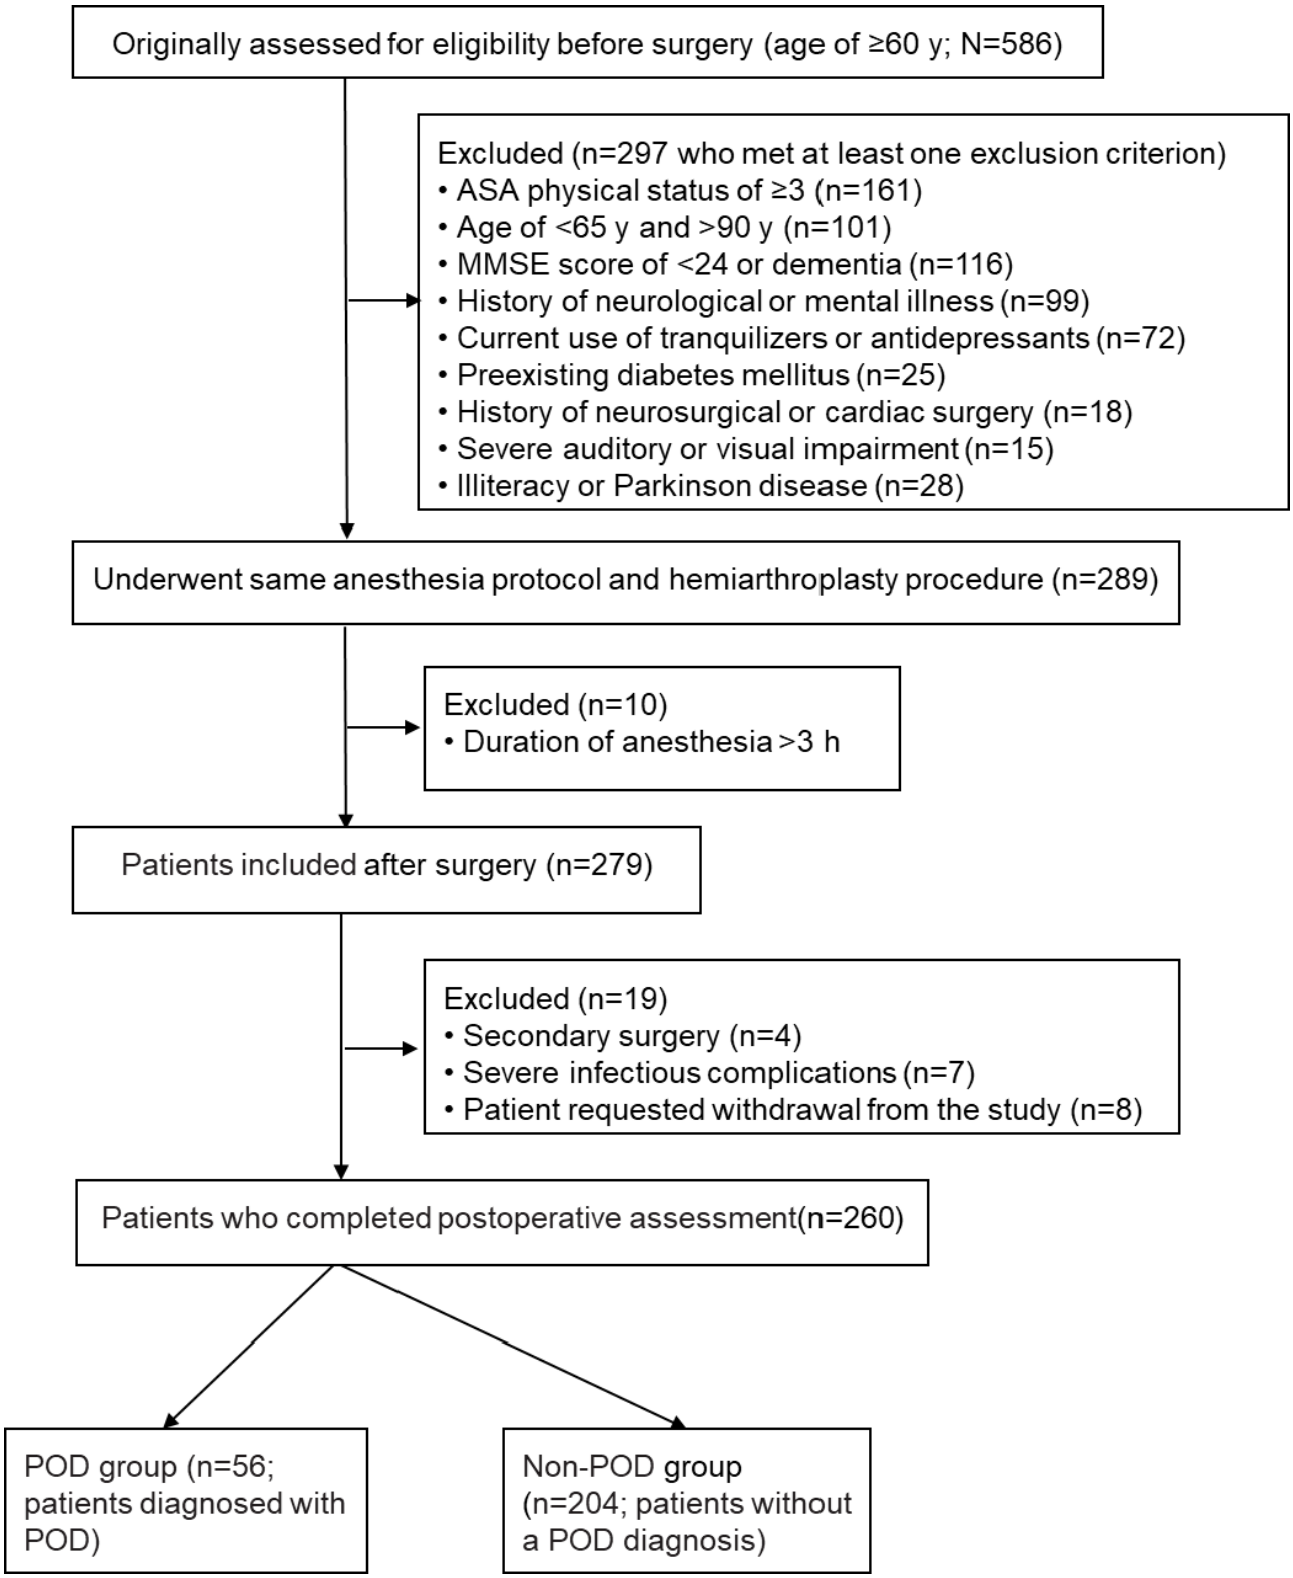
The 95% CIs for the AUC were calculated using the DeLong method [30], which accounts for the pairwise correlation between sensitivity and specificity across all possible thresholds.

Data Preprocessing and QC

Metabolites with more than 20% of missing values were excluded. In this study, all 201 targeted metabolites exhibited missing rates below 2%, and thus, no metabolites required exclusion. Given the minimal missingness, no imputation was performed to preserve data integrity. Batch effects were corrected using QC-based robust locally estimated scatterplot smoothing signal correction implemented in the QuanMET software. For class imbalance between the POD and non-POD groups (POD-to–non-POD ratio of approximately 1:3.6), class weight adjustment was applied to all machine learning models, with weights set inversely proportional to class frequencies.

Results

Summary Workflow Diagram to Illustrate the Complete Research Logic



A schematic overview summarizing the complete study workflow is provided in Figure S1 in Multimedia Appendix 1. This diagram visually integrates the key stages of the research, from participant recruitment and data collection to metabolomics profiling, machine learning model development, and the final predictive outcome for POD.

Comparison of General Characteristics Between the POD and Non-POD Groups

The study flowchart (Figure 1) illustrates the patient enrollment process in this multicenter observational cohort study. Ultimately, 260 patients met the inclusion criteria and completed the study protocol. Of these 260 patients, 56 (21.5%) were diagnosed with POD, constituting the POD group, whereas 204 (78.5%) without a POD diagnosis were categorized as the non-POD group. As shown in Table 1, no significant differences were observed between the 2 groups in demographic characteristics, surgical duration, or anesthesia time.

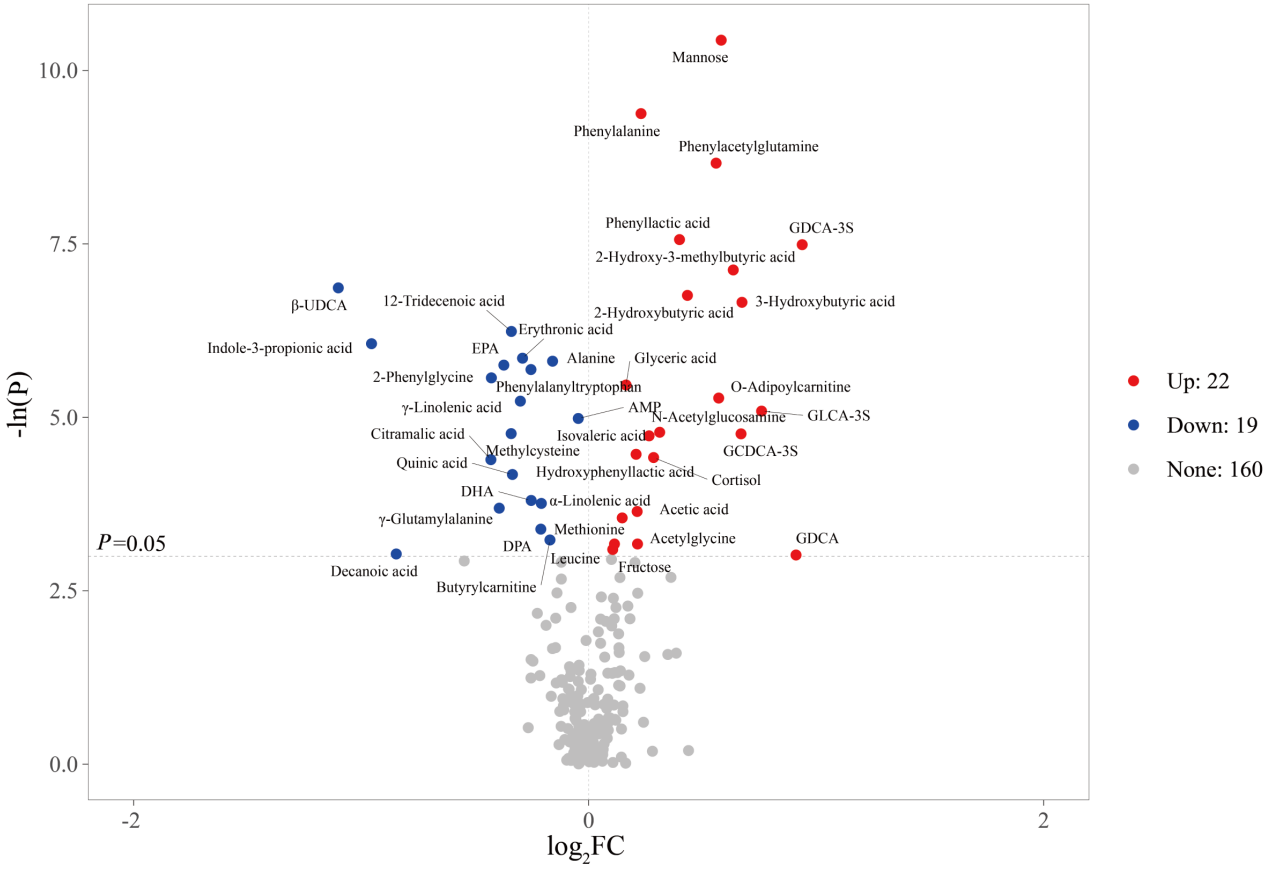
Ethical Reporting of Patient Flow and Handling of Attrition

The patient flow throughout the study is detailed in Figure 1. All cases of attrition were meticulously documented in the study case report forms, including the specific reason and time point of withdrawal. This documentation was reviewed and signed by the principal investigator at each site to ensure adherence to ethical standards.

Data from patients who dropped out were handled as follows:

- Patients excluded for medical reasons (n=11): data collected from these patients prior to their exclusion (eg, preoperative blood samples and baseline demographics) were not included in the final statistical analysis or model development. This conservative approach was taken to prevent the introduction of confounding factors related to their severe postoperative medical complications, which are distinct from the pathophysiology under investigation and could distort the association between metabolic profiles and POD.
- Patients lost to follow-up (n=8): as these patients withdrew consent for continued participation in the study protocol postoperatively, no further data were collected. Any preliminary data obtained prior to withdrawal were not used in the analysis, respecting patient autonomy and the ethical principle of voluntary participation.



This rigorous approach to reporting patient flow and handling missing data ensures the transparency, reproducibility, and ethical integrity of our research findings. The final analytical cohort (N=260) represents a complete-case dataset for the planned metabolomics and machine learning analyses.

Differences in Preoperative Serum Metabolites Identified Using a High-Throughput Targeted Metabolomics Platform Between the POD and Non-POD Groups

To compare metabolite profiles, we used UPLC coupled with triple quadrupole mass spectrometry for absolute quantification of 201 metabolites. As shown in Figure 2, absolute quantification of 201 metabolites revealed 41 (20.4%) significantly differentially expressed metabolites between the POD and non-POD groups (P<.05). These differential metabolites were primarily enriched within 4 core metabolic domains (amino acid metabolism, energy metabolism, lipid metabolism, and bile acid metabolism), suggesting that POD development is closely associated with disruptions in these key biological pathways.

XSL•FO
RenderX

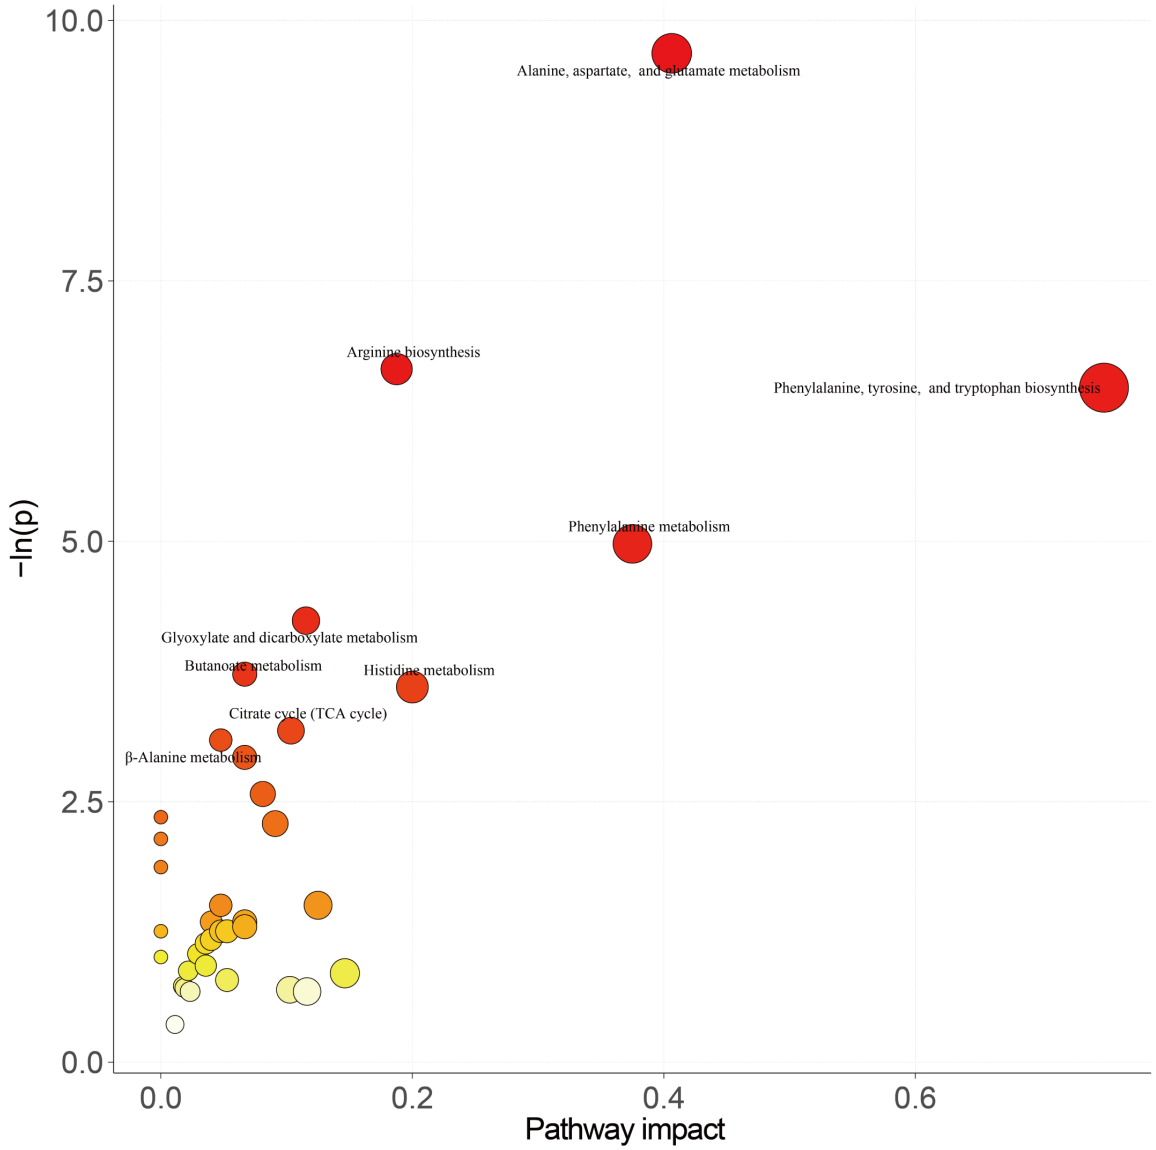


Figure 2. Volcano plot of differentially abundant preoperative serum metabolites between the postoperative delirium (POD) and non-POD groups (41 significant metabolites identified). β-UDCA: β-ursodeoxycholic acid; AMP: adenosine monophosphate; DHA: docosahexaenoic acid; DPA: docosapentaenoic acid; EPA: eicosapentaenoic acid; GCDCA-3S: glycochenodeoxycholic acid 3-sulfate; GDCA: glycodeoxycholic acid; GDCA-3S: glycodeoxycholic acid 3-sulfate; GLCA-3S: glycolithocholic acid 3-sulfate; log2FC: log 2 fold change.

Kyoto Encyclopedia of Genes and Genomes pathway enrichment analysis further confirmed that these differential metabolites were significantly enriched in key pathophysiological pathways, including alanine, aspartate, and glutamate metabolism (neurotransmitter synthesis); phenylalanine, tyrosine, and tryptophan biosynthesis (precursors for dopamine and serotonin); and the citrate cycle (TCA cycle and core energy metabolism; Figure 3).

Machine Learning–Powered Discovery of Specific Metabolic Biomarkers for Predictive Modeling of POD

By performing a union operation on the top 10 differentially abundant metabolites identified through RF model screening (Figure 4) and LASSO regression–based feature selection (Figure 5), we obtained 16 distinct metabolites (see Table S1 in Multimedia Appendix 1 for the complete list). These biomarkers span the aforementioned 4 core metabolic domains and collectively form the feature set for predictive modeling. Subsequently, predictive models were constructed using these 16 metabolites via gradient boosting, LR, and RF algorithms. Among these, the LR model demonstrated strong predictive performance, achieving an AUC of 0.855 (95% CI 0.800 - 0.910; Figure 6).

XSL•FO
RenderX

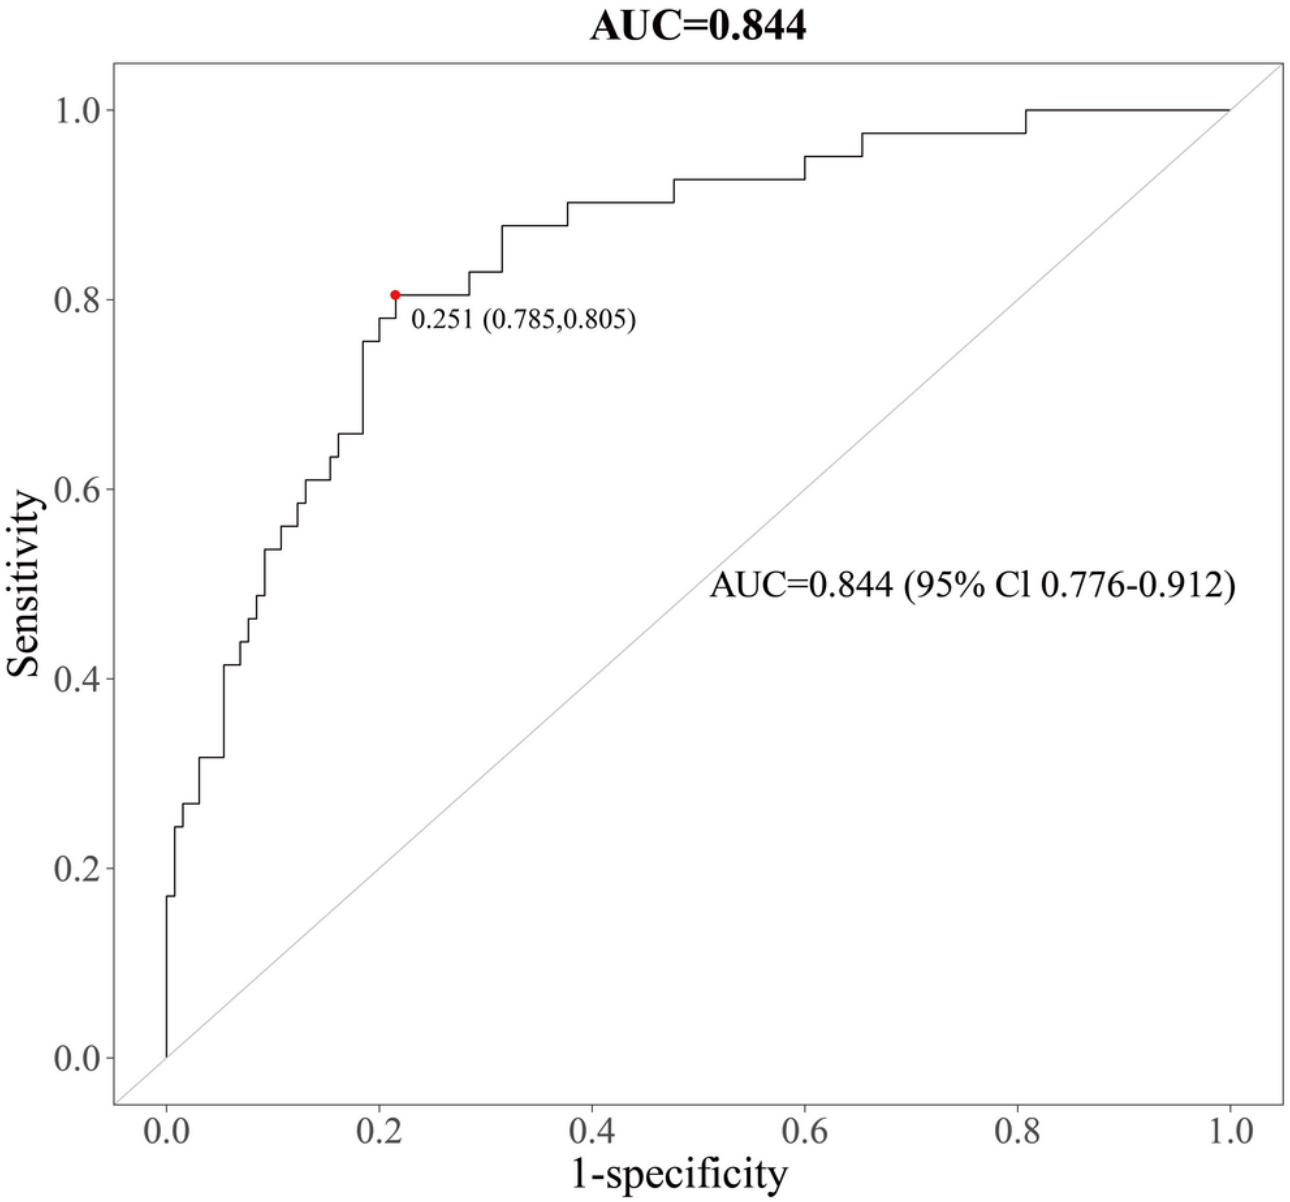
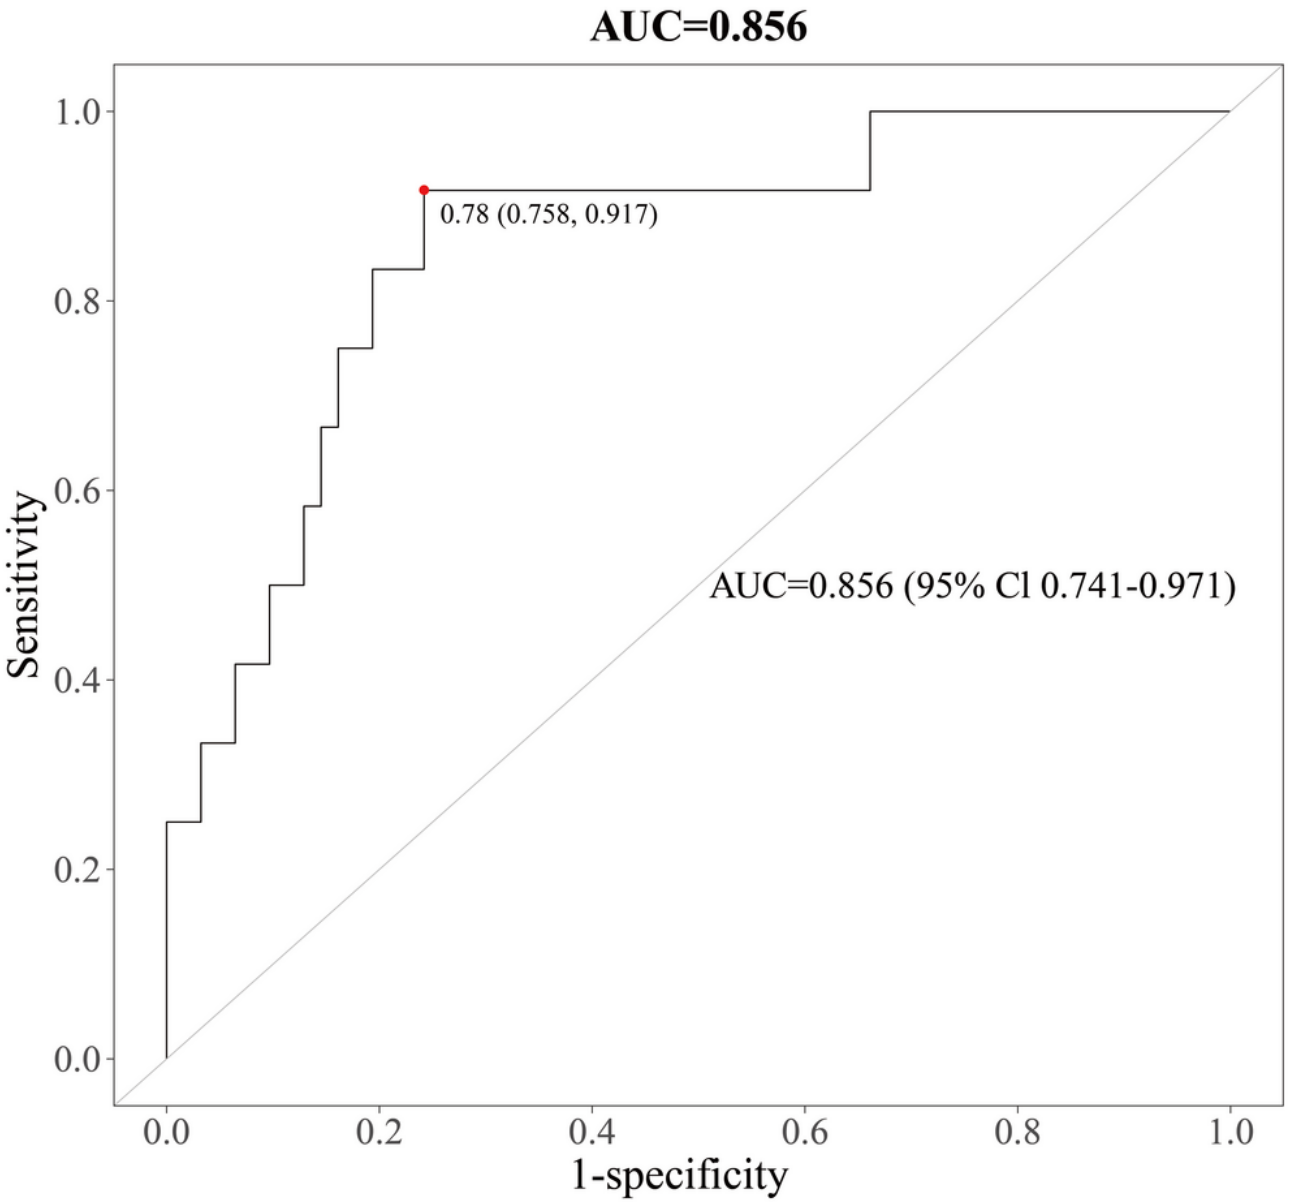
XSL•FO
RenderX

Figure 6. Receiver operating characteristic (ROC) curve of the logistic regression model for predicting postoperative delirium based on 16 core metabolites in the overall cohort (area under the ROC curve [AUC]=0.855, 95% CI 0.800 - 0.910).



Randomized Cohort Partition Into Training and Test Sets for Machine Learning Validation of the POD Prediction Model

Total samples were randomly partitioned into training and testing sets (7:3 ratio) via computerized randomization algorithms. Differential metabolites underwent rigorous LR modeling, demonstrating robust predictive performance with AUC values of 0.844 (95% CI 0.776–0.912) in the training cohort (Figure 7) and 0.856 (95% CI 0.741–0.971) in the independent test cohort (Figure 8), meeting TRIPOD (Transparent Reporting of a Multivariable Prediction Model for Individual Prognosis or Diagnosis) guidelines for clinical prediction models.



XSL•FO
RenderX

Figure 7. Receiver operating characteristic (ROC) curve of the logistic regression model based on 16 core metabolites in the training cohort (area under the ROC curve [AUC]=0.844, 95% CI 0.776 - 0.912).

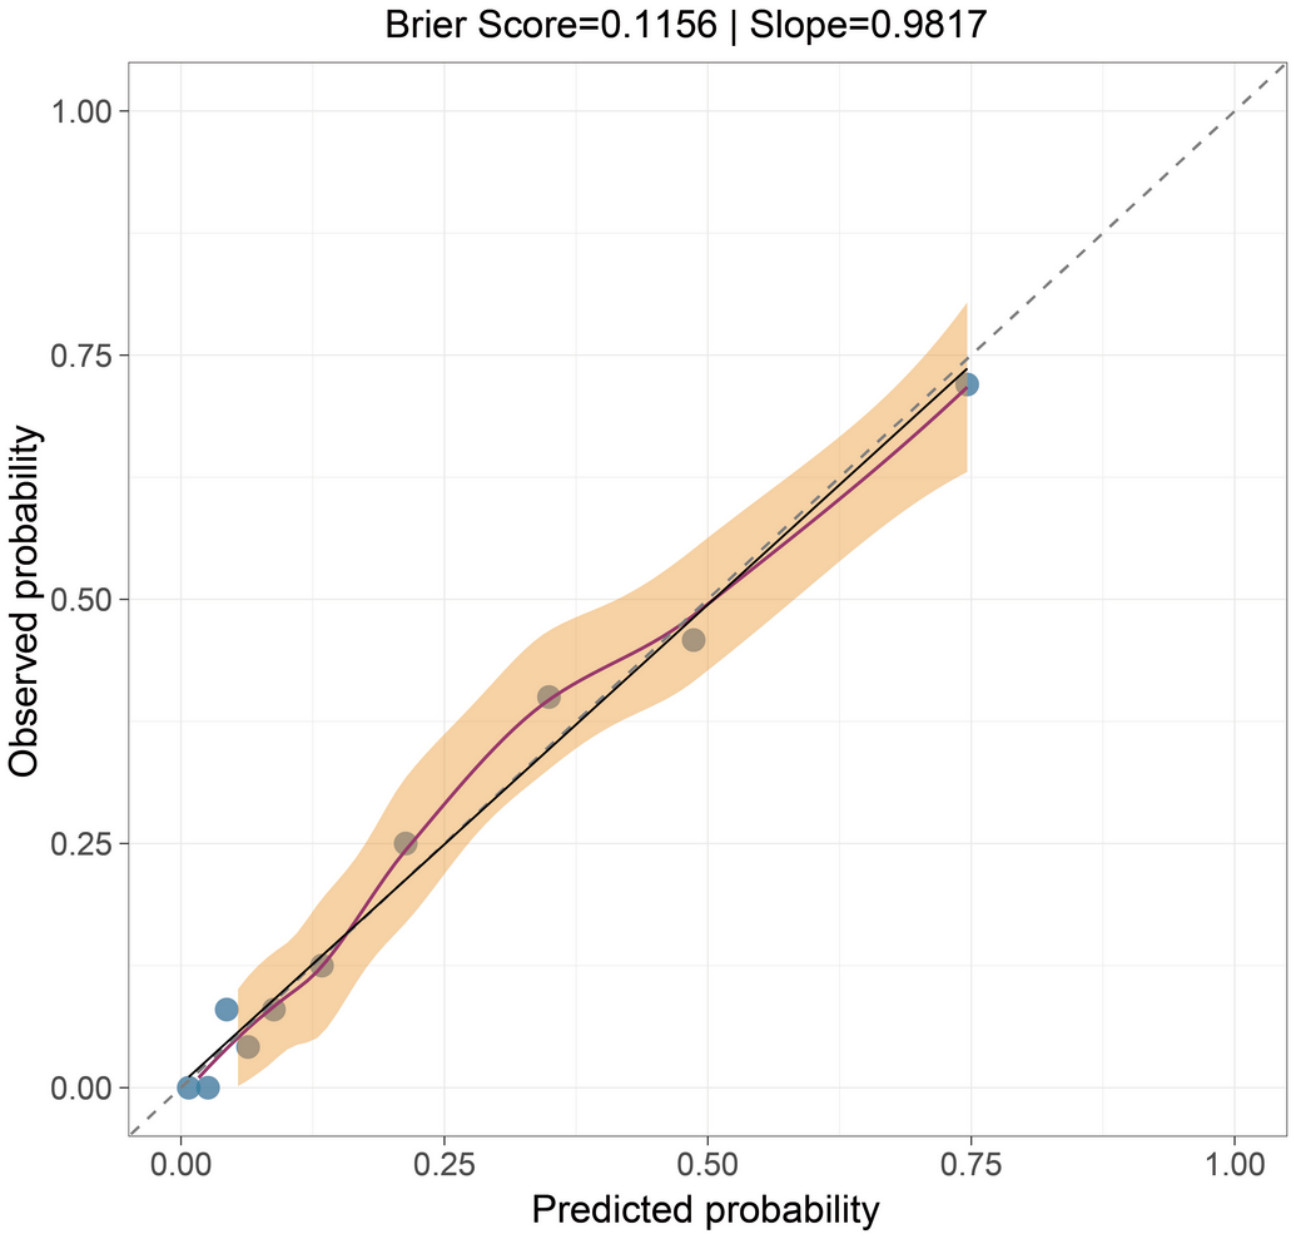
RenderX

Figure 8. Receiver operating characteristic (ROC) curve of the logistic regression model based on 16 core metabolites in the independent test cohort (area under the ROC curve [AUC]=0.856, 95% CI 0.741–0.971).



Comprehensive Evaluation of Model Performance: Discrimination, Calibration, and Clinical Utility

The final LR model was subjected to a comprehensive evaluation on the independent test set (n=78). The model demonstrated good overall accuracy, with a Brier score of 0.1156. The calibration plot (Figure 9) indicated excellent agreement between predicted probabilities and observed outcomes, with a calibration slope of 0.9817.

XSL•FO
RenderX

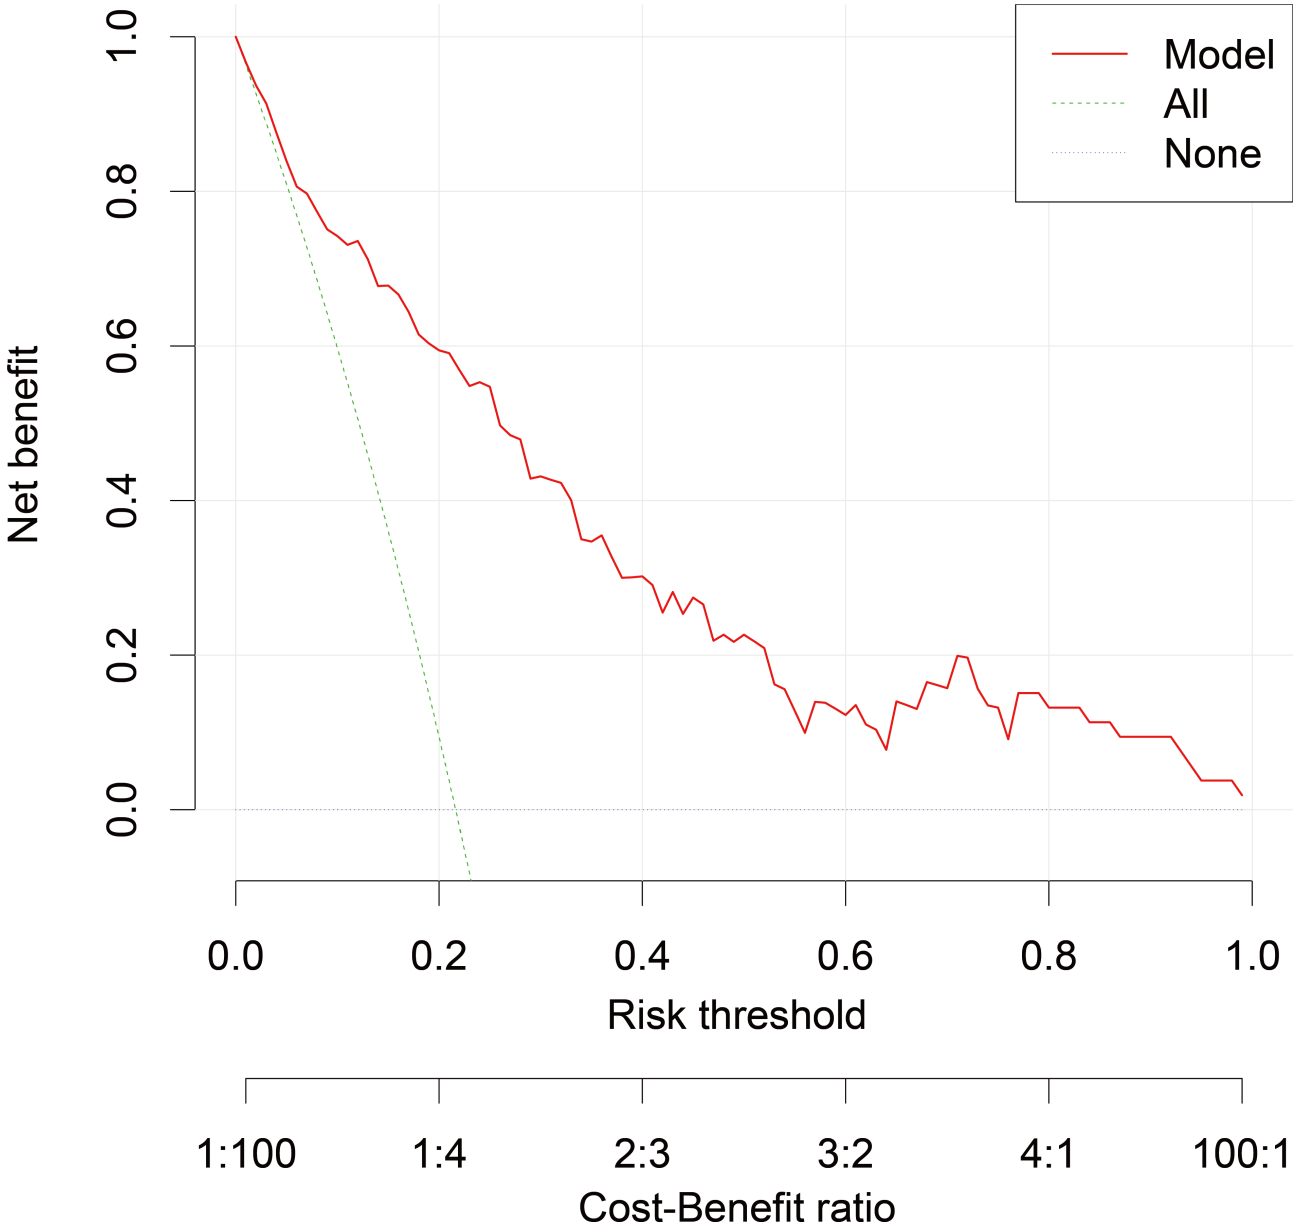


Figure 9. Calibration performance of the postoperative delirium prediction model, showing excellent fit (as indicated by the Brier score and calibration slope) between predictions and observations.

Decision curve analysis (Figure 10) revealed that using the metabolomics model for clinical decision-making provided a superior net benefit compared to strategies of intervening on all patients or intervening on no patients across a wide range of clinically reasonable probability thresholds (approximately 10% to 60%). This underscores the potential clinical utility of the model for targeting preventive interventions.

XSL•FO
RenderX

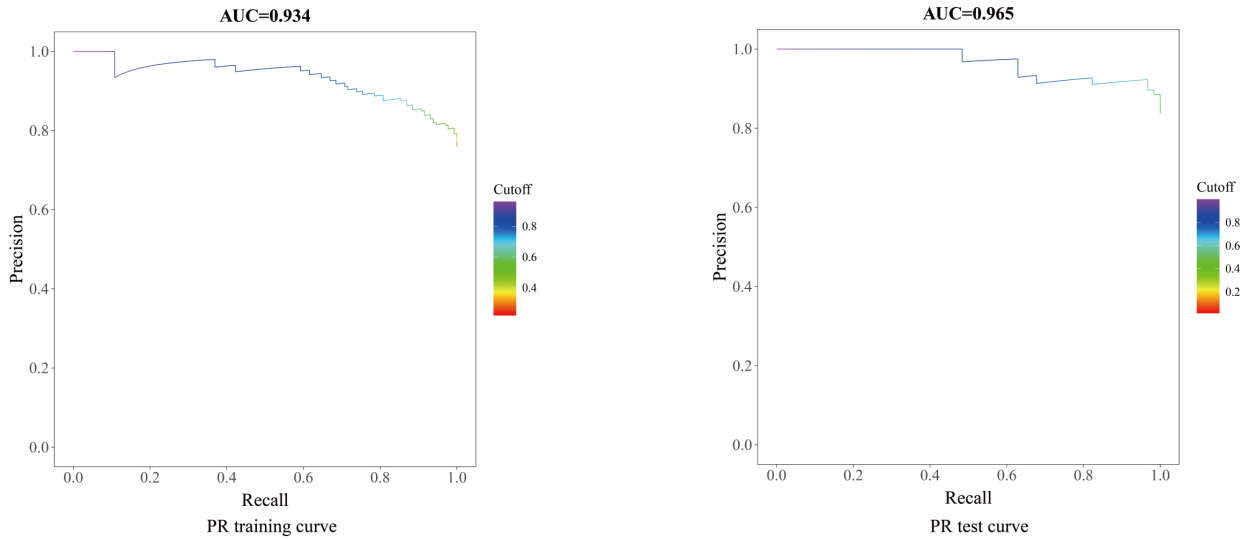

Figure 10. Decision curve analysis demonstrating the clinical utility of the metabolomics model, which provides a positive net benefit over a wide range of probability thresholds for postoperative delirium prediction.

In light of the class imbalance, PR curves were analyzed (Figure 11). The model achieved an AP of 0.965 on the test set (training set AP=0.934). This exceptionally high AP, in the context of a 21.5% (56/260) event rate, confirms the model's robust capability to identify patients with POD with high precision and recall. The PR curve is particularly informative for this imbalanced classification task as it focuses on the performance regarding the positive class (POD), unlike the ROC curve, which can be overly optimistic under class imbalance.

XSL•FO
RenderX

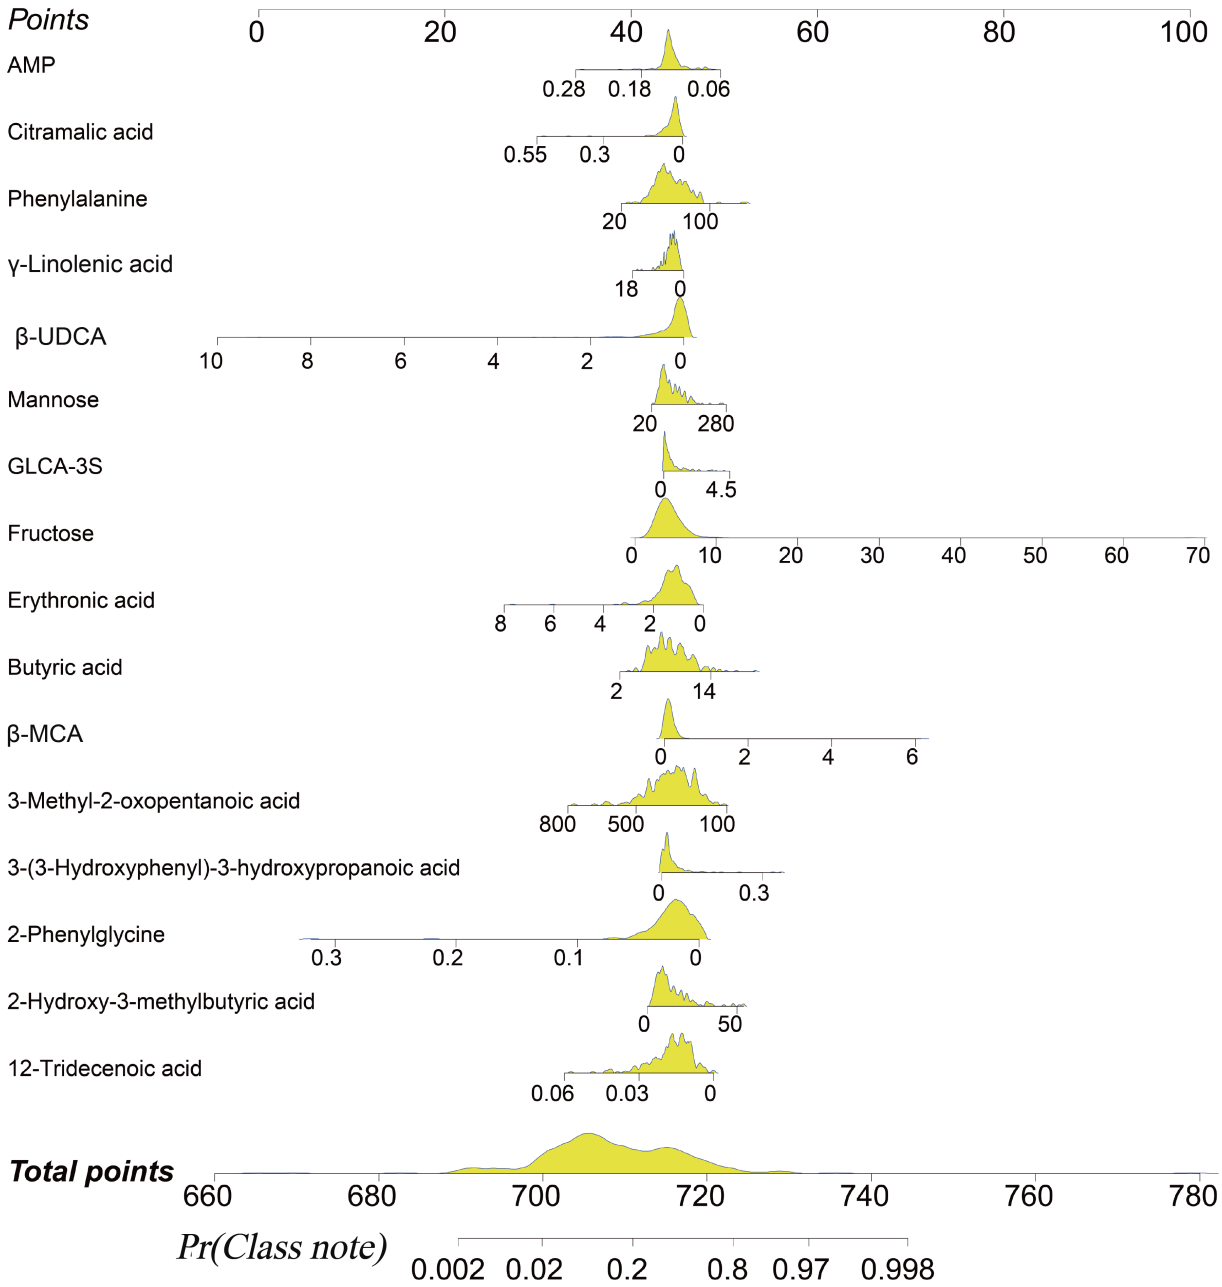

Figure 11. Precision-recall (PR) curves for the postoperative delirium prediction model. The high average precision scores on both the training and test sets confirm robust performance in identifying the minority class despite data imbalance. AUC: area under the receiver operating characteristic curve.

To facilitate clinical application, a nomogram was constructed based on the final LR model (Figure 12), allowing for the visual calculation of an individual patient's POD risk using the 16 preoperative metabolite levels.

XSL•FO
RenderX

Figure 12. Nomogram for individualized postoperative delirium (POD) risk prediction derived from the logistic regression model incorporating 16 preoperative metabolites. The total points from all metabolites correspond to an individual's predicted POD probability. β-MCA: β-muricholic acid; β-UDCA: β-ursodeoxycholic acid; AMP: adenosine monophosphate; GLCA-3S: glycolithocholic acid 3-sulfate.

Discussion

Principal Findings

POD, a severe neurological complication in older adult patients, is associated with neuroinflammation, oxidative stress, energy metabolism dysfunction, and cholinergic system imbalance [31]. Using a multicenter high-throughput targeted metabolomics approach combined with machine learning, we identified 16 differentially expressed metabolites as key biomarkers for constructing a POD prediction model.

Energy and Carbohydrate Metabolism

Altered levels of fructose and mannose indicate glucose metabolism dysregulation. Older adult patients often have insulin resistance, and postoperative stress exacerbates the imbalance between glycolysis and oxidative phosphorylation, leading to insufficient energy supply in the CNS [32]. Adenosine monophosphate, a key energy sensor, reflects mitochondrial dysfunction—overactivation of the adenosine monophosphate–activated protein kinase pathway under energy stress induces neuronal energy crisis linked to cognitive impairment in delirium [33].

Amino Acid Metabolism Dysregulation

Accumulation of phenylalanine, possibly due to reduced hepatic metabolism in older adults, disrupts the synthesis of catecholamine neurotransmitters (eg, dopamine and norepinephrine), exacerbating neuropsychiatric symptoms in

XSL•FO
RenderX

POD [34]. 2-Phenylglycine, a phenylalanine derivative, suggests dysregulation of aromatic amino acid metabolism associated with oxidative stress–induced neurotoxicity [35]. 3-Methyl-2-oxopentanoic acid, an intermediate of branched-chain amino acid metabolism, indicates dysfunction of the mitochondrial branched-chain ketoacid dehydrogenase complex, leading to CNS energy deficiency and neuroinflammatory cascades [35].

Lipid and Bile Acid Metabolism Disorders

Abnormal γ-linolenic acid levels, a polyunsaturated fatty acid, reflect membrane lipid homeostasis disruption, promoting proinflammatory mediator synthesis and neuroinflammation—a core mechanism of POD [36]. Butyric acid, a gut microbiota–derived short-chain fatty acid, regulates microglia anti-inflammatory function via the gut-brain axis; postoperative gut dysbiosis in older adult patients may reduce butyric acid, weakening its suppression of neuroinflammation [37]. β-Ursodeoxycholic acid and β-muricholic acid are associated with altered blood-brain barrier permeability; bile acids regulate neuroinflammation through the farnesoid X receptor and Takeda G protein–coupled receptor 5, and their imbalance activates astrocytes and impairs synaptic function [38]. Elevated glycolithocholic acid 3-sulfate suggests reduced hepatic detoxification, leading to toxic bile acid accumulation in the brain and neuronal injury [39].

Organic Acids and Oxidative Stress

Increased erythronic acid is linked to polyol pathway activation under oxidative stress, causing neuronal osmotic imbalance and reduced antioxidant capacity [40]. Citramalic acid, a TCA cycle intermediate, indicates mitochondrial citrate transporter dysfunction, leading to energy metabolism disorders and excessive reactive oxygen species production, intensifying neuronal oxidative damage [41]. 2-Hydroxy-3-methylbutyric acid, a leucine metabolite, is associated with enhanced catabolism under postoperative stress, indirectly reflecting the impact of systemic inflammatory load on the CNS [42]. Accumulation of 3-(3-hydroxyphenyl)-3-hydroxypropanoic acid, a phenylalanine metabolite, may result from abnormal phenylalanine hydroxylase activity, increasing neurotoxic metabolite production [43]. The role of 12-tridecenoic acid, a long-chain fatty acid, remains unclear but may involve membrane lipid regulation or inflammatory mediator synthesis, warranting further investigation [44].

Integration of Innovation Frameworks and Translational Implications

This study presents a distinctive research paradigm that integrates core principles from modern innovation frameworks. Our approach aligns with design thinking by centering on the clinical challenge of POD and iteratively developing an artificial intelligence–metabolomics model, with the resulting 16-metabolite panel representing a validated minimum viable product. This study follows the Lean Startup ethos through stringent RF- and LASSO-based feature selection to build a parsimonious yet powerful predictor (AUC>0.85), avoiding overengineering while enhancing clinical feasibility. Ultimately, this tool advances precision medicine by enabling individualized risk quantification based on objective metabolic profiles, facilitating a shift from reactive treatment to proactive prevention and demonstrating high translational potential in perioperative care.

This study also has limitations. Despite rigorous internal validation, the model requires validation in an external, geographically distinct cohort as our multicenter sample was drawn solely from Shanghai, potentially limiting generalizability. The model's scalability, while aided by its objective metabolic inputs, faces challenges including platform accessibility, ethnic variations in metabolic baselines requiring recalibration, and integration into diverse clinical workflows. Future work will focus on external validation across broader populations and surgical subtypes to advance clinical translation. Moreover, we agree that the clinical translation of our metabolomics-only model faces practical constraints regarding cost, turnaround time, and standardization. More fundamentally, as POD is multifactorial, a model relying solely on metabolites cannot incorporate key clinical risk factors such as frailty or comorbidity burden. To address these limitations, our primary future plan is to integrate this metabolomics panel with essential clinical variables to build a multimodal model. This integration is expected to enhance clinical practicality and robustness while maintaining high predictive performance. Furthermore, we have planned a prospective, external validation study to rigorously assess the model's generalizability.

Conclusions

This multicenter metabolomics study identified 16 differentially expressed metabolites involved in core pathological pathways of POD in older adult patients, including energy metabolism, amino acid homeostasis, bile acid regulation, and oxidative stress. These metabolites provide multidimensional biomarkers for early POD prediction and novel targets for interventions (eg, improving mitochondrial function and regulating gut microbiota). The machine learning–based prediction model has potential for integration into perioperative management to achieve precise POD prevention through dynamic metabolic profiling. However, to facilitate its clinical translation, future studies should focus on (1) integrating these metabolites with readily available key clinical variables to develop a more universally applicable and practical multimodal prediction tool; (2) rigorously validating the refined model in independent, multiregional external cohorts to assess its real-world performance; and (3) further elucidating the potential causal associations between these metabolites and the development of POD, and exploring their specific roles across different surgical subtypes.

Abstract

Background: Prostate-specific antigen (PSA) screening involves complex trade-offs between early detection and the risks of overdiagnosis. For older adults (aged ≥50 years), shared decision-making (SDM) is often hindered by limited health literacy, sensory or cognitive impairments, and multimorbidity, which complicate risk comprehension. Traditional decision aids provide foundational knowledge but are often nonpersonalized. Machine learning (ML) may offer individualized recommendations, yet the psychological and behavioral effects of ML-assisted SDM in geriatric populations remain poorly characterized.

Objective: This study aimed to develop and evaluate a web-based, ML-driven decision aid integrated into an SDM workflow to provide personalized PSA screening recommendations and to assess its effects on decisional conflict (primary outcome), state anxiety, and decision satisfaction among middle-aged and older men.

Methods: The study followed a 2-stage design. First, a model establishment group (n=507) was used to train and evaluate 6 ML algorithms based on clinical and values-clarification data. A random forest model was selected for its superior performance (mean area under the curve 0.933, SD 0.350; 95% CI 0.902-0.963). Second, a randomized controlled trial was conducted with 367 participants (mean age 64.34, SD 10.30 years) randomly assigned 1:1 to the ML suggestion group (MLSG; n=185) or the control group (CG; n=182). Both groups received video-based education, counseling, and values clarification; only the MLSG received an ML-generated "second opinion" recommendation. Primary and secondary outcomes were assessed using the Decisional Conflict Scale (DCS), Spielberger State-Trait Anxiety Inventory (STAI), and Satisfaction with Decision scale.

Results: In the randomized controlled trial (n=367), the MLSG reported significantly lower decisional conflict than the CG (total DCS score: mean difference [MD] –3.77, 95% CI –5.55 to −1.99; Cohen *d*=–0.44; P<.001). The MLSG reported greater perceived support (DCS7: adjusted *P*=.03), more adequate advice (DCS9: adjusted *P*<.001), and higher decision confidence (DCS10: adjusted *P*=.03; DCS11: adjusted *P*<.001). Regarding psychological well-being, although total anxiety scores did not differ, the MLSG reported reduced worry (STAI item 6: MD –0.98, 95% CI –1.20 to −0.76; *d*=–0.89; adjusted *P*<.001) and increased calmness (STAI item 1: MD 0.30, 95% CI 0.06-0.54; *d*=0.25; adjusted *P*=.01). Decision satisfaction was higher in the MLSG across all items (total Satisfaction with Decision score: MD –7.38, 95% CI –8.54 to −6.18; *P*<.001). Behavioral choices were strongly influenced by the ML recommendation: participants in the MLSG who received an "accept" recommendation were more likely to select "accept" (34/67, 50.7%) than those in the CG (44/182, 24.2%; *P*<.001). When the system suggested "not now," only 17.8% (21/118) chose "accept," which was lower than in the CG.

Conclusions: Integrating personalized ML recommendations into SDM workflows provides emotional scaffolding for older men, reducing decisional distress and enhancing confidence without undermining autonomy. By addressing geriatric-specific vulnerabilities through a facilitated digital interface, this ML-driven approach complements traditional clinical consultations. These findings support the scalable integration of artificial intelligence–assisted decision support to foster patient-centered care in aging populations.

KEYWORDS

prostate cancer; PSA screening; prostate-specific antigen; shared decision-making; decision aids; machine learning; personalized recommendations; decisional conflict; patient-centered care

Introduction

Over the past 2 decades, shared decision-making (SDM) has become a cornerstone of patient-centered care, enabling individuals to actively participate in health care choices [1,2]. In this process, clinicians and patients exchange information, deliberate on alternatives, and align decisions with patient values [3-5]. Guidelines generally outline 5 key steps in SDM: engaging the patient, presenting options, clarifying values, making the decision, and reviewing outcomes [6]. This structured approach has been shown to not only enhance patient satisfaction but also reduce decisional conflict [7-9].

Prostate cancer remains one of the most common malignancies among men globally. However, the decision to undergo prostate-specific antigen (PSA) screening involves complex trade-offs between the benefits of early detection and the risks of overdiagnosis or overtreatment [10-12]. Among older adults, SDM is indispensable because health literacy limitations, sensory or cognitive impairments, and multimorbidity can hinder risk comprehension and value clarification, thereby increasing reliance on physician-directed choices [13-16]. In time-pressured encounters, lower educational attainment further diminishes active patient participation, shifting decisions toward clinician preferences unless patient values are explicitly elicited and supported through tailored explanations [3,15-17].

Consequently, strategies to strengthen SDM for older adults should prioritize cultivating strong physician-patient relationships, explicitly addressing psychological determinants of choice, and implementing patient-tailored decision aids. Collectively, these approaches have been shown to improve knowledge without increasing anxiety and can sustain reductions in decisional conflict over time, helping patients critically appraise the benefits, risks, and uncertainties of PSA testing [18-20].

Efforts to support SDM in PSA screening have primarily relied on traditional decision aids (DAs), such as educational brochures, interactive questionnaires, and electronic platforms or videos [3,6,21]. Although machine learning (ML) approaches have gained traction in clinical practice, their application has largely focused on risk prediction rather than personalized decision support. Notably, fully personalized electronic decision interfaces remain underdeveloped [22-24]. Furthermore, few studies have explicitly evaluated the impact of ML-assisted recommendations on psychological outcomes—such as anxiety, uncertainty, and decisional conflict—which are critical indicators of acceptability and long-term efficacy.

To address these gaps, we developed a novel ML-based decision aid designed as a complementary component within existing SDM workflows for PSA screening consultations. Distinct from traditional aids, this tool integrates individualized risk profiles with structured preference elicitation to align recommendations with both patient values and clinical outcomes observed in comparable cohorts, thereby facilitating preference-concordant choices in geriatric care.

The primary objective of this study was to evaluate whether this ML-integrated strategy reduces decisional conflict (primary outcome) among middle-aged and older men compared to standard care. Secondary objectives included assessing its impact on decision self-efficacy, state anxiety, and decision regret, as well as its potential to improve informed choice and downstream quality-of-life outcomes. These findings will inform the scalable integration of ML-based recommendations into routine PSA screening workflows, with the ultimate goal of reducing overtreatment while empowering informed patient choice.

Methods

Establishment of a Preference-Sensitive DA

Drawing on the frameworks proposed by Eila et al [18], Rychetnik et al [25], and Ferrante et al [26], we developed the "importance for physiological and psychological impact" (IPPI) questionnaire to systematically evaluate participants' values and preferences regarding concerns related to PSA screening. The instrument consisted of 10 items across two dimensions: 4 assessing physiological impacts and 6 evaluating psychological impacts. The full questionnaire is available in Multimedia Appendix 1.

Validation of Questionnaires

This 10-item questionnaire underwent expert validity assessment by 10 urologists, each with more than 7 years of clinical experience. Reliability analysis, based on data from the first 300 patients, demonstrated strong internal consistency, with Cronbach α values of 0.838 for the physiological impact dimension and 0.900 for the psychological impact dimension.

Factor analysis of the IPPI was conducted using the maximum likelihood method, followed by Varimax rotation. Maximum likelihood estimation was selected for its superior parameter estimation and statistical testing capabilities [27]. Varimax rotation was used to maximize the variance of squared factor loadings, creating a simpler and more interpretable factor structure that approaches the Thurstone principle of simple structure [28,29]. This orthogonal rotation preserves factor independence, providing greater statistical stability and replicability compared to oblique methods [29]. The analysis extracted two factors: personal values concerning physiological impacts and personal values concerning psychological impacts.

XSL•FO
RenderX

In addition, the Chinese versions of the Decisional Conflict Scale (DCS) and the International Prostate Symptom Score (IPSS) were validated and used in this study (Multimedia Appendix 2). The short form of the Spielberger State-Trait Anxiety Inventory (STAI) and the Decision Satisfaction Questionnaire were translated into Chinese by 2 independent bilingual experts. Comprehensive details of all research instruments are provided in Multimedia Appendices 3 and 4.

Participants Recruitment

This study used a closed, face-to-face recruitment strategy at Taiwan St. Joseph Hospital. We recruited men who were eligible if they (1) were aged 50 years or above, (2) presented for routine care between October 2017 and April 2018, and (3) were able to provide informed consent and communicate in Mandarin Chinese. This age threshold aligns with US Preventive Services Task Force and American Urological Association guidelines recommending PSA screening discussions starting at age 50, with SDM particularly emphasized for men aged 55 - 69 years [30,31]. Men were excluded if they had (1) any documented psychiatric disorder that might impair decision-making capacity, (2) prior PSA testing (to ensure treatment-naïve status), or (3) a history of prostate surgery or prostate cancer. Participant identity and eligibility were verified against electronic medical records by research staff to prevent multiple entries. Notably, computer and internet literacy were not required; although the intervention used a web-based interface, all assessments and digital components were administered face-to-face by trained research staff. This supervised approach ensured accessibility for older adults regardless of technological proficiency and guaranteed that the study team had direct contact with all participants.

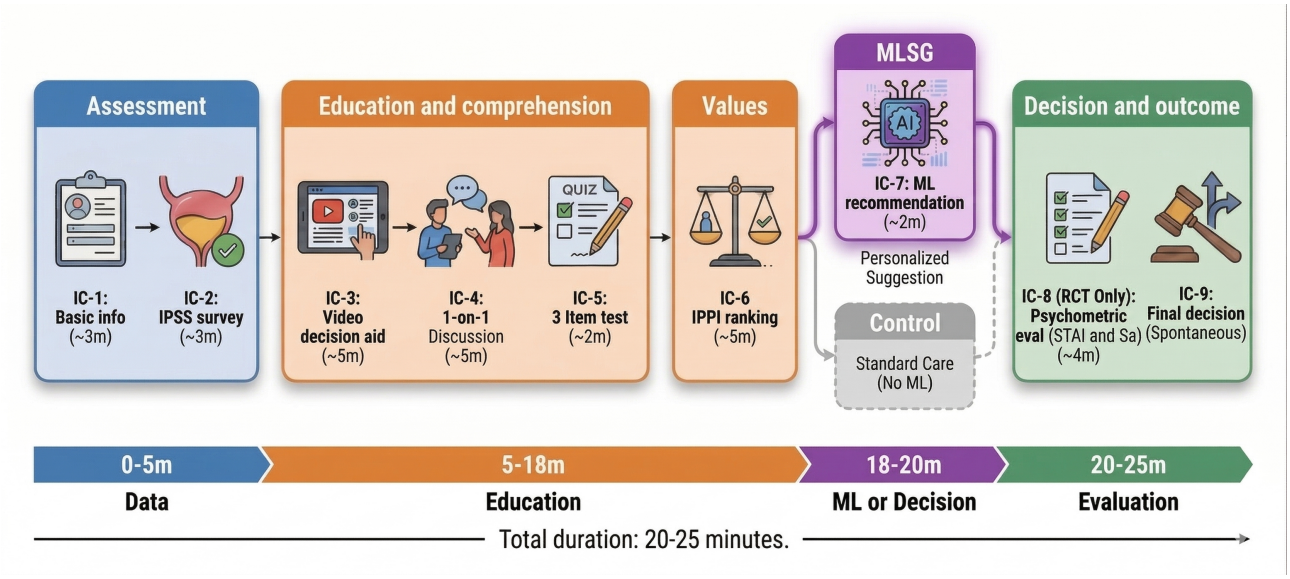
Study Group Design Framework

A total of 520 participants were initially recruited for model development. After excluding 13 individuals due to low-quality responses—defined as ten consecutive identical scores or rhythmic scoring patterns—the remaining 507 participants formed the model establishment group (MEG) for comprehensive training and validation. To ensure progressive optimization, the ML model was iteratively retrained after every batch of 20 new participants. This development phase continued until the model achieved a predefined performance criterion (area under the curve [AUC] ≥0.80), indicating sufficient predictive accuracy for potential clinical application.

Subsequently, we conducted a parallel-group randomized controlled trial to evaluate the impact of ML-based decision aid recommendations. An additional 380 participants were recruited and randomly assigned with a 1:1 allocation ratio to either the ML suggestion group (MLSG, n=190) or the control group (CG, n=190). The randomization sequence was computer-generated and integrated directly into the web-based study platform to ensure allocation concealment. Group assignment was revealed to the research staff only after each participant's baseline data had been fully entered and locked, thereby preventing any foreknowledge of the allocation sequence. The MLSG received standard SDM support supplemented by ML-assisted recommendations, while the CG received standard SDM alone. After excluding participants with low-quality responses, the final analysis included 185 participants in the MLSG (n=5 excluded) and 182 in the CG (n=8 excluded). Prior to study commencement, all participating medical staff completed a standardized 10-minute training session to ensure proficiency in navigating the DA. The study was conducted in accordance with the original protocol, and there were no changes to the methods (including eligibility criteria and outcomes) after trial commencement.

Ethical Considerations

This study was conducted in accordance with the Declaration of Helsinki and relevant ethical guidelines for research involving human subjects. The study protocol was reviewed and approved by the Institutional Review Board of Fu Jen Catholic University (approval C105142), and written informed consent was obtained from all participants before enrollment. The trial was registered in the Chinese Clinical Trial Registry (ChiCTR 2000034126). Only the patient medical record number was retained to protect privacy, and all study data were accessible exclusively to authorized research personnel; nonresearch staff were not permitted to access the dataset. To promote transparency and fairness, participants received a cash payment of NT $300 for their participation, which is equivalent to approximately US $9.38 based on an exchange rate of US $1=NT $31.97.



Intervention Specification

Intervention Flow and Core Components

The intervention comprised 9 standardized components delivered in approximately 20 - 25 minutes (Figure 1). Participants in the MEG completed components IC-1 to IC-6, whereas participants in the randomized controlled trial (RCT) completed the full sequence (IC-1 to IC-9). Initially, all participants provided baseline demographic and clinical data (IC-1; ~3 min), followed by a urinary symptom assessment using the IPSS (IC-2; ~2 min). The video-based decision aid (IC-3; ~5 min) then provided a structured introduction to PSA screening, sequentially covering (1) prostate physiology, (2) potential morbidity of prostate disease, and (3) benefits of early detection versus risks of overdiagnosis.

RenderX

Figure 1. Prostate-specific antigen screening decision support intervention procedure. IC: informed consent; IPPI: importance for physiological and psychological impact; IPSS: International Prostate Symptom Score; ML: machine learning; MLSG: machine learning suggestion group; RCT: randomized controlled trial; Sa: Satisfaction with Decision scale; STAI: Spielberger State-Trait Anxiety Inventory.

At IC-4 (~5 min), trained medical personnel conducted individual counseling to ensure comprehension. Using neutral, nondirective language and the teach-back method, staff confirmed understanding and corrected misconceptions without soliciting patient preferences. Participants were explicitly reminded that the final screening decision remained entirely their prerogative. Subsequently, at IC-5, participants completed a brief 3-item knowledge assessment (true/false/unsure) covering screening accuracy, disease progression, and biopsy limitations (items detailed in Multimedia Appendix 5). At IC-6 (~3 min), participants engaged in the IPPI values-clarification exercise, rating the personal importance of screening attributes and ranking them by priority.

Facilitated ML Recommendation (IC-7; MLSG Only)

Data collected during IC-1 (baseline demographics and clinical history), IC-2 (IPSS urinary symptom assessment), and IC-6 (IPPI values clarification) were completed within the same web-based interface and were used as inputs to the deployed ML model. After finishing IC-1-IC-6, in the RCT (n=367), participants randomized to the MLSG received a personalized, on-screen recommendation at IC-7 (~2 min) via this dedicated interface. Figure 2 presents representative screenshots of the user interface (original traditional Chinese version), including the integrated data-entry and values-clarification screens (Figure 2) and the recommendation output screen (Figure 3). To support international readability and replicability, full English translations of all interface text and items are provided in Multimedia Appendix 6. The interface displayed the recommendation with the exact wording: “Your most likely choice is: [Immediately accept screening]” or “[Reconsider or refuse to undergo screening].” Clinicians conveyed this result using standardized, age-appropriate language, explicitly emphasizing its nature as an advisory “second opinion” based on the choices of similar patients, intended to support rather than replace the patient’s autonomy.

Staff Training and Fidelity

To ensure digital equity and protocol adherence, the intervention was delivered in a facilitated setting. Prior to the study, all participating medical staff completed a comprehensive 10-minute training session focused on two key objectives: (1) technical proficiency in navigating the web-based decision aid to act as effective "digital navigators" and (2) adherence to a neutral facilitation protocol to avoid influencing participant decisions. Staff provided standardized, one-on-one technical assistance (eg, interface navigation and font enlargement) to any participant experiencing difficulty. This support was strictly operational, ensuring accessibility for older adults with varying technological proficiency while maintaining the neutrality of the SDM process. Periodic fidelity checks were conducted by the principal investigator to ensure standardized delivery.

Finally, all participants completed psychological measures (IC-8; ~4 min; STAI, SA, and DCS) and made their screening decision at IC-9 (self-paced).

Model Construction and Validation

Algorithm Selection and Optimization

To identify the optimal predictive model, we systematically benchmarked 5 baseline algorithms—logistic regression (LGR), random forest (RF), support vector machine, Extreme Gradient Boosting, and multilayer perceptron—alongside a deep neural network benchmark. All candidate models were evaluated using a rigorous 0.632 bootstrap protocol (n=507 iterations) to generate out-of-bag estimates of accuracy, sensitivity, specificity, and AUC. Technical specifications, including the hyperparameter optimization strategy (using design of experiments and ant lion optimizer), the full deep neural network architecture, and extended performance comparisons across all classifiers, are provided in Multimedia Appendix 7.

Model Deployment

Based on the comparative evaluation detailed in Multimedia Appendix 8, the RF model demonstrated the most robust performance, achieving the highest mean AUC of 0.933 (95% CI 0.902 - 0.963). Consequently, it was selected as the optimal algorithm for deployment. Using a standard probability threshold of 0.5 to generate binary recommendations ("accept" vs "not now"), the deployed model achieved a sensitivity of 0.69 and a specificity of 0.97. This high specificity was particularly valued to minimize false positive encouragement of screening, thereby reducing potential overdiagnosis. This finalized RF model was integrated into a secure web server (Shiny interface; Multimedia Appendix 6) to generate personalized recommendations for the intervention group.

Input Features and Outcome Definition

The deployed model used 17 input features derived from the MEG dataset (IC-1 to IC-6), including age, marital status, education, prior PSA knowledge, clinical history (eg, family history, prior biopsy), and IPPI-derived value priorities. Missing data were handled using complete case analysis, as the percentage of missing values was negligible (<1%) due to the forced-entry design of the digital interface. The prediction target was the participant's stated preference ("accept" vs "not now") recorded immediately after the values-clarification exercise but before viewing any ML recommendation, thus serving as an unbiased ground truth for supervised learning. Detailed definitions for all predictor variables are provided in Multimedia Appendix 9.

Statistical Analysis and Outcome Interpretation

Variable Scoring and Interpretation

To ensure consistent interpretation of group differences across psychological and decision-quality measures, scale directionality was defined as follows. For STAI, item direction varies: for negative affect items (STAI-2 tense, STAI-3 upset, STAI-6 worried), lower scores indicate lower anxiety; whereas for positive affect items (STAI-1 calm, STAI-4 relaxed, STAI-5 reassured), higher scores indicate greater calmness and reassurance. For the DCS, items were reverse scored (0 - 4; strongly agree=0, strongly disagree=4) such that higher scores indicate greater decisional conflict (worse decision quality). For Satisfaction with Decision (Sa), items were coded such that lower scores indicate greater satisfaction.

Statistical Methods

Continuous variables were compared using Student *t* tests, and categorical variables using χ^2 tests. To address multiplicity, we prioritized the total DCS score as the single primary end point; therefore, no adjustment was applied for this hypothesis. All other analyses, including subscales of the DCS, STAI, and Sa, were considered secondary and exploratory. For item-level comparisons within these scales, we controlled the false discovery rate using the Benjamini-Hochberg procedure to minimize type I errors. Adjusted *P* values are reported for these multiple comparisons.

Effect sizes were reported as Cohen *d* for continuous outcomes. Mean differences (MD) with 95% CIs were calculated. Statistical significance was defined as a 2-tailed $P<.05$. Analyses were performed using SPSS version 21.0 (IBM Corp) and R version 3.4.2 (R Core Team) (R package provided in Multimedia Appendix 10).

System Stability and Quality Control

The ML-based decision aid was deployed on a dedicated Shiny server. All intervention components (video content, questionnaires, IPPI interface, and the ML recommendation algorithm) were finalized and locked before randomization. No content modifications, algorithm updates, or bug fixes were implemented after the trial commenced. Study personnel remained consistent throughout the enrollment period, and no unexpected system failures affected data collection.

Results

Demographic Characteristics of the MEG Group

Baseline characteristics of the MEG cohort (n=507) are shown in Figure 4 and summarized in Table 1, with comprehensive results provided in Multimedia Appendix 11. Self-reported knowledge of PSA testing (KnowPSA score) was significantly higher in the accept group (mean 2.23, SD 0.81) than in the not now group (mean 2.07, SD 0.69; $P=.05$). Marital status

XSL•FO
RenderX

distribution also differed significantly between the 2 groups (P<.001), with a notably higher proportion of married individuals in the accept group. Regarding the IPSS, the accept group reported significantly higher scores for IPSS items 1‐5 (P values ≤.02) and item 7 (P<.001). Furthermore, a significant difference was observed in the IPSS Q3 (quality of life) score (P=.008), whereas no significant difference was found for IPSS item 6. For the IPPI questionnaire, the accept group scored significantly higher across all domains except for domain G (P=.34).

[a]MEG: model establishment group.

[b]KnowPSA: How would you rate your level of knowledge regarding prostate-specific antigen screening?

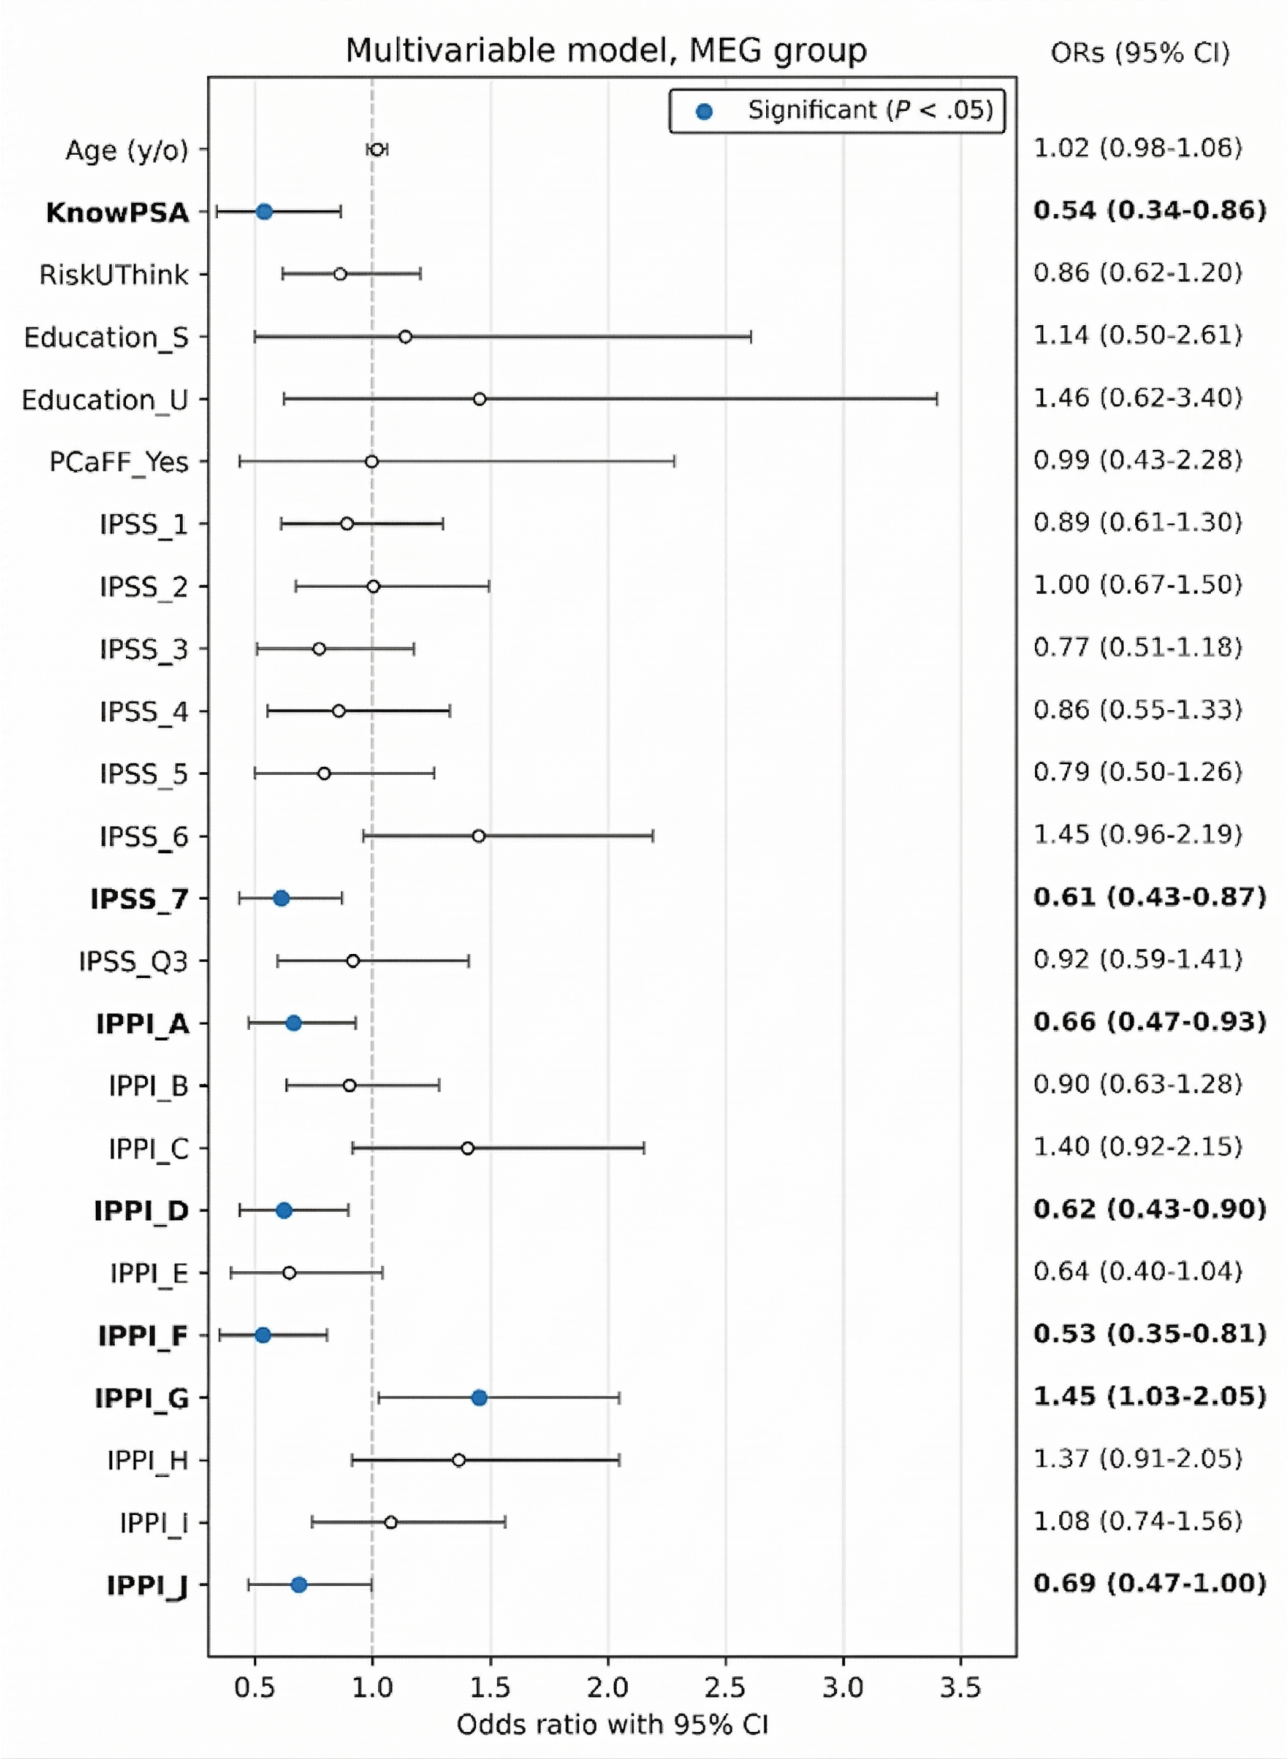
[c]PCaFF: prostate cancer among family or close friends.

[d]IPSS: International Prostate Symptom Score.

[e]Q3: quality of life.

[f]IPPI: importance for physiological and psychological impact.

[g]Decision factors derived from the Importance for IPPI questionnaire.



Regarding decision-making priorities, item A was most frequently identified as the primary factor in the accept group (n=32, 24.62%), which was significantly higher than in the not now group (14.85%; *P*=.01). In contrast, item B was more commonly prioritized as the first concern by the not now group (19.89%) compared to the accept group (7.69%; *P*=.001). Significant between-group differences were also noted for items D (*P*=.004) and E (*P*<.001). For the second most important factor, item E was significantly more endorsed by the accept group (20.77%) than the not now group (4.24%; *P*<.001), a trend also observed for item F (13.08% vs 3.18%; *P*<.001). Conversely, item H was less favored in the accept group (3.08%) compared to the not now group (11.41%; *P*=.004).

As for the third most important factor, item C was the leading choice overall (22.09%). However, item F was significantly emphasized in the accept group (14.62%) relative to the not now group (2.39%; *P*<.001). Additionally, significant between-group variations were observed for items E (*P*=.009) and J (*P*=.01). These findings highlight the differential influence of items A, B, C, E, F, and J on decision-making, suggesting nuanced variations in patient priorities as captured by the IPPI.

Figure 5 shows the multivariable LGR results for participants in the MEG group, presenting odds ratios (ORs) and 95% CIs for each covariate, with PSA screening uptake as the outcome. Statistically significant estimates (*P*<.05) are highlighted in blue, whereas nonsignificant estimates are shown as hollow markers. In this model, KnowPSA (OR 0.54, 95% CI 0.34 - 0.86; *P*=.01) and IPSS_7 (OR 0.61, 95% CI 0.43 - 0.87; *P*=.006) were statistically significant. Moreover, several IPPI subscales were also significantly associated with the outcome, including IPPI_A (OR 0.66, 95% CI 0.47 - 0.93; *P*=.02), IPPI_D (OR 0.62, 95% CI 0.43 - 0.90; *P*=.01), IPPI_F (OR 0.53, 95% CI 0.35 - 0.81; *P*=.003), IPPI_G (OR 0.53, 95% CI 0.35 - 0.81; *P*=.003), and IPPI_J (OR 0.69, 95% CI 0.47 - 1.00; *P*=.048). Together, these results suggest that both knowledge-related and psychological factors are associated with PSA screening decisions in this group. Among the significant predictors, KnowPSA, IPPI_A, IPPI_D, IPPI_F, and IPPI_G had the smallest ORs, and their 95% CIs were entirely below 1, supporting their independent associations with the outcome. Overall, these findings underscore the importance of addressing both informational and psychological dimensions when supporting patient decision-making in the context of ML-enhanced guidance.

Demographic Characteristics of the RCT Group

A total of 367 participants were included in the analysis, consisting of 185 in the MLSG group and 182 in the CG group (Table 2). Detailed results are provided in Multimedia Appendix 12. Regarding lower urinary tract symptoms measured by the IPSS, significant between-group differences were observed in specific domains. Specifically, scores for IPSS item 3 (0.93±1.28 vs 0.63±0.88; *P*=.008) and item 4 (0.93±1.33 vs 0.58±0.85; *P*=.003) were significantly higher in the MLSG group compared with the CG group.

Table . Baseline characteristics in the RCT[a] group.

Variables	RCT group			*P* value
	All (n=367)	MLSG[b] (n=185)	CG[c] (n=182)

[a]RCT: randomized controlled trial.

[b]MLSG: machine learning suggestion group.

[c]CG: control group.

[d]IPSS: International Prostate Symptom Score.

[e]Decision factors derived from the importance for physiological and psychological impact questionnaire.

When ranking primary decision-making concerns, item A was most frequently identified as the top priority overall (31.06%). Notably, a significantly larger proportion of the CG group selected item A as their first concern compared with the MLSG group (36.76% vs 25.27%; *P*=.01). Regarding subsequent priorities, item E was the most common second-ranked choice overall (19.89%), while item F was the most frequently selected third-ranked priority (22.89%).

Table 3 summarizes the impact of ML-based recommendations on participants' final decision-making outcomes. In the CG, 24.18% of participants selected "accept" as their final decision, while 75.82% chose "not now." In contrast, participants in the MLSG who received an "accept" recommendation were significantly more likely to select "accept" compared to those in the CG (50.75% vs 24.18%; *P*<.001).

Table . Effects of machine learning suggestions on final decision.

	Final decision		*P* value
	Accept	Not now	
MLSG[a] (decision aid suggestion)			<.001
Accept	34 (50.75)	33 (49.25)	
Not now	21 (17.80)	97 (82.20)	
CG[b]	44 (24.18)	138 (75.82)	—[c]

[a]MLSG: machine learning suggestion group.

[b]CG: control group.

[c]Not applicable.

XSL•FO
RenderX

Furthermore, when the ML system suggested "not now," only 17.8% of participants chose to "accept," which was lower than the baseline acceptance rate in the CG. These findings indicate that ML recommendations exerted a statistically significant influence on participants' decisions, substantially increasing the likelihood of selecting the recommended option.

Psychological Outcomes, Decision Satisfaction, and Decision Support Between MLSG and CG

For interpretability, lower scores on the DCS and Sa scale reflect better outcomes (ie, reduced conflict and enhanced satisfaction). Regarding the primary outcome, the total DCS score was significantly lower in the MLSG compared with the CG (MD –3.77, 95% CI –5.55 to −1.99; Cohen *d*=–0.44; *P*<.001), indicating superior overall decision quality. Item-level analysis revealed significant improvements in several key dimensions: participants in the MLSG reported greater perceived decision support (DCS7: adjusted *P*=.03), more adequate advice (DCS9: adjusted *P*<.001), higher decision confidence (DCS10: adjusted *P*=.03; DCS11: adjusted *P*<.001), and found the decision-making process significantly easier (DCS12: adjusted *P*<.001).

For decision satisfaction, the MLSG demonstrated a large and statistically significant improvement in the total Sa score (MD –7.38, 95% CI –8.54 to −6.18; *d*=–1.29; *P*<.001). Notably, the MLSG reported significantly higher satisfaction across all 5 items (adjusted *P* values <.001, Cohen $d \leq -1.10$). These gains were most pronounced in information adequacy (Sa1: MD −1.46, 95% CI –1.72 to −1.20), confidence that the decision was the best personal option (Sa2), alignment with personal values (Sa3), and a stronger intention to implement the chosen decision (Sa4).

Regarding anxiety, although the total STAI score did not differ significantly between groups (*P*=.37), item-level analysis identified significant improvements in specific psychological states. Participants in the MLSG reported feeling significantly less worried (STAI 6: MD –0.98, 95% CI –1.20 to −0.76; *d*=–0.89; adjusted *P*<.001) and significantly calmer (STAI 1: MD 0.30, 95% CI 0.06 to 0.54; *d*=0.25; adjusted *P*=.01) compared with the CG. Detailed item-level comparisons are presented in Table 4.

[a]STAI: Spielberger State-Trait Anxiety Inventory.

[b]Sa: Satisfaction with Decision.

[c]DCS: Decisional Conflict Scale.

[d]MLSG: machine learning suggestion group.

[e]CG: control group.

[f]RCT: randomized controlled trial.

[g]*P* values adjusted for multiplicity using the Benjamini-Hochberg false discovery rate method within each outcome (anxiety, decision satisfaction, decisional conflict). Italics values indicate statistical significance after adjustment (adjusted *P*<.05).

[h]MD: mean difference.

[i]Not applicable.

[j]Scale direction: For DCS and Sa, lower scores indicate better outcomes (ie, lower decisional conflict and higher decision satisfaction). For STAI, item direction varies: for STAI-6 (worry), lower scores indicate lower anxiety; whereas for STAI-1 (calm) and STAI-5 (reassured), higher scores indicate greater calmness and reassurance.

Discussion

Principal Findings

In this randomized controlled trial of 367 men aged 50 - 75 years, adding personalized ML recommendations to a structured SDM workflow was associated with significantly improved decision quality for PSA screening. Supported by a high-performing prediction model (AUC 0.93), the intervention group (MLSG) reported lower decisional conflict and reduced anxiety compared with standard care. Specifically, participants receiving ML-supported recommendations experienced greater calmness (STAI 1: adjusted *P*=.01) and less worry (STAI 6: adjusted *P*<.001). Beyond anxiety reduction, the intervention produced large, consistent improvements in decision satisfaction across all domains (Cohen *d* >1.10; adjusted *P* values <.001), including perceived adequacy of information and alignment with personal values.

Importantly, the intervention was designed to complement—rather than replace—clinician counseling. The ML output was presented as an advisory “second opinion” and reinforced by standardized clinician communication, ensuring that the final screening decision remained patient-directed. This approach is particularly relevant for older adults, who often face cognitive load and uncertainty when weighing the complex trade-offs of PSA screening [32].

Comparison With Prior Work

Although conventional prediction approaches (eg, LGR) can identify determinants associated with PSA screening intentions and uptake, they are generally not designed to deliver individualized, real-time recommendations at the point of decision-making [33]. Unlike prior decision-aid evaluations that focused primarily on presentation format or generic personalization, our intervention explicitly targeted decisional conflict and anxiety [34,35]—key barriers to informed choice in adults and aging populations [3,36]. Prior studies also suggest that education, age, symptom-related, and psychosocial factors influence screening behavior, and that incorporating constructs such as self-efficacy and emotional well-being may improve the use of decision support tools [37-39]. Watson et al [33] reported that men’s intention to undergo PSA testing was closely related to baseline knowledge, attitudes, and perceived risk, underscoring the central role of informational and psychological determinants.

Consistent with this literature, our multivariable LGR analysis in the MEG cohort confirmed that screening decisions were driven by a complex interplay of informational and preference-related factors. Specifically, higher PSA-related knowledge (KnowPSA) was independently associated with lower screening uptake (OR 0.54; *P*=.01). This inverse association suggests that participants with limited understanding may be more inclined to accept screening without fully weighing potential harms (eg, false positives, overdiagnosis), whereas greater awareness appears to foster a more cautious approach, reducing uninformed compliance.

In addition to knowledge, clinical symptoms and personal values were robust predictors of decision-making. Greater urinary symptom severity (IPSS item 7; OR 0.61; *P*=.006) was

XSL•FO
RenderX

associated with lower screening uptake, possibly reflecting a prioritization of symptom management over preventive screening in symptomatic individuals. Furthermore, several values-clarification subscales (IPPI items A, D, F, G, and J) significantly predicted screening behavior, indicating that participants who placed higher importance on specific physiological, psychological, or social impacts were more likely to decline or defer screening.

These results suggest that when patients are equipped with sufficient knowledge and an opportunity to clarify their values, they may become more discerning, potentially leading to informed decisions to decline screening based on their personal context. This aligns with the core tenet of SDM, which prioritizes value-concordant choices over passive adherence. The robust predictive power of these factors underscores the use of our ML model in capturing nuanced, individualized determinants, thereby moving beyond generic guidelines to support truly patient-centered care.

Clinical Implications

Recent evidence suggests that fewer than 25% of men aged 40 and older report discussing the benefits and harms of PSA testing with their providers, a gap even more pronounced among those with lower educational attainment [40]. The selection of the delivery mode for DAs is critical to addressing this disparity. Given that the target population for prostate cancer screening primarily consists of older adults, web-based DAs may present usability challenges due to age-related declines in fine motor control or limited digital literacy [41]. To mitigate these barriers, our intervention used a facilitated delivery approach. By providing personalized, accessible recommendations through a supported interface, our ML-driven decision aid ensures that screening decisions align with individual values rather than being driven by incomplete information or physician preference alone. Compared with conventional decision aids, ML recommendations significantly enhanced decisional confidence and yielded modest yet consistent increases in screening acceptance. This aligns with prior evidence that technology-supported tools can shape patient preferences and improve decision quality [24,42].

However, we emphasize that ML should be viewed as a decision-support tool, not a decision-maker. The modest increase in screening acceptance observed in the MLSG suggests that the tool facilitated decisive action, but ethical implementation requires ensuring that this influence does not coerce patients. Future integration into routine practice must prioritize transparency and physician training to maintain the delicate balance between algorithmic guidance and patient autonomy.

Taken together, these findings indicate that embedding personalized, ML-driven recommendations within SDM frameworks may not only improve decision quality but also enhance psychological outcomes. Before integrating ML-assisted tools into routine clinical practice, further research is warranted to evaluate their psychological and physiological safety. Such investigations are essential to determine not only the efficacy of ML recommendations in enhancing decision quality but also their broader implications for patient autonomy and well-being [43].

Limitations

Several limitations should be noted. First, while we provided uniform technical assistance, we did not formally assess baseline eHealth literacy or track the frequency of support required, limiting our ability to analyze effects based on digital proficiency. Future studies should incorporate validated measures like the eHealth Literacy Scale. Second, although our model demonstrated high discrimination (AUC >0.90), calibration metrics (eg, Brier score) were not assessed during the development phase; future work should include calibration plots to ensure risk estimates are accurate across subgroups. Third, unmeasured confounding remains a possibility, as factors such as physician influence or access barriers were not fully captured.

Finally, the current user interface provides binary recommendations (agree vs not now) without visualizing feature contributions. Integrating Explainable Artificial Intelligence techniques, such as Shapley Additive Explanations values, will be critical for future iterations to enhance transparency and trust.

Conclusion

This study demonstrates that integrating personalized ML recommendations into SDM frameworks can enhance decision quality while simultaneously reducing psychological burdens, such as anxiety and decisional conflict. Participants exposed to ML-supported recommendations reported greater confidence, reassurance, and satisfaction with their choices, underscoring the unique psychological value of individualized algorithmic guidance in prostate cancer screening.

Importantly, these findings suggest that ML-based decision support should be regarded as a complement to, rather than a replacement for, traditional decision aids and physician-patient discussions. By enriching the decision-making process with nuanced, personalized insights, ML has the potential to foster more supportive and less distressing decision environments.

Abstract

Background: As the demand for innovative older adult care grows alongside a shortage of care workers, personalization is key to optimizing services and enhancing long-term sustainability. This study proposes an adaptive reinforcement learning (RL)-based framework to promote precision digital care by dynamically assigning care programs based on individuals' unique characteristics and evolving needs. Its effectiveness was evaluated through simulation-based experiments comparing multiple allocation methods within an artificial intelligence (AI)-powered care call service for older adults.

Objective: This study aimed to develop and evaluate an RL-based model for personalizing digital care program allocation to optimize care engagement and health outcomes among low-income older adults living alone.

Methods: We developed the framework by using contextual bandits, specifically Thompson Sampling, to maximize user outcomes. Four program allocation strategies were tested using a synthetic dataset of user features and program attributes. Simulations were conducted over multiple iterations to evaluate how the model adapts over time and optimizes program assignments compared with static methods.

Results: Four program allocation methods were compared across 100 simulation runs (n=3000 assignments per run) using 2 datasets (AI Call: n=1196; Community Health Survey [CHS]: n=72,812): (1) systematic allocation (baseline), (2) single best program based on population average, (3) idealized personalized delivery (theoretical upper bound), and (4) precision digital care using Thompson Sampling. Precision digital care outperformed baseline and population-average approaches, achieving outcomes comparable to the theoretical upper bound. Compared to systematic allocation, call success rates increased by 84.2% (AI Call) and 54.4% (CHS), Patient Health Questionnaire-2 depression scores decreased by 32.1% (AI Call) and 41.4% (CHS), and self-reported health scores improved by 19% (AI Call) and 22% (CHS). It also showed improved learning efficiency, refining assignments dynamically as it learned from user responses.

Conclusions: Our findings emphasize the importance of personalization in digital care. We plan to refine and validate the model through a publicly funded AI care program for community-dwelling, low-income older adults living alone in the Republic of Korea. RL offers a scalable and effective approach to advance precision digital care delivery and support future innovations in aging services.

Introduction

The rapid aging of populations and increasing life expectancy demand integrated care and health services to support individuals throughout extended later life. Preventive care, aimed at promoting independent living and delaying institutionalization, has emerged as a key strategy in aging policies across developed countries [1]. Citizens increasingly expect robust social protection from their governments. Meanwhile, health and care workers are grappling with severe burnout and workforce shortages [2,3]. Despite numerous social policy reforms, traditional approaches to addressing the growing "care crisis" are proving inadequate. The failures of both policy and market-based strategies to protect vulnerable older adults during the COVID-19 pandemic underscore the urgent need for transformative changes to achieve global healthy aging [4].

Technological innovation is widely recognized as a powerful solution to the social risks posed by demographic shifts [5,6]. The COVID-19 pandemic catalyzed expansions in R&D and market investments, accelerating the transition from lab-based innovation to real-world applications, such as the widespread adoption of telemedicine [7]. In the postpandemic era, breakthroughs like GPT and large language models have ushered in a new age of digital health and care, opening unprecedented opportunities.

Within this digital health landscape, precision medicine has garnered significant attention [8]. The integration of big data from electronic medical records has propelled advancements in precision medicine, driving the development of personalized medical diagnostics and treatments [9,10]. These innovations hold immense promise, from curing previously untreatable diseases to rapidly discovering new drugs and materials. Consequently, many countries are actively investing in R&D and fostering global cooperation through public-private partnerships.

In contrast, the personalization of care services for older adults has received comparatively limited attention, despite significant progress in digital care for older adults. While precision medicine has primarily focused on genomics, biomarkers, and individualized treatment plans in clinical settings, precision care addresses broader contextual factors, including behavioral data, social determinants, and real-world service use. Precision medicine leverages structured biological data to optimize therapeutic decisions, often within highly controlled environments such as hospitals or labs. In contrast, precision care operates in complex, community-based settings and must contend with heterogeneous data types, evolving patient preferences, and ethical imperatives related to autonomy and accessibility.

We think precision care represents a paradigm shift that expands the individualization principle beyond disease treatment to service delivery and engagement support, especially in aging and chronic care domains. Therefore, the transition from precision medicine to precision care in this study reflects a shift in context, data sources, ethical priorities, and delivery models, rather than a simple semantic change. Several challenges impede this shift, including insufficient large-scale, high-quality care data, lack of data standardization, decentralized data governance, and fragmented health and care systems [11,12]. However, promising initiatives, such as the EU-funded iCare4Old project, demonstrate how these barriers can be overcome [13]. Such projects exemplify the potential of cross-national, standardized, comprehensive geriatric assessment databases linked to mortality and health care use data to support decision-making for older adults with complex chronic conditions.

Digital care is also a high policy priority in Korea, an East Asian country that is expected to face the most severe shortage of care workers among Organization for Economic Co-operation and Development countries by 2040 [2]. Various government-funded digital health and care programs have been developed and implemented to help delay cognitive decline and alleviate loneliness, with their delivery managed through diverse local government units. For example, the central agency for social services in Korea provides artificial intelligence (AI)-based care calls for older adults living alone for checking in and providing information [14]. Although still in the early stages of implementation both technologically and in terms of service design, many social welfare institutions have adopted the AI care call service to alleviate the overtime workload of direct care workers and to prevent unattended deaths among the older adults, an emerging social problem in Korea. The local government, in collaboration with interest groups from universities or industries, implements the Care Call program developed by these groups. While many programs are created through partnerships with local governments, users do not have a choice of programs; instead, the program they receive is determined by their location. As these programs expand to larger populations, they must be evaluated and delivered efficiently.

While AI-driven digital care is expanding, current approaches rely on rule-based or non-adaptive personalization, which may fail to optimize interventions dynamically at the individual level. In health care and digital interventions, the term personalization often refers to the adaptation of care strategies based on characteristics shared within predefined subgroups, such as age, gender, or geographic location. Individuals within these homogeneous groups receive the same intervention, under the assumption that group-level traits sufficiently capture variation in needs or responses. However, this approach can overlook meaningful individual differences. In contrast, hyper-personalization refers to a finer-grained strategy in which care is tailored at the individual level based on contextual signals such as prior responses, behavioral patterns, or dynamically changing health indicators. Rather than assigning treatments to groups, hyper-personalized care selects the best intervention for each instance, enabling adaptive learning and improved outcomes. Our work embraces this hyper-personalization framework by using contextual bandits to deliver care content that evolves with each person's unique context and feedback history.

Beyond technical optimization, hyper-personalization addresses a fundamental challenge in digital care for older persons: one-size-fits-all approaches often lead to disengagement, frustration, and abandonment among older adults [15]. Older people vary widely in cognitive capacity, health literacy, communication preferences, and daily routines [16]. Receiving

XSL•FO
RenderX

care content misaligned with these individual contexts can feel impersonal, patronizing, or irrelevant, undermining both engagement and dignity. For example, an older adult with mild cognitive impairment may benefit most from brief, frequent check-in calls, while someone experiencing loneliness may prefer longer, conversational interactions. By tailoring content to individual context and response patterns, precision digital care respects individual autonomy and maintains dignity through person-centered service delivery.

We model the care call assignment as a repeated decision-making problem, where the system observes individual-level context, selects a care message (action), receives feedback, and uses it to improve future decisions. This setting goes beyond supervised learning, which does not handle the need for sequential adaptation or balance between exploration and exploitation. While Q-learning and other reinforcement learning (RL) methods can technically be applied, they are designed for environments where actions influence future states—an unnecessary assumption in our context, where each care interaction is a standalone event with immediate feedback and does not affect the next person's reward. Contextual bandits with Thompson Sampling offer a natural, data-efficient, and interpretable approach for personalizing care at scale, without introducing unnecessary complexity.

This study proposes precision digital care as an RL-based framework using contextual bandits, specifically designed to personalize care services dynamically. This approach assigns care programs to individuals based on their unique characteristics and evolving care outcomes, continuously optimizing decisions over time. At its core, the framework leverages contextual bandits, a type of RL algorithm, specifically Thompson Sampling [17], to balance exploration and exploitation in digital health interventions. This computational approach enables the model to learn from user interactions, adapt in real time, and continuously refine program assignment decisions to maximize individual outcomes. Unlike traditional rule-based or static personalization methods, the proposed precision digital care approach dynamically optimizes care allocation, ensuring interventions remain responsive and effective.

By integrating Thompson Sampling, the proposed approach provides a scalable, data-driven solution for enhancing personalization, efficiency, and equity in digital health services, particularly in aging care. To evaluate its effectiveness, this study uses simulation-based experiments comparing multiple program allocation methods and analyzing their impact on key health and service-related outcomes. This study proposes precision digital care as an RL-based model designed to enhance quality of life in later years by delivering personalized, humane, and adaptive care. Rather than simply maximizing technical metrics, our approach uses RL as a tool to improve care engagement and health outcomes, supporting autonomy, reducing emotional distress, and ultimately enabling older adults to age in place with dignity. Importantly, by minimizing cumulative regret during the learning process, the approach reduces exposure to suboptimal care while enabling adaptive, sequential learning even in data-sparse or dynamically changing environments**.** By evaluating this approach through simulation, we aim to provide evidence for improving both efficiency and meaningful outcomes for vulnerable older adults before real-world implementation.

Methods

Aim of Simulations

In Korea, researchers are actively developing a range of government-funded digital care programs aimed at improving the well-being of older adults. These programs are administered by local authorities and are currently tailored to specific groups of older adults in distinct regions. As these initiatives progress, the accumulation of knowledge and data is expected to pave the way for large-scale implementation in the near future. This study focused on the critical role of personalization in enhancing the effectiveness of digital care. While personalization has not yet been fully integrated, demographic data on recipients of digital care programs is available. Leveraging this information, we conducted simulation studies that modeled the baseline characteristics of user populations, simulating the potential impact of personalized interventions.

Simulation Methods

To evaluate the potential of personalized digital care, we conducted a series of simulations mimicking the delivery of care programs to older adult residents in a community setting.

Four Allocation Methods

Our simulations were designed to evaluate the method that optimizes the outcome of interest. These 4 allocation methods were selected to represent commonly used approaches in digital health intervention deployment, ranging from traditional rule-based methods (systematic) to theoretically optimal but not feasible in practice (idealized personalized). By comparing these methods, we assessed the added value of the RL-based precision digital care approach in real-world care allocation settings.

Method 1: Systematic Delivery (Baseline)

This method reflects a common real-world practice, including the Korean local government model, where programs are assigned to users in a fixed order, without considering individual needs or program characteristics. This approach offers the simplest implementation, requiring no information about individual users or program effectiveness. However, it represents a naive baseline that can lead to suboptimal outcomes by ignoring potential benefits from personalized program allocation.

Method 2: Single Best Program (Theoretical Benchmark)

This method simulates a hypothetical situation where we know the single best program for the entire population based on average outcomes. This method mimics a scenario where the result of a large-scale randomized controlled trial, where individual characteristics are not used in program assignment, is known. This method provides a useful benchmark for comparison. It demonstrates the upper limit of effectiveness achievable when using a single program for everyone and highlights potential limitations of a one-size-fits-all approach.

XSL•FO
RenderX

If there were no individual variability, the one-size-fits-all approach would be optimal.

Method 3: Idealized Personalized Delivery (Theoretical Upper Bound)

This method assumes perfect knowledge of each individual's optimal program, representing an ideal but unattainable scenario in real-world settings. This method provides a theoretical upper bound on personalization benefits, demonstrating the best possible outcome achievable if we could perfectly predict the most effective program for each individual. Comparing this method to others highlights the potential gains from personalization.

Method 4: Precision Digital Care with Thompson Sampling (Personalized Approach)

This method addresses the challenge of sequentially assigning programs to individuals without prior knowledge of which program will be most effective for each person. This problem can be framed as a "sequential decision making under uncertainty" problem, where the goal is to maximize cumulative rewards over time. To tackle this, we used a contextual bandit framework, specifically using the linear Thompson Sampling algorithm [17].

In this setup, each care program is treated as an "arm" in the contextual bandit framework, where the reward function represents the expected benefit for a given user. The model dynamically updates its understanding of which arm (care program) is most effective based on observed user responses, allowing for personalized interventions over time. The relationship between the outcome (reward) and the context (individual characteristics and program features) is unknown and must be estimated as users experience the program. The challenge lies in balancing exploration (trying different programs to estimate or learn their effectiveness) and exploitation (assigning the program with the highest estimated reward based on current knowledge).

Among various contextual bandit algorithms, Thompson Sampling offers an effective approach for this setting. While upper confidence bound algorithms select arms by calculating an upper confidence bound on their estimated rewards, Thompson Sampling is motivated by a Bayesian approach. Specifically, it draws from the posterior distribution of each arm's reward, and the arm with the highest sampled reward is then selected.

This randomized approach effectively balances exploration and exploitation. In early stages, when uncertainty is high, the algorithm explores a wider range of programs due to the variability in sampled rewards. As more data is collected, the posterior distributions become more concentrated around the true reward values, and the algorithm increasingly exploits the program with the highest estimated reward for each individual. This approach enables precision digital care to adapt to individual differences and learn the optimal program assignment over time.

Data-Generating Mechanisms

To conduct simulation studies, we specified the distribution of the baseline user characteristics and the relationship between these characteristics and the outcomes. Our study involved a total of 6 distinct simulation scenarios, evaluating 3 different outcome measures (detailed in "Setup for Outcome Performance Measures") under 2 different assumptions about the user population and data availability, each informed by a specific Korean data source. The process for establishing these simulation environments was described below.

The first set of simulations aimed to closely mimic the characteristics and responses observed in a specific digital care intervention context. This was informed by data collected as part of a primary study involving approximately 1000 older adults actively engaging with an AI-based care call service (the "AI Call dataset"). This dataset provided detailed individual-level information on demographics, health status, intervention parameters (call success), and key outcomes (loneliness and self-rated health).

The second set of simulations aimed to represent a broader, more general population of older adults, reflecting demographic distributions found in large-scale surveys but potentially lacking detailed intervention-specific outcome data. This was informed by a representative sample from the national Community Health Survey (CHS) conducted in 2020 [18]. This survey provided robust population-level distributions for key demographic, health, and psychosocial variables. Table 1 describes the baseline distribution of key independent and dependent variables across the 2 datasets.

By comparing results across these 2 sets of simulations (AI Call dataset-based and CHS-based) for each outcome measure, we aimed to assess the robustness of our findings under different data conditions. The following sections detail how user profiles and the outcome generation process were specifically constructed for each simulation type.

[b]CHS: community health survey.

[c]Not applicable.

Setup for Baseline Distribution

To investigate the potential of personalized program allocation under different scenarios, we constructed synthetic user profiles representative of the 2 populations described above. User profiles were defined by a combination of 7 binary demographic and health-related features: age (older or younger), sex (male or female), region (rural or urban), economic status (unstable or stable), presence of multiple chronic conditions (present or absent), functional difficulty (present or absent), social isolation (high or low), cognition (intact or not intact), and living arrangement (alone or with others). The generation process differed depending on the simulation set:

For simulations based on the AI Call dataset: Synthetic user profiles were generated by sampling directly from the characteristics of about 1000 users in the raw AI Call dataset. This ensured the simulated users closely mirrored the specific population engaging with that service. For simulations based on the CHS dataset: since only aggregated distributional information (eg, percentage breakdowns for age, sex, and region) was available from the CHS summary data, synthetic user profiles were generated differently. Each user characteristic was randomly generated independently according to the proportions reported in the CHS data. This method produced a synthetic population whose overall marginal distributions matched the CHS population structure, assuming independence between characteristics based on the available information. Similarly, we created a pool of programs with varying attributes (content type, frequency, duration, and voice type). Parameters defining individuals (based on the methods above) and the range of programs were set to represent typical variations observed in Korean older adult care contexts.

Setup for the Relationship Between Reward and Context

A critical component defining each simulation scenario is the relationship between a user's characteristics, the assigned program attributes, and the resulting outcome or reward. This relationship models the differential program effectiveness, which

XSL•FO
RenderX

personalization aims to exploit. The construction of this relationship also differed between the two simulation sets: (1) For simulations based on the AI Call dataset, the parameters (coefficients) governing the relationship between user and program features and outcomes were informed by observed patterns in the actual AI Call data. Specifically, the direction (sign) of main effect coefficients was set to match observed trends (eg, whether rural users in the data had higher or lower call success). For simplicity, the magnitude of these data-informed coefficients was held constant; and (2) for simulations based on the CHS, since the CHS data lacked information on how user characteristics relate to outcomes from specific digital care programs, the coefficients defining the relationship between user and program features and outcomes were assigned randomly. This simulated outcome variability without imposing specific assumptions based on the limited data.

In both simulation sets, to explicitly model the potential for personalization, several user-program interaction effects were included. These were based on domain knowledge and plausible scenarios. Importantly, these interaction effect scenarios were applied consistently across all 3 outcome measures. Specific examples of modeled interactions include scenarios where:

1. Women derived higher rewards from longer calls.
2. Users with functional limitations benefited more from longer calls.
3. Rural users preferred more frequent calls.
4. Those with older age preferred check-in calls.
5. Those with low cognitive function preferred check-in calls.
6. Lonely individuals preferred intervention calls less.
7. Those with chronic disease preferred health information calls.

Setup for Outcome (Performance Measures)

Within the simulation framework described above, we modeled 3 key outcomes to assess program effectiveness. The generation of these outcomes for each user-program interaction followed the relationships defined in "Setup for the Relationship Between Reward and Context" (differing based on whether it was an AI Call or CHS-based simulation). We compared the average value of each outcome measure over 100 repetitions, each involving 3000 user-item interactions (call selections) with a randomly shuffled sequence of users. The three specific outcome measures we used are:

1. Call success: modeled using a logistic linear model, where a higher success rate (completion of the call) indicated a more desirable outcome. The probability of success for a given user and call type was determined by the model described in "Setup for the Relationship Between Reward and Context."
2. Patient Health Questionnaire-2 (PHQ-2) Score [19]: modeled using a linear model, where lower scores on the PHQ-2, a measure of depressive symptoms, indicated better mental well-being. The predicted PHQ-2 score depended on user context and program assignment according to the relationships in "Setup for the Relationship Between Reward and Context." While the underlying relationship was modeled linearly, the final simulated PHQ-2 outcome for an interaction was generated as an integer using probabilistic rounding based on the linear prediction, reflecting the discrete nature of the scale.
3. Self-Reported Health (SRH) [18]: modeled using a linear model, with higher scores on the 5-point SRH scale (1 being "very bad" and 5 being "very good") representing better perceived health status. Similar to PHQ-2, the predicted SRH score was a function of user and program characteristics as defined in "Setup for the Relationship Between Reward and Context." The final simulated SRH outcome was generated as an integer on the 5-point scale using probabilistic rounding based on the linear model's prediction.

Evaluation Methods

Four allocation methods were evaluated based on 2 metrics. The first metric was the distribution of the average outcome across simulation runs. For each of the 3 performance measures, call success, PHQ-2 score, and SRH, the average value of the outcome for each of the 4 allocation methods was calculated. This represents the average scores of the subjects who received the care call according to each allocation rule.

The second metric was average cumulative regret over time, or with the increasing number of subjects. Cumulative regret represents the loss incurred from selecting a suboptimal arm over time. For the first 2 allocation methods, regret never decreases, and cumulative regret increases linearly over time. For Method 3, both regret and cumulative regret are zero. For the proposed method, RL-based precision digital care, if the method learns the optimal arm, cumulative regret tapers off after increasing initially. The tapering nature indicates that the method is learning the optimal arm.

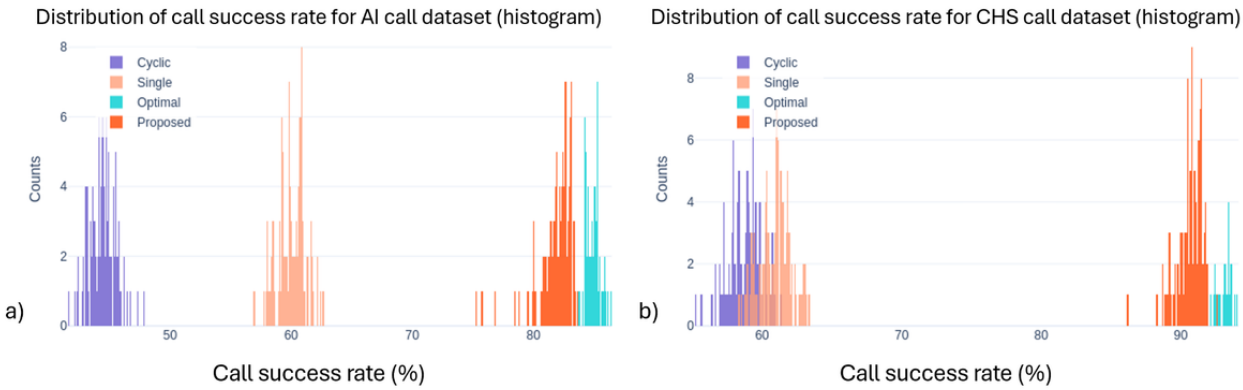
Ethical Considerations

This study was reviewed and determined to be exempt from ethical approval by the Institutional Review Board of Seoul National University (E2408/004-007; August 14, 2024), as it used publicly available and deidentified data that did not involve direct interaction with human participants. The study analyzed anonymized AI care call data and aggregated data from the Community Health Survey, and no personally identifiable information was accessed or retained. Because the study used deidentified secondary data and simulation-based analyses, informed consent from participants was not required. All procedures were conducted in accordance with the Declaration of Helsinki.

Results

We compared 4 program allocation methods: systematic, single best, optimal, and our proposed precision digital care with Thompson Sampling, across 3 outcome measures: call success rate, PHQ-2 score (depressive symptoms), and SRH. Figures 1-3 show the outcome distributions for each method over 100 simulation runs, each involving 3000 program assignments. The summary statistics for each outcome, including mean values and standard deviations across 100 simulation runs, are presented in Table 2.

XSL•FO
RenderX



Values represent means (SDs) across 100 simulation runs (n=3000 assignments per run).

Our results demonstrate the significant potential of precision digital care with Thompson Sampling for personalized program allocation. Across all 3 measures, the proposed precision digital care consistently achieved outcomes comparable to the idealized optimal method, which assumes perfect knowledge of individual preferences and program effectiveness. Compared with systematic allocation, the proposed precision digital care approach substantially improved outcomes across all 3 measures. Call success rates increased from 44.45% to 81.86% in the AI Call dataset (84.2% relative improvement) and from 58.72% to 90.68% in CHS (54.4%). PHQ-2 depression scores decreased from 2.87 to 1.95 (32.1% reduction, AI Call) and from 2.73 to 1.60 (41.4%, CHS), while SRH scores improved from 2.94 to 3.50 (19%, AI Call) and from 3.18 to 3.88 (22%, CHS). To compare outcome distributions between systematic allocation and the proposed method, chi-square tests were used for call success rates, and Mann-Whitney *U* tests for PHQ-2 and SRH scores; all comparisons were statistically significant ($P<.001$). These findings indicate that RL-based personalization leads to substantial gains in care effectiveness compared to rule-based or static allocation strategies. These also suggest that precision digital care can effectively learn and adapt to individual needs, leading to near-optimal outcomes even without prior knowledge of individual preferences. As expected, the nonpersonalized baseline methods (“systematic” (cyclic) and “single best”) yielded inferior performances compared to the personalized approaches. This highlights the limitations of assigning programs without considering individual needs and preferences.

Figure 4 illustrates cumulative regret over time or the number of users. Cumulative regret represents the loss incurred from selecting a suboptimal arm over time. It initially increases rapidly before tapering off, indicating that suboptimal arms are often selected in the beginning, followed by the selection of optimal arms. The figures also show that, depending on the outcome, learning occurs across a varying number of users. Since call success is binary, it takes more users to stabilize the learning process. This pattern suggests that precision digital care rapidly identifies optimal program assignments, reducing the frequency of ineffective interventions as it learns from accumulated user interactions. The stabilization of regret over time indicates that the RL model efficiently converges to near-optimal allocation decisions, ensuring that users receive the most suitable care programs based on their unique characteristics.

These findings underscore the potential of using contextual bandit algorithms like Thompson Sampling for personalized interventions. The ability to dynamically learn and adapt to individual needs can lead to significant improvements, especially when program effectiveness varies greatly across individuals. Overall, these results highlight the effectiveness of precision digital care in dynamically optimizing care program assignments, achieving outcomes close to the idealized optimal method. By leveraging RL, the proposed precision digital care has the potential to continuously improve care services based on user interactions, ultimately enhancing the quality and efficiency of digital health interventions.

Discussion

Principal Findings

Our findings highlight the potential of precision digital care with Thompson Sampling in optimizing digital care service allocation for older adults. Through simulation studies, we demonstrated that personalized program allocation leads to improved care outcomes compared to nonpersonalized methods. Specifically, the precision digital care approach outperformed both systematic and single-best allocation approaches, achieving results close to the idealized theoretical upper bound. This underscores the importance of hyper-personalization in digital health care, particularly in aging populations facing growing care demands and workforce shortages.

The outcomes evaluated in this simulation study represent key dimensions of effective care delivery for older adults living alone. Call success indicates sustained engagement with care services and regular monitoring, both critical for timely detection of health or safety concerns and prevention of unattended deaths-an emerging social problem in Korea [20]. PHQ-2 scores represent depressive symptoms that affect daily functioning, social participation, and self-care capacity, while self-reported health reflects subjective well-being and perceived ability to age in place.

In real-world implementation, improvements in these outcomes would support the delivery of responsive, person-centered care. Importantly, precision digital care is designed to augment (not replace) human care relationships. In Korea's context, direct care workers often face overtime burdens and emotional exhaustion, contributing to workforce shortages [2,3]. The proposed approach optimizes routine care allocation through AI-driven monitoring, allowing human workers to focus on complex cases requiring empathy, clinical judgment, and relational continuity. This human-AI collaboration model

XSL•FO
RenderX

addresses workforce sustainability while preserving the irreplaceable value of human connection in care relationships. Rather than automating care relationships, the system automates administrative burden, the repetitive monitoring tasks that overwhelm workers, enabling them to provide higher-quality human care where it matters most. Together, these outcomes support the goal of enabling older adults to age with dignity and autonomy while ensuring appropriate care allocation.

These findings align with previous research emphasizing the importance of personalization in digital health interventions for older adults. A scoping review of digital health interventions targeting older populations found that personalized features improve self-management and psychosocial health, but also noted that experimental studies validating these effects are scarce [21]. Our study contributes to this gap by providing a systematic, AI-driven approach to personalization, demonstrating through simulation that RL can effectively optimize program allocation based on user characteristics. Unlike previous work, which primarily relies on static program designs, our approach adapts dynamically, ensuring that interventions are continually optimized over time.

Our study also relates to research exploring contextual bandit algorithms in mobile health settings, where RL has been used to optimize treatment timing and intervention strategies [22]. Existing studies have demonstrated the feasibility of such approaches in personalized patient engagement and behavior change interventions [23]. However, most prior applications focus on mobile health and preventive care rather than digital older adult care services. Our findings extend these applications by showing that contextual bandits can optimize not just treatment timing but also care program selection for older adults in government-supported digital health initiatives. This represents a novel application of RL in aging-related digital interventions, offering a scalable solution for optimizing care programs at the population level.

Beyond demonstrating the effectiveness of RL for digital care optimization, our findings have broader implications for the scalability of AI-driven decision models in government-funded care programs. As governments invest in digital health solutions to address aging populations and workforce shortages, integrating AI-driven program allocation systems can improve care efficiency without requiring extensive prelabeled datasets [24]. The Korean AI care call program exemplifies this trend, yet current models lack individualized program allocation strategies. By applying the proposed precision digital care approach for personalization of care in such settings, policymakers could transition from standardized digital interventions to truly personalized care, ensuring that digital services maximize impact and cost efficiency. More broadly, the integration of AI-driven decision-making into digital care services aligns with global trends toward precision health and personalized medicine, advocating for a shift away from static care delivery models.

Despite these promising findings, several limitations must be acknowledged. This study relied on synthetic data and simulations, rather than real-world implementation. Although the data was constructed using existing survey datasets and AI care call user characteristics, real-world trials are necessary to validate these findings in practice. Additionally, the current model was developed within the Korean digital care context, and further research is needed to assess the adaptability of precision digital care in different health care systems and cultural settings.

This study's focus on low-income, socially isolated older adults living alone reflects an intentional equity commitment. These populations face compounded vulnerabilities, limited access to family support, health care services, and social resources, placing them at increased risk of adverse outcomes [25]. Precision digital care has particular promise for reducing geographic and functional disparities. Our simulations incorporated domain-informed interaction effects in which rural users and those with functional limitations were modeled as benefiting from different care configurations. For example, based on observed patterns in Korean older adult care contexts, rural older adults were modeled as preferring more frequent calls (potentially compensating for limited in-person service access), while those with functional difficulties were assumed to benefit from longer interaction times (allowing more comprehensive needs assessment). Similarly, older adults with cognitive limitations were modeled as engaging better with simpler check-in style calls rather than complex health information content.

By identifying and responding to these differential needs, precision digital care can help bridge urban-rural care gaps, accommodate varying cognitive and functional capacities, and ensure that digital care innovations reduce rather than exacerbate existing inequities. However, realizing this potential requires careful attention to digital literacy barriers, technology access, and culturally appropriate implementation, critical considerations for future real-world validation studies.

Beyond technical and operational concerns, AI-driven personalization in digital health raises ethical considerations, such as potential bias in program allocation, equity in digital access, and privacy concerns related to AI-driven recommendations [26]. Future studies should explore fairness-aware RL approaches to ensure equitable care distribution, particularly for older adults who may have limited digital literacy or reduced access to technology. Furthermore, while RL-based precision digital care optimizes individualized program assignments, its integration into broader multilevel care frameworks, such as clinical care coordination, home-based services, and telemedicine ecosystems, remains an open challenge. Ensuring seamless interoperability with existing digital health platforms will be essential for widespread adoption.

To address these limitations, we plan to conduct real-world validation studies in a publicly funded AI care call program in Korea, assessing precision digital care's impact on user satisfaction, health outcomes, and long-term engagement, with an expanded set of objective measures (eg, health care use and device-measured activity) to complement self-reports. Although equity was not quantitatively evaluated in this study, the intervention setting, a publicly funded AI care call program for low-income, socially vulnerable older adults living alone,

XSL•FO
RenderX

reflects an inherent focus on underserved populations. Future research should also explore hybrid AI models, integrating deep learning and RL to further refine personalized digital interventions. Additionally, a critical next step is to examine how RL-based precision digital care performs across diverse populations, ensuring that AI-driven personalization remains both effective and equitable across different health care systems.

Conclusions

This study introduced precision digital care, an AI-driven RL model for optimizing personalized digital care service allocation. Our simulation-based evaluation demonstrated that precision digital care significantly improves care outcomes by dynamically adapting interventions to individual user characteristics. These findings highlight the potential of AI-driven personalization in enhancing the efficiency and effectiveness of digital health interventions, particularly in aging populations where scalable, individualized care is increasingly needed.

As digital care programs expand, ensuring personalized, data-driven decision-making will be critical in maximizing their impact. Precision digital care offers a scalable approach to deliver dignified, person-centered care at scale. By using RL to understand and respond to individual needs, the proposed framework can help older adults maintain autonomy, social connection, and well-being while supporting sustainable care systems. The ultimate goal is not simply algorithmic optimization but improving lived experiences and quality of life in later years through adaptive, humane digital care that honors individual dignity and preferences. However, further real-world validation is required to confirm the effectiveness of precision digital care beyond simulations and to address practical implementation challenges.

Future research should focus on scaling and adapting precision digital care to diverse health care settings, ensuring ethical AI deployment, and integrating hybrid AI models to enhance personalization. Establishing fair, transparent, and explainable AI systems will be key to promoting trust and equitable access in digital health services for aging populations worldwide.

Funding

This work was supported by the National Research Foundation of Korea (NRF) grant funded by the Korean government (MSIT) (RS-2023-00276954) and the AI Institute at Seoul National University (AIIS) in 2025.

Data Availability

The datasets generated and/or analyzed during this study are not publicly available due to Institutional Review Board regulations, but are available from the corresponding author on reasonable request.

Authors' Contributions

HK contributed to conceptualization, funding acquisition, and led the writing of the original draft. MCP contributed to conceptualization, methodology, and writing of the original draft. KL was responsible for formal analysis and visualization, and JYY contributed to data curation. All authors participated in drafting sections of the manuscript and in reviewing and editing the final version.

(JMIR Aging 2026;9:e101284) doi:10.2196/101284

In "Development and Validation of Machine Learning Models for Predicting Falls Among Hospitalized Older Adults: Retrospective Cross-Sectional Study" [1], the authors noted one error.

In the Selection of Predictor Variables section, the following sentence was replaced:

> *Univariate LR identified 27 potential predictors (P<.05) in the training set, as detailed in Table S3 of Multimedia Appendix 1.*

The sentence now reads:

> *Univariate LR identified 26 potential predictors (P<.05) in the training set. The mBI did not reach statistical significance in the univariate analysis, but its P value was .054, which is very close to the threshold. Given that the mBI is an important clinical indicator associated with fall risk and to avoid omitting potentially influential factors due to a rigid threshold, we decided after expert discussion to include it as the 27th variable in the subsequent feature selection, as detailed in Table S3 of Multimedia Appendix 1.*

The correction will appear in the online version of the paper on the JMIR Publications website, together with the publication of this correction notice. Because this was made after submission to PubMed, PubMed Central, and other full-text repositories, the corrected article has also been resubmitted to those repositories.

Abstract

Background: Postoperative frailty is highly prevalent among older adults undergoing hip surgery and is closely linked to poor clinical outcomes. Despite growing interest in understanding its progression, the temporal patterns of frailty remain underexplored. Moreover, there is a lack of validated models that can predict frailty trajectories and stratify patients by risk in the early postoperative period.

Objective: This study aimed to identify distinct frailty trajectories within 6 months following hip surgery in older adults and to explore their associated predictors. An interpretable machine-learning model was developed and internally validated for individualized risk prediction and was implemented as a clinically accessible web-based calculator.

Methods: This prospective longitudinal observational study was conducted among older adults undergoing hip surgery at a tertiary hospital in China. Frailty assessments were performed preoperatively and at 1, 3, and 6 months postoperatively. A total of 209 participants who completed the 6-month follow-up were included in the analysis. Frailty was assessed using the Frailty Index, and group-based trajectory modeling was applied to identify distinct frailty progression patterns. Predictive variables were selected using the least absolute shrinkage and selection operator regression. An interpretable Extreme Gradient Boosting (XGBoost) model was developed using a 60:40 training-test data split. Model performance was evaluated in terms of discrimination, calibration, and clinical utility. Interpretability was assessed using SHAP (Shapley Additive Explanations) at both the global and individual levels.

Results: Three distinct frailty trajectories were identified: low-fluctuation frailty (55/209, 26%), high-improvement frailty (81/209, 39%), and high-deterioration frailty (73/209, 35%). Twelve predictors grounded in the Health Ecology Model were selected, spanning individual characteristics, interpersonal networks, and the living environment. The XGBoost model demonstrated excellent discrimination, with a microaverage area under the receiver operating characteristic curve of 0.98 (95% CI 0.96 - 0.99) in the training set and 0.93 (95% CI 0.90 - 0.96) in the test set. Calibration was acceptable, with a weighted Brier score of 0.0852. Decision curve analysis showed favorable clinical utility across a range of threshold probabilities. A web-based risk calculator was developed to facilitate personalized frailty trajectory prediction.

Conclusions: The XGBoost model demonstrated strong predictive performance and interpretability, enabling the early identification of older patients at risk for adverse frailty trajectories following hip surgery. This tool may support targeted interventions and improve perioperative care in geriatric populations.

Introduction

Population aging has emerged as a significant global public health challenge. With shifting demographic structures, the incidence of orthopedic conditions among older adults has risen substantially. In 2000, there were an estimated 1.6 million hip fracture cases worldwide, a number projected to increase to 6.3 million by 2050 [1]. Hip osteoarthritis is also common in older

XSL•FO
RenderX

adults, with an incidence of up to 10%, and its end-stage form leads to significant pain and disability, severely impacting quality of life [1]. For conditions such as hip fractures and advanced hip osteoarthritis, hip surgery remains the primary treatment, effectively alleviating pain, restoring joint function, and improving patient outcomes [2]. Notably, approximately 85% of patients undergoing hip surgery are aged 60 years or older and often present with multimorbidity and frailty [3].

Frailty is an age-related clinical syndrome characterized by a progressive decline in physiological function and multisystem reserve, which impairs the ability to withstand stressors, such as illness, trauma, or surgery, and increases vulnerability to adverse outcomes [4,5]. A growing body of evidence has identified frailty as an independent predictor of poor postoperative outcomes, including falls, functional decline, rehospitalization, and mortality [6-8]. Among older patients undergoing surgery, the prevalence of frailty ranges from 41.8% to 50.3% and may reach up to 65% in those undergoing hip surgery [9,10]. This elevated prevalence reflects the dual impact of both the underlying health status and surgical stress. On the one hand, hip fracture itself is often associated with frailty-related conditions such as sarcopenia, impaired balance, and malnutrition. On the other hand, perioperative factors such as prolonged bed rest, pain, and reduced mobility can accelerate muscle loss and disrupt homeostasis, further depleting physiological reserves through endocrine, metabolic, and immune dysregulation [11,12]. Common postoperative complications, including delirium and infection, may further delay recovery and exacerbate functional deterioration. Even 1 year after surgery, frailty remains present in 25.6% to 27.7% of patients [13].

Importantly, frailty is increasingly recognized as a dynamic and potentially reversible condition. Its core principle emphasizes that early identification and proactive intervention can delay or even reverse its progression [14]. The distinct phases of postoperative recovery, rehabilitation, and stabilization provide a critical window to observe changes in frailty status. These trajectories are shaped by factors such as baseline reserve, perioperative complications, and psychosocial conditions. While some patients recover steadily, others experience worsening frailty and increased dependency [15]. Studies suggest that frailty trajectory patterns better predict outcomes than static measurements, with rapid deterioration or high variability indicating increased risk [16]. These findings underscore the need for tools that can identify frailty trajectories early and guide intervention timing. While previous studies have examined frailty trajectories in various disease contexts, only a few have developed predictive models [17,18]. These models are typically restricted to specific populations, rely on a narrow set of variables, and employ conventional statistical approaches, limiting their robustness and generalizability. Furthermore, static frailty assessment tools, such as the Clinical Frailty Scale and the FRAIL Scale, fail to capture the multidimensional, nonlinear nature of frailty progression. Therefore, there is a pressing need for predictive models that integrate multilevel risk factors and offer strong interpretability.

The Health Ecology Model (HEM) offers a comprehensive framework for viewing health as the outcome of interactions among individual, behavioral, and environmental factors [19]. It emphasizes that health is determined by personal characteristics (eg, age, sex, body weight, psychological status, and lifestyle), as well as by social support, living conditions, economic status, and broader policy environments. This perspective aligns with the multifactorial etiology of frailty, which is shaped by both intrinsic and extrinsic factors [18,20]. Methodologically, Extreme Gradient Boosting (XGBoost) is a robust ensemble learning algorithm well-suited for modeling high-dimensional, nonlinear data and performs reliably even with relatively small sample sizes. SHAP (Shapley Additive Explanations), grounded in cooperative game theory, enhances the interpretability of machine-learning models by quantifying the global and individual-level contributions of each feature to prediction outcomes [21].

Therefore, guided by the HEM, this study integrates predictors across individual, behavioral, and environmental domains to construct an interpretable XGBoost-based predictive model for frailty trajectories within 6 months following hip surgery in older patients. SHAP is used to visualize and interpret the contribution of key predictors, and a web-based calculator is developed for clinical applications. This study aims to support the stratification of patients into distinct frailty trajectory subgroups, enabling more precise screening, targeted intervention, and optimized allocation of health care resources.

Methods

Study Design

This was a prospective, longitudinal cohort study, reported in accordance with the 2024 TRIPOD + AI (Transparent Reporting of a Multivariable Prediction Model for Individual Prognosis or Diagnosis—Artificial Intelligence) guidelines for the development and validation of multivariable prediction models [22].

Population

This study employed convenience sampling to recruit older adults who underwent hip surgery under general anesthesia at a tertiary hospital in China between March 2024 and March 2025. Eligible patients were followed prospectively for 6 months postoperatively, with follow-up assessments conducted from March 2024 to September 2025.

Inclusion criteria were age 60 years or older; scheduled for elective hip surgery, including total hip arthroplasty, hemiarthroplasty, or internal fixation; and sufficient communication ability to complete study assessments. Exclusion criteria were severe psychiatric disorders that prevented adequate cooperation; substantial hearing or visual impairments that precluded completion of questionnaires; palliative status (ie, life expectancy <6 mo); or current enrollment in other studies likely to affect frailty outcomes. Participants were withdrawn if they were lost to follow-up due to relocation or hospital transfer, voluntarily withdrew consent, or died of causes unrelated to the study protocol.

Baseline data and preoperative frailty assessments were collected through face-to-face interviews conducted by trained researchers. Follow-up assessments at 1, 3, and 6 months

XSL•FO
RenderX

postoperatively were conducted via structured telephone interviews.

Sample Size

As there is currently no universally accepted sample size calculation method for trajectory-based multiclass machine-learning prediction models, the sample size was pragmatically estimated using a conventional epidemiological formula to ensure adequate baseline cohort representativeness. The required sample size was calculated as follows [23]: n=(Zδ)2φ^(1−φ^), where *Z* is the critical value at a 95% CI, φ∧ is the estimated incidence of frailty, and δ is the acceptable margin of error. Based on a pilot study indicating a 6-month postoperative frailty incidence of 14% and setting *d* at 5%, the calculated sample size was 185. After accounting for a 10% attrition rate, the final target sample size was set at no fewer than 206 cases to ensure the epidemiological representativeness of the baseline cohort.

Ethical Considerations

Ethical approval for the study was obtained from the Ethics Committee of Sir Run Run Shaw Hospital, Zhejiang University School of Medicine (number 2024-2687-01). Informed consent was obtained from all participants before the study commenced.

Outcomes Definition

Frailty was assessed preoperatively and at 1, 3, and 6 months postoperatively using a modified Frailty Index (FI) based on the cumulative deficit model developed by Rockwood and Mitnitski [24]. Tailored to the clinical characteristics of older adults undergoing hip surgery, we developed a 37-item population-specific FI covering 6 domains: chronic diseases, mental health, activities of daily living (ADLs), cognitive function, and symptoms/signs. Although several predictive variables share conceptual domains with components of the FI, none of the specific indicators used to construct the FI were directly included as predictors in the model. FI scores ranged from 0 to 1, with higher scores indicating greater frailty. A score <0.25 was classified as nonfrail and a score ≥0.25 was classified as frail [25]. The full list of FI items is provided in Multimedia Appendix 1.

Candidate Predictor Variables

Based on a review of the literature and expert consultation, potential risk factors were explored within the HEM, encompassing individual characteristics, behavioral and psychological factors, interpersonal networks, and the living environment. Key individual characteristics included demographic and socioeconomic factors (eg, gender, marital status, education level, and income), physiological indicators (high-sensitivity C-reactive protein [hsCRP]), health behaviors (smoking and drinking), and clinical history (number of comorbidities and surgery type). Functional status was assessed using the Barthel Index for ADLs, with scores indicating varying levels of independence [26]. Nutritional status was evaluated via the Mini Nutritional Assessment–Short Form [27], with scores categorizing participants as malnourished, at risk, or well-nourished.

Behavioral and psychological factors, including depressive symptoms, were measured using the 5-item Geriatric Depression Scale, while sleep quality was assessed using the Pittsburgh Sleep Quality Index. For interpersonal networks, family function was assessed using the Family APGAR (Adaptability, Partnership, Growth, Affection, Resolve) Index [28], and social support was measured using the Social Support Rating Scale. Finally, environmental factors were evaluated using a self-developed Living Environment Questionnaire (LEQ), which assesses home adaptability, perceived environmental burden, community resource accessibility, and residential satisfaction. The LEQ demonstrated strong content validity and was tailored to the needs of older adults. Detailed descriptions of these variables and the respective scales are provided in Multimedia Appendix 1.

Statistical Analysis

A complete-case analysis was conducted. Missing data primarily arose from loss to follow-up during the longitudinal assessments, and participants with incomplete follow-up data were excluded from the analysis. To assess the missing data mechanism, the Little test for missing completely at random (MCAR) was performed. In addition, baseline characteristics between participants included in the final analysis and those who were lost to follow-up were compared to evaluate the potential for selection bias. Categorical variables are expressed as frequencies and percentages. Differences between the training and test sets were assessed using the chi-square test. Continuous variables with a normal distribution are presented as mean (SD), while nonnormally distributed variables are shown as median (IQR). Depending on the data distribution, the *t* test or the Mann-Whitney *U* test was applied.

Group-based trajectory modeling was utilized to identify frailty trajectories in older patients with hip fractures. The optimal model was selected based on clinical relevance, fit indices, and classification quality, with a preference for simpler models with fewer groups. Model fit was evaluated using the following criteria [29]: (1) Bayesian Information Criterion (BIC): lower values indicate a better fit; (2) average posterior probability (AvePP): AvePP greater than 0.7 for all groups, with the smallest group proportion exceeding 5%; (3) odds of correct classification (OCC): OCC was greater than 5; (4) relative entropy (E_k): E_k was higher than 0.8.

The data were randomly split into training and test sets in a 60:40 ratio using stratified sampling to preserve the original distribution of the 3 frailty trajectory classes across the dataset. To prevent overfitting, LASSO (least absolute shrinkage and selection operator) regression was applied to the training set for high-dimensional feature selection. The L1 regularization term enabled simultaneous variable selection and coefficient shrinkage. Model performance was evaluated using 10-fold cross-validation, with the optimal penalty parameter (λ) selected according to the 1 SE rule to ensure model parsimony and generalizability. To evaluate potential overlap and multicollinearity among predictors, variance inflation factors (VIFs) were calculated for variables retained after LASSO selection. A VIF <5 was considered to indicate no significant multicollinearity [30].

XSL•FO
RenderX

The selected features were used to construct the XGBoost model. Because no trajectory class represented an extremely small proportion of the sample, no additional class imbalance handling strategies (eg, oversampling or SMOTE [Synthetic Minority Oversampling Technique]) were applied during model training. To improve model robustness and reduce overfitting, regularization and subsampling strategies were incorporated into the XGBoost model. During training, a 3-fold inner cross-validation was employed to estimate performance. For the test set, the area under the receiver operating characteristic curve, accuracy, F_1-score, sensitivity, and specificity were computed. The calibration curve was used to compare predicted probabilities with actual outcomes across frailty trajectories. Decision curve analysis was performed to assess net clinical benefit. Finally, SHAP values were used to interpret the XGBoost model, ranking feature importance based on the mean absolute SHAP values. The XGBoost model was deployed on a cloud platform [31] using the "Shiny" package, creating an online prediction calculator for frailty trajectories following hip surgery.

Statistical analysis and graphical representations were performed using IBM SPSS 26.0, R 4.5.1 (R Core Team), and Python 3.9 (Python Software Foundation), with the "traj," "glmnet," "xgboost," and "shap" packages. All statistical tests were 2-sided, and statistical significance was set at α=.05.

Results

Characteristics of Participants

A total of 300 patients were screened for the study, of whom 78 were excluded due to severe hearing impairment, significant visual decline, communication barriers, or other factors. Four patients with incomplete data were also excluded, leaving 218 patients enrolled. Multimedia Appendix 2 presents the flowchart of the participants included in this study. During the follow-up period, 9 participants were lost to follow-up at 6 months, yielding an attrition rate of 4.1%. Given that frailty trajectories were identified using group-based trajectory modeling based on 3 repeated follow-up assessments, participants with incomplete longitudinal data were excluded to ensure the stability and interpretability of trajectory classification. To evaluate the missing data mechanism, we conducted a missing data analysis (Multimedia Appendix 2). The Little MCAR test indicated that the missing data were consistent with the assumption of MCAR (χ^2_4=3.750, P=.44). In addition, no significant differences were observed in baseline characteristics between participants retained in the analysis and those lost to follow-up (Multimedia Appendix 2), suggesting a low risk of selection bias.

Frailty Prevalence and Trajectories

Frailty levels among older patients undergoing hip surgery exhibited a dynamic trend, with an initial increase followed by a gradual decline. The prevalence of frailty was 70.81% (148/209) before surgery, peaked at 84.21% (176/209) at 1 month postoperatively, and subsequently decreased to 63.16% (132/209) at 3 months and 45.45% (95/209) at 6 months.

A 3-class trajectory model demonstrated the best fit based on BIC, AvePP, and E_k values (Multimedia Appendix 3). It showed the lowest BIC change (59.36). All classes had AvePP values greater than 0.7 and OCC values exceeding 5. The E_k was 0.905, indicating high classification precision. Therefore, the 3-trajectory model was selected to characterize postoperative frailty trajectories among older adults undergoing hip surgery. Based on the estimated intercepts and slopes, trajectory 0 was labeled as low-fluctuation frailty, comprising 55 out of 209 individuals (26%), with a lower baseline frailty level, a modest increase at 1 month, and a subsequent decline. Trajectory 1 was labeled as high-improvement frailty, including 81 out of 209 (39%) individuals who had a higher baseline frailty level and experienced continuous functional recovery. Trajectory 2 was labeled as high-deterioration frailty, consisting of 73 out of 209 (35%) individuals who started with a high frailty level and demonstrated progressive worsening over time. Detailed parameter estimates and visual representations are provided in Multimedia Appendix 3. Given the distinct clinical patterns observed among the 3 classes, a multiclass modeling approach was employed to support the subsequent predictive analysis.

Predictor Variable Selection

A total of 209 participants were randomly assigned to a training set (n=126) and a testing set (n=83) in a 60:40 ratio. The training set was used for model development, while the testing set was reserved for independent performance evaluation. Baseline demographic and clinical characteristics were compared between the 2 sets, with statistically significant differences observed only in marital status and type of medical insurance (Table 1).

Twenty-five candidate predictors were entered into the LASSO regression for feature selection. Using the 1 SE criterion (λ=0.0342), 12 variables were retained, including age, gender, living arrangement, albumin, hsCRP, drinking status, teeth number, comorbidities number, ADLs, nutritional status, social support level, and living environment. The feature selection process is illustrated in Figure 1, with additional details provided in Multimedia Appendix 4. Multicollinearity diagnostics showed that the VIF values of the retained predictors ranged from 1.07 to 1.67, with all values below 5, indicating no evidence of significant multicollinearity. Detailed results are presented in Multimedia Appendix 4. These variables were subsequently incorporated into the XGBoost model to predict postoperative frailty trajectories and to explore the relative contribution of each predictor to the classification outcomes.

Figure 1. Feature selection using the LASSO (least absolute shrinkage and selection operator) regression model. (A) LASSO coefficient profiles of the 25 candidate predictors. (B) Selection of the optimal tuning parameter (λ) using 10-fold cross-validation.

Model Development and Evaluation

To optimize XGBoost performance, key hyperparameters were tuned using grid search and cross-validation to improve model generalizability and accuracy. The model achieved excellent discriminative performance, with microaverage area under the receiver operating characteristic curve of 0.98 (95% CI 0.96 - 0.99) in the training set (Figure 2A) and 0.93 (95% CI 0.90 - 0.96) in the testing set (Figure 2B). Additional metrics, including accuracy, F_1-score, sensitivity, and specificity, are presented in Table 2. Calibration curves (Figure 2C) closely approximated the 45° line, indicating good agreement between predicted and observed probabilities, with a weighted Brier score of 0.085. Decision curve analysis demonstrated consistently greater net clinical benefit across a range of threshold probabilities compared to the "treat-all" and "treat-none" strategies, supporting the model's potential for clinical applications (Figure 2D).

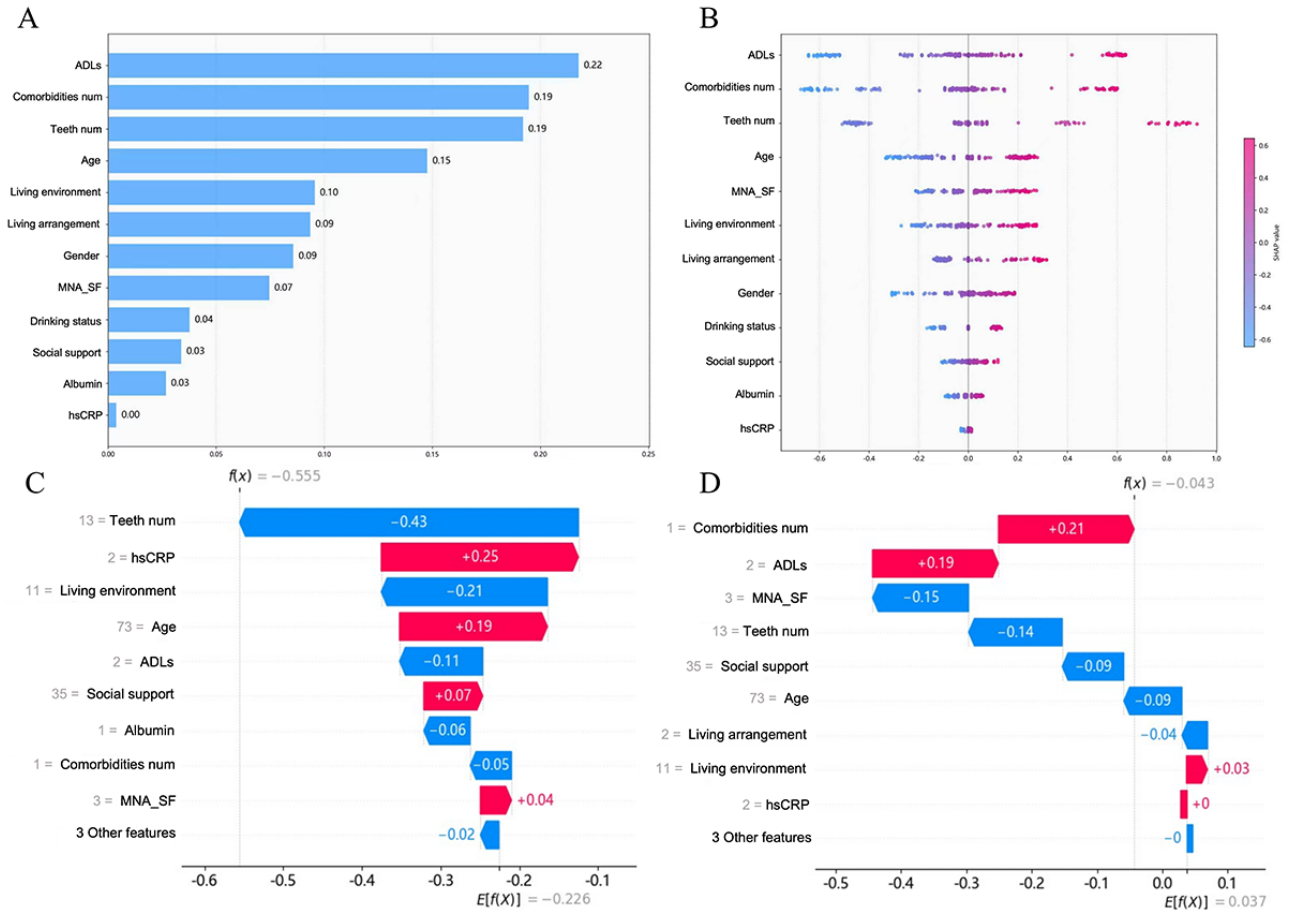
Figure 2. Predictive performance and clinical utility of the frailty trajectory models. (A) Receiver operating characteristic (ROC) curves for the training set. (B) ROC curves for the test set. (C) Calibration plot of the Extreme Gradient Boosting (XGBoost) model. (D) Decision curve analysis (DCA) of the XGBoost model. AUC: area under the ROC curve. Dashed and dotted lines indicate the strategies of treating “all” or “no” patients, respectively.



Model Interpretation

The SHAP algorithm was used to visualize and interpret the contribution of each predictor to the frailty trajectory model. As shown in Figure 3A, the bar plot displays the mean SHAP values of the 12 selected predictors, reflecting their average impact on the model output. ADLs had the greatest predictive importance, followed by the number of comorbidities and the number of teeth. Figure 3B presents the SHAP value distributions for each feature, with color gradients from blue (low values) to red (high values) representing the magnitude of each predictor and its influence on individual predictions.

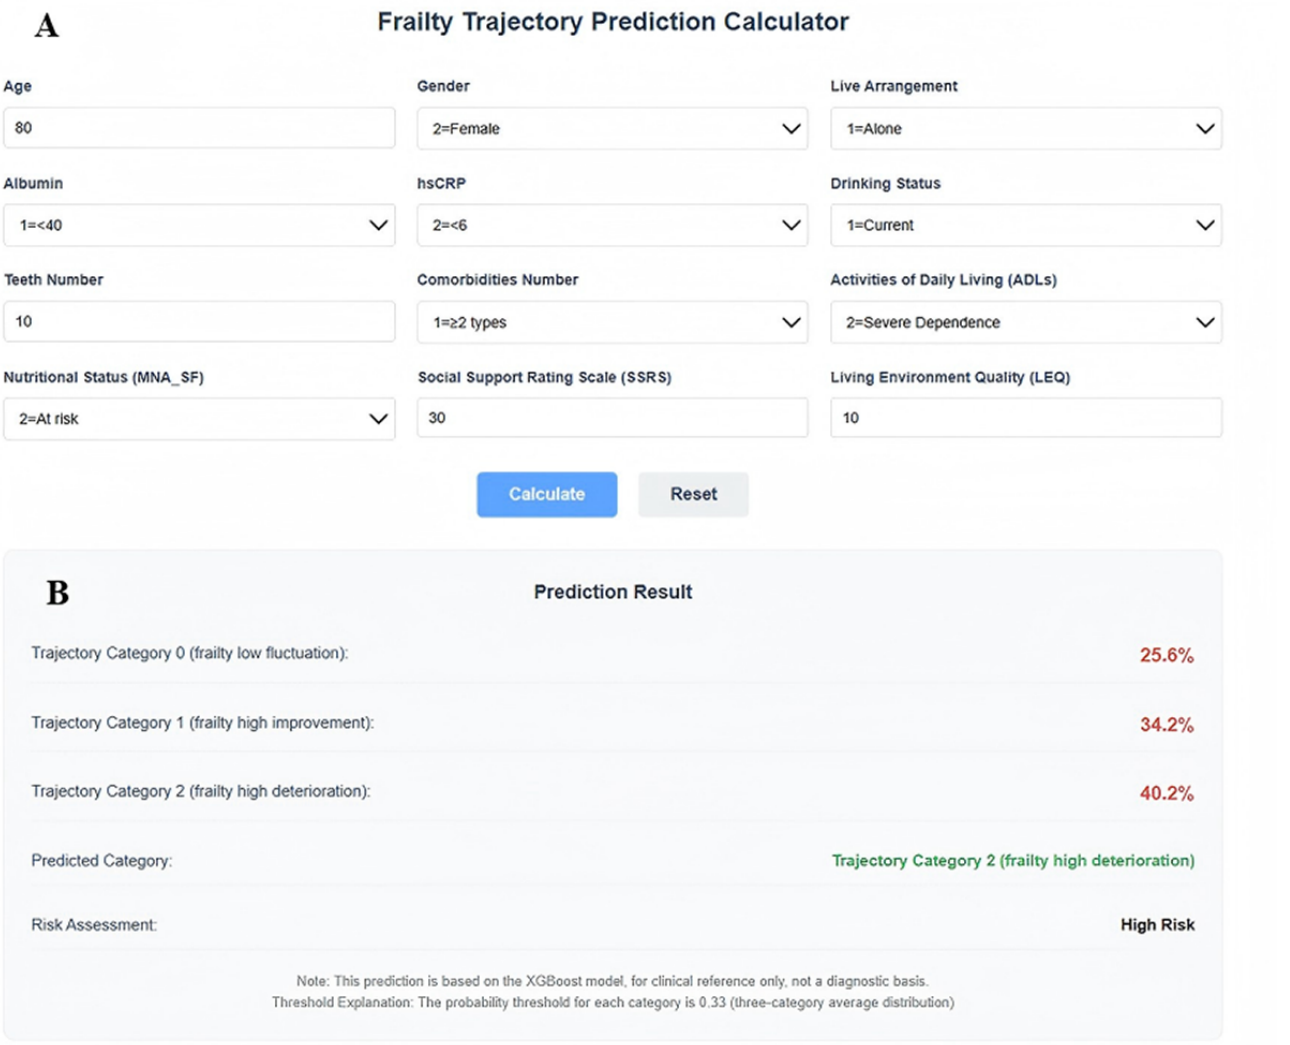
(D) The SHAP waterfall plot for an illustrative patient from the high-deterioration frailty trajectory. ADL: activities of daily living; hsCRP: high-sensitivity C-reactive protein; MNA-SF: Mini Nutritional Assessment–Short Form.



To visualize case-specific model explanations, Figure 3C and D presents SHAP waterfall plots for illustrative patients from the low-fluctuation and high-deterioration frailty trajectories, respectively. For these samples, the predicted model outputs were −0.555 and −0.043, compared with baseline values of −0.226 and 0.037. For the low-fluctuation trajectory, favorable living environments and higher teeth counts showed strong negative contributions to the model output, offsetting the positive contributions of age and hsCRP. In contrast, the high-deterioration trajectory was primarily characterized by positive contributions from comorbidities and ADL limitations, whereas nutritional status, social support, dental health, and age contributed negatively to the model output.

A web-based frailty trajectory prediction calculator was developed and is freely available online [32]. The user interface of the application is shown in Figure 4. This tool allows users to input key patient characteristics and obtain estimated probabilities for each frailty trajectory class, which may support frailty risk assessment and individualized management planning.

Discussion

Principal Findings

This study identified 3 distinct postoperative frailty trajectories among older adults following hip surgery: low fluctuation, high improvement, and high deterioration. These findings highlight that frailty after hip surgery is a dynamic process with substantial interindividual variability rather than a static condition. By moving beyond traditional binary outcomes [17,18], this trajectory-based approach provides a more nuanced understanding of recovery patterns that are often obscured in aggregate analyses. Furthermore, by integrating multidimensional predictors within the HEM, we developed a prediction model that demonstrated good discrimination and calibration performance. Collectively, these findings provide a basis for early risk stratification and the development of targeted, individualized intervention strategies in postoperative care.

Although the overall prevalence of frailty followed a rise-then-fall trajectory over the 6-month postoperative period, consistent with prior studies such as Huang et al [33], this general trend concealed the diversity of individual recovery paths. The early peak in frailty may be attributed to systemic inflammatory responses, catabolic stress, and functional limitations induced by postoperative pain, while the subsequent decline likely reflects recovery mechanisms, including tissue healing, pain relief, and rehabilitation engagement. Trajectory modeling in this study revealed 3 distinct frailty patterns: low fluctuation, high improvement, and high deterioration. These heterogeneous trajectories suggest that despite experiencing the same surgical stressor, older patients vary substantially in their recovery due to differences in baseline physiological reserve, comorbid conditions, social support, and environmental context.

A closer examination of these subgroups further highlights their clinical relevance. The low fluctuation group, despite having a relatively low baseline frailty level, experienced a notable increase at 1 month postoperatively. This transient deterioration may indicate reduced physiological resilience. Prior studies suggest that abrupt fluctuations in frailty may signal underlying instability and predict adverse events such as falls or rehospitalization more accurately than static frailty status [34]. For this group, interventions should aim to maintain functional stability by implementing prehabilitation, early mobilization, multimodal pain control, and prevention of iatrogenic complications [12]. In contrast, the high-improvement group demonstrated a steady recovery trajectory, likely reflecting

XSL•FO
RenderX

reversible functional impairments driven primarily by hip pathology. These patients may benefit from standard rehabilitation care without intensive resource input, allowing health care systems to prioritize those at greater risk. The high-deterioration group represents a clinically vulnerable subgroup with persistent decline, suggesting unresolved physiological or psychosocial deficits. Comprehensive geriatric assessments and tailored multidisciplinary interventions are warranted for this population, ideally guided by frameworks such as the World Health Organization (WHO)'s ICOPE (Integrated Care for Older People), which emphasizes multidomain support targeting mobility, cognition, nutrition, sensory function, and social engagement [35,36].

Based on the identified frailty trajectories, we developed a predictive model to support early risk identification and targeted intervention. Guided by the HEM, the model incorporated variables spanning individual characteristics, interpersonal networks, and living environment. Although some key predictors (eg, ADLs, comorbidity burden, and nutritional status) are conceptually related to domains of the FI, the multicollinearity analysis did not indicate significant statistical overlap among the predictors. This suggests that, despite conceptual relatedness, these variables do not represent redundant information from a statistical perspective. Nevertheless, these factors may partly reflect baseline vulnerability. Therefore, the model should not be interpreted as predicting frailty trajectory class membership entirely independent of baseline frailty severity. Instead, it is more appropriately viewed as an early risk stratification tool that integrates multidimensional information. Consistent with this interpretation, the SHAP analysis identified ADLs, number of comorbidities, number of teeth, age, and living environment as the top contributors to the model predictions.

In line with previous research [17,37], this study confirmed that impaired ADLs and a greater number of comorbidities were the strongest predictors of frailty deterioration. These variables represent fundamental aspects of functional dependence and chronic disease burden. Declining ADLs reflect a depletion of multisystem physiological reserves and may initiate a downward cycle in which the reduced function limits physical activity, weakens muscle strength, and accelerates frailty progression [37]. Similarly, multimorbidity contributes through persistent low-grade inflammation, polypharmacy, and cumulative organ damage, ultimately undermining mobility and physiological stability [38]. For individuals with impaired ADLs and multiple comorbidities, the early implementation of interventions such as individualized rehabilitation, optimized management of chronic conditions, and comprehensive medication review may be essential to interrupt this adverse trajectory [39,40]. In addition, age and teeth number were identified as important predictors. While age reflects irreversible biological decline, tooth loss serves as a modifiable marker of oral frailty. Reduced dentition in older adults impairs chewing function and nutritional intake, which in turn promotes sarcopenia and accelerates frailty [41]. These findings highlight the importance of incorporating oral health screening into perioperative management, along with timely interventions such as denture repair, chewing function training, and personalized nutrition support [14].

Among the identified predictors, living environment was the only environmental factor ranked among the top 5, highlighting its important role in frailty progression. Although the LEQ was a self-developed instrument, its core domains are conceptually aligned with the WHO age-friendly environment framework [42]. Previous studies have shown that environmental factors such as housing safety, community resources, social participation, and perceived environmental support are closely associated with frailty and its progression in older adults [43-45]. Notably, our findings demonstrated that living environment independently predicted frailty trajectories beyond individual-level characteristics. This finding is consistent with recent evidence showing that more positive perceptions of community environments are associated with lower frailty risk [46], as well as the findings of Mak et al [47], who reported sustained effects of environmental factors on frailty progression. For older adults undergoing hip surgery, environmental barriers after discharge may limit rehabilitation adherence and increase the risks of falls and readmission, thereby accelerating frailty progression. These findings emphasize the need to extend clinical care beyond hospital settings by incorporating environmental risk assessments into discharge planning and transitional care. Practical strategies may include predischarge home safety evaluations, caregiver education, and community linkage interventions to foster a more supportive recovery environment and reduce frailty-related risks [48].

In addition to the core predictors, the model identified several supplementary variables, including living arrangement, gender, nutritional status, drinking behavior, social support, albumin, and hsCRP. Although these variables contributed less individually, they enriched the understanding of frailty trajectories from physiological, behavioral, and demographic perspectives. These results indicate the importance of combining model-based risk identification with comprehensive biopsychosocial assessments to detect individualized frailty risk profiles and guide targeted interventions. Building on this, implementing a Fracture Liaison Service (FLS) may offer an effective integrative care pathway [49]. Through its structured components of assessment, education, intervention, and follow-up, Fracture Liaison Service enables continuous, coordinated management for older adults with hip fractures, supporting the transition from early risk prediction to precise clinical action.

Limitations

This study has several limitations. First, it was a prospective single-center study with a relatively small sample size, focusing exclusively on older patients undergoing elective hip surgery under general anesthesia, which may limit the generalizability of the findings to broader populations such as individuals receiving emergency surgery, regional anesthesia, or in other age groups. In addition, the relatively limited sample size for multiclass machine-learning modeling may increase the risk of overfitting and unstable feature selection despite the use of LASSO-based dimensionality reduction and internal cross-validation. Therefore, both the current prediction model and the associated web-based calculator should be considered exploratory and proof-of-concept tools rather than clinically deployable systems. Prospective multicenter external validation,

XSL•FO
RenderX

calibration assessment, and health-economic evaluation are warranted before routine clinical integration.

Second, a complete case analysis was used to handle missing data. Although the Little MCAR test suggested a completely-at-random mechanism and no baseline differences were observed between retained and excluded participants, departures from this assumption cannot be ruled out. If missingness were related to the severity of frailty or the presence of comorbidities, this could introduce bias and potentially affect trajectory classification and model performance. Therefore, the findings should be interpreted with caution. Future studies may consider more robust approaches for handling missing data, where appropriate, to further assess the robustness of the results.

Third, although the model incorporated multilevel predictors guided by the socioecological framework, some important but difficult-to-measure confounders, such as genetic predisposition or deeper physiological reserves, may have been missed. Future studies could leverage technologies such as wearable devices and multiomics approaches to improve measurement precision and expand variable inclusion. Finally, the 6-month follow-up period may capture only early or acute frailty changes and fail to reflect long-term trajectories. Longer follow-up and analytical methods such as competing risk models may help differentiate between temporary functional decline and persistent frailty, thus identifying critical intervention windows.

Conclusion

This study developed and internally validated a proof-of-concept machine-learning model to predict frailty trajectories within 6 months after hip surgery in older adults. Grounded in the HEM, the model integrated multidimensional predictors and showed good performance in discrimination, calibration, and clinical utility. Key contributing factors included functional status, comorbidity burden, oral health, age, and living environment. The model was translated into a web-based tool to support early identification and personalized frailty management; it currently serves as a foundational step. Comprehensive external validation across diverse clinical settings is strictly required before this tool can be deployed in routine clinical practice. These findings provide methodological and practical support for shifting perioperative care toward a proactive and individualized approach.

Acknowledgments

The authors thank Kaiqing Zhou (Shanghai Maritime University) for assistance with the data analysis and valuable discussion. They would like to express their gratitude for the funding provided, which enabled the completion of this study. During the preparation of this manuscript, generative artificial intelligence tools were used solely for English language editing and text polishing. The authors have thoroughly reviewed and edited the content and remain fully responsible for the accuracy, originality, and integrity of the final manuscript.

Funding

This work was supported by grants from the Department of Zhejiang Health Science and Technology Project Science and Technology (grant number 2025KY081).

Data Availability

The datasets generated and/or analyzed during this study are available from the corresponding author upon reasonable request. To ensure methodological transparency and reproducibility in compliance with the TRIPOD+AI (Transparent Reporting of a Multivariable Prediction Model for Individual Prognosis or Diagnosis—Artificial Intelligence) guidelines, the machine-learning pipelines (LASSO [least absolute shrinkage and selection operator] and Extreme Gradient Boosting–SHAP [Shapley Additive Explanations]) are publicly available on GitHub [50].

Abstract

Background: The theory of complexity in aging indicates that the complexity of sensor-derived physiological and behavioral signals reflects an older adult's adaptive capacity and, in turn, their frailty. Smart homes with ambient sensors offer a unique opportunity to longitudinally explore the complexity of older adults' indoor movement in a real-world setting. Here, we introduce a computational method to estimate behavior complexity from sensor data. We further conduct a multiple-methods case series to explore the relationship between entropy-measured smart home data complexity and older adult frailty.

Objective: This study aims to explore the relationship between entropy-measured ambient sensor data complexity and frailty in independent community-dwelling older adults.

Methods: The nature of older adults' indoor movement complexity is measured by quantifying the entropy of smart home data. Overall, 11 cases with persons aged 65 years and older were drawn from an ongoing smart home study to illustrate the method. We assessed weekly frailty for these cases using the Clinical Frailty Scale. For corresponding time ranges, we measured the complexity of smart home data using a fixed-width sliding window and an entropy-based complexity index (Rényi Complexity Index) built on a Universal Sequence Map (USM-Rényi). Descriptive statistics and graphical analysis were used to describe intraindividual frailty and sensor complexity change.

Results: The complexity of sensor-observed indoor movement does change over time in older adults as quantified by the computational method. In some individuals, these changes track with health transitions and frailty progression. The trends and monotonicity of complexity trajectories varied between cases. Overall, 3 of the cases demonstrated a negative association between frailty and complexity, while the association was not as clear for the other cases.

Conclusions: The complexity of older adults' smart home data is highly diverse. Changes in health and frailty influence indoor movement complexity. Although the findings suggest a relationship between frailty and complexity, confounding factors, such as home layout, visitors, external events, and technology disruptions, may influence sensor signals.

Introduction

Background

Frailty is a critical public health challenge among older adults globally. It is characterized as a clinically identifiable state of diminished physiologic reserve and heightened vulnerability to stressors and affects. An estimated 10% - 15% of community-dwelling individuals aged 65 years and older experience frailty, with the prevalence escalating to 51% among those aged 90 years and older [1]. This multifactorial syndrome, encompassing multiple impairments such as physical weakness, exhaustion, slow gait, low activity levels, and unintentional weight loss, elevates risks for adverse outcomes like falls, hospitalizations, functional decline, and mortality [1,2]. When unaddressed, frailty imposes substantial economic burdens, with frail older adult women incurring as much as 184% the health care cost of nonfrail older adult women [3,4]. Poor outcomes related to frailty strain health care systems and diminish quality of life [3-5].

Most older adults prefer to remain in their own homes and communities as they age. Despite this desire, age-related frailty and its sequelae remain a threat to their independence and quality of life. Older adults who are frail are more likely to present with atypical, nonspecific symptoms of acute illness, which include immobility, instability, incontinence, weakness, and delirium [6]. This can put them at risk for poorer outcomes

if such atypical signs are treated as the primary problem rather than merely the manifestation of underlying, seemingly unrelated illnesses. Thus, while frailty is a significant issue, it also functions as a gateway to a wide array of other salient health issues for older adults [7].

Two urgent challenges face older adults who wish to age in place: (1) needing validated methods to detect incipient frailty at home and (2) determining the best way to analyze these data for predicting frailty that focuses on the efforts of early intervention strategies [8]. This study addresses both challenges by exploring complexity as a feature of frailty in smart home sensor data. In the context of aging, the term "complexity" is often used to describe difficult problems that must be mitigated, making care more daunting [9]. While complex behavior is often seen as a challenge in caregiving, from a systems theory perspective, too little complexity may indicate diminished physiological adaptability. The theory of complexity in aging asserts that complexity is a direct indicator of the health of physiologic systems and aging reduces this complexity, resulting in frailty [10].

Sensors are ubiquitous in our world, and this reality is accompanied by an increasing interest in discovering indicators of human health using these sensors. These indicators serve a similar function as conventional biological and imaging biomarkers with less reliance on expensive lab equipment, visits to remote sites for time-consuming tests, or physically invasive procedures [11]. Digital biomarkers are valuable components of geriatric telehealth and precision medicine since these technologies support continuous, longitudinal, remotely delivered measurement of intraindividual changes in older adults' health [12]. Among this class of markers are behavior markers created from continuously collected sensor data, which open substantial opportunities to explore the complex dynamics of aging in an ecologically valid, real-world setting.

In this study, we enlist digital biomarkers to explore the relationships between behavior and frailty. This is increasingly important because the number of persons aged 80 years and older is expected to triple between 2020 and 2050 [13]. With the rise in age-related frailty and incidence of chronic conditions, meeting the health needs of older adults is increasingly burdensome. A review of unobtrusive frailty digital biomarkers concluded that passive infrared motion sensors, especially as part of a smart home, are the most promising type of embedded ambient sensor for detecting frailty [14]. Smart homes were promoted for their potential to uniquely inform individual responses to disease or treatment.

Older adults prefer digital biomarker technologies that minimally impose on their lifestyles [15]. From this perspective, digital behavior markers derived from completely passive monitoring (eg, ambient sensors embedded in residential environments) offer advantages over those measured via semipassive or active monitoring (eg, wearable sensors that must be routinely charged and positioned) [14]. Smart homes represent a passive biomarker technology that consists of ambient sensors to monitor movement and door interactions, combined with a computing infrastructure to collect, organize, and store the data [16]. The resulting time series data can be analyzed to understand the smart home resident's health status.

Prior Work

The theory of complexity in aging hypothesizes that measuring the complexity of a person's sensor-derived signals can indicate the underlying state of an older adult's adaptive capacity [17,18]. We analyze a person's behavioral signal complexity as an indicator of their adaptive capacity or functional reserve, referring to the capacity of their physiological and behavioral systems to maintain or regain function when perturbed. In a complex-systems view of aging, this reserve depends on the multiscale dynamics that are present between the system components [19]. These dynamics support homeostasis, the process that maintains internal stability while adapting to change.

In earlier work, researchers have investigated the use of multiscale entropy (MSE) to quantify complexity across time scales for physiological data. Bizovska et al [20] used MSE and Shannon entropy to analyze gait complexity as a mechanism for predicting fall risk in older adults. Castiglia et al [21] investigated the selection of MSE parameters that yield the best predictive probability in differentiating subjects with Parkinson disease from healthy subjects based on trunk acceleration patterns. Gao et al [22] use distribution entropy, which calculates the complexity of signal pattern distribution within a phase space representation, to determine whether pulse rate complexity is associated with corresponding cognitive decline in older adults.

Frailty is hypothesized to be an emergent state that arises from a critically dysregulated complex system [9]. In other words, the system dynamics may erode with aging and disease, causing complexity to decline and frailty vulnerability to increase. Evidence from cross-sectional studies suggests this process can be observed as a change in complexity in a diverse range of physiological and behavioral signals. For example, lower blood pressure interbeat interval complexity, when the beat-to-beat pattern becomes simpler and more uniform, is associated with greater frailty and dementia risk [23]. Similarly, lower moment-to-moment center-of-pressure complexity, such as simpler, more regular sway, during balance tasks is associated with increased future incidence of falls [24]. Reduced complexity of spontaneous brain activity, measured via the blood oxygenation signal, is associated with slower gait speed [25], and lower physical activity complexity and variance are associated with greater self-reported frailty [26] and mortality risk [27]. These examples suggest that reduced signal complexity may be a generalizable marker of physiologic decline.

Prior studies have measured the complexity of smart home data [28,29]. These earlier studies included complexity as one of a set of variables input to machine-learning models that were trained for specific tasks such as detecting visitors or predicting in-home movement [30,31]. Little is known regarding how within-person complexity, in isolation from other variables, evolves in relation to health outcomes over the long term. In a study by Schutz et al [28], Shannon entropy of refrigerator use was one of the strongest predictors of frailty (r=−0.25). However, this analysis did not explore the evolution of

XSL•FO
RenderX

complexity over time. A study by Takahashi et al [32] examined activities over a 2-year period and found that increased activity diversity manifested an inverse relationship with frailty. The findings support our hypothesis, but they are based on survey data rather than analysis of passively observed activity patterns.

Two prior studies applied complexity measures to data collected by the Center for Advanced Studies in Adaptive Systems (CASAS), the same data collection infrastructure used in this study. Specifically, Wang et al [30] estimated complexity using compression-based estimators to establish a theoretical limit on the predictability of indoor human mobility. In an earlier study by Gopalratnam and Cook [33], CASAS smart home data were analyzed with a Lempel-Ziv compression-based incremental parser to predict the resident's next interaction with the home. Although the smart home sites and analysis goals differed from this study, the prior work established the use of such behavior analyses from smart home data.

The common approach to predicting frailty leverages sources such as electronic health records and manually collected clinical data [34]. However, wearable sensors are increasingly accessible and offer a mechanism for passively sensing and detecting frailty [8]. Many frailty studies that analyze wearable data focus on predicting physical frailty components such as slowness and inactivity. These studies extract gait parameters such as cadence and indicators of time spent walking and standing [35,36]. One study instead analyzed Fitbit data that were collected while individuals performed an upper extremity function test [37]. While the primary component of these analyses is accelerometry, Merchant et al [38] combine these parameters with heart rate to analyze scripted movements such as sit-to-stand, walk, and climb stairs.

Wearable sensors have demonstrated the ability to sense and quantify changes in movement parameters that are associated with frailty. We focus here on monitoring activity and detecting frailty using ambient sensors in smart homes. Ambient sensors impose no user burden. Sensors collect data for multiple years on a charge, which results in continuous, uninterrupted monitoring of in-home behavior as a person's health status changes. Using wearable sensors, consistent multiday wear is challenging, and adherence varies with demographics and cognition [39]. While wearable sensors provide direct access to heart rate and gait parameters, the smart home sensors contribute context-rich information about location traces, sleep and wake routines, and activity patterns that are not easily modeled from wearable data [40]. Because we want to monitor uninterrupted longitudinal behavior patterns, we focus this analysis on data collected in smart home settings.

To address this knowledge gap, we present an exploratory case series investigating how the complexity of older adults' indoor movement patterns, as captured by the CASAS smart home, changes over time in relation to changes in their health status. Considering that this relationship between complexity and frailty has been observed across a diverse range of seemingly unrelated physiologic and behavioral signals, we hypothesize that changes in the complexity of time series obtained from smart home sensors are similarly associated with changes in health status and frailty of the older adult smart home occupant.

The case series design prioritizes investigation of intraindividual interpretation and allows us to integrate each participant's clinical narrative into the analysis. To promote replication of methods and application to new data, we make the analysis and visualization tools publicly available for the community to use in the calculation of sensor-derived behavior complexity.

Methods

Overview

We performed a multiple-methods exploratory case series, combining participant narrative and qualitative nursing data with complexity analysis of smart home sensor time series data to contextualize intraindividual changes in complexity of indoor movement. A case series analysis was chosen because the method is useful for exploring intricate, real-world issues in novel ways, especially when triangulating data from different sources to discover differences and similarities across similar cases. The method fosters a more nuanced, valid, and actionable understanding of the cases under study.

Participants

We used secondary data from sensors installed in the homes of community-dwelling older adults between October 2016 and December 2022 as part of the ongoing clinician-in-the-loop smart home research study [41]. To be included in the clinician-in-the-loop study, participants had to be aged 60 years and older, have at least 1 chronic condition, and had to be proficient in English. For this case study series, we applied the additional criteria of living alone without pets for the entire duration of the data collection and collected a minimum of 9 months of smart home data. Cases were further excluded if a majority of the days and sensors were missing. The resulting sample consisted of 11 cases, representing a balance between stable participants and those who exhibited frailty transitions. For this case series, each participant is considered as 1 case. Among these participants, cases 8 through 10 exhibited constant frailty scores, while the others experienced frailty that fluctuated throughout the data collection.
