Participant cases included in the present analysis lived in independent living apartments in continuing care retirement communities. Most cases' ages were in the range of 80 to 89 years, although 2 were aged 70 - 79 years and 1 was aged 90 - 99 years. All included cases identified as non-Hispanic White, and 7 of the cases identified as women. Information summarizing participants, their chronic health conditions, and their home characteristics is provided in Table 1.

XSL•FO
RenderX

Table . Demographics and data characteristics for each participant case.

Case	Age[a] (years)	Sex	Home type	Sensors	Days	Window size[b]	Chronic conditions
1	80 - 89	Female	1-bedroom apartment	15	310	25,159	CV[c], NM[d], Pain[e]
2	70 - 79	Female	1-bedroom apartment	13	416	63,419	CV, Pulm[f], Pain
3	80 - 89	Female	3-bedroom duplex	20	366	19,714	CV, Pulm, NM
4	80 - 89	Female	1-bedroom apartment	13	349	33,358	CV, Pulm, NM
5	80 - 89	Male	1-bedroom apartment	15	629	60,800	NM, Pain
6	80 - 89	Female	1-bedroom apartment	12	571	28,951	CV, Pulm, NM, Pain
7	80 - 89	Female	1-bedroom apartment	14	385	28,182	Pain, CI[g]
8	70 - 79	Male	2-bedroom duplex	22	330	49,303	CV, NM, Pain
9	80 - 89	Female	Studio apartment	11	354	35,310	CV, Pain, CI
10	90 - 99	Male	1-bedroom apartment	12	264	18,951	CV, NM, Pain
11	80 - 89	Male	1-bedroom apartment	13	286	34,903	CV, Pain

[a]To preserve privacy, age is given as a range.

[b]Sliding window size was determined by the maximum biweekly count of sensor messages (excluding OFF and CLOSE) observed in the participant's data.

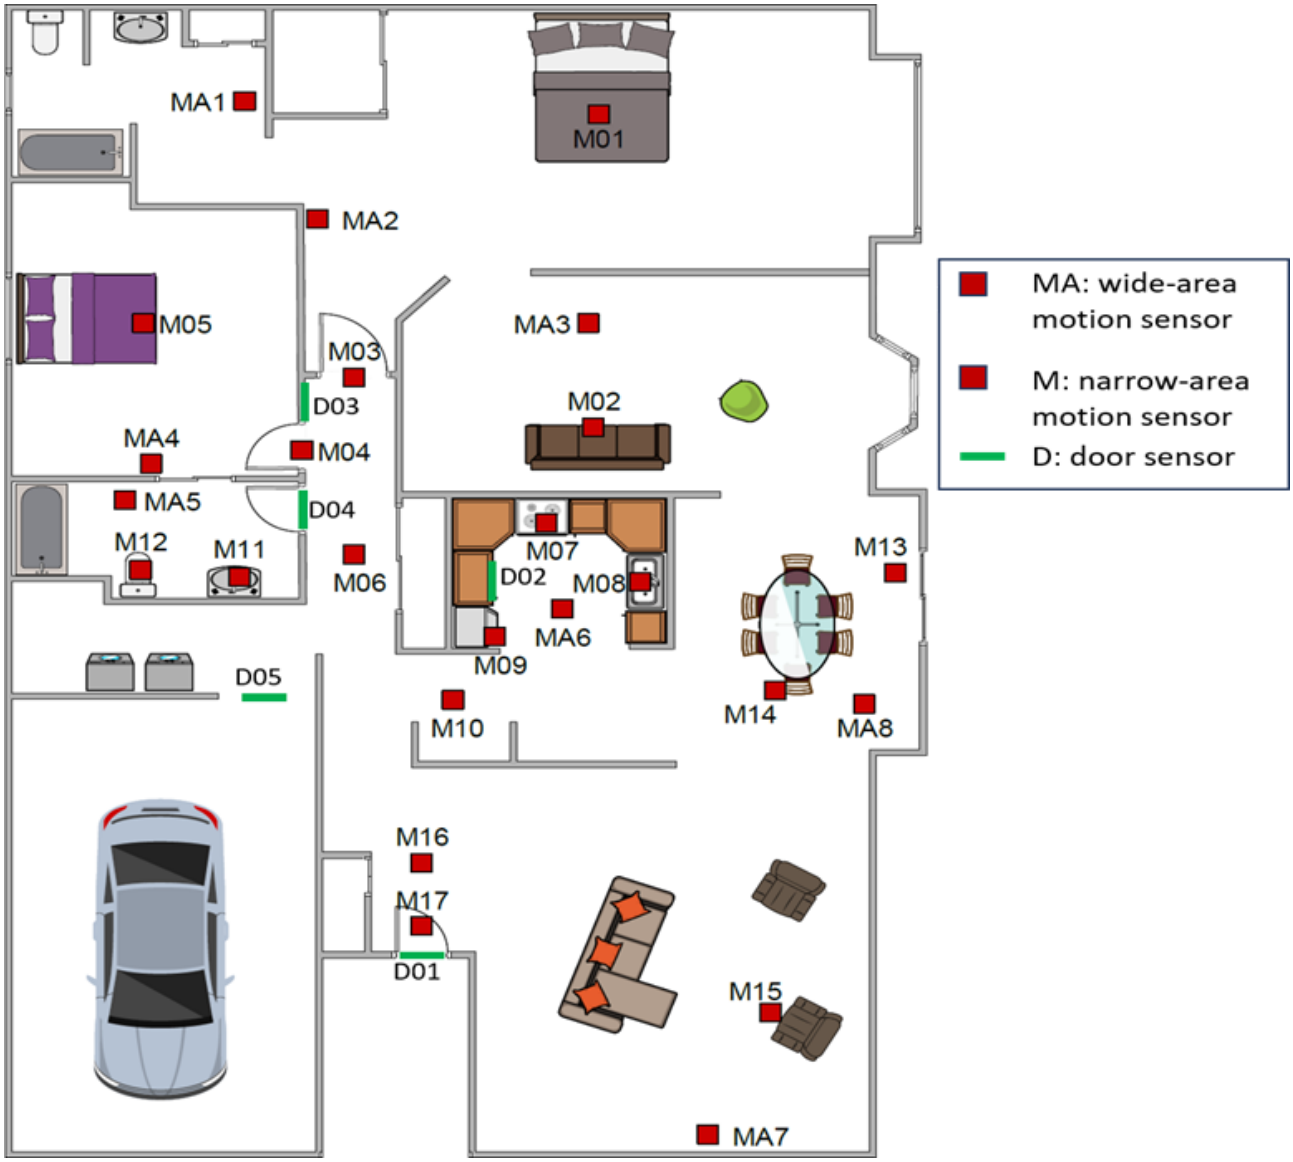
[c]CV: cardiovascular.

[d] NM: neuromuscular.

[e] Pain: chronic pain.

[f]Pulm: pulmonary.

[g]CI: cognitive impairment.



CASAS Smart Home

The CASAS smart home contains passive infrared motion detectors, light, magnetic door use, and temperature sensors. These sensors were installed strategically throughout each house to capture activity in critical locations (Figure 1). At least 1 motion detector with a 360^{o} view was installed in each room. Additional motion detectors with a narrower field of view (approximately 1 m in diameter) were positioned in areas of high use, such as the bed, sinks, toilet, and frequented furniture (eg, preferred living room chair). Because floor plans, furniture layouts, and daily routines differed across each home, the number of sensors installed for included cases ranged from 11 to 22.

CASAS sensors send messages containing their readings to a middleware layer resident on a Raspberry Pi [16]. Architecture components communicate using a Zigbee wireless mesh. The middleware publish and subscribe manager allows hardware components to publish and receive messages. And annotates sensor readings with the corresponding sensor identifier and timestamp. All collected data are encrypted and securely transmitted to a password-protected server for storage and analysis.

XSL•FO
RenderX

Figure 1. Location of sensors in a Center for Advanced Studies in Adaptive Systems smart home.

We examined data collected from the passive infrared and door-use sensors. Each sensor samples the environment at 1.25 Hz. Rather than report the state at a constant frequency, the sensors record data when a change in state is sensed (eg, a door is opened, motion is detected). Once triggered, the sensor sends a message reflecting the new state to a central relay, which labels each message with the sensor identifier and timestamp, then transmits the data to a secured database. The resulting dataset is a timestamped series of binary messages (“ON” or “OFF” for motion sensors, “OPEN” or “CLOSE” for door sensors) indicating the time and location of the sensor reading in the home. Because an ON message from a motion sensor is followed by an OFF message (marking the end of movement within the sensor’s field of view or lack of activity for 1.25 s), both ON and OFF messages artificially inflated the regularity of the data sequence. Following previous literature measuring the entropy of smart home data [30,42], we excluded all OFF messages from motion sensors and all CLOSE messages from door sensors. Example deidentified CASAS datasets are available online [43].

Clinical Data

For each participant, nurse researchers conducted an initial comprehensive geriatric assessment, including functional status in activities of daily living (ADL) and instrumental activities of daily living (IADL), current health diagnoses, health history, medications, fall history, psychosocial supports and family presence, assistive device use, review of body systems, and personal demographic history. Participants then received weekly follow-up telehealth calls from a nurse researcher to assess for any changes in health or function from baseline. Weekly nursing data included, but was not limited to, vital signs, pain, sleep quality, psychosocial well-being (including the presence of visitors), changes in ADL and IADL status, and a brief review of physiologic systems and daily routines [41].

Although frailty was not measured as part of the primary data collection, the clinical data collected during the study provided information to retrospectively estimate weekly frailty using the Clinical Frailty Scale (CFS) [44]. The CFS is a 9-point scale (1=very fit to 9=terminal illness) designed to guide a clinician in assessing a holistic picture of a person’s frailty status using

XSL•FO
RenderX

elements of a comprehensive geriatric assessment, including overall activity level, functional dependence, and management and control of chronic condition symptoms [45]. Two CFS-trained nurse scientists reviewed the clinical data for each participant and assigned a frailty score for each week of data collection (Table 2). Changes in ADL and IADL independence, use of a new assistive device, and descriptions of increasing fatigue or "slowing down" were the most common health changes associated with an upward shift in the participant's CFS score.

Table . Example Clinical Frailty Scale codebook with scores for case 4.

Week[a]	Date (2017)	CFS[b] score	Rationale
45	July 24	5	No change
46	July 31	5	No change
47	August 7	5	Decreased activity, increased weeping lower legs
48	August 14	6	"I have to be careful not to fall"
49	August 21	6	Considering assisted living but hiring in-home help
50	August 28	6	No change
51	September 4	6	Losing weight, legs improving
52	September 11	6	Legs continue weeping due to heart failure
53	September 18	6	Began using pursed-lip breathing, moving less
54	September 25	6	Doctor's visit, medication change
55	October 2	6	Legs improving, taking diuretic

[a]Weeks 1 - 44 (CFS score: mean 4.9, SD 0.33; range 4 - 5); weeks 56 - 60 (CFS score: mean 6.4, SD 0.89; range 6 - 8).

[b]CFS: Clinical Frailty Scale.

Data Preprocessing

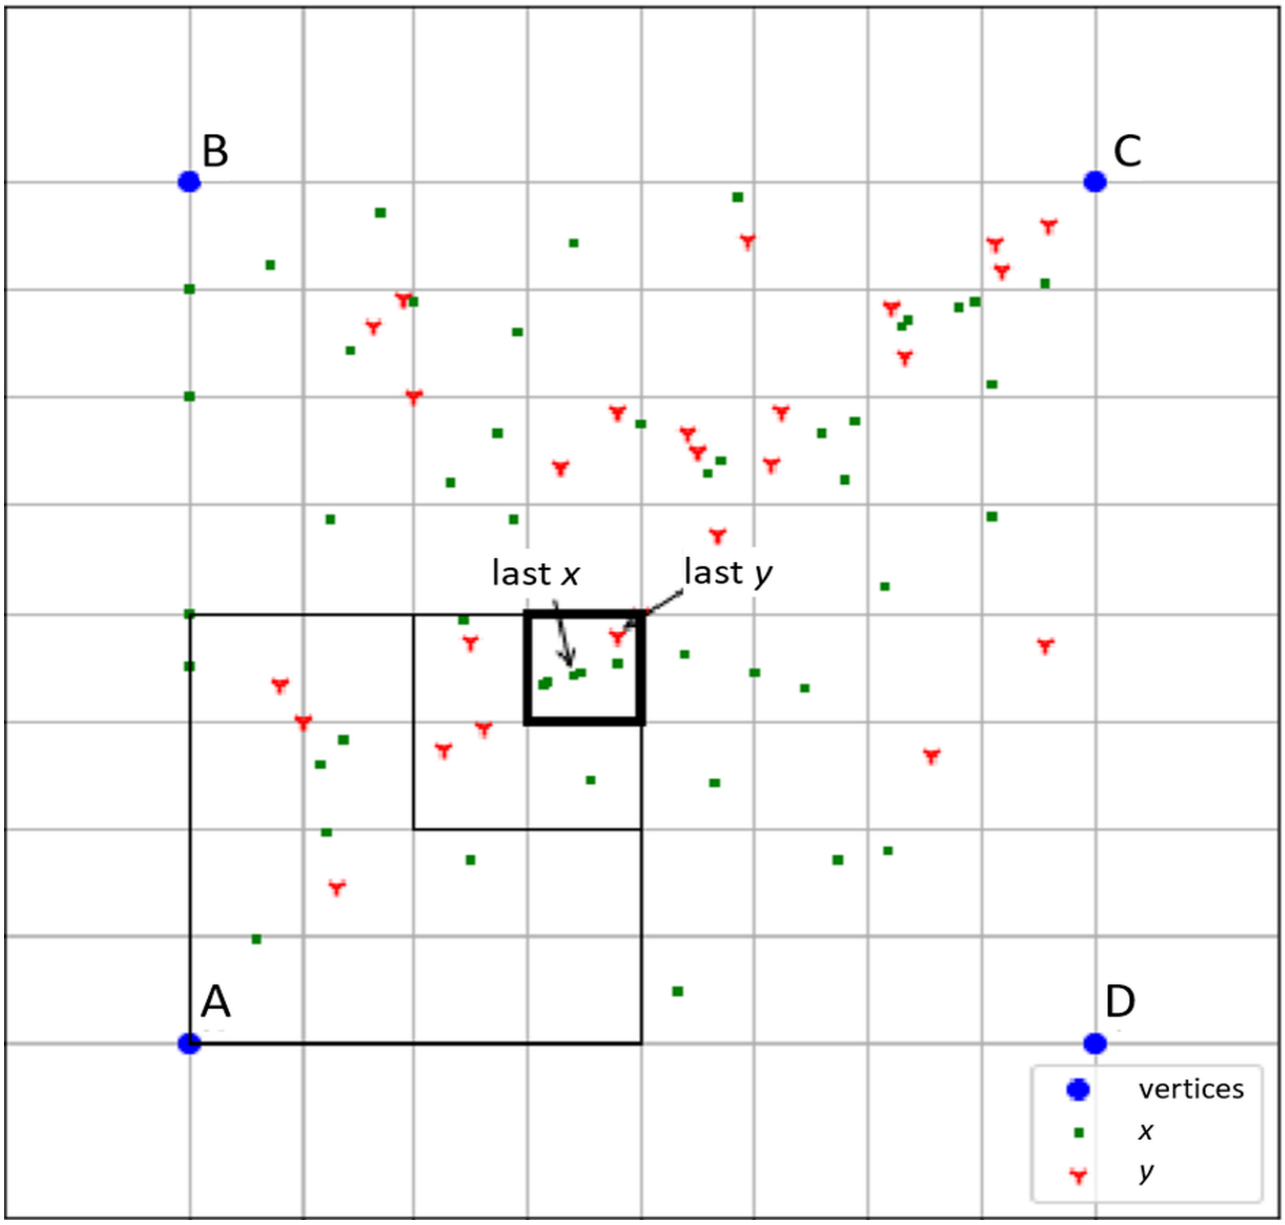
Because smart home data were collected in real-world settings over extended periods, we needed to address missing and noisy data. We screened each participant's sensor data for evidence of sensor malfunctioning, extended absences, and other issues. Periods associated with participant absence for more than one night (eg, vacation or hospitalization) were excluded from the analysis. Additionally, any periods where all sensors did not report readings, regardless of explanation, were excluded. Periods with no messages from a given sensor were cross-referenced with battery data from that sensor to confirm whether the absence was due to a change in behavior or a sensor malfunction. Sensors missing >50% of the observation time over one or more consecutive days were excluded. Sensors missing more than 50% of the observation period were either excluded or they were included, and the time associated with that sensor's absence was excluded.

The varying size of the homes and the corresponding number and density of sensors impact the scale of Rényi Complexity Index (RényiCI) values we observe in each home. A cross-sectional study would require that sensors be grouped into larger, consistently sized sets or that the values be normalized. For this study, we are interested in within-home RényiCI changes, so no adjustments are made to the per-home RényiCI scales. Because the sensors report binary state (motion ON or OFF, door OPEN or CLOSED), the raw sensor values are not normalized.

Some of the participants included in this study were enrolled during the onset of the COVID-19 pandemic, which had a dramatic global impact on daily activities. For those participants, if the majority of a participant's data were collected after the pandemic onset, data from before March 16, 2020, were excluded. Similarly, for participants with most data collected before the pandemic, we excluded data from March 16, 2020, onward.

Data cleaning included the removal of sensor data from analysis for sensors sending "error" signals, which can occur when low battery health or technical issues occur during installation. Only 2 homes were affected by this: case 1 (dining room area sensor, hallway, bathroom sink, and door for the primary bedroom) and case 5 (entry door, refrigerator, and bathroom area sensor). After data cleaning procedures were applied, the series of timestamped sensor messages was coded based on the sensor identifiers, resulting in a time series of discrete (categorical) sensor states. These discrete-valued series were then used to compute the complexity of sensor state transitions over time.

Complexity Measurement



Understanding patterns in human behavior, especially those that signal changes in health or frailty, requires tools that quantify how predictable or irregular those behaviors are over time. One such method is based on entropy, a way of measuring complexity or unpredictability in a sequence of events. Almeida and Vinga [46] introduced a technique to calculate this complexity using a Universal Sequence Map (USM). This approach turns a sequence of events (eg, daily activities recorded

XSL•FO
RenderX

in a smart home) into a set of coordinates in a multidimensional space. These coordinates reflect how often and in what sequence specific symbols (eg, messages from home sensors) occur relative to one another. Once the sequence has been mapped to this space, the method estimates how densely packed these points are in space using the kernel density estimation statistical technique. The resulting density provides insight into whether the behavior is highly repetitive (low complexity) or highly varied (high complexity). Highly repetitive behavior may, for example, reflect a person moving primarily between the living room and bathroom each day. A more complex behavior will vary the daily sequence and perhaps more frequently introduce additional areas, including the guest room, the garage, and the front door to leave the home.

Figure 2 illustrates the process of creating a USM. Unique sensor readings are converted to symbols (A-D). USM coordinates are calculated by assigning each unit symbol in the sequence to a position in a multidimensional space. The positions are defined so that each symbol is equally distant from the others, ensuring that no symbol is biased in how the space is structured. The number of dimensions of the space is chosen so that each distinct symbol can be uniquely represented using binary digits. The sequence is processed forward (considering prior context) and backward (considering subsequent context), and the 2 resulting maps are merged to capture bidirectional structure in the behavior.

Figure 2. Plot of 2 sequences in a Universal Sequence Map. The last 4 symbols of sequence x are *ACCA*, and the last 4 of sequence y are *CCCA*. The highlighted subquadrant contains the coordinate of the sequences' last symbol, *A*.

The resulting space creates a unified framework to measure the complexity of sequences from the resulting coordinates. To quantify the complexity of these mapped sequences, Vinga and Almeida [47] introduced a method that computes Rényi entropy, a generalization of Shannon entropy, from the density of the USM coordinate distribution. This approach is particularly

XSL•FO
RenderX

effective for relatively short sequences, such as those representing daily behavior in smart homes.

Since the idea of entropy was introduced in information theory, many variations have been introduced to measure complexity in different contexts. These measures vary by the type and quantity of data they process, their sensitivity to noise, and their assumptions about the underlying state space distribution. An ideal measure of sensor-based time series complexity is one that tends toward a minimum value for both deterministic and random sequences while handling varying alphabet sizes and being sensitive to changes in complexity over short sample lengths. Rényi entropy of USMs was selected for our analysis as a method that meets these constraints.

A key strength of this method is its flexibility: it can emphasize either common or rare patterns, depending on how the parameters are configured. Importantly, the frequency of any subsequence of any length can be estimated by analyzing how dense different regions of the USM space are. The kernel size (ie, the size of the region considered) controls the length of the subsequences being emphasized. We use this principle to estimate Rényi entropy at multiple scales, where each scale corresponds to a different behavioral timespan or sequence length. This flexibility enables a multiscale view of behavioral complexity, which we refer to as the RényiCI. An in-depth tutorial and code are provided online [48].

Statistical Analysis

Because this case series investigates how the complexity of motion sensor transitions, representing indoor movement trajectories, evolves over time, we computed RényiCI for each participant using a sliding window approach with a fixed window size, *n*. The actual RényiCI values will shift with the number of sensors in the space and the window size; thus, the values should be examined for change within a single home across multiple time points. Higher RényiCI values indicate more complex behavior, while lower values suggest simpler, more predictable patterns. The sliding window method evaluates the time series in overlapping segments: starting with the first *n* data points, it computes summary statistics, shifts the window forward by a set number of steps, and repeats the process.

To ensure each window captured both routine cyclic behaviors (eg, weekly housekeeping) and short-term variations, we defined each participant's window size as the maximum number of sensor messages observed within any 2-week period (Table 3). The window was advanced using a step size equal to one-quarter of the window size.

[a]Spearman rank correlation.

[b]CoV: coefficient of variance.

[c]Coefficient of variance was computed as the SD/mean.

[d]KS: Kolmogorov-Smirnov distance.

[e]Correlation is not provided because CFS is a constant.

To examine how the complexity of patterns relates to frailty status, we visualized RényiCI values using time series plots and categorical scatter (jitter) plots. Because RényiCI values can vary in scale depending on the number of sensors and the window size, we applied normalization within each case to enable comparison. To assess temporal fluctuations in complexity, we also computed the first-order difference of the normalized RényiCI sequence: ΔRenyiCI`t=RenyiCI`t-RenyiCI`t-1. Here, ΔRenyiCI`t represents the change in normalized complexity between consecutive windows.

To evaluate whether these complexity estimates varied systematically over time (in comparison to random changes in complexity), we applied Kolmogorov-Smirnov (KS) tests and runs tests to each participant's sequence of RényiCI values under the null hypothesis of randomness. The KS test checks whether the complexity values follow a normal distribution, as would be expected with random data. The runs test looks at the order of values in the sequence, rather than just the distribution, to determine if they appear in nonrandom patterns. Computation of USM-based RényiCI values was conducted in Python (version 3.9; Python Software Foundation) using our pyusm library [48]. This open-source package is publicly available and includes tools for computing USM, USM-Rényi, and generating 2D USM visualizations.

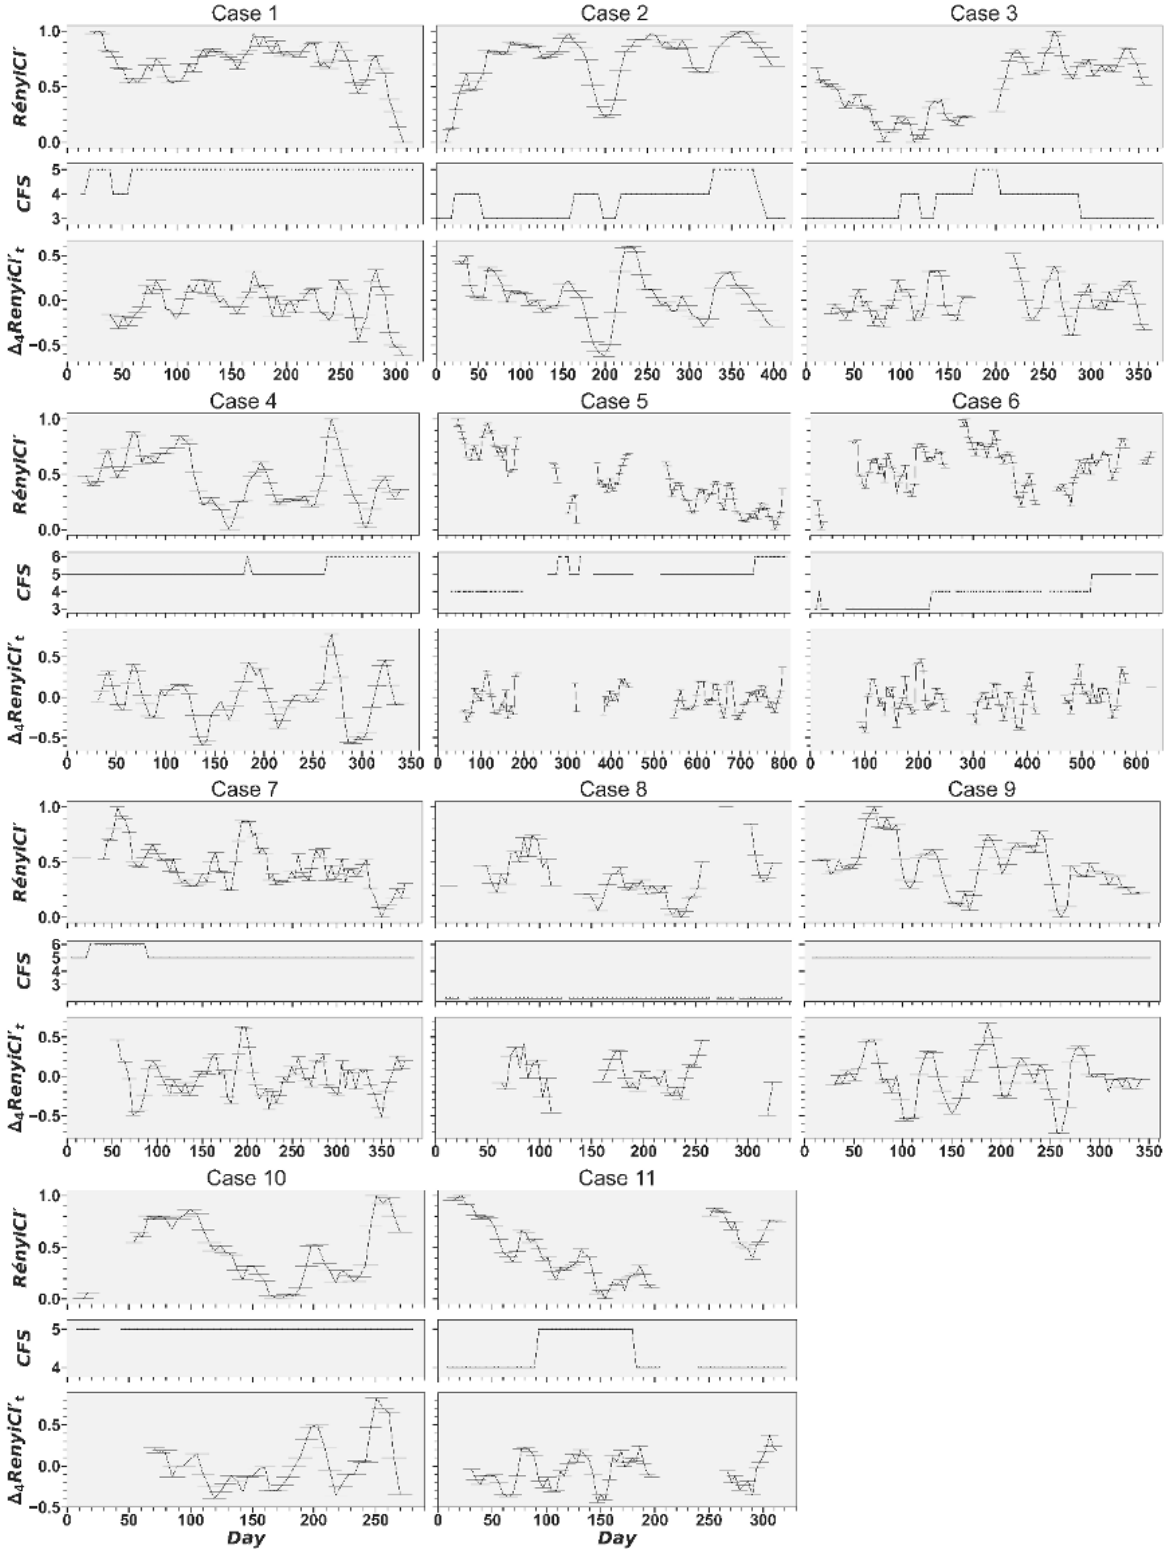
Finally, to resolve ambiguous quantitative results, sequential explanatory techniques were used. Quantitative results were reviewed alongside frailty scores assigned to each week of

XSL•FO
RenderX

nursing narrative documentation, which included written text about participants' physical and functional health recorded during weekly phone calls and monthly home visits. RényiCI complexity values were compared to recorded CFS scores. Lower complexity values combined with higher CFS scores meant the participant was frailer.

Ethical Considerations

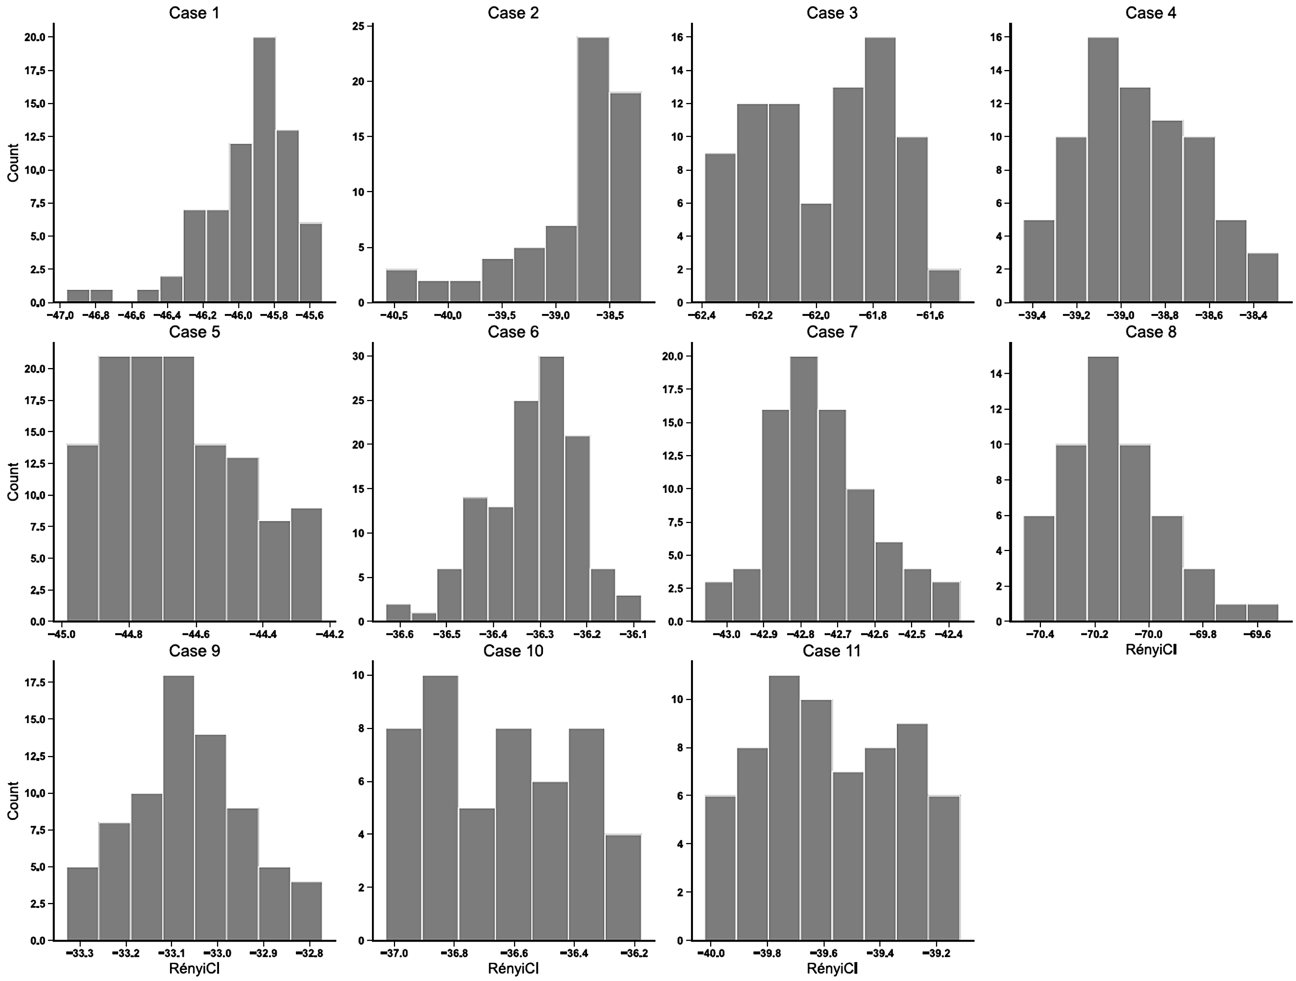
The Washington State University Institutional Review Board approved the presented secondary analysis (protocol 18764) and parent study (protocol 15412). All participants provided informed consent, and their data were deidentified and securely managed for analysis. Participation was voluntary and without compensation.



Results

Distributional Characteristics and Statistical Testing

Figure 3 presents time series plots of normalized RényiCI, frailty scores, and first-order differences in normalized RényiCI for each case. In the plots, time is measured in observation days. Summary statistics of overall RényiCI, KS, and Spearman rank correlation values are reported in Table 3. The shape of the RényiCI distributions varied notably across cases. Case 9 exhibited the only unimodal, symmetric distribution (Figure 4), while the remaining cases showed skewness or kurtosis. Cases 1 and 2 were strongly left-skewed, while cases 3, 5, 10, and 11 displayed low kurtosis. Cases 3 and 11 also showed bimodal distributions. Despite this heterogeneity, only case 2 showed a statistically significant deviation from a random normal distribution (P=.006) based on the KS test of normality.



XSL•FO
RenderX

Figure 3. Plots of complexity, frailty, and complexity change as a function of time. Lower values reflect less complexity. Δ_4RényiCI' represents the value difference between sliding windows at times *t* and *t-4*. CFS: Clinical Frailty Scale; RényiCI: Rényi Complexity Index.

XSL•FO
RenderX

Figure 4. Histograms of RényiCI values.

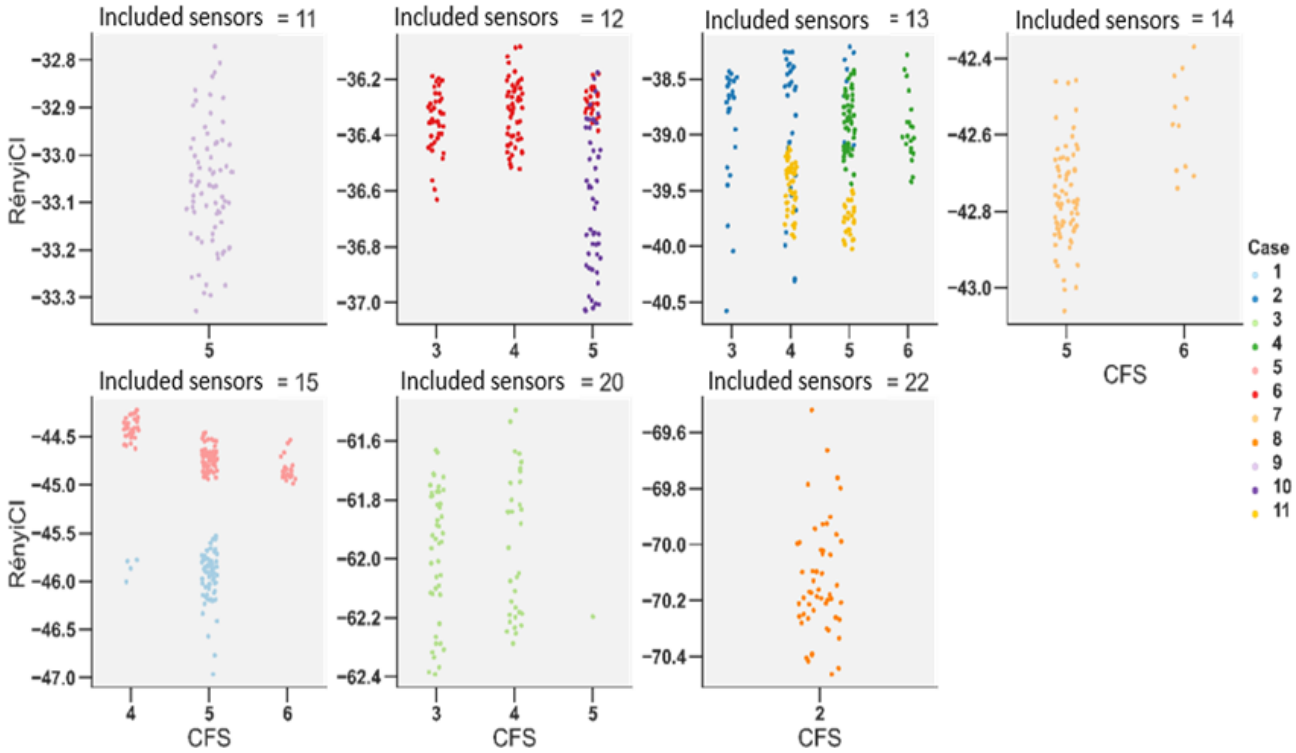
Overall, case participants ranged from "fit" (CFS=2) to "living with moderate frailty" (CFS=6), although the trajectories of frailty within each participant varied considerably (Figure 3). For example, cases 2, 3, 7, and 11 all experienced periods of elevated frailty but all recovered and returned to baseline by the end of observation. Cases 4, 5, and 6 were the only cases that increased in frailty over time, ending frailer than their baseline. Most cases exhibited 2 - 3 transitions in frailty over time, with the extreme being case 2 with 7 frailty transitions.

While the goal of this study is not to directly infer CFS from RényiCI values, we note that Table 3 shows a significant correlation for all cases that have variable frailty scores. While they are significant, the correlations are mostly quite small. The overall correlation for all combined values is ρ=−.055 (P<.001). These results indicate that while a relationship between behavioral complexity and frailty can be observed, other factors must be considered when assessing a person's frailty from smart home sensor readings.

As Figure 3 demonstrates, trajectories of sensor complexity were similarly varied. RényiCI values for cases 1, 5, 7, and 9 exhibited downward trends over time, while cases 3 and 6 demonstrated an overall positive trend. Case 11 showed a concave shape with a general downward trend in sensor RényiCI for the first half of the data, followed by a general upward trend. The remaining cases exhibited nonmonotonic fluctuations. In each case, RényiCI values and frailty trajectories aligned with frailty scores assigned by the CFS-trained researchers during qualitative processing of clinical data.

Frailty-Complexity Associations

The relationship between frailty level and sensor data complexity also varied from case to case. Figure 5 shows jitter plots of RényiCI values by CFS score grouped by the number of sensors installed in the home. Cases 5 and 11 exhibited a negative trend between complexity and frailty, while cases 3 and 7 demonstrated a mostly positive trend. The range and mean of USM-Rényi values shift farther from 0 as the number of sensors in the home increases. The range of RényiCI for the home with the fewest sensors (11 sensors) spanned approximately −34 to −32, while in the home with the most sensors (22 sensors), the range extended from about −71 to −69.



Initial runs tests applied to the full sequence of RényiCI values were statistically significant (P<.001) for all participants, suggesting nonrandom temporal ordering. To reduce potential autocorrelation introduced by overlapping windows, we repeated the runs tests on a downsampled sequence using every fourth window. Under this condition, only cases 3 (P<.001) and 5 (P=.002) remained statistically significant.

To account for these differences, Table 3 also includes the coefficient of variation (CoV) that normalizes the RényiCI SD by the mean for each case. Cases 6, 7, and 8 exhibited the least

XSL•FO
RenderX

amount of relative variability in RényiCI (CoV=0.003), while case 2 exhibited the highest (CoV=0.015).

Figure 5. Categorical scatter (jitter) plot of RényiCI values by frailty, grouped by sensor count and case. CFS: Clinical Frailty Scale.

The cases with statistically significant nonoverlapping runs tests, cases 3 and 5, also represented the clearest long-term monotonic trends. Case 3 demonstrated an overall increase in complexity between the start and end of her data, while case 5 demonstrated an overall decreasing trend. The only RényiCI distribution with a statistically significant KS test, case 2, had some of the most extreme variation among the cases, with an extremely left-skewed distribution and a coefficient of variation 5 times greater than the smallest coefficient of variation among the cases. To explore possible explanations for the diverse patterns of frailty and complexity trajectories observed, we compared the frailty and complexity trajectories of the cases with contextual information derived from the nursing assessment records.

Data selection for cases 2 and 3 started at the beginning of the COVID-19 pandemic shutdowns. The horizontal bars in Figure 3 represent sliding window durations (in days). For both cases, the shortest windows are at the beginning of the time series. The shorter sliding window durations during this period likely reflect increased in-home activity, with participants generating more sensor events due to spending more time indoors during COVID-19 lockdowns. However, where RényiCI increased steadily over the coming months for case 2, RényiCI decreased steadily for case 3 (Figure 3).

Cases 2 and 3 also showed pronounced shifts in RényiCI midway through the observation period. For both cases, this period roughly correlates to a time period of hazardous air quality caused by continued wildfire smoke over the course of about a month. However, the steep dip in RényiCI for case 2 occurring between days 186 and 212 is short, while for case 3, the sharp increase in RényiCI around day 231 appears to be a vertical shift in their average complexity that continues for the rest of her data.

Case Narratives

Case 2

A woman in her 70s with congestive heart failure and mild asthma. She was independent at baseline (CFS=3) and in stable health, which is consistent with the increasing RényiCI values plotted in Figure 3 at the beginning of data collection. This participant experienced 3 episodes of worsening fatigue and shortness of breath (days 20 - 54, 160 - 215, 258 - 397), which impacted her ADLs and IADLs and contributed to transient increases in frailty. During the first episode, the nurse's report indicated that "walking has been much more taxing on her this past week. She will walk around the building today but runs out of energy very quickly... her fatigue level has increased significantly over the past week." During the second episode, the nurse reported "the last 3 days she noticed … more soa [sic, shortness of air] and tired[ness]." During the third episode, the nurse recorded a direct quote from the participant indicating that she had "absolute fatigue beyond anything I've experienced." Two of these periods coincided with substantial troughs in RényiCI, suggesting alignment between behavioral simplification and functional decline. The primary movement patterns manifested in the CFS score and measured by RényiCI (ie, mechanisms of interest) were less in-home overall activity and less time spent out of the home on walks and social activities (frequency and duration). This case also had the highest variability in complexity and was the only one with a statistically significant KS test result. Possible gerontological clinical actions informed by these results include recommendations to follow up with the cardiologist, referral to a pulmonologist, and referral

XSL•FO
RenderX

to senior services to determine whether the patient qualifies for in-home care support services.

Case 3

A woman in her 80s with cardiovascular disease and allergy-induced asthma. Initially independent, she experienced progressive health decline, including 2 hospitalizations for acute hypertension and dyspnea. Her frailty peaked after the second hospitalization during a period of wildfire smoke, when she relied full-time on a walker for ambulation. Nursing records include statements during this timeframe like "no energy, has not left the house since Thursday [4 d]" and "overall health is declining." Following physical therapy, she recovered and reported no activity limitations by day 295. The nursing record indicated that she "went shopping" and had "several visitors over" across multiple days of the week. Her RényiCI trajectory reflected this pattern. As shown in Figure 3, the RényiCI values initially show a steady decrease aligned with the health issues. After she received treatment and improved her ambulation and functional independence, the RényiCI values showed a steady rise in complexity. Notably, this case showed a strong monotonic increase in RényiCI and passed the runs test even under downsampling. This result provides evidence that the pattern of increasing frailty, followed by improvement after treatment, is distinct and nonrandom. The mechanism of interest impacting her RényiCI trajectory was a renewed increase in time spent out of the home (frequency and duration) concurrent with an increase in the number of visitors. The case exemplifies how RényiCI trajectories could help clinical gerontologists understand treatment efficacy through novel remote patient monitoring tools that include sensor monitoring and associated behavior patterns.

Case 5

A man in his 80s with Parkinson disease. He began with mild frailty (CFS=4) and was independent but slowed by symptoms. Over time, he required increasing assistance with ADLs and IADLs. Nurses recorded that he began to require assistance "getting compression sock on in the morning and off at night" and "needing help with laundry and housekeeping" and that his daughter began assisting with bill paying. He experienced multiple hospitalizations and rehabilitation stays and ultimately progressed to moderate frailty (CFS=6). The moderate frailty score was based on the nurse reporting "unsteady gait" and that he "has cracked ribs from a fall last week" and his "symptoms of PD [are] increasing, [and] noticeable upon observation." His RényiCI trajectory followed a corresponding decline, with complexity peaking early and then falling across successive rehabilitation episodes. This case also exhibited a significant runs test and a clear downward trend in complexity. The mechanism of interest in this case was more overall time spent in his recliner chair, more nighttime sleeping in the recliner chair, and the decreased time spent out of the home (frequency and duration). This case illustrates how RényiCI trajectories may support automated smart home monitoring aimed at detecting increasing frailty upstream so interventions can be implemented.

Cases 4 and 10

Both cases involved sustained or increased caregiving over time. In case 4, RényiCI peaked just before caregiving began and declined thereafter. Case 10, who had consistent caregiving throughout, showed generally lower complexity than case 6, who lived alone with the same number of sensors. These comparisons suggest that increased caregiving frequency does not necessarily lead to increased behavioral complexity as measured by RényiCI. Older adults with consistent professional caregiving are likely to experience slower rates of decline due to the intentionality of caregiving, which aims to extend independence through building physical, functional, and cognitive strength. Findings could inform care planning and resource allocation.

Discussion

Principal Results

This study introduces and applies a novel entropy-based algorithm, the RényiCI, to quantify behavioral complexity from smart home sensor data in older adults. Using a USM framework with multiscale Rényi entropy, our method captures subtle temporal dynamics in sensor-derived movement sequences. In this exploratory case series, within-person indoor-movement complexity, as exhibited by RényiCI values, fluctuated over time. In several cases, these fluctuations coincided with frailty changes.

Across 11 participants, we observed diverse complexity trajectories, ranging from steady increases, steady declines, and concave patterns to nonmonotonic fluctuations. Case-level analysis revealed that greater fluctuations in complexity were frequently aligned with periods of functional decline or recovery. Notably, 2 cases (3 and 5) exhibited statistically significant nonrandom patterns in complexity over time, confirmed by runs tests on downsampled data, and showed clear monotonic trends in behavior complexity that matched health trajectories. Only one case (2) showed a RényiCI distribution that deviated significantly from normality, corresponding with extreme within-person variability and periods of worsening frailty. Scatter plots further revealed heterogeneous associations between complexity and frailty, with both positive and negative trends across cases. Importantly, increased caregiver presence was not associated with greater behavioral complexity, suggesting that RényiCI may reflect intrinsic changes in individual functional capacity rather than external support.

Changes in CFS scores fluctuated in alignment with changes in RényiCI values for some cases, like 2, 3, 6, and 7. These cases may suggest that changes in frailty do impact the person's behavioral routine and regularity. However, in cases 8 through 10, we observed changes in RényiCI values despite the lack of change in frailty scores. This observation highlights the fact that our findings provide 1 set of indicators of changes in frailty, but should not be analyzed in isolation. Other factors, such as visitors, seasonal effects, and external events, can also impact behavioral routines. These should be controlled for when examining frailty as a function of changes in RényiCI.

XSL•FO
RenderX

While observed repetitive behavior may correlate with frailty, the relationship is not one-to-one. Reduced complexity of movement often, but not always, aligns with frailty progression. Repetitive behavior can signal frailty because it reflects narrowed activity routines, reduced introduction of new routine elements, and corresponding reduced adaptability. At the same time, we note that complexity is multifactorial. Other influences, such as visitors in the home, home layout, and external events, also affected the entropy measures. The results showed nonmonotonic relationships in those cases. To interpret complexity, it is therefore best to consider an individual over time rather than compare cross-sectionally. Moreover, interventions aimed at slowing the impact of frailty on maintaining independence, like a smart home that projects RényiCI trajectories, would be more helpful for older adults living alone. Mechanisms of interest become difficult to automatically recognize in multiresident homes where ambient sensors detect movement from all residents.

Limitations

Several factors impacted the interpretation and generalizability of our findings. First, entropy-based measures like RényiCI are inherently sensitive to sample length and the number of sensors deployed in a participant's home. To prioritize intraindividual validity, we customized the sliding window size for each participant using a fixed number of sensor messages (n), rather than a fixed time duration. This approach allowed for consistent comparisons within individuals but introduced variability in the time span covered by each window, both within and across cases, limiting our ability to analyze complexity as a direct function of chronological time. Future work could develop correction factors for RényiCI to account for sample length, enabling the detection of periodic, seasonal, or event-driven patterns in indoor behavior.

Relatedly, interindividual comparisons were constrained by differences in sensor configurations across homes. Participants varied in the number and placement of sensors, affecting both the density of event data and the scale of RényiCI values. Standardizing sensor deployments in future studies would facilitate more robust cross-participant comparisons and support investigation into whether home-level sensor complexity systematically relates to frailty markers at the population level.

The impact of the COVID-19 pandemic further complicates interpretation. Several participants were enrolled during or shortly after the onset of pandemic-related lockdowns, which led to changes in daily routines, increased time spent indoors, and potentially long-term shifts in behavior and social support. These behavioral changes may have altered both the complexity of movement and its relationship to frailty. Additionally, one period of the study coincided with prolonged hazardous air quality due to regional wildfires, which may have further restricted participants' movement and contributed to abrupt changes in sensor complexity. Such exogenous events likely altered daily routines independent of health. We therefore interpret Rényi changes within homes and in the presence of annotated event periods. We also provide event-excluded sensitivities to reduce confounding.

Sensor noise and dropout also presented challenges. While preprocessing steps excluded known periods of sensor failure or participant absence, subtle forms of sensor drift or inconsistent message delivery could still introduce noise into the RényiCI estimates. Further improvements to sensor reliability and the integration of sensor health metrics into complexity analysis pipelines would strengthen future research.

In terms of statistical methods, the runs test was useful in identifying nonrandom patterns in behavioral complexity over time, but it is not well-suited to detecting more complex temporal structures such as oscillatory or nonlinear trends. Future research may benefit from time series models drawn from signal processing or machine learning that can more precisely characterize evolving behavioral dynamics.

Frailty measurement also posed a limitation. Because frailty was not a primary outcome in the parent study, we relied on retrospective CFS scoring based on weekly nursing reports. This limits temporal precision and may miss subtle fluctuations in functional status. Larger-scale studies using prospectively collected frailty data, including both clinician-reported and self-reported measures, could reveal more detailed associations between complexity and health.

Finally, this sample was racially and culturally homogeneous, limiting the generalizability of our findings. RényiCI analyses should be interpreted as a within-home monitoring signal rather than a cross-sectional diagnostic tool. As efforts to diversify smart home research populations expand, it will be essential to explore whether the relationships between sensor-derived behavioral complexity and frailty differ across racial, cultural, and socioeconomic groups. Inclusive, representative samples are critical to ensuring that digital biomarkers are both effective and equitable.

Conclusions

Detection of incipient frailty in community-dwelling older adults is a key component to supporting their independence. The findings in this study demonstrate that RényiCI, as a passive and unobtrusive complexity metric, offers a promising tool for monitoring functional health changes in aging populations and may help enable early detection of frailty in real-world settings. The PyUSM software package developed for this analysis is publicly available and supports future application of this method in diverse behavioral monitoring contexts. These findings support the potential of entropy-based digital behavior markers to unobtrusively monitor intraindividual health changes and capture early signs of frailty in aging-in-place.

Future enhancements of this analysis may reveal additional factors that influence change in indoor movement complexity and inform how the complexity of smart home data may inform clinical practice. For example, significant departures of RényiCI values from a person's complexity baseline may trigger a nurse call or follow-up when integrated into a remote monitoring or telemonitoring system. In routine care, weekly summaries of the analysis would support triage and help care providers select appropriate actions. Additionally, when performing a functional assessment of an individual, a summary of the complexity trend augments traditional frailty analysis to improve assessment and

XSL•FO
RenderX

treatment options. Future work will also emphasize analytical validity (repeatability and robustness across sensors and windowing), clinical validity (prospective prediction of frailty transitions), and clinical use (impact on downstream outcomes such as unplanned care, falls, and functional decline) for diverse homes and populations.

Additionally, future work should focus on integrating RényiCI in machine learning predictive modeling as a high-level feature to assist with identifying meaningful digital biomarkers [49]. Other temporal activities associated with frailty (eg, walking speed, ADL, and IADL behaviors) could also be integrated to optimize frailty classifications. Machine learning integration of features from RényiCI values that signal possible increasing frailty will support nurses and caregivers in providing timely interventions, thereby potentially extending independence and optimizing older adults' outcomes.

Acknowledgments

The authors would like to thank Jason Minor, Bryan Minor, and Brian Thomas for their assistance with the smart homes and Shandeigh Nikki Berry, Samantha Denison, and Ellen Hinderlie for their data collection contributions.

Funding

This work is supported in part by the National Institute of Nursing Research under grant R01NR016732, Touchmark Foundation, and the Washington State University College of Nursing's Linblad Scholarship funds.

Data Availability

Sensor data are available at CASAS DataDownloader [50]. Deidentified medical information about frailty cases included in this study may be made available for authorized research use upon request.

Conflicts of Interest

None declared.

Abstract

Background: With the aging of the global population, preventing the onset of mobility limitations is considered a worldwide public health priority.

Objective: This study aimed to develop a predictive model for incident early mobility limitations (EMLs) in late middle-aged and older adults, based on a simple functional test and modifiable lifestyle factors to facilitate a home-based self-assessment of early mobility decline and promote lifestyle intervention strategies.

Methods: Our study population was community dwellers aged 45 years and above who participated in the second and fourth waves of the Guangzhou Nutrition and Health Study. The included participants were healthy, nonfrail adults reporting no limitations in activities of daily living at baseline. At the 6-year follow-up, participants with poor physical performance (walking speed <1 m/s or handgrip strength <28 kg for males and <18 kg for females) or reporting some difficulty in walking and/or climbing stairs were classified as experiencing EMLs. Least absolute shrinkage and selection operator (LASSO) was used to identify predictors from various factors, and 6 machine learning models were trained and evaluated for EML prediction, using bootstrap-based techniques to address class imbalance. Predictive ability was quantified using the area under the receiver operating characteristic curve (AUC). Variable importance analysis was used to identify key predictors.

Results: A total of 1344 participants were included in the analysis, of which 206 (15.33%) developed EMLs after a median follow-up of 6.67 (IQR 5.91 - 7.26) years. Those who developed EMLs were older, had a higher BMI, a lower alternate Mediterranean diet score, and poorer performance in the sit-to-stand (STS) test, as well as lower estimated muscle power from the STS at baseline. The final models included 6 out of 9 predictors: age, sex, BMI, alternate Mediterranean diet score, STS power, and dietary calcium intake. Four machine learning models (logistic regression, LASSO, support vector machine, and neural network) achieved an acceptable AUC value (≥0.70) or slightly below in the testing dataset, with the neural network performing the best (AUC 0.70, 95% CI 0.63 - 0.77). Curve analysis showed positive net benefits for LASSO and logistic regression. Bootstrapping did not improve classification performance. Advanced age, lower adherence to Mediterranean diet, lower muscle power estimated from STS test, and higher BMI at baseline emerged as the most important predictors of EMLs.

Conclusions: This study shows that EMLs in Chinese adults aged 45 years and older can be predicted using easy-to-obtain physical performance measures, age, sex, BMI, and specific nutritional factors. The combination of prediction models and variable importance analysis provides valuable insights for the early identification and intervention of EMLs. More efforts are needed to validate our findings in external cohorts.

Introduction

Maintaining optimal locomotive capacity—in this study referred to as "mobility"—is essential to successful aging. Optimal mobility determines the capacity to perform activities of daily living (ADLs) and engage in social and leisure activities. However, aging has a negative impact on mobility, underpinned by multiple mechanisms affecting the musculoskeletal, cardiorespiratory, and neurological systems. Along with the onset of chronic conditions, the aging process increases the likelihood of developing mobility limitations, such as difficulties in running, walking, or climbing stairs. These limitations often cause older adults to lose independence, reducing their quality of life and dramatically increasing health care costs. Therefore, with the aging of the global population, preventing the onset of mobility limitations is considered a worldwide public health priority [1,2].

Mobility limitations are often the first signs of further functional decline. The interplay between the emergence of mobility limitations, sarcopenia, and physical frailty involves intricate relationships. Sarcopenia, defined as "a progressive and generalized loss of skeletal muscle mass and strength" [3,4], requires the presence of at least 1 mobility limitation for its diagnosis, assessed through objective physical performance tests. In turn, sarcopenia is an important component of the physical frailty syndrome [5], where mobility limitations make up 2 out of 5 total diagnostic criteria, together with weight loss, low energy expenditure, and exhaustion [6]. The development of mobility limitations is therefore a critical component at the intersection of sarcopenia and physical frailty, serving as a primary target for interventions. In accordance, the World Health Organization has recently called health care professionals and gerontologists to focus on strategies for maximizing and preserving mobility across the entire life course independent of any specific disease.

The early stage of mobility decline is a window of opportunity for interventions, such as adequate nutrition intake and active exercise, to positively modify the trajectory in later life. Once physical frailty becomes manifest in older adults, it is increasingly challenging to reverse the development of mobility limitations [7]. Notably, the progressive age-related mobility decline may not clinically manifest at early stages because during the aging process, people unconsciously modify the way tasks are performed routinely to compensate for the accumulating physiological deficits [8]. For example, older adults typically increase the step width to preserve their balance while walking [9]. This strategy is maintained until the capacity reserve is exhausted and limitations become manifest. Therefore, to prevent mobility limitations, it is important to identify people who do not yet manifest them but who are at risk for their onset in the near future [10]. A recent scoping review and expert consensus supports the use of the term preclinical or early mobility limitation (EML), referring to such subtle and often unconscious changes in performance [11].

Models to predict EMLs in late middle-aged adults are scarce. Most of the models available were developed to predict mobility disability in older adults based on common physical performance measures, such as gait speed, balance tests, and handgrip strength [12-15]. However, these measures have poor sensitivity to detect mobility deficits in younger adults (under 65 y) [16,17]. Notably, measuring muscle power may increase the sensitivity of prognostic models compared to more commonly used muscle strength measures, such as handgrip strength. Muscle power declines at an earlier and faster rate than muscle strength and is likely to be a more discriminant predictor of mobility limitations [18,19]. Specifically, sit-to-stand (STS) transitions have been shown to decline about 2 decades earlier than handgrip strength and gait speed [16]. Therefore, it is possible that new predictive models built with power-based measures can improve their prognostic value among middle-aged adults. Recently, a formula to calculate muscle power from the STS test has been developed and validated, overcoming the difficulties of evaluating muscle power without any instrument [20,21].

Similarly, the importance of nutrition in preserving mobility has been studied [22,23]. Including nutrition elements in the prediction model would enable a holistic intervention approach to reduce the risk of mobility limitation. To date, few studies have investigated the association between muscle power-based physical performance measures or dietary factors and the development of EML among late middle-aged adults.

In the present study, we aimed to develop and internally validate a model to predict future preclinical mobility limitations in late middle-aged and older adults for patient self-assessment, based on simple–to-obtain measurements, including self-reported data and the STS test, using a cohort of healthy adults aged 45 years and above recruited in a community-based study in the south of China. This model could be used to identify which persons may benefit from preventive strategies at middle and older age to decelerate or delay the onset of mobility limitations in the Chinese population.

Methods

Guidelines for Model Development and Validation

We adhered to the TRIPOD (Transparent Reporting of a multivariable prediction model for Individual Prognosis or Diagnosis) guidelines, which provide transparent reporting standards for developing and validating prediction models for individual prognosis or diagnosis [24,25].

Study Design and Participants

This retrospective cohort study used data from the Guangzhou Nutrition and Health Study (GNHS), which is a longitudinal community-based cohort conducted by the School of Public Health, Sun Yat-sen University, Guangzhou, China. Between 2008 and 2013, a total of 4048 participants aged between 40 and 80 years, who lived in Guangzhou city for at least 5 years, were enrolled in the GNHS and have been followed up every 3 years approximately. Detailed information about the cohort protocol and baseline characteristics can be found elsewhere [26]. Briefly, data were collected from study visits from healthy participants, including physical performance tests, body composition measurements, dietary, and lifestyle factors. A validated semiquantitative Food Frequency Questionnaire was

XSL•FO
RenderX

used to collect dietary intake information [27]. Exclusion criteria such as myocardial infarction, stroke, diabetes, cancer, low-energy fractures, mental and physical disability, and chronic liver and kidney diseases were confirmed at the first enrollment.

Participants in the current analysis participated in 2 follow-ups of the GNHS (waves 2 and 4). At wave 2, from October 2013 to July 2017, 2970 participants were asked to take the 5-time STS test. Therefore, this study used wave 2 as the baseline. In addition, participants completed the ADL Scale questionnaire, grip strength test, and 4-minute walking test in wave 2 and subsequent follow-ups. The latest follow-up with available ADL and performance data was selected to allow EMLs to develop. At wave 4, from October 2020 to December 2023, 1952 participants had been followed-up.

Ethical Considerations

Written informed consent was obtained from all participants. The GNHS was approved by the Ethics Committee of the School of Public Health, Sun Yat-sen University (approval code: SYSU-GWYL2018048; approval date: July 17, 2018) and registered at ClinicalTrials.gov (NCT03179657). All procedures followed were in accordance with the ethical standards of the responsible committee on human experimentation (institutional and national) and with the World Medical Association Declaration of Helsinki. Data were anonymized and were accessible only to the research team. No financial compensation was provided.

Predicted Outcome

Mobility limitations were assessed using objective mobility tests and perceived difficulties by ADL questionnaire. Participants rated their ease at walking and climbing stairs as independent, have some difficulties, need help, and unable to mobilize. In the predictive model, EML was determined for those individuals meeting at least 1 of the following 3 criteria: (1) some difficulty in walking and/or climbing stairs; (2) poor handgrip strength (handgrip strength <28 kg for males and <18 kg for females); and (3) slow walking speed (<1 m/s).

Validated preclinical thresholds for middle-aged adults were lacking at the time of the study. Gait speed <1 m/s is a common threshold of slow walking speed among well-functioning older adults, and is often treated as a functional benchmark in middle-aged and older adults [28-31]. This threshold is recommended by the Asian Working Group on Sarcopenia (AWGS 2019) to screen for possible sarcopenia and has been applied to cohorts that include midlife participants across Asian countries, including China [32,33]. Similarly, for low handgrip strength, the threshold proposed by the AWGS 2019 was used in this study.

Baseline Candidate Predictors

The STS test is used to assess functional lower limb strength, transitional movements, balance, and fall risk in older adults. STS test score is based on the amount of time (to the nearest decimal in seconds) a participant is able to transfer from a seated to a standing position and back to sitting 5 times. The equipment needed to perform the STS test includes a stopwatch and standard height chair with straight back (42 cm high). Estimated STS power is calculated based on the results of the STS test, using the subject's height and BMI and the height of the chair.

In addition to STS power, other prefrailty phenotype-related predictors were considered, such as age, sex, BMI, alternate Mediterranean diet score (aMDS), energy-adjusted daily intake of vitamin D, protein, and calcium (Ca), and the use of vitamin supplements. Age, gender, and vitamin supplement use were self-reported by participants. BMI was measured by physical examination, the details of which are described in our previous study [26]. Nutrient intake levels were estimated based on a semiquantitative Food Frequency Questionnaire. The adherence to the alternate Mediterranean diet was measured by aMDS, calculated by summing the dichotomous points for the items of higher intakes of whole grain, vegetables, fruits, legumes, nuts, fish, and the ratio of monounsaturated fatty acids:saturated fatty acids, lower red meat, and moderate ethanol consumption, as described previously [34].

Finally, a least absolute shrinkage and selection operator (LASSO) regression model was built to screen the predictors for machine learning (ML) model. Feature selection was performed only in the training dataset. After feature selection, 6 variables (age, sex, BMI, aMDS, STS power, and dietary Ca intake) were selected from 9 predictors to construct a prediction model (Figure S1 in Multimedia Appendix 1).

Statistical Analysis

The continuous measurement data were represented as mean (SD). Student *t* test was used to compare differences between the EML and the normal (no EML) groups. The chi-squared test was used to compare categorical variables. Data were analyzed using R software (version 4.1.0; R Foundation for Statistical Computing).

ML Stages

The data were preprocessed before the models were trained. The predictors exhibit nonzero variance, and there is no significant correlation between them (Pearson correlation coefficient <0.75). Subsequently, the original dataset was randomly divided into a training dataset with 70% (940/1344) of the sample (796 normal and 144 EMLs) and a testing dataset with 30% (404/1344) of the sample (342 normal and 62 EMLs). Some predictor variables had a percentage of missing data of <10% (Figure S2 in Multimedia Appendix 1). For missing data, the training dataset was imputed with the random forest (RF) method by "mice" package [35]. Missing values of the testing dataset were imputed using median (for numerical) and mode (for categorical), with imputation parameters estimated from the training dataset to avoid leakage. This study performed variable (categorical and numerical) standardization on both the training and testing datasets.

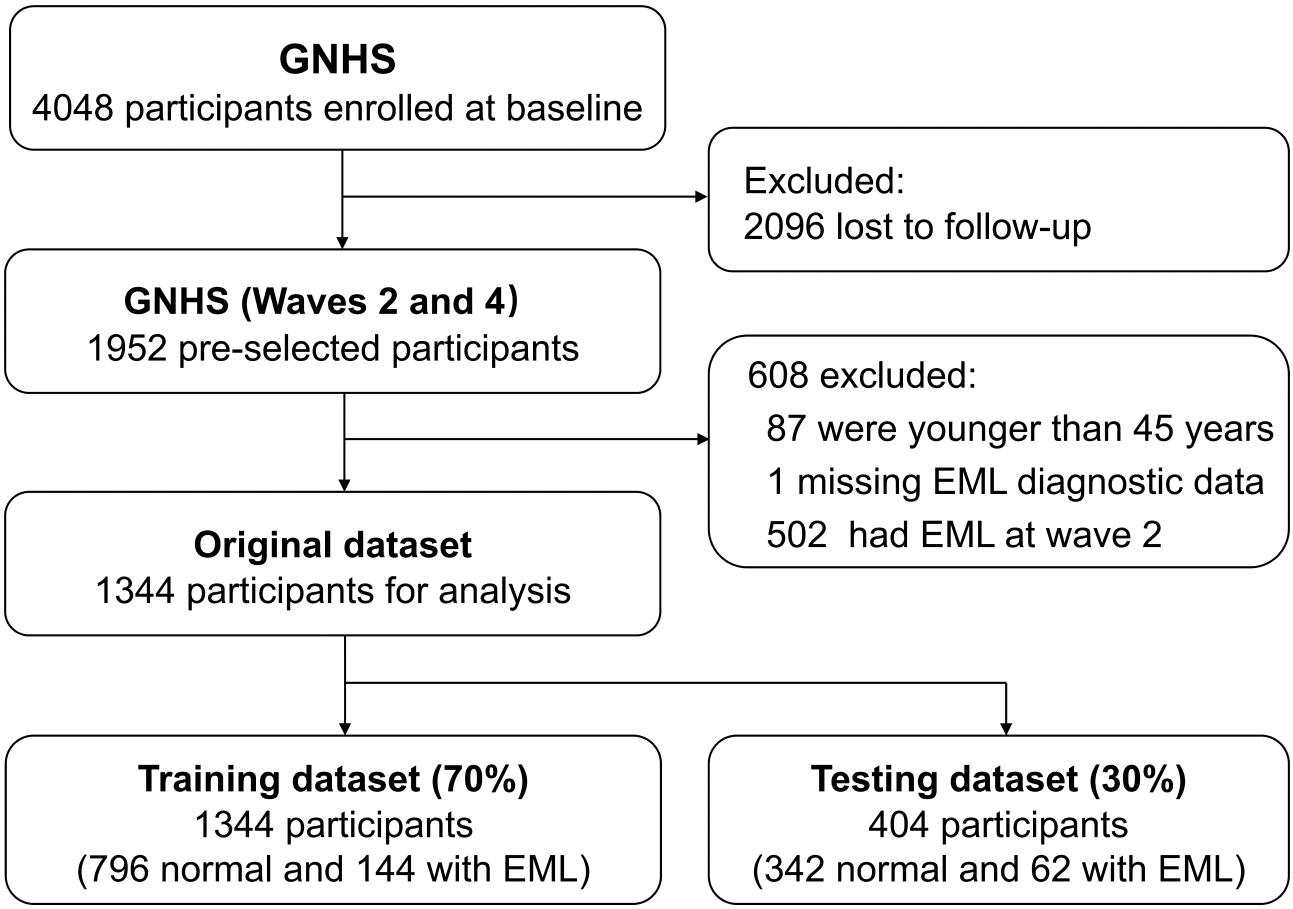
Class imbalance is a common challenge encountered in medical datasets, and it can significantly impact the performance of classification models. The presence of imbalanced classes often leads to overfitting of the majority class data by learning algorithms, resulting in decreased classification performance [36]. Sampling is a widely used technique for adjusting the size of training datasets, and undersampling and oversampling are common approaches [37]. To deal with binary classification

XSL•FO
RenderX

problems in the presence of imbalanced classes, synthetic balanced samples were generated according to "ROSE (Random Over-Sampling Examples)" package [38]. ROSE is a bootstrap-based technique that aids the task of binary classification in the presence of rare classes. We combined oversampling and undersampling to rectify the imbalance in data classification. The distribution of the observations by category-wise in the balanced and imbalanced training datasets is shown in Figure S3 in Multimedia Appendix 1.

After the work of preprocessing, the imbalanced and balanced datasets were divided into 5 random parts in the cross-validation test, which was repeated 10 times to randomize the training dataset and improve model performance. In this stage, the models were manually adjusted during training and selected based on the best value of the receiver operating characteristic (ROC), specificity, and sensitivity. The values of these metrics and the parameters used are shown in Table S1 in Multimedia Appendix 1. Calibration curve and decision curve analyses (DCA) were used to evaluate the calibration and clinical utility of the models. The following 6 ML models were trained: logistics regression (LR), RF, support vector machine (SVM), neural network (NNET), lasso regression (LASSO), and Light Gradient-Boosting Machine (LightGBM).

Finally, the testing dataset was used to evaluate the performance of the models trained on the imbalanced and balanced datasets, to assess how well these models fitted the data that was not used during the training stage into the testing dataset. The ROC and precision-recall curves and the metrics area under the receiver operating characteristic curve (AUC), F_1-score, accuracy, balanced accuracy, specificity, sensitivity, positive predictive value (PPV), and negative predictive value were used to assess the performance of the 6 models. The Youden index was used to determine the optimal threshold for the prediction of EML by optimizing specificity and sensitivity. The "tidymodels" package was used in the ML stages.



The Shapley Additive Explanations (SHAP) analysis was used to interpret the model and assess the marginal contribution of each feature to the model output. The waterfall of individualized SHAP was used to interpret single-sample data, illustrating the direction and strength of influence that an individual's variable values have on the predictive outcome.

Results

Population Characteristics

In the final analysis, 1344 participants attended the follow-up and were included. At baseline, the median age was 61.99 (IQR 59.03 - 65.68) years, and most participants were women (945/1344, 70.3%). After a median follow-up of 6.67 (IQR 5.91 - 7.26) years, 15.33% (206/1344) participants developed EMLs at 6-year follow-up (Figure 1). Those who developed EMLs were older, had a higher BMI, a lower aMDS, and poorer performance in the STS test, as well as lower estimated muscle power from the test (STS power) at baseline (Table 1).

[g]STS: sit-to-stand test.

Models' Performance

Figure 2 shows the AUC values for the 6 ML models trained with imbalanced (AUC range 0.62-0.70; Figure 2A) and balanced (AUC range 0.56-0.69; Figure 2B) datasets. All 6 ML models selected all 6 variables (age, sex, BMI, aMDS, STS power, and dietary calcium intake) with different importance (Figure 3), except the LightGBM model for which age, BMI, and dietary calcium intake were not selected. The performance of most models on unseen data remained stable or decreased when the balanced dataset was used, and the LR model maintained the best performance across both datasets.

Figure 3. The SHAP for feature importance of the models trained with balanced datasets: (A) logistic regression; (B) random forest; (C) support vector machine; (D) neural network; (E) least absolute shrinkage and selection operator regression; and (F) Light Gradient-Boosting Machine. aMDS: alternate Mediterranean diet score; SHAP: Shapley Additive Explanations; STS: sit-to-stand test.

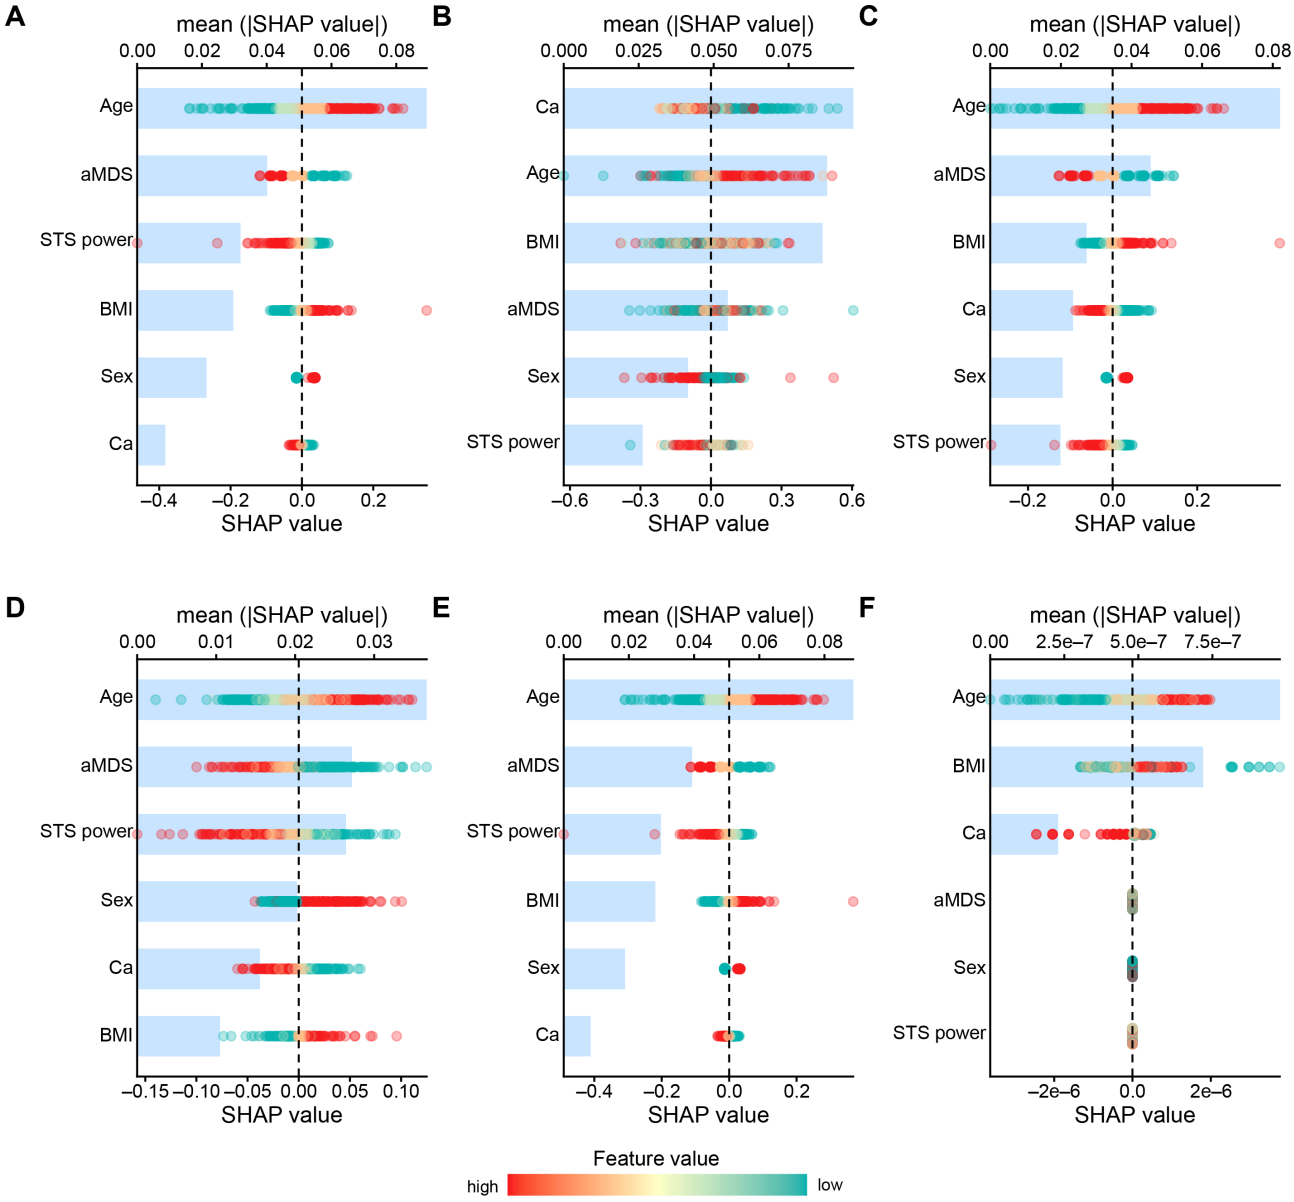

Table 2 shows the performance of the ML models on unseen data, trained with imbalanced and balanced datasets, based on different metrics. Some models (RF, SVM, and NNET) yielded better values for metric accuracy when they were trained with balanced data, whereas the unbalanced dataset showed better performance in all the other metrics and the rest of the models. LR, NNET, SVM, and LASSO had acceptable values for AUC (≥0.70) or slightly below when trained with imbalanced data, among which NNET had the best values for AUC (0.70; 95% CI 0.63 - 0.77) and balanced accuracy (0.68) compared with all the other models trained with imbalanced data. However, NNET models are typically more complex and prone to overfitting. Hence, in conditions of similar performance, simpler models like LR or LASSO may be preferred due to their interpretability and lower risk of overfitting. Specifically, the straightforward coefficients in LR can be easily understood in terms of odds ratios.

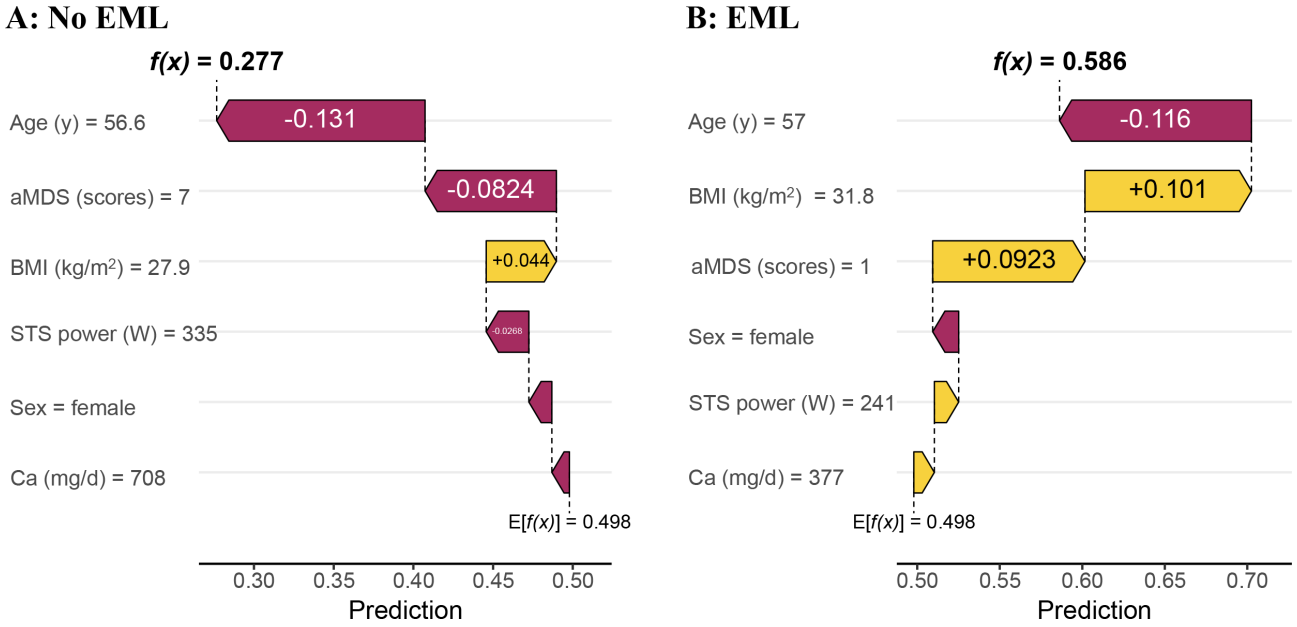
DCA (Figure S8 in Multimedia Appendix 1) results showed that prediction model's effective range for test datasets are concentrated at low thresholds. All prediction model curves demonstrate positive net benefits exceeding the "no treatment" baseline only within the threshold range of 0% to 50%. When the threshold exceeds 50%, the model's net benefit drops below zero, losing clinical value.

In calibration curves (Figures S5 and S7 in Multimedia Appendix 1), LASSO regression and logistic regression exhibit relatively good calibration on imbalanced test datasets. However, in balanced datasets, most predictive models show that the predicted probabilities are higher than the actual probabilities, indicating that the models are overconfident in their predictions. For implementation in the real world, prediction models need to be further calibrated according to the specific application scenario.

In addition to discrimination metrics, we assessed model performance using the net reclassification improvement. Logistic regression was selected as reference because it represents a widely used baseline approach for binary risk prediction in preventive settings. Net reclassification improvement was decomposed into event and nonevent components to better understand potential gains and tradeoffs in risk stratification across modeling approaches, and the results are reported separately for models trained on imbalanced and balanced datasets (Table S1 in Multimedia Appendix 1). Only RF achieved a modest improvement in risk reclassification over

XSL•FO
RenderX



logistic regression, whereas other ML models did not demonstrate meaningful net reclassification gains.

Model Interpretability

The SHAP model was used to provide both global and local interpretations of the models. Globally, the more significant contributors to the models trained with the balanced dataset were age, aMDS, STS power, and BMI. Age was among the top 3 most important variables in all 6 models, followed by aMDS in 4 models (LR, SVM, NNET, and LASSO) and STS power (LR, NNET, and LASSO) and BMI (RF, SVM, and light GBM) in 3 models (Figure 3).

In the single-sample waterfall plot, baseline SHAP value was 0.498, model output values for a randomly selected individual with no EML was 0.277 (Figure 4A), and for an EML individual was 0.586 (Figure 4B). In no EML individuals, lower age as well as higher aMDS scores and STS power were identified as features that had a negative impact on EML, while higher BMI was considered to have a positive impact (Figure 4A). Among EML individuals, lower age was identified as a feature that negatively affected EML, while higher BMI and lower aMDS scores were considered to have a positive impact (Figure 4B).

Figure 4. Individualized SHAP waterfall plot for no EML (A) and EML participants (B), demonstrating the personalized contribution of each predictor to the risk score. aMDS: alternate Mediterranean diet score; EML: early mobility limitation; SHAP: Shapley Additive Explanations; STS: sit-to-stand test.

The SHAP bar plot ranks features by their overall importance, calculated as the mean absolute SHAP value across all participants.

The SHAP beeswarm plot illustrates the impact of each feature on the model's output for every participant. Each dot represents a participant; its position on the x - axis indicates the SHAP value (positive values increase the prediction of EML), and its color represents the feature's value (red for high, green for low).

Discussion

Principal Results

In this study, we developed 6 prediction models using ML for EML in healthy, mobility-intact middle-aged and older adults from a longitudinal Chinese population-based cohort who were followed-up over 6.67 years. A LASSO regression model was built to select the predictors. Finally, 6 variables (age, sex, BMI, aMDS, STS power, and dietary calcium intake) were identified and included in the model training process. The performance of the different ML models trained with balanced and imbalanced datasets was compared. Advanced age, lower adherence to Mediterranean diet, lower STS power, and higher BMI were identified as the most important predictors of EMLs.

Comparison to Prior Work

In this study, we have attempted to use commonly used ML models for binary variable prediction, including LR, RF, SVM, NNET, LASSO, and LightGBM. In a recent study with a large sample size (5466), ML models such as SVM, K-nearest neighbor, NNET, RF, and extreme gradient boosting demonstrated good results in predicting frailty among senior people in Canada [39]. Although our database may not have a comparable size, we were interested in exploring the feasibility of applying these ML models to the cohort in Guangzhou, China.

The discrimination power of 4 models (LR, NNET, SVM, and LASSO) trained with the imbalanced data was found acceptable (AUC≥0.70) or slightly below in the testing dataset. The performance moderately decreased when trained with the balanced dataset, with NNET (0.69), LR (0.68), SVM (0.67), and LASSO (0.68) achieving the highest AUC values and, therefore, showing more robust discrimination across datasets (Table 2). Royston et al [40] noted that the AUC of prognostic models is typically between 0.6 and 0.85. The commonly used prognostic tests include the ratio of total plasma cholesterol to high-density lipoprotein cholesterol level, with an AUC of 0.72 for predicting the risk of coronary heart disease [41], and the 6-minute walking test, with an AUC of 0.60 for predicting

XSL•FO
RenderX

increased risk of hospitalization among patients with chronic obstructive pulmonary disease [42]. Therefore, the predictive power of our models compares well with that of risk assessment tests widely used in clinical practice that are more invasive (eg, TC/HDL-C from a blood test) or burdensome (eg, 6-minute walking test requiring time and space). Additional DCA of the models trained with imbalanced datasets showed meaningful positive net benefits for LASSO and LR only, supporting the clinical utility of these 2 models within the threshold range of 0% to 35%, but no positive net benefits were found for the balanced trained models (Figure S8 in Multimedia Appendix 1). The incremental predictive benefit of other ML models compared to LR did not demonstrate meaningful net reclassification gains.

Similar ROC-AUC results were obtained by Chaves et al [43], who developed a screening tool from simple–to-obtain self-reported performance measures for predicting the probability of 18-month incident mobility difficulty in community-dwelling women aged 70 to 80 years, with an AUC of 0.73. However, a test is likely to be more sensitive when the prevalence of concomitant risk factors is higher, as it would be expected from older individuals such as those included in that study [44]. Likewise, as the time to event decreases, the predictive accuracy of a model tends to improve [45], leading to less uncertainty in short-term predictions like in the study by Chaves et al [43]. Taken together, considering the challenges of predicting the onset of the early stages of an unspecific and multifactorial condition such as EML in mobility-intact adults who are generally healthy, drawing mostly from modifiable predictors, this study yielded acceptable results for the LASSO and LR imbalanced trained models, with positive net benefits. Given the models' intended use for early identification of individuals who may benefit from low-risk lifestyle interventions, their limited discrimination remains potentially valuable.

The models developed in this study were designed to maximize clinical applicability. All 6 predictors (age, sex, BMI, STS power, aMDS, and dietary calcium intake) can be easily collected by individuals using a standard chair, a stopwatch, and a short diet questionnaire. These inputs could be incorporated into a digital self-assessment platform or mobile health tool to support interpretation and reporting. Because the predictors include modifiable factors such as diet quality, micronutrient intake, physical function, and body weight, such a tool could help identify individuals at higher risk of mobility decline and provide personalized lifestyle recommendations. The decision threshold can be implemented within preventive care workflows, with thresholds in the range of 10% to 20%—as supported by DCA—offering a balance between early intervention benefits and the likelihood of false positives. This approach may empower individuals to monitor and preserve their mobility health without requiring specialized training or extensive resources.

As expected, age was the most important predictor of incident EML across the different ML models. Advanced age is a risk factor in developing mobility limitations and has been consistently identified as a predictor of mobility outcomes in many predictive equations [46,47]. Therefore, the finding that advanced age was the most important variable across the different ML models as determined by SHAP values (Figure 3) served as a positive control variable in developing our models to predict EML. Other important variables were adherence to the Mediterranean diet, STS power, and BMI. Among the rest of the baseline candidate predictors selected by LASSO regression, other less important variables across the different ML models included being female and lower energy-adjusted calcium intake. Many of these variables confirm some of the risk factors most frequently found to be independently linked to mobility limitations in older people, which include advanced age, higher BMI, and reduced muscle function measured through performance tests [48]. However, our results cast a new light on the predictive ability of estimated muscle power from STS and diet quality.

This study found support for STS power as an important predictor of incident EML in older, as well as in late middle-aged adults. The STS test has been consistently identified as a predictor of subsequent falls, mobility limitations [49], disability [14], osteoporotic hip fractures, and mortality among older adults. Remarkably, we found a higher statistically significant difference and relative difference for STS power (7.79%, P=.002) than for STS time values (4.87%, P=.003) at baseline between the group developing EML and their counterparts (Table 1). Therefore, only STS power was included among the baseline candidate predictors. Whereas the STS test measures the minimum duration required to rise from a chair a specific number of times (eg, 5-time STS) or the maximum number of STS repetitions within a specified timeframe (eg, 30-s STS), the STS power formula also considers the chair height, and the subject's body mass and height. Previous evidence in older people suggests that STS power values are more clinically relevant in regard to physical function, cognitive function, and sarcopenia compared to traditional STS measures [20]. Consistent with these findings in older adults, our results extend the predictive value of STS power to identify prospective mobility limitations in late middle-aged adults.

Notably, although normative values for STS power in Asian populations are lacking, the 5-time STS values observed in our study suggest a rather optimal level of physical function in both the EML group (mean 8.01, SD 1.67 s) and the normal group (mean 7.62, SD 1.92 s) at baseline. Specifically, current guidelines from the AWGS 2019 recommend a cut-off of 12 seconds or more to screen for low physical performance and sarcopenia, based on a review of evidence from different Asian cohorts. The striking distance between that cut-off and the baseline functional performance observed in our cohort underlines the ability of our models to identify incident mobility limitations earlier in time, even in the absence of noticeable performance decline. Remarkably, a recent study redefined the cut-off value recommended by the AWGS to 9.2 seconds in men and 10.8 seconds in women aged 60 to 69 years, significantly improving the detection rate of sarcopenia among Chinese adults [50]. These lower thresholds tie well with the values observed in our study and further support the predictive value of subtle deficits in performance tests.

A further novel finding was the importance of diet quality, measured as adherence to the Mediterranean diet, to predict

XSL•FO
RenderX

incident EML. Studying the influence of dietary factors on mobility limitation has practical importance, and the findings could provide opportunities for dietary intervention to reduce the potential risk. In this study, we identified adherence to the Mediterranean diet as a predictor of mobility limitations, with a higher adherence score associated with a lower probability of having mobility limitations. This finding is consistent with the previous studies. The aMDS was found positively associated with skeletal muscle mass index, which is an important aspect of mobility, in the Chinese population aged 40 to 75 years [34]. Silva et al [51] conducted a meta-analysis in community-dwelling older people and found that higher adherence to the Mediterranean diet was inversely associated with frailty. The anti-inflammatory and antioxidant properties of some nutrients typically found in higher amounts in Mediterranean diets, such as vitamin C and vitamin E or carotenoids, could contribute to that benefit [52]. Future intervention studies are needed to provide direct evidence on the risk reduction of mobility limitation by adherence to aMDS and improvement of calcium intake among individuals aged 45 years and older.

Strengths and Limitations

Although many prediction models for mobility limitations or disability have been developed in older people with poorer baseline health and functional performance, to our knowledge, comparable models are lacking for mobility-intact adults under 65 years of age. Therefore, a major strength of the study is the sample selection of healthier and younger participants, allowing for the observation of the early transition from intact mobility to impairment. This design facilitates the identification of early predictors and risk factors of mobility limitations, which might be overlooked in studies restricted to older or already impaired individuals.

Another positive aspect of the study is the selected set of predictor variables, which can be easily self-assessed at home with a smartphone and comprises several modifiable risk factors such as diet, physical function, and weight. As a result, the information collected for the prognostic test could be used for guiding potential intervention strategies. Finally, despite the common practice among ML researchers of using extensive datasets and training models with numerous predictors, this research has shown the feasibility of applying ML in datasets with a reasonable number of predictors and in cases where the classes are initially unbalanced.

There are some limitations of the study. First, the composite outcome EML measured in this research integrated both patient-reported and performance-based measures, as recommended by Richardson et al [11]. The expert group conceptualized the term *early* or *preclinical* mobility limitations to capture subtle decrements in mobility; however, a standardized measure has not yet been established. Further research examining the reliability, validity, and responsiveness of outcome measures is necessary to strengthen the evidence base on preclinical mobility limitation.

Second, the PPV, which indicates the likelihood that a positive test result is a true positive, was not optimal across models. These results should be interpreted considering the relatively low prevalence of EML observed in our cohort (15.3%) compared to that reported in other studies with similar operationalizations of EML among Chinese (27.9%) [53]. Because predictive values are prevalence-dependent, this may have increased the proportion of false positives, lowering the PPVs of our models [54]. This prevalence discrepancy may stem from the high proportion of lost-to–follow-up participants in our study, over 50%. The cohort in this study was followed in a designated location, introducing attrition bias for participants who were more frail, developed disability, or moved to care facilities. To address this discrepancy, we recalculated the PPV using the prevalence in the target population (27.9% in China) for the LR, SVM, NNET, and LASSO models. The PPV increases to approximately 43% to 44% indicating a substantially higher probability that individuals classified as high risk will truly experience the outcome when the model is applied in the intended population. In addition, proper calibration of the models may further optimize the PPV [55]. Notably, in the context of rule-in tests, it is crucial to balance the benefits of correctly identifying at-risk individuals against the potential harm of false positives [56]. The prognostic models developed in this study are aimed at promoting healthy lifestyle advice, like increased physical activity and improved nutrition, which are particularly relevant for the intended at-risk population. Therefore, the limited PPVs observed in our sample shall not limit the applicability of some of our models to identify individuals who may benefit the most from low-risk preventive interventions in the target Chinese population. In particular, a consistent net benefit was shown in DCA for SVM and LR across threshold probabilities roughly in the 10% to 35% band.

Another major limitation of the study was the validation of the models with an internal testing dataset. Further studies on independent cohorts need to be undertaken to establish the validity of our findings. Lastly, we suffered from an imbalanced dataset with only 206 subjects developing EML out of the 1344 sample. Similar imbalance problems have been observed in related studies [37], and this imbalance can lead to biased estimates of training performance [36]. This is because algorithms always tend to predict negative outcomes to achieve higher accuracy, which can also bring implementation challenges, such as when the primary interest lies in discovering the predictive results for EML, and biased predictions render the algorithm meaningless. However, in this study, we used the ROSE bootstrap-based technique [38] to remedy the imbalanced data and generate synthetic balanced samples, leading to more reliable and consistent evaluation of our models across 2 datasets.

Conclusions

This study is the first, to the authors' knowledge, to develop a prediction model for identifying the onset of EMLs in middle-aged and older adults based exclusively on at-home, simple–to-obtain measurements. The evaluation of model performance on a testing dataset, considering both imbalanced and balanced data training, indicates the potential utility of the ML approach in identifying individuals who developed EMLs over time. LASSO and logistic regression yielded the most meaningful positive net benefits, supporting their potential clinical utility for early identification of individuals who may

XSL•FO
RenderX

benefit from low-risk lifestyle interventions, though external validation is still required. Across models, age, adherence to the Mediterranean diet, STS power, and BMI consistently emerged as the most important predictors. These models provide an initial foundation for developing a digital self-assessment tool to identify individuals at higher risk of mobility decline and support personalized preventive strategies in clinical and at-home settings.

Abstract

Background: Dementia poses a significant public health challenge. Early detection is crucial for timely intervention but remains difficult in community settings, as many existing cognitive screening tools are either insufficiently sensitive to subtle decline or too burdensome for widespread use.

Objective: This study aimed to develop and validate a novel combined audiovisual-semantic digital tool for rapid and acceptable community-based screening of cognitive decline in older adults.

Methods: A total of 156 older adults completed 6 progressively complex task variants shifting from unimodal to multimodal stimuli and from basic to superordinate semantic categorization. Performance was measured using reaction time, accuracy, false alarms, and inverse efficiency. Diagnostic utility was assessed via logistic regression and receiver operating characteristic curve analysis, whereas qualitative interviews evaluated acceptability.

Results: Task outcomes showed significant declines across the cognitive continuum from no cognitive impairment to mild cognitive impairment to dementia (P<.001). The integrated audiovisual-semantic condition at the basic categorization level reliably differentiated cognitive groups and achieved higher area under the curve values for distinguishing no cognitive impairment from cognitive impairment and mild cognitive impairment from dementia compared to basic-level tasks. Incorporating semantic processing enhanced diagnostic discrimination. Participant feedback was highly positive, with 48.7% (76/156) describing the tasks as "fun/interesting."

Conclusions: The audiovisual-semantic integrated digital tool is a valid, well-accepted, and time-efficient instrument for cognitive screening in older adults. Its design, which increases cognitive load through multimodal and semantic integration, improves sensitivity to early decline, supporting its potential for practical community application.

cognitive decline; working memory; audiovisual integration; semantic categorization; go/no-go task; community screening

Introduction

Dementia is one of the major causes of disability and dependency among older people, posing a significant public health challenge worldwide [1]. While dementia currently lacks effective treatment, it is understood to be a progressive continuum. There is cumulative evidence suggesting that early identification of and intervention for cognitive decline confer both clinical and health-economic benefits [2]. Notably, approximately 14.4% to 38% of individuals with mild cognitive impairment (MCI) who are identified through screening and receive interventions revert to normal cognitive functioning [3,4]. Consequently, screening tools with high specificity and sensitivity are critical. Current assessment methods, which primarily include physiological indicators, neuroimaging techniques, and questionnaires, are often invasive, costly, and time-consuming [5]. In contrast, some digital tools (eg, voice based or virtual reality [VR]) show substantial clinical promise

XSL•FO
RenderX

by addressing these shortcomings [6,7]. However, these new tools still have limitations (eg, cybersickness in VR and accent-related transcription errors) and require further exploration [5,6,8].

Impairment of working memory is a hallmark early symptom of dementia [9]. Working memory is a limited-capacity cognitive system that provides temporary storage and manipulation of information to support a wide range of complex activities such as reasoning, comprehension, and learning [10]. Neuroimaging studies have demonstrated altered activation in working memory–related brain regions during cognitive tasks in the early disease continuum [11,12]. However, translating these findings into early diagnostic tools remains a challenge as it hinges on deconstructing working memory into its measurable component processes. The multicomponent model of working memory by Baddeley [10] offers a simple yet robust framework that makes such deconstruction possible. This proposed framework comprises 4 core components: the central executive system, phonological loop, visuospatial sketchpad, and episodic buffer [13]. External sensory input is initially handled by the phonological loop and visuospatial sketchpad. The episodic buffer then binds this information with existing knowledge from long-term memory. Finally, the central executive system acts as the control system, achieving cognitive processes by regulating attention, updating information, and inhibiting irrelevant information [13]. Previous research has reported that inhibitory control represents the most frequently impaired executive domain in MCI [14]. Indeed, the central executive system has been confirmed as an interconnected network where inhibitory control relies on attention, inhibition, and other functions that are integrated across neural networks in an interactive manner [14]. Furthermore, the association between working memory capacity and higher-order cognitive abilities is more pronounced, with these differences largely attributed to attentional capacity [15]. Therefore, researchers believe that access to working memory is governed by inhibitory attention processes [16].

The go/no-go task is widely used as a measure of inhibition, attention, and impulsivity [17]. By designing tasks that require participants to respond to specific stimuli (“go”) and withhold responses to “no-go” stimuli, which assesses the ability of executive control, extensive behavioral and neuroimaging studies have demonstrated the neurobiological foundation of the go/no-go task [17-19]. Cognitive control–related tasks consistently elicit increased frontal midline θ power, which is a key neural marker for cognitive control, response inhibition, conflict monitoring, and attention allocation [18]. The increase in frontal midline θ power during go/no-go tasks is driven by both inhibitory and noninhibitory (attention-related) processing [19]. Furthermore, rapid response inhibition activates the prefrontal cortex (PFC), particularly the middle and inferior frontal gyri, as well as the parietal and temporal lobes and their functional networks [20]. Abnormalities in these regions are considered predictive of cognitive status [20]. Significantly, the PFC is particularly vulnerable to aging [21]. Some researchers have even proposed the frontal or executive decline hypothesis, suggesting that age-related cognitive decline may stem from damage to the prefrontal lobe and executive functions [22]. Therefore, the go/no-go task is an experimental paradigm that effectively reflects executive control and has been reported to be a potential practical early screening tool for cognitive decline [23,24].

According to the model by Baddeley [10], processing stimuli involves a multisensory operation that necessitates cross-modal integration within the episodic buffer. However, go/no-go tasks predominantly use visual stimuli [25]. Given that sensory function decline is a natural consequence of aging, relying on a single sensory modality may introduce measurement bias. Previous research has indicated that multisensory integration accelerates reaction time (RT) in older adults, potentially serving as a compensatory mechanism to enhance brain information processing efficiency [26]. Beyond facilitation effects, multisensory processing exhibits illusory effects such as the McGurk effect and the double-flash illusion [27]. These illusory effects are mediated by anatomical and functional connections between different brain regions, particularly the cross-modal associations involving neural resources in the PFC [28]. Cross-modal information is represented within the capacity-constrained episodic buffer, where more complex inputs entail the binding of a greater number of information sources, thereby elevating processing load [29]. Moreover, multisensory integration can be affected by top-down factors, also termed endogenous attention [30]. Endogenous attention requires purposeful and effort-intensive cognitive processing, whereas multisensory integration performance may exhibit instability or illusions under high–cognitive load conditions.

Semantic memory is a key component of long-term memory. Its integration with working memory occurs in the episodic buffer, followed by complex processing in the central executive system to support motor behavior. Prior research suggests that working memory is not related to basic sensory processing (eg, color or shape discrimination) but shows a reliable association with semantic tasks [31]. A meta-analysis revealed that semantic deficits constitute a crucial and early feature of MCI and should be incorporated into routine clinical assessments [32]. Furthermore, the complexity of conceptual semantic representations systematically influences inhibitory processing [33]. However, most published go/no-go studies measure perceptual discrimination of stimuli such as shapes or numbers, with little attention paid to changes in abstract concepts [34]. This neglect may result in insufficient sensitivity of go/no-go tasks in capturing early and subtle cognitive decline.

To sum up, based on the theoretical framework by Baddeley [10] and existing empirical evidence, we hypothesize that combining visual-auditory fusion and semantic categorization with the go/no-go task can heighten demand on central executive resources, which might lead to a better identification of cognitive decline. The aim of this study was to develop an integrated audiovisual-semantic go/no-go task and evaluate its performance in discriminating cognitive decline, as well as the task’s acceptability among older adults.

Methods

Study Design and Participants

This cross-sectional pilot study was conducted to preliminarily investigate and develop a digital tool integrating audiovisual-semantic stimuli for the detection of cognitive decline. From April 2025 to August 2025, a total of 156 participants aged 60 years and above were recruited from 7 communities in Hangzhou, China. Exclusion criteria were (1) individuals who had significant verbal and hearing impairments and were unable to see or hear the stimuli despite adjusting the volume or image size (by controlling the resolution in the E-Prime software [Psychology Software Tools]) and (2) those with major depression and other psychiatric disorders.

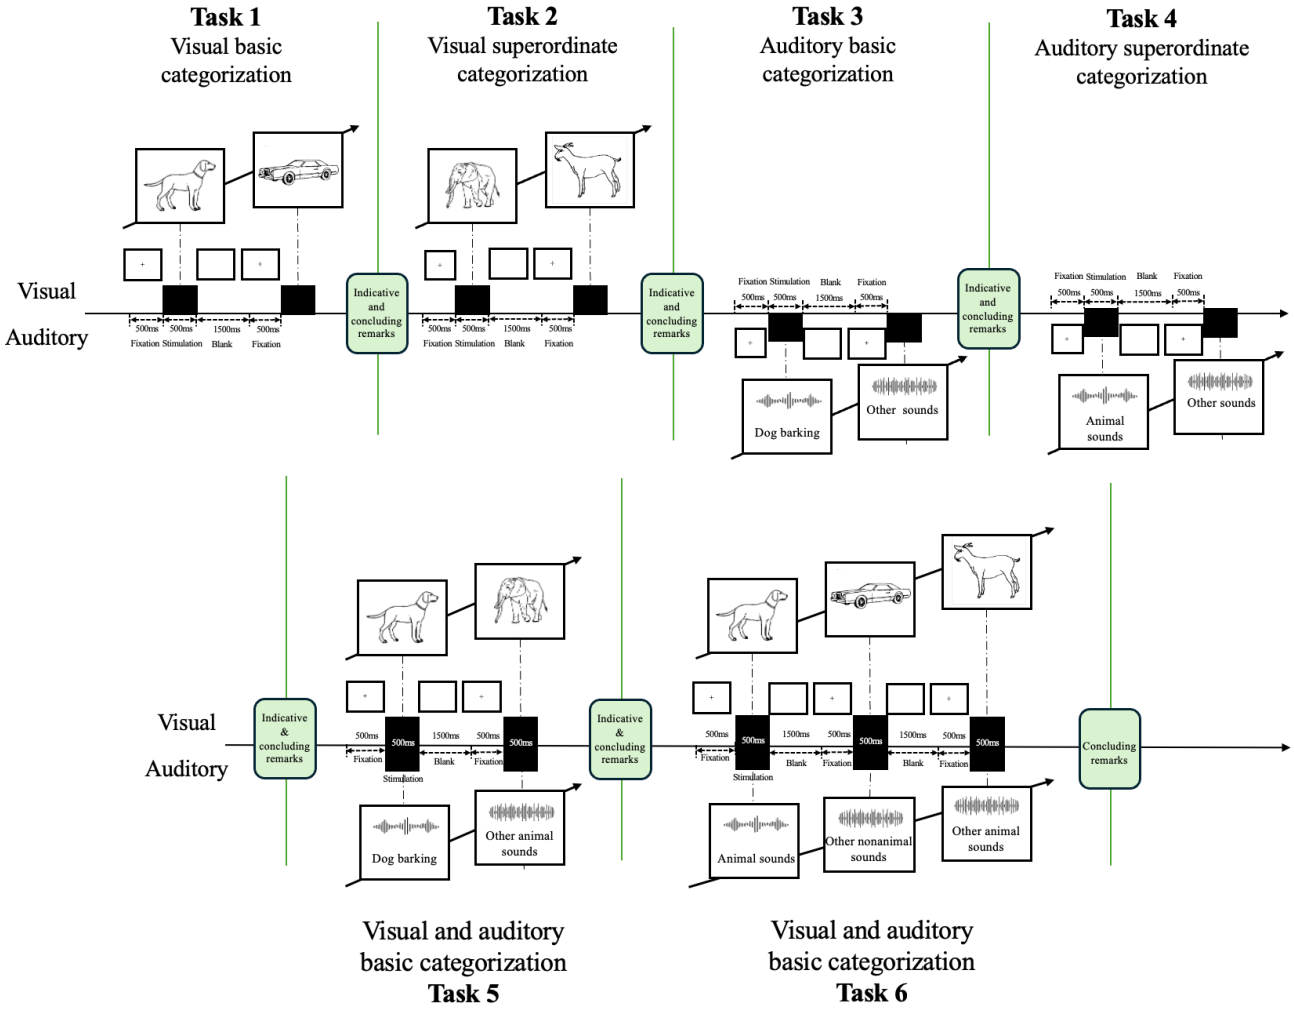
Data Collection

Overview

Data collection was conducted during a single session. All participants or their legally acceptable representatives signed a written consent form agreeing to take part in this study. After that, all participants underwent face-to-face interviews conducted by a trained staff member to collect the demographic information (eg, age and gender). We administered the Montreal Cognitive Assessment (MoCA) and the go/no-go tasks in an interleaved and alternating manner using a number-calling strategy, with at least a 30-minute interval between the 2 assessments. The MoCA assessment was conducted by trained research personnel.

Cognitive Assessment

The MoCA is a well-validated, multidomain, paper-and-pencil test that assesses a range of cognitive functions, including visuospatial and executive functions, naming, memory, attention, abstraction, and orientation [35]. We defined participants' cognitive status using the following MoCA cutoff scores (adjusted education; the MoCA should be scored based on educational level to reduce bias. According to the standard MoCA scoring rules, one point is added to the total score for participants with less than 6 years of education): a score of 23 or higher was categorized as no cognitive impairment (NCI), a score ranging from 14 to 22 was categorized as MCI, and a score of less than 14 was categorized as dementia [5].



The Modified Go/No-Go Task

The task design was built on previous research and finalized through consensus among all authors [24]. This study comprised 6 go/no-go tasks (Figure 1), including visual, auditory, and audiovisual integration tasks. Every task consisted of 5 runs of 16 trials each (80 total trials). The total completion time for the 6 tasks was approximately 18 minutes (170 seconds per task). Participants were allowed a 1-minute break after every task. The tasks were conducted in a quiet environment (≤45 dB), verified using a decibel meter (model DLX-PS02303; Delixi Electric). Participants sat at approximately 58 cm from a 14-inch laptop computer (ThinkPad T480s-i7; Lenovo). Auditory stimuli were presented through wired headphones (model HD350BT; Sennheiser Electronic SE & Co). Volume was adjusted to a level clearly audible to participants before testing commenced. Visual materials were sourced from a canonical set of line drawings [36], and auditory materials were obtained from the Aigei website. As prior research has suggested that humans are more sensitive to biological sounds compared to nonbiological sounds, the auditory stimuli were designed as animal sound recognition tasks [37]. Visual and auditory stimulus materials underwent processing to standardize the image size and sound pressure level before being inserted into E-Prime (version 2.0). The sequence of stimuli in each task was fixed. A single-key keyboard (model K1-LY-WX; Yingyu IoT) was connected to the computer and positioned in front of the participant's dominant hand. Each stimulus was presented for 500 ms, with a 1500-ms intertrial interval during which a blank screen with a fixation cross was displayed. Each task was preceded by 12 practice trials at the same pace as the formal study trials (go/no-go ratio of 3:1) to ensure participant comprehension of task requirements. The go/no-go metrics evaluated were as follows:

- RT: mean response time for correct "go" trials
- "Go" trial accuracy: percentage of correct responses on "go" trials
- False alarm rate: percentage of incorrect responses on "no-go" trials
- Inverse efficiency score: RT divided by the overall proportion of correct responses

XSL•FO
RenderX

Figure 1. Go/no-go tasks.

A lower score reflects better inhibitory control by integrating speed and accuracy. All go/no-go metrics were standardized into *Z*-scores before performing regression analysis.

Informal Interview

Following completion of the MoCA and modified go/no-go tasks, we conducted informal interviews lasting approximately 3 to 5 minutes with participants. Semistructured questions included the following: “How did you feel about the overall testing process of Go/No-go?” “How was your experience with the Go/No-go task compared with the MoCA questionnaire?” “How do you feel about implementing this Go/No-go task for cognitive decline screening in a community setting?” Interviewers recorded key content words related to feelings, with each unique word recorded only once per participant.

Data Analysis

Statistical analyses were performed using SPSS (version 31; IBM Corp). As the data in this study did not pass normality tests, medians and IQRs were used for description. Kruskal-Wallis tests were used for demographic characteristics and go/no-go task–related metric analyses. Logistic regression analyses were conducted while controlling for age and educational level (P<.05 in both cases). We used backward likelihood ratio logistic regression analysis, with a P value of .05 for entry and .10 for removal. Backward likelihood ratio is considered more robust based on overall model fit changes [38]. The features extracted from the task were entered into a logistic regression model, where the diagnostic group (NCI vs cognitive impairment, MCI, or dementia and MCI vs dementia) was considered as the dependent variable and the task-extracted features were used as the independent variables.

To examine go/no-go diagnostic validity, receiver operating characteristic (ROC) curves were used to establish area under the curve (AUC) values for the following groups: NCI vs cognitive impairment (cognitive impairment including MCI and dementia), NCI vs MCI, NCI vs dementia, and MCI vs dementia. The optimal Youden index was used to calculate discrimination metrics, including sensitivity and specificity. AUC 95% CIs were calculated using bootstrap methods. To compare the discriminative validity of different tasks, additional ROC analyses were performed using the DeLong method. To analyze the qualitative data, the R package *wordcloud2* (R Foundation for Statistical Computing) was used to generate word clouds.

Ethical Considerations

All procedures were approved by the Ethics Committee for Human Studies of the Fourth Affiliated Hospital of Zhejiang University School of Medicine (2025-0326-1-F1). Written informed consent was obtained from all participants prior to measurements, in accordance with the Declaration of Helsinki. No identifying details are included in this paper or the

XSL•FO

supplementary materials. Participants did not receive compensation. Access to raw data is restricted to research team members.

Results

Characteristics of the Participants

A total of 156 participants took part in this study, including those with NCI (n=75, 48.1%), MCI (n=66, 42.3%), and dementia (n=15, 9.6%). Baseline characteristics (Table 1) showed significant differences among the 3 groups in age, educational level, and MoCA scores (P<.001). No statistically significant differences were observed in gender or smoking or alcohol consumption habits across the 3 groups.

Figure 2. Receiver operating characteristic curve performance of different tasks: (A) different task performance for identification of no cognitive impairment (NCI) vs cognitive impairment (CI), (B) different task performance for identification of NCI vs mild CI (MCI), (C) different task performance for identification of NCI vs dementia, and (D) different task performance for identification of MCI vs dementia.

Across all 6 go/no-go tasks, performance on the RT, “go” trial accuracy, inverse efficiency score, and false alarm rate metrics demonstrated a significant declining trend from NCI to dementia (Table 3), with no collinearity issues among metrics (variance inflation factor<10). Compared with participants with NCI, participants with both MCI and dementia exhibited slower RTs, lower accuracy, higher omission rates, and poorer inhibitory control (Table 3).

[a]NCI: no cognitive impairment.
[b]MCI: mild cognitive impairment.
[c]Kruskal-Wallis test.
[d]RT: reaction time.
[e]GTA: "go" trial accuracy.
[f]Compared with NCI; *P*<.05.
[g]IES: inverse efficiency score.
[h]FAR: false alarm rate.
[i]Compared with MCI; *P*<.05.

ROC Results

As shown in Table 2 and Figure 2, we examined the discriminatory ability of different tasks for varying degrees of cognitive decline. The AUC ranges for the diagnostic comparisons were 0.877 to 0.926 for NCI vs cognitive impairment, 0.861 to 0.916 for NCI vs MCI, 0.909 to 0.968 for NCI vs dementia, and 0.724 to 0.855 for MCI vs dementia. Considering accuracy, sensitivity, specificity, and AUC simultaneously, tasks 5 and 6 demonstrated optimal performance in discriminating NCI from cognitive impairment compared to other discrimination models. Task 5 exhibited the most stable performance in discriminating NCI from cognitive impairment, MCI, and dementia (accuracy: 0.837-0.933; sensitivity: 0.742-0.933; specificity: 0.606-0.933; AUC: 0.744-0.977).

In the DeLong test for paired ROC curves, the AUC of task 5 was significantly higher than that of task 2 in discriminating NCI from cognitive impairment (Z=–2.129; ΔAUC=–0.048, 95% CI –0.093 to −0.004; P=.03) and from MCI (Z=–2.182; ΔAUC=–0.055, 95% CI –0.104 to –0.006; P=.03). The AUC of task 2 significantly outperformed task 1 when discriminating NCI from dementia (Z=–2.05; ΔAUC=–0.049, 95% CI –0.095 to –0.002; P=.04).

Acceptability

In informal interviews, "fun/interesting" emerged as the most frequently mentioned term (76/156, 48.7%), followed by "thinking" (65/156, 41.7%) and "high-tech vibe" (61/156, 39.1%). Participants also expressed perceptions of task difficulty, such as "easy" (57/156, 36.5%), "lagging" (43/156, 27.6%), and "difficult" (13/156, 8.3%). When comparing with standardized scales, participants mentioned the terms "engaging" (43/156, 27.6%) and "novelty" (30/156, 19.2%), with practical application perceptions including "convenient" and "roll out" (Multimedia Appendix 2).

Discussion

Principal Findings

Overview

This study provides empirical evidence that the increased cognitive load imposed by integrating visual-auditory stimuli and semantic categorization into a go/no-go task effectively amplifies performance differences across cognitive states, thereby supporting its utility as a discriminative tool. This novel approach indirectly assessed the episodic buffer's ability to form coherent episodic representations, enabling early detection of cognitive decline. Our findings showed that the task complexity incrementally increased from unimodal stimuli (visual or auditory) to multimodal stimuli (audiovisual integration) and from a basic level (concrete objects such as "dog") to a superordinate level (abstract categories such as "animal"), consistent with our hypothesis. Older adults with cognitive decline exhibited progressively worse performance in these incrementally difficult tasks.

Measuring Using Multimodal Stimuli

Unimodal tasks (task 1 and 3), which relied on basic sensory discrimination, did not demonstrate superior overall performance in discriminating between cognitive statuses. Such an observation is likely due to dependence on automatic processing and low-level perception, yielding similar performance across groups. In contrast, both cross-modal matching tasks (tasks 5 and 6) performed well; in particular, they outperformed the auditory-only MoCA-attention cognitive domain (AUC=88.7%, 95% CI 88.0% - 89.4%), suggesting that multisensory integration is a reliable biomarker for cognitive impairment [39]. This is supported by findings from The Irish Longitudinal Study on Ageing, which reported broad associations between multisensory integration and multiple cognitive domains rather than links to any specific subdomain [40]. This implies that measuring multisensory integration could serve as a window into global cognition. Furthermore, as noted previously, multisensory stimulation may serve as a compensatory strategy for older adults, enhancing behavioral performance in those with NCI [26]. However, this compensatory mechanism is limited as behavioral responses are governed by the central executive system, which may account for the more pronounced deficits observed in individuals with progressive cognitive decline. Bayesian integration theory further supports this premise, proposing that perceptual reliability weighting affects audiovisual integration. In other words, the brain optimally combines sensory inputs based on their relative reliability, but cognitive decline may change this weighting process [41]. Apart from that, some scholars regard temporal synchrony and functional connectivity as 2 primary mechanisms that facilitate audiovisual integration [42]. The integration time window posits 2 sequential, interdependent stages: initial parallel peripheral processing of stimuli followed by central processes involving audiovisual integration and motor response initiation [43]. This process may help explain impairments observed in cognitive decline. Previous research indicates that patients with MCI and Alzheimer disease exhibit delayed audiovisual integration compared to older adults with normal cognitive function, with MCI populations perceiving more sound-induced flash illusions [27]. However, patients with MCI and Alzheimer disease experience attentional deficits, and these patients become

XSL•FO
RenderX

distracted by irrelevant information, demonstrating impaired attention-switching speed [44]. This aligns with the theory by Baddeley [10]. Impaired performance of the episodic buffer may contribute to working memory deficit, particularly in cognitively declining populations [10]. Therefore, we propose that assessment methods involving multisensory processing can evaluate central executive performance and better identify cognitive decline.

Task Complexity

Task 5, rather than the more cognitively demanding task 6, exhibited the most stable discriminative performance across cognitive states. This suggests that excessive complexity may overwhelm the limitations of the episodic buffer and central executive system. A study indicated that older adults tend to adopt conservative action strategies when performing complex tasks, reflecting speed-accuracy trade-offs. Specifically, they adjust their decision boundaries to increase response caution, which results in prolonged RT as a means to enhance or maintain accuracy [45]. However, a study by Chen et al [46] showed different results, with MCI and dementia populations potentially exhibiting random performance without deliberation, resulting in shorter RTs when compared to normal groups. Nonetheless, the adaptive training trials at the beginning of each task in this study could, to some extent, strengthen participants' understanding of the tasks and avoid performance variability. However, such training for task 6, which placed the highest demands on central executive resources, may still have been insufficient, leading participants to adopt response strategies that influenced the outcomes. According to the Yerkes-Dodson law (an arousal-modulated mechanism) [47], task 5 likely reaches the peak of the inverted U-shaped curve, enhancing arousal and performance discrimination, whereas the increased cognitive load imposed by task 6 exceeds this optimum, resulting in overload and diminished utility. This may also explain why task 5 demonstrated greater stability than task 6. The findings further suggest that task difficulty must be carefully calibrated to avoid overloading the episodic buffer, which could undermine measurement consistency. Additionally, the fixed task order (task 1 to task 6) used in this study means that the decline in performance on task 6 may be partially attributable to time-on-task effects, manifested as decreased attention and less effective decision-making [48]. Previous research has shown that tasks shorter than 15 minutes are unlikely to induce significant fatigue, whereas subjective fatigue increases after 20 minutes of task engagement [49]. Although rest breaks were provided between tasks, this potential confounder should be considered when interpreting the results. Future studies should use task randomization or repeated measurements to rule out this alternative explanation.

Prospective Clinical Application

At present, the go/no-go task is typically used as an experimental paradigm in conjunction with other objective indicators and has not been widely adopted for screening purposes. In contrast, traditional instruments such as the Mini-Mental State Examination and MoCA require 5 to 15 minutes for administration [24,35]. These traditional tools require trained assessors and additional time and workload and could introduce potential bias from personnel differences [5]. Regarding diagnostic accuracy, our tool demonstrated a performance comparable to that of emerging digital screening instruments, including VR and voice-based tools (AUC=0.83-0.89; sensitivity=0.79-0.83; specificity=0.67-0.91) [7,8,50]. Nevertheless, in comparison with these tools, our novel tool effectively retains the diagnostic benefits of multisensory stimulation while eliminating adverse physical effects and high scene production costs [5-7].

Notably, after accounting for the influence of educational level, the tasks retained their independent predictive value. Within the tasks with independent predictive value, task 5, as the best-performing task, can be completed within 3 minutes. Thus, the use of task 5 as a stand-alone tool for efficient and rapid screening in community settings is highly promising. Task 5 can be integrated into various digital platforms (eg, smartphones or tablets) to quickly flag at-risk individuals for follow-up assessments and can also be deployed as a self-administered tool, thereby enabling timely interventions in resource-limited environments.

Results from the informal interview with community-dwelling older adults showed a positive perception of the modified go/no-go task, with nearly half of the participants describing it as interesting. This favorable experience is important for promoting community-based screening and aligns with previous reports of older adults' increasing willingness to use digital tools [51]. Additionally, participants' subjective evaluations of task difficulty were consistent with the study sample proportions of participants with NCI and dementia, indicating that the task's difficulty gradient was perceptible.

Limitations

The uneven distribution of participants with dementia, which accounted for 9.6% (15/156) of the total sample, might lead to wide CIs and present a risk of overfitting. This may be related to our community-based data collection. This potential bias calls for future validation studies expanding the sample size of older adults with dementia. Additionally, this study did not repeat measures for test-retest reliability. Therefore, we are currently conducting a follow-up study to fully assess the reliability of the modified go/no-go task. Furthermore, as a cross-sectional study, our findings demonstrate associations but cannot determine the tool's predictive validity for future dementia onset, which requires longitudinal investigation.

Conclusions

This study modified and validated a novel go/no-go task incorporating audiovisual stimuli and semantic categorization as an effective tool for early detection of cognitive decline. Positive participant feedback on engagement and novelty supports its feasibility. The applicability and reliability of the modified go/no-go task warrant further investigation in a larger-scale community-based setting.

Abstract

Background: Cognitive decline in older adults is often accompanied by subtle motor alterations. Digital handwriting analysis has emerged as a promising noninvasive approach for detecting these changes, but its usefulness in community-based settings remains unclear.

Objective: This study aims to examine the association of handwriting kinematics and physical performance measures with pentagon-copy performance classification in community-dwelling older adults.

Methods: This cross-sectional study included 174 community-dwelling adults aged 60 years or older (mean age 73.9, SD 6.1 years; 108/174, 62% women). Participants completed 10 digital handwriting tasks and a battery of physical performance tests assessing strength, balance, gait, and cardiorespiratory fitness. Group classification was based on pentagon-copy performance and categorized as normal (93/174, 53% participants) or altered (81/174, 46% participants). Adjusted linear regression models included group as the main predictor and age and sex as covariates. Multiple comparisons were controlled using the Benjamini-Hochberg false discovery rate.

Results: After adjustment for age, sex, and multiple comparisons, selected handwriting variables remained significantly associated with altered pentagon-copy performance, whereas no physical performance variables remained statistically significant. The most consistent differences were observed in cognitive effort and mechanical tasks, where participants with altered pentagon-copy performance showed longer contact time (β=526.8 ms; P<.001) and time on air (β=1111.5 ms; P<.001), together with lower mean writing pressure (β=–2058.8 au; P=.003). Overall, group differences were more consistently detected in handwriting-derived variables than in conventional physical performance outcomes after adjusted analyses.

Conclusions: Selected digital handwriting variables, particularly temporal measures, were more consistently associated with altered pentagon-copy performance than physical performance outcomes. These findings suggest that digital handwriting analysis may represent a sensitive complementary approach for exploring subtle functional differences in community-based settings.

fine motor control; motor biomarkers; older adults; pentagon-copy test; visuoconstructional performance

Introduction

The global population is experiencing a marked demographic shift toward aging. According to the World Health Organization [1], the proportion of individuals aged 60 years or older is projected to nearly double, rising from 12% in 2015 to 22% by 2050. Furthermore, it is anticipated that by midcentury, approximately 80% of older adults will reside in low- and middle-income countries.

Aging is intrinsically associated with physiological changes that increase susceptibility to age-related conditions, including cardiovascular disease, musculoskeletal disorders, and neurodegeneration [2], thereby compromising individuals' functional capacity. To monitor changes in functionality, different tests have been developed to evaluate functional capacity in older adults, with particular emphasis on muscle strength, balance, and overall physical performance. Commonly used tests include handgrip strength, Timed Up and Go (TUG), 6-Minute Walk Test (6MWT), One-Leg Stand Test (OLST), Short Physical Performance Battery (SPPB), countermovement jump (CMJ), and midthigh pull test, all of which have demonstrated reliability and safety in older populations, including those with cognitive impairments [3-6]. Importantly, regular physical activity and structured exercise play a key role in maintaining functional capacity, delaying functional decline, and supporting healthy aging [7].

In parallel with these physical alterations, aging is also characterized by a progressive decline in cognitive function. Cognitive decline encompasses a broad continuum, ranging from normal age-associated cognitive deterioration to pathological dementia [8]. Numerous factors contribute to cognitive decline, with advancing age recognized as the primary independent risk factor, followed by genetic, socioeconomic, and environmental determinants, including nutrition and physical activity [9]. Cognitive functions comprise a range of mental processes integral to acquiring knowledge, processing information, and reasoning, which include perception, memory, learning, attention, decision-making, and language [10]. These domains are essential for the effective execution of activities of daily living.

It is well documented that functional decline is associated with cognitive deterioration in older adults [11,12], and there is evidence that targeted physical exercise interventions may alleviate or reverse these effects [13,14]. Consequently, early detection of functional and cognitive decline is vital for implementing appropriate medical and exercise interventions to slow disease progression. Traditional methods for assessing cognitive decline include verbal and written tests, such as the Mini-Mental State Examination [15], Clock Drawing Test [16,17], Trail Making Test (TMT) [18], and pentagon copying test [17]. Although failure on the intersecting-pentagons task strongly suggests underlying neurocognitive dysfunction, especially in visuospatial and constructional domains, the published literature indicates that the task functions best as a screening marker rather than an isolated diagnostic standard. Studies have shown its usefulness in older adult cognitive screening, in distinguishing Alzheimer disease from healthy aging, and in characterizing visuospatial impairment in dementia with Lewy bodies, while mechanistic work also shows that pentagon-copy errors reflect multifaceted constructional apraxia linked to parietal systems [19,20]. Accordingly, altered pentagon-copy performance can reasonably be interpreted as evidence of probable cognitive vulnerability, but not as sufficient on its own to establish clinical cognitive impairment. Additionally, physical assessments such as gait speed and balance tests have been shown to correlate with cognitive status [21,22].

Handwriting, a complex motor-cognitive task, is notably affected in individuals with neurodegenerative conditions, particularly in text production [23,24], and its kinematic characteristics may provide valuable insights into cognitive status [25,26]. For example, patients with Alzheimer disease and mild cognitive impairment (MCI) often exhibit slower handwriting speeds, increased in-air to on-surface time ratios, prolonged reaction times, decreased fluency, impaired coordination, and reduced consistency in their writing tasks [24,27]. Recent findings have also demonstrated that combining handwriting analysis with gait parameters enhances the classification accuracy of individuals with cognitive impairments [23].

While existing literature has predominantly focused on identifying behavioral markers and cognitive tests associated with cognitive decline, there remains a significant gap in research regarding the detection of cognitive deterioration through simple, noninvasive, and time-efficient motor assessments, such as handwriting analysis and physical performance tests.

Therefore, the aim of this study was to examine whether handwriting kinematic and physical performance variables differ by pentagon-copy performance classification in community-dwelling older adults. We hypothesized that altered pentagon-copy performance would be associated with poorer physical performance and less efficient handwriting kinematics.

Methods

Study Design and Population

We conducted a cross-sectional study of community-dwelling participants aged 60 years or older. Participants with a negative medical recommendation to exercise were excluded from the study. A total of 174 participants (age: 73.88, SD 6.05 years; weight: 70.93, SD 13.07 kg; height: 159.07, SD 9.47 cm) divided into men (n=66; age: 73.63, SD 5.96 years; weight: 71.47, SD 13.16 kg; height: 159.56, SD 9.52 cm) and women (n=108; age: 73.90, SD 6.06 years; weight: 70.85, SD 13.10 kg; height: 158.95, SD 9.44 cm), participated in this study.

Anthropometry and Body Composition

Anthropometric data, including height assessed with a wall-mounted stadiometer (Seca 220) and weight assessed with a scale (Tanita, MC 780-P MA), were collected. Fat-free mass and fat mass were assessed using a bioimpedance analysis system, the BIA 101 Biva Pro (Akern). This provided detailed body composition measurements for the study. Participants were assessed barefoot and in minimal clothing. They were also instructed to refrain from consuming alcohol for 48 hours before the assessments, avoid intense physical activity for at least 12 hours before the assessments, and not wear any metallic objects during the evaluation.

Handwriting Signal Acquisition

Overview

Handwriting signals were recorded using a digitizing tablet and stylus (Wacom Cintiq Pro 16, equipped with the Wacom Pro Pen 2), using an online data acquisition method. This approach represents a significant advancement over traditional offline acquisition, wherein handwriting is performed manually on paper and subsequently digitized through scanning. A principal advantage of online acquisition lies in its capacity to capture pen movements not only during direct contact with the writing surface but also during "in-air" phases, when the pen is lifted and moving above the surface [28]. The tablet operated at a sampling frequency of 100 Hz, recording spatial coordinates (x, y), pen pressure, pen tilt (altitude and azimuth angles), and pen status (pen-up/pen-down). These high-resolution temporal and spatial data allow for a comprehensive characterization of motor behavior during handwriting and drawing tasks.

Participants completed 10 handwriting tasks, each falling into 1 of 3 distinct categories as proposed by Garnacho-Castaño et al [29]: cognitive effort tasks, fine motor control tasks, and mechanical tasks.

Cognitive Effort Tasks

This category involves tasks that require substantial mental effort to replicate a complex figure or pattern. Successful completion necessitates working memory, spatial planning, and attentional control to remember the sequence of elements that have already been drawn and to anticipate those yet to follow. Such tasks are often particularly challenging for individuals with cognitive impairments [17], including MCI or early-stage dementia. Included in this category are the pentagon copying test (task 1) and the House Drawing Task (task 2).

Fine Motor Control Tasks

Fine motor control tasks, while not demanding in terms of cognitive processing, require precise motor execution. The visual patterns are generally simple and easily memorized after brief exposure; however, successful performance hinges on neuromotor control and sensorimotor integration. Tasks in this category include the Archimedean spiral (task 3), straight-line trace (task 4), spring trace (task 5), and concentric circles (task 6). These tasks are commonly used in neurological assessments and have demonstrated diagnostic value in conditions such as Parkinson disease, where subtle irregularities in amplitude, velocity, and timing of movement serve as early markers of dysfunction [30].

In certain tasks (eg, concentric circles), participants are instructed to trace a preprinted shape with minimal deviation, thereby assessing spatial fidelity and tremor control. Other tasks, such as the continuous line or spring patterns, emphasize rhythmicity, temporal consistency, and trajectory maintenance. The ability to sustain smooth and uniform movement represents an important marker of neuromotor function [31].

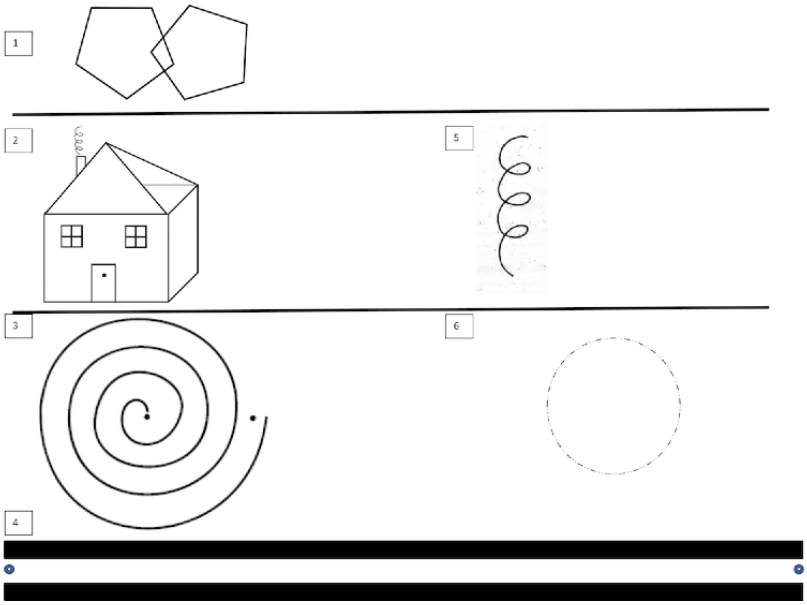
Mechanical Tasks

Mechanical tasks are characterized by low cognitive demands and involve automatic, overlearned motor patterns commonly used in daily routines. Examples include producing an individual's signature (tasks 7 and 10), writing capital letters (task 8), and copying a phrase (task 9). These tasks are generally straightforward for healthy individuals and are frequently used in biometric identification systems because of their high consistency and user specificity [32]. Given their automatic nature, deviations in task execution may be more easily attributed to motor abnormalities rather than cognitive deficits [33].

The sheet templates used for each of the 10 tasks are shown in Figures 1 and 2.

XSL•FO
RenderX

Figure 1. Drawing task sheet template, each identified by a number from 1 to 6.



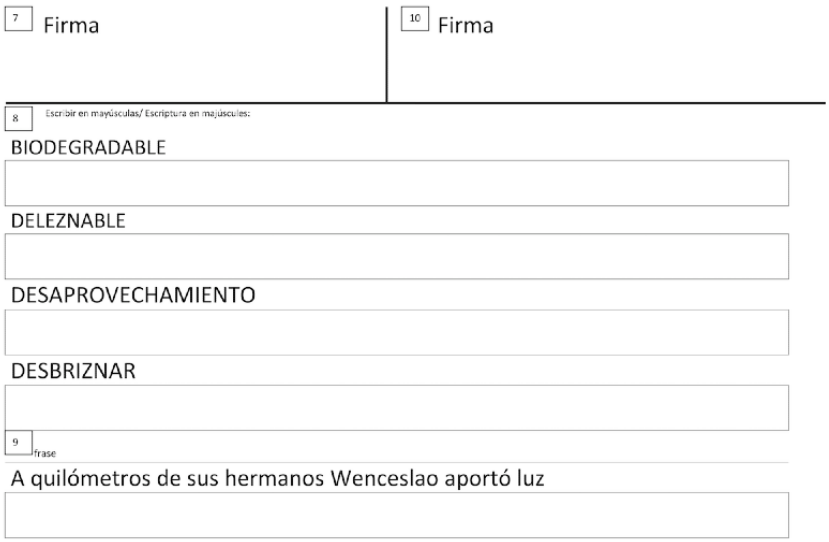


Figure 2. Writing task sheet template, each identified by a number from 7 to 10.

Handwriting Feature Extraction

The main variables obtained from each handwriting task were as follows:

Time on Air

Measured in milliseconds (ms) and refers to the total amount of time during which the pen is not in contact with the tablet surface, typically when the hand moves between letters or words. This measure reflects motor planning and writing fluency [34]. Higher values may suggest reduced motor efficiency or greater cognitive demand during the planning of subsequent strokes.

Time Down

Measured in milliseconds and refers to the total duration during which the pen remains in contact with the tablet surface while writing. This variable is closely associated with writing speed and the sustained pressure exerted during the task. Higher values may indicate a slower, more controlled writing process, often requiring greater cognitive or motor effort, whereas lower values may reflect a more automated and fluent execution.

Mean and Maximum Pressure

Measured in arbitrary units (au) and refer to the average and peak levels of pressure applied by the pen while in contact with the tablet surface. Mean pressure indicates the general force exerted throughout the writing task, whereas maximum pressure reflects the highest force recorded during a single stroke. These parameters are indicative of fine motor control and the physical effort involved in writing [35]. Deviations from typical values may be associated with motor rigidity, tremor, or impaired ability to modulate pressure during handwriting.

Mean and Maximum Speed

Measured in mm/s and refer to the average and highest velocities reached by the pen during the writing process, typically

XSL•FO
RenderX

measured as the distance covered per unit of time. Mean speed provides an overall indication of the writing pace, whereas maximum speed captures brief moments of rapid movement. These measures reflect the general rhythm and fluidity of handwriting. Alterations in speed may indicate motor slowing or, conversely, impulsive motor patterns characterized by sudden bursts of high velocity.

Mean and Maximum Acceleration

Measured in mm/s^2 and refer to the average and highest rates of change in the pen's velocity during the writing task. Mean acceleration reflects the general smoothness and consistency of pen movement, whereas maximum acceleration captures sudden, sharp changes in speed. These variables are closely linked to movement coordination and motor control. Elevated or irregular acceleration values may be indicative of tremors, spasmodic movements, or poor regulation of handwriting dynamics.

Group Classification Based on Pentagon-Copy Performance

To assess classification, the pentagon copying test from the Montreal Cognitive Assessment [36] was administered. In this task, participants were instructed to replicate a specific geometric figure, a pentagon. The test evaluates visuospatial abilities, executive functioning, and attention. Participants were provided with a digital sheet featuring a predrawn pentagon and instructed to replicate the figure by connecting its vertices using straight lines. The task aimed to ensure the accurate completion of the shape in accordance with the specified guidelines.

The test was scored based on the accuracy of the drawing and adherence to the instructions. Errors such as incorrect line placement, additional lines, or failure to follow instructions may indicate impairments in visuospatial processing and executive functioning, which are cognitive domains commonly affected in neurological conditions. Most experts assign a binary score of 0 or 1, with a correct response defined as producing 2 pentagons, each with 5 sides, and a correctly intersected region between them. If these criteria are not met, the score is 0. This scoring process is both straightforward and efficient.

In some contexts, a more granular scoring approach is used, particularly in computerized versions of the test. For example, Nagaratnam et al [19] proposed a scoring system ranging from 1 to 10 based on the quality of the drawing. In line with the original criteria, factors such as figure rotation and tremor were disregarded. In this study, a binary scoring system was adopted because the aim was to classify participants according to pentagon-copy performance rather than to perform a detailed visuoconstructive assessment. Importantly, pentagon-copy performance was used as a task-specific grouping variable and not as a diagnostic criterion or cognitive screening reference standard for cognitive impairment.

The same database used in this study was previously used to investigate cognitive impairment detection through a frontal camera during handwriting tasks, where we reported up to 83% accuracy based on head movement analysis, highlighting the potential of this approach as an automatic assessment method [37].

Strength Assessment

To evaluate muscular strength and power, a series of standardized tests targeting both upper- and lower-body performance were conducted. These tests included measures of isometric, dynamic, and explosive strength, as described below.

The handgrip strength test was used as a measure of muscular strength [38], particularly for assessing overall upper-body strength. Participants were instructed to grip a Jamar hand dynamometer (Patterson Medical) with maximal force for several seconds. The test was performed on both hands, and the highest value, measured in kilograms, was recorded as the result.

The 30-second arm curl test was used to evaluate upper-body strength and endurance [39]. Participants performed as many bicep curls as possible within 30 seconds using a 2.3 kg dumbbell for women and a 3.6 kg dumbbell for men, with the total number of repetitions recorded as the score.

The midthigh pull test was used to assess lower-body strength [40]. For this test, participants gripped a fixed bar connected to a strength sensor (Chronojump) positioned at midthigh height while maintaining a partial squat posture. They were instructed to pull upward with maximal effort for 3 to 5 seconds, with the peak force generated, measured in Newtons, recorded as a measure of lower-body strength.

The CMJ was used to dynamically assess lower-body explosive strength [41]. Participants started from an upright standing position, performed a rapid downward movement, and immediately jumped vertically as high as possible. Jump height (cm), flight time (ms), and power output (W/kg) were recorded using a force platform (MuscleLab). Each participant performed 3 trials with a 1-minute rest interval, and the highest value was used for analysis.

Cardiorespiratory Assessment

Cardiorespiratory fitness was evaluated using the 6MWT [42]. The test was conducted on a hardened surface along a 30-m straight-line circuit. Participants were instructed to walk at their fastest pace, without transitioning to running, to cover the greatest possible distance within 6 minutes. They wore comfortable clothing and footwear and were allowed to rest or stop if necessary. To objectively measure ventilatory parameters, participants were equipped with a portable gas analyzer (K5 COSMED). Peak oxygen (peak VO_2 , mL/kg/min) uptake was recorded as an indicator of cardiorespiratory fitness, alongside peak carbon dioxide (peak VCO_2 , mL/kg/min) production and pulmonary ventilation (VE; L/min) to assess ventilatory efficiency.

Functional Test and Balance Stability Assessment

To evaluate participants' functional mobility, balance, and strength, a series of standardized tests were used, including the TUG test, 400-m walking test, and SPPB. These assessments are designed to measure key aspects of physical performance, such as gait speed over short and medium distances, balance, and the ability to perform dynamic movements. The results from these tests help classify individuals based on their functional abilities and identify potential areas of decline in mobility and stability.

XSL•FO
RenderX

The TUG test involves measuring the time required for an individual to rise from a chair, walk 3 m as quickly as possible, turn around, and return to sit down. A completion time of less than 10 seconds is generally considered to be within normal limits. The onset of functional decline is indicated by times ranging from 10 to 20 seconds, although the individual may still be capable of performing basic transfers independently [43].

The 400-m walking test was incorporated within the 6MWT protocol, during which the total time taken by participants to complete a distance of 400 m was recorded. This measurement provides a practical indicator of functional walking capacity and endurance [44].

The SPPB comprises 3 components: a balance assessment, a 4-m gait speed test, and a sit-to-stand test involving 5 repetitions.

The balance assessment evaluates the participant's ability to maintain specific standing positions for 10 seconds each: feet side by side, semitandem, and tandem. For the feet side by side and semitandem positions, participants received scores of 0 or 1 based on their ability to hold the position (0 points for less than 10 seconds and 1 point for 10 seconds or more). For the tandem position, scoring ranges from 0 to 2 points (0 points for less than 3 seconds, 1 point for 3 to less than 10 seconds, and 2 points for 10 seconds or more) [45]. The total balance assessment score ranged from 0 to 4 points.

Gait speed was measured over an 8-m course, which included 2 m for acceleration, 4 m for timing, and 2 m for deceleration, thereby minimizing early braking bias. Participants were instructed to walk at their usual pace, as if walking on a street. Timing started on the command "Go," following a 3-second countdown, and concluded as the participant crossed the 4-m mark. Scoring was determined as follows: 0 points if the participant was unable to perform the test, 1 point for times exceeding 6.52 seconds, 2 points for times between 4.66 and 6.52 seconds, 3 points for times between 3.62 and 4.65 seconds, and 4 points for times below 3.62 seconds [45].

The sit-to-stand test involved a straight-backed chair stabilized against a wall. Participants were instructed to cross their arms over their chest and stand up and sit down 5 times as quickly as possible. Timing began from the initial seated position and ended when the participant reached the final standing position after the fifth repetition. The scoring for this component was based on the total time taken to complete the task: 0 points for more than 60 seconds or inability to perform the test, 1 point for between 16.7 and 59 seconds, 2 points for between 13.70 and 16.69 seconds, 3 points for between 11.20 and 13.69 seconds, and 4 points for less than 11.19 seconds [45].

A composite score ranging from 0 to 12 points was derived from all components, categorizing individuals into the following groups: severe limitations (0-3 points), moderate limitations (4-6 points), mild limitations (7-9 points), and minimal limitations (10-12 points) [46].

Static balance was assessed using a force platform (MuscleLab) [47]. Participants stood barefoot on both feet for up to 30 seconds across 3 trials, each separated by a 1-minute rest interval, without external support. The test was performed bilaterally to evaluate balance ability. Center of pressure parameters were recorded, including mean path velocity (mm/s), anteroposterior and mediolateral path velocities (mm/s), anteroposterior and mediolateral oscillation frequencies (Hz), and mean center of pressure displacement (mm).

Statistical Analysis

Continuous variables were expressed as mean (SD) and categorical variables as frequencies (%). Initial between-group comparisons were performed using 2-tailed Student *t* tests or Mann–Whitney U test, as appropriate, and chi-square tests for categorical variables.

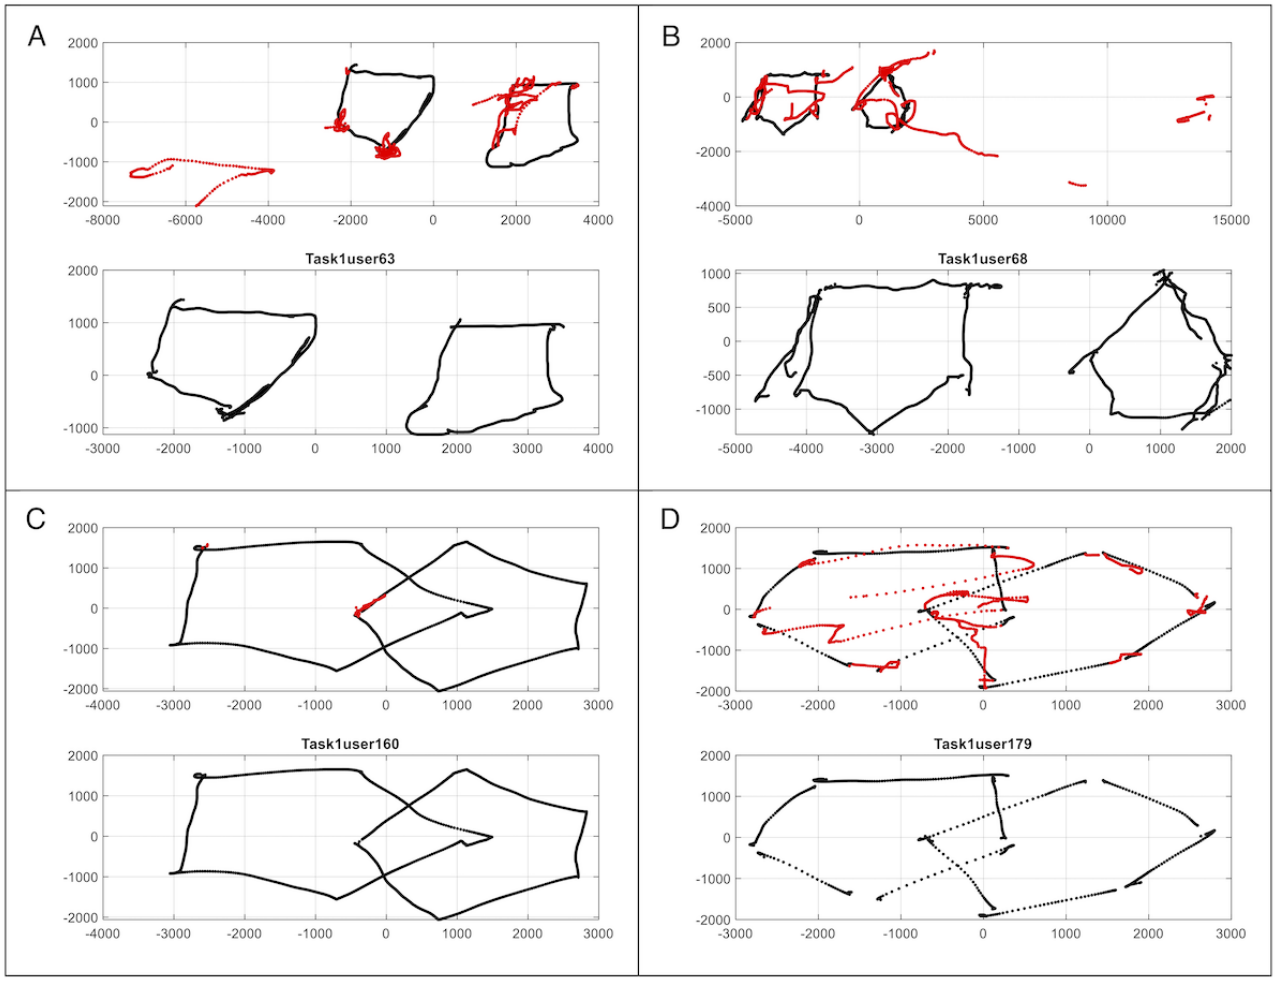
Adjusted analyses were conducted using linear regression models, including group as the main predictor and age and sex as covariates. Regression coefficients (β) with 95% CIs were reported.

Variables with nonnormal distributions were log transformed before analysis.

Given the number of comparisons, the false discovery rate (FDR) was controlled using the Benjamini-Hochberg procedure, and both raw and adjusted *P* values are presented. Statistical significance was set at $P<.05$.

Ethical Considerations

All participants were informed about the aims and procedures of the study and provided written informed consent before participation. The study protocol was approved by the Ethics Committee of Universitat TecnoCampus Mataró-Maresme (CEI1/2022) and was conducted in accordance with the Declaration of Helsinki. To ensure privacy and confidentiality, all participant data were anonymized before analysis and stored securely in password-protected files accessible only to authorized members of the research team. No financial or other compensation was provided to participants for taking part in the study.



Results

Group Classification

Group classification was based on the results of the pentagon copying test. All drawings were manually reviewed, and participants were classified as either having normal pentagon-copy performance or altered pentagon-copy performance, depending on whether the drawing met the criteria: the presence of 2 pentagons, each with 5 sides, and a correctly formed intersection region between them. Participants who fulfilled these criteria received 1 point; those who did not were given a score of 0. Figure 3 presents the results of this task, illustrating the classification of 4 participants into 2 distinct groups: normal pentagon-copy performance and altered pentagon-copy performance.

XSL•FO
RenderX

Figure 3. Differences in pentagon-copying test performance between participants with altered pentagon-copy performance (A and B) and those with normal pentagon-copy performance (C and D).

Of the total sample, 93 participants were classified as having normal pentagon-copy performance (mean age 69.6, SD 5.9 years) and 81 as having altered pentagon-copy performance (mean age 72.9, SD 5.6 years). Among them, 56.1% (37/66) men and 51.9% (56/108) women were classified as having normal pentagon-copy performance, whereas 43.9% (29/66) men and 48.1% (52/108) women were classified as having altered pentagon-copy performance. Differences in pentagon-copy performance across age groups are presented in Table 1.

Table 1. Pentagon-copy performance by age group.

Age group (years)	Normal pentagon-copy performance, n (%)	Altered pentagon-copy performance, n (%)
60-69	57 (69.5)	25 (30.5)
70-79	31 (38.8)	49 (61.3)
≥80	5 (41.7)	7 (58.3)

Handwriting Performance

After adjustment for age and sex and correction for multiple comparisons using the FDR, several handwriting variables remained significantly associated with group classification based on pentagon-copy performance. The number of statistically significant differences, as well as mean values, regression coefficients, confidence intervals, and *P* values, are presented in Tables 2-5.

XSL•FO
RenderX

Table 2. Number of significant differences, after Benjamini–Hochberg correction applied, observed across task types in writing performance variables.

Task type (task numbers)	Total tasks, n	Time on air, n	Time down	Mean pressure, n	Max pressure, n	Mean speed, n	Max speed, n	Mean acceleration, n	Max acceleration, n
Cognitive (T1 and T2)	2	0	2	1	0	0	0	0	0
Fine motor control (T3, T4, T5, and T6)	4	0	0	0	0	0	0	1	0
Mechanical (T7, T8, T9, and T10)	4	2	2	1	0	0	1	0	1

[b]Statistically significant differences.

The most consistent differences between groups were observed in temporal variables. In particular, time down was significantly higher in participants with altered pentagon-copy performance in tasks 1, 2, 8, and 9. In addition, time on air was significantly higher in this group in tasks 8 and 9.

Significant between-group differences were also found in pressure-related variables. Mean pressure was significantly lower in participants with altered pentagon-copy performance in tasks 1 and 8 after FDR correction.

For kinematic variables, significant differences after FDR adjustment were identified in selected tasks only. In task 6, participants with altered pentagon-copy performance showed significantly higher mean acceleration. In task 8, this group showed significantly higher maximum speed and maximum acceleration.

Overall, the greatest number of significant differences after FDR correction was observed in tasks 8 and 9. No other handwriting variables remained statistically significant after adjustment for multiple comparisons.

Physical Performance Results

In relation to physical performance tests, the unadjusted analyses showed statistically significant differences between participants with normal and altered pentagon-copy performance in selected variables, including CMJ height and flight time, anteroposterior axis balance stability, and 400-m walking time. However, after adjustment for age and sex, these differences were no longer statistically significant. Likewise, after controlling for multiple comparisons using the FDR, none of the physical performance variables remained statistically significant. No statistically significant differences were observed between the groups in other strength tests, such as handgrip strength, the 30-second arm curl test, or chair stand tests, nor in 4-m gait speed, total distance covered in the 6MWT, the TUG test, or metabolic variables such as peak VO_2 . The adjusted results for physical performance variables are presented in Table S1 in Multimedia Appendix 1. The number of participants differed across some tests because certain individuals were unable to complete them.

Discussion

Overview

The objective of this study was to examine whether handwriting kinematic and physical performance variables differ according to pentagon-copy performance classification in community-dwelling adults aged 60 years or older. After adjustment for age, sex, and multiple comparisons, only selected handwriting-derived variables remained significantly associated with altered pentagon-copy performance, whereas no physical performance variables remained significant.

The findings of this study should be interpreted within the context of a community-based sample without confirmed clinical diagnoses of cognitive impairment, in which group classification was based on pentagon-copy performance as a marker of task performance potentially related to cognitive vulnerability [20] rather than on a formal neuropsychological or clinical diagnostic assessment. Although failure on the intersecting-pentagons task is generally considered suggestive of underlying neurocognitive dysfunction, particularly in visuospatial and constructional domains, the literature supports its use primarily as a screening marker rather than as an isolated diagnostic standard [19,20]. Accordingly, altered pentagon-copy performance in this study should be interpreted as a marker of probable cognitive vulnerability within a community-based sample, but not as sufficient evidence on its own to establish clinical cognitive impairment. This study was not designed as a cognitive screening validation study; rather, it examined associations between handwriting and physical performance variables and group classification based on pentagon-copy performance in a community-based sample. Within this group-classification framework, differences were observed between individuals with normal and altered pentagon-copy performance in selected kinematic parameters recorded during digital handwriting tasks, whereas no corresponding differences were found in physical performance measures after adjusted analyses. These results are consistent with the hypothesis that early cognitive-related alterations may be reflected in fine motor execution [48], although not in overall physical performance in the present sample, in contrast to previous literature [49].

In the cognitively demanding handwriting tasks, which require mental planning, sustained attention, and working memory, the most consistent differences were observed between the 2 groups. Participants with altered pentagon-copy performance exhibited a significantly prolonged contact time with the screen and a markedly lower mean writing pressure. This pattern may reflect, among other possible explanations, greater disruption in movement planning during the writing process, a finding consistent with previous studies that have documented task execution slowing in complex sequential activities, as well as reductions in applied writing pressure among individuals with cognitive impairment [30,50]. Although velocity values in these tasks were not consistently lower in the altered pentagon-copy performance group, a nonsignificant tendency toward lower mean velocity was observed in some recordings, which may be indicative of less stable writing performance.

In fine motor control tasks, the altered pentagon-copy performance group exhibited higher values in mean acceleration. Contrary to what might be interpreted as an indicator of superior performance, this increase in acceleration likely reflects, among other possible explanations, reduced motor self-regulation and a more impulsive and inefficient execution. Previous evidence suggests that in contexts of cognitive impairment, individuals tend to adopt more erratic motor patterns, characterized by lower temporal and spatial consistency in stroke execution [30]. Higher acceleration in tasks demanding graphical precision may reflect less regulated motor execution.

The mechanically oriented tasks, designed to assess motor execution without additional cognitive demands, also revealed noteworthy differences. In tasks 8 and 9, the altered pentagon-copy performance group demonstrated a significantly longer total execution time (8749 ms vs 4839.2 ms and 5611

XSL•FO
RenderX

ms vs 3005.5, respectively) and higher time on air (7146.5 ms vs 5456.3 ms and 4840.9 ms vs 3599.7 ms, respectively). In addition, the altered pentagon-copy performance group showed lower mean writing pressure (6579.1 au vs 7855.5 au), higher maximum writing speed (10252.7 mm/s vs 9060.5 mm/s), and higher maximum acceleration (10252.8 mm/s^2 vs 9059.4 mm/s^2) in task 8. These results suggest reduced motor efficiency even in low-complexity tasks, consistent with previous evidence indicating that cognitive decline may compromise the basal function of motor networks involved in handwriting [27,51], even in the absence of overt clinical signs detectable through conventional neurological assessments.

The findings for physical performance should also be interpreted with caution. Although the unadjusted analyses initially suggested between-group differences in selected variables, including CMJ height and flight time, anteroposterior balance parameters, and 400-m walking time, these associations were no longer statistically significant after adjustment for age and sex. Furthermore, none of the physical performance variables remained significant after correction for multiple comparisons using the FDR, indicating that the initial differences were not robust after statistical adjustment. These findings suggest that, in this community-based sample, conventional physical performance measures may lack sensitivity to detect subtle functional differences associated with pentagon-copy performance classification. Previous studies have identified reduced explosive force production as a robust indicator of cognitively healthy aging [52], and associations have also been reported between MCI and other physical performance measures, including handgrip strength, TUG performance, gait speed, postural control, and cardiorespiratory fitness [53-59]. In this study, however, physical performance measures did not provide support as independent markers of group classification based on pentagon-copy performance. This discrepancy may reflect the relatively subtle nature of the classification approach used, the older age of participants with altered pentagon-copy performance, and other differences in study design, participant characteristics, cognitive reference standards, and severity of impairment across studies. It is also possible that such associations may become more evident in populations with more advanced cognitive impairment.

From a methodological perspective, this study provides a novel contribution by combining noninvasive digital tools for the precise quantification of handwriting kinematics with standardized assessments of physical performance in a community-based sample of older adults. This multimodal approach enabled the simultaneous evaluation of fine motor and functional measures in relation to group classification based on pentagon-copy performance. After adjustment for age, sex, and multiple comparisons, the most consistent associations were observed in selected handwriting-derived variables, particularly temporal measures, whereas physical performance outcomes did not remain statistically significant. In this context, digital handwriting analysis may represent a sensitive and scalable complementary approach for detecting subtle functional differences in community-based settings.

Several limitations should be acknowledged. First, the cross-sectional design does not allow conclusions regarding causality or predictive value. Second, group classification was based on pentagon-copy performance and does not constitute a clinical diagnosis of cognitive impairment. Third, participants with altered pentagon-copy performance were older on average, which may have contributed to the initial unadjusted differences despite statistical adjustment. Fourth, pentagon-copy performance may be influenced by factors other than cognitive status, such as visuoconstructional deficits, fine motor impairment, tremor, or visual difficulties. Finally, the study was conducted in a real-world community setting, where comprehensive neuropsychological evaluation was not feasible.

Future studies should examine these associations using more robust and clinically validated cognitive reference standards, such as the Montreal Cognitive Assessment total score, the Mini-Mental State Examination, or formal neuropsychological assessment. Longitudinal designs will also be needed to determine the predictive value of the handwriting variables identified here and to establish whether these measures may contribute to the development of digital screening tools or automated risk assessment models in primary care and community-based settings.

Conclusion

In this community-based sample of older adults, only a limited subset of digital handwriting variables remained significantly associated with group classification based on pentagon-copy performance after adjustment for age, sex, and multiple comparisons. The most consistent associations were observed in temporal handwriting measures, particularly time down and time on air, together with selected pressure and kinematic parameters, whereas none of the assessed physical performance variables remained statistically significant after adjusted analyses.

These findings suggest that digital handwriting analysis may be a more sensitive complementary approach than conventional physical performance tests for identifying subtle functional differences associated with altered pentagon-copy performance in older adults. However, because group classification was based on a single visuoconstructional task rather than on a formal clinical or neuropsychological diagnosis, the results should be interpreted with caution and should not be considered evidence of diagnostic screening performance for cognitive impairment.

Overall, this study supports the potential value of digital handwriting analysis as a noninvasive and scalable complementary approach for community-based assessment. Future research should use validated cognitive reference standards and longitudinal designs to determine the clinical relevance, predictive value, and potential application of these handwriting-derived measures in digital screening strategies for older adults.

Abstract

Background: Alzheimer disease (AD) is a leading cause of dementia, and there is growing interest in scalable approaches for early screening using speech-based tasks. While prior work has demonstrated promising results using either transcript-based language features or acoustic cues, most approaches remain unimodal or rely on simple fusion strategies that do not explicitly consider interactions across modalities.

Objective: In this study, we propose an attention-based trimodal fusion framework that integrates text, audio, and image representations of the Cookie Theft picture, which serves as the shared visual stimulus in the picture-description task.

Methods: Our method uses a new bidirectional cross-attention mechanism to achieve a unified multimodal embedding for downstream tasks. We evaluate the approach on 2 tasks: AD detection by classifying whether the participant has AD or not, and AD severity assessment by predicting Mini-Mental Status Examination cognitive scores.

Results: On the AD detection task, trimodal fusion achieves the best overall performance (F_1-score=0.8667, area under the receiver operating characteristic curve=0.9032), outperforming unimodal baselines, bimodal fusion, and conventional early or late fusion methods. For AD severity assessment, the proposed multimodal representation reduces prediction error of root mean squared error to about 4.20, improving over both unimodal and bimodal fusion settings. We further perform the ablation analysis to show that bidirectional cross-attention consistently outperforms conventional unidirectional cross-attention.

Conclusions: These results demonstrate that attention-based multimodal fusion can enhance dementia prediction from picture-description responses and provide a strong foundation for developing multimodal cognitive screening pipelines.

Alzheimer disease; multimodal fusion; speech analysis; cognitive assessment; cross-attention

Introduction

Alzheimer disease (AD) is a progressive neurodegenerative disorder and a leading cause of dementia worldwide, with a growing public health impact due to aging populations [1,2]. Early screening and continuous monitoring are critical for timely intervention, planning, and patient support [3]. However, conventional clinical assessments remain resource-intensive, often requiring specialized expertise, controlled administration environments, expensive clinical facilities, and repeated in-person visits [4,5]. These limitations motivate scalable, accessible, noninvasive, and low-burden approaches for cognitive screening that can be deployed in realistic settings.

Spontaneous speech has emerged as a particularly promising biomarker for dementia because it reflects a wide range of cognitive-linguistic processes, including lexical retrieval, syntactic organization, semantic coherence, and executive control [6-8]. A substantial body of work demonstrates that spontaneous speech contains clinically meaningful signals for AD screening and diagnosis. However, most existing studies remain unimodal, relying solely on either textual features derived from transcripts or acoustic features extracted from audio, thereby neglecting complementary information that is critical for robust inference. More recent approaches have explored bimodal models (eg, audio + text), which generally outperform unimodal baselines by aligning linguistic and acoustic cues [8-10]. Despite these advances, bimodal analyses primarily focus on local speech characteristics such as pauses and lexical diversity and often fail to capture global discourse-level phenomena, including disrupted topic

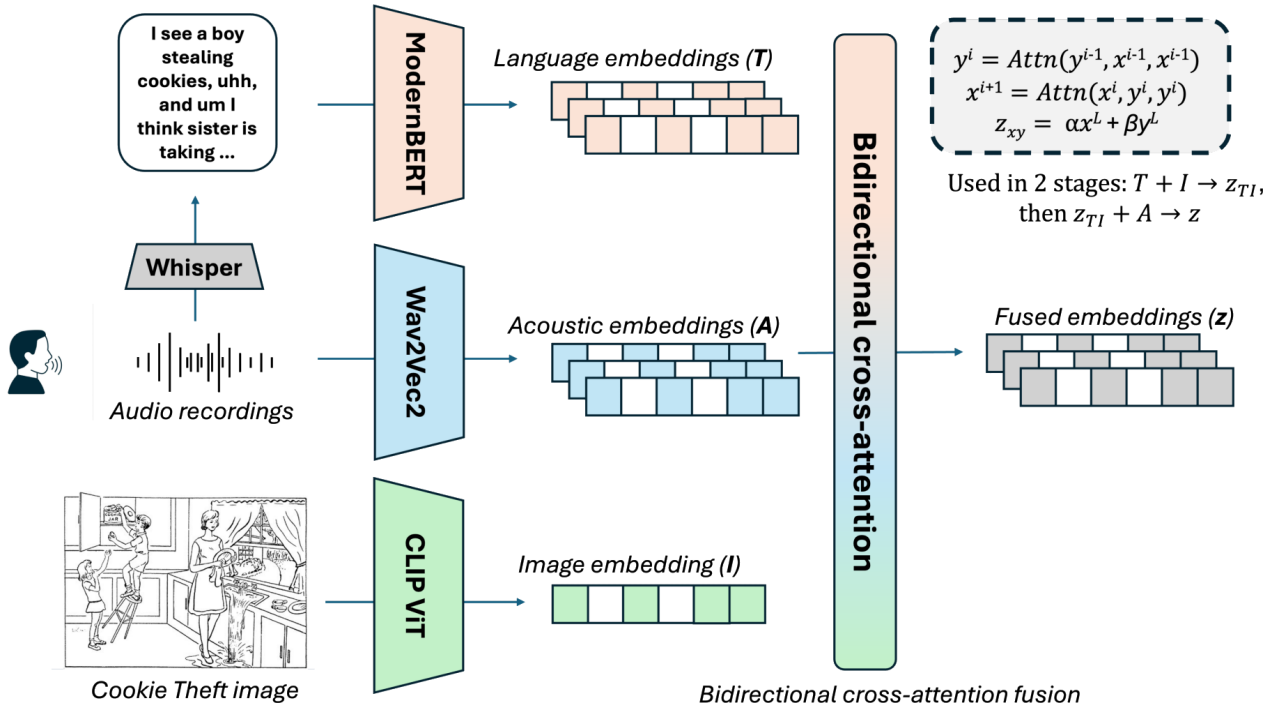
maintenance and cross-modal inconsistencies between spoken narratives and visual image.

To address these limitations, we introduce image information into AD prediction by jointly modeling text, audio, and image representations in the Cookie Theft picture-description task. Because the Cookie Theft picture is identical across all participants, the visual modality is not intended to encode participant-specific variability; instead, it provides shared visual context that grounds the spoken narrative during multimodal fusion. This visual context helps relate the narrative to the scene being described and serves as a semantic anchor for fusion. Each modality contributes different information. Text captures lexical choice, semantic content, coherence, and informativeness of the spoken description. Audio contributes complementary paralinguistic cues, including pauses, hesitation, rhythm, fluency, and other prosodic features not fully preserved in transcripts. The Cookie Theft picture provides shared visual context that grounds the narrative and helps assess how well the spoken description aligns with the scene.

Multimodal integration is commonly approached through 3 fusion strategies: early (data-level), intermediate (joint), and late (decision-level) fusion. Early fusion projects features from different modalities into a single shared space, but it often fails to capture higher-order cross-modal interactions. Late fusion, by contrast, aggregates the outputs of modality-specific models, preserving individual modality strengths while overlooking deeper interdependencies among them [11-13]. Intermediate, or joint, fusion offers a principled compromise by explicitly modeling interactions across modalities during representation learning. In this context, Transformer-based cross-attention has emerged as a key mechanism for capturing fine-grained and long-range intermodal relationships [14]. Intuitively, cross-attention allows one modality to look at another and selectively use the parts that are most relevant for the task. For example, a text representation can attend to complementary information in the audio or visual representation, so the fused embedding reflects not only what was said, but also how it was spoken and how well it aligns with the Cookie Theft picture context.

Cross-attention has been widely adopted in language-vision representation learning [8,15], audio-text integration [11], and more recently in dementia prediction [16]. However, existing approaches typically rely on unidirectional cross-attention, in which one modality queries another, resulting in asymmetric information flow. To overcome this limitation, we propose a bidirectional cross-attention mechanism that enables symmetric and iterative information exchange across modalities. In this design, each modality both attends to and is updated by the other, allowing representations to be refined in both directions. This iterative bidirectional interaction facilitates richer cross-modal integration [8,15], promotes balanced modality contributions, and mitigates the risk of modality dominance. Building on this perspective, our trimodal fusion architecture leverages bidirectional cross-attention to produce unified embeddings that capture both complementary evidence and cross-modal agreement, rather than relying on fixed or heuristic fusion rules. Simply put, rather than allowing only one modality to query information from another, bidirectional cross-attention enables both modalities to interact and refine each other, resulting in a fused representation derived from 2-way information exchange rather than 1-way conditioning.



Taken together, we propose a trimodal embedding-level fusion architecture that integrates text, audio, and image through bidirectional cross-attention (Figure 1). The resulting fused embedding is used for downstream AD detection and cognitive score prediction. We evaluate this approach on the ADReSSo 2021 picture-description task against unimodal baselines, bimodal fusion models, and conventional early- and late-fusion strategies.

Our main contributions are as follows:

- We introduce a staged bidirectional cross-attention fusion framework for integrating text, audio, and image representations in the AD picture-description setting.
- On the ADReSSo 2021 picture-description task, we show that trimodal fusion improves over unimodal baselines and outperforms bimodal fusion for both AD detection and Mini-Mental Status Examination (MMSE) prediction.
- We show that the proposed fusion framework performs better than conventional fusion strategies, including early fusion and late fusion.
- We further show that bidirectional cross-attention yields more effective and stable performance than a standard 1-way cross-attention under the same task setting.

Figure 1. Proposed trimodal fusion architecture for dementia prediction. Pretrained 768-dimensional embeddings are extracted from text (ModernBERT), audio (Wav2Vec 2.0), and the Cookie Theft picture (contrastive language–image pretraining [CLIP] ViT-L/14). Fusion is performed in 2 stages for clarity. In stage 1, text and image are fused through a bidirectional bimodal cross-attention block to obtain an intermediate representation, *TI*. In stage 2, this intermediate *TI* representation is fused with audio through the same bidirectional fusion block to produce the final multimodal embedding, *z*, which is used for downstream classification and regression. The inset illustrates the generic bimodal fusion module used in each stage, where 2 modality embeddings are updated sequentially across layers by attending to one another, enabling reciprocal information exchange beyond standard 1-way cross-attention.

Methods

Dataset Description

The dataset used in this study is derived from the ADReSSo 2021 Challenge and consists of speech recordings from a picture-description task [8], where cognitively normal participants and individuals diagnosed with AD were asked to describe the Cookie Theft image from the Boston Diagnostic Aphasia Examination [17,18]. In total, the dataset contains 237 recordings, split into a 70/30 train–test partition with demographic balancing, resulting in 166 samples for training and 71 for testing. Within the training set, there are 87 AD and 79 non-AD (healthy control) recordings.

A key strength of ADReSSo is its focus on reducing common sources of bias in dementia screening benchmarks. The dataset was carefully curated to mitigate confounds such as repeated speech samples from the same individual, variation in recording quality, and imbalances in age and gender. Demographic matching was performed using a propensity-score procedure as described by Luz et al [8], yielding standardized mean differences below 0.001 for both age and gender, which helps ensure that downstream model performance reflects disease-related signal rather than demographic artifacts.

Dataset Preprocessing and Feature Representation

We preprocess the ADReSSo picture-description recordings to obtain aligned audio, text, and image representations, which serve as inputs to our multimodal fusion architecture. For the audio modality, we extract embeddings using Wav2Vec 2.0 [19], a self-supervised speech representation model trained to learn rich acoustic features directly from raw waveforms. Given an input recording, we obtain a sequence of frame-level hidden states and apply mean pooling over time to produce a fixed-dimensional 768-D audio embedding per sample.

For the text modality, we first transcribe each recording using OpenAI Whisper [20], which provides robust automatic speech recognition for spontaneous speech. To better preserve clinically relevant phenomena commonly observed in AD speech, we supply an initial decoding prompt (“Umm, Uhh, let me think like, hmm... Okay, here’s what I’m, like, thinking.") that encourages retention of fillers, disfluencies, repetitions, and incomplete phrases, rather than normalizing them away. We then encode the resulting transcripts using ModernBERT [21], a modern bidirectional Transformer encoder optimized for producing strong sentence-level representations. Similar to the audio pipeline, we derive a fixed-length 768-D text embedding for each transcript, providing a compact semantic representation that captures content, coherence, and lexical organization.

For the image modality, we represent the Cookie Theft stimulus using contrastive language–image pretraining (CLIP; ViT-L/14), a vision-language model trained via contrastive learning to align visual and textual representations in a shared embedding space. We extract the image encoder output and use a 768-D image embedding, which provides a high-level description of the visual scene structure and salient objects.

Attention-Based Multimodal Fusion

A central component of our fusion approach is bidirectional cross-attention, where each modality is updated by attending

XSL•FO
RenderX

to the others, allowing text, audio, and image embeddings to exchange information in both directions rather than being combined through simple concatenation. Unlike simple fusion methods (eg, concatenation), cross-attention allows the model to learn which parts of one representation are most relevant given the other representation, which is especially important in dementia screening where different modalities may carry complementary cues. Formally, we use the standard attention operation represented by Attention(Q,K,V)=softmax(QKTdk)V, where *Q* (queries) represents what we want to "look for," while *K* (keys) and *V* (values) represent the information we want to retrieve from.

Intuitively, bidirectional cross-attention can be understood as a 2-way exchange between modalities. In one direction, the text representation asks which parts of the audio or image are most relevant for interpreting what was said; in the other direction, the audio or image representation is also updated by attending back to the text. This allows the fused representation to reflect not only the content of the spoken description, but also how it was delivered and how well it aligns with the shared Cookie Theft picture context. In practice, the bidirectional design helps the model avoid treating one modality as fixed context for another and instead encourages reciprocal refinement of the modality embeddings across layers.

To combine information from text, image, and audio in a way that goes beyond simple concatenation, we propose an attention-based fusion module (Figure 1) that learns how modalities complement each other when predicting AD status and cognitive outcomes. The key idea is that each modality carries different but related information: text reflects linguistic content and coherence, audio captures acoustic patterns such as hesitation and fluency, and the image provides the visual context that grounds the picture-description narrative. Rather than assuming each modality contributes equally, our fusion approach learns to emphasize the most informative signals dynamically.

Our architecture performs multimodal fusion using bidirectional cross-attention, enabling each modality to iteratively incorporate information from the others. Rather than simply concatenating embeddings, the model allows the text representation to attend to complementary cues from the image and audio, while the non-text modalities also attend back to the evolving text representation. This bidirectional exchange supports richer alignment between what is said, how it is spoken, and the visual context of the picture-description stimulus. As a result, the fusion module produces a single multimodal embedding that reflects both modality-specific evidence and cross-modal dependencies, which is then used for downstream AD classification and its severity assessment.

For the implementation, we use a multilayer attention block that alternates between the 2 inputs, allowing one modality to "look at" and incorporate information from the other. Intuitively, this helps the model learn cross-modal interactions. For example, how acoustic hesitation patterns relate to lexical choice or how a visually grounded narrative differs between cognitively normal and impaired speakers. The final output is a single fused embedding per sample, which is passed to downstream classifiers or regressors for AD detection and its severity assessment.

Training Regimen

We train the proposed trimodal fusion model using the ADReSSo training split and further reserve 20% of the training data as a validation set for model selection and early stopping. This validation split is created randomly but reproducibly using a fixed seed of 42, ensuring consistent comparisons across experiments. To enforce reproducibility, the same seed is applied across Python, NumPy, and PyTorch (central processing unit and Compute Unified Device Architecture), with deterministic CUDA deep neural network behavior enabled. During training, samples are loaded in batches of 32. The fusion backbone uses a shared projection dimension of 768, with 4 attention heads and 3 cross-attention layer pairs per fusion stage, and models are trained for up to 50 epochs with a dropout rate of 0.1. To reduce scale mismatch across modalities, we apply L2 normalization to the input embeddings prior to fusion.

The model parameters are optimized using AdamW with a learning rate of 0.0001 and weight decay of 1×10^{-4}. For AD detection, we minimize cross-entropy loss, and for AD severity assessment, we use mean squared error loss. To stabilize learning, we use a ReduceLROnPlateau scheduler that monitors validation loss and reduces the learning rate by a factor of 0.5 after 2 consecutive epochs without improvement. We additionally apply gradient clipping with a maximum norm of 1.0. Early stopping is based on validation loss with a patience of 5 epochs, and the model weights from the epoch with the lowest validation loss are restored for final evaluation and embedding extraction.

AD Detection Task

The AD detection task is formulated as a binary classification problem, where the goal is to distinguish between participants with AD and cognitively normal (non-AD) participants using picture-description responses from the ADReSSo dataset. Because dementia-related signals can manifest across multiple modalities, we evaluate models using (1) audio-only representations, (2) text-only representations, and (3) multimodal fusion representations derived from combinations of text, audio, and image. Audio representations are extracted from Wav2Vec 2.0 embeddings, text representations are extracted from ModernBERT embeddings computed over Whisper transcripts, and image representations are extracted using CLIP ViT-L/14. We primarily use 3 standard machine-learning models for the AD classification task. These include support vector classifier (SVC), random forest (RF), and logistic regression (LR), all of which are implemented from the scikit-learn package [22-25].

AD Severity Assessment Task

In addition to AD classification, we evaluate our approach for AD severity assessment by predicting MMSE cognitive score, formulated as a regression problem. The objective is to predict a participant's cognitive score directly from their picture-description response, enabling a finer-grained estimate of cognitive status beyond binary diagnosis. Similar to the classification setting, we investigate the predictive use of multiple modalities by training models with audio-only,

XSL•FO
RenderX

text-only, and image-only representations, as well as multimodal fusion representations that combine complementary cues across modalities. Specifically, we use support vector regressor (SVR), random forest regressor (RFR), and ridge regression (Ridge) as our machine learning models [23-26]. For this task, we use the same feature representations described in the preprocessing pipeline: Wav2Vec 2.0 embeddings for audio, ModernBERT embeddings derived from Whisper transcripts for text, and CLIP ViT-L/14 embeddings for the image stimulus. We compare our proposed attention-based trimodal fusion model against unimodal baselines and bimodal fusion models.

Evaluation Metrics

We evaluate performance separately for the AD classification and AD severity assessment tasks. For the binary classification setting, we report accuracy, precision, recall, and F_1-score, providing a balanced view of overall correctness as well as performance on the positive AD class. Additionally, we also show the receiver operating characteristic (ROC) curve for modality comparisons and report the area under the ROC curve. For the regression task, we quantify prediction error using root mean squared error (RMSE), which measures the average magnitude of score prediction deviations. For all classical machine-learning baselines, optimal hyperparameters are selected using grid search with 5-fold cross-validation performed on the training split only. This ensures that model configuration is tuned in a statistically robust manner while keeping the held-out test set strictly reserved for final evaluation.

To better characterize uncertainty in model performance, we additionally report 95% CIs for the major classification and regression results using nonparametric bootstrap resampling of the held-out test set. For each metric, CIs were estimated from the empirical bootstrap distribution across 1000 repeated resamples. Note that the observed performance differences were not tested for statistical significance to avoid overreliance on arbitrary significance thresholds (eg, $P<.05$) and potential misinterpretations of P values.

Attention Variant Study (Bidirectional Cross-Attention Versus Cross-Attention Only)

To assess the impact of reciprocal information exchange during multimodal fusion, we compare 2 attention configurations under an otherwise identical fusion framework. The cross-attention-only, namely standard cross-attention, performs fusion using a single cross-attention direction, where 1 modality attends to another to incorporate complementary information. In contrast, the bidirectional cross-attention applies cross-attention in both directions, allowing each modality to be updated using information from the other in a sequential manner. Both variants use the same pretrained embeddings, projection dimensionality, optimization settings, and train or validation split, enabling a controlled comparison of the attention mechanisms.

Comparison with Conventional Fusion Methods

To assess whether the proposed attention-based multimodal fusion provides benefits beyond standard approaches, we compare it against 2 widely used conventional fusion strategies for the AD classification task: early fusion and late fusion. These baselines are commonly adopted in multimodal machine learning due to their simplicity, but they often struggle to capture complex interactions between modalities. For early fusion, we construct a single feature vector by concatenating the modality-specific embeddings (text, audio, and image) and train a classifier directly on the combined representation. While straightforward, early fusion does not explicitly model cross-modal relationships and instead relies on the downstream classifier to learn interactions implicitly from the concatenated embedding.

For late fusion, we train separate unimodal classifiers and combine their predictions at the decision level using majority voting. Because the visual stimulus is identical across all samples in the ADReSSo picture-description setting, an image-only classifier would not be meaningful for late fusion. Therefore, we report late-fusion performance using only the text and audio unimodal models. This comparison helps isolate the benefit of our attention-based fusion, which can jointly reason over modalities and learn cross-modal dependencies rather than combining independent unimodal decisions.

In addition to these conventional fusion strategies, we include a neural network baseline trained on the concatenated multimodal embeddings. The neural network architecture consisted of 2 hidden layers with 512 and 128 nodes, respectively, using the rectified linear unit activation function. This funnel-like bottleneck design by progressively stepping down from the high-dimensional input space to 512 and then 128 nodes was chosen to systematically compress the multimodal features. This encourages the network to learn robust, high-level representations while mitigating the risk of overfitting on the relatively small dataset [27]. The network was optimized using the Adam solver with an initial learning rate of 0.001. To further mitigate overfitting and ensure optimal generalization, we implemented early stopping. Specifically, 10% of the training data were set aside as a validation set, and training was terminated if the validation score did not improve by at least 1×10^{-4} for 10 consecutive epochs. This baseline provides a stronger learned comparison than linear or tree-based classifiers on early-fusion features, while still operating on the same underlying embedding inputs. In this way, we can assess whether any observed gains arise simply from using a more flexible classifier on concatenated features or from the proposed bidirectional fusion mechanism itself.

Ethical Considerations

The ADReSSo Challenge data used in this study are available through DementiaBank with approved credentials. The studies involving human participants were reviewed and approved by the DementiaBank consortium. All enrolled participants provided informed written consent to participate in this study. All data analyses in this work were conducted using deidentified data.

Results

AD Detection Task

Unimodal Baselines

In Table 1, we compare the performance of text and audio embeddings using the different classifiers. From the table, we can see that text provides stronger prediction for AD than the audio. With ModernBERT embeddings, SVC attains an F_1-score of 0.8334, outperforming LR which has an F_1-score of 0.7910 and RF which has an F_1-score of 0.7713. In general, audio (wav2vec2) is weaker across all the classifiers as the best audio-only result is achieved by RF with an F_1-score of 0.6736 and an accuracy of 0.7048. This performance gap between text and audio underscores that picture-description transcripts capture more discriminative information than the audio embeddings.

Table . Unimodal baselines on the ADReSSo 2021 unseen test set (n=71)[a].

Classifier	Accuracy (95% CI)	Precision (95% CI)	Recall (95% CI)	F_1-score (95% CI)
SVC^{b}_{text}	0.8448 (0.7606 - 0.9296)	0.8744 (0.7500 - 0.9714)	0.7999 (0.6571 - 0.9231)	0.8334 (0.7241 - 0.9231)

LR^{c}_{text}	0.7876 (0.6901 - 0.8732)	0.7618 (0.6190 - 0.8919)	0.8275 (0.6969 - 0.9429)	0.7910 (0.6774 - 0.8889)
LR_{audio}	0.6617 (0.5493 - 0.7746)	0.6886 (0.5161 - 0.8519)	0.5712 (0.3953 - 0.7317)	0.6207 (0.4666 - 0.7500)
RF^{d}_{text}	0.8029 (0.7042 - 0.8873)	0.8886 (0.7500 - 1.0000)	0.6859 (0.5294 - 0.8333)	0.7713 (0.6429 - 0.8772)
RF_{audio}	0.7048 (0.5915 - 0.8169)	0.7338 (0.5714 - 0.8846)	0.6284 (0.4643 - 0.7858)	0.6736 (0.5283 - 0.7949)

[a]Performance of text-only (ModernBERT embeddings) and audio-only (wav2vec 2.0 embeddings) representations with 3 standard classifiers (support vector classifier, logistic regression, and random forest) is shown.

[b]SVC: support vector classifier.

[c]LR: logistic regression.

[d]RF: random forest.

Bimodal Fusion (2-Way)

Combining text and image embeddings yields consistently strong performance as shown in Table 2, reflecting the benefit of pairing transcript semantics with visual context from the Cookie Theft stimulus. Across classifiers, the results remain close to the text-only baselines, suggesting that the image modality provides incremental gain rather than a major boost in this setting. The top configuration is achieved by SVC, reaching an F_1-score of 0.8371 with an accuracy of 0.8437, slightly exceeding the text-only SVC F_1-score (0.8358). RF also performs competitively (F_1-score=0.8428), while LR attains an F_1-score of 0.8011. Overall, text continues to dominate prediction quality, while image representations appear to offer modest complementary signal.

Table . Text + image fusion for Alzheimer disease (AD) classification[a].

Classifier	Accuracy (95% CI)	Precision (95% CI)	Recall (95% CI)	F_1-score (95% CI)
SVC^{b}	0.8437 (0.7465 - 0.9296)	0.8509 (0.7241 - 0.9655)	0.8275 (0.6944 - 0.9429)	0.8371 (0.7333 - 0.9247)
LR^{c}	0.8011 (0.7042 - 0.8873)	0.7978 (0.6571 - 0.9231)	0.7987 (0.6571 - 0.9259)	0.7959 (0.6857 - 0.8919)
RF^{d}	0.8428 (0.7606 - 0.9296)	0.8731 (0.7500 - 0.9714)	0.7987 (0.6571 - 0.9286)	0.8321 (0.7241 - 0.9231)

[a]Performance of bimodal text + image representations on the ADReSSo 2021 unseen test set (n=71) using 3 classifiers (support vector classifier, logistic regression, and random forest) is shown. Text embeddings are extracted with ModernBERT, and image embeddings are extracted with contrastive language–image pretraining ViT-L/14.

[b]SVC: support vector classifier.

[c]LR: logistic regression.

[d]RF: random forest.

The text + audio pairing produces the best bimodal performance in Table 3 among all 2-way combinations. In particular, incorporating audio improves performance beyond transcript-only models, suggesting that features such as speech rhythm, hesitation patterns, and fluency irregularities provide additional discriminative value. The best overall results are obtained with SVC, which achieves an accuracy of 0.8584 and an F_1-score of 0.8503, outperforming both the text-only SVC model (F_1-score=0.8358) and the other bimodal settings. RF remains strong (F_1-score=0.8325), whereas LR performs slightly lower (F_1-score=0.7903). These results support the benefit of integrating acoustic information when strong text representations are available.

[a]Performance of bimodal text + audio representations on the ADReSSo 2021 unseen test set (n=71) using 3 classifiers (support vector classifier, logistic regression, and random forest) is shown. Text embeddings are extracted with ModernBERT, and audio embeddings are extracted with Wav2Vec 2.0.

[b]SVC: support vector classifier.

[c]LR: logistic regression.

[d]RF: random forest.

Table 4 shows results for audio + image fusion, a pairing that excludes transcript information and relies only on acoustic patterns and visual context. Performance is notably lower than text-based bimodal models, but it improves substantially over audio-only baselines, suggesting that image features contribute useful grounding signals when linguistic embeddings are not available. The top performance is achieved by SVC, with an accuracy of 0.7188 and an F_1-score of 0.6934, followed closely by RF (F_1-score=0.6830). LR produces a slightly weaker result (F_1-score=0.6530). Overall, these results reinforce that while audio + image alone can support AD prediction above chance, transcript-derived text embeddings remain critical for achieving top performance on picture-description based dementia screening.

[b]SVC: support vector classifier.

[c]LR: logistic regression.

[d]RF: random forest.

Multimodal Fusion (3-Way)

Using all 3 modalities (text, audio, and image) leads to the highest AD classification performance in our experiments. Among the 3 classifiers, SVC achieves the best overall results, with an accuracy of 0.8722 and an F_1-score of 0.8667. LR attains an F_1-score of 0.8542, while RF achieves an F_1-score of 0.8371. Overall, the 3-way fusion setting produces strong and stable performance across classifiers, with SVC providing the highest classification scores (Table 5).

Table . Multimodal fusion for Alzheimer disease (AD) classification[a].

Classifier	Accuracy (95% CI)	Precision (95% CI)	Recall (95% CI)	F_1-score
SVC[b]	0.8722 (0.7887 - 0.9437)	0.8806 (0.7632 - 0.9730)	0.8564 (0.7317 - 0.9688)	0.8667 (0.7692 - 0.9474)
LR[c]	0.8582 (0.7746 - 0.9437)	0.8558 (0.7250 - 0.9677)	0.8563 (0.7273 - 0.9678)	0.8542 (0.7536 - 0.9367)
RF[d]	0.8437 (0.7465 - 0.9296)	0.8509 (0.7241 - 0.9655)	0.8275 (0.6944 - 0.9429)	0.8371 (0.7333 - 0.9247)

ROC Curve Comparison Between Bimodal and Multimodal Fusion

Figure 2 compares ROC curves across bimodal fusion settings and the proposed trimodal multimodal fusion model for AD classification. Among the bimodal approaches, text + audio achieves the highest discrimination performance (area under the receiver operating characteristic curve [AUC]=0.8714), followed closely by text + image (AUC=0.8595), while audio + image performs notably lower (AUC=0.7937). The proposed multimodal fusion model yields the strong overall ROC performance with an AUC of 0.9032, indicating improved separability between participants with AD and without AD relative to all bimodal alternatives.

Figure 2. Receiver operating characteristic (ROC) comparison across bimodal and multimodal fusion (Alzheimer disease [AD] classification). ROC curves on the ADReSSo 2021 unseen test set (n=71) compare bimodal fusion models (audio + image, text + image, text + audio) against the proposed trimodal multimodal fusion (text + audio + image). The legend reports the area under the receiver operating characteristic curve (AUC) for each method.

Comparison to Other Fusion Methods

Table 6 compares the proposed multimodal fusion with conventional early fusion, late fusion, and a neural network baseline trained on concatenated embeddings. For SVC, both early fusion and late fusion achieve an accuracy of 0.8169, with F_1-scores of 0.7937 and 0.8000, respectively. The neural network baseline improves this comparison to an accuracy of 0.8311 and an F_1-score of 0.8099. In contrast, the proposed multimodal fusion achieves a higher accuracy of 0.8722 and a higher F_1-score of 0.8667. A similar pattern is observed across the other classifier families, indicating that the advantage of the proposed fusion is not limited to comparison against only simple conventional baselines.

XSL•FO

$RF_{multimodal\ fusion}$	0.8437	0.8509	0.8275	0.8371

[a]Performance comparison between early fusion (feature concatenation), late fusion (decision-level fusion of text and audio), a neural network baseline trained on concatenated embeddings, and the proposed attention-based multimodal fusion (text + audio + image) on the ADReSSo 2021 unseen test set (n=71) is shown.

[b]SVC: support vector classifier.

[c]LR: logistic regression.

[d]RF: random forest.

Bidirectional Cross-Attention Versus Cross-Attention Only

We evaluate 2 fusion variants to quantify the impact of the bidirectional cross attention. Across all 3 classifiers (Table 7), the bidirectional cross-attention configuration achieves stronger overall performance than cross-attention only. For SVC, cross-attention alone attains an F_1-score of 0.8571 with accuracy of 0.8732, while our bidirectional cross attention improves results to an F_1-score of 0.8667 and an accuracy of 0.8722. A similar trend is observed for LR. For RF, the cross-attention only baseline achieves an F_1-score of 0.8125 (accuracy=0.8309), and the bidirectional cross-attention variant improves to an F_1-score of 0.8371 (accuracy=0.8437). Overall, bidirectional cross-attention produces balanced AD classification performance metrics.

Table . Performance comparison between cross-attention–only fusion and the proposed bidirectional cross-attention fusion on the ADReSSo 2021 unseen test set (n=71) across 3 classifiers (support vector classifier [SVC], logistic regression [LR], random forest [RF]).

Fusion method	Accuracy	Precision	Recall	F_1-score
$SVC_{cross_attention}$	0.8732	0.9642	0.7714	0.8571
$SVC_{bidirectional}$	0.8722	0.8806	0.8564	0.8667
$LR_{cross_attention}$	0.8028	0.7837	0.8285	0.8055
$LR_{bidirectional}$	0.8582	0.8558	0.8563	0.8542
$RF_{cross_attention}$	0.8309	0.8965	0.7428	0.8125
$RF_{bidirectional}$	0.8437	0.8509	0.8275	0.8371

AD Severity Assessment Task

Overview

We evaluated how well individual modalities support continuous MMSE score prediction and compare them to pairwise and their multimodal counterparts (Table 8). Across all 3 modalities for regression, text embeddings again outperform audio. With ModernBERT features, Ridge regression attains the lowest text-only error, followed closely by SVR and RFR. In contrast, the corresponding audio-only models with wav2vec2 embeddings are substantially less accurate.

XSL•FO
RenderX

Table . Mini-Mental Status Examination (MMSE) score prediction across unimodal, bimodal, and trimodal fusion settings on the ADReSSo 2021 unseen test set (n=71)[a].

Model and classifier	RMSE[b] (95% CI)
Unimodal	
SVR^{c}_{text}	4.3959 (3.7870 - 5.0445)
SVR_{audio}	6.0146 (4.6954 - 7.2511)
$Ridge^{d}_{text}$	4.5951 (3.7248 - 5.4198)
$Ridge_{audio}$	5.9914 (4.9110 - 7.1118)
RFR^{e}_{text}	4.5806 (3.8630 - 5.3138)
RFR_{audio}	8.0297 (6.8131 - 9.2356)
Pairwise	
$SVR_{text + image}$	4.3897 (3.7793 - 4.9916)
$Ridge_{text + image}$	4.3333 (3.5186 - 4.7430)
$RFR_{text + image}$	4.4310 (3.6517 - 5.2476)
$SVR_{audio + image}$	6.0201 (4.6987 - 7.2746)
$Ridge_{audio + image}$	5.8611 (4.9170 - 6.8695)
$RFR_{audio + image}$	6.1440 (5.0956 - 7.1654)
$SVR_{text + audio}$	4.6745 (3.9837 - 5.3725)
$Ridge_{text + audio}$	4.3122 (3.7134 - 4.9219)
$RFR_{text + audio}$	4.7432 (4.0348 - 5.4675)
Multimodal	
$SVR_{text + audio + image}$	4.2134 (3.4898 - 5.0544)
$Ridge_{text + audio + image}$	4.1440 (3.5511 - 4.7421)
$RFR_{text + audio + image}$	4.3856 (3.8126 - 5.0012)

[a]Root mean squared error with 95% CI is reported for unimodal models using text-only (ModernBERT embeddings) and audio-only (Wav2Vec 2.0 embeddings), bimodal fusion models using text + image, text + audio, and audio + image representations, and the proposed trimodal fusion model using text + audio + image. The results are shown for 3 regression heads: support vector regressor, ridge regression, and random forest regressor.

[b]RMSE: root mean squared error.

[c]SVR: support vector regressor.

[d]Ridge: ridge regression.

[e]RFR: random forest regressor.

For pairwise fusion, the lowest prediction error is achieved when text is included in the fusion pair, while combinations that exclude text remain substantially weaker. The best-performing bimodal configuration is Ridge with text + image, which attains the lowest RMSE of 4.3333, followed closely by SVR. These results indicate that integrating a second modality alongside text can reduce prediction error relative to text-only baselines. In contrast, pairings based on audio + image perform consistently worse across all regression heads.

Across the 3 regression heads, multimodal fusion achieves consistently low error, with Ridge obtaining the best overall RMSE of 4.1440, followed closely by SVR regression. RFR also performs competitively with an RMSE of 4.3856. Overall, the 3-way fusion setting yields strong and stable MMSE prediction accuracy across model families, with SVR and Ridge producing the lowest errors.

Comparison With Representative ADReSSo 2021 Multimodal and Transformer-Based Studies

To further position our method relative to recent benchmark-relevant approaches, we conducted a targeted scoping review of ADReSSo 2021 studies using multimodal, transformer, and attention-based methods. From this review, we selected e representative ADReSSo 2021 comparator studies for focused comparison: Wang et al [28], Zhu et al [29], Bang et al [30], and Shao and Fang [31]. These studies span attention-based multimodal fusion, wav2vec2 + Bidirectional Encoder Representations from Transformers (BERT) hybrid modeling, large language model–augmented multimodal modeling, and co-attention acoustic-text fusion, respectively.

XSL•FO
RenderX

Table 9 summarizes their reported AD classification performance alongside our proposed model. Details of the scoping-review procedure are provided in Multimedia Appendix 1.

Table . Comparison with representative modern ADReSSo 2021 multimodal and transformer-based comparator models for Alzheimer disease (AD) classification[a].

Study and year	Modalities	Model	Accuracy	F_1-score
Wang et al [28], 2021	Linguistic + IS10 + X-Vector	DNN[b]	0.80	0.83
Zhu et al [29], 2021	Audio + ASR[c] text	Wav2vec2 + BERT[d]	0.83	0.83
Bang et al [30], 2024	Audio + text + LLM[e]-generated “opinion” feature	ChatGPT-assisted multimodal model	0.87	0.87
Shao and Fang [31], 2025	Acoustic + ASR text	Co-attention multimodal model	0.83	0.84
Ours	Audio + text + image	Bidirectional attention + SVC	0.87	0.87

[a]The table reports a focused comparison between our proposed audio + text + image bidirectional attention framework and four representative ADReSSo 2021 studies selected from the targeted scoping review: Wang et al [28] (attention-based multimodal deep neural network), Zhu et al [29] (wav2vec2 + BERT), Bang et al [30] (large language model–augmented multimodal model), and Shao and Fang [31] (co-attention multimodal fusion). Accuracy and F_1-score are reported as provided in the respective studies.

[b]DNN: deep neural network.

[c]ASR: automatic speech recognition.

[d]BERT: Bidirectional Encoder Representations from Transformers.

[e]LLM: large language model.

Discussion

Our findings indicate that trimodal fusion of text, audio, and image provides the overall strong performance on ADReSSo for both AD classification and MMSE prediction. Relative to unimodal and bimodal alternatives, the trimodal setting yields the best overall classification performance and the lowest or near-lowest regression error across model families. Because ADReSSo was designed to reduce common confounds such as demographic imbalance, these gains are likely to reflect disease-relevant information rather than spurious correlations [8].

A consistent trend across the tasks is that text representations dominate unimodal performance, with transcript-derived embeddings outperforming audio-only models by a substantial margin. This aligns with longstanding clinical and computational evidence that connected speech contains measurable dementia-related changes in lexical selection, semantic content, and syntactic organization [32]. In our experiments, ModernBERT-based embeddings preserve much of this discriminative linguistic structure, yielding the strong unimodal baselines across both classification and MMSE prediction.

Although audio-only performance is weaker, audio contributes useful complementary information when paired with text, particularly for AD classification where text + audio is a rather competitive bimodal configuration and for MMSE prediction. This is consistent with prior work on paralinguistic and timing-related markers in dementia, such as pausing, hesitation, and fluency disruptions, which are not fully captured in transcripts alone [33]. The use of self-supervised acoustic representations such as wav2vec 2.0 provides a principled way to encode these cues from raw speech [19].

The image modality plays a more nuanced role in this benchmark. Because the Cookie Theft stimulus is fixed across participants, an image-only system is not expected to be discriminative; however, our results suggest that including image embeddings can still improve performance when used jointly with text and audio. One plausible explanation is that the image representation acts as a shared contextual anchor for the narrative. This interpretation is supported by several findings. First, drawing on the image-text matching approach [34], prior work [35] shows that healthy and dementia samples differ in their relevance to the target picture, with healthy samples yielding higher relevance scores. This finding suggests that visual information can contribute meaningfully to dementia detection. Second, we conducted a series of comparisons to evaluate the added value of the image modality (Tables 1-5), including text versus text + image, audio versus audio + image, and text + audio versus text + audio + image. Across all settings, incorporating the image leads to consistent, albeit modest, performance gains when combined with other modalities. Third, we performed a control analysis by randomly shuffling half of the image patches in the text + image fusion model. This manipulation resulted in a drop in performance relative to the original images (F_1-score: 0.84 vs 0.79), providing direct evidence that preserving the visual structure is important for model effectiveness. Taken together, these results indicate that the image serves as a semantic anchor to leverage the full contextual information available. Since the same image is used for every participant, the study demonstrates the usefulness of shared stimulus grounding rather than the predictive value of participant-specific image data.

A key methodological advance from our ablation study is that bidirectional cross-attention consistently outperforms standard

XSL•FO
RenderX

1-way cross-attention across classifier families. This suggests that reciprocal information exchange between modalities is more effective than a single one-way update for this task. In other words, allowing each modality to attend to and be updated by the other leads to stronger fusion than unidirectional conditioning alone [12]. The comparison with early and late fusion further shows that how modalities are integrated matters. Early fusion and late fusion are simple and widely used, but they do not model cross-modal relationships as explicitly as attention-based intermediate fusion. Their weaker performance in our experiments supports the value of learned cross-modal interaction over heuristic fusion strategies [35].

Across tasks, the regression results mirror classification trends: text-only is the strongest among unimodal baselines, bimodal improvements are most pronounced when text is included, and trimodal fusion produces the lowest overall error. This consistency suggests that the multimodal embedding learned through attention mechanisms supports both discrete diagnostic labeling and continuous cognitive assessment, a useful property for clinical decision support where disease manifestations often exist on a spectrum rather than a binary boundary. At the same time, RMSE values remain nontrivial, highlighting that cognitive score prediction remains a challenging objective likely influenced by heterogeneity in impairment profiles and the limited size of available labeled data.

Beyond the in-benchmark comparisons reported in the *Results* section, Table 9 provides additional context against representative modern ADReSSo 2021 multimodal and transformer-based studies. As shown in Table 9, our method remains competitive relative to these comparator models. At the same time, direct one-to-one comparison remains imperfect even within the ADReSSo-only subset because studies differ in modality definitions, auxiliary cues, and evaluation protocols. We therefore use Table 9 as a focused benchmark-context comparison rather than as a strict ranked state-of-the-art table.

Several limitations should be considered when interpreting these findings. First, the findings have not yet been validated across an independent dataset, a different elicitation image, or a different clinical population. ADReSSo is a relatively small benchmark dataset for training and evaluating multimodal deep learning models, with 237 total samples and a held-out test set of 71 recordings. Although the dataset is carefully curated and demographically balanced, the limited sample size may constrain generalizability and increase the possibility that strong performance partly reflects benchmark-specific characteristics rather than broader robustness across populations or recording conditions. Accordingly, this study should be interpreted primarily as a benchmarked methodological investigation on ADReSSo that evaluates the potential of bidirectional multimodal fusion, rather than as definitive evidence of clinical generalization. Second, picture-description tasks represent a structured elicitation paradigm; performance may differ for more naturalistic conversational speech, where topic drift and dialogue dynamics introduce additional complexity. Third, transcript-based modeling depends on automatic speech recognition quality; while Whisper-style transcription is robust in many conditions, transcription choices around disfluencies and fillers can influence downstream embedding behavior especially in tasks where such markers may carry clinical signal.

Finally, these results suggest several directions for future work. More fine-grained alignment strategies (eg, segment-level coupling between audio and text representations) may strengthen the ability of cross-attention to learn clinically meaningful correspondences. Additionally, evaluation across multiple elicitation tasks and datasets would help clarify whether the observed gains extend beyond Cookie Theft.

In this work, we introduced an attention-based trimodal fusion framework for dementia screening that integrates text, audio, and image through bidirectional attention. Evaluated on the ADReSSo Cookie Theft picture-description benchmark, the proposed approach achieved overall strong performance for both AD classification and MMSE prediction, outperforming unimodal baselines, bimodal fusion models, and conventional early- and late-fusion strategies. The ablation analysis further showed that bidirectional cross-attention performs better than standard 1-way cross-attention, highlighting the value of reciprocal cross-modal interaction for dementia-related prediction.

Acknowledgments

We are grateful for the ADReSSo Challenge data that were available via DementiaBank. Abstract

Background: Storytelling interventions have demonstrated substantial potential in improving emotional well-being, cognitive function, and quality of life for older adults. However, its effectiveness is often limited by the challenges of processing disorganized and redundant life stories, which impose substantial cognitive demands on caregivers. Although storytelling interventions are a well-established therapeutic approach, current practices depend heavily on manual narrative organization, restricting both the scalability and consistency of treatment delivery. Prior research has primarily focused on validating the clinical outcomes of storytelling interventions, with insufficient attention given to technological solutions that could enhance narrative processing while preserving therapeutic integrity. Digital approaches to life story structuring remain underexplored, despite their potential to amplify storytelling benefits by reducing cognitive load and improving recall accuracy.

Objective: This study aims to design an event timeline generation algorithm to optimize the prior work of the Story Mosaic system. The optimized system enables (1) the automatic extraction of event elements from life narratives, (2) the automatic organization of fragmented life stories into structured timelines, and (3) the preservation of clinically relevant contextual details during compression. The goal is to reduce manual intervention costs while increasing treatment efficacy through artificial intelligence–driven narrative structuring.

Methods: We have designed a novel method, CARE event timeline (CARE-ET), which combines a temporal attention mechanism with graph-based event relationship modeling. Furthermore, we used the CARE-ET algorithm to optimize existing story collage systems. The system uses multifeature extraction technology to capture event clues from oral histories, prioritizes the 6 elements of events through a hierarchical attention mechanism, and uses adaptive compression algorithms to reduce redundancy while maintaining narrative continuity. To verify the effectiveness of the CARE-ET method, this paper adopts a multidimensional evaluation framework, which encompasses event summary assessment, timeline quality evaluation, and usability testing of the optimized system.

Results: The proposed CARE-ET algorithm outperforms the baseline in both narrative flow and temporal accuracy. The Story Mosaic system, optimized by the CARE-ET algorithm, underwent usability evaluation by 10 caregivers recruited for this study. Based on standardized assessment metrics, the system received an A rating for usability. The comprehensive experimental results demonstrate that the CARE-ET method can effectively structure fragmented narratives from older adults, enhancing the usability of the Story Mosaic system.

Conclusions: The proposed method enables the structured extraction of representative event summaries, transforming disorganized life stories into an event timeline for caregiver-supported older adult well-being interventions. Future research should investigate longitudinal effects on cognitive preservation and explore integration with existing dementia care protocols. This work establishes a critical foundation for intelligent assistive technologies in geriatric mental health interventions.

Introduction

Cognitive impairment is a common condition affecting the health of older adults, and it is difficult to treat through medication [1]. People with mild cognitive impairment may encounter the following issues: (1) impaired short-term and long-term memory with reduced recall efficiency [2]; (2) deteriorated social functioning, exhibiting social withdrawal and diminished emotional interaction, which can lead to social

XSL•FO
RenderX

isolation [3, 4]; and (3) declined executive function in daily activities [5,6].

Through the analysis of over a hundred studies, Zhang et al [7] demonstrated that digital health technologies can effectively address the limitations of traditional medical models by delivering personalized and highly accessible intervention strategies, thereby facilitating timely intervention during the early stages of cognitive decline. Storytelling is an important application of digital health technology, which plays a significant role in the field of reminiscence [8]. Harnessing the power of storytelling, people with mild cognitive impairment can be encouraged to participate more proactively in their health care [9]. Additionally, life stories can serve as a database and decision support tool for understanding older adults and providing personalized services [10-13]. In practice, Zhu et al [14] have demonstrated that storytelling requires older adults to recall, organize, and narrate personal experiences—a process that naturally exercises cognitive functions such as memory, attention, and language abilities.

Interviews and daily interactions with older adults are a common way to access their life stories [15]. However, these life stories often have problems such as redundant content and disorganized structure, which increase the cognitive load on caregivers when learning them [16]. Moreover, as the number of exchanges grows and the volume of life stories continues to expand, the scattered information becomes increasingly difficult for caregivers to process [17,18]. In our prior work, our team developed the Story Mosaic system, designed to assist caregivers in integrating and organizing life stories for older adults. The findings were published in the international journal *JMIR Aging*. However, this version of the system has significant limitations in functional implementation: the extraction of story elements and the arrangement of narrative logic remain highly dependent on manual operations. This not only substantially increases the workload for caregivers but also necessitates the assistance of volunteers in practical applications to complete the recording and organization of older adults' life stories [17].

An effective solution is to extract the core events from older adults' life stories, rearrange the events in the order in which they occurred, and generate an event timeline structure of older adults' life stories. Then, based on the algorithm, develop a visualization system to present the timeline of older adults. An event timeline is a series of events, activities, or important moments recorded and displayed in chronological order, with a simple and clear presentation that allows users to quickly understand the temporal relationship and development of events. The structuring of life stories lies at the critical intersection point between the basic data infrastructure and artificial intelligence applications. It addresses the current problem of "fragmented data and lack of depth" in personalized intervention research, laying the foundation for the development of an intelligent intervention system that truly "understands you" [19].

Existing studies have made some progress in personal event timeline generation, but there are still limitations that do not meet the requirements of older adults' life stories. The Twitter (subsequently rebranded X) event extraction method proposed by Li et al [20] treats frequent mentions of events as general events, which contradicts the characteristics of older adults' narratives. Althoff et al's [21] timeline construction method relies on precise temporal information, which is difficult to apply to the temporally ambiguous life stories. Sun et al's [22] stage-by-stage story line generation method ensures plot integrity but lacks a generalized description of key events. The pretraining with extracted gap-sentences for abstractive summarization model learns to generate summaries by pretraining with masked key sentences, but its reliance on document structural integrity and sentence coherence makes it difficult to handle issues such as temporal confusion, information redundancy, or fragmentation in the life stories of older adults [23]. The long text-to-text transfer transformer model uses a local-global attention mechanism to efficiently process long texts and avoid excessive information repetition, but its limited ability to capture fine-grained temporal relationships constrains its performance in strictly reorganizing fragmented life events into chronological timelines [24]. The pyramid-based masked sentence pretraining for multidocument summarization model enhances multidocument information integration through pyramid-based masked pretraining; however, as the life stories of older adults are often fragmented and narrated individually, the lack of cross-document structural associations limits the effectiveness of its hierarchical modeling approach [25]. The life stories of older adults exhibit intrinsic particularities, such as ambiguous temporal information, conflicting event elements, and difficulty in determining event significance. These characteristics directly contribute to the limitations of existing methods in processing such narratives.

To address limitations in existing approaches to organizing life stories for older adults, this paper proposes a CARE event timeline (CARE-ET), an innovative event timeline generation method that systematically structures narratives through optimized event relevance analysis and implements the practical Story Mosaic system for caregiver application. Our research makes the following three key contributions. First, we developed a multimodal event fusion method using a 2-layer encoder-decoder architecture that integrates event triggers and timestamps. This structured representation model significantly improves accuracy in extracting key events from older adult narratives. Second, the theoretical novelty lies in the synergistic integration of graph attention networks (GATs) and deep belief networks (DBNs). In contrast to existing hybrids where DBNs serve merely as static feature extractors, the CARE-ET model uses a joint self-supervised module. Here, the latent clustering probability distribution generated by the DBN acts as a global before regularizing the GAT attention coefficients. This ensures that the learned values are optimized not only for local semantic alignment but also for global thematic coherence across the life story timeline. Finally, building upon the CARE-ET method, we have optimized and enhanced the previously developed Story Mosaic system. The improved system is designed to construct more logically coherent life story timelines for older adults, thereby providing reliable data support for personalized care.

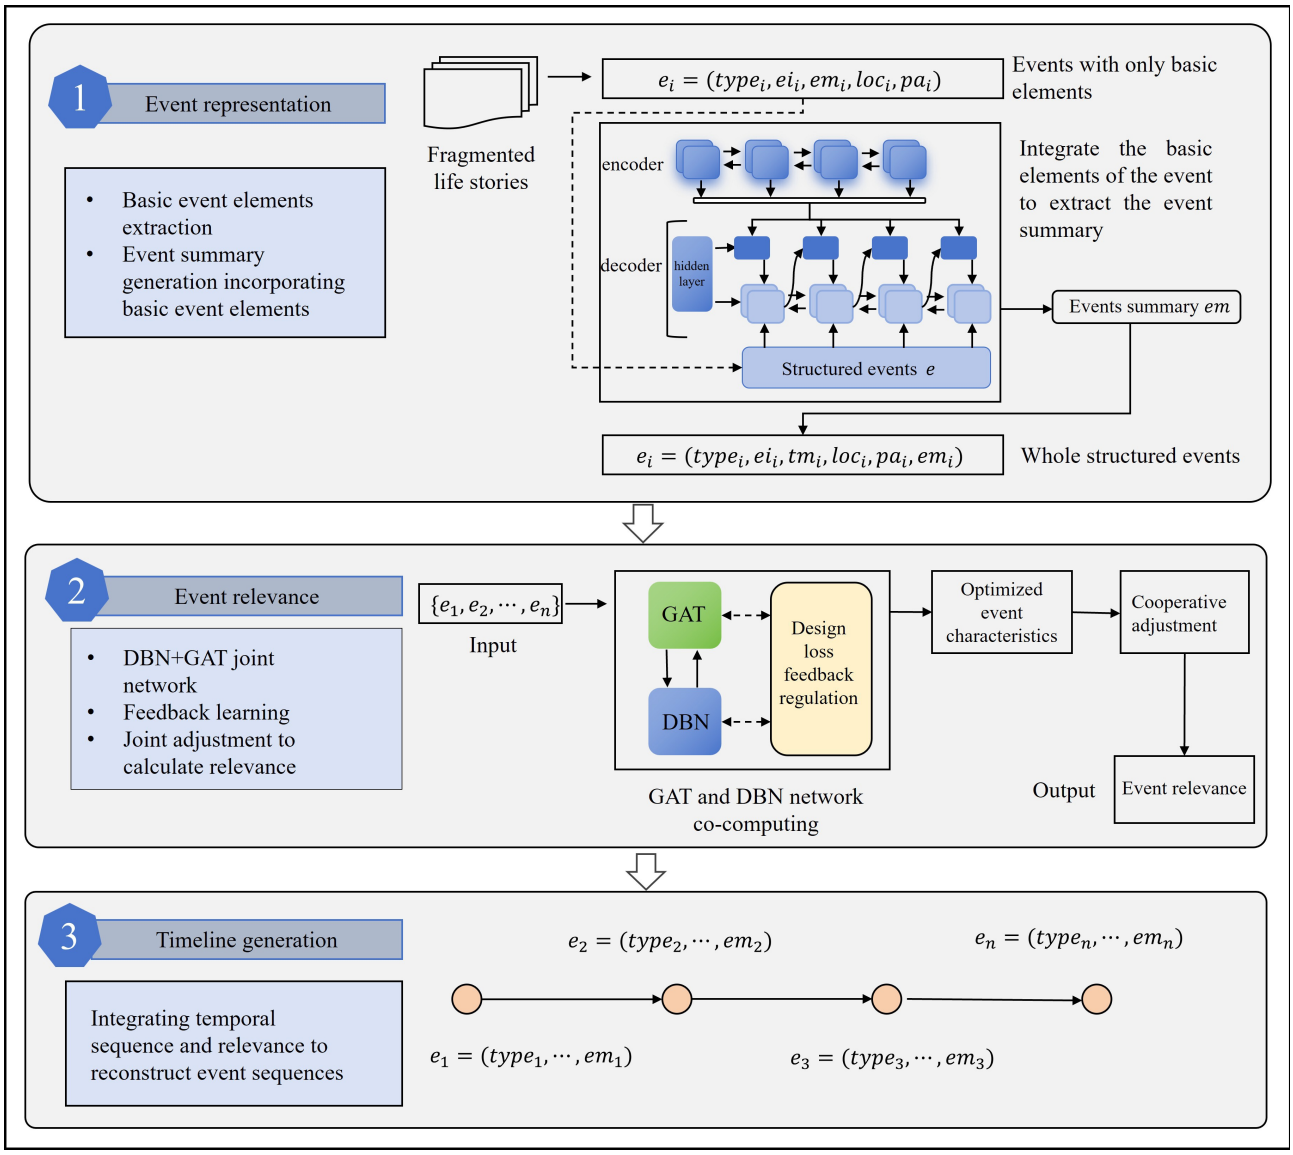
XSL•FO
RenderX

Methods

This section first elaborates on the overall algorithmic framework of the CARE-ET method and concludes with an introduction to the optimized and enhanced functionalities of the Story Mosaic system.

Ethical Considerations

This study aims to propose a novel algorithm to optimize the Story Mosaic system, thereby better facilitating the automatic organization of fragmented life stories of older adults. This study has been approved by the research ethics committees of Hefei University of Technology (HFUT20220921001) and Chuzhou University (CZSC2025-021), respectively. All participants, including older adults and caregivers, signed a written informed consent form before the initiation of the study. The informed consent form explicitly included authorization for audio recording of the interviews, verbatim transcription of the recorded content, and the use of such materials for academic research purposes. Participation is entirely voluntary. Participants have the right to withdraw unconditionally at any stage of the study without assuming any liability or providing a reason. Given the nature and objectives of this study, there are no circumstances that necessitate the provision of financial or any other form of compensation to participants. All data collected during the research process (including interview recordings and transcribed texts) have undergone rigorous anonymization. All personally identifiable information has been removed or replaced, and comprehensive privacy protection measures have been implemented. The relevant information and images related to the older adults presented in this paper do not involve any personal privacy.



CARE-ET Method

Overview

The CARE-ET method automatically generates life story timelines through a three-stage computational process, as shown in Figure 1: (1) bidirectional long short-term memory (BiLSTM)-based event extraction and representation, which synthesizes triggers, time stamps, and semantic context into structured events; (2) hybrid DBN-GAT modeling for self-supervised event correlation computation using optimized loss functions and distance-density joint adjustment; and (3) integrating temporal features with semantic correlations to produce coherent event timelines.

XSL•FO
RenderX

Figure 1. The CARE event timeline (CARE-ET) algorithmic framework for automated life story structuring. The framework comprises three stages: (1) event extraction via bidirectional long short-term memory (BiLSTM), (2) relevance modeling using the joint network of graph attention network (GAT) and deep belief network (DBN), and (3) timeline generation. Rectangles represent computational modules, while arrows indicate the flow of feature vectors and processed narrative data.

Event Extraction and Presentation

Event extraction and representation consist of 2 main processes: the extraction of basic event elements and the generation of event summaries incorporating the basic event elements. Event information is extracted from older adults' life stories. The structured event representations include event type, event trigger word, time, location, participant, and event summary, and the formal expression is: ei=type,eii,tmi,loci,pai,emi(1)

Structured Event Extraction

The module achieves coreference resolution by using ALBERT (A Lite Bidirectional Encoder Representations from Transformers for Self-supervised Learning of Language Representations) embeddings with a 512-token sliding window for context management. Similarity between candidate expressions is measured via cosine distance, with a threshold of 0.8 established to determine coreferentiality [26,27]. We adopt a semisupervised open domain event extraction approach to expand event templates through manual annotation of triggers and types, enabling systematic extraction of basic event elements (type, trigger, time, location, and participants) for structured representation of older adults' life stories [28].

Context-Aware Summary Generation

This module builds a dual-level encoder-decoder architecture. It uses ALBERT-BiLSTM for encoding and combines BiLSTM decoding with dynamic attention mechanisms [16]. The model prioritizes event-centric content by jointly analyzing word or sentence-level features alongside spatiotemporal and participant context. For event-level summarization, the system selects the top three most salient sentences using maximal marginal relevance based on ALBERT's cross-attention scores. This ensures that the selected content maximizes coverage of the event trigger while minimizing information redundancy between sentences.

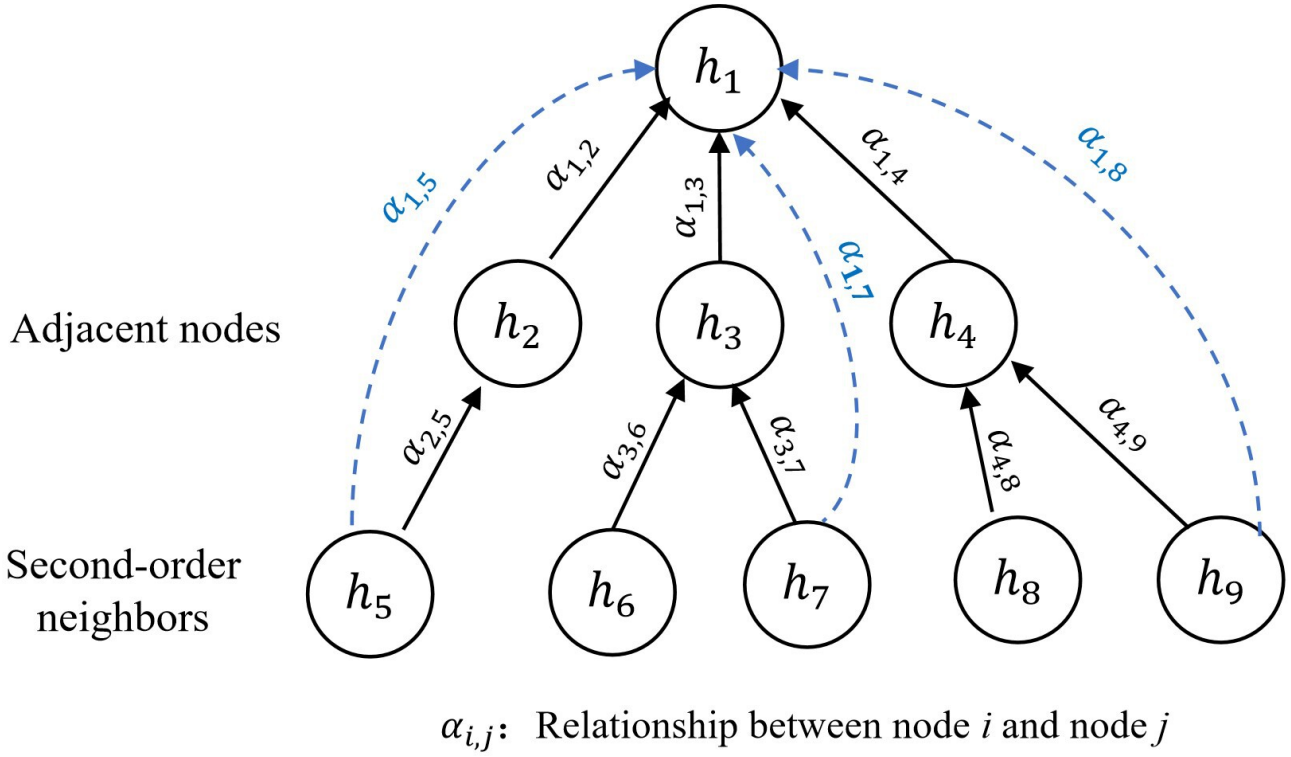
Event Relevance Calculation

Overview

After the event extraction module extracts the structured events for each life story, we need to calculate event correlations to arrange the event nodes on the timeline.

The CARE-ET method uses a novel GAT-DBN collaborative model to compute event relationships for timeline construction [29]. The architecture combines: (1) an enhanced GAT network that captures multihop event dependencies through dynamic attention weights, extending influence beyond immediate neighbors; (2) a DBN component that learns compressed event representations while preserving relational semantics; and (3) a hybrid k-means or density-based spatial clustering of applications with noise (DBSCAN) self-supervision module that optimizes feature clustering through distance-density joint optimization [30], as shown in Figure 2. This integrated approach automatically learns hierarchical event relationships while maintaining computational efficiency through backpropagation-based training.

Figure 2. Detailed architecture of the event relevance computing model. This diagram illustrates the collaborative workflow between the graph attention network (GAT; which captures global dependencies) and the deep belief network (DBN; which performs feature compression). The joint adjustment module integrates the results to output refined correlation coefficients used for timeline sequencing.



The Improved GAT Network

The proposed GAT extension structure advances traditional attention mechanisms by incorporating multihop node relationships during state updates. While standard GAT computes attention weights based solely on direct neighbors [31], our method dynamically integrates deeper network contexts through an adaptive depth strategy, enabling more comprehensive feature representation while maintaining computational efficiency. This enhancement allows each node to capture richer structural patterns by considering both immediate connections and semantically relevant indirect relationships within life story narratives.

Figure 3 illustrates the GAT network's enhanced state update mechanism, where each node's output (eg, $_1$) incorporates weighted influences from both direct neighbors ($_2$, $_3$, $_4$) and secondary neighbors ($_5$, $_7$, $_9$). The model automatically filters insignificant connections (eg, $_6$ and $_8$) through threshold-based attention weights, enabling efficient multihop relationship modeling while maintaining computational efficiency. This dynamic depth perception improves event relationship characterization without compromising network performance.

XSL•FO
RenderX

Figure 3. The mechanism of graph attention network node updates based on multihop relationships. Circles represent events $_i$. Solid arrows indicate direct influence from immediate neighbors, while dashed arrows denote filtered indirect connections identified by the adaptive depth strategy. Gray nodes (eg, $_6$ and $_8$) represent connections that have been discarded due to the similarity threshold.

Assuming that a total of events exist, denotes the event, and each event is characterized as an -dimensional vector. All event features can be represented as the set = { $_1$, $_2$, , }. Based on this, the features of all events can be integrated into a sample feature matrix of × :

(2)Φ=[e11e21 en1e12e22 en2 e1me2m enm]

The GAT network can be described as:

(3)O = G(Φ)

The improved GAT network facilitates node feature evolution through linear transformations and attention-weighted aggregation. The feature update for each node in a specific layer is defined as:

(4)hil=σ(∑j∈ (Ni∪Ii)aijlWlhjl→)

where is the network input, denotes the network function, and denotes the network output. Thus, the GAT network can be described as:

(5)O=[o11o21 on1o12o22 on2 o1m′o2m′ onm′]

where ′ is the new dimension of each event vector element, the actual output is a matrix consisting of new vectors describing each event.

The core of the GAT model lies in the graph attention layer, which maps the upper-layer graph node states to the lower-layer graph node states. The input to the graph attention layer, $^{l-1}$, is the set of graph node feature vectors output from the upper layer.

(6)Hl−1={e1Hl−1,e2Hl−1, ,enHl−1}

is the number of nodes in the network, and $^{-1}$ is the dimension of the output features of the previous layer. Thus, the size of the matrix $^{l-1}$ is × $^{-1}$:

(7)H=[h11h12h1nh21h22h2nhn1hn2hnn]

The output of this layer is a new set of node feature vectors M′, denoted as:

(8)M′={e1Hl,e2Hl, ,enHl}

The attention coefficient θij is computed using a single-layer feed-forward neural network, parameterized by a weight vector a, which operates on the concatenated features of the node pair:

(9)θij=a→(Wh→i,Wh→j)

(10)θij=LeakyReLu(a→T[Wh→i||Wh→j])

The proposed model extends traditional GAT attention computation through a dynamic coefficient function that incorporates both direct neighbors and validated indirect connections , as shown in Figure 3. By enhancing the masked attention mechanism with SoftMax regularization, the system captures multi-hop dependencies while maintaining stable gradient propagation, significantly improving relationship modeling for life event networks compared to standard single-hop approaches.

This formula represents the attention coefficient of node *i* to node *j*, where α is not a constant but a node-dependent function, and *W* denotes the trainable weight parameters. The key innovation of our GAT enhancement lies in its refined attention allocation mechanism.

Unlike traditional GAT models, which compute attention solely over the direct neighbors of node *i*, our improved masked

XSL•FO
RenderX

attention mechanism extends the scope of attention coefficient computation, enabling the exploration of indirect node relationships. Additionally, we introduce a SoftMax function to normalize attention scores across both direct neighbors and selected indirect nodes meeting specific criteria (equation 9). This modification enhances information propagation and dependency modeling between nodes:

(11)αij=softmaxj(θij)=exp (θij)∑(k∈ Ni∪Ii) exp (θik)

where denotes the set of adjacent nodes for node *i*, while represents the set of qualified indirect nodes for node *i*. According to the definition of and Ii, only events with a similarity exceeding a predefined threshold are established as related events.

Our GAT extension introduces an adaptive second-hop set Ii based on semantic relevance thresholds. While heterogeneous graph attention typically focuses on predefined meta-paths [32], our approach dynamically identifies high-influence indirect neighbors in the narrative graph. By redefining the training of attention coefficients α over Ii, the model captures long-range dependencies in disorganized oral histories while mitigating the oversmoothing issues common in deep GNNs.

The network function determines the node influence weights based on the correlation between the 2 events. The cosine similarity function is used to calculate the event similarity between the 2 events and :

(12)ϕ(ei,ej)=ei·ej|ei||ej|

To model the structural relevance of life events, we define the neighbor set Ni for a given event node ei as:

(13)Ni={ej ∣ cos_simhi,hj§amp;gt;τ1}

where τ1=0.6.

For global consistency adjustment, the second-order inference set Ii is constructed as:

(14)Ii={ek ∣ ∃ej∈ Ni,cos_simhj,hk§amp;gt;τ2}

where τ2=0.8.

Next, the LeakyReLU function is adopted as the single-layer feed-forward function of the attention mechanism, and the improved attention mechanism is shown below:

(15)[illegible]

The attention function can calculate the attention coefficients between different nodes and predict the output characteristics of each node. The output characteristics are:

(16)h→i=σ(∑j∈ (Ni∪Ii) aijWh→j)

Meanwhile, this method adopts the multihead attention mechanism, which can make the attention training more stable. The core idea is to execute *m* attention functions independently and use the average distribution of *m* attention outputs as the output of the overall attention mechanism:

(17)hi′→=σ(1m∑1m ∑j∈ (Ni∪Ii) aijmWmh→j)

GAT Synergy With DBN Networks

The model integrates GAT and DBN through a bidirectional encoding-decoding framework. GAT captures interevent correlations via attention-weighted node interactions, while DBN performs hierarchical feature compression through multilayer transformations. Their synergistic operation—alternating GAT's encoded outputs with DBN's hidden states during each encoding round—preserves individual event characteristics while enhancing semantic relationships. The complementary decoding process ensures reconstructed features maintain fidelity to original inputs while optimizing them for correlation computation, achieving both dimensionality reduction and relationship-aware representation learning.

In this synergistic interaction model, the inputs and outputs of each layer of the DBN coding part are shown in equation 16:

(18)hi+=sigmoid(∑j |Hj|wjvj+bi)

Also, the inputs and outputs of each GAT network can be adapted in the following form:

(19)Oi=G(Oi−1,hi−1+)

Self-Monitoring Module

To address the coordination challenge between GAT and DBN networks, we introduce a novel self-supervised joint adjustment module that serves as an integrative optimizer. This module dynamically aligns the feature representations from both networks during prediction by: (1) generating target distributions through hybrid k-means or DBSCAN clustering, (2) constructing a unified loss function for backpropagation, and (3) enabling simultaneous parameter optimization across both architectures. The resulting feature representations are specifically tuned for accurate event correlation computation while maintaining the distinct advantages of each network's processing paradigm.

If the 2 events are highly correlated, their features should also be highly similar. Multiple events describing similar contexts will form clusters in the feature space. In this paper, we use the output features of the DBN as inputs to the joint adjustment module to compute the interevent correlation and cluster structure. This is done by calculating the similarity between each event feature within a cluster and the center event feature of that cluster, which in turn generates a distribution *D* that contains the correlations of all the events, where $_i$ denotes the DBN feature of the i^{th} event, is the center event of the j^{th} cluster, and $_{cj}$ is the center event feature and is a fixed parameter. The construction of the correlation distribution is accomplished by traversing all clusters and their center events. The correlation distribution of the th event belonging to the th class is shown in equation 18:

(20)dij=(1+|hi−hcj|2vc)−(vc+1)∑n (1+|hi−hcn|2vc)−(vc+1)

The self-supervised module enhances event feature representations by optimizing correlations between individual events and their cluster centroids, thereby improving semantic similarity grouping among related events. The target distribution of event relevance is first computed :

(21)pij=dij2/fi∑j′dij2/fi

where = ∑ is the sum of the frequencies of a category of event correlation, and ∑j`dij2/fi is the sum of the frequencies of all categories of event correlation, where ′ denotes the

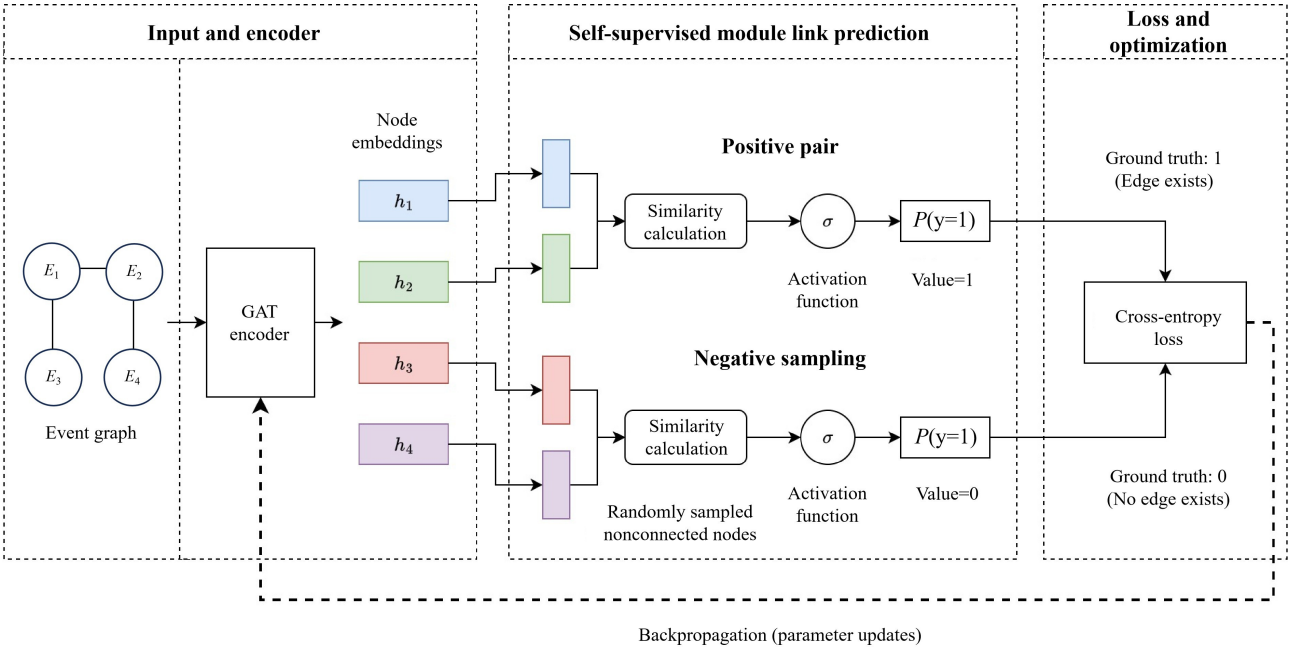
XSL•FO
RenderX

individual categories in the computation. The following loss function is constructed from the distributions P and D for inverse training the DBN. The self-supervision module uses the Kullback-Leibler divergence to quantify the discrepancy between the predictive and target distributions. The joint loss function is formally defined as:

(22)L=KL(P|D)=∑i ∑j pijlog pijdij

GAT also requires backpropagation training. Since both distributions P and D depend on the features generated by the DBN, more noise may be introduced if the loss(P|D) is used directly to compute the loss of GAT. The GAT network itself can generate a distribution (which is also the output of the last GAT network), using K instead of the DBN-generated distribution D, using K and P to compute the loss. In this way, the GAT-generated distribution K is supervised by the distribution P, and the loss is designed to be used for the backpropagation of the GAT, where is in the last network output matrix .

(23)loss(P|K)=∑i ∑j pijlog pijkij



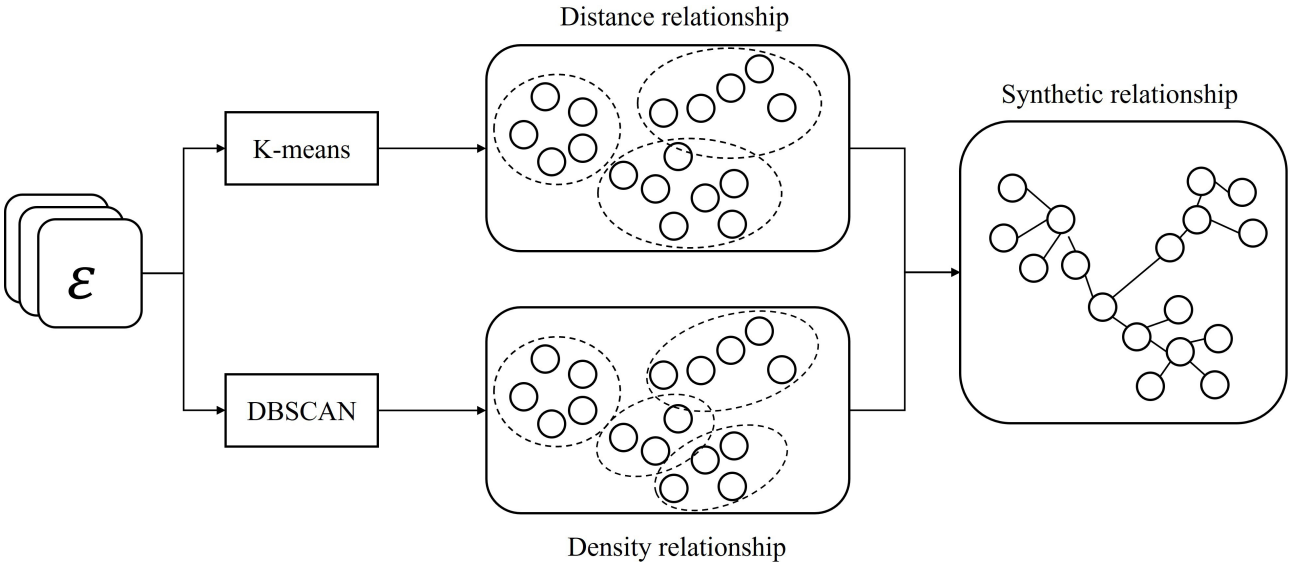
Intuitively, the self-monitoring module acts as an "internal auditor." While GAT makes initial predictions about event relevance based on local connections, the DBN provides a global thematic template. The module calculates the "surprise" or discrepancy between these two (via Kullback-Leibler divergence) and forces the model to self-correct, ensuring that local narrative links do not deviate from the overall life story logic.

The optimal number of clusters K in the joint adjustment module is determined using the silhouette coefficient and the elbow method applied to a validation subset of narratives. To prevent overfitting, we use L2 regularization and dropout (rate=0.5) within the GAT layers. Furthermore, the self-supervised loss function itself acts as a structural regularizer, penalizing the model when it focuses excessively on transient noise in individual narratives at the expense of global consistency.

The joint loss function is configured as Ltotal=λ1LGAT+λ2Ljoint, where λ1=0.7 and λ2=0.3 were empirically chosen to prioritize structural accuracy while maintaining global coherence. Optimization was performed using the AdamW routine with a weight decay of 0.01 and a linear learning rate scheduler that warmed up for the first 10% of total training steps.

Figure 4 illustrates the operational mechanism of the self-supervised module.

Figure 4. Self-supervised link prediction. A graph attention network (GAT) encoder generates node embeddings hi from the input graph. Positive and negative pairs are evaluated via dot products and sigmoid activation. The model minimizes cross-entropy loss through backpropagation to update encoder parameters and optimize latent representations.



Joint Relevance Adjustment

The proposed method integrates k-means and DBSCAN clustering to compute event correlations through a dual-metric approach, as shown in Figure 5. K-means evaluates co-clustered events using relative centroid distances, while DBSCAN assesses connectivity through minimum path lengths between nodes. Both algorithms assign zero correlation to nonclustered event pairs.

XSL•FO
RenderX

Figure 5. Framework of the joint adjustment module combining geometric and density metrics. The process integrates k-means (based on Euclidean distance to centroids) and density-based spatial clustering of applications with noise (DBSCAN; based on local density connectivity). The final correlation score is a weighted fusion of these 2 metrics to ensure structural robustness in narrative clustering.

The final correlation coefficient synergistically combines both clustering results, leveraging k-means' geometric precision and DBSCAN's density awareness. This hybrid approach captures complementary aspects of event relationships while maintaining computational efficiency through conditional zero assignments for unrelated events.

Timeline Generation

To address temporal ambiguity in life stories, we first standardize diverse time expressions (eg, relative dates like "three years ago" or historical references like "Liberation War"). For events lacking absolute dates, we calculate cosine similarity between their text features and a curated historical event database, assigning standardized timestamps when similarity exceeds 0.85. This process ensures consistent temporal representation across both precise and ambiguous event references.

The generation algorithm first arranges temporally annotated events chronologically as the timeline backbone. For undated events, it calculates semantic similarity with existing timeline nodes to determine optimal insertion points between adjacent events. To integrate undated events Eu into the anchor timeline Tanchor={e1,e2,…,en}, we propose a relevance-based greedy insertion algorithm. For each eu∈ Eu, the optimal position i is determined by:

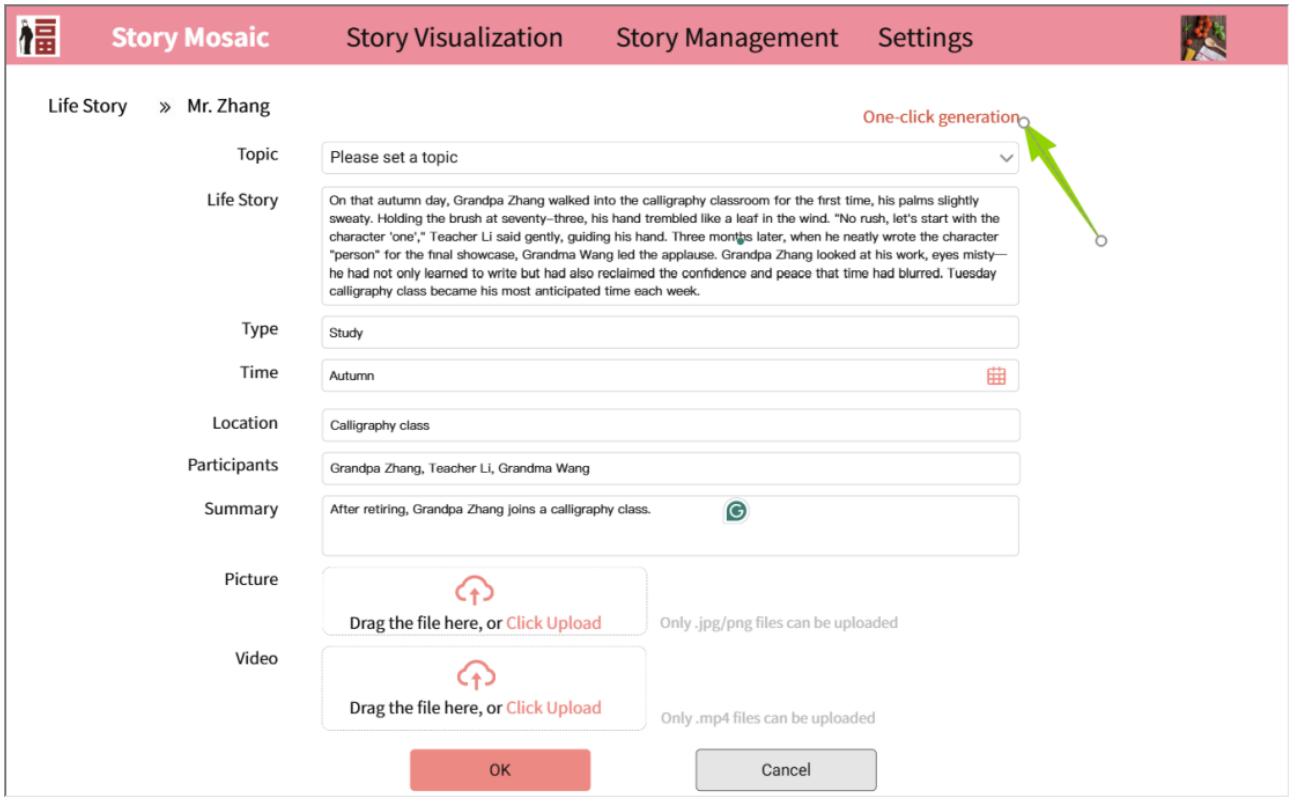
$$(21) i* = \arg\max_{0 \le i \le n} (\alpha \cdot \mathrm{Rel}(ei, eu) + (1-\alpha) \cdot \mathrm{Rel}(eu, ei+1))$$

where e0 and en+1 are virtual start and end nodes. If multiple positions yield the same maximum score, the tie is resolved by selecting the position that maintains the original narrative proximity in the transcript. This dual consideration of temporal sequence and semantic coherence produces timelines that maintain both chronological accuracy and narrative flow, essential for effective reminiscence therapy applications.

The cosine similarity threshold of 0.85 was empirically determined through a sensitivity analysis. In our pilot tests, thresholds above 0.95 resulted in a 36% loss of valid temporal anchors, while thresholds below 0.75 introduced significant "semantic drift," where personal anecdotes were incorrectly mapped to unrelated historical events. To mitigate the impact of potential misalignment on timeline validity, we introduced a "confidence flag" mechanism: events with similarity scores between 0.70 and 0.85 are flagged for human-in-the-loop verification by caregivers. Error analysis indicates that inaccuracies primarily occur in narratives with vague temporal adverbs (eg, "back then"), which the system addresses by placing them in a relative sequence based on narrative flow rather than fixed historical coordinates.

The Historical Event Database used for mapping undated narratives contains approximately 5000 major historical events spanning from 1900 to 2000, curated from open-source repositories including Wikipedia and Baidu Baike. It focuses on events highly relevant to the Chinese older adult cohort (eg, social movements, economic reforms, and significant natural disasters). The database is maintained in Chinese and is licensed under CC-BY-SA 4.0 for research purposes.

Story Mosaic System



The core architecture of the Story Mosaic system is built around three principal functional modules: (1) a story input module supporting multiple formats, including text, images, and videos, with temporal annotations available for manual or automatic addition; (2) a theme-based content organization module that allows for customizable categorization (eg, "Career" and "Family Life"); and (3) a chronological timeline generation module for key life events [17].

In the preliminary work of the Story Mosaic system, the generation of life event timelines, while algorithmically automated, exhibited limited accuracy, with event elements largely reliant on manual annotation during story input. In this study, the timeline generation module has been specifically optimized based on the CARE-ET method. This enhanced module leverages the structured framework of the CARE-ET approach, integrating three core functions: event extraction, temporal sequencing, and narrative coherence, as shown in

XSL•FO
RenderX

Figure 6. It enables the automated generation of accurate event summaries and timelines, thereby alleviating the data entry burden on caregivers.

Figure 6. Schematic diagram of the automatic event feature generation module, supporting 1-click generation of event features.

Results

We conducted a comprehensive evaluation of the proposed system, organized into two key aspects: (1) quantitative assessment of event representation and timeline quality, and (2) systematic usability testing.

Datasets

We selected 2 datasets for the experiments to verify the effectiveness of the event timeline generation method. The first is the self-constructed OALS (Older Adults' Life Stories) dataset, which contains the event data TimID (timeline identity) that has been annotated with timelines. The second is the Chinese news summary dataset LCSTS (Large Scale Chinese Short Text Summarization), organized by the Harbin Institute of Technology, which is constructed based on Sina microblog text. For detailed information about the datasets, please refer to Multimedia Appendix 1.

Experimental Setup

Our model was implemented using PyTorch 1.12 (PyTorch Foundation) and trained on an NVIDIA Tesla T4 GPU (16GB VRAM). The ALBERT-base-v2 model was fine-tuned for 10 epochs with a learning rate of 2×10 , a batch size of 16, and a weight decay of 0.01 using the AdamW optimizer. Early stopping was implemented with a patience of 3 epochs based on validation loss. Random seeds were fixed at 42 for reproducibility. The more detailed parameters are listed in Table 1. For the CARE-ET framework, the GAT neighbor selection threshold was set to 0.6, and the joint adjustment threshold to 0.8. An 80/10/10 split was used for training, validation, and testing. To facilitate reproducibility, the code is provided as supplementary material for review and will be made public upon acceptance. The more detailed parameters are listed in Table 2.

[b]ALBERT: A Lite Bidirectional Encoder Representations from Transformers for Self-supervised Learning of Language Representations.

The CARE-ET model was trained on a dataset of 3142 annotated narrative segments derived from 118 sessions. The annotation workflow involved 2 gerontology specialists who independently labeled event triggers and temporal relations; interannotator agreement reached a Cohen κ of 0.77. For model evaluation, we used a 5-fold cross-validation strategy to ensure the robustness of the results across different storytelling styles.

To ensure the statistical rigor of our results, we conducted bootstrap significance testing (n=1000) and used the paired 2-tailed *t* test to compare CARE-ET against the strongest baseline. Statistical significance is $P<.05$.

Event Summary Assessment

Life story event summarization enables caregivers to efficiently retrieve relevant narratives while providing the structural foundation for organizing fragmented life stories, with evaluation conducted using Recall-Oriented Understudy for Gisting Evaluation (ROUGE) metrics [33]. ROUGE is a commonly used evaluation method for automated text summarization, which measures the quality of summaries by calculating the overlap between automated summaries and human-referenced summaries for unigram words (ROUGE-1), bigram words (ROUGE-2), and the longest common subsequence (ROUGE-L). The method is simple, intuitive, highly consistent with manual evaluation results, and is one of the most effective evaluation metrics for current text summarization tasks.

For automated summarization evaluation, we report the F_1-scores of ROUGE-1, ROUGE-2, and ROUGE-L. All metrics were computed using the Python *rouge-score* package with Porter stemming enabled and standard English stopwords removed. To ensure the reliability of performance gains, we conducted bootstrap significance testing (n=1000) to report 95% CIs and *P* values against the baselines.

Table 3 and Table 4 present the experimental evaluations on both the OALS and LCSTS datasets [34], demonstrating CARE-ET's superior performance in event summarization tasks compared to several baseline methods (evolutionary timeline summarization, Timeline-sumy, temporally sensitive submodularity framework for timeline summarization, crisis

XSL•FO
RenderX

local timeline line-up summarization, pretraining with extracted gap-sentences for abstractive summarization, LongT5, and pyramid-based masked sentence pretraining for multidocument summarization) [23-25,35-38]. Using median and mean text lengths as input parameters (58/210 bytes for OALS; 234/248 bytes for LCSTS), CARE-ET consistently achieved higher accuracy across all test conditions, with particularly notable advantages in full-length input scenarios, showing 0.6% (SD 1.20%) and 1.6% (SD 0.69%) average improvements over the strongest baseline in OALS and LCSTS, respectively. These results validate the model's effectiveness in extracting structured event summaries from both domain-specific life story data (OALS) and general narrative texts (LCSTS), confirming its robust generalization capabilities while maintaining processing accuracy across variable input lengths.

To evaluate the specific contributions of each component, we conducted a rigorous ablation study. Table 5 indicates that replacing ALBERT with Word2Vec leads to a 1% drop in F_1-score, highlighting the necessity of contextual embeddings. Furthermore, the GAT-DBN synergy outperforms GAT-only and DBN-only configurations by 2.8% and 3.4%, respectively. The self-supervised module provides an additional 0.9% gain in timeline consistency. Our model contains 64M parameters, and the average training time per fold is approximately 4.5 (SD 0.34) hours on a Tesla T4 GPU, representing a balanced tradeoff between complexity and performance.

Qualitative Analysis

To further understand the performance of CARE-ET, we present 2 anonymized case studies comparing the generated timelines against the therapeutic ground truth.

Case 1 (Success in Long-Range Dependencies)

During an interview, the participant mentioned family-related milestones (eg, marriage and grandchildren) and their prime years in a later segment. CARE-ET effectively captured the cross-segment dependencies, chronologically positioning these events after related life stages while maintaining the semantic links between the memories.

Case 2 (Failure in Near-Duplicate Events)

During a session discussing a wedding, the participant mentioned the date and event details in different segments. The model failed to merge these, creating two independent nodes for the same event (a redundancy error). This failure suggests that current GAT-based relevance thresholding remains insufficient for fine-grained deduplication in repetitive, fragmented oral testimonies.

Quality Assessment of Timelines

In this paper, sequence link evaluation (SLEU) metrics and TimID metrics are used to assess the quality of event timelines.

Sequence Link Evaluation

In this paper, the evaluation metrics of SLEU are used to verify the quality of the timeline [22]. The sentences in the system-generated storyline are ^{1}, ^{2},… , where *s*1 is the beginning of the story and is the end of the story. The sentences of the reference storyline are $^{\prime}_{1}$, $^{\prime}_{2}$, … $^{\prime}$. n is the number of stages, and h-gram and h-gram′ denote a sequence of h sentences in a storyline, not necessarily consecutive, generated by the reference storyline and the generated storyline. The collocation of information between sentences in a storyline is utilized to compute the probability of the occurrence of the storyline and thus determine whether the storyline is complete or coherent.

The cosine similarity between (∈ [1,]) and (∈ [1,]) is first calculated. Then the probability of h-gram matching between the 2 storylines is calculated separately:

$$(22) ph=min(Countmatch(h-gram),Countmatch(h-gram′))Count(h-gram)$$

The possible values of the variable h depend on the specific case and are represented by the set H. The set H is a set of 1-grams. Storylines using 1-grams tend to satisfy the synthesis requirement more easily. Longer h-gram matches indicate better coherence. The count (h-gram) denotes the number of comparable h-grams (eg, if h=4, count(2-gram)=6). The count(hgram') equals count(h-gram). The $count_{match}$(h-gram) denotes the number of h-grams that can be matched (ie, h-grams against h-grams). The $count_{match}$(h-gram) denotes the number of h-grams that can be matched (ie, the number of h-gram pairs for which the similarity of the corresponding sentences exceeds a specific threshold λ). In the experiments, we set λ=0.2. Then SLEU = (∑ ∈ log) is computed. The SLEU metric value ranges from 0 to 1 and is used to quantitatively assess the quality of the storyline.

XSL•FO
RenderX

We standardized the timeline consistency metric as SLEU. It evaluates the structural integrity of the generated timeline by calculating the weighted sum of correct temporal transitions:

$$(23)\text{SLEU}=\sum h=1\text{H}wh\cdot \exp(-\lambda\cdot |\text{pospred}-\text{posref}|)$$

where H=3 denotes the maximum historical hop distance considered, wh represents the weight assigned to the h-th hop (set as 1/h), and λ=0.5 is the decay constant for distance penalties.

TimID

The study introduces TimID, a temporal annotation marker embedded within a novel life story dataset for older adults, enabling precise evaluation of event chronology through 2 complementary dimensions. Absolute position accuracy quantifies deviations between generated event nodes and their corresponding TimID reference points, where smaller positional differences indicate higher timeline fidelity. Simultaneously, relative order preservation assesses the correctness of pairwise event sequences by verifying their alignment with ground-truth temporal relationships. This dual-metric approach ensures comprehensive validation of both event placement precision and chronological logic in life story reconstruction.

TimID is defined to measure the precision of event placement. The "absolute position" of an event is defined as its normalized rank ri=i/N, where N is the total number of events. The relative order preservation is computed using the Kendall τ coefficient, which quantifies the ordinal correlation between the predicted sequence and the gold-standard therapeutic timeline.

Experimental Results Based on SLEU and TimID

The study uses 2 complementary assessment frameworks: SLEU evaluates storyline coherence through sentence-level probability analysis, while TimID assesses timeline quality via absolute position accuracy and relative order consistency. As shown in Table 6, CARE-ET outperforms baseline methods across both metrics, achieving superior SLEU scores (0.021 - 0.061 higher) and TimID performance (0.08% - 0.24%% better relative order accuracy, with 0.8 - 1.7 lower positional deviations). These results demonstrate significant improvements in both narrative flow and temporal precision.

Table . Performance on the dataset OALS (Older Adults' Life Stories) using sequence link evaluation (SLEU) and timeline identity (TimID).

Method	SLEU	TimID-ap[a]	TimID-rp[b]
ETS[c]	0.47 (0.02)	4.51 (0.38)	0.43 (0.03)
Timeline-Sumy	0.48 (0.02)	4.12 (0.25)	0.51 (0.03)
TSSF-TLS[d]	0.47 (0.02)	4.21 (0.31)	0.48 (0.03)
CrisisLTLSum[e]	0.51 (0.02)	3.64 (0.18)	0.59 (0.02)
CARE-ET[f]	0.53 (0.01)[g]	2.79 (0.15)[g]	0.67 (0.02)[g]

[a]TimID-ap: timeline identity–absolute position.

[b]TimID-rp: timeline identity–relatable position.

[c]ETS: evolutionary timeline summarization.

[d]TSSF-TLS: temporally sensitive submodularity framework for timeline summarization.

[e]CrisisLTLSum: crisis local timeline line-up summarization.

[f]CARE-ET: CARE event timeline.

[g]Statistically significant, $P<.05$.

The metrics validate CARE-ET's dual capacity to generate clinically meaningful timelines: SLEU confirms enhanced narrative coherence, which is crucial for therapeutic applications, while TimID verifies improved chronological accuracy that aligns with human cognition. This combination of strong textual fluency and precise event sequencing enhances both the interpretability of life stories for caregivers and their therapeutic use in reminiscence interventions, advancing digital health solutions for older adult care.

System Usability Assessment

This study has established cooperative relationships with the Hefei Tianyu Elderly Care Institution and the Chuzhou Lekang Elderly Care Institution. The system has been deployed within the daily care management platforms of both institutions, serving a total of 36 older adult users (21 at the Tianyu Institution and 15 at the Lekang Institution). For the optimized Story Mosaic system, we invited 4 caregivers and 1 manager from both the Tianyu and Lekang senior care facilities to complete the System Usability Scale (SUS) [39]. The statistical information for the 10 participants is shown in Table 7. Four participants (A1, C2, C3, and C4) had previously participated in the feasibility study of our published Story Mosaic system, while the other 6 were newly recruited for this study. The participants included 2 core roles—administrators and caregivers—with balanced gender representation. Aged 35 to 62 years, they represented young, middle-aged, and senior practitioner cohorts, while their elder care tenure (4 - 23 y) reflected experiential disparities among novice, proficient, and senior workers. Their educational qualifications showed a gradient distribution, ranging from no formal education to master's degrees. Participant selection ensured diversity across roles, sex, age, tenure, education, and affiliated institutions. This sampling strategy represented the target user groups and provided empirical support for the scientific rigor and objectivity of the system usability evaluation.

XSL•FO
RenderX

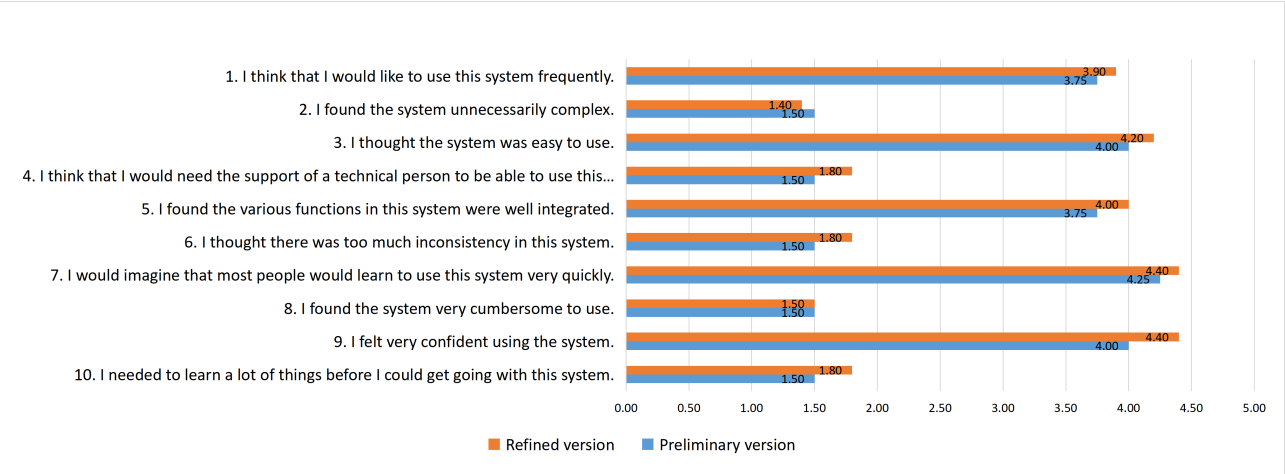

Table . Demographic characteristics of participants.

ID	Identity	Sex	Age (y)	Tenure	Education	Affiliated institution
A1	Administrator	Male	37	13	Master's degree	Tianyu
A2	Administrator	Female	52	23	Junior high school	Lekang
C1	Caregiver	Female	56	10	Primary school	Tianyu
C2	Caregiver	Female	48	6	Junior high school	Tianyu
C3	Caregiver	Male	36	5	Junior high school	Tianyu
C4	Caregiver	Female	57	8	Primary school	Tianyu
C5	Caregiver	Male	35	4	Bachelor's degree	Lekang
C6	Caregiver	Female	45	9	Junior high school	Lekang
C7	Caregiver	Female	62	14	Null[a]	Lekang
C8	Caregiver	Female	58	8	Primary school	Lekang

[a]Null: no education has been received.

In the preliminary work of the Story Mosaic system, the average SUS score was 82.63, achieving an A– grade. After enhancing the system based on the CARE-ET algorithm, a usability test was conducted again, and the evaluation results are shown in Figure 7 with SUS scores from both the preliminary and refined versions.

Figure 7. System Usability Scale scores from the preliminary and refined versions.

A comparison of the refined and preliminary versions of the SUS scale shows the following: for positively worded items (1, 3, 5, 7, 9), the refined version scored higher, reflecting more positive evaluations of the system's usability. For negatively worded items (2, 4, 6, 8, 10), the refined version still had relatively high scores, indicating that users perceived some remaining operational complexity. This is mainly because the refined version's evaluators included caregivers with primary education or no formal education. While these users gave high scores on item 7 ("Most people can learn to use this system quickly"), their actual onboarding speed was slower. Moving forward, it will be necessary to simplify processes and add basic guidance for this group to improve their efficiency.

In addition to the above questions, we also asked an open-ended question: "What other ways do you think the timelines can help you care for older adults"? One participant noted:

> *Timelines are critical in the care of older adults with cognitive impairment. These older adults' behavioral and psychological symptoms are closely related to their past experiences. Timelines help us understand their experiences and act appropriately to the situation.*

Objective Comparisons

To objectively evaluate the impact of the Story Mosaic system on cognitive load, we conducted a comparative study between the artificial intelligence–assisted workflow and a traditional manual workflow. We used the NASA Task Load Index, which assesses cognitive demand across 6 dimensions: mental demand, physical demand, temporal demand, performance, effort, and frustration [40]. The comparative evaluation results are shown in Table 8. Focusing on the 3 core dimensions of mental demand, temporal demand, and physical effort prioritized by participants, the Story Mosaic system achieved load reductions of 37.5%, 36.4%, and 42.9%, respectively, in these metrics. It precisely addressed users' key needs by effectively alleviating cognitive pressure, time constraints, and energy input. Meanwhile, the system also optimized loads across other

XSL•FO
RenderX

dimensions, cutting the overall workload by 37.4% and demonstrating excellent human-machine compatibility.

Table . NASA Task Load Index (NASA-TLX) evaluation of the manual workflow and the Story Mosaic system.

Metric	Manual workflow, mean (SD)	Story Mosaic system, mean (SD)	Relative reduction (%)
Mental demand	76.0 (13.1)	47.5 (23.6)	37.5
Physical demand	27.0 (7.50)	25.0 (8.5)	7.4
Temporal demand	77.0 (10.1)	49.0 (19.3)	36.4
Performance	43.0 (16.7)	31.0 (16.3)	27.9
Effort	73.5 (13.8)	42.0 (15.1)	42.9
Frustration	62.5 (14.4)	34.0 (14.3)	45.6
Overall workload	65.7 (13.6)	41.2 (16.9)	37.4

Discussion

Principal Results

The GAT framework incorporates dynamic node filtering using multilevel semantic similarity thresholds, automatically preserving clinically meaningful life event relationships. This adaptive graph optimization enhances event relationship modeling precision while maintaining computational efficiency for real-world care applications.

CARE-ET demonstrates robust performance across both specialized life story datasets and general narratives through its novel integration of event triggers, spatiotemporal markers, and contextual encoding. The system outperforms conventional methods in extracting key life events from older adult narratives, providing a solid foundation for timeline construction.

Rigorous evaluation confirms that the generated timelines meet clinical standards for both narrative coherence and temporal accuracy. Caregiver assessments highlight superior readability and content generalization, validating the system's ability to transform fragmented life stories into structured therapeutic materials for cognitive reminiscence therapy.

Limitations

While CARE-ET demonstrates promising results, several limitations warrant consideration. First, the method's performance relies heavily on the quality of temporal annotations (TimID) in the training data, which may limit generalizability to life stories with sparse or ambiguous time references. Second, the current implementation focuses primarily on textual narratives, potentially underutilizing multimodal cues (eg, emotional valence in vocal tones or visual context) that could enhance event interpretation. Third, the evaluation involved relatively small-scale caregiver assessments (n=10), necessitating broader clinical validation to confirm real-world utility across diverse older adult populations and care settings.

Furthermore, the collection and processing of older adult individuals' personal life stories involve highly sensitive data with significant privacy implications. Although this study followed ethical protocols including approval, informed consent, and data anonymization, several challenges persist. These include ensuring long-term data security, preserving participants' ongoing control over their narratives, and addressing potential emotional impacts from recalling personal memories—each representing key ethical considerations in this research domain.

Addressing these current limitations, future work will focus on advancing research in the following areas: First, the development of weakly supervised temporal annotation enhancement algorithms will leverage cross-modal temporal reasoning and the mining of implicit temporal cues to improve the model's robustness in parsing life stories with sparse temporal information. Second, the construction of a multimodal fusion framework that integrates speech emotion analysis, visual scene understanding, and textual semantic representation to establish a cross-modally aligned paradigm for life event comprehension. Third, collaboration with more elder care institutions to evaluate the long-term use of the system in real-world care scenarios.

Conclusions

This study proposes the CARE-ET method, which enables the structured extraction of core events from life stories through multimodal event element fusion–based summary generation techniques and improves the accuracy of event relevance calculation via a collaborative computation model of GAT and DBN. Experiments on the OALS and LCSTS datasets show that CARE-ET significantly reduces redundancy and disorder in narrative texts, generating event timelines that outperform baseline methods in readability and structural rationality. This study provides an effective technical solution for the digital presentation of older adult life stories, with important application value for enhancing the personalization and precision of older adult care services.

Abstract

Background: Cardiovascular magnetic resonance (CMR) is widely used across various cardiac conditions and systematically assesses cardiac anatomical structures and functional dynamics. Machine learning (ML) can accurately predict outcomes and understand the inherent features of clinical data.

Objective: This study aimed to derive CMR phenotypes related to cardiovascular aging, investigate the relationship between these phenotypes and stroke risk, and relearn these phenotypes using supervised ML.

Methods: We enrolled 36,467 participants without stroke and extracted CMR parameters from the UK Biobank, with follow-up data extending until September 30, 2023. Using the generative topographic mapping technique, we identified latent grid nodes among participants and then derived phenotypes through agglomerative hierarchical clustering. We used supervised ML models to predict cardiac function phenotypes and used Cox proportional hazards models to assess the association between these phenotypes and long-term stroke risk.

Results: We enrolled 36,467 participants in the study. The mean age was 54.9 (SD 7.5) years, with 17,442 (47.8%) male participants. During a mean follow-up time of 14.7 (SD 1.1) years, 500 (1.4%) participants developed stroke and 664 (1.8%) participants died, respectively. After generative topographic mapping modeling, we identified 2 distinct phenotypes: phenotype 1, characterized by adverse cardiac function and an accumulation of cardiovascular risk factors, reflecting cardiovascular aging; and phenotype 2, associated with a lower risk of stroke (hazard ratio 0.695, 95% CI 0.559-0.864; *P*=.001), which remained significant after accounting for competing mortality (hazard ratio 0.578, 95% CI 0.484-0.691; *P*<.001). We selected the random forest model as the optimal model for the phenotypes, demonstrating high accuracy (area under the curve 0.914, 95% CI 0.911-0.918 for training and 0.867, 95% CI 0.858-0.876 for validation) and calibration ability (Brier score 0.111, 95% CI 0.109-0.113 for training and 0.132, 95% CI 0.127-0.137 for validation).

Conclusions: By integrating unsupervised and supervised ML methods, we identified cardiovascular aging–related phenotypes that demonstrate robust predictive ability for incident stroke, which may have the potential to improve preventive and therapeutic strategies for high-risk populations.

Introduction

Stroke is a major cause of mortality and morbidity worldwide [1]. Aging is associated with progressive structural and functional deterioration of the cardiovascular system [2]. Several conditions associated with cardiovascular aging [3,4], including atrial fibrillation, heart failure, and myocardial infarction, are recognized as important risk factors for stroke [5-8]. Cardiovascular magnetic resonance (CMR) enables systematic assessment of cardiac structural and functional remodeling and has been reported to be associated with the aging process [9].

XSL•FO
RenderX

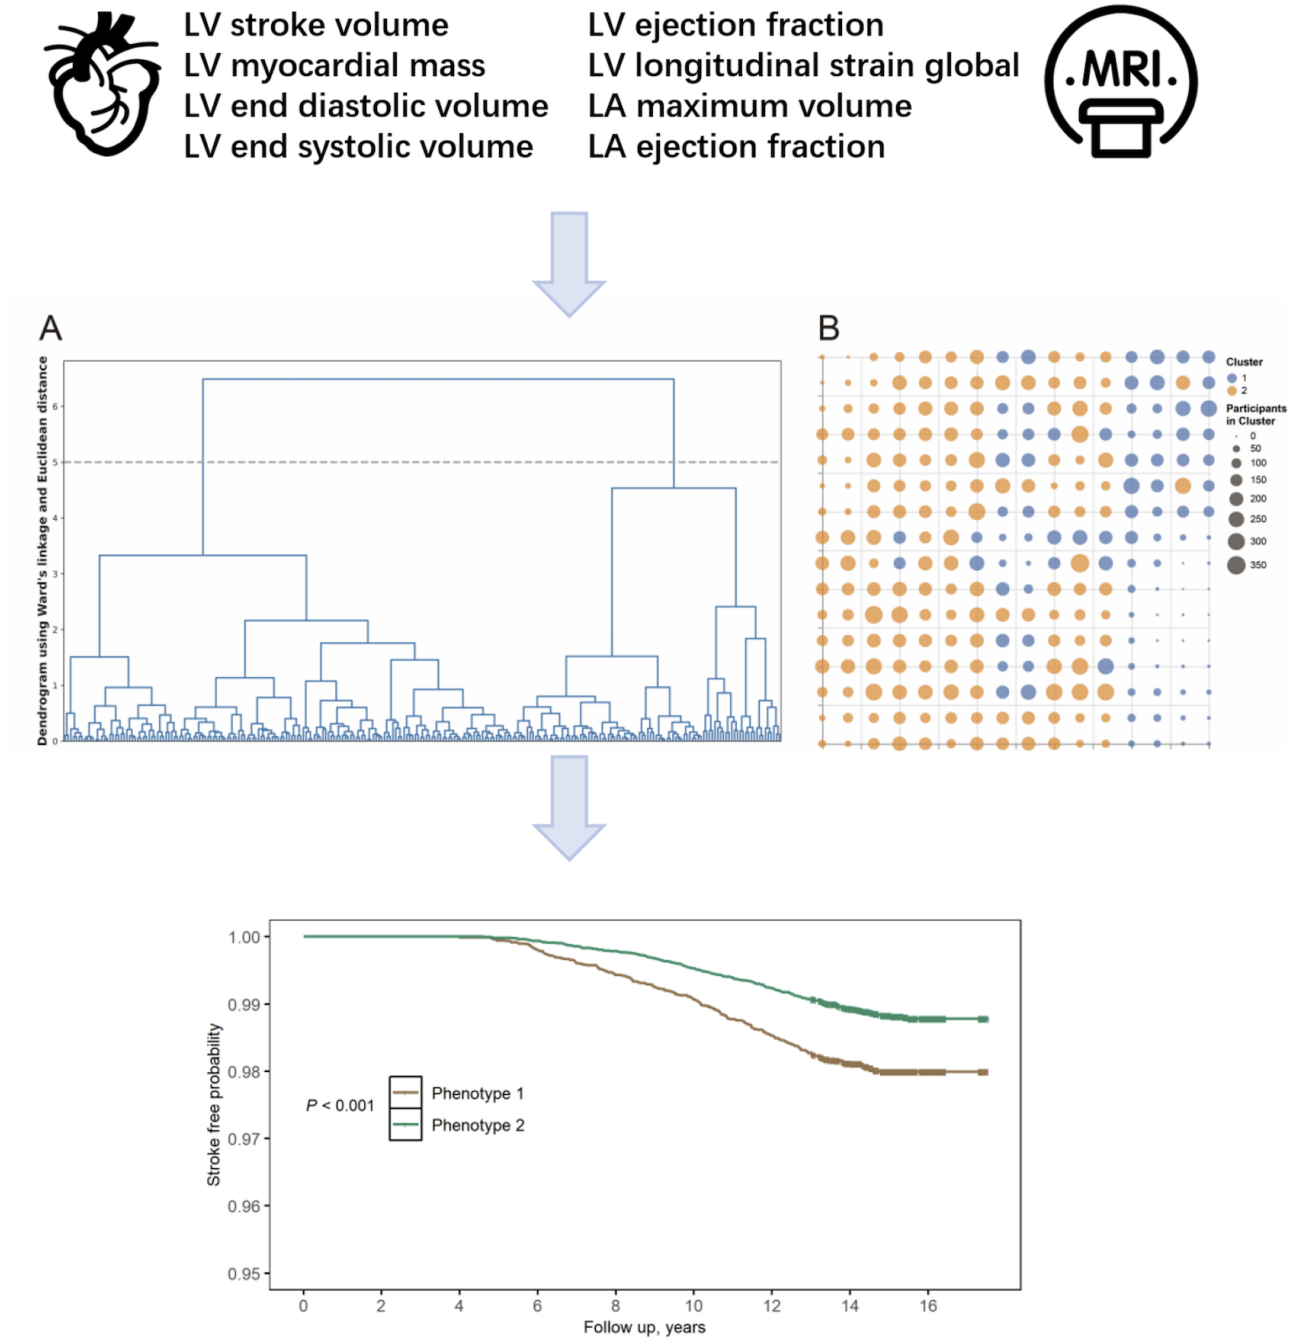
Previous studies have shown that atrial mechanical dysfunction and left ventricular (LV) structural abnormalities assessed by CMR are associated with stroke events [10,11]. However, CMR metrics are relatively complex, and extracting phenotypes from these metrics may provide insight into their relationship with cardiovascular aging and help clarify their association with stroke risk.

The application of artificial intelligence in clinical practice for disease prediction and detection has grown tremendously in recent years [12,13]. Supervised machine learning (ML) can accurately predict clinical outcomes, while unsupervised ML can identify the inherent features of data without requiring labeled outcomes [14]. Previous studies have used unsupervised ML models to delineate prognostically distinct clusters using variables related to LV diastolic function derived from transthoracic echocardiography [15]. Additionally, the hierarchical k-means clustering algorithm has also been effective in distinguishing potential embolic source groups in cryptogenic stroke [16]. Generative topographic mapping (GTM) is a probabilistic model used for dimensionality reduction and data visualization, exhibiting superiority over the self-organizing map algorithm by explicitly modeling probability distributions [17,18]. GTM can reduce data dimensionality to a latent space and reveal the underlying structure with robustness across diverse sources [19]. However, previous studies applying GTM to derive phenotypes have been limited, with applications reported in general and critical care populations [20].

Therefore, the aim of this study was to use the GTM model to identify distinct cardiac function phenotypes related to cardiovascular aging, examine their association with long-term stroke risk, and develop supervised ML models to predict these phenotypes using data from a prospective longitudinal cohort.

Methods

Study Population



The UK Biobank is a large, population-based prospective cohort study comprising more than 500,000 participants aged 49 to 69 years, enrolled from 22 assessment centers in the United Kingdom between 2006 and 2010. Details of the UK Biobank protocols are accessible online [21]. Participants diagnosed with stroke at baseline (n=7780, 1.5%), lacking follow-up information (n=20,251, 4%), or without CMR data (n=437,713, 87.2%) were excluded, resulting in a final cohort of 36,467 (7.3%) participants.

We included the following CMR measures in the study: LV stroke volume (LVSV), LV myocardial mass (LVMM), LV end-diastolic volume (LVEDV), LV end-systolic volume (LVESV), LV ejection fraction (LVEF), LV global longitudinal strain (LVGLS), left atrial (LA) maximum volume (LAMV), and LA ejection fraction (LAEF) (Figure 1).

Stroke diagnosis was ascertained through linkage to self-reported medical conditions, hospital inpatient data, and death register records based on *International Classification of Diseases* codes, with the earliest recorded date of outcome provided in Table S1 in Multimedia Appendix 1. The follow-up time was defined as the interval from the date of recruitment to the occurrence of stroke, all-cause mortality, loss to follow-up, or September 30, 2023, whichever came first. Details of covariates were shown in Table S2 in Multimedia Appendix 1. This study was reported according to the transparent reporting of a multivariable prediction model for individual prognosis or diagnosis (TRIPOD) guidelines (Checklist 1).

Figure 1. Cardiovascular aging phenotypes and stroke. LA: left atrial; LV: left ventricular.

GTM Modeling and Phenotypes

Inspired by the algorithm introduced by Bellfield et al [20], we used a Gaussian mixture model to train the GTM model and visualize the distribution of data in the latent space. GTM uses a soft assignment method to estimate the probability of each participant being assigned to a cluster. The high-dimensional data were then visualized in a 2D latent space. After preprocessing the dataset, we used the *ugtm* Python (Python Software Foundation) package for GTM modeling and applied 10-fold cross-validation with the expectation-maximization algorithm to optimize the parameters. After GTM modeling, the generated latent space illustrated the distribution of participants in each cluster, with darker colors indicating higher densities. The modeling parameters (cardiac function variables) demonstrated the impact of cardiac function on each latent grid node in the GTM model. We aggregated the latent grid nodes by calculating the Euclidean distances between their modeling parameters and applied agglomerative hierarchical clustering using the Ward minimum variance method to derive phenotypes [22]. The characteristics of the phenotypes were compared to evaluate the distribution of risk factors for cardiovascular aging.

Phenotypes and Stroke Risk

We used Cox proportional hazards models to evaluate the association between cardiac function phenotypes and long-term stroke risk, reporting results as hazard ratios (HRs) with 95% CIs. In multivariable analyses, model 1 was an unadjusted model; model 2 was adjusted for age at recruitment, sex, Townsend deprivation index at recruitment, smoking status, alcohol intake frequency, systolic blood pressure, diastolic blood pressure, and BMI; and model 3 was additionally adjusted for

XSL•FO
RenderX

atrial fibrillation, type 2 diabetes, coronary heart disease, heart failure, antihypertensive drugs, and statins. In sensitivity analyses, we explored the association of cardiac function phenotypes with the risk of different stroke types. Additionally, we performed a competing risk analysis for stroke risk using the Fine and Gray method, accounting for mortality as the competing event.

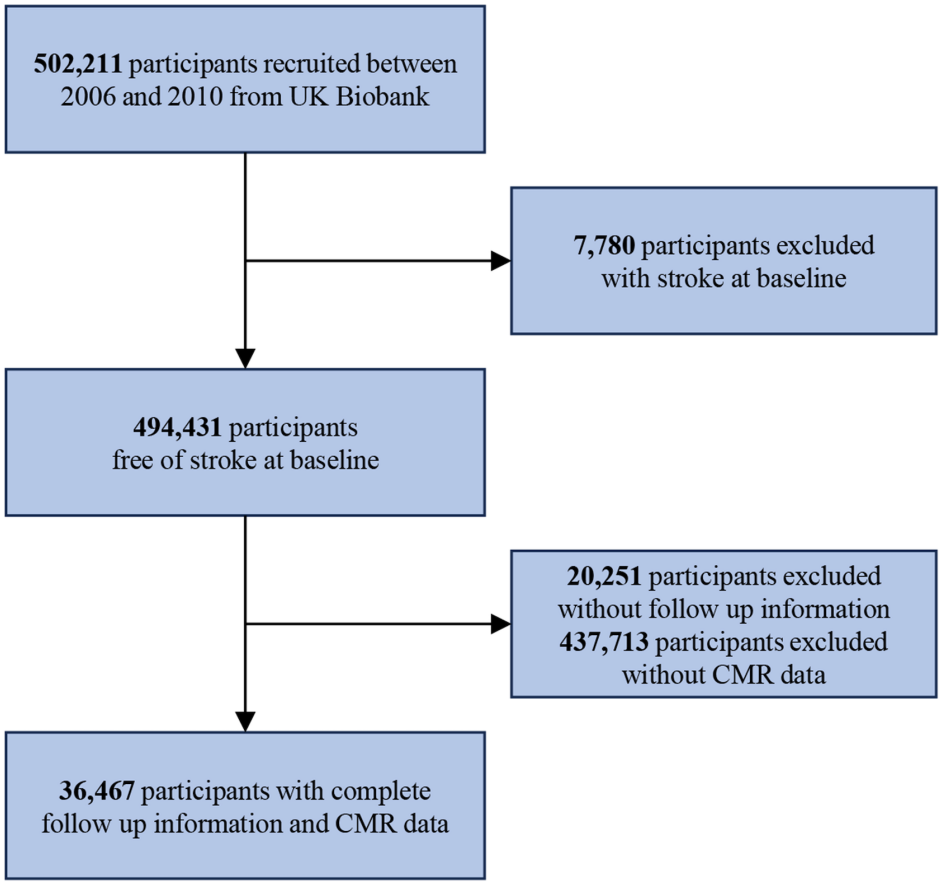
Supervised ML Frameworks

Following the categorization of participants into different phenotypes through the GTM approach, we deployed several supervised ML models to predict cardiac function phenotypes. Hyperparameters for each model are detailed in Table S3 in Multimedia Appendix 1. Hyperparameter optimization was conducted using grid search and Bayesian optimization. Discriminatory ability was evaluated using the receiver operating characteristic curve. Calibration performance was assessed using the calibration curve. We selected the best-performing method as the final algorithm for developing a phenotype prediction model. We constructed a website using the Flask framework and the DeepSeek-R1 API (application programming interface). The predicted probabilities and individualized metrics were sent to the DeepSeek-R1 model to generate a detailed analysis of health status and provide professional recommendations. Detailed descriptions of the methods are provided in Multimedia Appendix 1.

Ethical Considerations

The ethical framework of the UK Biobank was approved by the North West Multi-centre Research Ethics Committee (11/NW/0382). All participants provided informed consent through electronic signature at enrollment.

Statistical Analysis



Normally distributed continuous data are presented as mean (SD), and group comparisons were performed using 2-tailed *t* tests. Categorical data were presented as frequency (percentage), and group comparisons were conducted using chi-square tests. To account for multiple comparisons, *P* values were adjusted using the false discovery rate method. Statistical tests were conducted with R software (version 4.2.1; R Foundation for Statistical Computing), and a 2-sided *P* value <.05 was considered statistically significant.

Results

Study Population

The study design is shown in Figure 2. Of the 36,467 participants included in the study (Figure 2), the mean age was 54.9 (SD 7.5) years, with 17,442 (47.8%) male participants. In total, 14,373 (39.5%) of participants were current or former smokers, 8180 (22.4%) had daily or almost daily alcohol intake, 1047 (2.9%) had type 2 diabetes, 345 (0.9%) had atrial fibrillation, and 48 (0.1%) had heart failure at baseline. During a mean follow-up time of 14.7 (SD 1.1) years, 500 (1.4%) and 664 (1.8%) participants developed stroke and died, respectively (Table 1).

GTM Modeling and Cardiac Aging Phenotypes

Figure 3 illustrates the latent space generated by the GTM model. The number of participants in clusters is represented using the "viridis" color scheme and visualized as circles, where a deeper blue hue and larger circle diameter indicate a higher number of participants. LVSV, LVMM, LVEDV, LVESV, LVEF, LVGLS, LAMV, and LAEF are aligned point-to-point with their latent space in a light teal blue scheme. In the dendrogram plot, 2 cardiac function phenotypes are identified, clearly separating the dataset into 2 major branches at a relatively large linkage distance. Figure S1 in Multimedia Appendix 1 illustrates that stroke diagnoses among participants were mainly distributed in the area of phenotype 1.

XSL•FO
RenderX

Figure 3. Derived phenotypes of cardiac function. (A) Latent space showing the distribution of participants; (B) latent space displaying the distribution of cardiac function markers derived from cardiovascular magnetic resonance; (C) dendrogram using Ward linkage and Euclidean distance to identify 2 cardiac function phenotypes; and (D) phenotypes and latent grid nodes of cardiac function. LA: left atrial; LV: left ventricular.

To further characterize the phenotype patterns, we compared the distributions of investigatory variables and visualized them on the latent space with the light orange color scheme (Figures S2-S7 in Multimedia Appendix 1). Significant differences were observed between the 2 cardiac function phenotypes across demographic characteristics, cardiovascular risk factors, and cardiac function parameters. Participants in phenotype 1 exhibited larger cardiac chamber volumes and greater myocardial mass, with higher LVEF and LAEF but lower LVSV, LVMM, LVEDV, LVESV, LVGLS, and LAMV compared with phenotype 2 (all $P<.001$). In addition, phenotype 1 demonstrated a higher burden of cardiovascular risk factors and comorbidities, including a greater prevalence of major adverse cardiac events, atrial fibrillation, heart failure, coronary heart disease, and type 2 diabetes ($P<.001$). Participants in phenotype 1 also had higher blood pressure, arterial stiffness index, and more adverse metabolic profiles. Taken together, these structural, functional, and clinical differences suggest that phenotype 1 represents a cardiovascular aging–related phenotype, characterized by cardiac remodeling, increased cardiovascular risk burden, and elevated incidence of stroke and mortality (Table 1 and Table S4 in Multimedia Appendix 1).

Phenotypes and Stroke Risk

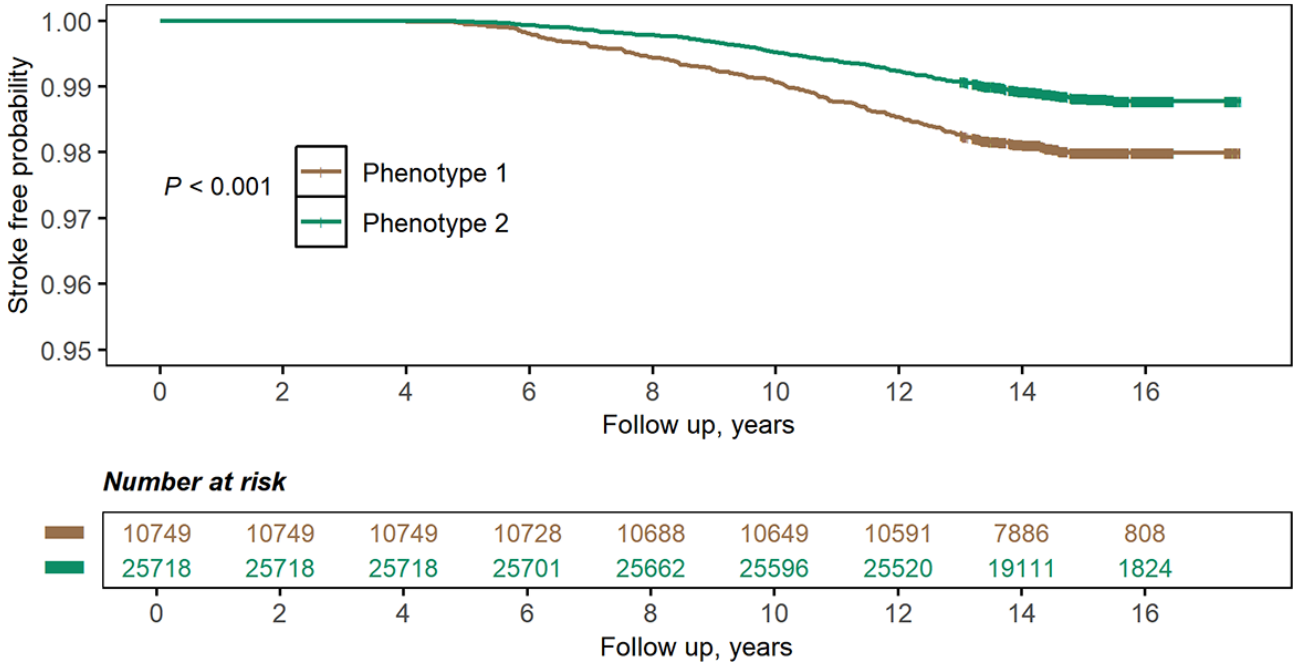
Multivariable modeling identified that cardiovascular aging phenotypes were associated with the long-term risk of stroke and mortality. Compared with phenotype 1, phenotype 2 was significantly associated with a decreased risk of stroke in the unadjusted model (HR 0.579, 95% CI 0.484-0.691; $P<.001$); model 2 (HR 0.671, 95% CI 0.541-0.833; $P<.001$); and model 3 (HR 0.695, 95% CI 0.559-0.864; $P=.001$; Table 2).

XSL•FO
RenderX

Table . Association between cardiovascular aging phenotypes and long-term risk of stroke and mortality.

Outcome (phenotype 2 vs phenotype 1)	Stroke		Mortality	
	HR[a] (95% CI)	*P* value	HR (95% CI)	*P* value
Model 1[b]	0.579 (0.484-0.691)	<.001	0.625 (0.535-0.730)	<.001
Model 2[c]	0.671 (0.541-0.833)	<.001	0.760 (0.632-0.913)	.003
Model 3[d]	0.695 (0.559-0.864)	.001	0.772 (0.641-0.929)	.006

[a]HR: hazard ratio.



[b]Model 1 was unadjusted.

[c]Model 2 was adjusted for age at recruitment, sex, Townsend deprivation index at recruitment, smoking status, alcohol intake frequency, systolic blood pressure, diastolic blood pressure, and BMI.

[d]Model 3 was additionally adjusted for atrial fibrillation, type 2 diabetes, coronary heart disease, heart failure, antihypertensive drugs, and statins.

Kaplan-Meier survival curves revealed that the phenotype 1 group had a higher risk of stroke (*P*<.001; Figure 4).

Figure 4. Kaplan-Meier survival curves of stroke-free probability by phenotype.

Regarding stroke subtypes, cardiac function phenotypes were associated with cerebral infarction and other nontraumatic intracranial hemorrhage (all *P*<.05; Table S5 in Multimedia Appendix 1). When mortality was considered as a competing risk, phenotype 2 remained significantly associated with stroke risk (HR 0.578, 95% CI 0.484-0.691; *P*<.001; Figure S8 in Multimedia Appendix 1).

Supervised ML

Basal metabolic rate, sex, testosterone, standing height, weight, forced vital capacity, waist circumference, creatinine, forced expiratory volume in 1 second, and urate were included in the ML models (Table S6 in Multimedia Appendix 1). By integrating the accuracy in the training and validation sets, we selected the random forest model as the optimal model based on its excellent accuracy (area under the curve 0.914, 95% CI 0.911-0.918 for training and 0.867, 95% CI 0.858-0.876 for validation; and accuracy 0.837, 95% CI 0.833-0.841 for training and 0.805, 95% CI 0.804-0.806 for validation) without overfitting the training set (Figure 5). Calibration plots exhibited that the random forest model had good performance in the calibration quality (Brier score 0.111, 95% CI 0.109-0.113 for training and 0.132, 95% CI 0.127-0.137 for validation; Table 3 and Tables S7 and S8 in Multimedia Appendix 1). We drew a feature importance plot to better visualize the contributions of the predictors to the predictive power of the random forest model (Figure S9 in Multimedia Appendix 1).

Extreme Gradient Boosting	0.799 (0.795-0.804)	0.134 (0.132-0.137)	0.804 (0.804-0.804)	0.132 (0.127-0.137)
Artificial neural networks	0.797 (0.793-0.802)	0.136 (0.133-0.138)	0.803 (0.803-0.804)	0.132 (0.127-0.136)

After entering the participant information, the local model calculated the corresponding phenotype, and the DeepSeek-R1 model provided an analysis of the participant's health status along with recommendations for potential clinical application (Figure S10 in Multimedia Appendix 1).

Discussion

Principal Findings

In this study, we identified distinct cardiac function phenotypes related to cardiovascular aging using the GTM model based on CMR parameters. These phenotypes were significantly associated with long-term stroke risk and could be reliably predicted by supervised ML models.

CMR is important for evaluating cardiovascular pathologies and for assessing the etiology and prognosis of patients with stroke. A previous study demonstrated that cardiovascular aging is associated with reduced LV volumes and increased LV concentricity on CMR, with notable sex-specific differences in systolic cardiac function [9]. CMR also exhibited high sensitivity in detecting intraventricular thrombi and thrombi within the LA appendage [23]. Additionally, CMR imaging could affect the management of acute stroke by detecting aortic plaques, cardiac structural abnormalities, and intracardiac thrombi in patients with stroke [24,25]. However, CMR metrics represented multidimensional data with complex interrelations, potentially involving collinearity and interaction effects. Using unsupervised ML may improve the ability to reveal the inherent structure of the data and achieve more accurate classification.

GTM incorporated probability distribution functions to refine the self-organizing map algorithms and mitigated their inherent limitations, such as convergence issues, insufficient neighborhood preservation, and the absence of a distinct objective function. Moreover, GTM was capable of visually representing phenotypes through latent spaces [17]. Sattarov et al [26] applied GTM to explore the latent space of Simplified Molecular Input Line Entry System–based autoencoders for generating targeted molecular libraries and visualized the autoencoder latent space on a 2D topographic map. These findings indicated a promising application of GTM in structure-based affinity assessments. However, unsupervised ML faces challenges related to limited interpretability and scalability, making the derived phenotypes and their clinical relevance difficult to translate into real-world medical practice. Therefore, we innovatively applied supervised ML to relearn the phenotype labels obtained from GTM, constructing a random forest model that accurately predicted the 2 distinct phenotypes. Given the high cost and inconvenience of CMR scans for patients with stroke [27], using clinical variables allowed for a reduction in model application requirements while preserving accuracy, making the classification model more suitable for clinical use.

The phenotypes derived from CMR metrics may reflect distinct patterns of cardiac structural and functional remodeling associated with cardiovascular aging. Key variables contributing to phenotype differentiation, including LVMM and concentric geometry, have been linked to vascular aging markers, supporting the connection between cardiovascular aging and cardiac structural changes [28]. LA enlargement and functional impairment are also recognized markers of cardiovascular aging and are related to chronic diastolic dysfunction and atrial fibrillation [29]. In addition, accelerated cardiovascular aging driven by cumulative risk factors such as hypertension, obesity, diabetes, and coronary artery disease may further promote cardiac remodeling, consistent with the differing comorbidity profiles observed between the phenotypes in our study [30]. Notably, the cardiovascular aging–related phenotype in our study was characterized by LV and LA abnormalities indicative of volume or pressure overload and myocardial dysfunction. These alterations have been associated with increased risks of cardioembolic stroke and subclinical cerebral infarction [31,32]. Therefore, the CMR-derived phenotypes may capture different stages of cardiovascular aging and help explain the heterogeneity of cardiac remodeling and its potential contribution to long-term stroke risk.

In our study, supervised ML models identified several clinical parameters as predictors for cardiac function phenotypes. Notably, basal metabolic rate is the energy required to maintain essential functions in a healthy state. Prior research indicated that basal metabolic rate was independently linked to heart failure, atrial fibrillation, and flutter and acted as a risk factor for cardiovascular mortality [33,34]. Furthermore, a pooled analysis of 8 cohorts showed that obstructive and restrictive physiology were associated with incident heart failure with reduced or preserved ejection fraction [35]. Moreover, a distinctive J-shaped curve was noted between BMI and waist

XSL•FO
RenderX

circumference and the risk of heart failure [36]. Additionally, renal impairment in chronic heart failure was typically linked to decreased cardiac output and subsequent renal hypoperfusion, and targeting volume overload may improve outcomes in cardiac dysfunction [37]. These findings suggested that the ML model could reflect systemic metabolic, cardiopulmonary, and renal alterations that may explain the clinical characteristics of the identified cardiac function phenotypes.

To the best of our knowledge, this was the first study to use GTM for clustering CMR parameters and to identify cardiovascular aging phenotypes associated with long-term stroke risk. However, there were several limitations to our study. First, the CMR parameters extracted from the UK Biobank were collected according to the cohort's standardized protocols. Because the CMR examination protocol may differ in other studies, this should be considered when applying our model to other cohorts. Second, while trained on the UK Biobank's large sample, the model's applicability to other cohorts may be limited by environmental, genetic, and cultural variations. Third, given the predominantly White and healthy population in the UK Biobank, selection and health biases may be inevitable. The generalizability of our findings to ancestrally diverse individuals will assist in determining whether more appropriate and ethnically relevant decisions are needed.

Conclusions

In conclusion, we used GTM to identify cardiac function phenotypes based on CMR parameters. The identified phenotypes were significantly associated with stroke risk, with the high-risk phenotype characterized by impaired cardiac function and features related to cardiovascular aging. Furthermore, we relearned phenotype labels using supervised ML models, enabling phenotype prediction from clinical variables. These models may facilitate the identification of individuals at higher risk and support the development of preventive and therapeutic strategies. Further studies are warranted to explore the potential mechanisms linking cardiovascular aging, cardiac phenotypic heterogeneity, and stroke risk.

Abstract

Background: Continuous advancements in voice artificial intelligence technologies aim to assist older adults and caregivers, potentially improving quality of life and reducing caregiving burdens. Although research has explored the potential of voice-enabled artificial intelligence (VAI) assistants, such as Alexa (Amazon.com, Inc) and Google Home, to support older adults' health in informal care settings, there remains a significant gap in understanding the ethical dimensions and values that may influence their future adoption by caregivers and care recipients.

Objective: This research aims to explore older adult and informal family caregivers' perspectives of VAI assistants for supporting informal care, including the ethical dimensions and values that influence their decisions about future adoption for these purposes.

Methods: This research uses participatory speculative design to explore older adults' and informal family caregivers' perspectives of how VAI might support informal care in the future, and the ethical concerns they have about adopting VAI technologies. We conducted 8 workshop sessions with older adults and caregivers (n=9) over four months. Each phase focused on one of three goals: (1) to understand existing experiences, (2) to envision future VAI technologies, and (3) to reflect on ethical values that shape acceptance. In workshops, we aimed to gain insights into their experiences and challenges in managing informal care tasks and how future implementation of VAI might support the caregiving process to address their needs and concerns while emphasizing the ethical dimensions they value.

Results: The findings suggest older adults and informal family caregivers see potential opportunities for VAIs to support informal aging care by automating daily health tasks to improve efficiency, enhancing mental health and well-being, and offering companionship. However, participants felt that VAI alone might not be sufficient to address the complex needs of informal care. Additionally, they raised several ethical concerns related to transparency, privacy, inclusiveness, trust, affordability, and autonomy, which they felt needed to be addressed to encourage adoption of VAI technologies for informal care in the future.

Conclusions: Based on the findings, we offer insights and design implications for VAI systems that balance efficiency with ethical values to support diverse caregiving needs and potentially encourage future adoption in the informal care space.

Introduction

Background

Often unpaid, informal family caregivers play an important role in helping older adults age in place by assisting with activities of daily living and other health and wellness needs [1,2]. As more caregiving tasks move into the home, older adult-informal care relationships become increasingly important in supporting older adults in maintaining and achieving positive health outcomes [3]. At the same time, voice-enabled artificial intelligence (VAI) assistants (eg, Alexa or Siri [Apple Inc]), which leverage voice input/output and artificial intelligence (AI), are becoming increasingly prevalent in consumer homes and show promise for supporting older adults and their caregivers [1,2,4]. VAI assistants are generally helpful for addressing various accessibility needs among older adults [5-7]. However, research also indicates that older adults and informal caregivers see VAIs as potentially useful for supporting health

XSL•FO
RenderX

care and other care needs at home [8-10]. For instance, VAIs have been found to be beneficial for informal caregivers and older adults with mild cognitive impairment [8], informal care dyads [10], and for scaffolding conversations between older adults and informal caregivers [9]. Thus, VAIs present a promising approach for enhancing the quality of life for older adults while helping to reduce some of the burdens faced by caregivers.

Significant prior research highlights the potential of VAIs to improve health care management and quality of life for older adults [10-12]. For older adult caregiving, research has also focused on understanding desired VAI features [4] and the benefits for tasks such as medication reminders, appointment scheduling [8,13], and improving communication between older adults and their informal caregivers [9,10]. Yet, ethical concerns such as privacy and transparency remain barriers to the acceptance and adoption of AI technologies such as VAIs generally [14,15], and these concerns are heightened within the health care context [16], where safety and confidentiality are paramount. Studies acknowledge that it is crucial to understand ethical considerations such as trust and transparency when considering AI-augmented health care interventions [17,18], calling for more emphasis on user values in health-related AI design and implementation [16]. However, little research has specifically explored the ethical values and dimensions that caregivers and older adults prioritize regarding VAI interactions in an informal caregiving context and how they might impact future adoption. Due to the diverse values individuals may have about AI use in health care [16], the growing ubiquity of VAIs for older adults' health [10-12], and the importance of exploring values in different contexts [19], it is important to explore ethical values specific to the older adult informal caregiving context.

In this study, we use participatory speculative design to explore older adults and informal family caregivers' ethical concerns about adopting VAI technologies. We aimed to gain insights into their experiences and challenges in managing informal care tasks, how future VAI features might support the caregiving process, and the ethical dimensions they value, including how those dimensions might impact potential acceptance. Based on our findings, we provide the following contributions: (1) We provide extended user perspectives on the role of VAIs in addressing informal caregiving needs, including the socioemotional aspects and burdens of informal care. (2) We highlight the ethical dimensions and values important to older adults and caregivers when considering accepting and adopting VAI assistants and the need to balance efficiency and ethical values in design to do good while doing no harm.

Prior Work

We provide background on the importance of informal, unpaid caregiving for supporting older adults' health and wellness needs, noting VAI assistants as emerging tools for supporting older adults and caregivers. We discuss open challenges of VAI acceptance and adoption for health and concerns raised in prior work that limit the adoption of VAI for health among older adults.

Informal Caregiving and VAI to Support Older Adults' Care

Informal caregiving usually involves unpaid assistance with activities of daily living and other health tasks [2] by someone, usually a family member or a close friend, who is outside of the formal health care system [20]. As informal caregivers, family or close friends take on responsibilities of looking after another's health and daily needs in addition to their own [2]. Informal caregiving tasks can include helping with feeding or personal hygiene, administering medication, accompanying care recipients to medical appointments, and fulfilling other essential needs in their daily lives [2]. For older adults, informal caregivers can play a significant role in maintaining their health when they are physically or mentally unable to perform daily tasks and self-care activities [3]. This form of caregiving can be physically and emotionally demanding, leading to exhaustion, neglecting one's health, and financial strain among those who provide care [2,3,20]. Due to the demanding nature of caregiving for older adults, assessing and reducing the workload for these individuals overseeing their care is crucial.

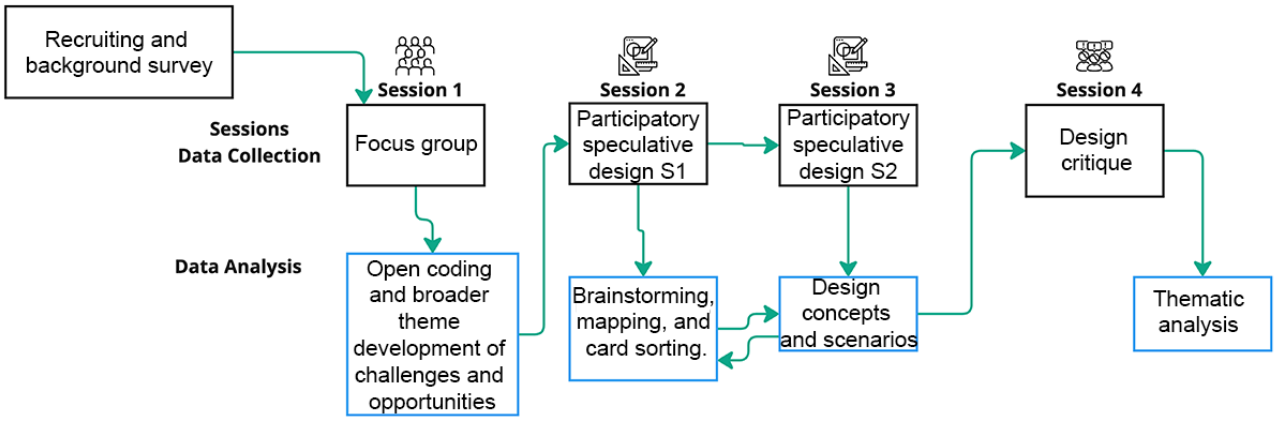
One technology, VAI assistants, has emerged in recent years as a potentially accessible support for older adults and their caregivers. Recent studies [10-12,21-23] have suggested that including VAI assistants such as Alexa or Google Home within households has the potential to improve health care management and quality of life for older adults. There has also been an emerging focus on the potential of physiologically expressive voice-based conversational agents to deliver valuable social support in health care contexts [24,25]. In addition to these individual care tasks, researchers have also explored how VAI might support informal caregiving environments, focusing on supporting caregiving relationships and collaboration. Research has indicated that despite some open concerns, both hired (eg, paid) and family (unpaid) informal caregivers felt that VAI systems could benefit home care settings, including supporting tasks related to documentation, care coordination, and person-centered care [13]. Researchers have found that VAI assistants are viewed as potentially useful for supporting older adults and their caregiver dyads generally [10], as well as for supporting the care of those with mild cognitive impairment [8]. Rudnik et al [9] also found VAIs useful for helping older adults and caregivers scaffold care conversations. Therefore, there is evidence that older adults and caregivers feel VAI might help support informal caregiving environments. Yet open challenges exist.

Ethical Concerns in Voice Activated-Augmented Care

Some of the challenges of VAIs in health relate to unmet needs for desired interactions that are tailored to specific caregiving needs and tasks. For example, Corbett et al [10] found that while older adults and caregivers found existing voice assistants useful, they wanted additional features to help them with health and medical information. Zubatiy et al [8] found preferences for more assistance with activities of daily living. Therefore, while virtual assistants for older adults represent a notable step forward in developing socially adept conversational agents, there is a consensus that further refinement is necessary, especially in the health care context. Part of this refinement aims to ensure that

XSL•FO
RenderX

these technologies are equipped to meet the demands of diverse real-world scenarios and align more closely with the user expectations and accessibility needs required to provide reliable interactions [11,22,24,26-28]. AI-enabled conversational health assistants such as VAIs have demonstrated their potential for accommodating individual preferences, particularly in situations where sensitivity plays a pivotal role, underscoring their relevance in health care and other contexts where tailored interactions are crucial [29]. However, while acknowledging these potential advantages, older adults and caregivers have also voiced ethical and trust concerns when leveraging AI-enabled health tools more generally [17], and these concerns have been found in VAI health research.



Ethics seeks to determine what is right, just, and morally acceptable within a given context or society [14]. Ethics in AI is a complex and evolving field, with convergence around 5 key principles: transparency, justice and fairness, trust, responsibility, and privacy [14]. Examining ethical components and their value when designing AI systems is thought to be the foundation of any successful interaction between humans and AI systems. VAI assistants have been found to raise ethical concerns with users [15,19,30-32]. The systematic examination of ethical concerns regarding voice assistants by Seymour et al [19] (eg, Amazon Alexa and Google Home) more broadly found that privacy was the most cited concern, yet other concerns related to accessibility, social interaction (eg, anthropomorphism and emotional connection to machines), and social order (eg, impact on parent-child relationships) were also discussed. Similar concerns apply to VAIs used within a health care context; however, examining ethical values is particularly important due to health care's safety-critical and privacy-sensitive nature [33]. For example, research has shown that the degree of health information sensitivity can impact users' preferences for interactions with VAI assistants such as Google Home [34]. Patients tend to prioritize trustworthiness and transparency when engaging with health-related assistants [21], and different aspects of trust, such as credibility and service quality, have also been found to impact perceptions of health-related VAIs and users' intentions to use them [33]. Therefore, though AI-driven assistive and voice-based interfaces offer substantial benefits, studies suggest an imperative need for tailored approaches that prioritize differences in context and individual and group experiences to establish trust and ethical standards [17], including exploring participatory methods to democratize design, expand who is included in the design, and prioritize usefulness [33,35].

Methods

Study Design

We conducted a 3-phase study (Figure 1) using participatory speculative design to explore how future VAI assistants might support informal caregiving practices among older adults and caregivers, as well as the values influencing the potential adoption of these technologies. Each phase addressed one of three goals: (1) understanding existing experiences, (2) envisioning future VAI technologies, and (3) reflecting on ethical values that shape acceptance. This study focused on the following research questions (RQs): (RQ1) How do participants perceive the role of VAIs in supporting caregiving tasks? (RQ2) What values do caregivers and older adults have around VAI assistants that support day-to-day care tasks? (RQ3) What ethical concerns do caregivers and older adults have about VAI assistants that support day-to-day care tasks?

Figure 1. Image of the participatory speculative design process. The process included 4 workshop sessions, including a focus group, two participatory speculative design sessions, and one design critique session.

Ethical Considerations

The Institutional Review Board at Indiana University reviewed and approved this study as exempt (Institutional Review Board application #21351) before recruitment or data collection began. In the first workshop session (session #1), we provided participants with a printed study information sheet that explained this study, the data we would collect, their rights as participants, and our procedures for minimizing risks to privacy and confidentiality. We allowed time for participants to read the sheet and also explained the information verbally. This study's information sheet included details on payment procedures (US $35 per session completed), principal investigator contact information, and how to contact our Institutional Review Board office. Participants were also informed of efforts to keep their personal information confidential, including restricting access to their data to only the research team and destroying identifiable data (such as audio or video recordings) at the end of this study. They were also told that their data might be shared with the University or the federal agency funding the research, if required

XSL•FO
RenderX

by law. Participants were informed of their right to withdraw from this study at any time. In accordance with our university's procedures for exempt research, participants provided verbal consent to continue after reviewing and asking questions about this study's information sheet.

Rationale for Participatory Speculative Design

While voice-activated technologies such as Siri and Alexa are currently available to consumers, they are often designed primarily for non–health-related uses. Therefore, while the current study of these tools for health is growing as an emerging technology, they are not commonly leveraged in health settings due to open concerns about safety [36] and privacy, and are typically not widely available outside of a research context. We chose speculative participatory design as an approach because it provided the flexibility for participants to imagine a future for these technologies in a health context, specifically for supporting informal, aging care, and to reflect on the ethical considerations around future adoption and integration within the home and informal care environment.

Speculative design offers users a way to speculate about future AI technologies and enables researchers to analyze those speculations to uncover values [37], which is a powerful approach for exploring ethics in the rapidly developing field of AI design [38]. The proposed method intersects with other human-computer interaction (HCI) methods, including participatory design [39], value-sensitive design [40], and design fiction [37]. While each of these approaches has been found useful for designing AI systems [21,41], speculative approaches have been useful for helping users envision future AI systems and the corresponding values that may not yet exist, or for imagining possible new futures [31,37,42-44]. Formally, speculative design often leverages the collective strengths of each method to use fictional stories to "collectively envision, design, and critique future AI agents," thereby allowing researchers to understand how people imagine future technologies and the values they consider important when designing them [37]. As an approach, it allows for the imaginative exploration of "future configurations of technology and society within the world" by adopting both creative and critical perspectives, including critiquing existing AI practices [38,45].

Recruitment and Participants

We recruited 9 participants, including 3 older adults and 6 caregivers, for a 4-month study (January-April 2024). The criteria for caregiver participation were that individuals be 18 years of age or older and serve as an informal, unpaid, family or friend caregiver to an individual 65 years of age or older. The criteria for older adult participation were that the individual be 65 years of age or older and be the recipient of informal (eg, family or friend), unpaid care. Additionally, because of our goal of speculative co-design of VAI technologies, we required that participants be currently using or have an interest in potentially adopting or using these technologies in an informal care setting in the future.

Our recruitment method was purposeful, aligning with our need for participants with specific caregiving experiences and interests in using and designing VAI assistants for that space. During recruitment, we found that 4 of 6 of our caregiving participants also self-identified as older adults. In those cases, we provided participants the flexibility to choose which role they would like to take on for the workshop sessions, letting them know that they could also share their perspectives as older adults receiving care. However, we did experience participant dropout over the 4 months. A total of 7 participants attended all 4 sessions. Further, 1 caregiver attended only 2 sessions in their series, and 1 caregiver attended only 3 sessions. Participants did not continue due to busy schedules and other time commitments (Table 1).

Table . Participant demographics and participation in study sessions.

Participant	Age group (years)	Sex	Caregiver or older adult	Sessions participated
P1	35 - 45	Female	Caregiver	S1, S2, S3, S4
P2	55 - 65	Female	Caregiver	S1, S2, S3, S4
P3	65 - 75	Male	Caregiver	S1, S2, S3, S4
P4	65 - 75	Female	Caregiver	S1, S2
P5	65 - 75	Female	Caregiver	S1, S2, S3
P6	65 - 75	Female	Caregiver	S1, S2, S3, S4
P7	75 - 85	Female	Older adult	S1, S2, S3, S4
P8	75 - 85	Male	Older adult	S1, S2, S3, S4
P9	75 - 85	Female	Older adult	S1, S2, S3, S4

Informal caregiver participants served primarily as family caregivers, including spouses, children, and siblings of the care recipient (Table 1). Their ages ranged from 35 to 75 years, with the majority also self-identifying as older adults (65-75 years). Most caregivers were primary caregivers (ie, the responsible party for providing care), although some occasionally received additional help from others. Caregiver participants supported individuals with a wide range of conditions, including dementia, chronic diseases, amputations, and cancer. Their caregiving durations spanned from 6 months to more than 10 years. The type of care tasks they assisted with involved primarily instrumental activities of daily living (eg, housework, transportation, and managing finances), companionship and emotional support, routine activities of daily living (eg, bathing,

XSL•FO
RenderX

toileting, and eating), and medical and nursing tasks, such as injections and colostomy care.

Older adult participants ranged from 75 to 85 years of age and had children or spouses as primary caregivers. They had from 2 to 5 doctors and nurses on their health care team in addition to 1 - 2 other caregivers who help them out with additional health tasks either daily or a few times a year. Older adults and caregivers were familiar to very familiar with voice assistants such as Siri and Alexa.

Participatory Design Sessions

Overview

Each group of participants (older adults and caregivers) engaged in 4 workshop sessions over the 4 months (Figure 1). Therefore, we conducted 8 group workshops in total, 4 with informal caregivers and 4 with older adults who receive care from family or friends. Topics and session progression were similar for both groups. Workshops were conducted online and in person. Initially, workshops were planned for in person; however, to accommodate participants with mobility and other challenges that prevented them from attending in person, we held some sessions online. During in-person workshops, participants engaged in activities such as card sorting, collaborative sketching, and crafting scenarios through role-play and discussion (Figure S2 in Multimedia Appendix 1). In-person and online workshops were conducted similarly, using online tools including videoconferencing software with breakout rooms and online collaboration tools (eg, Miro) to pivot and replicate activities for online participants. Each workshop session lasted approximately 1 - 1.5 hours (60 - 90 min), and participants were paid US $35 per session.

Session 1: Understanding Current Informal Caregiving Experiences

In the first workshop session, we aimed to create a common foundation for envisioning future technologies by understanding participants' experiences with caregiving, AI, and VAI technologies. We sought to gain a comprehensive understanding of the dynamics of informal family caregiving by engaging both caregivers and care recipients in an initial focus group to explore experiences shaping their caregiving values. We asked them to describe their daily routines, experiences, challenges, and key areas for improvement.

We also introduced AI and VAI assistants, sharing definitions of AI, its capabilities, and common VAI scenarios. We provided examples of consumer-facing VAI assistants, such as Siri, Alexa, and Google Assistant, and facilitated open discussions to address questions and assess participants' existing knowledge. We noted key points about experiences or challenges with caregiving or VAIs on sticky notes to prepare for session 2. The focus groups lasted approximately 60 minutes.

Sessions 2 and 3: Imagining VAI Informal Caregiving Futures

The second and third sessions aimed to envision VAI assistants that support informal caregiving. We used participatory speculative design to conceptualize AI voice applications that participants believed could help them in informal caregiving settings (Figure 1). In session 2, the group reviewed and validated notes from session 1 about participants' caregiving experiences and concerns. Participants used affinity mapping and brainstorming to identify and prioritize how VAI could support their informal caregiving experiences. To help prioritize initial ideas for further discussion, participants used card sorting to rank ideas and reflected as a group on (1) the potential feasibility of each idea and (2) how it might meet their needs.

After brainstorming and card-sorting, we used prompts, as shown in Figure S1 in Multimedia Appendix 1, to engage participants in co-design activities, such as scenario-based role-playing. Using these prompts, they brainstormed and created concepts for VAI interfaces suited for informal caregiving. During the third session, we continued these activities to complete the design concepts by creating a final set of scenarios. Consistent with the principles of speculative design [37], our goal was to explore values through the design of future technologies within the context of participants' narratives of use. While emphasizing VAI applications to keep discussions grounded in participants' stories of future use, sessions 2 - 3 also aimed to understand why participants made specific design choices, thereby enhancing our insight into their ethical values. Each workshop lasted about 90 minutes.

Session 4: Ethical Critiques of VAI for Informal Care

In the fourth session, we asked participants to revisit the concepts and scenarios they generated in sessions 2 - 3 to reflect more deeply on their ethical values. Some ethical values emerged naturally in sessions 2 - 3 as participants discussed ideas; however, in session 4, we asked participants to deliberately critique their scenarios through the lens of different ethical dimensions (eg, privacy, transparency, trust, and user autonomy) [14], consider potential challenges that could restrict their adoption, and discuss any needs related to various ethical dimensions, whether positive or negative. We also encouraged them to discuss additional issues that might not have been listed, using their own words, which we later categorized during analysis. The workshop lasted approximately 90 minutes.

Data Analysis

Each focus group and workshop session lasted 60 - 90 minutes. All sessions were recorded with the participants' permission. Data included transcripts generated from over 660 minutes of audio recordings from 8 workshops (4 with older adults and 4 with caregivers), researcher notes, and physical artifacts. While we did experience dropout during recruitment, resulting in a smaller sample, we observed recurring themes (thematic saturation) [46]. We used thematic analysis [47] to analyze the data. To conduct the analysis, the first author reviewed transcripts using memos to highlight interesting aspects of the data. Using a reflexive thematic process [47], we then used inductive and deductive coding to identify recurring themes from the data, focusing both within and across participant groups. Inductive coding was initially used to identify codes related to questions about caregiving experiences, opinions about VAIs, and discussions of ethical concerns. We later used deductive coding to further categorize ethical concerns into existing ethical dimensions: transparency, trust, privacy, justice and fairness, and freedom and autonomy (Table S1 in

XSL•FO
RenderX

Multimedia Appendix 1), aligning with known AI ethical dimensions identified in prior literature [14]. We met iteratively [48] to synthesize data, discussing and categorizing codes into themes. We used an axial coding process to organize the identified codes into broader categories. Analysis of data from participatory design activities, such as lists of caregiving challenges and VAI ideas, was taken directly from data generated during those activities and was refined by the research team using affinity diagramming to merge similar themes across workshops. Three high-level themes emerged: (1) caregiving experiences, (2) opinions about VAIs for caregiving, and (3) ethical dimensions and values aligning with study goals. A detailed summary of themes and subcodes is included in Table S2 in Multimedia Appendix 1.

Results

Overview

Findings from this study shed light on the complex interplay of emotional, physical, and logistical difficulties experienced by older adults and caregivers when engaging in caregiving tasks, as well as their needs and challenges, and their ideas for how VAI might support informal care in the future. Our findings also highlight tensions regarding the potential benefits of VAI and ethical concerns associated with its adoption in a care environment.

Envisioning VAI for Informal Care Support

Caregiving Experiences

From session 1, we learned that caregivers and care recipients represented varied caregiving experiences. However, some caregivers and care recipients have overlapping experiences of care. Aligned with HCI work exploring technology experiences of smaller numbers of participants [49], we present these experiences as personas. Our personas were based on real data and represent a grouping of common experiences across different participants. This method was used in the study by Waycott et al [49] exploring nontech use, where participant numbers were low (10 total) to balance sharing data about experiences while respecting participant confidentiality.

Our participants shared how they came to need care and the emotions surrounding that transition. Caregivers' experiences included (1) long-term caregivers beginning to care for an ill parent as a child into adulthood and older age, (2) partner caregivers who became primary caregivers of a partner due to a life-altering event, and (3) sandwich generation caregivers who were primary caregivers to both older parents and younger children (Figure 2).

Care recipients had similar varied experiences ranging from (1) needing care after an unexpected medical event, (2) needing care to support chronic illness management, and (3) needing shorter-term care after a serious medical procedure (Figure 3).

RenderX

Figure 2. Caregiver personas representing experiences providing care for an older adult friend or family member.

The long-term caregiver

Margaret is in her mid-forties and is married with two children: a teenager who is 17 and a pre-teen who is 12. Margaret has been taking care of her parents since she was young. At 10, her mother was diagnosed with cancer, and as the eldest daughter, she began helping to care for her. Shortly after, her father was diagnosed with chronic heart failure and, due to his diabetes, went through multiple amputations. She dedicated her time to fully becoming a caregiver for her parents. Her responsibilities included assisting with daily tasks, managing medications and medical equipment, accompanying them to medical appointments, and ensuring their overall well-being. Being the only caregiver, she also took care of specific tasks like changing her mother's catheter, which was an unpleasant experience for her. She also, over time, faced the challenge of persuading her aging parents to accept necessary changes in their lifestyle, such as giving up driving or wearing diapers, without making them feel demeaned or dependent. Since she took the role of a caregiver from a very young age, it also took an emotional and physical toll on her. She went through emotional turmoil and stress and barely got time for herself. Moreover, she often suffers from back problems as well. Despite the discomfort and difficulty, Margaret perseveres, driven by her deep sense of duty and love for her family.

The partner caregiver

Jane is in her 50s and is married to her long-term partner, Tim. Recently, Tim had a stroke, which caused him to become paralyzed on his left side, making it difficult for him to get around. Before the stroke, Tim worked full-time and contributed to household expenses. However, after the stroke, Tim can no longer work and get around on his own. Jane has continued working at her job but has had to reduce her hours to become Tim's primary caregiver. With Tim unable to work, Jane faces the burden of being the sole breadwinner for the household. Reducing her work hours to care for Tim further impacts their financial stability, adding stress to an already difficult situation. She is also responsible for helping Tim get around to his appointments and managing his medication regimen. Balancing caregiving duties with her job responsibilities has become a daily struggle for her. Witnessing her partner's sudden disability and the loss of his independence is emotionally draining for her. Jane seeks moments of detachment, acknowledging the necessity of not fixating solely on one task or challenge as she finds clarity and balance amid the chaos of caregiving.

The sandwich generation caregiver

Betty is a 35-year-old woman who has a 5-year-old daughter. Recently, her mother was diagnosed with a leaky heart valve, and she feels her world has been turned upside down. This diagnosis not only brought a wave of worry and concern but also a significant shift in Betty's daily life. She finds herself sandwiched between the needs of her child and the increasing demands of caregiving for her ailing mother. She turned her daughter's room into a makeshift hospital room equipped with medical apparatus and necessities to accommodate her mother's condition. Betty encounters resistance from her mother, who struggles with relying on others for physical assistance. The shift from being cared for to becoming the primary caregiver strains their bond, as Betty longs for the comforting presence of her mother. She faces a relentless struggle to secure resources for caregiving tasks, from fixing wheelchairs to deciphering insurance policies and acquiring vital medical equipment for her mother's care. The demands of caregiving often leave Betty feeling isolated from friends, family, and her community.

XSL•FO
RenderX

Figure 3. Older adult personas representing experiences collaborating with a friend or family member for informal care.

Donna is 66, and her life took a sudden and unexpected turn when she was involved in a severe accident that left her with a metal rod in her leg, extending almost to her knee. This life-altering event added a new layer of challenges to Donna's already complex medical history. Ten years before the accident, Donna had faced another significant health battle when she underwent radiation treatment. The emotional toll of battling cancer was immense, and during this challenging time, Donna leaned heavily on the support of her husband, who served as her primary caregiver. Alongside him, Donna also received care from 3-4 professional caregivers. One of the most significant hurdles she faced was the loss of control and autonomy over her own body. Donna grappled with a deep-seated fear of the unknown, particularly regarding her recovery and what the future held in store. *What's gonna happen? Am I gonna get better?* - she thought to herself. During these times, she relied on her friends and connected with them often to chat, and it helped her with her anxiety.

Care after an unexpected medical event

Shawn, a man in his 60s, had always prided himself on his independence and self-sufficiency. He had lived a full life, working hard, raising a family, and cherishing every moment spent with his loved ones. However, when he was diagnosed with a chronic illness, cancer, his world was suddenly turned upside down. Shawn was fortunate to have the unwavering support of his daughter and granddaughter by his side. They became his primary caregivers, providing him with the physical and emotional support he needed to navigate his illness. Whether helping him with daily tasks, accompanying him to medical appointments, or simply offering a listening ear, their presence brought comfort and reassurance during tough moments. One of the most significant challenges Shawn faced was the loss of his independence. As someone who had always been fiercely independent, relying on others for assistance was a bitter pill to swallow. The feeling of helplessness and the loss of control over his own life weighed heavily on him, leaving him feeling frustrated.

Care after a chronic illness diagnosis

Annie's life took an unexpected turn when she underwent a major surgery—a hysterectomy—that left her physically weakened and dependent on the support of her three children and husband. Her three children and husband rallied around her, becoming her pillars of strength during this difficult time. From helping her with daily tasks like bathing and dressing to ensuring she took her medication on time, they spared no effort in ensuring her comfort. The stress of managing illness weighed heavily on Annie's shoulders as she navigated the complexities of her recovery. The most challenging part for her was adjusting to a new reality where she needed assistance with even the simplest tasks. The inability to do things quickly or independently left her feeling frustrated and restless. She missed driving and being able to do grocery shopping herself. Furthermore, Annie felt the pressure to maintain a positive outlook for her family and loved ones, even when she struggled internally.

Care after serious medical procedure

Both older adults and caregivers appreciated the caregiving relationship but noted challenges. For caregivers, most challenges were related to managing and coordinating care, including adjusting to their role, navigating the health care system, and accessing resources (Textbox 1). However, they also shared emotional and social challenges such as feelings of isolation, lack of support, and coping with feelings of being overwhelmed. They also shared that informal caregivers are often not trained; therefore, finding resources and training on different care-related tasks, such as navigating financial policies or communicating sensitive topics, made things more difficult. Textbox 1 lists the range of challenges caregivers listed during the session.

XSL•FO
RenderX

Textbox 1. Caregivers' caregiving needs and challenges.

- Lack of resources and information
  - Scarcity of external support networks
  - No access to information about available services
  - Potential loss of income due to caregiving responsibilities
  - Lack of understanding about financial policies
  - Shortcomings of training programs
  - Navigating health care systems and tasks
  - Managing medical appointments and tasks
  - Managing medical equipment and administering medication
  - Convincing older adults to accept help, medication, or medical devices
  - Advocating for the care recipient
- Emotional and psychological toll
  - Feelings of sadness, frustration, and guilt
  - Enduring emotional strain in prolonged caregiving
  - Witnessing decline in health and independence of loved ones
  - Lack of time for personal reflection
  - Dealing with the unpredictability of caregiving tasks
- Isolation and social dynamics
  - Transitioning roles within relationships or role reversal
  - Experiences of social isolation
  - Managing family dynamics
  - Balancing caregiving duties with other commitments
  - =Lack of self-care
- Communication and sensitive interactions
  - Communicating sensitive topics
  - Difficulty finding solutions to specific issues
  - Convincing older adults to accept help, medication, or medical devices

Older adults shared difficulties they had in transitioning to needing care. They discussed difficulties with losing independence, feeling like a burden, and needing to depend on others (Textbox 2). They shared that the transition to needing care came with a lot of emotional tolls, including adjusting to feelings of social isolation and loneliness, and frequently needing to balance positive and negative feelings that come along with needing care. Textbox 2 lists the range of challenges reported by older adult participants during the session.

XSL•FO
RenderX

Textbox 2. Older adults' caregiving needs and challenges.

- Loss of independence and autonomy
  - Loss of independence
  - Dependence on others
  - Sense of loss of control or autonomy
  - Asking for help with basic tasks such as picking up items from the floor
  - Not being able to drive
- Physical and emotional toll
  - Managing the stress of illness or injury
  - Physical limitations
  - Emotional toll
  - Feeling impatient because of not being able to do a task or do it quickly
- Sense of isolation and social disconnection
  - Sense of isolation
  - Fear of future and uncertainty about what lies ahead
  - Feelings of burdening or bothering others for assistance
- Feelings of burden and responsibility
  - Burden of trying to be better for others
  - Feelings of burdening or bothering others for assistance
- Balancing negative and positive emotions
  - Sense of kindness (despite struggles)
  - Sense of kindness (toward those providing help)

During the first session, participants reflected on their caregiving experiences and needs, prioritizing the challenges that VAIs might address. During sessions 2 and 3, caregiver and older adult participants brainstormed different ideas for how VAI assistants might augment and support them as caregivers and care recipients and address the challenges they experienced.

Many initial design ideas from caregivers and care recipients emphasized how they felt VAI could help make caregiving tasks more efficient, or how VAI might help shift caregiver time spent on physical or informational caregiving tasks toward more social and emotional ones. For example, during session 1, participants shared that informal caregivers often lack professional caregiving experience and frequently encounter unfamiliar situations, navigating uncharted territory. Therefore, when asked to prioritize how they felt VAI could address concerns listed from the initial focus group session, caregivers ranked their need for caregiving support as a top priority. They discussed how VAI might help them be more efficient by supporting them with (1) immediate access to relevant information and resources, (2) proactive assistance with caregiving tasks and resources, (3) persuading older adults to accept help, and (4) connecting for socioemotional support as top priorities. A full list of brainstormed ideas is included in Table S3 of Multimedia Appendix 1.

While informal caregivers generated more ideas in their sessions, some overlapped with those of older adults. As with caregivers, older adult participants saw opportunities for VAI to support health information needs with caregiving relationships and to provide socioemotional support for them and their caregivers. Older adults' ideas primarily focused on VAI providing support through (1) immediate access to relevant information and resources, and (2) connecting for socioemotional support as top priorities. A full list of brainstormed ideas is listed in Table S4 in Multimedia Appendix 1. The following subsections discuss the primary VAI concepts that caregivers and older adults prioritized for supporting informal care.

Providing Immediate Access to Information and Resources

Both older adults and caregivers felt that features of VAIs, such as voice input and automation, could help to make health information and other caregiving tasks more efficient. Caregiver participants shared that they manage different types of health information, ranging from supporting the care recipient's daily health care needs to navigating insurance coverage. For example, one participant gave an example of navigating insurance as a caregiver, C3, W2, "Some things get covered [by insurance]. Some things don't... You don't find out until somebody screams [at you] in the financial section of the hospital." They felt VAI

XSL•FO
RenderX

could help them find and navigate this and other information more easily and efficiently.

Older adult participants also expressed interest in using existing VAI to support health information needs, such as receiving reminders and alerts for appointments or events, and to provide efficient access to information for managing their health. They recognized the role VAI could play in helping them stay organized and on track with their schedules. They felt that voice-activated information requests, similar to voice-based Google searches, could be convenient for accessing information more quickly and easily. While these initial ideas align somewhat with what current VAI assistants might do, many of the systems on the market are not tailored to support health or care needs.

Proactive Assistance With Caregiving Tasks and Resources

Older adult participants tended to discuss ways they foresaw VAIs helping them better manage their health tasks, such as scheduling or quick access to health information. Caregiver participants also envisioned the potential for a more sophisticated VAI information assistant (beyond what currently exists) that could talk to or nudge them proactively, helping them streamline their schedules and manage caregiving tasks. Participants envision this system using their existing health information to intelligently set reminders, manage appointments, and optimize their time, acting as a proactive decision support assistant.

Caregiver participants discussed the potential of VAIs to reason to anticipate future caregiving duties by efficiently providing relevant information about the older adult patient's health. One participant described a VAI that could bring together relevant information around a caregiving task to help them complete it. C1, W2 described, "So basically, it's [the VAI] gonna say like you need a ramp, you need a hospital bed, you need to make sure they have the wheelchair you need. So, it's gonna give you a list of all the stuff you need and potentially where you get it and who pays for it." Another participant suggested a VAI that could help troubleshoot problems by understanding patterns and symptoms to identify potential causes (Figure 4). C2, W3 explained, "If it could troubleshoot and identify what their areas of need are, if this person is up all night, what can you do? Are they going to the bathroom too much? Are they irritable? And then suggest: These are the steps that might be able to help them." They felt this additional support could be valuable in reducing their feelings of being overwhelmed when managing various caregiving tasks and responsibilities.

Figure 4. Scenario demonstrating desired interactions between an informal caregiver and VAI that provides advice or tips to help them address caregiving concerns. UTI: urinary tract infection; VAI: vvoice-enabled artificial intelligence.

Persuading Older Adults to Accept Help

Caregiving recipients discussed VAI's potential to support their caregiving routines through virtual companionship; however, their ideas centered on ways virtual companions might leverage human-like characteristics to build trust and persuade older adults they care for to accept assistance, medication, and treatments prescribed for them. One idea presented was using VAI to mimic the voice of a trusted person, such as a celebrity, to encourage acceptance of essential care, such as transitioning to using adult diapers. C1, W2 described, "I'm imagining Harrison Ford making a video saying, Hey, it's ok to do these things [wear an adult diaper]." Challenging this notion, another caregiver, C3, W2, who also self-identified as an older adult, offered a contrasting perspective, suggesting that "with old age, you get fairly tough skin, so a diaper is a diaper." They explained that older adults may not find discussing topics such as diapers stigmatizing over time. However, participants generally agreed that leveraging VAI to imitate others to persuade or provide comfort might be helpful in specific scenarios. C1,W3 shared, "...so say the person's having trouble going to sleep if maybe a book or a scripture passage was read in the caregiver's voice. I do think something like that in the caregiver's voice, I think that would be real helpful."

Connecting for Socioemotional Support

Opportunities to Support Mental Health and Well-Being

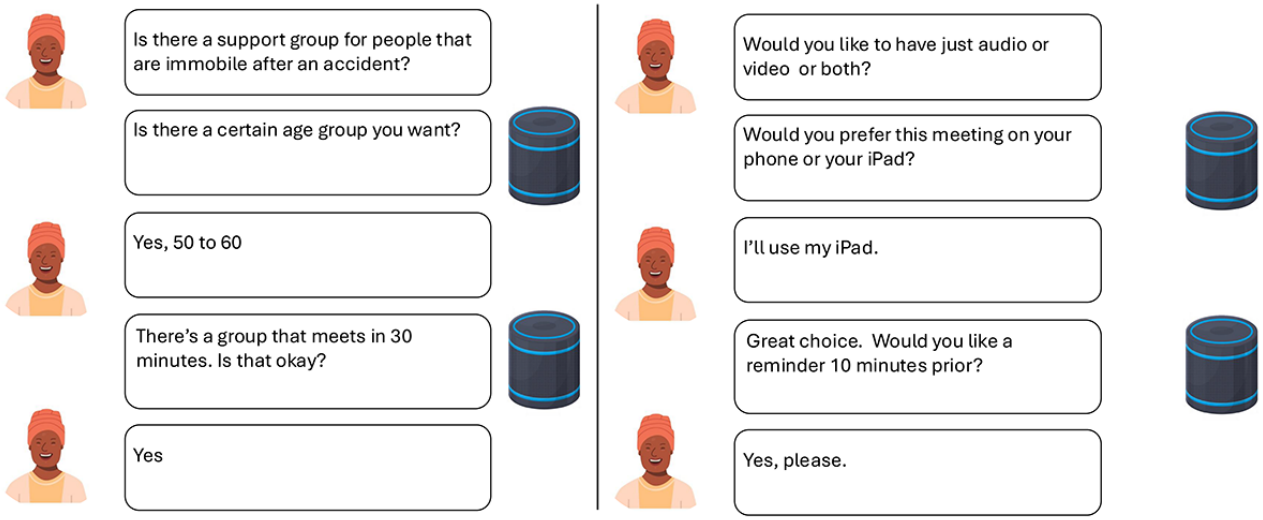
Both older adult and caregiver participants saw opportunities for VAIs to support their mental health and well-being. Caregiver participants tended to focus on how VAIs could support their mental health through reducing caregiving management tasks and through direct mental health support.

Supporting Caregiving Management

One set of ideas from caregivers focused on tools that could ease some of the mental burden of managing care. For example, one participant saw promise in the VAI for recording older adult patient requests, ensuring care continuity while reducing the burden of constantly being in "caregiver mode." Reflecting on their conversations with their mother, one caregiving participant

XSL•FO
RenderX

shared that their relationship with their mother shifted over time. They initially had typical mother-daughter interactions; however, because of her dual roles as caregiver and daughter, preserving the natural relationship became more difficult. Therefore, C3,W3 suggested using voice-recorded messages could be helpful, stating "later on it [my role] became more caregiver. And so when we'd wake up in the morning, instead of being like, 'Hey mom, good morning,' it would be like, 'I need this, and I need this, and I need that.' So if she could leave a message saying I need all this, then it could open up the morning into being, 'Hello, good morning. I love you,' and then I can check the message. So, the request can be via the system so that you still have some of that relationship left." Participants suggested enhanced VAI systems with more reasoning capabilities could also provide more significant support in caregiving situations. For example, they discussed VAI systems that proactively provide a tailored review of patients' conditions to first responders in emergencies. C1,W2 described, "If there was an emergency and you called the fire department and they showed up, maybe they'd be able to connect to it [referring to the VAI], and that would immediately tell them what the patient's conditions are, what medications they're on."



Supporting Caregiver's Mental Well-Being

Another set of ideas revolved around how VAI might directly support caregivers' mental health needs. Caregivers explained that being in a caregiving environment often comes with much stress, and therefore, they saw opportunities for VAI to support self-care and mental wellness. Participants suggested ideas for VAI to help them curate self-care plans, with occasional reminders to care for themselves or to complete self-care activities. C3, W2 shared, "It [the VAI] could give me a reminder to go do something for myself as self-care and maybe not for long periods of time because as a caregiver you don't have a lot of time ... also like have a self-care plan so that while it is reassuring, it can also walk you through yours." C3,W3 suggested using VAI as an emotional support, "I want this thing [VAI system] to comfort me in some way to. I want it to be like, look, I'm here to help you take a deep breath. It's gonna be OK." As shown in Figure S3 in Multimedia Appendix 1, participants brainstormed ways VAI systems that identify stress cues could offer positive affirmations or prompt caregivers to take breaks when needed. For example, the VAI could also converse with them to comfort them in difficult times. In addition, they explained that caregivers are often isolated, and the VAI could help connect them to support groups or people in similar situations.

Supporting Older Adult Self-Care

As with caregivers, older adults also felt VAI could help support self-care and well-being. They shared ideas for VAI systems to help them find leisure activities, viewing them as an accessible resource for quickly finding books, movies, or other media to enjoy as part of their well-being and self-care. Older adult participants, as with caregivers, also discussed generally using VAI for emergencies to establish instant connections to emergency services or loved ones, especially in times of crisis, when they expressed the need for an instant connection to emergency contacts. However, as with caregivers, most ideas centered around VAI as a facilitator for connecting with others (Figure 5). They shared ideas about the possibility of VAI helping them connect to their friends or loved ones through voice commands on a screen. O2,W2 explained, "I think [VAI] could be helpful in the emotional sense. If you're in bed and you don't wanna get up, you could always say call John." O3,W2 made similar suggestions, "It would be uh trained to be supportive of all their emotional needs and [when] you kind of shut down . she[the VAI] . on how much can we help this person who seems to have bouts of crying or they're really depressed and get to know them and see what the problems are and then [be] smart enough to try .and act out what would help that person get back to a stable emotional point." Participants also discussed the potential for VAI to connect them with people who have experienced similar situations automatically. O2,W2 later asked, "Is there a way that with AI, you could say connect me to the support group for people with recent car accidents, for instance."

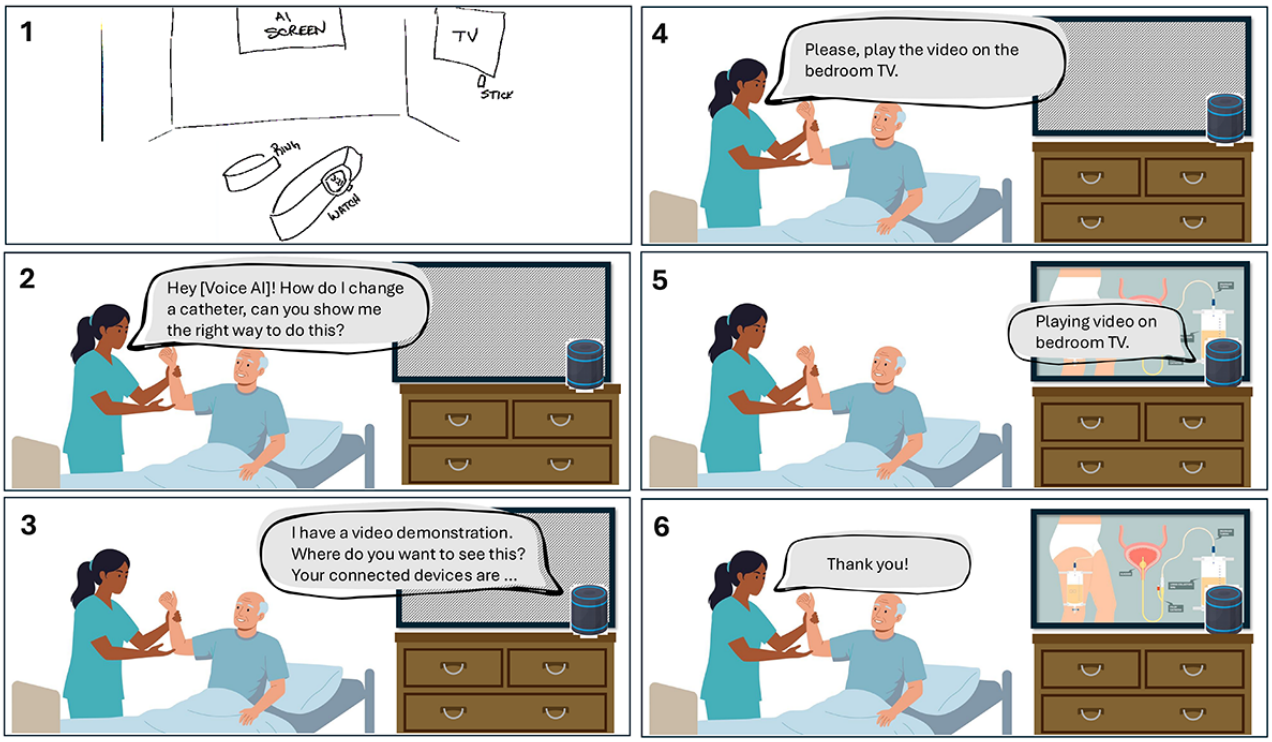
Figure 5. Scenario representing a conversation between a person and a VAI assistant, discussing joining a support group for older adults experiencing mobility changes. VAI: voice-enabled artificial intelligence.

XSL•FO
RenderX

Supporting Older Adults Through Virtual Companionship

Older adult participants envisioned new ways in which VAI could enrich their lives as care recipients by providing companionship and social support. Participants envisioned new ways to engage in dialogue and interact with VAI as a virtual companion, which they felt could help alleviate feelings of loneliness during periods of solitude or immobility. Participants described a VAI system as an "AI girlfriend" (eg, a romance chatbot or robot). O3,W2 explained, "...they say [AI girlfriends] actually learn what they[the human partner] need and are looking for, and they're able to change how they respond to meet those needs. And if they can do that with AI girlfriends, I'm guessing they could absolutely do it with people that were depressed or down emotionally and actually learn what it is that that person is going through." However, participants also expressed apprehension about the possibility of humans developing emotional attachments to AI entities. O1,W2 posed, "The question is, can AI really meet someone's emotional needs?" At the same time, they expressed discomfort at conversing with a system rather than a human, stating, "Some of it [VAI] also scares me when they pretend, they're human or sound human."

Participants were also unsure whether a virtual companion should be embodied. One participant suggested embedding a VAI in robotic entities, such as robotic puppies equipped with AI to interact verbally and physically with individuals and to simulate lifelike behavior, such as mouth movements or eye blinking. In response, another participant shared that they preferred a discreet, compact device rather than a visually conspicuous one. They voiced concerns about potential discomfort associated with being constantly monitored by a visible robotic assistant, highlighting worries about their appearance or attire. 02,W2 mentioned, "I'm kind of stuck on something like a small device .I wouldn't necessarily want to see me . that'd be another thing to think about. Am I dressed or whatever? And I like to think that even though Alexa hears everything, she can't see anything." Older adult participants also considered that, while virtual assistants such as Alexa may capture audio, they lack visual capabilities. The idea of a small voice assistant device appealed to them because it is nonintrusive and occupies minimal space in a room.



VAI Can Help, but it Is Not Enough

Older adult and caregiver participants viewed VAI as a potentially valuable tool to support their caregiving activities. However, participants also consistently pointed out that VAI would not be comprehensive enough to support the complex environment of caring for an older adult. Therefore, both groups also noted their desire for VAI to be considered broadly as one of several tools that might seamlessly integrate into a more extensive system. We learned that participants' reasoning for this perspective was related to several factors, including a desire to support various access and accessibility needs, to promote more integrated care, and to ensure fair access.

Participants suggested that VAI could be used as a tool to help them connect with multiple screens, noting that it may also be important for some users to have visual aids to enhance assistance and support varied accessibility needs. Additionally, participants noted that they sometimes preferred video demonstrations for tasks that might benefit from seeing them performed (eg, changing a catheter). They suggested that VAI-enhanced visual guidance might help them better perform the caregiving tasks (Figure 6). C3,W2 explained, "I would prefer having someone with a video showing me [for some tasks] every time [I was changing a catheter]. I like to see how things are done." These examples suggested that some participants preferred prioritizing the modality of information delivery that best supports the care task at hand, rather than defaulting to VAI alone.

XSL•FO
RenderX

Figure 6. Scenario representing a VAI caregiving ecosystem that connects other devices, such as smartwatches, televisions, and voice assistants, to coordinate various care tasks. On the wall, there is an "AI SCREEN" and a "TV" with an Amazon Fire TV Stick labeled "STICK." Next to it are a "RING" and a "WATCH" displaying the time. Followed is a storyboard of the VAI ecosystem scenarios participants discussed, showing a person interacting with a VAI to play a video demonstration of how to insert a catheter. AI: artificial intelligence; TV: television; VAI: voice-enabled artificial intelligence.

Caregivers also expressed the need for VAI to connect to multiple devices, enabling a more comprehensive approach to care support. C1,W3 discussed that it would be essential for the solution to have "different modalities because if something is also tracking their vital signs and everything, it has to be attached to the patient as well." They asked their group, "So what does that look like?" C2,W3 noted, "I personally would say again, things are gonna get smaller all the time, but like a ring, … or, you know, a watch. The necklace [fall necklace] got taken off much of the time. It got yanked. An Apple Watch?" C3, W3 explained, "The connectivity[has to be] built in with at least the phone." C1, W3 summarized, "Maybe this is like one program that can get attached to different equipment. Like your ring or watch or your TV, for that matter. And it can also attach to, like, you know, how Alexa can control your lights and everything. So, like something that can control different things differently, because, like it, when I was taking care of my mom, um, I'd have her watching TV, so I would want two separate units so that she could be watching TV while I was maybe watching something like a procedure." The participants drew a sketch illustrating their vision of a device ecosystem they would prefer to see integrated with VAI (Figure 6).

In addition to caregivers' perspectives, older adults emphasized the importance of VAI seamlessly integrating with the devices and technology they already use in their daily lives. For example, older adults wanted to give voice commands to the AI system to find information or pull up a book to read on their iPad (Apple Inc). They explained that the difference between their envisioned and existing VAI systems is that the primary agent assists in managing and connecting these different systems. They felt that integrating VAI could extend the flexibility and convenience of other devices, making care and wellness tasks easier for them overall. O2,W2 noted, "Maybe something that you can turn on if you want to talk, that could turn on through your television or through an iPad. So that if you want it to pull up something for you to read, for instance, Alexa, find me a good book on whatever. I mean, that's going pretty far out." In describing an interaction with the system, a participant demonstrated how they envision the VAI providing options when choosing a mode of interaction, for example, connecting them to a support group. Overall, participants view VAI as a tool within a broader ecosystem that supports care environments, and therefore proposed that a multimodal approach integrating VAI with other technologies would be ideal for addressing the complexities of caregiving support.

Exploring Ethical Values and Dimensions: Ethical Critiques of Envisioned VAI Concepts

Balancing Needs for Informal Care Support and Ethical Concerns

In the final workshop, participants provided ethical critiques of their VAI concepts, reflecting on and discussing potential ethical concerns about integrating solutions they designed into informal care. During workshops 2 and 3, we observed participants navigating various design tensions as they brainstormed ideas, revealing some contrasting perspectives and conflicting opinions regarding how VAI might support the care relationship (or not). For example, when suggesting ideas for VAI as emotional support, we found that participants questioned whether VAI should provide emotional support.

XSL•FO
RenderX

Further, while both older adult and caregiver participants remained positive about VAI's potential efficiency, in workshops 2‐3, we saw some different ideas of how VAIs might support their care. We expected some differences due to their experiences in their caregiving roles, although many of our caregivers were also older adults and provided perspectives from both roles. However, we found that when discussing ethical values, older adults and caregiver participants shared overlapping ethical concerns and expectations about how VAIs might handle health data and system transparency, as well as varied older adult needs, system trust and accountability, privacy and confidentiality, fairness and affordability, and shared autonomy. Therefore, participants highlighted a need to balance efficiency and ethics in designing and implementing such technologies. They discussed that if systems could address their ethical values, they would consider integrating VAI into their caregiving routines in the future.

To structure the discussion on ethical values, we report the ethical values and dimensions participants discussed to align with the 11 dimensions of AI ethics by Jobin et al [14], which include transparency, justice and fairness, nonmaleficence, responsibility, privacy, beneficence, freedom and autonomy, trust, sustainability, dignity, and solidarity. Similar to Jobin et al [14], we found that many of these dimensions overlap; however, of the eleven dimensions Jobin et al found in literature, our participants discussed seven dimensions: (1) transparency, (2) privacy, and (3) trust (including (4) nonmaleficence and (5) responsibility), (6) justice and fairness, and (7) freedom and autonomy.

Transparency, Privacy, and Trust

Overview

We found that participants considered the ethical dimensions of transparency, privacy, and trust to be essential yet complementary components in designing ethical VAI systems for informal care. While participants often discussed these components separately, the main takeaway was that the systems needed to provide avenues to build trust among users through transparent interactions, respect for privacy, and accurate information. Participants voiced a desire for clear, honest communication from VAI systems handling health data to ensure transparency about the systems and actions that help them better trust the system. At the same time, participants expected that systems would build trust by respecting their privacy, both by ensuring data confidentiality and by promoting privacy best practices. Relatedly, participants expected that VAI systems should proactively cultivate trust by ensuring the accuracy of information through personalization and contextually informed responses while limiting misinformation.

Ensure Sufficient Transparency of Health Data and System Actions

Discussions around transparency values related to data handling practices and knowledge of "how the system worked." Participants felt it was important to understand how the system handled their data, especially any health-related data or activity, including voice recordings of the surrounding environment or video capture, as they may contain sensitive data. Participants also wanted information about sources of responses and information from a VAI system. In a discussion about transparent communication of sources, a caregiver, C1,W4, stated that "I think there will be a lot of users that would not even care [about a VAI answer source], but there are people that would be like me, I really want to know where they got this information." However, while participants felt that knowing the source would be necessary, there was no consensus on how the system should provide it. The participant later noted that they would not want source information to be intrusive or prominently displayed, stating, "I think you want access to it, but don't put it in my face." Another participant, C2,W4, acknowledged that in critical or sensitive situations, the immediate need for assistance would likely take precedence over reviewing sources, stating, "I would absolutely wanna research so much of this information, but like in a situation that you're just thrown into, you just want the help, and you'll research it a little bit later."

Older adult participants shared that they often lacked understanding of the workings of AI systems and expressed that it would be important to have broader support for understanding the technology's capabilities and limitations. They emphasized the need to be informed about what they can and cannot do with it, noting that this has been an issue with past VAI technologies. O1, W4 referenced an incident in which Alexa altered its voice during the interaction, prompting them to question whether it was mimicking or mocking them. They shared, "this was just an experiment with my Echo, I just said, I love you. And she came back in a human-sounding voice. I thought that was kind of interesting in a weird way. Was it mocking?" Therefore, in addition to being transparent about answers and recommendations, participants also valued having a general understanding of "How an AI works." The participant mentioned, "What would make me trust it [VAI] is education, knowing more about it, reading more about it, learning how they do it."

Mitigate Privacy and Confidentiality Concerns Around Sensitive Data Handling

Caregivers and older adults voiced concerns about the substantial volume of sensitive data that VAI technology would need to effectively assist them with some caregiving tasks. They believed that accessing that volume of sensitive data carries the inherent risk of data breaches associated with storing and processing such confidential information. C2,W4 participant noted, "We're asking it to be kind of the keeper of all information. What if it were hacked?" Additionally, caregivers proposed implementing an authorization process for VAI technology, given its handling of health care information, noting that this process would ensure that only authorized individuals can issue commands and receive information. C1,W4 explained, "...if a new person is there [attempting to access personal health data], they should be authorized in some way to use this technology... the technology should only interact with the people it has registered as, like the usual voices." Here, the participant suggested that voice could be used as a unique identifier, similar to fingerprints or face recognition, to restrict or grant access to people using the system.

XSL•FO
RenderX

In one of the discussions, older adults contemplated whether asking sensitive questions or seeking personal information (eg, asking about "finding an economical nursing home") might pose additional risk compared to a traditional online search. They explained that they would be more reluctant to disclose certain types of sensitive health information to AI systems. O3,W3 noted, "I don't think I'd ever give my charge card numbers to AI. I guess one of the privacy things I thought about was just simply, do I want AI to know?" They indicated a reluctance to entrust AI with sensitive information, such as credit card numbers used to pay medical bills, even if it would be convenient, preferring not to "throw it out into the World Wide Web." They acknowledged that while some companies claim not to share information, they are often skeptical of such claims.

Cultivate Trust in the System and Be Accountable to Recommendations

Participants mainly discussed trust and accountability values through the lens of accuracy, highlighting their importance. Participants felt that, in a health care context, a VAI would need to be as accurate as possible. They felt this was true for any health care technology but discussed the unique benefits and challenges of accuracy in a VAI system.

Older adult participants discussed their worries about receiving incorrect information from a VAI system, especially for sensitive topics such as health. Caregivers and older adults, therefore, shared apprehensions about reliance on VAI technologies in caregiving situations. O2,W4 stated, "If I got a response that was totally crazy... I wouldn't use it anymore," explaining that if the system provided an answer that they felt was inaccurate, it would impact their use. O3,W4 discussed that in the news, they heard anecdotes about VAIs that might fabricate responses to appease the user. One older adult participant shared, "the little bits that I've really read about AI is that it tries real hard, and if it can't find what the legitimate answers are, it'll make stuff up to try and make sure that it satisfies."

Some participants also discussed the potential value of having a system that could personalize responses. They emphasized that they would value and trust personalized VAI systems that could provide contextually relevant responses tailored to individual needs and situations, rather than more abstract, generalized responses. A C1,W4 noted, "just having the technology to be able to individualize it to the environment, the person, and... their situation, I think. that'd be pretty accurate." In care-related contexts, participants felt that a degree of personalization was essential for providing more relevant responses to aid decision-making.

Older adult participants expressed concerns about the lack of fine-grained control they feel creators have over how AI might respond to queries, leading to inaccurate and unexpected responses. O3,W3 shared, "...I think AI, right now, I'm afraid they [big companies/AI developers] don't know how to control it." Similarly, they explained that they knew humans ultimately created AI systems, but felt humans could be limited in their ability to control how AI evolves because of how AI systems learn. O3,W3 said, "I know there's a programmer who writes the programs, but the way AI is evolving, it's really no longer under the control of a programmer; it's evolving on its own." As a result, participants mentioned that they would still consider AI-generated answers to some extent but would approach them with skepticism and exercise caution. Moreover, C3,W4 mentioned that they felt a trusted medical organization, such as the American Medical Association (ie, a trusted nonprofit organization in the United States consisting of medical professionals, students, and other stakeholders focused on issues related to patient care and policy), should validate and endorse any VAI caregiving system.

Justice and Fairness

Participants noted that they would expect ethically designed VAIs to consider the diversity of experiences in the design, including accessibility needs and inclusive design for older adults. While affordability was not identified as a component of current AI ethical dimensions in prior work [14], participants also noted that cost should be taken into account, as it could further widen gaps in access to health care resources.

Be Inclusive of Varying Older Adult Needs

Regarding accessibility, participants felt that while a VAI system could improve accessibility in some cases, it could also create additional accessibility challenges in others. A participant in the older adult session highlighted the potential benefits of voice commands in technology, noting that they may experience vision limitations as they age. O1,W4 explained, "...someday I won't be able to see very well, it enters my mind, and I would need help. ...It'll be helpful for you in a way if you can operate something with your voice, let's say you can just say, hey Alexa, connect me to this friend of mine, and they just do it." However, participants felt that if the VAI included the smaller screens found in commercial devices, access challenges could arise for people with visual disabilities. While they noted that the VAI could leverage voice as an alternative input method, larger screens could facilitate easier navigation and interaction and open possibilities for new functionalities, such as virtual doctor visits. O1,W3 explained, "So if I was developing a system and instead of Alexa, it was called nurse K or whatever that. Ok, that system and I think they're gonna move to screens on pretty much everything." O3,W3 agreed, noting access to a screen can be helpful, "Uh, I think Ring [the camera system] is one that comes with screens now. And so, it does the same thing Alexa does, it can search the internet or play songs or whatever, but it also has video and .I think you can get it on your phone or your laptop or iPad." Participants also emphasized the importance of adequate volume levels to address hearing loss among older adults. Therefore, participants raised concerns about balancing the introduction of a new interaction modality, VAI, with its inherent access challenges.

Participants also discussed values related to the diversity of speech when interacting with a VAI specifically designed to assist with care. Caregiver participants stressed the importance of representing diverse dialects to ensure the VAI system sounds natural and is easily understood, as overly mechanical voices can present challenges for users and make them less comfortable. C1,W3 explained, "because a lot of elderly people have hearing loss. So, I think it's important that we make sure the volume is good for them . and that the person's dialect is

XSL•FO
RenderX

represented. That's critical because if it sounds not too foreign but too mechanical, that could be a challenge too."

Make It Affordable, Promote Fair Access to Health Resources

Participants felt that affordability was an ethical concern for VAI systems that support caregiving. Participants felt that while the VAI system had the potential to improve efficiency, it would also incur higher costs. At the same time, cost is not always a factor formally considered in discussions of ethics. Participants noted that affordability could be a factor in determining who has access to these systems. Therefore, they related cost and affordability to justice and fairness in this context. They felt it was important that, if these VAI systems became available for caregiving purposes, they should be accessible to all who might elect to use them, so that all who wish to benefit might do so. Therefore, caregivers particularly emphasized a preference for integrating health-related VAI systems with insurance or existing health care systems, such as "MyChart," a patient-centered health record and messaging system, which already centralizes patients' health care information:

> *I go to Saint Francis, and they have something called MyChart … could it tie into something that's already existing like that …like a booster to that system. It would be good if it could tag on to what already exists out there that people are familiar with and be an enhancement. That would give you some legitimacy.* [C2,W4]

Moreover, older adults expressed apprehension about the future maintenance costs of such systems, especially because they felt their vigilance about maintaining subscriptions might decrease with age. A participant in the older adults' group, O2, W3, gave an example of how they were surprised to find that Alexa could facilitate games such as Jeopardy; however, they were surprised when it prompted them to start a free trial that later required a monthly payment of US $7.95. They shared, "I don't know much, and I asked my echo what she can do and, you know, it's funny. I said she could do games, and so she and I picked Jeopardy, and the music played, and I thought, well, this is really neat for people who can't get up and around, and it said you can start a free trial for a week. And then after that, it's $7.95 a month. Never occurred to me that there would be extra things on there that would cost money. I was kind of surprised by that. Another observation is dependency." Participants noted that in situations where they might rely on these types of VAI devices to support their care, they sometimes face a dilemma between continued care support (ie, from the system) and managing ongoing costs, which may limit access.

Freedom and Autonomy

Participants' discussions of freedom and autonomy mainly focused on the right to choose where and how VAIs are integrated into the care relationship, and on having sufficient autonomy to prioritize human relationships over functional support.

Participants voiced concerns about balancing technology-enabled caregiving assistance and the human touch. While acknowledging the potential benefits of technological support in caregiving, caregivers emphasized that it was essential to ensure that any technology, including VAI, does not overshadow or replace human interaction and compassion. They noted that the system must respect their values and rights to care autonomy (eg, rights to self-govern their care environment and experiences). O1,W2 shared, "I think the human touch and kindness is very important." C1,W4 shared, "It would be really important the individual is interacting with it [the VAI] instead of it taking over because it's real easy to do that."

Caregivers also emphasized that if technology aids caregiving activities, it should not be overly assertive, especially when empathy, compassion, and understanding of the situation and context might be necessary rather than a strict ultimatum. They gave the example of a VAI that might recommend an individual's water intake based on a predefined number of ounces, using established health guidelines. C1,W4 shared that it may not be productive for the VAI to recommend, "The person needs to drink a gallon of water a day when you're lucky to get eight ounces of water in them. I guess you wouldn't want it to be too aggressive." They felt that this was a situation where a human would understand the situation more holistically, and that an assertive AI might end up being discouraging rather than motivating.

Older adults expressed appreciation for the assistance and accountability that VAI technology could provide, including reminders to engage in beneficial activities such as stretching. However, they discussed that they felt it was important to maintain control over the technology's level of involvement in their care and have the option to override its actions if they feel it becomes too intrusive or overpowering. O3,W4 shared, "If it goes too far and I'm unhappy with it, I just want that kill switch to say no, you're done."

Discussion

Summary of Findings

In this study, we used a 3-phase research approach to explore the potential of VAI for informal caregiving and identify ethical dimensions that might impact adoption. We aimed to answer the following research questions: (RQ1) How do participants perceive the role of VAIs in supporting caregiving tasks? (RQ2) What values do caregivers and older adults have around VAI assistants that support day-to-day care tasks? (RQ3) What ethical concerns do caregivers and older adults have about VAI assistants that support day-to-day care tasks?

The findings illuminate a core tension between the perceived benefits and efficiency of VAI for supporting informal care and the ethical considerations surrounding its implementation. Participants identified several ways VAI could enhance caregiving efficiency, streamline caregiving tasks, and provide emotional, social, and training or educational support. Nevertheless, caregivers and older adults express apprehensions regarding the ethical implications of AI-driven caregiving solutions. Based on these findings, we also provide design considerations regarding the role of VAIs in assisting informal aging care and in addressing ethical concerns from a harm-reduction perspective.

XSL•FO
RenderX

Role of Voice-Activated Assistance in Informal Care: How Can Voice-Activated Systems Help?

Related to RQ1 and RQ2, we found that the primary appeal of VAI systems was the potential capacity to streamline caregiving routines, allowing caregivers and older adults to manage care tasks quickly and conveniently. Participants felt that this efficiency is particularly valuable when timely support and task management are critical. This finding aligns with other studies in the health care context, in which researchers have found that older adults desire VAI features that help with caregiving tasks, such as scheduling and appointment management, or medication reminders, for perceived convenience and efficiency [4,8,10,13]. We also found that VAI was viewed not only as a practical tool but also as a potential source of companionship to mitigate the feelings of loneliness and social isolation prevalent among caregivers and care recipients. Although not explicitly situated in the context of informal caregiving, prior work has explored the use of VAI as companions for older adults [4,5,50-53] and its potential to support social connections [54,55]. Rudnik et al [9] explored how a VAI system might benefit care conversations between older adults and caregivers. Yet our work extends prior work by finding that designing VAI for companionship and supporting social dimensions within a caregiving relationship will likely require careful additional exploration of existing relational values that form the foundation of the caregiving relationship. For example, participants envisioned VAI as a way to support socioemotional aspects of informal care, but also raised concerns about privacy, emotional attachment, and the erosion of human connection that VAI might bring. Therefore, our work suggests that, when designing, there needs to be a broader ethical discourse on integrating VAI and on the broader user values surrounding social relationships and human connectedness in caregiving contexts. Future work is likely needed to better understand those values and how they might shape the design of VAI technologies for informal care.

While some work has explored how VAI might be integrated to reduce caregiver burden [9,13], we also found that caregivers felt that a VAI system could help address the emotional toll of providing informal care. They saw opportunities for VAI to be a proactive companion in helping them remember to practice self-care and find related opportunities. Examples included proactively conducting self-care checks or guiding them through exercises when they felt overwhelmed. Additionally, we found that part of the emotional toll of caregiving lies in learning to provide care, as one must learn on the "job." VAI was also seen as potentially useful for helping caregivers adjust by providing an efficient way to obtain the training, resources, and information they need to function as informal caregivers. For example, VAIs might be integrated within a do-it-yourself smart home setup to provide caregivers with a hands-free way to interact with educational materials and resources. Researchers have found that older adults see potential in conversational agents to support access to personal health records and to help find and understand health data [27]. Voice-enabled systems might integrate with patient portals to create more accessible interactions with the health data included there. Future work should explore more ways VAI might assist with education, training, and support in informal care.

Our research findings also suggest that participants generally felt that relying solely on the voice modality is insufficient for fully addressing the complexities of a caregiving environment. While they felt that VAI provides a valuable interface for interaction, they felt its effectiveness would likely be enhanced if integrated into a broader care ecosystem that included multimodal features, such as visual displays, tactile feedback, and contextual cues. They discussed how often different caregiving tasks require different approaches and that different environments might have different needs. Therefore, in the future, it may be beneficial for designers to consider ways VAI might act as a facilitator of care tasks within informal care environments, for example, by exploring interoperable or multiplatform facilitation and connecting disparate devices into a connected ecosystem. For example, participants suggested that voice input and output be a way for them to seamlessly connect with different devices that support their self-care, health, and well-being, including wearable devices such as smartwatches and smart rings, instructional videos for caregivers, and smart televisions, to allow older adults and caregivers a more comprehensive picture of their health, while also supporting older adults' independence and reducing caregiver tasks.

Assist Me, but Do No Harm: What Ethical Values Should VAIs for Informal Care Consider?

Users' ethical concerns about AI technologies are not new and have been raised in other research [14]. For example, within health care, researchers have explored ethical concerns around using conversational agents for health-related areas such as mental health [56] and more broadly care providers [57] and public health [58], noting potential risks such as algorithmic bias, user harms, and privacy concerns due to users' unawareness that they are interacting with a virtual agent. Others have noted safety concerns, particularly in voice-only applications, due to a lack of transparency [36]. Privacy remains a core ethical concern among those using VAI systems, along with others related to personification and emotional connections to machines [19]. In parallel, general concerns about user personification of VAI technologies are well-known, with the HCI literature suggesting that the "human-like" aspect of voice user interfaces can sometimes be an enhancement or a detriment to ethical design, depending on context [59]. Therefore, while VAIs can have promising applications in health care, it is often not well known how ethical concerns vary among users and across contexts [19]. This has been found especially true within health-related contexts, where users tend to hold AI technologies to different standards depending on the context, given the sensitive data passed and the potential harms (eg, safety-related) that might arise from its use [33].

Related to RQ3, our findings highlight that VAIs are beneficial primarily because of perceptions of improved efficiency and social or emotional support for informal caregiving tasks. However, our research reveals a critical tension between the efficiency gains offered by VAI in caregiving and the ethical considerations that accompany its use. Therefore, the efficiency provided by VAI must be balanced against these ethical considerations, ensuring that the technology remains a tool for empowerment rather than a source of control or intrusion.

XSL•FO
RenderX

Within health care, the idea of interventional harm is typically associated with safety or injury [60]. However, in recent years, researchers have noted the significant potential harm of social-behavioral interventions that may not have immediate safety concerns, but due to the disruption they cause to complex social systems and needs for human agency, can lead to unintended effects [60]. Therefore, more emphasis has been placed on unearthing non–safety-related and unintentional harms to explore the potential impact of those concerns on intervention success (eg, acceptance and adoption) [60,61]. For example, Allen-Scott et al [61] found that for public health interventions, five high-level unintended harms are often associated with unsuccessful public health intervention deployment, including (1) physical, (2) psychosocial, (3) economic, (4) cultural, and (5) environmental which often occur for reasons including lack of community engagement when developing the intervention and ignoring root causes which lead to a lack of understanding of what users want. Examining harm is also a topic that has been explored among VAI technologies more generally [62,63]. For example, Reeves [62] examined the trade-off between framing VAI interactions as conversations and the potential for user harm. Aligned with these efforts, we summarize the ethical values highlighted by older adults and caregivers into broad categories of potential unintended harms that may ultimately lead to nonacceptance and nonuse of VAIs for informal care.

Physical Harms

Aligned with prior work on VAI systems, our findings suggest that assessing the potential safety-related harms of health-related VAI technologies remains paramount to users. Safety concerns associated with VAI use in health have been raised in studies where physicians note the potential harms to patients who rely on voice assistants for health information search [36]. However, beyond safety implications associated with receiving inaccurate health information or recommendations, our participants noted broader transparency issues that should be considered, such as helping users understand how decisions are made and/or the data privacy consequences that could affect their ability to receive care and resources (eg, breaches that impact insurance availability).

Financial Harms

Two categories related to finances emerged from our data: (1) the potential harm associated with data privacy breaches of sensitive information, and (2) increasing inequities in access to health resources due to limited financial resources to adopt health VAIs. Therefore, the implications of a financial data breach involving VAIs that could affect a user's financial wellness should be considered. Additionally, while not often listed as an ethical consideration for AI generally [14], others have found that cost is an aspect users consider in VAI adoption [11]. Therefore, cost and other financial factors should be considered in efforts to reduce inequities in access to caregiving resources. Mitigating the trade-offs between the efficiency gains and the ongoing costs of adoption would be essential to ensure that the benefits of VAI reach a wider population of users.

Relational or Social Harms

Our findings align with the informal caregiving literature, which notes that the social, relational, and emotional aspects of informal caregiving are just as important as physical caregiving tasks. However, we found that human autonomy concerns [64], such as shared governance of caregiving tasks, emerged when discussing the social or relational elements of VAI design for informal care, including those related to physical tasks that required social interaction. These findings suggest that users may value VAI in ways that can support social and relational engagement if it is designed in a way that does not overstep the boundaries of what makes certain aspects of an informal caregiving relationship a uniquely human endeavor (eg, human touch, social connectedness, human relationship building, and inclusiveness). Other researchers have found that the social aspects of VAI technologies, such as how they engage users, can impact perceptions, for example, among marginalized groups [65]. Therefore, while providing human-like characteristics to VAI systems is generally thought to have potential advantages for supporting health-related applications [66], our findings suggest that it may be necessary to further explore the impact of adding human-like characteristics on users' perceptions of autonomy when governing their caregiving relationships.

Design Considerations for Ethical VAI for Aging and Informal Care

Based on participants' suggestions, to further address RQ3, we also provide design implications for addressing their desired interactions and ethical values related to (1) transparency, privacy, and trust (including nonmaleficence and responsibility), (2) justice and fairness, and (3) freedom and autonomy when engaging with VAI, which supports informal caregiving practices.

We suggest that designers and developers encourage trust by incorporating features that help users assess the credibility of the information they receive (D1). Prior work has found that limited access to source information makes it difficult to assess the credibility of VAI systems for health [28,67], and the ability to view source information can reduce those concerns [27]. As VAIs - often inherently have less transparency due to the lack of visual guidance, VAIs designed for informal care should consider ways of integrating transparency within conversational design, such as allowing users to ask questions verbally about how their data is used or how the system works, or through multimodal approaches that allow users to better understand who has access to their data or fact-check information sources.

Older adults' privacy concerns related to VAI technologies have been well-documented in the literature [68,69]. Our findings suggest that older adults and caregivers have similar concerns about VAIs that are integrated into their care processes, including unauthorized access to personal health data. We suggest that designers and developers consider the dynamic privacy needs of potential users of these systems, including older adults, informal caregivers, and others involved in the informal care process (D2). Due to the sensitive nature of health data, VAI systems should implement industry-standard security protocols and help users build greater trust in the system through

XSL•FO
RenderX

transparent, clear communication about privacy policies. Systems should also emphasize user autonomy in data sharing, allowing users to control how their data is shared with others and third parties. Systems can also leverage VAI biometrics to prevent unauthorized access to sensitive information.

Prior literature also notes that older adults desire personalized experiences with intelligent voice technologies to support efficient task completion [11,21,22]. For example, Brewer et al [22] found in their study of older adults' use of current voice assistants for health information seeking that older adults asked for more personalized health information, feedback, and recommendations. In clinical settings, extending voice capabilities to personalize experiences has been found beneficial [70]. Our findings suggest that designers and developers should consider leveraging personalization to address diverse caregiving needs (D3). For example, VAIs might leverage contextual cues from users and environmental information to provide more personalized responses (eg, gauging mood to support caregiver wellness or older adult well-being).

Finally, balancing assistance and control is a longstanding open challenge in systems that automate tasks [71], leading to approaches such as mixed-initiative interaction [72] and, more recently, a focus on understanding human autonomy in AI systems [64]. Studying autonomy in AI-enabled systems has also been longstanding in technology designed for older adults [73-77], given frequent discussions of independence and agency as well as balancing AI and the human aspects of care [78]. Findings suggest that the successful integration of VAIs into informal caregiving relationships requires researchers to consider broader ethical values around the importance of the human aspects of caregiving relationships (D4). Further, participants noted that VAI alone is not enough to support the complex environment of informal care. Instead of viewing VAI as a standalone solution, designers should explore ways to leverage its capabilities to support more holistic care within the caregiving environment (D5). This can include exploring ways to leverage VAI to provide accessible information and resources to older adults and caregivers, support independence, or complement the broader care ecosystem through a set of connected devices. We summarize design implications for VAIs for informal aging care in Table 3.

XSL•FO
RenderX

Table . Design implications for informal VAI[a] care systems.

Design implication	Ethical dimensions addressed	Suggestions
D1: encourage trust through transparency	Transparency, trust	• Incorporate subtle opportunities for accessing information sources • Help users gauge when AI[b] is unsure by adding fact-checking features or the ability to flag information of uncertain origin
D2: prevent unauthorized access	Trust, privacy	• Implement industry-standard security protocols to protect user data • Be transparent about privacy policies at the start of the interaction • Let users control the kind of information they share with companies and caregivers • Leverage VAI capabilities (eg, voice biometrics) to automate system authorization processes • Suggest alternatives to voice commands, such as text input
D3: provide personalization through context	Justice and fairness	• Leverage contextual awareness such as environmental and user cues to deliver more relevant and dynamic responses (eg, gauging mood) and ensure more secure interactions (eg, verifying access)
D4: support autonomy through awareness	Freedom and autonomy	• Incorporate clear and user-friendly features that let users easily override or disable AI suggestions whenever they want • Enable personalization or automatically recognize and respond proactively to cues that indicate a need for human interaction
D5: provide flexibility through integrated support	Justice and fairness	• Leverage voice input and output to provide accessible information and resources • Leverage voice input to enhance older adults' independence in managing self-care and well-being • Leverage voice input and output for hands-free interaction with other devices that support care (eg, health education and demonstration materials, and wearables)

[a]VAI: voice-enabled artificial intelligence.

[b]AI: artificial intelligence.

Limitations

This research includes some limitations. While we conducted some in-person studies, much of the work took place online to make it more convenient for our participants. Moving the studies online might have prevented some participants from engaging in the work. For example, those who have lower digital literacy or limited access to technology. This study also had more caregiver participants than older adult participants. Although we did see recurring themes within and between groups, our sample was also smaller overall. We also acknowledge that, because of the age similarities between our older adult participants and caregiving participants (one caregiving participant was aged younger than 55 years) and the flexibility of caregivers to also comment on their experiences as older adults, older caregiver perspectives may be overrepresented. Additionally, while we attempt to provide a rich description [46] of the participants and their experiences through demographic data and personas, because individuals' care experiences vary, the participants' experiences in our study may not transfer to all populations and contexts. There may be additional ethical values that did not emerge from our data, or that may not apply in different contexts.

Conclusions

This study explores the experiences and challenges of older adults and informal family caregivers in managing informal care. Through participatory speculative design, we explore how future VAI technologies might support the caregiving process and address caregivers' needs and concerns. We intentionally explore the ethical dimensions that participants value, and that may affect the potential adoption of VAI technology in informal care. Our findings provide insight into the need for VAI systems

XSL•FO
RenderX

designed for the informal care context to balance efficiency and ethical values, supporting care processes while doing no harm.

Acknowledgments

We would like to thank the participants who took the time to share their experiences and opinions with us. No generative artificial intelligence tools were used at any stage in the preparation of this paper. The authors take full responsibility for the accuracy, originality, and integrity of all content, including all references and citations.

Abstract

Background: Population aging has emerged as a global concern, older adults' ability to access health knowledge and manage their well-being impacts their health outcomes. In the artificial intelligence era, generative artificial intelligence (GenAI) videos hold promise for enhancing geriatric health management. However, their potential and the needs of older adults in using GenAI videos for health-related purposes deserve a more in-depth investigation.

Objective: This study aims to explore the application potential and multifaceted needs of older adults in using GenAI videos for health information acquisition and management, while providing actionable recommendations for future aging-friendly GenAI video tools.

Methods: A qualitative approach was adopted. Twenty older adults (aged ≥60 y) with basic digital literacy were recruited from communities for participation in iterative GenAI video workshops. Semistructured interviews were conducted. Thematic analysis, following Braun and Clarke's 6-phase reflexive framework, was used to identify key themes from interview transcripts.

Results: Our results have identified a 3-layer hierarchical structure of needs when older adults interact with GenAI videos. The first layer is technical accessibility, which suggests the direct barriers preventing them from operating GenAI tools independently. The second layer is age-friendly design, which depicts the needs of age-friendly design adaptations, which can help older adults to better use GenAI features. The final layer is integration with professional resources, highlighting the need for integrating professional medical information resources with GenAI tools, so that the GenAI videos can be more appropriately used for health management purposes. By triangulating the core needs of older adults, the capabilities of GenAI, and their remaining gaps, we have found that the existing gaps limit the extent to which the health needs of older adults are met, and also inversely restrain the acceptance and use of GenAI videos by older adults.

Conclusions: This study explored the potential and gaps of using GenAI videos in older adults' health management. GenAI videos are prominent for self-management of health, but our triangular model reveals coexisting opportunities and challenges. While the core needs drive the development directions of GenAI video technologies, our study suggests that GenAI health videos can benefit from the improvements in technical capabilities, service innovation, localization, and integration of health resources.

older adults; artificial intelligence; generative AI videos; health management; iterative workshop

Introduction

The global process of population aging is advancing at an unprecedented rate. United Nations' data indicate that the global population aged 60 years and older is projected to surge from approximately one billion in 2020 to nearly 2.1 billion by 2050 [1], with the proportion of this age group rising from 13% to 22% [2]. Effective acquisition of health knowledge and adoption of scientific health management strategies impact the quality of life and well-being of older adults [3]. From daily dietary planning and exercise regimen formulation to self-monitoring and management of chronic diseases [4], enhanced health knowledge and management capabilities empower older adults to better understand their health status [5], proactively prevent diseases, and thereby improve their autonomy and social participation [6]. Proper dietary combinations provide adequate nutrition to maintain physiological functions; moderate exercise enhances muscle strength, improves cardiopulmonary function, and optimizes sleep quality [7]. For older adults with chronic

XSL•FO
RenderX

conditions (eg, hypertension, diabetes, and cardiovascular diseases), effective health management controls disease progression, reduces complication risks, and lowers medical expenses [8]. Studies indicate that effective health management can decrease the incidence of chronic diseases and associated costs [9]. Older adults actively engaged in health management exhibit better mental health, with lower rates of depression and anxiety [10]. Thus, improving health management among older adults is essential for achieving active aging and intergenerational bonds [11].

In the context of rapid artificial intelligence (AI) advancements, leveraging generative artificial intelligence (GenAI) offers a new technology to assist older adults in health management by enhancing the efficient acquisition of health information and self-management [12]. GenAI, a cutting-edge technology integrating algorithms, such as deep learning and neural networks [13], excels not merely at content generation but, critically, at creating highly personalized, on-demand media. GenAI's advanced natural language processing [14], data analytics, and learning capacities allow it to transform complex medical knowledge into accessible content [15,16]. Traditional health videos often lack the personalization and real-time adaptability required for complex, individualized health needs [17]. GenAI directly addresses this gap. GenAI-based health videos have emerged as an innovative solution because they can dynamically tailor content based on users' demographics, specific health conditions, and preferences, for example, generating a short video on "low-sodium recipes for hypertension," improving relevance and engagement [18]. GenAI videos also enable interactive features, such as personalized recommendations and real-time feedback, which can further support older adults in navigating complex health topics [19]. GenAI videos can generate multilingual and culturally adapted content, reducing barriers for diverse older populations. Despite this immense potential to deliver granular, customized health information, the empirical study of GenAI video adoption and user experience in geriatric health management remains in its infancy.

Despite its potential, older adults face barriers in adopting AI technologies, including the GenAI-based ones. Age-related cognitive decline, manifesting as memory, attention, and reaction time impairments, hinders the understanding and operation of emerging technologies [20]. Neuroscientific research indicates that prefrontal cortex atrophy in older adults reduces multitasking capacity, complicating the execution of complex commands [21]. A historical lack of digital education leaves many unfamiliar with basic operations (eg, searching and installing apps), impeding independent use [22]. Information overload and the proliferation of misinformation further exacerbate challenges in accessing accurate health knowledge [23]. The internet's rapid, high-volume dissemination overwhelms older users, who struggle to discern reliable content [24]. Misleading health information, often disseminated via sensationalized headlines on social media, exploits these vulnerabilities, leading to misguided decisions [25]. Additionally, technology interfaces often neglect the physiological characteristics (eg, declining vision and hearing) and usage habits of older adults, resulting in poor usability [26]. Most devices and apps feature small fonts, complex icons, and convoluted workflows, rendering them inaccessible to those with sensory impairments [27]. Gesture-dependent interactions and ambiguous feedback mechanisms further increase operational difficulty [28]. Survey data reveal that fewer older adults proficiently use health management apps, with many expressing low trust in GenAI, preferring traditional consultations [29]. This digital divide not only limits GenAI videos' application in geriatric health management but also underscores urgent needs for age-friendly technological adaptations [30].

Currently, GenAI video applications in geriatric health management remain emergent, with designs and service models inadequately tailored to older adults' needs, necessitating in-depth research and improvement [31]. Existing tools exhibit unfriendly interaction modes, with content formats and delivery methods failing to accommodate cognitive traits and reading habits [32]. For instance, a study reports that older participants find GenAI videos' speech interaction too fast and their interfaces overly complex [33]. There is a gap regarding studies that focus specifically on older adults' interaction experiences, needs, and barriers when using GenAI for health. Against this backdrop, our research aims to investigate older adults' needs when using GenAI videos for health information acquisition and management, providing targeted recommendations for designing age-friendly GenAI health videos. This research addresses this identified gap in GenAI video applications for geriatric health management, offering evidence-based insights for developers, health care providers, and policy makers to construct human-centric, age-adapted intelligent health systems, ultimately advancing older adults' health and well-being. Based on these considerations, the following research questions are proposed:

1. What difficulties do older adults face, and what are their needs when using GenAI videos to access health information?
2. What functionalities and services can GenAI videos provide for geriatric health management, and where are the gaps?
3. How can technological design and interaction optimization enhance GenAI video's applicability and user experience in geriatric health management scenarios?

Addressing these questions will guide future research, offering theoretical and practical foundations for innovative GenAI video applications in geriatric health management. Resolving these issues will facilitate GenAI video's role in improving health management, narrowing the digital divide, and promoting social equity and harmony.

Methods

Participant Recruitment

With the assistance of community partners, we initially recruited 26 older adults residing in nearby communities to participate in an iterative GenAI health video workshop through offline posters. The following inclusion criteria were applied: Participants were aged 60 years or older, possessed basic operational skills with smart devices (eg, smartphones and tablet

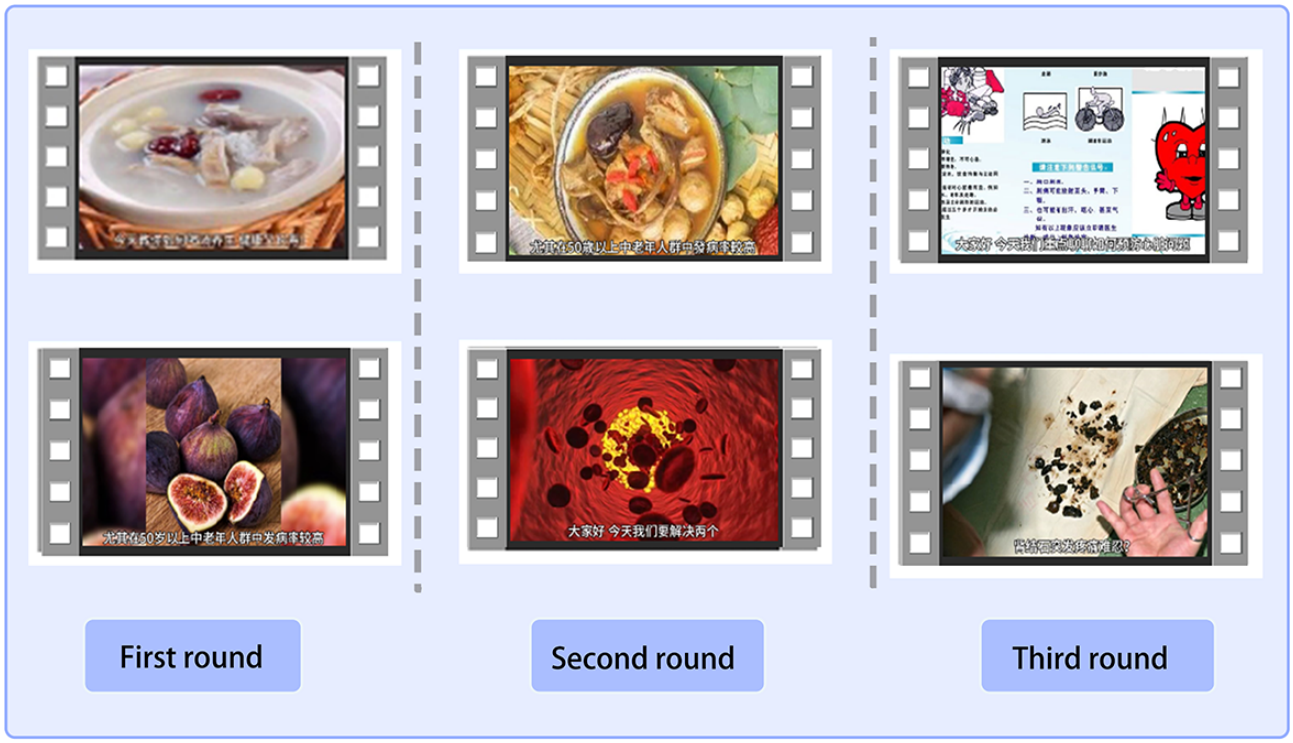
XSL•FO
RenderX

PCs). Eventually, the results of 20 older adult participants were included in the study. As a qualitative study using thematic analysis, the final sample size of 20 participants was determined based on the principle of thematic saturation. Data collection and analysis proceeded iteratively, and after the 17th interview, minimal new codes or themes emerged, indicating that the core needs and challenges regarding GenAI videos had been sufficiently captured. The subsequent 3 interviews confirmed this saturation point, covering the hierarchical structure of needs. This sample selection was also designed to maximize information power through the deliberate inclusion of participants with diverse demographic factors (eg, varying educational levels and living arrangements) and heterogeneous health needs (eg, hypertension, joint health, and sleep disorders). This deliberate heterogeneity ensured a rich dataset and robust identification of core themes, justifying the sufficiency of the final sample size.

All participants expressed motivation and a need to leverage GenAI and health videos for better self-health management. Participants exhibited diverse health conditions (chronic diseases, healthy, and mild conditions) and living arrangements (eg, living alone, with family, or in care facilities). To clarify the health status definitions: Chronic Disease referred to participants who reported having a long-term medical condition requiring ongoing management, such as hypertension, hyperlipidemia, or diabetes. Mild condition referred to those who reported minor, nonchronic health issues or temporary discomforts that did not impair their daily function. Healthy referred to participants who did not report any diagnosed chronic disease or ongoing medical conditions.

In addition, community workers participated in the research. These professionals are engaged in community health-related work, possess a background in medical knowledge, and have experience assisting older adults with technological tools. Participants voluntarily joined the workshop and did not receive any additional compensation, though tea and snacks were offered. It is important to note that the participant sample, limited to 20 individuals from a single urban context and skewed heavily female (80%), limits the generalizability of the findings and may not fully capture the diverse experiences of the broader older adult population, particularly men and those in rural or low-income settings. We confirmed with the recruiting community workers that this gender imbalance is a common limitation in community-based research, reflecting the higher propensity of female older adults to actively participate in community health and social activities. This limitation is discussed further in the Discussion section.

Research Design



To reduce older adults' cognitive load, the study adopted a participatory iterative approach. Each participant received a 15-minute introduction to GenAI to ensure their basic understanding. Before the start of the workshop, a pretest was conducted to collect baseline data, such as participants' GenAI videos perceptions, technical skills, and self-evaluations of prior knowledge.

The methodology and approach were initially guided by established theoretical models, specifically the Technology Acceptance Model (TAM) [34] and the concept of self-efficacy [35]. We used TAM, which posits that perceived usefulness and perceived ease of use predict technology adoption, to structure the pre and posttest data collection and the iterative refinement process, focusing on understanding factors that influence the acceptance of GenAI-generated health videos among older adults.

The workshop implementation comprised four steps: (1) Participants proposed a health-related topic that suited their personal health needs. Then, they provided this health topic to GenAI, which converted it into a prompt for generating the GenAI video. They provided the video script generated by GenAI to the video production software CapCut to create the first video. Before generating the video scripts for GenAI, we conducted pretraining on them. We set the generated video scripts to introduce diseases or health issues, solutions and countermeasures, suggested structure generation, and recommended a duration of 3 - 5 minutes for short videos to prevent overly long video content from causing cognitive overload for older adults; (2) participants viewed the initial video, discussed their experiences, provided feedback, and proposed new requirements, which were refined into updated prompts for the second video generation; (3) this iterative process was repeated for a total of 3 cycles, culminating in a final optimized video; and (4) after each video generation, community health workers reviewed the content, flagged potential inaccuracies (eg, incorrect medical advice or misleading health claims), and explained the rationale to participants, ensuring discussions were grounded in reliable information. Finally, a posttest was performed to reassess satisfaction, acceptance, and needs after interacting with GenAI videos. The content and process of generating the videos are shown in Figure 1.

XSL•FO
RenderX

Figure 1. The content and process of generating the videos.

Data Collection and Analysis

Data sources included pre- and posttest interview transcripts. We conducted semistructured interviews in participants' native language (Cantonese) with audio recording to capture the challenges encountered by the participants and their preferences during the consumption of GenAI videos. The interview transcripts were analyzed with the thematic analysis approach following Braun and Clarke's 6-phase framework [36]. To ensure data reliability, 2 researchers [TL and PP] independently entered and cross-checked data and resolved discrepancies when disagreements occurred.

Ethical Considerations

This study was approved by the Human Ethics Committee of Macao Polytechnic University (Approval No.: HEA006-FCA-2025). All participants provided written informed consent before interviews, ensuring comprehension of the study's purpose, procedures, and potential impacts. All participants have signed an informed consent form before participation. Data were anonymized, with strict confidentiality maintained for personal identifiers. Before workshops, participants were informed that AI-generated content should supplement professional advice, with consent forms emphasizing technical limitations. To reduce the chance of adverse effects caused by misinformation from GenAI videos, community health workers guided the workshops, in which they confirmed the validity of information and stopped the video generation when problems occurred. No compensation was offered to the participants for their involvement in the study.

Results

Participant Characteristics

In total, 20 older adults participated (Table 1). Age ranged from 60 to 84 years (mean 71.4, SD 8.16): 8 out of 20 (40%) aged 60 - 69, 9 out of 20 (45%) aged 70 - 79, and 3 out of 20 (15%) aged ≥80. Gender skewed female (16/20, 80%) versus male (4/20, 20%), possibly reflecting higher female community engagement. Health status: 10 out of 20 (50%) had chronic diseases (hypertension, hyperlipidemia, etc), 8 out of 20 (40%) were healthy, and 2 out of 20 (10%) had mild conditions, highlighting prevalent health management needs. Living arrangements: 9 out of 20 (45%) lived alone, 11 out of 20 (55%) with family, suggesting varying reliance on external support. Education: 7 out of 20 (35%) primary school, 5 out of 20 (25%) junior high, 4 out of 20 (20%) high school, 4 out of 20 (20%) college or university, indicating diverse digital literacy levels. GenAI video experience: 17 out of 20 (85%) were naive users, 3 out of 20 (15%) had limited exposure, ensuring exploration of initial adoption needs. Health topics varied: joint health (n=5), diet (n=4), hypertension (n=3), sleep disorders (n=2), cardiovascular health (n=1), general health (n=2), exercise (n=1), obesity (n=1), and thyroid disease (n=1), reflecting diverse needs and opportunities for GenAI videos' applications.

[a]GenAI: generative artificial intelligence.

Thematic Analysis

Theme 1: Technical and Accessibility Barriers

Older adults faced foundational challenges in accessing and operating GenAI video tools, stemming from limited digital literacy and interaction difficulties. These barriers highlight a cognitive load required for adoption. Cognitive and digital literacy limitations were prevalent, with participants struggling with fundamental technological tasks. Participant #4 noted, “I have a poor memory and learn new things slowly,” a common reflection of age-related cognitive decline that hinders mastering complex workflows. Participant #12 admitted, “I am illiterate,” revealing the impact of basic educational background on technology adoption and independence. Operational and interface design flaws further compounded these issues, especially given physical challenges. Participant #16 reported, “Poor eyesight affects my typing, so I can only use voice or ask my granddaughter for help,” illustrating a hardware-software mismatch. Participant #14 criticized the “complex button functions” and convoluted workflows that were difficult to follow without prior experience. Consequently, participants often expressed feelings of exclusion, with #13 stating, “GenAI is currently more youth-friendly; it feels designed to make me make mistakes.” Furthermore, localization and support gaps

XSL•FO
RenderX

complicated accessibility, such as #4's explicit request for "Cantonese voice guidance" for better comprehension, and #8's frustration with having to rely on young family members "for downloading and setting up every new app." These findings underscore systemic shortcomings in age-friendly interface design and support structures.

Theme 2: Trust and Accuracy Expectations

Participants demonstrated a heightened level of caution and demanded rigorous verification regarding the accuracy and reliability of AI-generated health information, indicating a trust deficit. Concerns about misinformation were widespread, with participants often viewing GenAI as a source that requires external validation. Participant #3 expressed direct concerns about being misled, stating, "I worry about being misled by false content from GenAI, especially with medical advice that could harm me." This led to demands for professional verification and transparency. Participant #14 strongly emphasized the need for human input: "GenAI outputs must be validated by professionals, like a pharmacist or doctor, before I act on it." Participant #8 reiterated this cautious approach, insisting, "I will consult a doctor before acting on GenAI's advice; the video is just a starting point." To build trust, participants requested greater transparency, with #12 advocating for "source citations in AI-generated health information, showing where the medical facts came from," and #16 suggesting "alerts for abnormal data or warnings if the advice is outside standard guidelines." This cautious trust stems from their awareness of technological limitations, as #9 cautioned, "GenAI video might misdiagnose my health condition if I input the wrong symptoms." Despite these concerns, participants acknowledged the medium's potential, with #7 praising its format: "Videos are more intuitive than text; I can see how an exercise should be done."

Theme 3: Personalized Health Guidance

Participants expressed clear expectations for personalized functionalities that extended beyond generic content, spanning monitoring, risk assessment, and localized solutions. Demands for tailored monitoring and trend analysis were prominent, reflecting needs related to self-management of chronic diseases. Participant #1 requested the tool to provide "automated trend analysis of my blood glucose data over the last 2 weeks, not just today's number," while #4 needed specific, daily "calorie, intake calculations for my low-sodium diet." For risk assessment and nonpharmacological solutions, participants sought customized advice specific to their conditions. Participant #9 inquired about "joint health evaluations based on my walking data," and #17 sought "nonpharmacological hypertension solutions tailored to my limited mobility." The need for cultural and localized adaptation was also a key theme, demonstrating that personalization must consider the daily life context. Participant #4 requested "healthy recipe modifications for local Cantonese dishes" to make diet changes practical, and #10 desired "local hospital lookup features integrated into the video advice." Current GenAI tools fall short of these nuanced expectations. Participant #12 criticized the content as "too-fast, oversimplified video content that doesn't answer my specific questions," revealing a gap between generic output and true personalization.

Theme 4: Basic Health Management Needs

While GenAI videos demonstrated capability in offering foundational health functions, gaps persisted in terms of depth, integration, and systematic support. Foundational functions and clarity showed progress, such as #3 learning about heart disease basics and #9 understanding osteoporosis risks through visual content. However, limitations were evident in addressing multifaceted health scenarios. Participant #1's need for combined management of diabetes and cardiovascular concerns went unaddressed by single-topic videos, illustrating a lack of integrated care guidance. Similarly, #9's need for personalized solutions for concurrent osteoporosis and lung health issues lacked comprehensive guidance due to insufficient data integration. Gaps in professional support were clearly visible, with #14's request for "thyroid self-check guidance" and #19's need for a "local hospital locator" being unfulfilled. Consequently, participants often defaulted to traditional support channels, such as #8's preference for "doctor-confirmed advice" and #15's reliance on "family assistance" to navigate complex information, highlighting the tools' current inability to serve as a reliable, standalone health resource.

Theme 5: Diverse Health Concerns

The older adult population exhibited a highly diversified spectrum of health management needs, necessitating a flexible and broad application scope for GenAI video content. Chronic disease management was a central concern, with #1 explicitly highlighting the need for diabetes prevention, emphasizing blood glucose trend monitoring and personalized dietary recommendations. Health literacy through visualization was sought for complex topics, such as #3, focusing on cardiovascular health and stressing the importance of using GenAI video animations to understand electrocardiogram principles. Needs extended to highly specific daily life and preventative issues, including joint and sleep health, where #15 stated, "I want to understand sleep issues as I have had sleep apnea for over a decade," and #12 articulated comprehensive requirements for joint pain relief and vitamin supplementation. Furthermore, dietary and safety validation emerged as a distinct concern, with #12 asking, "I heard honeydew melon and eggs are harmful together—is this true?" reflecting a need for rapid validation of common health myths. This diversity confirms that GenAI videos must shift from single-disease treatment to comprehensive, highly specialized prevention and daily health information services in geriatric health management.

The abovementioned themes were summarized into three high layers of needs, representing the needs of (1) technical accessibility, (2) age-friendly design adaptations, and (3) integration with professional medical information resources. Table 2 lists the layers, themes, and subthemes described in this subsection.

XSL•FO
RenderX

Table . Summary of results of thematic analysis.

Layers, themes, and subthemes	Key insights from interview texts
Layer 1: Technical accessibility	
Technical and accessibility barriers: digital literacy limitations and language and localization gaps	• Inability to operate tools independently (eg, typing, navigating interfaces) • Insufficient Cantonese support and local specific health resources
Layer 2: Age-friendly design adaptations	
AI usage barriers: digital literacy challenges and interface simplicity needs	• Difficulty in operating complex interfaces due to poor memory or illiteracy • Demand for voice interaction, large fonts, and step-by-step guidance
Trust and accuracy expectations: cautious trust in AI[a] and localization and age-friendly features	• Openness to try but requiring human verification for critical decisions • Preference for Cantonese voice, localized services, and age-adapted design
Layer 3: Integration with professional medical information resources	
Personalized health guidance: dynamic health monitoring, visualized knowledge delivery, and multimodal interaction	• Autogenerated reports (eg, blood glucose trends and sleep reports) • Animated videos explaining medical concepts (eg, ECG[b] and osteoporosis) • Voice-guided operations and large-font interfaces
Basic health management needs: symptom identification, nonpharmacological solutions, professional medical diagnosis, and critical decision-making	• Early warning for osteoporosis, cardiovascular risks, and digestive issues • Sleep improvement tips and joint protection exercises • Inability to replace doctors for definitive diagnoses (eg, osteoporosis and sleep apnea) • Lack of human verification for health suggestions (eg, medication and surgery)
Diverse health concerns: chronic disease management, joint health and injury prevention, sleep health improvement, and digestive health and dietary safety	• Need for personalized monitoring and guidance on hypertension, diabetes, and cardiovascular diseases • Guidance on joint protection exercises and fall prevention during travel • Nonpharmacological solutions for insomnia and sleep apnea • Personalized dietary recommendations and food compatibility validation

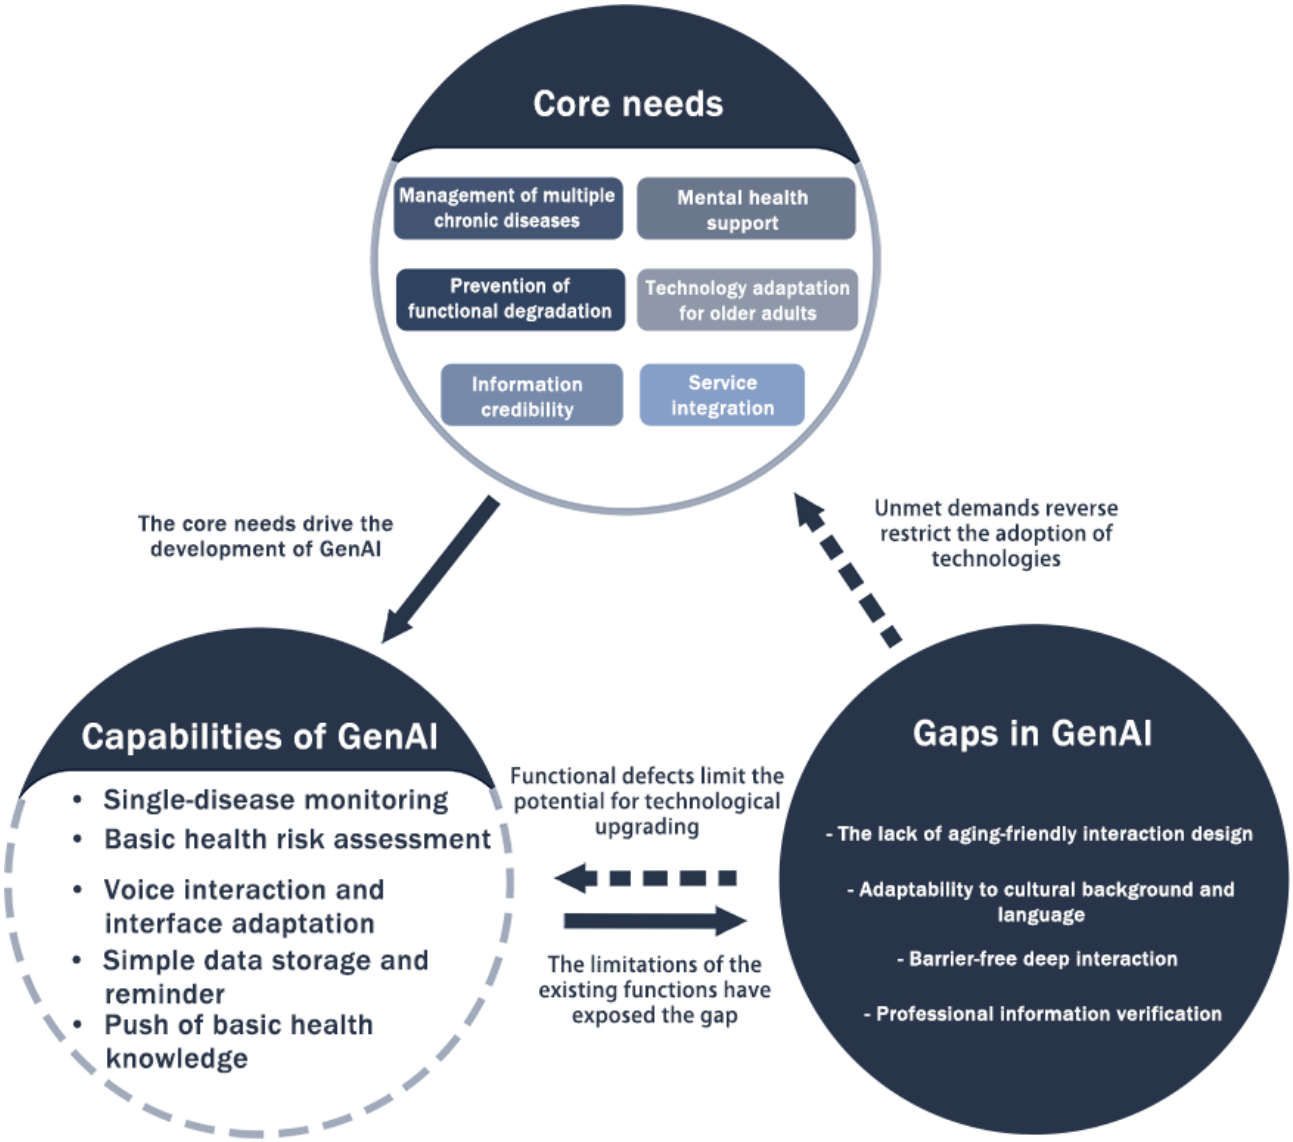
[b]ECG: electrocardiogram.



Discussion

Principal Findings

The results demonstrate the interactive relationship among the needs of older adults in using GenAI videos for health management, the capabilities of GenAI videos, and the existing gaps in GenAI video tools, as synthesized in Figure 2. The core needs of older adults drive the development and application direction of GenAI video technology, promoting the realization of its functions in areas such as health monitoring and information interaction. However, the current capabilities of GenAI video tools reveal unmet gaps in areas such as multidisease integration and professional medical diagnosis. On one hand, these gaps directly limit the extent to which the health needs of older adults are met; on the other hand, they also inversely restrain the further acceptance and use of GenAI video technology by older adults. As such, this forms a dynamic triangular relationship that requires more attention among user needs, GenAI capabilities, and the gaps to be filled.

XSL•FO
RenderX

Figure 2. Dynamic relation of the needs, capabilities, and gaps of generative artificial intelligence videos. GenAI: generative artificial intelligence.

This closed loop shows that the digital transformation in the field of geriatric health management is not a linear process of progress but rather a complex relationship where the potential of technological empowerment coexists with the challenges of age-friendly adaptation. Achieving sustainable alignment between technological development and user needs requires systematic design to balance efficiency and humanistic care. Table 3 also provides a detailed list of the specific context regarding the needs of older adults, the capabilities of GenAI video, and the gaps in GenAI video, which highlights the multidimensional characteristics and the mismatch of needs of current tools.

XSL•FO
RenderX

Table . The comparison of the needs, capabilities, and gaps of generative artificial intelligence videos.

Core dimension	Core needs	Capabilities of GenAI[a]	Gaps in GenAI
Health needs coverage	Comprehensive management of multiple chronic diseases, personalized health guidance, and mental health support	Single-disease monitoring (eg, blood glucose) and basic health risk assessment	Integrated management of multiple diseases, professional medical diagnosis, and solutions for complex health issues
Technical adaptability	Simple operations, cultural adaptation (dialect or localized content), and barrier-free interaction	Basic voice interaction and large-font interface	Fully text-free operation, automated complex tasks, and deep cultural customization
Information interaction	Authoritative and trustworthy information, personalized recommendations, and human verification channels	Basic information prompts and simple data recording	Medical-grade information verification, dynamic credibility rating, and real-time human validation
Service integration	Integration of medical, family, and community resources and end-to-end health management	Health data storage and basic consultation services	Real-time integration with medical systems and family-community resource network

[a]GenAI: generative artificial intelligence.

The health needs of older adults show a trend toward diversification and refinement, covering multiple areas, such as chronic disease management, prevention of functional decline, and mental health support, with highly heterogeneous combinations of needs among different individuals. At the level of technology use, insufficient digital literacy and interface interaction barriers constitute the main barriers to use, manifesting as fear of complex operations, dependence on clear guidance, and an urgent demand for culturally adapted features. In terms of trust, older adults exhibit a conservative attitude, recognizing the efficiency advantages of GenAI in information presentation and basic services while maintaining reservations about the reliability of professional medical advice and emphasizing the importance of human verification and professional support. Regarding functional supply, existing GenAI video tools have made initial progress in standardized service areas, such as basic health monitoring and visualized knowledge delivery, but they still show deficiencies in the depth of personalized adaptation, the ability to handle complex scenarios, and the level of integration with professional medical services.

Multidimensional Needs of Older Adults Using GenAI Video for Health Management

The core needs of older adults for GenAI-driven health management exhibit a hierarchical structure, which can be systematically deconstructed into 3 progressive dimensions. The first layer focuses on technological accessibility and operational inclusivity, manifesting as urgent demands for simplified interaction workflows [37], enhanced multimodal interactions [38], and interface designs adapted to physiological decline [39]. These needs stem from the structural deficiencies in digital literacy among older adults, characterized by barriers in comprehending complex technical logic and heightened sensitivity to operational memory load [40]. This cognitive load is not merely an individual failing but a manifestation of the digital divide, wherein technologies often neglect the specific cognitive and physical requirements of older users, reflecting ageism in design standards.

The second layer emphasizes personalized and precise health management adaptations, encompassing dynamic risk assessments based on longitudinal health data, culturally sensitive content delivery, and cross-scenario health guidance. This layer reflects a paradigm shift from passive acceptance to active participation in health management.

The last layer centers on professional medical support and system integration capabilities, including disease risk prediction models approaching clinical decision-support levels, interoperable health data exchange across medical institutions, and integrated emergency response systems. Such needs highlight a functional expectation shift from “information assistance” to “decision participation” for GenAI video tools. The corresponding challenges arise from multifaceted technical and social constraints. On the technical front, digital divides manifest as high learning costs, lack of age-friendly design, and complex functional logic [41]. Socially, these challenges are reflected in the lagging digital transformation of medical trust systems [42], fractured intergenerational digital support networks [43], and uneven regional health resource distribution [44]. The interplay between these needs and barriers underscores a structural mismatch in digital transformation. Specifically, the contradiction between standardized technological supply and personalized health demands, as well as the imbalance between digital access opportunities and capacity building. The persistent reliance on human verification is closely tied to low eHealth literacy, where users lack the critical skills to evaluate information quality, amplifying a lack of trust in nontraditional sources such as GenAI.

Capabilities of GenAI Video for Older Adults’ Health Management

GenAI video has achieved foundational breakthroughs in older adults’ health management across 3 interconnected dimensions. First, information delivery efficiency has improved [45], with natural language processing and multimodal interactions transforming medical knowledge into accessible formats, such as animated explanations and voice narrations, thereby lowering health information acquisition barriers [45]. Second, the level of service automation has increased, as big data analytics and

XSL•FO
RenderX

rule-based engines enable health monitoring, basic risk assessments, and standardized recommendations [46]. Third, accessibility has been enhanced through cloud computing and mobile internet technologies, transcending temporal and spatial constraints [47]. These advancements have facilitated a shift from experience-driven to data-driven health management. However, the operational scope of GenAI video tools remains generic, while video generation with complex information or expert knowledge still requires human guidance [48]. GenAI videos' role remains tool-oriented, and people tend to use them for enhancing efficiency rather than replacing professional medical opinions.

Gaps of GenAI Video for Older Adults' Health Management

Current applications of GenAI videos exhibit limitations that require breakthroughs in several areas. From the health care perspective, there is not enough integration of accurate health information in managing complex chronic diseases [49]. Regarding emotional interaction, the system shows a weak capacity to interpret unstructured health demands, such as ambiguous expressions, or provide empathetic responses [50]. Concerning system integration, barriers to interoperability within health care ecosystems persist [31]. Additionally, the cultural sensitivity of GenAI video tools remains insufficient, with inadequate adaptation to regional variations and traditional health beliefs, such as limited support of different spoken languages [51]. Technologically, it is essential to develop lightweight, age-friendly solutions, such as offline voice assistants and multimodal sensors, and enhance algorithm transparency. Regarding service models, exploring "AI+human expert" hybrid collaboration mechanisms will be crucial. Policy-wise, establishing cross-sector digital health standards, including data security protocols and service quality metrics, is necessary. Socially, activating family-community-health care collaboration networks will foster an inclusive ecosystem. The improvement strategies involve constructing a collaborative framework across technology, health care, and social domains. On the health care side, establishing clinical validation standards for AI-assisted diagnostics is crucial [52]. From the societal point of view, developing intergenerational digital support networks and community-based digital literacy programs will be necessary [53]. These gaps, particularly the lack of integrated, verified professional support, reinforce the existing digital divide by making the tool unreliable for those with lower health literacy, potentially deepening health inequities. These measures will facilitate the evolution of GenAI videos from a "basic service" to a "comprehensive health management partner."

Practical Implications

Based on the identified hierarchical needs and capability gaps, our findings offer concrete, actionable recommendations for key stakeholders to enhance the real-world applicability of GenAI health videos. For AI developers and designers, this means implementing mandatory Age-friendly interface design principles, prioritizing simplified, one-step workflows to reduce cognitive load, large-font visual interfaces, and enhanced multimodal interactions, especially high-accuracy dialect-supported voice control to overcome digital literacy barriers. Developers must also integrate transparent features showing the data source and reliability score for all medical claims. In parallel, health care organizations and policy makers should establish clinical vetting standards and certification processes for AI-generated health content to bolster trust. Policy makers should mandate the development of interoperable health systems that allow secure, real-time data exchange between GenAI tools and eHealth records, enabling true personalized, integrated chronic disease management. Community and social support networks have a crucial role in investing in community-based digital literacy programs that specifically teach older adults how to critically evaluate AI-generated health information, rather than just teaching basic operations. Implementation guidelines should focus on hybrid models where community health workers act as the "human verification" bridge between the AI tool and the end user.

Ethical Considerations in GenAI Video for Older Adults' Health Management

The application of GenAI videos in geriatric health management raises complex ethical issues that necessitate a comprehensive framework across technological design, service delivery, and policy regulation [54]. First, the balance between informed consent and autonomy presents a core challenge. Cognitive decline may hinder older adults' understanding of AI risks, while the over-reliance on proxies risks infringing their autonomy [55]. Solutions include developing visualized consent processes and clearly defining human-AI responsibility boundaries [56]. Second, algorithmic fairness and health inequities require urgent attention. Training data biases may exacerbate disparities, while hardware limitations could exclude economically disadvantaged groups [57]. Mitigation strategies involve privacy-preserving data integration and promoting affordable, age-friendly devices [58]. Third, the conflict between data privacy and generational security is prominent [59]. Finally, ambiguity in responsibility attribution challenges traditional medical ethics. Errors in AI-generated advice involve multiple stakeholders, including developers, clinicians, and users, necessitating decision-tracking systems and legislation for scenario-specific accountability [60]. These challenges underscore the need for a governance framework that balances efficiency, equity, and security through interdisciplinary collaboration.

Recommendations for Future Research

The sustainable development of GenAI videos for older adults' health management requires integrated strategies across multiple dimensions, which sheds light on the directions of future research. The ultimate goal is to create an inclusive health ecosystem where GenAI video empowers rather than replaces human care. Future research should focus on designing adaptive interfaces that accommodate the diverse digital literacy levels of older adults. This includes developing progressive disclosure mechanisms and context-aware guidance systems to reduce cognitive load, alongside iterative usability testing with age-diverse cohorts to refine interaction paradigms. From a gerontological standpoint, longitudinal studies are needed to map the dynamic evolution of older adults' digital competencies, identifying age-related changes in technology adoption patterns,

XSL•FO
RenderX

generational differences, culturally tailored content, and community-based digital literacy programs. For computer science researchers, the priority lies in advancing GenAI algorithms to enhance personalization accuracy. By integrating insights from these 3 domains, we can develop GenAI video systems that not only optimize technological efficiency but also embed humanistic values, ultimately fostering active aging through inclusive, empowering, and sustainable digital solutions.

Limitations

We acknowledge several limitations in this work. First, the single-point-in-time design limits our ability to capture the dynamic changes in older adults' digital literacy and GenAI acceptance over time; the barriers identified here may change rapidly as users gain experience, and a longitudinal study would be necessary to map the learning curve and long-term acceptance trajectory. Second, the sample primarily comprised urban, middle- to high-income older adults, with a notable skew toward female participants. While this skew reflects higher community engagement among this demographic, it may overestimate the average digital literacy level and underrepresent the unique health management needs and severe technological barriers faced by older adults in rural or low-income settings, particularly men. Finally, the qualitative nature of this study provides rich, deep insights into user needs but limits the statistical generalizability of the findings. While these limitations persist, they provide valuable directions for future research.

Conclusions

Based on a series of iterative workshops, this study systematically explored the opportunities and challenges of using GenAI videos for older adults' health management, yielding the following key conclusions. First, the needs of older adults for GenAI video exhibit a clear hierarchical structure: their fundamental needs focus on technological accessibility, then move to the emphasis of personalized adaptation, and the highest layer of needs prioritizes the integration with professional health information. The study confirms that GenAI videos have demonstrated potential in geriatric health management, notably enhancing information delivery efficiency, lowering the barriers of health knowledge acquisition, and transcending temporal and spatial constraints of health management. However, notable gaps remain between the features of GenAI video tools and older adults' needs, particularly in the depth of personalization, the capabilities of complicated responses, localization, as well as the accuracy and reliability of medical knowledge. The value of our research lies in recognizing the advantages and limitations of GenAI videos in this context, which can shed light on future research and solutions that can benefit older adults.

Abstract

Background: Cognitive decline in the aging population presents an unprecedented challenge worldwide. Recent research has shown the potential of cognitive training programs to mitigate cognitive decline. However, these interventions require sustained adherence to be effective, which can be challenging.

Objective: In this study, we aim to enhance the accuracy of predicting adherence patterns in cognitive training programs for older adults, with the goal of developing personalized support systems that promote adherence and improve cognitive outcomes.

Methods: A major challenge in developing deep neural networks for predicting adherence patterns is the limited availability of individual participants' training data. Although domain adaptation techniques can address this issue by leveraging training data from other clinical studies, our research considers a more practical scenario where the use of such data from other studies is restricted due to privacy and confidentiality concerns. Therefore, we used source-free domain adaptation (SFDA), which uses models trained on other cognitive studies without requiring access to the corresponding datasets. To the best of our knowledge, this is the first effort to use SFDA to predict older adults' daily adherence to cognitive training programs.

Results: Using data from 3 previously conducted cognitive training intervention studies, our results demonstrated the efficacy of deep learning models combined with SFDA to accurately predict adherence lapses while addressing data privacy concerns.

Conclusions: Our findings indicate that deep learning and SFDA techniques can be useful in the development of adherence support systems for computerized cognitive training, aimed at improving the health and well-being of older adults.

Introduction

Background

Cognitive decline presents significant challenges for older people, impacting their well-being, decision-making, and overall quality of life. Although some cognitive decline is normal with age, severe cognitive impairments such as dementia and Alzheimer disease present greater risks [1]. Dementia currently ranks as the seventh leading cause of global deaths, and its prevalence could triple by 2050 [2]. The number of older adults

XSL•FO
RenderX

is increasing substantially, particularly among those aged 85 years and older, who represent the fastest-growing age category among older adults [3]. With the US population aged 65 years and older expected to nearly double in the next 40 years [4], addressing age-related cognitive changes is essential for promoting independence, improving quality of life, and reducing caregiving burdens on families and health care systems.

Cognitive training interventions have emerged as a promising approach to address cognitive decline. These interventions often involve technology-based training programs that target specific cognitive functions such as memory, attention, and problem-solving [5-8]. Recent studies have underscored the potential of digital cognitive training programs in improving cognitive performance and daily activities in older adults [9-11]. Lövdén et al [12] assert the following in their theoretical account of the necessary conditions for inducing cognitive plasticity: (1) mismatches between functional supply and experienced environmental demands drive manifestations of plasticity and (2) mismatches need to be maintained for extended periods to induce plasticity. Keeping people engaged and adherent for extended periods while performing tasks that force them to operate slightly above their cognitive limits is a major challenge. A necessary first step in promoting adherence is the ability to predict lapses and to find effective ways to intervene "just-in-time" to maintain engagement.

Recently, Li et al [13] conducted a meta-analysis that included 55 randomized controlled trials with 4455 participants (spanning normal cognition, mild cognitive impairment, and neurodegenerative dementia) to assess the effects of cognitive training in older adults. The study demonstrated that participants who maintained an adherence rate of 80% or higher experienced significant cognitive benefits. This systematic review further highlights the critical role of sustained adherence in augmenting the efficacy of cognitive training and underscores the importance of predicting adherence lapses. Studies also indicate that adherence to cognitive training is influenced by factors such as mental capacity, physical function, and program design [14-19]. Hence, understanding adherence to these interventions and developing strategies to enhance them are essential for improving the effectiveness and optimizing outcomes of computer-based cognitive training programs [20,21].

To this end, in our recent research, we have applied advanced machine learning (ML) and deep learning (DL) techniques to predict adherence lapses based on past behaviors among older adults participating in cognitive training programs [22,23]. Deep neural networks, together with techniques such as data augmentation, adaptive window size estimation, and temporal data clustering, have shown tremendous promise in predicting adherence patterns [24]. To capture the individual differences across participants, we trained a separate prediction model for each participant rather than a single model for all participants. However, the limited availability of data for each participant (only 30 days) made it difficult to train a reliable prediction model for each participant. In our recent work [25], we leveraged the potential of domain adaptation (DA) to address this challenge by using training data from participants in a similar, previously conducted clinical trial. Although the results were promising, this method required access to data from other participants in a different trial, which can raise privacy concerns, as health care data can contain personal or confidential information.

In this study, we used data from 3 technology-based cognitive intervention studies to predict adherence patterns among participants while also addressing data privacy issues. Although these datasets are deidentified, previous publications have shown that deidentification of health data, commonly used to protect privacy, is ineffective because modern techniques can easily reidentify individuals by linking deidentified datasets with external information [26,27]. Similarly, ML techniques can successfully reidentify individuals from incomplete datasets with high likelihood [28]. Despite these limitations, deidentified data are widely shared and sold without patient consent, highlighting the need for stronger protection and privacy practices in health care research.

In this work, we used state-of-the-art source-free domain adaptation (SFDA) techniques to address the challenge of limited training data for each participant and the privacy concerns surrounding clinical data. Our framework requires access only to a *deep neural network model trained on data from a different clinical study, and not the confidential data themselves*, thereby addressing data privacy concerns. Our extensive empirical analyses demonstrated that SFDA can efficiently leverage knowledge from other clinical studies to develop participant-specific deep neural network models to predict adherence patterns, while addressing data privacy issues at the same time.

Overall, our research highlights the potential of deep neural networks and SFDA techniques in predicting adherence lapses and developing personalized support systems for cognitive training programs. SFDA not only improves the prediction accuracy but also preserves the privacy of clinical datasets, which is crucial for confidentiality. By leveraging these technologies, we can enhance engagement and optimize the benefits of cognitive interventions, ultimately improving the quality of life for older people with cognitive impairments. To the best of our knowledge, this study represents the first effort to apply SFDA techniques to predict daily adherence among older adults participating in cognitive training programs.

Objectives

This research sought to address the following objectives:

1. Determine the potential of convolutional neural networks (CNNs) to predict adherence to cognitive training programs based on past behavior
2. Explore the use of SFDA techniques to address training data scarcity and maintain data privacy while predicting adherence patterns
3. Investigate how artificial intelligence (AI)–driven approaches can be implemented to predict engagement in cognitive training programs

Overall, by identifying adherence patterns, these approaches can inform the development of more effective interventions, benefiting individuals and society by improving conditions associated with aging.

Methods

Research Design

For this study, we investigated older adults' engagement with Mind Frontiers (Aptima Inc), an Android-based cognitive training game platform. The platform features a Wild West–themed interface with 7 interactive minigames designed to enhance key cognitive functions, including memory, attention, spatial navigation, multitasking, and logical reasoning. Cognitive training was conducted on Lenovo 10 tablets, with all participants receiving instructions on device operation and gameplay. The levels reached in the games ranged from 1 to 58, and the cognitive training program included 5 possible outcomes: *defeat*, *stalemate*, *victory*, *abort*, and *not yet finished*. After completing each game, participants received feedback, and the game's difficulty was adjusted based on their previous performance. This structured approach ensured consistent engagement and systematic data collection for assessing cognitive improvement over time.

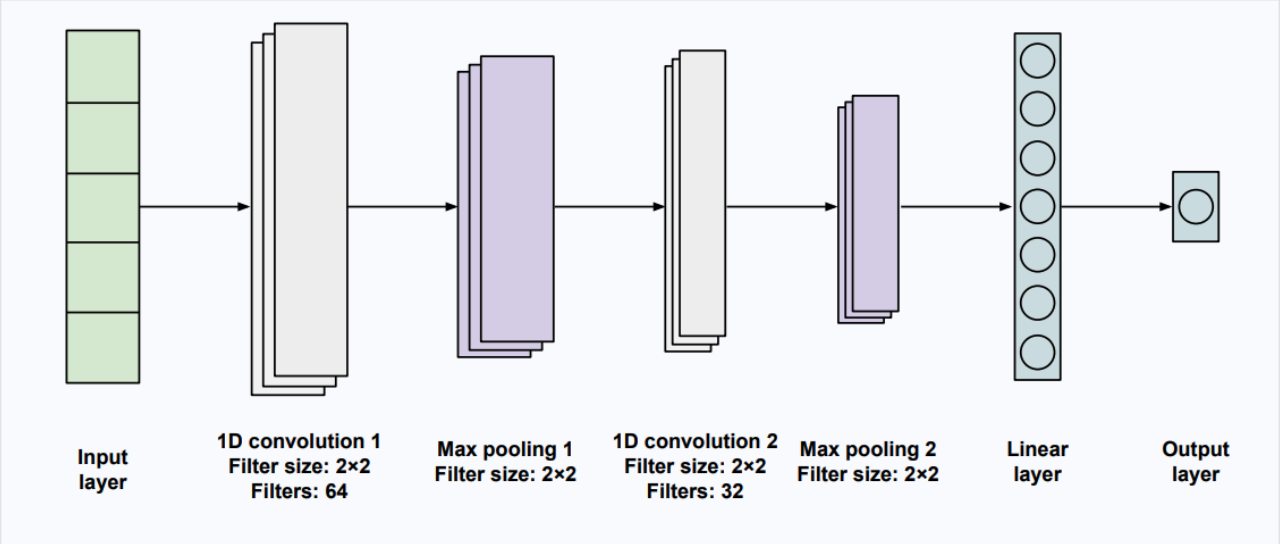
Datasets

In this study, we used 3 distinct datasets, each derived from separate clinical research trials. The study 1 dataset [29] consisted of a 2-phase protocol. In the first phase of 12 weeks, participants were asked to follow a structured schedule, engaging in cognitive training for 45 minutes per day, 5 days per week. In contrast, the subsequent 6-week phase was unstructured, allowing participants to engage at their discretion. In our study, we analyzed data only from the structured phase, as adherence metrics rely on the prescribed game-playing schedule. The dataset is derived from 118 participants with a mean age of 72.6 (SD 5.5) years, including 78 (66.2%) female participants and 40 (33.8%) male participants. The dataset included multiple cognitive assessments, such as technical proficiency, self-efficacy, subjective cognition, perceived benefits, and objective cognitive measures such as processing speed and memory.

The study 2 dataset [30] came from a similar but independent cognitive training study that involved 120 adults aged 64 years and older from Leon County, Florida, and surrounding areas. Of these, 116 (96.7%) participants completed the structured phase, which included baseline and postintervention cognitive measures. The average age of participants was 70 (SD 4.42) years, with a range of 64 to 84 years; 77 (64.2%) participants were female, while 43 (35.8%) participants were male. Although participants were expected to complete both phases, the second phase did not require participants to engage in gaming interventions for specific time intervals.

The study 3 dataset also came from an independent cognitive training trial consisting of 92 participants. Among these, 90 (97.8%) participants provided complete demographic information, with ages ranging from 62 to 84 years and an average age of approximately 71 (SD 4.97) years. Of the participants, 67 (74.4%) were female and 20 (22.2%) were male, while 2 (2.2%) participants preferred not to disclose their sex, and 1 (1.1%) participant indicated that none of the listed sex options described them.

DL for Adherence Prediction



In this study, we used deep CNNs [31], which were initially designed for image data but are also widely used for time-series classification and forecasting tasks [32,33]. CNNs consist of convolutional layers comprising filters that slide over the input data to extract local patterns and features. For 1D time-series data, 1D convolution is applied, in which the kernel slides unidirectionally from the start of the time series to its end. For an input vector f of length n and a kernel g of length m, the convolution ($f \times g$) of f and g is defined as follows:

In this study, we used a DL architecture consisting of 2 convolutional blocks, each comprising a convolutional layer followed by a maximum pooling layer. The pooling layer down-samples the feature maps by selecting the maximum value within a predefined window, thus effectively retaining salient features. These blocks are succeeded by a linear layer and an output layer, as depicted in Figure 1.

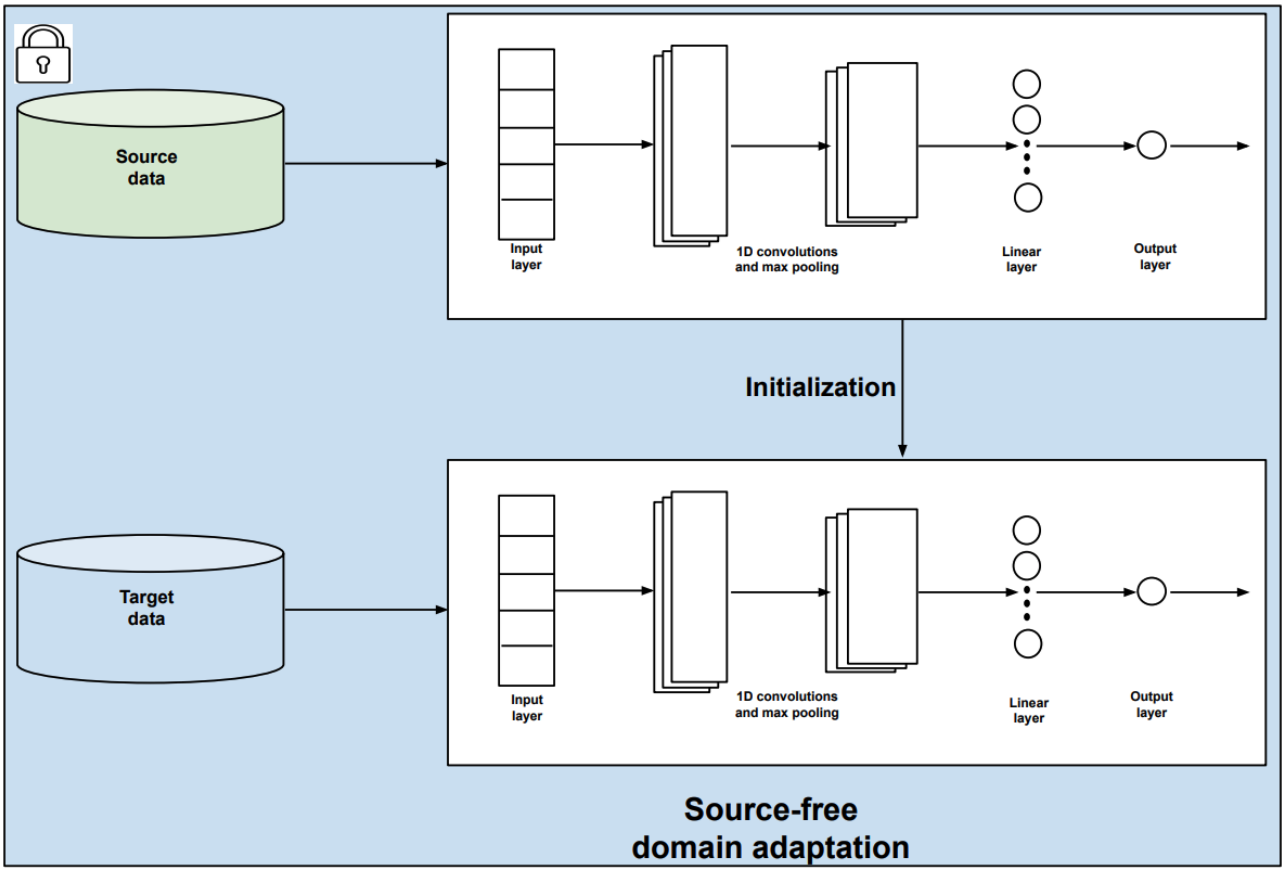
XSL•FO
RenderX

Figure 1. Network architecture used in our experiments. It consists of 2 convolutional blocks, each comprising a convolutional layer followed by a max pooling layer. These blocks are succeeded by a linear layer and an output layer.

SFDA for Adherence Prediction

A key challenge in our study was the limited availability of labeled training data for each participant (only 30 days of training data). DA is a well-researched technique in the ML literature for addressing the challenge of training models with limited labeled data. DA algorithms use labeled data from a source domain to enhance the performance of DL models in a target domain of interest with limited labeled data, under the constraint that the data from the 2 domains are derived from different probability distributions [34,35]. Although DA is predominantly used in computer vision, recent studies have demonstrated its applicability in adapting temporal data patterns [36,37].

In our recent research [25], we studied the performance of adversarial DA [38] to enhance the accuracy of personalized adherence prediction models by using training data from participants in a different, previously conducted clinical study. For a given target participant, all participants from the other study, with similar play patterns (determined through a clustering algorithm), were considered source participants. Each participant has a unique play pattern; that is, the data for each participant are derived from a different probability distribution. Adversarial DA was used to address this disparity between the source and target domains, so that the data from the source participants can also be used to train a personalized model for the target participant. Our results demonstrated that DA consistently produced more accurate personalized adherence prediction models for each participant, compared with the case when only the data from the target participant was used to train the model for this participant, without using the data from the other clinical study.



Although these results were promising, the DA algorithm required access to the source participants' data from the other clinical trial. This can pose privacy concerns as clinical data typically contain personal or confidential information. In this paper, we considered a more practical scenario, assuming we would only have access to a *deep neural network model trained on the source participants' data, rather than the raw data*. We attempted to leverage the source domain knowledge encoded in the trained source model to train an accurate adherence prediction model for a given target participant. This category of DA is referred to as SFDA [39-45].

Although much SFDA research focuses on computer vision, recent studies have extended SFDA approaches to medical and time-series domains. For instance, Ragab et al [39] introduced a temporal imputation strategy tailored for time-series SFDA, demonstrating improved performance on physiological datasets such as human activity recognition and sleep stage classification. Similarly, studies by Li et al [42] and Wu et al [43] applied SFDA techniques for medical image segmentation, including applications to fundus imaging. Moreover, Yang et al [44] explored the use of SFDA with Fourier-style feature mining for tasks such as polyp and prostate segmentation.

SFDA is effective in addressing data privacy concerns, as only a model trained on source domain data is used for knowledge transfer, rather than the raw source domain data. This is depicted in Figure 2. Our framework thus offers a safer mechanism for clinical trials to inform one another. In this work, we demonstrate the utility of our method using the 3 datasets mentioned as test cases. Our framework will be especially useful for datasets that contain even more sensitive information, given the ease of reidentifying the deidentified data as discussed previously.

Figure 2. Illustration of source-free domain adaptation (SFDA). We only have access to a deep neural network model trained on the source participants' data, rather than the raw data. SFDA is effective in addressing data privacy concerns, as only a model trained on source-domain data is used for knowledge transfer to the target-domain participants, rather than the raw source-domain data.

We used in our study the SFDA method proposed by Yang et al [40]. This method performs adaptation to the target domain without access to source domain data by using local structure clustering (LSC). The main rationale of this method is that although the features of the target domain can be shifted with respect to the features of the source domain, the classes will still form clusters in the feature space. Thus, LSC attempts to move clusters of data points toward their most likely class prediction. Before adaptation, some target features given by the source model are expected to deviate from the corresponding dense source feature region due to domain shift. These samples will most likely be incorrectly predicted by the classifier. However, we assumed that the target features from the same class would be clustered together. Therefore, the nearest neighbors of target features would have a high probability of having the same class labels. To exploit this fact, LSC encourages samples that are close in the feature space to have similar predictions to those of their nearest neighbors. Consequently, clusters of points that are close in feature space will move jointly toward a common class. Thus, this process can correctly classify target features that would otherwise have been wrongly classified. Additional information about this method can be found in the study by Yang et al [40]. Figure 3 presents a visual illustration of the LSC method. To further validate the effectiveness of SFDA, we also conducted an additional experiment using the SFDA method proposed by Yang et al [45] in our setting.

Figure 3. Illustration of local structure clustering (LSC) for SFDA (as described in the studies by Yang et al [40,45]). Some target features from the source model will deviate from dense source feature regions due to domain shift. LSC aims to cluster target features based on their semantically close neighbors.

Experimental Setup

For all the experiments, we used the network architecture illustrated in Figure 1. The network was trained for up to 130 epochs, with early stopping applied when the validation loss ceased to decrease. We used the Adam optimizer with an initial learning rate of 1×10^{-3}, which is reduced by a factor of 0.5 every 20 epochs. All models are trained on an Ubuntu 20.04 system equipped with a 20 GB NVIDIA RTX A4500 graphics processing unit. The training of a single model takes approximately 45 minutes. We set aside 15% of the training data for validation and monitored the validation loss to ensure proper model convergence.

In our experiments, we divided each participant's data into 2 segments for training and testing. The first 30 days of data were considered for training, and the subsequent 30 days of data were used for testing. This division aligns with psychological research indicating that approximately 30 days is the median time required for habit formation to plateau [46].

The input to the CNN consisted of multivariate time-series data, including (1) play duration, (2) session count, (3) maximum level achieved, and (4) number of tasks completed. We established a threshold of 10 minutes of playing time per day to classify participants as adherent (*playing time ≥10 minutes*) or nonadherent, consistent with our previous work [22,24]. Our objective was to train deep neural networks to predict adherence on the (N + 1)th day based on data from the previous N days. We set the window size, N, to 7 in this study. A personalized model was trained for all participants to capture their unique playing patterns. We used accuracy, precision, recall, and F_1-scores as the metrics for evaluation. Precision, recall, and F_1-scores were used to assess the model's performance on positive predictions, whereas accuracy evaluated overall performance. The reported final scores represented the average performances across all participants. We conducted 2 different sets of experiments and performed a 1-tailed t test to assess the statistical significance of the obtained results. The sets of experiments were as follows: first, no source; in this setting, an individual DL model was trained for each target participant using only the training data of that participant. No information from any other dataset was used for model training. Second, SFDA; here, the SFDA method [40] was used to train personalized DL models for each target participant by transferring relevant knowledge from a source model trained on a source dataset.

For instance, when study 1 served as the source dataset, we first trained a deep model on all the participants' data from study 1. If the target participant belonged to study 2, the deep model was fine-tuned using data from all other participants in study 2, excluding the target participant. Subsequently, only the trained model, without direct access to the original study 1 dataset, was used to transfer relevant knowledge for developing a personalized adherence prediction model for the target participant.

Ethical Considerations

This study was approved by the Florida State University Institutional Review Board (study ID 2017.20622 and STUDY00000005). Informed consent was obtained from all participants, and participants were given the opportunity to opt out at any time. This consent process included institutional review board–approved language stating that the collected data could be made available for secondary analysis by other research teams and that any shared data would not include personal identifiers. Data were labeled with participant IDs, meaning that the data were deidentified in this study. Participants were compensated a total of US $200 (study 1) or US $75 (study 2) for their participation, with the difference driven by the shorter commitment involved in study 2.

Results

The results of our study are presented in Tables 1-3 for the study 1-3 datasets, respectively (using the SFDA method proposed in the study by Yang et al [40]). Each table reports the values of the evaluation metrics on the test sets of the respective datasets. The values reported are the average scores across all participants. The tables show that performance across all the metrics was lowest when no DA technique was applied.

Table 1. Average scores of source-free domain adaptation (SFDA) models on the study 1 dataset[a].

Experiment type	Accuracy (%), mean (SD)	Precision (%), mean (SD)	Recall (%), mean (SD)	F_1-score (%), mean (SD)
No source	63 (0.24)	58 (0.23)	57 (0.24)	54 (0.25)
SFDA with the study 2 dataset as the source	69 (0.20)	63 (0.20)	61 (0.19)	60 (0.21)
SFDA with the study 3 dataset as the source	65 (0.23)	58 (0.23)	56 (0.22)	56 (0.20)

[a]The scores are calculated by averaging the respective scores across all the participants.

Table 2. Average scores of source-free domain adaptation (SFDA) models on the study 2 dataset[a].

Experiment type	Accuracy (%), mean (SD)	Precision (%), mean (SD)	Recall (%), mean (SD)	F_1-score (%), mean (SD)
No source	57 (0.22)	54 (0.19)	52 (0.20)	49 (0.20)
SFDA with the study 1 dataset as the source	68 (0.20)	57 (0.21)	58 (0.19)	56 (0.21)
SFDA with the study 3 dataset as the source	64 (0.21)	55 (0.23)	57 (0.20)	54 (0.20)

[a]The scores are calculated by averaging the respective scores across all the participants.

Table 3. Average scores of source-free domain adaptation (SFDA) on the study 3 dataset[a].

Experiment type	Accuracy (%), mean (SD)	Precision (%), mean (SD)	Recall (%), mean (SD)	F_1-score (%), mean (SD)
No source	56 (0.20)	53 (0.19)	51 (0.22)	50 (0.23)
SFDA with the study 2 dataset as the source	62 (0.20)	61 (0.22)	58 (0.18)	56 (0.21)
SFDA with the study 1 dataset as the source	65 (0.21)	62 (0.25)	59 (0.19)	58 (0.23)

[a]The scores are calculated by averaging the respective scores across all the participants.

For instance, in the study 2 dataset (Table 2), the average accuracy was 57% when only the data for a given target participant was used to train a model for that participant, without access to any other source dataset. This shows that using only the limited participant-specific training data may result in prediction models with poor generalization capability. Using information from the other datasets through SFDA consistently produced better performance in terms of all the evaluation metrics.

For the study 2 dataset, using the study 1 dataset as the source yielded an accuracy of 68% (11% improvement), whereas using the study 3 dataset as the source produced an accuracy of 64% (7% improvement). The corresponding improvements on the F_1-score were 7% and 5%, respectively. A similar pattern was observed for the other 2 datasets.

For the study 1 dataset, using the other 2 datasets as the source datasets resulted in an improvement of 6% and 2% in accuracy and 6% and 2% in the F_1-scores, respectively. For the study 3 dataset, the improvements in accuracy and F_1-score were 6% and 9%, and 6% and 8%, respectively, when using the other 2 datasets as a source, compared with the "No source" setting.

Similarly, using the SFDA technique proposed in the study by Yang et al [45], the improvements in accuracy and F_1-score were 3% and 4%, and 6% and 7%, respectively, compared with the "No source" setting for the study 3 dataset, as depicted in Table 4. The greater performance gains observed when using the study 1 or study 2 datasets as the source dataset, compared with the study 3 dataset, are attributed to the larger sample size of the study 1 (118 participants) and study 2 (116 participants) datasets, compared with the study 3 dataset (92 participants).

Table 4. Average scores of source-free domain adaptation (SFDA) on the study 3 dataset (calculated by the method proposed in the study by Yang et al [45])[a].

Experiment type	Accuracy (%), mean (SD)	Precision (%), mean (SD)	Recall (%), mean (SD)	F_1-score (%), mean (SD)
No source	56 (0.20)	53 (0.19)	51 (0.22)	50 (0.23)
SFDA with the study 1 dataset as the source	59 (0.22)	56 (0.23)	55 (0.19)	56 (0.20)
SFDA with the study 2 dataset as the source	60 (0.23)	58 (0.24)	57 (0.20)	57 (0.25)

[a]The scores are calculated by averaging the respective scores across all the participants.

These results unanimously corroborate the potential of SFDA algorithms to not only develop more accurate personalized DL models for predicting adherence to cognitive training programs among older adults but also help address privacy and confidentiality concerns that are inherent in clinical datasets.

Additionally, we conducted statistical tests of significance using *t* tests (Table 5) and the Wilcoxon signed-rank test (Table 6) to assess whether the improvement in performance achieved by our SFDA method is statistically significant when compared with the *"no source"* method. We computed the *P* values on accuracy scores for all the experiments detailed in Tables 1-3. Tables 5 and 6 show that all *P* values were ≤.05 for all tests, signifying that the performance improvement achieved by the SFDA method over the *"no source"* method is statistically significant. These results further support the effectiveness of SFDA in improving the performance of DL models for predicting adherence to cognitive training programs among older adults while maintaining data privacy and confidentiality.

Discussion

Principal Results

The findings of this study have several significant implications for adherence prediction in cognitive training programs for older adults. Our results demonstrate that CNNs can analyze behavioral patterns and predict adherence trends in cognitive training interventions. CNNs learn meaningful patterns and trends from past data and predict future adherence, which can be used to design more personalized and effective cognitive training programs. These findings contribute to the growing body of research supporting AI-driven approaches for optimizing health care interventions in the aging population.

Our work demonstrates that SFDA techniques can effectively leverage information from external datasets and substantially improve the predictive accuracy of DL models, particularly when limited training data are available for developing personalized models for individual participants. More importantly, these methods offer the critical advantage of preserving data privacy, as they only require access to a model trained on a different clinical dataset, without requiring access to the raw data. Given strict privacy concerns in clinical applications and the ability of modern ML techniques to reidentify the deidentified data, training effective predictive models without direct access to the source data is a significant advancement. To the best of our knowledge, this study is the first to apply SFDA techniques to the domain of adherence prediction in cognitive training programs. The ability to maintain data privacy while still achieving competitive predictive accuracy has significant potential benefits in health care settings.

Furthermore, our study's findings have important practical and theoretical implications for the design of future cognitive training interventions. By enabling accurate day-level adherence prediction from limited individual data, SFDA provides the foundation for just-in-time adaptive interventions that can detect early signs of disengagement. Early detection helps to deliver tailored support such as personalized reminders, motivational prompts, difficulty adjustments, and behavioral coaching. This predictive capability is critical for sustaining the prolonged engagement required for cognitive plasticity, as described in theoretical models of adult learning [12]. The results also indicate that adherence behaviors exhibit stable, transferable structural patterns, revealing a promising direction for using DA theory to model behavioral time-series and examine habit formation and individual differences in engagement. As SFDA enables cross-cohort knowledge transfer without accessing sensitive data, it supports the development of scalable, privacy-preserving personalized adherence support systems that can be deployed across sites and studies. From a practical

XSL•FO
RenderX

standpoint, improving adherence prediction has direct implications for clinical trials, where consistent participant engagement is essential for accurately evaluating the effectiveness of cognitive training interventions. By improving the predictive accuracy of CNNs, SFDA-enhanced systems could make cognitive training trials more reliable, efficient, and informative.

Limitations

Despite its advantages, applying SFDA in our study presents certain limitations. Deploying personalized models in real-world cognitive training applications raises several ethical and practical concerns, as users' experiences with AI-health systems depend heavily on trust, privacy, and output interpretability [47]. Although SFDA ensures data privacy and personalized models enhance user engagement, it remains crucial to address issues related to user trust, transparency, and interpretability.

In addition to SFDA, other privacy-preserving techniques such as federated learning (FL) and homomorphic encryption exist. However, our focus on SFDA is motivated by its practicality in small-scale clinical studies. FL requires distributed infrastructure, multiple rounds of communication, and active collaboration among participants, increasing both computational burden and vulnerability to privacy attacks [48,49]. In contrast, SFDA involves sharing only a single source model without accessing source data or maintaining continuous client interactions. Hence, it is more suitable for our setting, in which trials are completed, and no live infrastructure exists for FL deployment.

Furthermore, there is a risk of domain mismatch when transferring personalized models to new cognitive games or different user populations. Models trained on limited individual-level data may overfit to short-term noise, reducing reliability. Moreover, tailoring models using only 30 days of data may introduce bias and restrict external generalizability, as early playing patterns may not fully capture long-term patterns. Finally, all 3 datasets used in our study were derived from the same cognitive training platform (Mind Frontiers) and involve participants with similar demographic and geographic characteristics, which may further limit generalizability. In future work, we will focus on evaluating SFDA across different cognitive training platforms, more diverse populations, and varied intervention types to assess the robustness and broader applicability of our approach.

Conclusions

In conclusion, our research contributes to the growing body of research supporting AI-driven approaches to optimizing health care interventions for the aging population. Specifically, the findings support the use of DL and SFDA techniques for predicting adherence to cognitive training programs. With accurate adherence prediction models, AI-assisted personalized support systems can be developed to improve long-term engagement in cognitive training programs and maximize cognitive health benefits for older adults. We hope that our research will motivate further exploration of DA, particularly SFDA techniques in other contexts and populations, with the ultimate goal of improving the effectiveness of cognitive training interventions.

Abstract

Background: Older adult activity recognition is a critical task in long-term care monitoring; yet, it remains challenging due to postural deformities and health-related variability. These factors cause different activities to appear visually similar, or the same activity to appear dissimilar, undermining the effectiveness of traditional human activity recognition models developed for the general population.

Objective: This study aims to develop an improved older adult activity recognition method that integrates care assessment information with motion data to capture and understand movement variability arising from different health conditions.

Methods: To achieve our objective, we propose a care-assessment-aware spatiotemporal transformer (CSTT) model that integrates body key points, heatmaps, and care level data for personalized and context-aware activity recognition. The model dynamically adjusts its attention mechanism based on care level context to improve recognition accuracy. CSTT was trained and validated on real-world older adult motion data. A total of 51 older adult participants (30 men and 21 women; age range of 64-95 years) were included in the study. Among them, 7 (13.7%) required high care assistance, 26 (51.0%) required medium care assistance, and 18 (35.3%) required low care assistance.

Results: Despite data imbalance and considerable intraclass variation due to differing care needs, the proposed CSTT model achieved an F_1-score and accuracy of 0.96 and area under the curve is 0.98. Analysis revealed that movement patterns differ significantly across care levels and that similar motions occur in distinct activities, highlighting the importance of care-aware modeling.

Conclusions: Incorporating care level information into activity recognition models significantly enhances performance in older adult care settings. The proposed CSTT framework demonstrates the value of personalized, context-sensitive approaches for accurate and ethical monitoring in long-term care environments.

Introduction

Background

Advancements in medical science and technology have led to a global demographic shift, with the older adult population projected to reach 1.2 billion by 2025 and 2 billion by 2050 [1]. By 2050, nearly 20% of the world's population will be older adults [2]. As life expectancy increases, age-related physical and cognitive decline necessitates long-term care (LTC) [3], placing significant strain on health care systems and LTC facilities [4-8].

Caregivers in LTC facilities perform essential tasks, including hygiene assistance, feeding, dressing, and mobility support [7-10], while also providing emotional and psychological care [11]. However, their close interaction with residents exposes them to emotionally taxing experiences, such as witnessing chronic pain, cognitive decline, and end-of-life care [12], leading to compassion fatigue and emotional exhaustion. Caregivers also navigate ethical dilemmas, balancing residents' autonomy with safety, managing conflicts with families, and making complex decisions [13-15]. These challenges heighten stress and contribute to burnout [16-18], exacerbating the global caregiver shortage, particularly in Central Asia and Eastern Europe. High annual turnover rates (19%-55%) [19-21] worsen staff shortages, increase workloads, and reduce care quality [22]. To address shortages, LTC facilities increasingly rely on health care assistants and auxiliary nurses [23]. While vital, their limited training can hinder the care of residents with cognitive impairments or chronic conditions [24], affecting both caregiver well-being and overall health care sustainability. Ensuring caregiver well-being while maintaining high-quality older adult care is essential, as excessive strain can impact both mental health and service quality. Automatic monitoring systems offer a promising solution; however, their real-world implementation requires a robust human activity recognition (HAR) framework that accounts for older adult–specific mobility and health variations. Existing HAR methods mostly use RGB or RGB-D camera [25] and inertial measurement units [26]. Wearable inertial measurement units, although effective, can be intrusive and uncomfortable. In contrast, depth sensors and RGB cameras provide a nonintrusive, cost-effective alternative, advancing HAR through wireless sensor networks and the Internet of Things.

HAR approaches typically rely on RGB-based [27-29] or skeleton-based [30-32] methods, which perform well in general settings but degrade significantly for older adult individuals due to posture and mobility differences influenced by health conditions. A key limitation of traditional HAR models is the lack of care assessment scores (CASs), which are critical in older adult care. Caregivers assign CASs such as the activities of daily living score, Barthel Index, and care level (CL) to assess mobility, physical dependency, and assistance needs. These scores provide vital insights into an individual's functional abilities, yet state-of-the-art HAR methods fail to incorporate them, limiting their applicability to older adult populations. Since posture and motion patterns are directly affected by health conditions, neglecting these factors leads to poor generalization. Moreover, widely used HAR datasets such as RGBD-HuDaAct [33], 3D Action Pairs [34], MSR-DailyActivity [35], NTU RGB+D 120 [36], and UTD-MHAD [37] lack older adult–specific data, as they primarily feature younger or healthier participants. This demographic gap hinders HAR models from accurately recognizing older adult activities. To address this challenge, integrating CASs into HAR models is essential for personalized, context-aware monitoring, enabling more adaptive and accurate older adult activity recognition.

Related Works

Traditional HAR methods struggle with older adult individuals, leading to research on tailored models and datasets. However, challenges remain. This section reviews state-of-the-art HAR and older adult HAR methods using skeleton and video data, together with older adult–specific datasets.

Older Adult Activity Recognition

RGB-based HAR is widely used, particularly for monitoring applications. It primarily extracts motion information from video frames and can be classified into 2 categories: 2-stream networks and 3D convolutional networks. Two-stream networks leverage RGB data for spatial representation and optical flow for temporal dynamics [38-44]. However, computing optical flow is computationally expensive, creating bottlenecks in real-time applications. In contrast, 3D convolutional networks [45-48] aim to capture spatiotemporal features directly from video sequences but face challenges related to occlusions, camera motion, and environmental complexities [49]. These limitations are even more pronounced in older adult activity recognition, where subtle motion variations and fine-grained details play a crucial role. Skeleton-based approaches offer a compact and robust representation of human motion by focusing on skeletal joints and their temporal evolution. Early works used spatial graph-based models [50-53], while later studies introduced temporal relationships through recurrent and convolutional architectures [54-58]. However, skeleton-based methods lack environmental context, limiting their effectiveness in recognizing human-object interactions—an essential factor for assessing functional abilities in older adult individuals. To address the limitations of unimodal methods, researchers have explored multimodal fusion techniques that integrate RGB and skeleton data [59,60]. These methods typically extract features from each modality independently before performing fusion, with some incorporating contextual information such as human-object interactions and location data [61-63]. Despite improved recognition accuracy, existing multimodal approaches struggle with effective feature aggregation, as irrelevant modality-specific information can degrade overall performance. More importantly, these methods are predominantly trained on young, healthy individuals and lack adaptations tailored for older adult populations. A notable older adult HAR system was introduced in the study by Kim et al [64], using depth video and skeleton joint features. While effective in controlled environments, this approach failed to generalize well to real-world scenarios due to the exclusion of contextual and health-related mobility variations and the lack of real-world continuous activity patterns in the training data. Another older adult HAR method proposed a feature fusion model combining

XSL•FO
RenderX

handcrafted and deep-learned features using a dedicated dataset [65]. However, this approach remains limited by its reliance on a homogeneous environment and its inability to capture long-range dependencies.

To overcome the limitations of existing methods, we propose a cross-modal and personalized HAR approach that considers older adult health conditions. Our base model is built on transformers, which have demonstrated exceptional performance in HAR due to their ability to model long-range dependencies through self-attention mechanisms. Most transformer-based HAR methods process RGB frames as input tokens [66,67] or, less commonly, skeleton data [68,69]. However, these approaches suffer from high computational costs, restricting their applicability in real-time older adult care environments. In addition, existing transformer-based models do not efficiently integrate cross-modal information, limiting their ability to leverage multimodal dependencies for older adult HAR. To address these challenges, we propose a depth map-based approach instead of RGB to reduce computational costs. We have designed a care-aware attention mechanism (CAM) and incorporated it into the spatial layer, replacing the standard self-attention mechanism in transformers. This effectively facilitates cross-modal analysis by integrating care assessment information, skeleton data, and depth images, thereby enhancing older adult HAR performance.

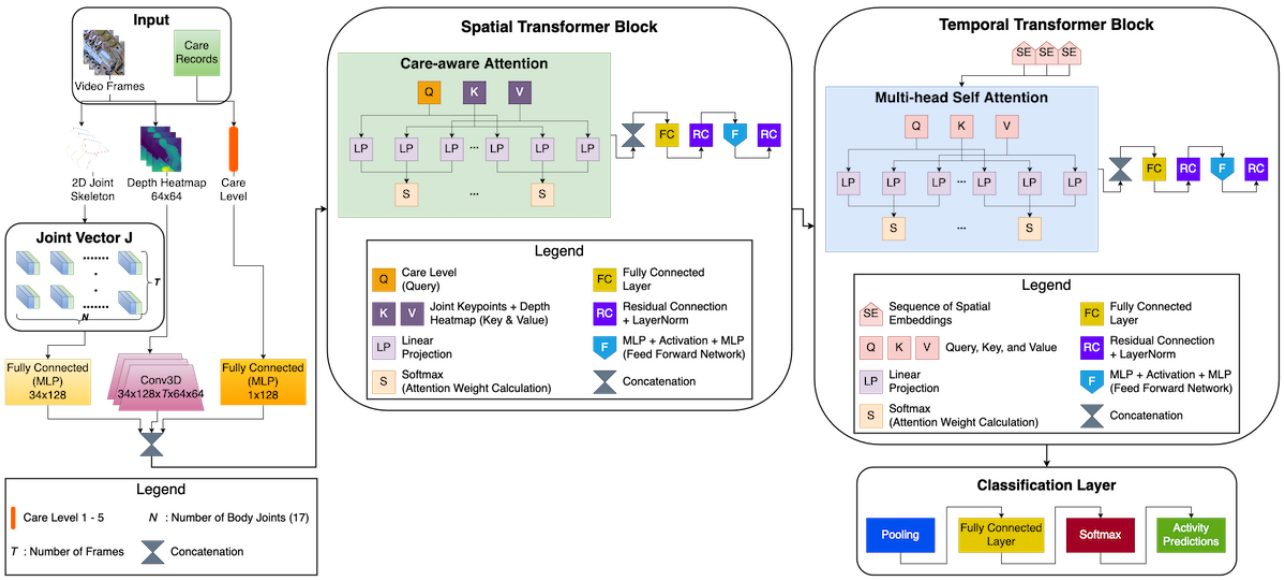
Older Adult Dataset

Although most benchmark HAR datasets are designed for the general population, some datasets have been specifically collected to study older adult individuals. EGOFALLS [70] focuses on fall detection using egocentric camera data, containing 10,948 video samples from 14 participants, including 12 young adults and only 2 older adult individuals. Despite its large size, the dataset has a significantly small sample of older adult participants. Additionally, its controlled environment and lack of health condition–based variations make it unsuitable for real-world application training. The Toyota Smarthome Dataset [71] captures daily living activities using 7 Kinect sensors from 18 volunteers aged 60-80 years over 8 hours in a controlled apartment setting. While it includes interactions with household objects, its limitations stem from the controlled environment and the absence of health condition–based variations. IntelliRehabDS [72] was collected using a Kinect motion sensor and comprises 9 repetitive gestures performed by 29 individuals, including 15 patients and 14 healthy controls. It provides 3D body joint coordinates and depth maps, annotated for gesture type and position (sitting or standing). However, the dataset has a narrow older adult age range (20-60+ years), is collected in controlled conditions, and lacks health condition–specific data. ETRI-Activity3D [73] is a large-scale dataset that includes RGB videos, depth maps, and skeleton sequences from 100 participants—50 older adult individuals (aged 64-88 years, with an average age of 77 years) and 50 younger adults (average age of 23 years). Despite its scale, the dataset has limitations, including a lack of intervention data, health condition–based variations, and continuous activity recordings. Overall, existing older adult HAR datasets suffer from small and homogeneous older adult sample sizes, controlled environment constraints, and limited continuous activity data, often lacking health condition–specific variations. To address these issues, we collected our dataset in a real care facility without intervention or manipulation, capturing mealtime sessions of 28 older adult participants aged 62-95 years, representing 5 distinct CLs.

Objective and Contributions

In this work, our objective is to develop an improved older adult activity recognition method that integrates care assessment information with motion data to effectively capture and understand movement variability caused by different health conditions. To achieve this, we incorporated CL, one of the most widely used CASs in older adult care facilities, due to its availability and relevance in evaluating functional abilities, and introduced a care-assessment-aware spatiotemporal transformer (CSTT) that adapts its attention to key points and depth-based motion patterns based on an individual's CL, enabling personalized feature prioritization and improved activity prediction. We also addressed the issue of the lack of suitable data and collected a real-world older adult activity dataset incorporating CL information. The key contributions of our work can be summarized as follows:

1. We propose the first care-assessment-aware activity recognition approach by modeling the correlation between health conditions using CL and movement patterns to personalize and improve older adult activity recognition.
2. We propose CSTT, integrating skeleton, depth heatmaps, and CL information. Our proposed CAM dynamically adjusts focus based on care needs, ensuring personalized recognition while enhancing robustness and efficiency.
3. We present the first motion dataset with CL information, capturing real-world mealtime sessions to reflect aging and health impacts on mobility with high ecological validity.
4. This work improves older adult activity recognition by integrating care assessment information and capturing motion variations influenced by these conditions for improved accuracy.



Methods

Study Design

In this work, we tackled the challenge of older adult activity recognition, which is complicated by pose deformities and motion limitations in older adults. To address these issues, we proposed a heterogeneous spatiotemporal motion transformer with CAM, specifically designed for recognizing older adult activities. For model training, we collected a dataset with informed consent and ethical permission,  where, X_i consists of body key points, depth images, and CL information, while y_i represents the corresponding activity label, and N denotes the number of training samples. The objective is to learn a function $f: X \rightarrow y$ that accurately classifies activities. In this section, we provide a detailed explanation of our data processing, followed by an in-depth discussion of the CSTT transformer. The overall architecture is illustrated in Figure 1.

XSL•FO
RenderX

Figure 1. Care-assessment-aware spatiotemporal transformer architecture. This transformer enhances older adult activity recognition by integrating joint skeleton data, depth heatmaps, and CL information. The Spatial Transformer Block uses a care-aware attention mechanism, where the care level acts as a query to capture spatial relationships. The Temporal Transformer Block uses multihead self-attention to model temporal dependencies across frames. Finally, the Classification Layer processes the learned representations to predict activity labels using a fully connected network and softmax activation.

Data Collection and Validation Method

Overview

The dataset was gathered in partnership with Global Care, a care facility in Japan, dedicated to supporting patients with dementia, which is equipped with an in-house video-monitoring system. The camera used for the monitoring is the AXIS M3048-P [74], a cost-effective fixed dome fish-eye camera featuring a 12-megapixel sensor. This camera is designed to provide a comprehensive 360° view of the surroundings, with distortion-corrected display options such as panoramic views, specific areas, corridors, corners, and quad displays, all offering exceptional sharpness. Additionally, the camera comes prefocused, eliminating the need for manual adjustments. To maintain the authenticity of the care environment, we chose not to incorporate any additional sensors. In collaboration with the care facilities, we accessed their video recordings, which specifically captured activities of 51 older adult people. For dataset 1, data was collected from 28 elderly during lunch mealtime from 3 different sites over a span of 15 days. Each recorded session lasted between 30 and 60 minutes. Older adult participants' ages are ranging from 64 to 95 (mean 79.5) years. The placement of each participant was predetermined and managed by the staff of the care facility. To maintain the facility's natural workflow, our team provided no instructions or interventions. In site 2, as shown in Figure 2, patient 7 was assigned multiple positions, as their location was occasionally adjusted by the staff during certain sessions. This variation in positioning was carefully considered during the data processing phase to ensure the accuracy of the labels. For dataset 2, the other 23 participants' data were collected from open-gathering space of dining and living area in site 4 from 2 different floor. Participants are aged between 71 and 92 (mean 81.5) years. The data were collected over 15 days period through continuous 24 hours monitoring. The site layouts are given in Multimedia Appendix 1.

Due to the limitations in posture and mobility, the activities of older adult individuals differ significantly from those of healthy individuals. Similar activities may present with different postures depending on CL, while different activities might appear with similar postures across different CL groups. As a result, CL may infer crucial insights for older adult activity recognition. To address this, we have collected each older adult person's CL alongside the video data. The score was provided by the medical professionals based on assistance requirements in meal, bath, excretion, movement, and dress-up. These levels, ranging from 1 (minimal assistance) to 5 (maximum assistance), determine the extent of supervision and support required [75]. Table 1 shows the explanation regarding the CL. For easier understanding of the readers, we have categorized the CLs based on assistance requirements into low, mid, and high.

From the recorded videos, skeleton data and depth images were extracted for analysis. For the purpose of this study, only skeleton data, depth images, and care-related information were used, while RGB images were excluded from the analysis. In Table 2, baseline comparison is shown between the 2 collected dataset.

Comparing the components between the 2 datasets in Table 2, we found that gender, care assistance requirement, and data collection time are significantly different. The age does not have much variation because the target group of our research is 60 above to 100.

To highlight the necessity of incorporating care context with motion data for activity recognition, we used 2 similarity comparison approaches. The first involves calculating pairwise similarity among different CL groups, while the second focuses on comparing the pairwise similarity between low and medium CL groups for various activities. To compute similarity scores,

XSL•FO
RenderX

we used mean per joint angle difference (MPJAD), cosine similarity (CS), and histogram of oriented gradients (HOG) similarity. Detailed explanations of the score calculation methods are given in the following sections:

Figure 2. Model performance evaluation: the receiver operating characteristic curve illustrates care-assessment-aware spatiotemporal transformer's prediction accuracy across different activities (class 0: sitting, class 1: eating, class 2: stand up, and class 3: trying to stand up). ROC: receiver operating characteristic curve.

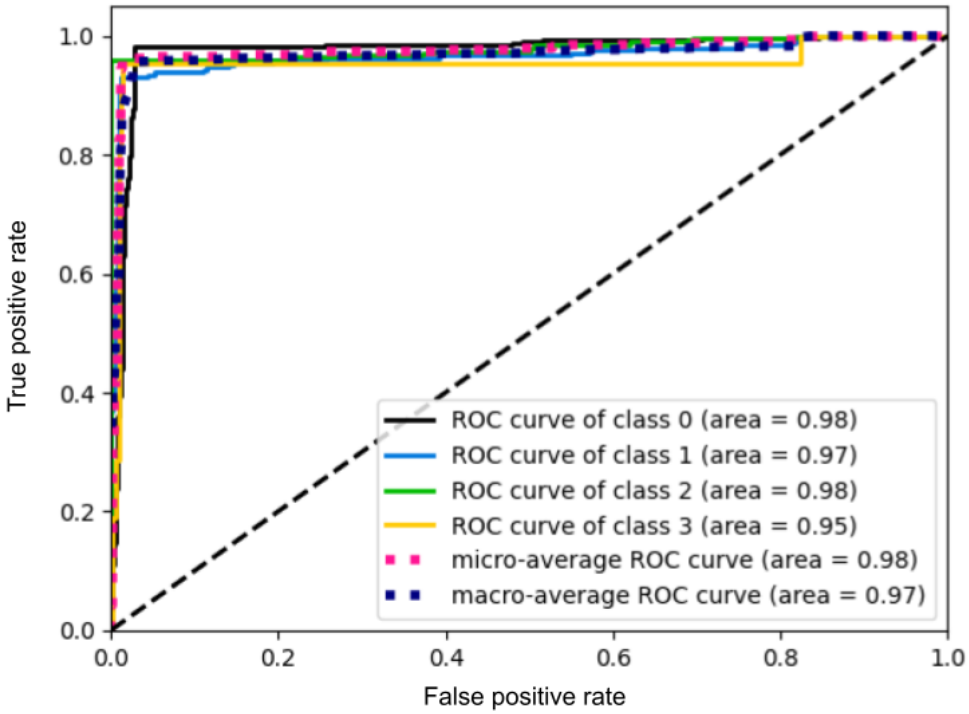


Table 1. Care-level interpretation for the older adult individuals.

AR[a]	CLs[b]	Older adult condition
Low	1 and 2	Older adult individuals in this group can move independently or with minimal aid. They sometimes require monitoring and reminders for meals, excretion, and baths. For dress-up, they sometimes need monitoring or partial assistance. They generally maintain an upright posture, with only minor stooping due to age-related spinal degeneration.
Mid	3	Older adult individuals at this stage require full support from caregivers for movement; however, they can stand up with the support of assistive devices. They require monitoring, reminders, and partial assistance for meals, excretion, and baths. For dress-up, they need full assistance. Posture is often characterized by forward leaning or hunching due to weakened core muscles and joint instability. Sitting may involve slumping as maintaining an upright position becomes difficult.
High	4 and 5	Older adult individuals at this stage require full support from caregivers for everything. They are predominantly immobile. Postural control is severely compromised. No standard posture can be seen.

[a]AR: Assistance requirement.

[b]CLs: care levels.

RenderX

Table 2. Baseline comparison between the datasets.

Components	Dataset 1	Dataset 2	*P* value
Age (years), mean (SD)	79.5 (8.95)	81.5 (6.06)	.35
Gender			
Men	10	20	<.001
Women	18	3	
Care assistance requirement			
High	6	1	<.01
Medium	8	18	
Low	14	4	
Data collection time (minute)	750	21,600	<.001

Mean per Joint Angle Difference

MPJAD measures the average angular difference between 2 motion sequences across all frames and joints. Given 2 motion sequences and , the MPJAD is computed as:

(1)

Where P is the set of all motion sequence pairs, M is the number of motion sequence pairs, T_{ij} is the number of frames common between sequences S_i and S_j, N is the total number of joints (17 in this case),  is the joint angle at joint k and frame t in sequence S_i, and  is the absolute difference in joint angles. A lower MPJAD value indicates a higher similarity between motion sequences. The 2 motions follow similar joint movement patterns. A higher MPJAD value indicates greater dissimilarity between motion sequences. The 2 motions have significantly different joint movements.

Cosine Similarity

CS measures the angle between 2 vectors in a multidimensional space. Given 2 motion sequences S_i and S_j, the CS is computed by following the steps:

Derive the cosine dissimilarity (used to measure homogeneity):

(2)

Where S_i and S_j are the flattened motion sequences represented as vectors. $S_i \cdot S_j$ is the dot product of the 2 vectors. $|S_i|$ and $|S_j|$ are the Euclidean norms (magnitudes). Compute the mean pairwise cosine dissimilarity within the class:

(3)

Where N is the total number of unique pairs (i,j) within the class. Lower values of cosine dissimilarity indicate higher homogeneity (motion vectors within the class are closely aligned). Higher values of cosine dissimilarity indicate lower homogeneity (motion vectors within the class are more divergent).

HOG Similarity

HOG measures how structurally similar 2 images are based on their gradient information. Once the HOG feature vectors H_1 and H_2 are extracted for 2 images, their similarity is computed using the CS formula:

(4)

Where $H_1 \cdot H_2$ is the dot product of the 2 HOG feature vectors. $|H_1|$ and $|H_2|$ are the Euclidean norms of the vectors. If the HOG score is 1, it means the images have nearly identical edge and gradient structures, and if it is 0, it means the images have no similarity in gradient structure.

Ethical Considerations

This work involved human participants or animals in its research. Approval of all ethical and experimental procedures and protocols was granted by the research ethics board at Kyushu Institute of Technology (application no. 24-15). No participant compensation was provided. The data are not publicly available but they would be shared with upon the collaboration request only for research purpose to the applicants who adhere to the ethical and privacy policy of the ethical committee after careful consideration.

Skeleton Data Generation

To ensure robustness, we used skeleton data in our study. To get the skeleton data we used YOLOv7 [76], a state-of-the-art real-time object detection framework that builds upon the foundational YOLO (You Only Look Once) [77] family, offering enhanced performance in terms of accuracy. It maintains high precision in both detection and key point localization, and the architecture can handle multiple scales and dense environments effectively. The input is an RGB image, $I_{RGB} \in R^{H \times W \times 3}$ where H is the height of the image, W is the width of the image, and 3 represents the number of color channels (ie, red, green, and blue). YOLOv7 identifies bounding boxes for human figures in the input RGB image. Each bounding box B_k is represented as $B_k = (x_{min}, y_{min}, x_{max}, y_{max}, c_k)$, where (x_{min}, y_{min})

XSL•FO
RenderX

and (x_{max},y_{max}) define the corners of the box and c_k is the confidence score. Within each bounding box, the model then predicts the locations and confidence scores for the 17 key points $X = \{X_1,X_2,\ldots,X_{17}\}$, where each key point X_i is defined as $X_i = (x_i,y_i,c_i)$, i$\in$ {1,2,…,17}. Here, x_i,y_i: 2D coordinates of the ith key point in the image and c_i: confidence score indicating the likelihood that the ith key point is correctly detected ($c_i \in$ [2]). So, the whole body can be represented as:

(5)

where the total key point feature vector has 34 dimensions (17 key points × 2 coordinates).

Depth Image Generation

Skeleton data are highly robust but fail to capture the environmental context. In contrast, RGB data often include excessive information, which can lead to confusion due to varying lighting conditions. However, depth images offer valuable spatial insights, providing detailed information about the distance and positions of objects and body parts. Therefore, we generated depth maps from RGB images and incorporated them into our study. To achieve this, we used the "Depth Anything" model [78], an advanced monocular depth estimation technique that transforms RGB images into depth maps. This model leverages deep learning (DL) to predict pixelwise depth values based on visual features in the image. Trained on extensive datasets of RGB-depth pairs, the model knows how to estimate depth using visual information alone. Each pixel in the image has 3 values corresponding to its red, green, and blue intensities. The goal of the model is to convert this 3-channel image into a depth map, where each pixel value corresponds to the distance from the camera to the object in the scene. Let f_θ represent the trained model that maps an RGB image IRGB to its predicted depth map D. The model was learned from large datasets containing paired RGB images and their corresponding depth maps during training. The depth estimation function is given by $D = f_\theta(I_{RGB})$. Then, each pixel of the depth map represents that the estimated distance to the camera can be denoted by

(6)

where (x, y) are the coordinates of the pixel in the image. The value D (x, y) represents the depth of the corresponding point in the scene.

Care-Assessment-Aware Spatiotemporal Transformer

Our proposed CSTT analyzes body key points, heatmaps, and CL to predict human activities in a personalized manner. As a spatiotemporal heterogeneous transformer, it captures spatial features (key points and heatmaps) and temporal dynamics (motion sequences over time) while integrating multiple modalities with distinct representations—numerical key points, image-based heatmaps, and scalar CL—through CAM. In the Spatial Transformer, key points and heatmaps are processed to extract movement-related features, with the CL serving as an attention guide, determining which body movements and heatmap regions are most relevant. This enables the model to dynamically prioritize motion patterns based on an individual's care needs. The Temporal Transformer then analyzes the sequence of spatial features, capturing motion dynamics over time. Learning temporal dependencies helps recognize activities and transitions between postures. Finally, the extracted spatiotemporal features are passed to a classifier, which predicts the activity category.

Spatial Transformer

The Spatial Transformer extracts meaningful representations from the key points and heatmap while considering the CL as a crucial guiding factor. The CL attends to the key points and heatmap, allowing the model to emphasize relevant body parts or movements based on the older adult person's health condition.

Feature Embedding

Overview

To transform the raw input data into a meaningful and structured format suitable for further processing, we used an embedding mechanism. This step is crucial as it converts different types of input data—body key points, heatmaps, and CL—into a shared latent representation that can be effectively used by the transformer model. By mapping these diverse inputs into a common latent space of dimension d, the embedding process ensures that the model can seamlessly integrate and compare information from multiple modalities, facilitating efficient learning and cross-modal interactions. There are 3 types of feature embedding done here as mentioned in the following sections.

Key Point Embedding

The 2D pose key points (17 joints, each with (x,y) coordinates) are flattened and passed through a linear layer:

(7)

Where $X \in R^{B\times17\times2}$ is the input key point tensor and $W_k \in R^{(17\times2)\times d}$ is the weight matrix, which learns spatial dependencies. $K \in R^{B\times d}$ is the key point embedding.

Heatmap Embedding

The heatmap (grayscale image of size 64 × 64) is processed through a 3D convolution layer to capture local spatial dependencies and activation patterns:

(8)

where, $D \in R^{B\times1\times64\times64}$ is the heatmap input. $H \in R^{B\times T\times d}$ is the heatmap embedding after convolution, where T represents the number of spatial patches.

CL Embedding

The CL (a scalar value) is passed through a linear layer:

XSL•FO
RenderX

(9)

Where $c \in R^{B\times 1}$ is the CL tensor and $Wc \in R^{1\times d}$ is the weight matrix. $C \in R^{B\times d}$ is the CL embedding.

Care-Aware Attention Mechanism

Overview

Unlike conventional transformer self-attention mechanisms that treat all inputs equally, our proposed CAM dynamically adjusts attention based on CL. Using CL embeddings as queries in a multihead attention mechanism prioritizes key body parts and movements. Key points and heatmaps form key value pairs, allowing the model to focus on relevant features. The attended features are refined through a feedforward network, enhancing learning. By explicitly integrating CL into feature learning, CAM improves interpretability and efficiency, making activity recognition more personalized and accurate. The entire process is depicted as follows:

Attention Score Computation

The traditional attention mechanism follows the scaled dot product attention formulation:

(10)

Here, we made the modification in the embeddings of Q, K, and V values. CL embedding $C \in R^{B\times 1\times d}$ is assigned to Q (Query). Concatenated Key point + Heatmap Features $[K,H] \in R^{B\times(T+1)\times d}$ is assigned to both K (Key) and V (Value). So the modified attention weights computation formula is:

(11)

This results in a weighted sum of key points and heatmap features, emphasizing relevant information based on the CL.

Multihead Attention

To enhance model expressiveness, we use multihead attention, where different heads capture different aspects of the input:

(12)

where each head performs attention independently, and the outputs are concatenated and projected using W_o.

Feedforward Network

After attention, the output is passed through a feedforward network:

(13)

This enhances the feature representation before passing it to the temporal transformer.

Temporal Transformer

The temporal transformer is designed to capture and model the sequential dependencies that exist across frames. Since traditional transformers do not inherently account for the order of sequences, we incorporate positional encoding to inject information about the temporal order of the frames, allowing the model to distinguish between the different points in time:

(14)

Where ρ is a constant eprecally calculated and the value of ρ is 10,000. The Transformer Encoder then applies self-attention across the temporal dimension, processing a sequence of spatial features Z_t obtained from various timesteps. This process is mathematically represented as:

(15)

Where $Z_t \in R^{T\times d}$ is the temporal sequence of spatial representations and  is the transformed sequence after passing through the encoder. Throughout this process, the model allows the frames to “attend” to one another, meaning each frame is evaluated in relation to others. This enables the model to capture the dependencies of motion, such as recognizing how a body part moves or changes over time, effectively tracking the progression of movement across frames. After the temporal sequence is processed, the features are aggregated using mean pooling to summarize the sequence of attended frames into a single fixed-size representation:

(16)

This pooled feature vector encapsulates the entire movement sequence, providing a compact yet informative summary. Finally, this aggregated representation is passed into a classifier for further interpretation, enabling the model to make predictions based on the captured temporal dynamics.

Classification

The final feature vector encapsulates the entire activity, providing a contextual representation of the movement. After the pooled feature vector is obtained from the Temporal Transformer, it is passed through a softmax classifier for classification:

(17)

In this equation, W_{cis} and b_{cis} are learnable parameters that the model optimizes during training. Specifically, W_{cis} is responsible for projecting the final feature vector into activity categories,

XSL•FO
RenderX

effectively mapping the feature space to the set of possible classes. The softmax function then assigns probabilities to each of these activity categories, indicating the likelihood of each class being the correct one.

Results

In this work, we have proposed a care-assessment-aware approach for older adult activity recognition. This section presents the validation results for our dataset and evaluates the model's performance. In addition, we have conducted an ablation study and provided a detailed discussion of the obtained results.

Dataset Validation

To assess the dataset and demonstrate the importance of integrating care context, we applied 2 similarity-based evaluation strategies. The first measures pairwise similarity across all care-level groups, shown in Table 3 and the second examines pairwise similarity specifically between the low- and medium-care groups for each activity, shown in Table 4. Similarity was quantified using MPJAD, CS, and HOG similarity.

From Table 3, it is evident that the movement patterns of eating and sitting activities in the high care assistance group differ significantly from those in the other 2 groups. Since individuals in this category are almost immobile, activities such as trying to stand up and standing up are absent. For the low and medium care assistance groups, we conducted a pairwise similarity analysis of activities, as we observed that the motion patterns of trying to stand up and standing up share some similarities and yet exhibit notable differences. From Table 4, we can see that, despite being different activities, certain motion patterns show a high degree of similarity. In particular, the pairs eating–trying to stand up and standing up–trying to stand up demonstrate strong similarities, which is uncommon in standard activity recognition scenarios. These findings confirm that care context plays a crucial role in older adult activity motion patterns. To strengthen our claim, we also analyzed motion patterns using a comparative group of young adults. Since the study primarily focuses on older adult participants, these additional results are provided in Multimedia Appendix 1 for reference. All these comparison results validate our claim that care information plays a significant role in accurately distinguishing activities.

Model Performance Evaluation

To evaluate the model's performance, we analyzed the attention weight matrix (AWM), the receiver operating characteristic curve, and the cumulative gain plot. The AWM in Figure 3 validates that the CSTT model efficiently integrates CL, body key points, and depth heatmaps through CAM. The model dynamically adjusts the importance assigned to different input features, demonstrating its ability to capture hierarchical dependencies. Notably, CL serves as a guiding factor, influencing how attention is distributed across other features. The receiver operating characteristic curve in Figure 2 evaluates the model's ability to distinguish activity classes by plotting the true-positive rate versus the false-positive rate. The area under the curve (AUC) values range from 0.95 to 0.98, indicating excellent classification performance. The microaverage AUC (0.98) reflects strong overall accuracy, while the macroaverage AUC (0.97) shows balanced performance across classes. Classes 0, 1, and 2 have the highest AUC values, ensuring clear separation, while class 3 (0.95) shows slight overlap but still performs well. The cumulative gain plot in Figure 4 highlights the model's ability to rank correct predictions early. The steep rise in curves shows effective prioritization. This confirms that the CSTT efficiently ranks true positives early, which is critical for applications needing confident and rapid classification.

We selected both machine learning and DL models as baselines to evaluate our approach. Table 5 presents the results with and without CL information, except for our model, where care context is essential when the data are benchmarked using a cross-day approach, applying an 80-20 train-test split. Machine learning models used only skeleton data, resulting in comparatively lower performance. However, adding just care context significantly improved all models' performance. Our model outperformed the traditional spatiotemporal transformer, achieving a 5% higher accuracy and a 9% increased F_1-score.

Ablation Study

In the ablation study, we removed components from the key and value pairs to analyze their impact. Also, we have randomly removed some key points to create partial skeleton data. We compared the traditional spatiotemporal transformer without the CAM layer, a care-assessment-aware transformer using only skeleton data (CSTT [S + C]), a care-assessment-aware transformer using only partial skeleton data (CSTT [Sp + C]), one using only depth images (CSTT [D + C]), our full model integrating partial skeleton data (CSTT [Sp + D + C]), and our full model integrating all (CSTT [S + D + C]). As shown in Table 6, CSTT (S + C) outperforms CSTT (D + C), aligning with the AWM analysis in Figure 3. Also, CSTT (Sp + C) performs poorly compared with others, but CSTT (Sp + D + C) performance is in the acceptable range. This shows that the model is comparatively robust.

Figure 3. Model performance evaluation: attention weight matrix demonstrates the effective incorporation of care level through care-aware attention mechanism in care-assessment-aware spatiotemporal transformer.

Deployment

All experiments were implemented using the PyTorch DL framework and executed on an NVIDIA RTX 4080 GPU. The models were trained with a batch size of 8, an initial learning rate of 0.001, a weight decay of 0.0005, and for a total of 25 epochs. The trained model achieved an inference speed of 0.0043 seconds per sample, with approximately 1.2 M parameters and 1.09 Giga Floating-Point Operations per Second, indicating high computational efficiency.

Discussion

Principal Findings

This study demonstrated that older adult activity recognition can be significantly improved by integrating care-level

XSL•FO
RenderX

information into model design. The proposed CSTT effectively captured variations in motion patterns caused by differing health conditions and care requirements. Results revealed that even for the same activity, movements differed across CLs, while visually similar motions appeared in distinct activities (eg, eating vs trying to stand up). Despite class imbalance and naturally occurring variations, CSTT achieved high recognition performance. Misclassifications—such as confusion between eating and sitting—were primarily linked to overlapping movements during caregiver assistance. These findings validate that incorporating care assessment information enables more robust, context-aware, and personalized activity recognition, aligning closely with real-world monitoring needs in long-term older adult care environments.

Care-Assessment-Aware Older Adult Activity Recognition

Older adult activity recognition presents unique challenges due to the pose deformities, motion limitations, and variations in mobility caused by differing health conditions. Traditional HAR models often fail to capture these subtleties, as they are designed primarily for younger, healthy individuals and do not incorporate health-related variations. Furthermore, existing HAR approaches used for monitoring predominantly rely on RGB-based methods or, to a lesser extent, skeleton data, both of which struggle with computational efficiency and real-time applicability in older adult care environments. Our goal is to develop a context-aware HAR model that integrates CL assessments with motion data for personalized and accurate older adult activity recognition. To achieve this, we introduced CSTT, a heterogeneous spatiotemporal motion transformer incorporating skeleton data, depth-based heatmaps, and CL information, with CAM for improved adaptability. To ensure that the model captures real older adult activity patterns, we collected a motion dataset with CL annotations, recording uninterrupted mealtime sessions in a care facility for greater ecological validity. For model training, we focused on 4 key activities: eating, sitting, trying to stand up, and standing up. These were selected based on real nursing challenges—monitoring whether individuals are eating or sitting idle (requiring intervention if necessary) and ensuring continuous supervision during standing attempts to prevent falls. Unlike controlled datasets, our activity selection reflects real-world monitoring needs, capturing long-range dependencies in continuous time data, which aligns more closely with practical older adult care scenarios.

Performance of Care-Assessment-Aware Older Adult Activity Recognition

The results in Tables 3 and 4 support our initial hypothesis that older adult activity recognition differs from conventional methods, as their motion patterns are heavily influenced by their health conditions. Even for the same activity, movement can vary significantly across different CLs, while similar motion patterns may appear in completely different activities (eg, eating and trying to stand up). Our data collection was conducted without intervention to preserve real-world conditions. However, the dataset is highly imbalanced, particularly for the “trying to stand up” activity, which has significantly fewer samples than the other 3 classes. This reflects real-world scenarios but presents a challenge for recognition models. From Figure 5, the prediction accuracy for this class is 0.95, which is slightly lower than others. Among all classes, “eating” has the lowest accuracy at 0.93. Examining the confusion matrices provides insights into this misclassification. In Figure 6, eating is frequently confused with sitting, which is reasonable since caregivers often assist older adult individuals, reducing distinct motion patterns between these activities. In Figure 7, eating is often mistaken for trying to stand up, likely because older adult individuals extend their hands and lean forward for support when getting up—movements similar to hovering over a tray to pick up food. However, as seen in Figure 8, low care assistance individuals do not exhibit such overlapping movements, leading to perfect recognition of the eating activity. Based on overall performance, our model successfully outperforms the baselines.

Current Limitations and Future Work

Although our dataset reflects real-world scenarios, it remains imbalanced, with activities such as “trying to stand up” having fewer samples. This affects classification accuracy (Figure 5), where “trying to stand up” achieves 0.95 and “eating” the lowest at 0.93 due to motion similarities, especially with caregiver assistance. We did not apply any data imbalance handling techniques, as “trying to stand up” naturally occurs less frequently in real-world settings. We did not apply data augmentation to address class imbalance because in older adult care monitoring, maintaining natural motion patterns and ecological validity is crucial. In cases of severe imbalance, augmentation risks producing unrealistic or biased samples, distorting class distributions, and leading to overfitting to synthetic data. The absence of CL annotations in existing datasets restricted direct comparisons with previous older adult HAR approaches. Although we manually annotated CLs for the ETRI Activity3D and Toyota Smarthome datasets to enable comparison, the potential inaccuracy of these inferred labels and the no representation of high-assistance older adult groups led us to include these results in Multimedia Appendix 2 rather than in the main manuscript. Future work will focus on

XSL•FO
RenderX

annotating CLs in public datasets with medical professionals for comparative analysis. Due to ethical restrictions, our dataset cannot be publicly shared but may be accessed through collaboration. To support replication, we provide references and guidelines for collecting similar datasets with integrated CL information. Since our model depends on accurate CL assessments, misclassification can impact recognition, emphasizing the importance of expert collaboration in dataset development.

Conclusions

In this work, we address the challenge of older adult activity recognition by considering the variability in movements influenced by CLs, which is often overlooked in existing datasets. To overcome this, we introduced a novel older adult motion dataset that includes CL information, collected from 51 older adult participants during real-world mealtime sessions in an ethical and privacy-preserving manner. We proposed CSTT, a spatiotemporal heterogeneous transformer model that integrates body key points, heatmaps, and CLs to predict activities in a personalized way by dynamically adjusting attention based on CLs. Our model surpassed the conventional spatiotemporal transformer, achieving a 5% higher accuracy and a 9% improvement in F_1-score, highlighting the significance of incorporating CL data. However, limitations include dataset imbalance and the inability to compare with similar works due to a lack of comparable datasets, as well as ethical restrictions on sharing the dataset. In conclusion, our work lays the foundation for more accurate, context-aware older adult activity recognition, with future research focusing on dataset expansion, model refinement, and real-world applications in care settings.

Abstract

Background: Artificial intelligence (AI) has the potential to improve health among older adults, yet how different stakeholders decide to develop, finance, and adopt AI innovations is not well understood.

Objective: This study aimed to understand the decision-making of different stakeholders regarding AI and technologies for the health care of older adults.

Methods: We conducted semistructured interviews with 15 older adults and care partners, 15 clinicians, 8 health system or insurance leaders, 5 investors, and 6 technology developers. Data were analyzed using thematic content analysis.

Results: All stakeholders considered cost, value, and usability important in adopting AI health technologies but emphasized different aspects of each concept. Older adults and care partners prioritized out-of-pocket costs and ease of use, whereas payers emphasized disease prevalence and implementation feasibility. Developers and investors focused on profitability and scalability, resulting in tension with end users' priorities. Participant suggestions included problem-driven design, greater stakeholder engagement, public-private partnerships, and educating older adults about AI.

Conclusions: As with prior health-related technology innovations, aligning decisional priorities across stakeholders is critical to motivate impactful AI health technologies for older adults.

KEYWORDS

artificial intelligence; AI; novel technology; older adults; decision-making; artificial intelligence adoption; AI adoption; usability; technology acceptance model; perceived usefulness

Introduction

AI and novel technologies offer tremendous potential for improving the health of older adults. They are becoming an important focus for technologies that facilitate aging in place, reduce care partner burden, and improve health system efficiency [1-3]. AI, which uses various approaches to simulate human intelligence and behavior, has increasingly been used in health care, often paired with other digital health tools such as wearable sensors, smart home devices, virtual assistants, and robotics [4,5]. For example, wearable sensors combined with AI algorithms can monitor functional status, sleep patterns, and mobility to detect early signs of cognitive or physical decline in community-dwelling older adults [6-8]. AI-enabled robotics with autonomous navigation, multimodal sensing, and assistive manipulation capabilities improve health care efficiency by continuously monitoring patient function, supporting clinical workflows, and reducing preventable hospitalizations for older adults [9-11]. Despite these advancements, the broad adoption of such technologies remains limited.

The literature has examined facilitators of and barriers to general technological adoption by end users, including older adults, care partners, and clinicians [12-15]. These factors, such as perceived usefulness, ease of use, trust, cost, privacy concerns, and social support, are key determinants of technology acceptance in older adult populations [16-19]. The findings have been synthesized in conceptual frameworks that describe the key influences in technology adoption. A commonly used framework is the technology acceptance model (TAM) [20]. The TAM proposes that individuals' acceptance and use of a technology are primarily determined by 2 key factors: perceived usefulness and perceived ease of use [16]. Subsequent extensions of the TAM have also emphasized additional contextual factors, including trust, cost, privacy, and organizational support, that may influence technology adoption in health care settings [14,16]. Some recent studies have examined attitudes toward and acceptance of technology that can be paired with AI, such as wearable devices and robots [12,14,21,22]. However, we did not find studies that specifically examined how key stakeholders made decisions about AI health technologies designed to improve the care of older adults. We also did not find perspectives on how health system leaders and payers consider technology adoption and how investors and developers consider the decision of what technological products to develop and finance. As health system payers, investors, and developers are responsible for making novel health technologies available, understanding their decision-making in conjunction with that of the end users is critically important.

To address the above-mentioned knowledge gaps, we conducted a qualitative study to explore the perspectives of different stakeholder groups—older adults, care partners, clinicians, payers, investors, and technology developers—regarding their decision-making on the development, financing, and adoption of AI and novel technologies to improve the health of older adults. We aimed to identify areas of consensus and potential differences to help understand how to align stakeholders' key drivers of decision-making to accelerate the implementation of impactful technologies for the health and well-being of older adults.

Methods

Design, Study Setting, and Participant Recruitment

We chose to use qualitative semistructured individual interviews to explore stakeholder perspectives. This project is part of a larger study in which we also explored stakeholder perspectives on priority areas for AI applications, perceived benefits of and concerns about AI, and educational needs; these results have been reported previously [23,24]. In this paper, we report stakeholder perspectives on decision-making on the development, financing, and adoption of AI applications in the care of older adults. This study focused on stakeholders, including older adults (defined as those aged 60 years or older) and care partners for older adults (via self-report); clinicians; health system or health insurance leaders involved in technology adoption, such as the chief information officer (hereafter referred to as "payers"); and investors and technology developers. We combined older adults and care partners in the same group as many older adults were or had been care partners.

This project was supported by the Johns Hopkins Artificial Intelligence and Technology Collaboratory (JHU-AITC) for Aging Research [25]. The Stakeholder Engagement Core within the JHU-AITC engages longitudinally with a stakeholder council of older adults, care partners, and clinicians from Maryland and Iowa. We recruited older adults, care partners, and clinicians via referrals from the study team and council members; we recruited payers, investors, and technology developers via referrals from the study team, JHU-AITC colleagues, and the coordinating center that supports artificial intelligence and technology collaboratories. We also used snowball sampling to recruit contacts of existing participants. Recruitment continued until information saturation was reached.

All participants needed to be English speaking and be able to provide informed consent. Each participant was offered a US $50 gift card.

Interview Guide

The interview guide was developed by the study team, which included expertise from engineering, business development, patient engagement, geriatric medicine, and social and behavioral science. We defined AI as "technologies where machines try to do what human beings do" and described that there were many types of AI applications, such as alerts, sensors, prediction algorithms, or robots. For older adults, care partners, clinicians, and payers, we asked how they decided whether to use an AI product; for investors, we asked how they decided to invest in an AI product; for developers, we asked how they made decisions on what type of AI product to work on or move

XSL•FO
RenderX

forward with in development. The full interview guide is available in Multimedia Appendix 1.

Data Collection and Analysis

Three team members (NLS, KC, and JM) conducted interviews in person (at private workspaces) or virtually from May 2023 to January 2024. All 3 team members had prior qualitative research experience. One team member (NLS) had prior working relationships with some of the clinician participants.

Interviews were audio recorded and transcribed verbatim; the average duration of the interviews was 34 (SD 11) minutes. We collected demographic information from all participants. For older adults and care partners, we collected information about education, financial strain, health literacy, self-rated health, and duration of caregiving. For clinicians, we asked about their practice setting. For all other participants, we asked about their professional roles and the duration working in that role.

We analyzed interview transcripts using reflexive thematic analysis informed by the approach by Braun and Clarke [26] to identifying, analyzing, and reporting patterns of meaning across qualitative data. This method was appropriate because our study aimed to examine how different stakeholder groups described decision-making on the development, financing, and adoption of AI health technologies for older adults. Consistent with the guidance from Braun and Clarke [26] on good practice in thematic analysis, we used an iterative analytic process that emphasized methodological clarity; reflexive engagement with the data; and alignment among the research questions, analytic procedures, and resulting themes.

To code the transcripts, we used thematic analysis with an integrated approach that used both inductive coding and a deductive organizing framework that drew conceptually from the TAM [16,20]. Specifically, a codebook was developed based on the interview guide and revised iteratively to add new codes generated inductively based on the review of 9 randomly selected transcripts. We organized the codes, when applicable, by domains in the TAM and compared our findings to the TAM during the interpretation of the results. Each transcript was independently coded using the finalized codebook by at least 2 investigators (NLS, KC, and JM), and differences were reconciled through consensus. The investigators involved in the analysis had training in clinical general or geriatric medicine, health service research, and/or qualitative research. Results were summarized into major themes and illustrated via representative quotes. Analysis used the ATLAS.ti software (version 24; ATLAS.ti Scientific Software Development GmbH).

Reflexivity was addressed throughout data collection and analysis. The study team included members with expertise in engineering, business development, patient engagement, geriatric medicine, and social and behavioral science, which allowed for multiple disciplinary perspectives to inform interpretation. At the same time, our team recognized that these professional backgrounds, as well as prior relationships with some participants, could shape data collection and interpretation. To address this, the team discussed emerging interpretations, considered alternative explanations, and examined how researchers' assumptions and disciplinary perspectives may have influenced theme development.

Several strategies were used to enhance trustworthiness. Credibility was supported through independent coding by multiple investigators and consensus discussions using transcripts. Dependability was strengthened by maintaining documentation of analytic decisions, including codebook revisions, coding discussions, and theme refinement. Confirmability was supported through team-based reflexive discussion and by grounding interpretations in the data rather than a priori assumptions. Transferability was supported by describing the study sample, stakeholder groups, recruitment approach, interview procedures, and analytic process in sufficient detail to allow readers to assess the relevance of the findings to other settings and populations.

Ethical Considerations

This project was approved by the Johns Hopkins Medicine Institutional Review Board (IRB00356437). The reporting of this study followed the COREQ (Consolidated Criteria for Reporting Qualitative Research) reporting guidelines [27]. Consent to participate was obtained for this project, and it adheres to human ethics guidelines. This study used deidentified data and posed minimal risk to participants.

Results

Participants

The 49 participants included 15 (30.6%) older adults or care partners, 15 (30.6%) clinicians, 8 (16.3%) payers, 5 (10.2%) investors, and 6 (12.2%) technology developers (Table 1). The older adult group had a mean age of 71.3 years; 60% (9/15) of the older adults reported caregiving experience. Clinicians comprised physicians, nurses, pharmacists, rehabilitation therapists, and a dentist. Most of the older adult or care partner participants (14/15, 93.3%) and all the clinician participants (15/15, 100%) were from Maryland and Iowa, whereas payer, investor, and technology developer participants were from 9 different states.

[a]Washington, DC.

[b]Colorado, Florida, Massachusetts, and Minnesota.

[c]California, Massachusetts, Virginia, and Washington, DC.

[d]Not asked for these participants.

[e]Financial strain was assessed using the following question: “During the last year, were there any times when you did not have enough money to pay rent or utilities or medical bills?” The response “yes” was counted as having self-reported financial strain [20].

[f]Low health literacy was assessed using the following question: “How confident are you in filling out medical forms by yourself?” Responses of “somewhat,” “a little bit,” and “not at all” were counted as low health literacy [14].

Themes

Three themes emerged from the interviews. First, stakeholders across groups identified cost, usability, and value as key considerations when making decisions about AI health technologies for older adults, although the meaning of these concepts differed by stakeholder group. Second, these differing

XSL•FO
RenderX

interpretations contributed to tensions between end users (older adults, care partners, and clinicians) and those responsible for developing and financing technologies (investors and developers), particularly regarding affordability and the design process. Third, participants described several potential strategies to better align stakeholder priorities and support the adoption of AI technologies for older adults. We describe each of the 3 themes below in detail.

Theme 1: The Value of AI Meant Different Things to Different Stakeholders

Overview

We found that all key stakeholders viewed cost, added value, and usability as important when considering AI health technologies for older adults, but each stakeholder group had different considerations within each concept. Although cost, value, and usability have been previously described as important to technology adoption in the literature, here, we contextualize each by stakeholder group and highlight that the same words encompass vastly different considerations (Table 2).

Table 2. Perspectives across stakeholder groups on cost, value, and usability when making decisions about AI health technologies for older adults.

	Consideration	Illustrative quote
Cost and value		
Older adults and care partners	Patient's out-of-pocket cost	"Price would be a barrier." [Older adult 5]
Clinicians	Patient's out-of-pocket cost	"Many older adults are on fixed incomes.... The group of older adults that probably need what AI might be able to deliver are just not going to have finance to do that." [Clinician 1]
Payers	Health system cost for purchasing, integrating, and maintaining the technology relative to health system savings from improvement in clinical outcomes	"...what are the things that improve quality outcomes and decrease cost." [Payer 2]
Investors and technology developers	Return on investment	"Bluntly, can you make money off of this?" [Investor 1]
Usability		
Older adults and care partners	Ease of use for older adults	"It has to be user-friendly. It has to be simple...accommodate slow fingers, eyes that don't see so well and ears that don't hear so well." [Older adult 4]
Clinicians	Ease of use for older adults and for clinicians	"If it's too complex then it makes it harder for our staff to use it and it becomes cumbersome." [Clinician 9]
Payers	Compatibility with existing health system	"It's the integration into the workflow and the health system that's important.... We were looking at a product that...I said, 'come back to us when [it'll] exist inside our electronic health record.' Because it just doesn't work well with the workflow." [Payer 8]
Investors and technology developers	Usability needs across other stakeholder groups	"You have to think like a doctor...about the healthcare need and impact of your project...then there are the technical and engineering type of things you have to think about...there's also the business related things...commercialization, finance, competition...and the actual implementation." [Technology developer 5]

Subtheme 1a: Cost and Value

Older adults, care partners, and clinicians made similar comments focused on the patients' out-of-pocket costs, and most were concerned about affordability. However, some commented on being willing to take on the cost if the technology offered sufficient value; one older adult said the following:

> *What is the return on investment? I'd rather go without some food if this type of technology could help me.* [Older adult 1]

Payers considered cost and value as a balance among the upfront cost of the technology to the health system or insurance plan, the expected improvement in clinical outcomes, and the potential savings from those outcome improvements. As such, payers commented that they were more likely to invest in technology that targeted high-cost or high-frequency health events. One payer said the following:

> *Rare event, but very detrimental and/or costly to the health system...something we really want to try to avoid, [we'd] make the investment there. Something that maybe doesn't have on an individual basis a lot of impact but is very common like hypertension, [we'd] make the investment there.* [Payer 8]

Payers also considered indirect costs required for supporting the technology:

> *If I have technology that we've acquired that I then need to hire an employee to interface with. Even though [the technology] is reimbursed, do I get enough reimbursement to hire the people? People*

XSL•FO
RenderX

> *are expensive, so I really need a massive return on investment to justify it.* [Payer 8]

Investors and technology developers considered cost and value as the magnitude of return on investment, which in turn included consideration of the potential market size for a given technology and whether the revenue stream for the technology would be directly from consumers or from insurance reimbursement. One investor said the following:

> *Who's going to pay for this and is the market large enough?* [Investor 1]

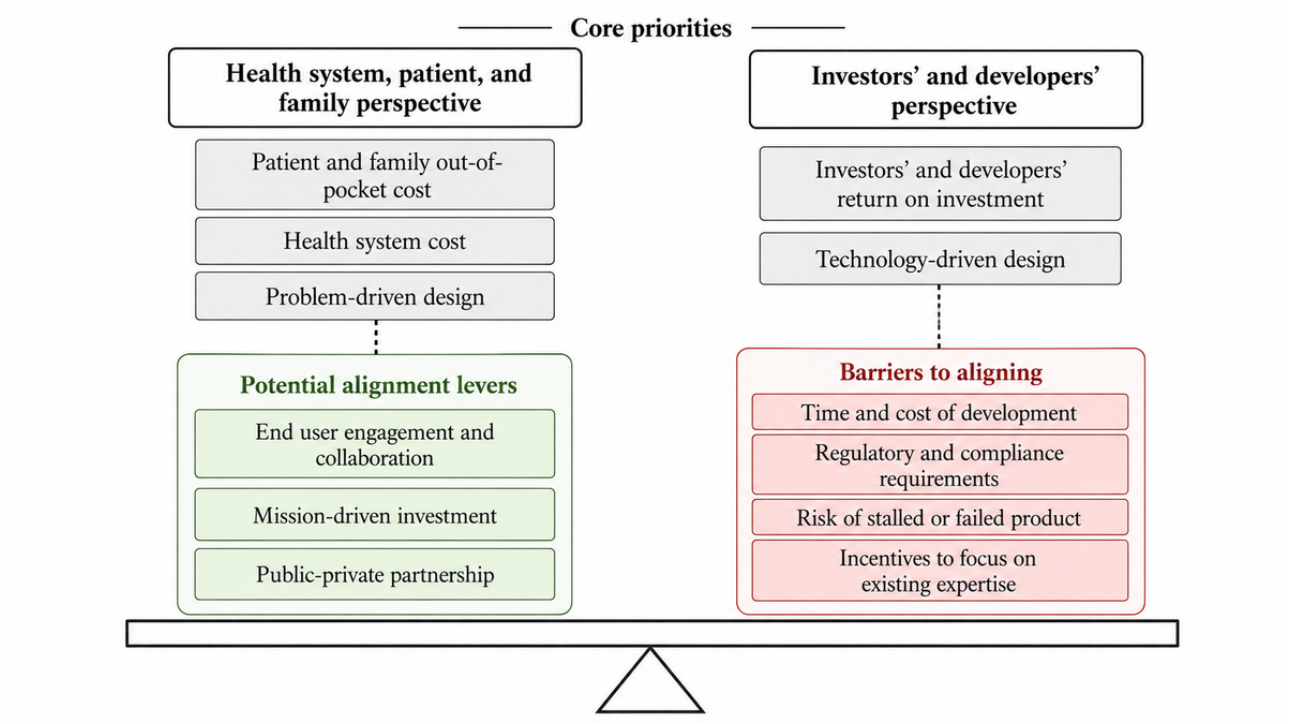
Subtheme 1b: Usability

Similarly, all stakeholder groups agreed on the importance of technology being easy to use, but they had distinct ideas on what that meant (Table 2). Older adults and care partners commented on technology being user-friendly and adapted to the needs of older adults who may have physical, sensory, and/or cognitive impairments. One older adult said the following:

> *Artificial intelligence can do many things, but it must be as simple as possible, and it must be user-friendly. If there's an awful lot that has to be learned by the person dealing with the artificial intelligence, it defeats its purpose.* [Older adult 4]

Clinicians considered the technology's user-friendliness to patients as well as to clinicians, especially in light of the existing clinical demands. One clinician said the following:

> *It has to be really user-friendly for me to be able to use it.* [Clinician 9]



Another commented that "it has to be simple enough" (clinician 2), especially for clinicians who may already be burned out. Payers also commented on user-friendliness for clinicians but were more concerned about the ease of integration with existing systems. Finally, investors and developers commented on the complexity of trying to understand each stakeholder group's needs and expectations. One investor talked about an AI technology that was designed to help clinicians generate message responses to patients:

> *...it's like a quagmire of validation [with each group].... We talk to physicians...we talk to their staff...we talk to patients, do they like receiving automated AI response?... Then there's IT security issue.... We have to work with [the electronic health record vendor]..., and we are talking to payers to understand...if we were to bill for this, are you going to accept charges of an AI.* [Investor 1]

Theme 2: Tensions in Decision-Making Priorities

We observed tension between the decision-making priorities of the end users (eg, older adults, care partners, and clinicians) and those of the developers and investors. The decisional factors that were important to end users were at times in conflict with those that were important to investors and developers. Two areas of tension included the affordability of the technology and the design process (Figure 1).

Figure 1. Two identified tension areas between the decision-making priorities of end users and investors and developers were related to cost considerations and the design process. Suggested facilitators of aligning priorities are depicted in green, and existing barriers to aligning priorities are depicted in red.

As stated above, older adults, care partners, and clinicians valued low cost (ie, "costs should be kept as minimal as possible" [older adult 3]). On the other hand, investors and developers commented on multiple considerations in the development process that drive up cost due to the significant risk and the long time horizon involved in developing AI health technologies. Both investors and developers commented that direct-to-consumer products are much higher risk:

XSL•FO
RenderX

> *...consumer investments are very high risk, especially at early stages.* [Investor 4]

However, the alternative involves more regulatory cost and time:

> *...if you decide to go through the prescription route [where] you hope it becomes insured. The cost just balloons, it can be two, three, ten times more expensive...because the [medical device] industry is so conservative...you have to go through a lot of red tape to get it to market.... You are looking at 4 or 5 years to get from napkin sketch to through the FDA.* [Investor 4]

A developer commented the following on a recent publication looking at novel medical devices:

> *...after going through the FDA, which [is] very difficult, on average they had to wait 7 years for insurers to cover their technologies...and 44% didn't even get coverage at all.* [Technology developer 5]

The investment risks and the long wait, in turn, drive up cost:

> *...when you have odds like that for novel technologies...investors are going to ask for a big return because the risk is so high. You can't wait 10 years for a return on something without [the profit] being massive.... There are these huge pressures that drive cost up.* [Technology developer 5]

A second area of tension was regarding the design process for novel technologies. All stakeholder groups agreed that AI health applications should be designed after first understanding the target users and the health problem. However, many commented that, often, they saw the reverse—that existing technologies were offered to older adults even when they were not the most suitable solutions. One older adult said the following about health technology:

> *[It feels like] they are designing solutions in search of a problem.* [Older adult 1]

One engineer said the following:

> *I think the vast majority of engineers are coming from a place where we have a solution already and we think it might apply to this problem. Because that's by far easier.... It's very difficult to come from a purely problem-oriented perspective...even though I think that's ideal.* [Technology developer 5]

Another AI researcher commented on the incentive structure being a barrier to problem-driven design:

> *We have incentive structures to improve on what we already have in our areas of expertise, rather than pursuing new problems and things that may not work. For example, the geriatric population is not extremely well studied from an AI perspective.... It's much more risky for a researcher to start in the geriatric population and try to come up with a problem that fits AI than to take the AI and fit it to the geriatric population.* [Technology developer 2]

Theme 3: Promising Trends and Suggestions for Aligning Priorities

Subtheme 3a: Public Education About AI Health Technologies

Promising trends and suggestions can help enhance adoption and align decision-making priorities regarding AI health technology for older adults. Participants commented that older adults may not be sufficiently aware of AI health technology to recognize its value and that better promotion and public education are needed. One older adult said the following:

> *People need to do a much better job in educating the public on what AI really means and what AI can really do.* [Older adult 15]

An older adult suggested education through health care providers:

> *When they go into the doctor's office, they [can] have information about AI, how it can help.* [Older adult 10]

Another older adult talked about leveraging television shows to change cultural norms:

> *...a lot of people watch the soaps and regular TV, if those characters are using technology...it's going to make it more acceptable.* [Older adult 4]

One payer commented on more patient-friendly descriptions of AI:

> *The terminology of AI is not a natural, comfortable, or welcoming description for seniors. I think it's confusing, threatening, and it doesn't really get to the fact of helping you.... I would strongly recommend [improving] how we describe this new technology.* [Payer 4]

Subtheme 3b: Multi-Stakeholder Engagement and Problem-Driven Design Are Vital

Participants commented on the importance of engagement and collaboration to better understand the needs and expectations across stakeholder groups and approach technology design with a problem-driven mindset (Figure 1). All stakeholder groups commented on the importance of engaging older adults, care partners, and clinicians in the development of novel technologies. Several investors commented that they now used stakeholder engagement as a metric in evaluating potential projects:

> *...all good startup should be talking to their stakeholders before they even start developing a product...so we [ask]...how many people have you chatted with? What kind of feedback did they give?* [Investor 3]

Going beyond unilateral engagement from developers to end users, several participants also commented on the importance of collaboration and active participation from the public and clinicians. One payer who was also a clinician advocated for clinicians to be involved in technology development:

XSL•FO
RenderX

> *I wish more physicians realized the central place that software takes in our care, and realized that you can be just as much a physician designing a [health] application as you can on the wards.* [Payer 6]

Subtheme 3c: Public-Private Partnerships May Reduce Cost Barriers

Finally, participants commented on trends and suggestions to help align cost expectations for new technologies (Figure 1). One investor commented that some investors are willing to accept less profit because they are passionate about older adults and improving their health:

> *...there are...founders who don't care about the money part as much, and they are really passionate about a certain idea.... Maybe they had a family member that went through the same thing and they really want to solve this issue.* [Investor 3]

Another commented on public-private partnerships that can help align incentives:

> *...the economics may not be there to develop a solution for this...group, but if you can de-risk the research and development costs, [which] is the whole premise of the federal government funding, then it changes the dynamics for commercialization of those ideas.* [Investor 1]

Discussion

Principal Findings

This is the first study, to our knowledge, to examine decision-making related to AI technology development, financing, and adoption across diverse stakeholder groups. While previous research and frameworks such as the TAM have broadly acknowledged that cost, usability, and perceived value are significant determinants of technology acceptance by end users [28], this study adds depth by demonstrating how these concepts hold varied and nuanced meanings among stakeholder groups. In general, older adults and clinicians shared similar perspectives as end users, whereas investors and technology developers shared similar perspectives as those responsible for bringing about innovation; payers tended to have distinct perspectives from those of the other groups as they focused on broader, system-level concerns. The findings on the tension areas between decision-making priorities across stakeholder groups are also novel, drawing attention to factors in the existing technology development process that contribute to competing priorities.

How the different stakeholders viewed cost, value, and usability is consistent with what has been reported regarding other health technologies, but these have usually been reported *separately* and in different fields of study. For example, older adults, care partners, and clinicians primarily interpreted cost in terms of affordability, which has also been shown in studies on patient behavior regarding adoption of health care technologies [17,29]. Payers framed cost and value in terms of return on investment through reduced costs associated with high-frequency or high-severity clinical outcomes, a viewpoint common in the health care economics literature [30,31]. Investors and technology developers interpreted cost and value through the economic lens of market viability and profitability [32]. Our study design offering a juxtaposition of perspectives is a strength. A comparison of stakeholder perspectives has been described in the adoption of other technologies, such as patient portal use, but has focused on implementation without including the perspectives of developers or investors [18,33].

Recognizing that the same words and labels (eg, "cost" or "usability") represent different concepts to different stakeholders can help entrepreneurs and technology developers be more considerate and specific in the design process to meet stakeholder needs. More specific descriptions of these considerations may help highlight their importance. For example, instead of cost and usability, it may be more helpful for developers to recognize that older adults value products that are affordable and easy to use for individual users, whereas payers value technology that reduces health care costs and is easy to implement within an existing health care system. Similarly, funders of AI health technology research can evaluate proposals with metrics that are inclusive of different stakeholder viewpoints, for example, ensuring that a project addresses both individual usability and ease of health system–level implementation.

AI is unique in that the same underlying product can be used in multiple contexts. For example, large language models can be a direct-to-consumer tool (eg, ChatGPT) or a clinician-facing decision support system (eg, OpenEvidence). In contrast, prior health technologies such as patient portals have much more defined and stable target users. AI's adaptability means that the target user can shift after a product has already been developed and deployed. This has important implications for stakeholder alignment: the cost, usability requirements, accountability structures, and regulatory pathways may differ substantially depending on the target user. This flexibility creates both opportunity, allowing products to find their highest-value use case, and risk as it can obscure whose needs the technology was actually designed to serve.

Considering multiple perspectives together revealed critical tensions between end users (older adults, care partners, and clinicians) and technology creators (developers and investors). These tensions, particularly regarding affordability and design processes, signal significant barriers to wider adoption of patient-centered, impactful AI technologies for older adults. AI operates within a uniquely heterogeneous regulatory landscape where AI health applications can enter the market through multiple channels [34]. Some can be marketed directly to consumers as wellness products, which are subject to minimal regulatory oversight, whereas others may be considered medical devices that need to meet rigorous requirements before approval by the Food and Drug Administration [35]. Investors and developers highlighted factors in both pathways that contributed to tensions regarding affordability and design of AI health applications, including that direct consumer-facing technologies posed substantial financial risks whereas regulated products faced significant regulatory hurdles and lengthy approval timelines. The related incentive misalignments favor incremental enhancements to existing technologies over exploratory

XSL•FO
RenderX

problem-driven innovations addressing complex issues in older populations, which is a phenomenon that has also been reported in more traditional medical device development [35]. Indeed, the current health technology development infrastructure may very well inadvertently motivate high-cost products that are "solutions in search of a problem," and our results highlight the need for change.

Potential changes may include a revised or new regulatory and approval pathway for AI health technologies that is better tailored to the specific risks involved. Another change may involve altering the incentive structures, at least in research environments with a mission of discovery, to motivate problem-driven design and exploration of new ideas over honing existing expertise. We also identified actionable suggestions to facilitate adoption and align decision-making priorities from participants. Closer engagement across stakeholder groups throughout the development process was suggested by participants as one key solution to problem-driven design, which has also been reported in prior literature [12]. However, for older adults and clinicians to be interested and willing to engage, there first needs to be better public education and awareness campaigns to demystify AI and make clear its potential benefits. Participants suggested specific approaches for educating older adults about AI, such as through health care providers as well as media and cultural norms. Participants also suggested including stakeholder engagement as an explicit criterion for investment or funding, which can enhance accountability. Another suggestion by participants identified financial models such as public-private partnerships to balance cost considerations across stakeholders. The JHU-AITC is an example of one such partnership where public funding is awarded to promising pilot AI projects in very early development to help them advance to a stage where they can successfully attract private investment. Finally, it may be important to learn from other countries and health care models in terms of how they approach stakeholder engagement in AI health application development.

We acknowledge that our study has limitations. First, our participants were only restricted to English speakers, which may limit the generalizability of our findings to non-English speakers. Second, most older adult, caregiver, and clinician participants were based in Maryland and Iowa in the United States, which may limit geographic transferability. However, the inclusion of Iowa residents allowed us to obtain perspectives from rural residents and clinicians, where technology adoption is often delayed or limited. Third, several stakeholder groups lacked gender and racial diversity. For instance, all investor and technology developer participants were male. We did not assess prior experiences and familiarity with AI among our participants. Our future work should build on these findings through larger surveys with more diverse and representative samples across stakeholder groups.

Conclusions

In sum, we found that, across diverse stakeholder groups, the concepts of cost, usability, and value were considered universally important but had different meanings across different groups. This finding can help inform future research and technology development by highlighting that different elements of cost, usability, and value need to be separately considered and evaluated to meet the needs of diverse stakeholders. We also found competing decision-making priorities among different stakeholder groups when considering AI health applications for older adults, especially between those responsible for making new AI technologies available and the end users of such technologies. Implementing participant suggestions and other strategies to better align these priorities is essential for ensuring the widespread adoption of patient-centered, impactful AI solutions for older adults.

Funding

This study was supported by a grant from the Johns Hopkins Artificial Intelligence and Technology Collaboratory for Aging Research (P30AG073104). ZZ acknowledges funding from the National Institute on Aging (T32AG066576).

Authors' Contributions

ZZ was responsible for research design, data analysis, and writing of the manuscript. NLS and TKMC were responsible for study conception and design and data acquisition. KC and AIA conducted data preprocessing. SA, JM, PP, PA, and MU provided critical interpretation of the results. NLS supervised the overall project and secured funding. All authors contributed to the review and revision of the manuscript.

Abstract

This research letter proposes a novel model design leveraging natively multimodal large language models to identify fall risks and generate visualizations of recommended home environmental modifications, aiming to improve the accessibility and impact of personalized fall prevention advice for older adults. Through a pilot rating study, this work demonstrates that multimodal large language models can generate safe and actionable advice to reduce fall risk in lived spaces of older adults, and also generate realistic edits based on original images. While this concept needs further testing and clinical comparison, it highlights a promising avenue for further innovation of fall prevention tactics.

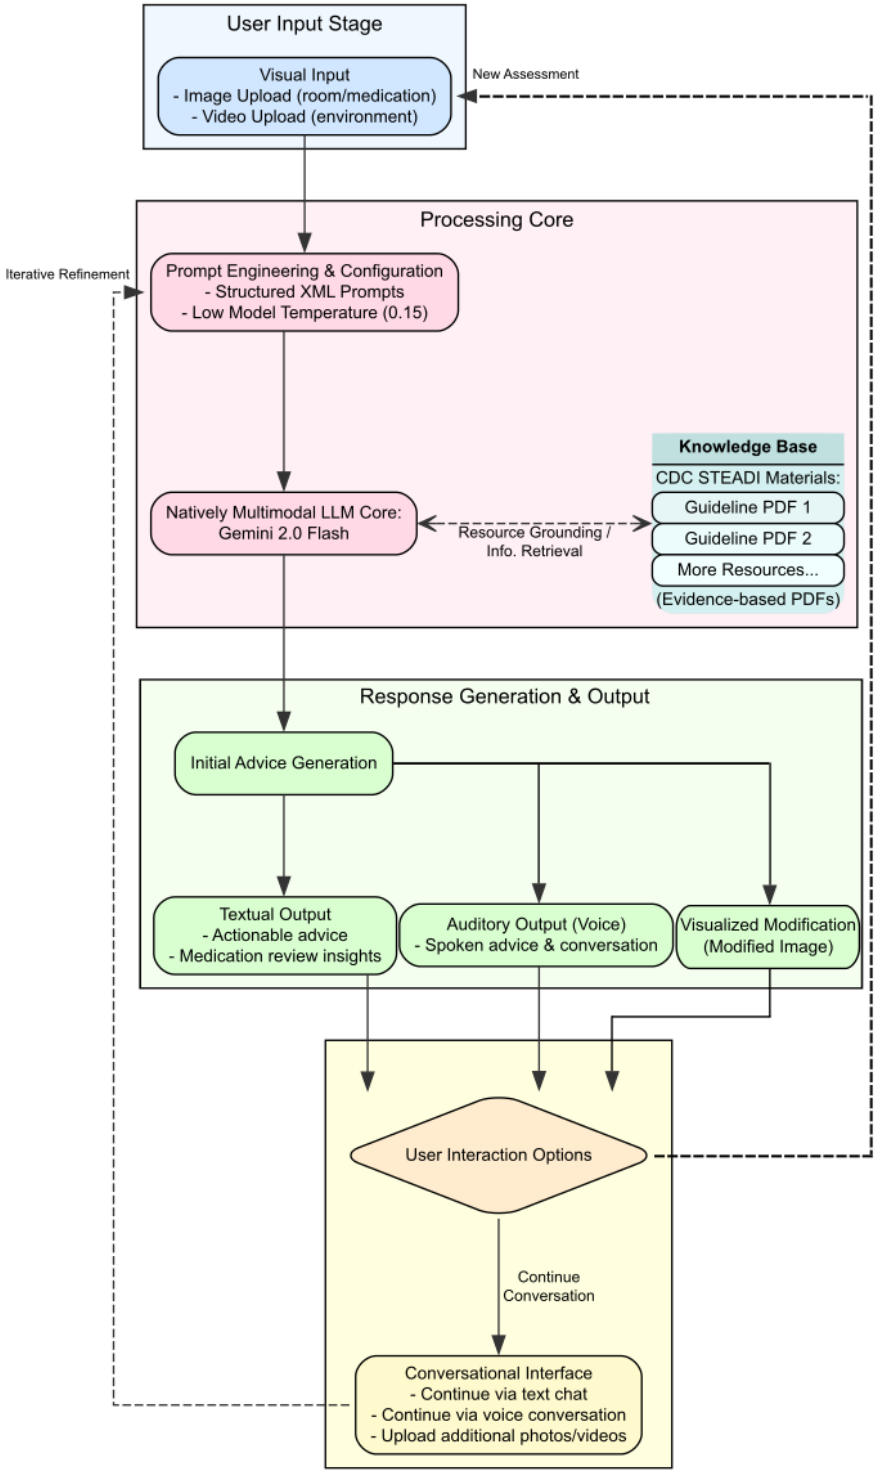
(JMIR Aging 2026;9:e77591) doi:10.2196/77591

KEYWORDS

LLM; multimodal; image generation; fall risk; older adults; large language model

Introduction

Falls among older adults cause significant mortality and increased health care costs [1]. Current literature has identified combined behavioral and exercise interventions as effective preventions for fall risks, improving balance performance, and reducing fear of falls [2], while limited evidence exists regarding medication-induced falls [3]. Home environmental intervention is also effective: safety assessments have been shown to reduce fall rate by 23% - 36% [1], with applied home modifications contributing a 7% risk reduction [4]. However, both external (insurance) and self-imposed (ie, the perception that safety assessments are invasive) barriers impede widespread implementation [5]. While research on frailty assessments is robust, gaps remain in technology-enabled interventions [6]. Prior studies have shown acceptability by older adults to embrace digital and electronic tools [5]. Existing remote home assessment protocols rely on caregiver camera operation, written instructions comprehension, and professional review of footage [7], while telehealth occupational therapy (OT) assessments may require insurance authorization, creating both obstacles and delays. Multimodal large language models (LLM) can fuse visual and text information, offering a scalable alternative while preventing encroachment on user values. This study aims to evaluate the ability of LLMs to produce safe, clinically useful, and actionable outputs that identify fall risks from user-provided home imagery and uniquely generate visualizations of the recommended environmental modifications.



Methods

We selected Google's Gemini family due to its strong visual reasoning performance supported by validated benchmarks [8]. We designed our framework to focus on providing reliable output by employing a low model temperature (0.15), in-context learning through grounding responses in evidence-based CDC STEADI patient materials (Figure 1), and structured XML prompts iterated using artificial intelligence (AI)-driven prompt engineering. The core innovation of this study used the gemini-2.0-flash-exp-image-generation model to directly modify the uploaded images with the model's suggested changes. The model leverages a two-shot prompting system (Multimedia Appendix 1, Multimedia Appendix 2), in which the primary LLM generates textual recommendations based on an input image/video, then directs the image generation model to visually render these changes (eg, adding grab bars, removing hazards) onto the original image, iterating until the generated image reflects the proposed modifications. We conducted a formative, blinded, paired comparison of outputs generated from 27 publicly licensed "lived-in" home interior images. We compared a non-optimized baseline prompt with an enhanced multimodal pipeline ("Steadi"). Text and image outputs were compared based on clinical usefulness, safety, image fidelity/plausibility, and preference between baseline prompt output and our

XSL•FO
RenderX

enhanced multimodal pipeline output. Detailed methods and output can be found in Multimedia Appendices 3 and 4.

Figure 1. Enhanced model architecture for advice generation and multimodal interaction. CDC: Centers for Disease Control and Prevention; LLM: large language model; STEADI: Stopping Elderly Accidents, Deaths, & Injuries.

Results

Initial Advice Generation, Multimodal Communication, and Modification Visualization

The model takes an uploaded image or video and provides specific, actionable advice supported by evidence-based resources. The proposed architecture successfully applies both additive and subtractive modifications to images, providing users with a concrete visual representation of a safer environment.

XSL•FO
RenderX

Model Comparisons

We find that overall, our raters preferred the "Steadi" system output of both image and text (40/54 times (74.1%), Table 1). We demonstrate that contemporary LLMs produce relatively safe recommendations, regardless of the prompting system, with only one set of recommendations rated as unsafe in the baseline prompting system and none in the enhanced. We find that when given specific issues to visualize, image editing LLMs produce edits with good visualization fidelity (46/54 times, 85.2% for baseline and 43/54 times, 79.6% for enhanced; Table 1), and low rates of implausible/hazard-producing edits (6/54 times, 11.1% for both systems; Table 1). Text recommendations and visualized outputs ranged from generally "somewhat actionable" for the baseline system to highly actionable for our enhanced system.

Table . Results of rating study.

Outcome	Baseline	Enhanced	Comparison[a]
Q1 Overall clinical usefulness (preference)	Preferred: 10/54 (18.5%)	Preferred: 40/54 (74.1%)	Win rate: 40/50 (80.0%, 95% CI 67.0 - 88.8); sign test $P \leq .001$; ties=4
Q2 Unsafe/inappropriate recommendation rate (Yes)	1/54 (1.9%, 95% CI 0.3 - 9.8)	0/54 (0.0%, 95% CI 0.0 - 6.6)	Risk difference (Enhanced-Baseline): −1.9 pp
Q3 Visualization fidelity rate (Yes)	46/54 (85.2%, 95% CI 73.4 - 92.3)	43/54 (79.6%, 95% CI 67.1 - 88.2)	Risk difference (Enhanced-Baseline): −5.6 pp
Q4 Hazard-introducing/implausible edit rate (Yes)	6/54 (11.1%, 95% CI 5.2 - 22.2)	6/54 (11.1%, 95% CI 5.2 - 22.2)	Risk difference (Enhanced-Baseline):+0.0 pp
Q5 Actionability (1 - 5 Likert)	median 3.0 (IQR 3.0 - 4.0)	median 5.0 (IQR 4.0 - 5.0)	Δmedian (Enhanced-Baseline):+1.0 (IQR 0.0 - 2.0)

[a]n=rater case evaluations; outcomes are descriptive; Q1 sign test is exploratory.

Discussion

Principal Findings

This study introduces a novel application of multimodal LLMs, leveraging their image-generation capabilities for visualizing personalized home safety recommendations. We demonstrate that enhanced frameworks, such as structured prompting and grounding using trusted resources, produce safe, clinically useful, and actionable outputs that categorically rate better than outputs from baseline LLMs. The inherent flexibility of LLMs supports diverse interaction methods, uniquely enabling users to interact with their "consultant" in their preferred mode. LLMs may mitigate delays caused by insurance authorizations and restore autonomy to users.

The visual output capability is also key: generating suggestions directly onto uploaded images offers more intuitive, actionable guidance than abstract text instructions alone. The drive to protect the familiarity of their home from change was identified to be a major motive for older adults rejecting modification advice from OT [5]; direct visualization of user-fed images may help overcome this hurdle and increase acceptance. There are still limitations to the technology, namely outputs may be illogical such as the recommended soap placement, and movement of furniture and door in Multimedia Appendix 1. However, overall, this study demonstrates that LLMs generally produce visual outputs with high fidelity, low hazard introduction rates, and high actionability.

To adhere to HIPAA (Health Insurance Portability and Accountability Act) compliance, future work should consider working with LLM providers to sign a HIPAA Business Associate Amendment or other HIPAA-compliant program. Ethical considerations, such as disclosure of privacy and data protection, should be implemented in accordance with WHO guidance on AI in health [9].

Limitations

Further testing must be conducted against the current standard for in-home assessments to discover if the proposed model provides comparable advice to professionals. Implementation trials will be needed to mitigate concerns such as the digital divide and ensure accessibility among varying cognitive/visual functions. Implementations must comply with FDA digital health guidance, and characterization and limitation of unsafe output generation must be explored. This model is designed as a supplemental service to be integrated with OT rather than a replacement.

Conclusions

Multimodal LLMs that integrate image generation offer a novel, innovative approach to increasing end users' accessibility to personalized home environment recommendations for fall prevention. This capability represents a potential supplement to current care services that may enhance patient understanding, motivation, and adherence, serving as a valuable resource to patients who defer or cannot access in-home safety assessments. Rigorous validation of clinical efficacy and user acceptance is essential to translate this technological potential into improved patient outcomes.

Acknowledgments

We would like to extend our gratitude to Robert Pugliese and MaryEllen Daley for all of their generous support throughout this project. We would also like to thank Dr. Bracken Babula, MD, Dr. Zhe Chen, MD, Dr. Ryan Tomlinson, PhD, Dr. Deanna Gray-Miceli, PhD, CRNP, Dr. Christine Hsieh, MD, and Dr. Brooke Salzman, MD, for their feedback and guidance on this project. No generative AI was used in any portion of the manuscript text generation. We used the generative AI Tool "Gemini 1.5 Pro" made by Google to draft the system prompt found in Multimedia Appendix 2, with review and editing from the study group. Image portions of Multimedia Appendices 1, 4 and 5 were generated using "Gemini 2.0 Flash Image Preview" as described in the manuscript text as part of the model design. Image portions of Multimedia Appendices 1, 4 and 5 were generated using "Gemini 2.5 Flash Image" as described in the manuscript text as part of the model design.

Funding

No external financial support or grants were received from any public, commercial, or not-for-profit entities for the research, authorship, or publication of this article.

Abstract

Background: As telehealth has become an increasingly common mode of care delivery, older adults may face structural, technological, and interactional barriers that limit their ability to engage with video-based care. Although digital ageism, defined as the presence of age-related stereotypes, lowered expectations, or assumptions about older adults' technology-related competence, has been described in prior literature, less is known about how such dynamics surface during real-time telehealth encounters and how they may shape participation in technology-focused clinical trials.

Objective: This formative ethnographic study aimed to (1) document real-world barriers encountered by older adults immediately before and during video telehealth visits and (2) inform recruitment and implementation procedures for a subsequent telepharmacy randomized controlled trial.

Methods: We conducted in-home, real-time ethnographic observation of 20 community-dwelling veterans aged ≥65 years participating in pharmacist-led video visits for medication management. Recruitment occurred over approximately 6 to 10 months using mailed invitation letters (>300 sent), supplemented with outbound telephone calls. Data sources included structured field notes completed independently by an in-house anthropologist and the remote clinical pharmacist, as well as observational documentation of previsit preparation, visit navigation, and postvisit reflections. Data were analyzed using qualitative rapid analysis, with iterative team review and triangulation across data sources.

Results: Participants had a mean age of 74 (SD 3.18) years; 19 of 20 (95%) were male, and 18 of 20 (90%) identified as White. All participants completed a video visit with technical support as needed. Structural barriers (eg, broadband access and device availability) and usability challenges (eg, audio-video setup and navigation) were common. Although digital ageism was not a predefined analytical category, age-related assumptions about technology emerged during observation, including participants attributing anticipated or experienced difficulties to age and expressing surprise or pride following successful completion of the visit. These age-related interpretations were analytically distinct from access and usability barriers and were interpreted as manifestations of digital ageism, particularly as internalized age-based expectations.

Conclusions: Formative ethnographic observation provided critical insights into how older adults experience telehealth encounters in real-world contexts and informed adaptations to recruitment and implementation procedures for a subsequent randomized controlled trial. Although digital ageism was not an original study aim, age-related assumptions about technology emerged as an important interpretive factor shaping engagement with video-based care. Incorporating ethnographic methods prior to trial implementation may help identify otherwise overlooked barriers and improve the inclusivity and feasibility of technology-focused clinical research involving older adults.

KEYWORDS

digital ageism; telehealth; ethnographic research; older adults; telepharmacy; digital divide

Introduction

The COVID-19 pandemic accelerated the adoption of video telehealth as a primary mode of outpatient care delivery, including among older veterans [1-5]. Telehealth, defined by the National Institute on Aging as the use of communication technologies to exchange information and deliver health care services, holds the promise of increasing access to care and reducing logistical barriers while maintaining clinical effectiveness [6]. However, despite widespread interest in telemedicine among older adults, significant obstacles remain [7-12]. Limited broadband access and the high costs of digital devices and internet services—issues that are especially pronounced in rural and low-income communities—restrict many older adults' ability to engage with telehealth, potentially worsening health inequities [13-18]. Another critical challenge is digital ageism: the assumption that older individuals are less capable of using digital tools [19]. This bias can manifest through technological, structural, and attitudinal barriers [20,21]. Many virtual care platforms are not designed with older users in mind, often featuring small fonts, complex navigation, and controls that are not accommodating for those with motor or visual impairments [13]. In addition, the expectation of digital literacy can alienate individuals who have had limited exposure to technology, leading to frustration and disengagement [12,16,20]. Research within the Department of Veterans Affairs (VA), for example, has shown that while many older veterans are interested in video visits, they often require significant personalized assistance to participate effectively [1,17,22]. Furthermore, some health care providers may default to telephone visits or fail to offer adequate digital literacy support, reinforcing the notion that telemedicine is "not for them" and further discouraging engagement [21,23,24].

Although disparities in video telehealth use among older adults are well documented, a more nuanced understanding of the real-life barriers these individuals face is essential for designing digital tools and platforms that truly meet their needs. To address this gap, we conducted a formative ethnographic assessment of older adults' experiences during virtual visits with a clinician. This formative ethnographic study aimed to (1) document real-world barriers encountered by older adults immediately before and during a video telehealth visit and (2) inform recruitment and study procedures for a subsequent telepharmacy randomized controlled trial (RCT). Although digital ageism was not a predefined analytical category, age-related assumptions about technology were examined as an emergent interpretative theme.

Methods

Study Overview

This study draws on the same formative ethnographic dataset described in our prior publication examining feasibility and practical implementation solutions for pharmacist video visits among older veterans [25]. This manuscript extends that work by focusing on how ethnographic methods can identify and disentangle age-related assumptions from technology familiarity in the design of technology-based clinical trials. The analytical focus and conceptual framing in this manuscript are distinct from those in the prior implementation publication.

Ethical Considerations

This study was reviewed and approved by the VA Central Institutional Review Board (approval number 19-35). All participants provided informed consent prior to participation. Study staff explained the purpose of the study, procedures, potential risks, and voluntary nature of participation, and participants were informed of their right to withdraw at any time without consequences to their care. To protect participant privacy and confidentiality, all data were deidentified at the time of analysis. Field notes and observational data were stored on secure, VA-approved servers with access limited to authorized study personnel. No personally identifiable information is reported in this manuscript. Participants received a US $50 gift card as compensation for their time.

Recruitment

Potential participants were identified using an electronic health record–generated list of veterans aged ≥65 years who met the inclusion criteria (eg, ≥2 chronic conditions, no diagnosis of dementia, and at least 1 primary care visit in the prior year). Participants were recruited over approximately 10 months using a combination of mailed invitations and outbound telephone calls. In total, 316 invitation letters were mailed to veterans identified through the electronic health record as potentially eligible. Overall, 64 veterans responded to the mailed invitation; 41 indicated they were not interested in participating, and 23 initially agreed. Of these, 2 veterans subsequently declined enrollment due to personal reasons (ongoing cancer treatment and caregiving responsibilities) and 1 could not be scheduled within the recruitment window; recruitment stopped once the target sample size (n=20) was reached.

To supplement mailed invitations, the study staff conducted outbound telephone calls to veterans who did not respond to the letter. Across mail and telephone contact attempts, veterans either declined participation after learning more about the study or could not be reached (eg, disconnected phone numbers or no response after repeated attempts). In total, 17 veterans were determined to be ineligible due to no longer meeting the study criteria (eg, not currently taking ≥5 medications, recent diagnosis of cognitive decline, or enrollment in a VA satellite clinic). Recruitment ceased once the target sample size (N=20) was reached. All enrolled participants completed the observed telehealth visit.

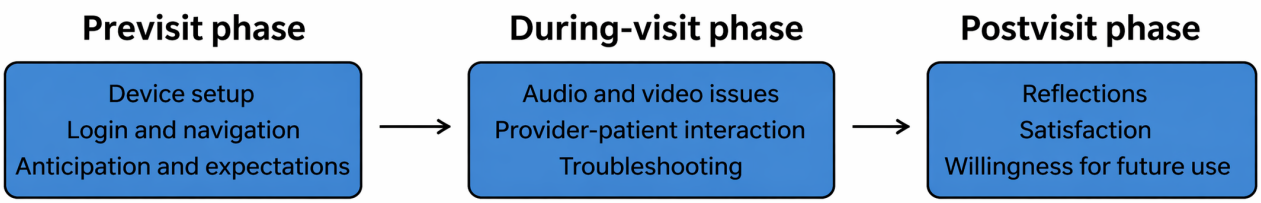
Our ethnographic assessment used direct observation and structured field notes to capture the real-world experiences of

XSL•FO
RenderX

older adults as they navigated a clinical video visit using the VA's synchronous video platform VA Video Connect (VVC). An experienced anthropologist led this assessment by recruiting and enrolling participants and joining each participant at home before and during their virtual visit.

To participate, all veterans needed internet access at home and a device with a camera and microphone. For those lacking a video-capable device, the anthropologist arranged for the provision of a VA-loaned tablet. The VA's tablet distribution program was instrumental in bridging the digital divide for veterans with limited access to video care. Veterans receiving a tablet were scheduled for a test visit with a local VA employee, while others received a demonstration from the anthropologist prior to their pharmacist video visit. Before the video visit, the anthropologist provided a video demonstration when needed. Subsequently, the participant and pharmacist connected via VVC.

Ethnographic methods in anthropology involve qualitative techniques—such as semistructured interviews and focus groups—with a unique emphasis on situating specific events within their broader real-life contexts [22,26,27]. Unlike surveys or post hoc interviews, ethnographic methods also rely on in-situ, real-time observations to capture sociocultural, behavioral, and technical challenges that participants may not articulate in interviews [27]. In this assessment, field notes and direct observation notes were critical in documenting the technical, logistical, and emotional dimensions of older adults' virtual care experiences.



Field notes are detailed, descriptive records that researchers, particularly anthropologists and ethnographers, take during participant observation and interviews [28,29]. We designed a standardized field note form informed by a priori concepts from the Consolidated Framework for Implementation Research (CFIR) [30] and insights from experienced clinical pharmacists (Multimedia Appendix 1). Field notes are generally understood to be primary data collected in the field to document observations, interactions, and insights gained through immersive research methods [28]. Both the in-house anthropologist and the remote clinical pharmacist completed field notes for each participant. The anthropologist's (in-house) and the clinical pharmacist's (remote) field notes complemented each other by capturing a range of experiences and challenges, including the following:

- Technical challenges and troubleshooting; difficulties with video connections, microphone access, and screen navigation
- Participant engagement and reactions; variations in comfort, frustration, confidence, or hesitation in using virtual care platforms
- Health care provider interactions; the level of guidance provided, communication tone, and patience in assisting older adults
- Environmental and sociocultural factors; home setup, presence of caregivers, privacy concerns, and distractions

Direct observation is an ethnographic method ideal for studies on naturally occurring behaviors, actions, or events [29]. For example, observation is particularly useful for understanding patients' experiences because it provides an insider perspective and thus allows researchers to understand end users' experiences of a problem. Direct observation was conducted before, during, and after the virtual visit session to fully understand the participant's experience. Key components included the following (Figure 1):

- Previsit observations; how participants prepared (eg, setting up devices and logging in), their anxiety or reluctance related to technology use, and the role of caregivers
- During the virtual care visit; navigation challenges (eg, adjusting volume and enabling the camera), participant-provider interactions, and unanticipated disruptions such as device malfunctions or environmental distractions
- Postvisit reflections; participant feedback on the ease of use, overall satisfaction, willingness to use virtual care in the future, and any adaptive strategies used (eg, using written notes or seeking caregiver assistance)

Figure 1. Direct observation in telehealth interactions. This diagram outlines the key stages of direct observation in telehealth research with older adults, including previsit, during-visit, and postvisit phases.

XSL•FO

Data Analysis

This formative ethnographic assessment was not originally designed to study digital ageism as a primary construct. Rather, the study focused on understanding how older adults navigated real-time telehealth encounters to inform the implementation of a subsequent RCT. Because the study population consisted exclusively of older adults, we anticipated that age-related assumptions about technology, whether expressed by participants, embedded in clinical workflows, or reflected in research procedures, might emerge alongside structural and usability barriers. Data sources included structured field notes completed independently by the in-house anthropologist and the remote clinical pharmacist for each observed visit, as well as observational documentation of previsit preparation and postvisit reflections. All field notes were compiled and organized by participant and visit stage.

We analyzed the ethnographic data (structured field notes and direct observation summaries) using a qualitative rapid analysis approach commonly applied in health services and implementation research, emphasizing matrix-based summarization, team-based interpretation, and iterative refinement of themes [31,32]. This approach is consistent with pragmatic ethnographic methods, including Rapid Assessment Procedure–Informed Clinical Ethnography, which integrates ethnographic observation with rapid, implementation-focused analysis [33].

The rapid qualitative analytic process proceeded in 4 iterative steps. First, field notes were summarized using structured analytic matrices organized by participant; visit phase (previsit, during visit, and postvisit); and focal domains (eg, technical barriers, participant responses, environmental context, and caregiver involvement). This step allowed for systematic comparison across cases while preserving contextual detail. Second, 2 analysts (the anthropologist and the clinical pharmacist) independently reviewed matrix summaries to identify recurring patterns and salient observations. Preliminary themes were generated inductively, with attention to both anticipated implementation challenges (eg, technology access and usability) and emergent phenomena observed during visits.

Third, the 2 primary analysts met weekly over a 6-month period to compare interpretations, refine thematic definitions, and resolve discrepancies through discussion and reference back to the original field notes. These meetings focused on clarifying analytic boundaries, distinguishing overlapping concepts, and ensuring consistency across cases. Fourth, biweekly analytic meetings with a senior qualitative methodologist and a clinical subject matter expert provided an additional layer of review. These meetings were used to challenge emerging interpretations, assess analytic coherence, and confirm that themes were grounded in observational evidence.

Several strategies were used to enhance analytic rigor and credibility [34]. First, triangulation across data sources (anthropologist field notes, pharmacist field notes, and direct observation) allowed for cross-validation of findings. Second, team-based analysis and consensus discussions reduced reliance on a single analyst's interpretation. Finally, analytic decisions were documented through iterative matrix revisions and meeting notes, creating an audit trail of theme development. This rapid, iterative analytic process enabled the identification of implementation-relevant insights while maintaining methodological transparency and rigor appropriate for ethnographic research embedded within clinical trial preparation.

We distinguished digital ageism from related but distinct phenomena, such as structural barriers to access (eg, broadband availability and device ownership) and usability or design limitations of telehealth platforms. We reserved the term "digital ageism" for age-related stereotypes, lowered expectations, and identity-based assumptions, whether externally imposed or internalized, that shaped participants' perceptions of their own technological competence and their engagement with virtual care. Consequently, digital ageism was used as an interpretive lens during analysis, rather than as a priori coding framework or outcome.

Results

Participant Characteristics

Participants had a mean age of 74 (SD 3.18) years; of 20 participants, 18 (90%) were male, and 18 (90%) identified as White. In total, 11 (55%) participants had completed high school or a General Educational Development test, and 13 (65%) participants reported some prior experience with digital technology (eg, owning or using a smartphone, tablet, or computer). However, experience with video-based platforms was limited for many participants, and assistance was frequently required; 7 (35%) participants reported neither regular access to a video-capable device nor prior experience using such technology and required assistance both before and during the virtual visit. Additionally, 3 (15%) participants reported having access to a device and some experience with technology but nonetheless encountered technical difficulties during the visit that required real-time support.

Lessons Learned to Refine the Implementation of a Subsequent Telepharmacy RCT

Overview

Direct in-home guidance was associated with successful visit completion, and participants frequently expressed comfort with specific tasks (eg, logging in and adjusting audio or video) during or after the visit. These observations informed mitigation strategies incorporated into the subsequent RCT protocol. Common challenges included difficulty navigating devices, audio-visual setup problems, and unstable internet connectivity. These barriers were identified prior to full trial implementation, allowing the study team to develop mitigation strategies such as providing VA-loaned tablets, offering previsit device and platform demonstrations, and delivering real-time troubleshooting support.

Identifying and Addressing Barriers Before the Trial

Pretrial qualitative and direct observation helped identify technological and structural barriers that would impact trial retention and data integrity. Direct in-home observations revealed challenges in device navigation, audio-visual accessibility, and broadband connectivity, allowing for proactive

XSL•FO
RenderX

solutions such as providing VA-loaned tablets and real-time technical assistance. These observations informed mitigation strategies for the subsequent RCT (eg, previsit platform demonstrations and caregiver involvement strategies).

Enhancing Participant Recruitment and Retention

Recruitment was the first opportunity to engage potential participants and build trust. We recruited 20 individuals over approximately 10 months during the COVID-19 pandemic. Despite the challenges of masks and the recommended 6-foot physical distance between parties, participants were accommodating and tolerant of the masking and other restrictions. For some veterans, the anthropologist was the only in-person visitor they had had in months and was greatly welcomed. By meeting patients at their home, we eliminated several barriers to research that homebound older adults face, such as a lack of transportation or mobility issues that limit their ability to participate in hospital-based research. The anthropologist was available via telephone for questions or concerns and was flexible, driving to participants' homes (sometimes 45 to 75 minutes away in rural locations) to conduct the enrollment and baseline screening when needed, and then returned to observe the in-home pharmacist video visit and conduct the postvisit interview. Often, this occurred immediately following the baseline screening to reduce the burden and infection-related safety risks of scheduling several in-person appointments with the participant. This unconventional approach proved to be successful in reaching out and engaging a population traditionally excluded from clinical and technology-based research and allowed our anthropologist to understand the physical constraints and isolation that many older adults experience on a day-to-day basis.

Improving Intervention Implementation

Observational field notes further captured deviations from the planned protocol that would not have been apparent in a traditional trial setting, including extended time needed for technical setup, the role of caregivers in facilitating participation, and the cumulative burden of scheduling multiple appointments. These insights informed refinements to streamline procedures and reduce participant burden. Our ethnographic assessment allowed for adaptation of the intervention before full-scale RCT implementation, such as:

- Adjusting session scheduling to minimize participant burden
- Integrating troubleshooting strategies for common technical difficulties
- Addressing digital literacy gaps before the RCT to improve participant readiness, reduce technical failures, and reduce user frustration during actual trial sessions

By iteratively refining procedures based on our direct observations in the participants' homes, our ethnographic approach ensured that the RCT was not only scientifically rigorous but also practical and participant-centered. The opportunity to be in the home of the participants ensured that older adults could access the technology and complete the visit and, more importantly, that the anthropologist was able to witness the process by which the video visit was delivered from the patient's perspective. This step was valuable in understanding how actual implementation differs from planned implementation and in identifying issues important to the transferability of an effective intervention outside experimental conditions [27].

Analytic Findings

Emergent Age-Related Assumptions Shaping Telehealth Engagement

Although digital ageism was not a predefined analytic category, age-related assumptions about technology emerged consistently during observation and participant interaction. We analytically distinguished age-related assumptions from participants' actual familiarity with technology or prior exposure to digital tools. Although technical challenges and levels of experience varied, age-related assumptions were evident when participants explicitly invoked age to explain anticipated reluctance to engage with technology, rather than when challenges reflected task-specific skills or access alone.

Multifaceted Barriers to Video Telehealth Engagement

Older adults faced technological barriers, such as difficulty navigating videoconferencing platforms, small touchscreens, and poor audio-visual accessibility. Structural barriers, including a lack of broadband access, reliance on outdated technology, and the need for assistance with device setup, limited participation in virtual visits. To overcome these hurdles, the anthropologist in our study brought a VA-owned tablet to the homes of those who did not have access to their own device. She also provided a quick demonstration of how to use the VA tablet before the scheduled video visit with the pharmacist. This was especially useful for those who were unfamiliar with touch screens and video call platforms. For participants who did not have access to a device or to reliable broadband internet, the study team took advantage of a national VA program to arrange for a 4G-enabled, VA-issued tablet to be sent to the veteran that included cellular service. Similar task-specific challenges (eg, navigating apps, managing passwords, and enabling audio permissions) were observed among participants with different levels of technology experience and skills, suggesting that difficulty alone did not map cleanly onto age-related assumptions. Furthermore, the anthropologist noted that participants voiced fewer concerns about technology when provided with access to a device and hands-on guided tutorials before and during the virtual visit, when needed.

Hands-On Support: Illuminated Barriers and Work-Arounds for Older Adults

Real-time troubleshooting, such as enabling microphone access, adjusting volume settings, or assisting with log-in procedures, was critical in ensuring the successful completion of the video visit with the clinician. We also learned where participants were encountering difficulties and needed support, allowing us to further adapt our protocols. For example, for the RCT, we began asking participants to bring their devices to the consent appointment so that study staff could assist them with tasks such as allowing the VVC app to use the camera and microphone.

XSL•FO
RenderX

Direct Engagement With Technology Challenges: Internalized Ageism

In addition to structural and usability barriers, ethnographic field notes documented age-related assumptions that shaped how participants engaged with video visits. Successful completion of the video visit was often accompanied by expressions of relief, appreciation, or surprise, particularly among participants with limited prior experience using video-based care independently. For example, a female participant in her late 70s was at first reluctant to participate in the study because she lacked prior experience with technology. However, when given the opportunity to learn a new skill through hands-on support, she agreed to participate. The participant did not own a smartphone or computer and was skeptical that a clinical video visit would provide the same "whole picture view" as an in-person visit. Prior to the scheduled video visit, the anthropologist provided a short demonstration of how to navigate the tablet, how to set it up, and how to handle it if asked to walk around during the virtual visit. The participant was a little intimidated by the touchscreen modality, as she only owned a flip phone and had never used such a device before. The anthropologist encouraged the participant to practice using the onscreen keyboard, test the video modality, and type her own information into the registration form. During the scheduled video visit, the participant was able to connect and navigate the tablet with no issues. She walked around and showed the clinician her surroundings; she was particularly proud of her home and garden. The participant was able to show the clinician the places where she stored her medications. After the home video visit, the participant was highly satisfied with the experience, indicating that it felt like an in-person visit.

Personalized Adaptations for Older Adults

For those participants with no digital technological skills, the anthropologist demonstrated how to use the video app before the actual clinical video visit and often had to assist the participant during the video visit by solving small issues such as enabling the video app, increasing the volume, or resolving Wi-Fi connection issues. However, even for those with more digital literacy, telemedicine and video telehealth policies often assume that older adults can seamlessly transition to digital platforms, without accounting for the need for additional training or technical support for practical issues.

For example, 1 participant had an older desktop without a camera that he used for email but had access to an iPad tablet with an integrated camera, which he had never used for email. The anthropologist sent instructions on how to add an email account to his iPad. However, as is common with many older adults, his internet service provider was also his email provider. The participant attempted to add his email to his iPad but gave up, stating, "I'm too old for this."

Adding an email account to a new device can be challenging for older adults who do not have much technical experience (even for those who are tech-savvy, as the instructions can be lengthy and difficult to follow). Similarly, email technology is not always up to date, which introduces potential problems: the interface may be difficult to use or may not work with web browsers. We used FaceTime (Apple Inc) briefly as a practice video call to familiarize the participant with camera and audio controls; the pharmacist visit itself occurred via VVC. The anthropologist assisted with enabling the video app and manually toggled the camera switch when needed. Participants described feeling respected and listened to during pharmacist interactions and emphasized the value of being able to speak "face to face" while accessing medications in their home. These responses reflected shifts in how participants evaluated their own capacity to engage with telehealth and their ability to speak openly with a pharmacist about medication-related questions.

Sociocultural and Environmental Factors Influence Virtual Care Success

Home setup challenges (eg, lack of private space, poor lighting, or technical constraints) impacted the quality and comfort of virtual care interactions. Participants with higher digital literacy or prior exposure to technology were more likely to engage diligently in virtual care, while those with minimal digital experience required more ongoing support. The anthropologist noted that some participants changed their environment by figuring out ways to prop up a device to be hands-free such as stacking books. Ethnographic observation further revealed that negative prior experiences with technology shaped participants' expectations and behaviors. Some participants expressed distrust of digital technologies due to concerns about privacy, hacking, and fraud, citing repeated scam calls or prior financial compromises. These concerns influenced device use practices, such as disabling or covering cameras, frequently changing passwords, or limiting technology use to specific tasks, such as email or banking. Thus, for these participants, reluctance to use video visits was rooted not only in technical skill but also in perceived risk and vulnerability. Family and caregiver involvement played a crucial role in supporting digital engagement. Some participants reported having their spouses, grandchildren, or children assisting with technical support when engaging with technology in general, as one participant noted, "You know who I learned that from? My granddaughter. She knows how to do this."

Discussion

Principal Findings

This formative ethnographic study examined how older adults engaged with video-based telehealth encounters in real-world settings to inform recruitment and implementation strategies for a subsequent telepharmacy randomized clinical trial. Through in-home observation conducted before, during, and after pharmacist video visits, we identified a range of structural, technological, and sociocultural factors that shaped telehealth engagement. Through direct observation, we gained insight into the disconnect between technological design and user needs, highlighting where telehealth platforms fail to accommodate older adults and how digital ageism manifests in real-world health care settings. These insights directly informed the development of recruitment and technology troubleshooting methods for the subsequent RCT focused on pharmacist video visits for medication management among older adults. In addition, although digital ageism was not a core focus of our study, age-related assumptions emerged as an important

XSL•FO
RenderX

interpretative factor that influenced how participants anticipated, experienced, and evaluated their own video visits.

Consistent with prior work, our findings underscore that telehealth engagement among older adults cannot be understood only in terms of individual technical skills or motivation [4-7,9-15]; our in-depth observational approach uniquely highlights both the facilitators and obstacles encountered before and during video visits. Structural barriers such as broadband access, device ownership, and email access intersect with sociocultural factors, including household layout, rurality, and caregiver presence. In-home observation allowed us to identify challenges that would not have been apparent through remote assessment alone, such as difficulty transporting devices within the home, concerns about privacy, and other physical limitations.

Family members frequently served as informal technology facilitators, assisting in device setup, account management, and troubleshooting. This finding highlights the importance of considering digital literacy programs tailored to older adults' needs as potentially dyadic, including community-based initiatives and caregiver-led tutorials [25,35].

Age-related assumptions about technology surfaced during observation and participant interaction. Participants' reluctance to engage with video visits was attributed to older age and lower technical experience. Although successful completion of video visits was frequently accompanied by expressions of surprise or pride, suggesting that telehealth encounters functioned as moments in which age-related self-perceptions were reinforced. These patterns can be further understood through a sociopsychological identity framework, which conceptualizes age and generational status as socially constructed identities rather than fixed deficits. As described by Lee and Hartanto [36], individuals' engagement with technology is shaped not only by skills or access but also by identity-relevant meanings, stereotypes, and expectations associated with belonging to an age group. From this perspective, observed changes in confidence reflect changes in how participants interpreted their own age-related technological competence rather than simple resolution of usability barriers.

It is important to note that not all age-related considerations observed in this study should be interpreted as manifestations of ageism. Some adaptations, such as preparing for visual, hearing, or mobility limitations, enabled and supported successful participation in the study. These practices reflect responsive design rather than ageist assumptions. The analytical challenge lies in distinguishing between accommodations that enhance inclusion and assumptions that lower expectations or discourage engagement. Although similar technology challenges might arise in younger populations with limited technology exposure, the tendency to attribute difficulty to age identity and the meaning attached to this appeared to be specific to older adults' experiences in this context.

Our findings suggest that incorporating ethnographic methods prior to trial implementation can surface otherwise overlooked barriers and facilitators to telehealth engagement among older adults. In-home observation provided actionable insights that informed protocol refinements, recruitment strategies, and support mechanisms for the subsequent randomized trial. Broadly, these methods may help ensure that technology-focused clinical research does not inadvertently exclude older adults by assuming access, skills, or comfort with digital tools.

Limitations

As with most qualitative research, our findings are not broadly generalizable to populations at large. The sample size was small and drawn from veterans willing to participate in a formative telehealth study and thus does not reflect the demographics of older adults in the United States. Given the technology acceptance and uptake during the COVID pandemic, the individuals enrolled in our study likely had additional motivation to learn to use video technology and thus participate in our study. Additionally, as this was a formative qualitative study, findings reflect observed experiences and reported perceptions rather than measured intervention effects. Finally, our hands-on ethnographic approach to recruitment and participant engagement with technology may not be feasible for all studies, especially those that are larger and time limited.

Conclusions

We conducted a focused ethnographic assessment of 20 older individuals engaging in a virtual clinical visit. We illustrate that the application of ethnographic methods to identify and reduce critical barriers to participation and retention in complex health interventions among older adults can yield critical information to improve an RCT. We offered critical insights into how older adults experience telehealth encounters in everyday contexts and revealed the interplay of structural barriers, social support, and age-related self-perceptions. Although digital ageism was not an initial focus of this study, age-related assumptions about technology emerged as a factor shaping engagement with virtual care. Integrating ethnographic approaches and methods into telehealth research and implementation efforts may help improve inclusivity, feasibility, and responsiveness for older adult populations.

Abstract

Background: Ageist beliefs tend to take root in one's formative years and persist into adulthood, making it crucial to unpack the ways in which children are socialized to view old age. This study is the first to analyze portrayals of old age in nursery rhymes. Related literature has concentrated largely on depictions of older adults in books or movies targeted at children. As a staple of early childhood education, nursery rhymes merit examination as a vehicle through which age stereotypes are disseminated and reinforced.

Objective: Our content analysis of nursery rhymes is grounded in 3 research questions: to what extent is old age represented in nursery rhymes? What are the prevailing stereotypes associated with old age in nursery rhymes? Are these stereotypes primarily positive or negative?

Methods: To build a comprehensive dataset, we gathered material from the following websites, each of which houses an extensive collection of rhymes, including BBC Nursery Rhymes and Songs, the Nursery Rhyme Collections, All Nursery Rhymes, and NurseryRhymes.org. A web ingestion tool was used to compile the data. In total, 735 unique nursery rhymes were retrieved. To identify rhymes related to old age, we conducted a search using various terms related to old age (eg, old, aged, grandfather, and grandma), which yielded 85 nursery rhymes. After applying a rigorous set of exclusion criteria, 29 rhymes remained. Both deductive and inductive modes of reasoning guided our content analysis.

Results: Old age was a central theme in 4% (N=29) of the 735 nursery rhymes. Of the 29 rhymes analyzed, more than half contained negative age stereotypes (17/29, 59%), and a third (10/29, 34%) contained positive ones. A small proportion portrayed old age in a neutral manner (2/29, 7%). Examples of negative stereotypes include being physically debilitated, cognitively impaired, helpless, unhygienic, and incompetent. Examples of positive stereotypes include being wise, affectionate, and jovial. Neutral portrayals framed aging as a natural part of life.

Conclusions: In the context of an aging population, it is paramount that people embrace a less pessimistic outlook on aging. Although nursery rhymes may seem like mere tales not to be taken seriously, they are powerful cultural artifacts capable of molding thought processes. Our study highlights the need to give children access to more accurate and nuanced stories about older adults. By doing so, society can move beyond passively assimilating negative views of aging to actively fostering healthier ones, thus building a future where all are valued regardless of age.

portrayals of old age; ageism; reframing aging; text as data; psychomics; age stereotypes

Introduction

Background

Ageism refers to stereotyping, discrimination, and prejudice on the grounds of age [1,2]. Globally, one in two individuals aged 16 years and older exhibits ageist attitudes toward older adults [1]. Such ageist beliefs tend to take root in one's formative years and persist into adulthood [3,4], making it crucial to unpack the ways in which children are socialized to view old age. In this study, we analyze depictions of old age in nursery rhymes.

Nursery rhymes are traditional poems, lullabies, or songs typically read or sung to children with the intention of instilling in them positive behaviors [5]. Most well-known nursery rhymes were penned decades or centuries ago but continue to be a staple of early childhood education [6]. On top of being entertaining, nursery rhymes support multiple aspects of a child's development [6], which could explain their enduring appeal. Today, nursery rhymes are enjoyed not only through books but also through television shows and videos, where they have amassed billions of views.

XSL•FO
RenderX

Theoretical Background

Central to the theory of cultivation is the notion that prolonged exposure to the media leads the individual to imbibe the views and values depicted [7,8]. Though originally formulated to elucidate the impact that television can have on viewers, the theory has since evolved to encompass different forms of media, including movies and books [9]. An important aspect of the theory of cultivation is the idea of mainstreaming, which posits that constant exposure to the media can result in a homogenization of perspectives. More specifically, through the process of mainstreaming, audiences who would otherwise hold very different views of the world come to assume a common view of reality [10]. There is evidence that the more people watch television programs that propagate negative messages about older adults, the more they perceive older adults unfavorably [11].

The communicative ecology model of successful aging postulates that perceptions of aging are derived from the routine ways in which aging is discursively constructed, whether through direct or mediated communication [12]. A key plank of this model is that uncertainty about aging influences one's sense of self-efficacy in navigating the aging process. As a form of early socialization, nursery rhymes contribute to this broader communicative ecology, molding perceptions of aging from a young age. When negative messages about aging are conveyed through these rhymes, they may induce feelings of uncertainty about later life. Meanwhile, positive depictions of aging can bolster one's sense of self-efficacy and promote more empowering attitudes toward later life [13].

There is evidence of a general prejudice against older adults among children [14-16]. Negative stereotypes of older persons have been observed in children as young as 3 years old [14,15]. By the time they reach elementary school, they may even verbalize these stereotypes [17]. The theory of stereotype embodiment submits that age stereotypes are internalized throughout one's life span and eventually become self-stereotypes that affect one's health. It is well documented that the assimilation of negative age stereotypes into one's self-concept correlates with poorer health outcomes such as a higher risk of depression and a shorter lifespan [3,18-21]. Meanwhile, positive age stereotypes are associated with improved functional health and overall well-being [3,18,19]. The types of stereotypes espoused early in one's life matter too. Research shows that younger individuals who hold negative age stereotypes are more likely to experience a cardiovascular event in later life than those with positive stereotypes [22]. In addition to being a threat to public health, ageism also constitutes a major economic burden. One study discovered that ageism costs the health care system in the United States approximately US $63 billion every year [23].

Existing Research and Gaps

Thus far, there have not been any studies exploring depictions of old age in nursery rhymes. Instead, related literature has concentrated largely on portrayals of older adults in books or movies targeted at children. The most foundational of these studies is by Ansello [24], whose content analysis of more than 600 children's books revealed that over 80% of them did not feature older characters. When older characters did appear, they were often typecast as sick, feeble, old-fashioned, out-of-touch, and unproductive. Younger characters were described with terms related to physical appearance or personality, while older characters were commonly reduced to their age. When additional descriptors were used, they usually had negative connotations, such as "poor" or "sad." Younger characters were also portrayed as multifaceted and integral to the plot, while older characters were presented as one-dimensional and peripheral to the storyline.

Findings from Ansello's [24] seminal study have since been corroborated by other scholars. In Hurst's analysis of children's picture books [25], 48% of older characters were explicitly called "old," with common descriptors including "nice," "funny," "small," "grumpy," "lonely," and "weak." Dodson and Hause [26] noted that older individuals were frequently depicted as "unhealthy," "ugly," "eccentric," and "passive" in books targeted at readers from kindergarten through adulthood. Janelli [27] argued that the diversity of the older demographic was not captured in picture books. In her review of over 73 storybooks, she noticed that older characters were commonly portrayed as bespectacled, having gray hair, and using walking sticks. Danowki and Robinson's [9] analysis of more than 700 literary works published between 2000 and 2010 in the United States observed that older adults were underrepresented, though there was a marked improvement in the overall portrayal of older characters in picture books over time. Robinson et al [28], conceded that commendable effort had been made to feature more older characters in Disney films. Nonetheless, these characters remained underrepresented and mainly inhabited roles of minimal significance to the plot [28].

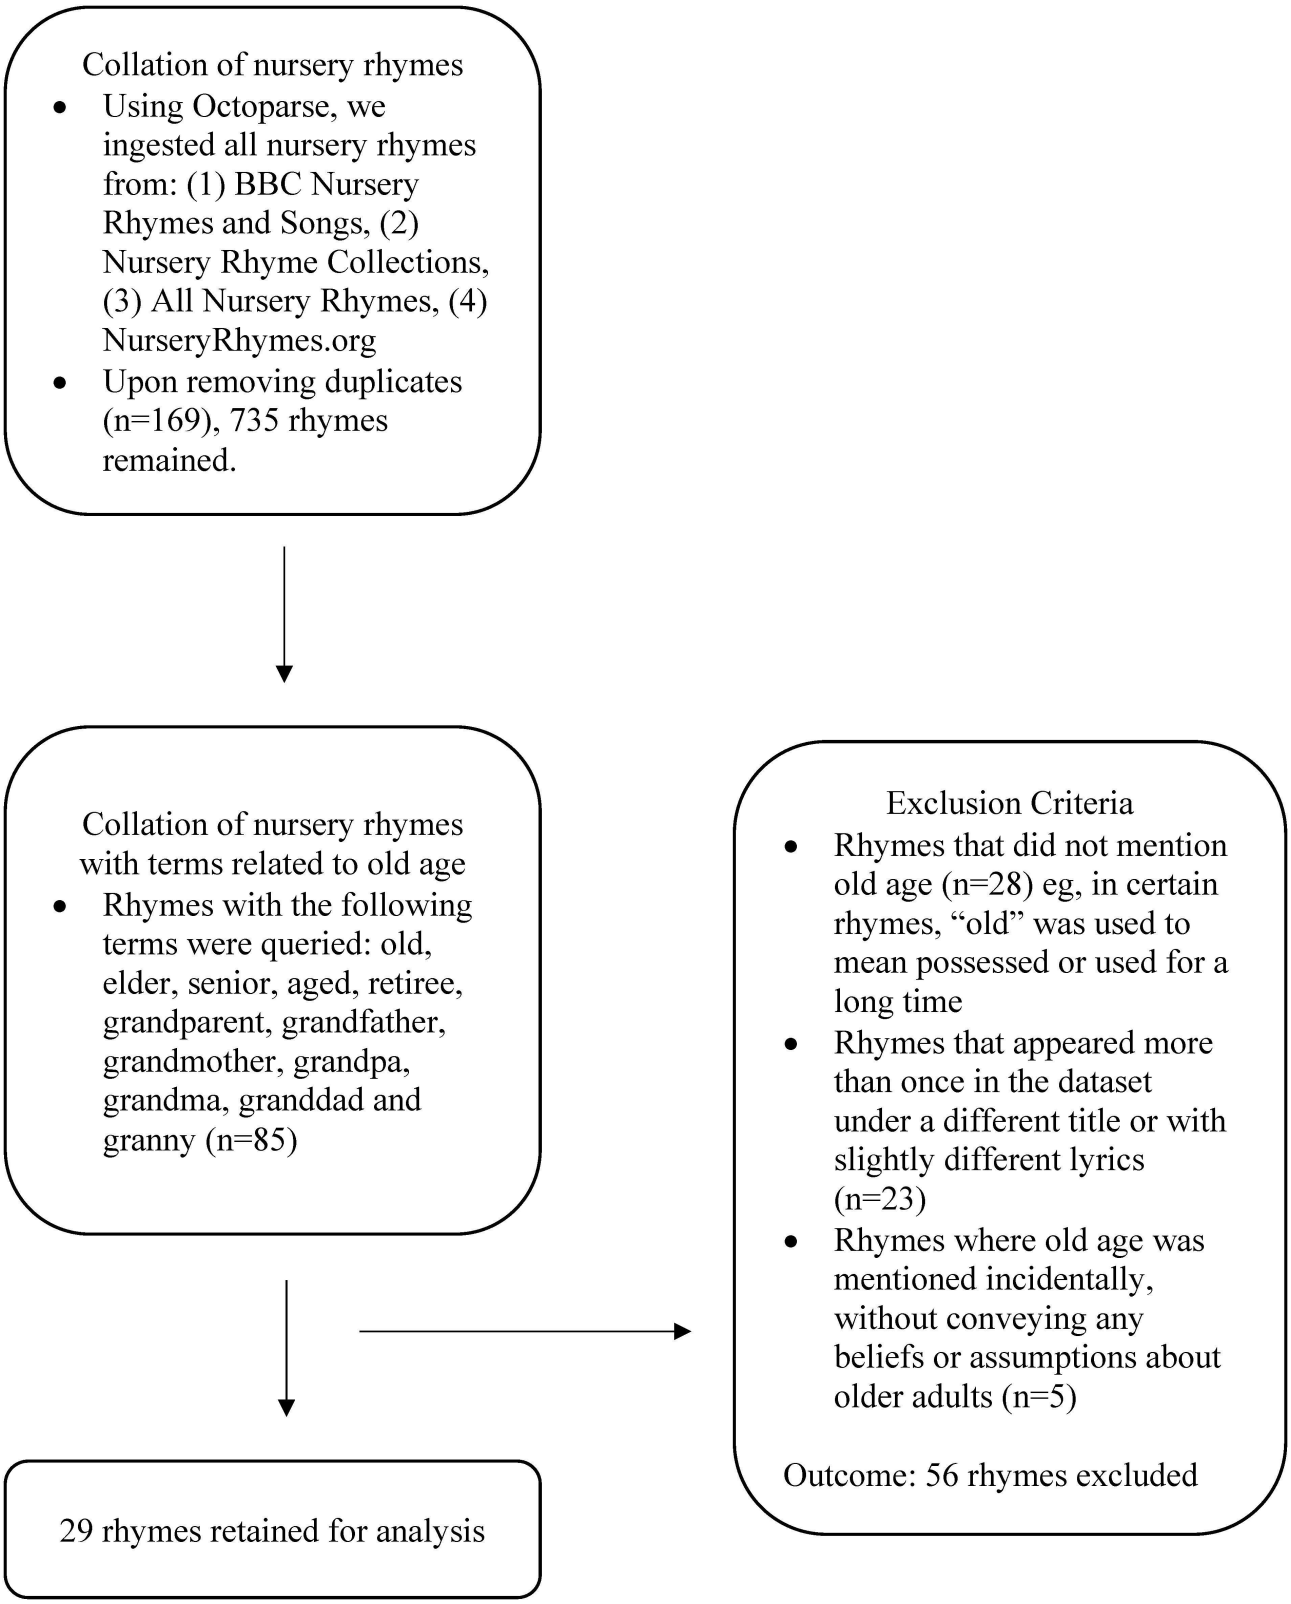
This Study

From a conceptual standpoint, this study is the first to look at the ways in which old age is portrayed in nursery rhymes. Stereotypes and attitudes take hold early in life to become stable and influential guiding forces [29]. Besides affecting attitudes toward older people, age stereotypes exact a toll on one's self-concept [3]. From a practical standpoint, this study provides insights that can inform interventions to counteract negative portrayals of old age in nursery rhymes, thus paving the way for a more age-friendly society.

Our content analysis of nursery rhymes is grounded in three research questions: To what extent is old age represented in nursery rhymes? What are the prevailing stereotypes associated with old age in nursery rhymes? Are these stereotypes primarily positive or negative?

Methods

Dataset



We gathered material from the following websites, each of which houses an extensive collection of rhymes: BBC Nursery Rhymes and Songs [30], the Nursery Rhyme Collections [31], All Nursery Rhymes [32], and NurseryRhymes.org [33]. Octoparse (Octopus Data Inc), a web-ingestion tool, was used to compile the dataset. In total, 904 nursery rhymes were retrieved. After filtering out duplicates (n=169), 735 rhymes

XSL•FO
RenderX

remained. Next, to identify rhymes related to old age, we conducted a search using the following terms: old, elder, senior, aged, retiree, grandparent, grandfather, grandmother, grandpa, grandma, granddad, and granny. This search yielded a total of 85 nursery rhymes. We subsequently removed rhymes where (1) the word “old” was used to mean possessed or used for a long time rather than having lived for a long time (n=28), (2) the rhyme appeared more than once in the dataset under a different title or with minor variations in lyrics (n=23), and (3) old age was mentioned incidentally, without conveying any beliefs or assumptions about the traits of older adults, whether positive, negative, or neutral (n=5). Any rhyme that referenced “old” in relation to old age was retained even if the term was used to describe animals instead of people. This left us with 29 nursery rhymes. Figure 1 depicts the process of collecting the data.

XSL•FO
RenderX

Figure 1. Process of collating nursery rhymes where old age was a central theme.

Content Coding of Nursery Rhymes

Following past scholarship [34-37], we conducted a thematic analysis. The coding rubric was designed using both deductive and inductive modes of reasoning [38]. We started by identifying a set of categories based on previous research [39-42] to develop a preliminary codebook. The analysis was then conducted in several stages, with the words of each rhyme read twice by the authors to ensure familiarity with the data. The aim of the first reading was to ascertain the validity of the initial set of categories, as well as to modify the codebook until all variables were refined and defined clearly. During this first reading, a new category was added whenever a rhyme featured a particular attribute that could not be suitably coded into any of the existing categories and appeared frequently enough to warrant its own category. The aim of the second reading was to make sure we

XSL•FO
RenderX

had a framework sufficiently representative of the different types of rhymes so as to finalize the coding rubric. To ensure rigor in the analysis, the 2 coders had regular discussions during which any discrepancies were reviewed and adjudicated. Areas of major overlap were identified and sectioned into broader themes. The percentage agreement between the 2 raters was 93.5% and the weighted Cohen κ was 0.91 (P<.001), indicating high interrater reliability.

Results

Summary of Insights From Content Analysis

Old age was a central theme in 4% (N=29) of the 735 nursery rhymes. Of the 29 rhymes, more than half contained negative age stereotypes (17/29, 59%) and a third contained positive ones (10/29, 34%). A small proportion portrayed old age in a neutral manner (2/29, 7%; Table 1).

Table . Themes and subthemes in portrayals of old age in nursery rhymes. Percentages may not sum to exactly 100 due to rounding.

Category and themes	Percentage
Negative portrayals of old age	59
Physically debilitated	14
Unlikable	14
Helpless	10
Cognitively impaired	7
Irresponsible	7
Unhygienic	3
Incompetent	3
Positive portrayals of old age	34
Wise	17
Affectionate	10
Jovial	7
Neutral portrayals of old age	7
Aging as natural	7

Negative Portrayals of Old Age (17/29, 59%)

Negative age stereotypes covered include being physically debilitated, cognitively impaired, unhygienic, helpless, unlikable, irresponsible, and incompetent.

Physically Debilitated

“Boom, Boom, Ain’t It Great to Be Crazy?” features a character named Peck, an older doctor who “(falls) down the well and (breaks) his neck.” The older man in “It’s Raining, It’s Pouring” is unable to “get up in the morning” after he “bump(s) his head.” “Michael Finnegan” revolves around a series of misadventures befalling an accident-prone older man. He “(catches) a fish and (drops) it in,” “(climbs) a tree and (barks) his shin,” and “(slides) back down and (scrapes) his skin.”

Cognitively Impaired

“I Know an Old Lady who Swallowed a Fly” depicts the titular character ingesting various creatures, including a “fly,” “spider,” “bird,” and “cat.” The repetitive and nonsensical nature of her actions suggests a possible decline in her mental faculties. In “Old Mother Hubbard,” old age is insinuated as being a time of forgetfulness. Old Mother Hubbard goes to the “fishmonger’s,” “grocer’s,” and “baker’s” but seemingly forgets to buy her dog food.

Unhygienic

Old age is equated with unkemptness in “Desperate Dan.” The eponymous character is classed as a “scruffy old man.” The portrayal of him “wash(ing) his face in a frying pan” and “comb(ing) his hair with a leg of a chair” adds to the depiction of someone who neglects personal hygiene. This eccentric behavior also suggests confusion and possibly cognitive decline or dementia.

Helpless

In “There was an Old Woman (As I’ve Heard Tell),” old age is positioned as a time of helplessness. After the older lady “(falls) asleep on the King’s highway” on her journey to the market, a peddler takes advantage of her by “(cutting) her petticoat up,” leaving her to “shiver and freeze.” She later wakes up disoriented and struggles to recognize herself. She says, “If it be I as I hope it may be,” her dog would be able to recognize her. When the dog barks at her, a sign it does not recognize her, she cries, “Oh dearie me.” In ”Christmas is Coming,” the line “put a penny in the old man’s hat” illustrates an impoverished older person dependent on the goodwill of others.

Unlikable

“The Old Woman Who Lived in a Shoe” describes a mother who provides her children “broth without any bread.” The phrase “[whipping] them all soundly” emphasizes her callous approach to parenting. “Goosey Goosey Gander” presents the older man

XSL•FO
RenderX

as uncooperative as he refuses to "say his prayers," leading the protagonist to take the former "by the left leg and [throw] him down the stairs."

Irresponsible

"Old Mother Leary" portrays the protagonist as behaving impetuously. She "[leaves] a lantern in the shed," which results in a fire when a "cow [kicks] it over." Her wink as the fire breaks out implies she took pleasure in the ensuing chaos.

Incompetent

In the sea shanty "Blow the Man Down," the "old skipper" is derided as incompetent. He is described as someone who "once played a remarkable game" but is now unable to navigate his ship, which is "becalmed in the tropical sea." The lyrics further underscore his nautical ineptitude by stating that he "whistled all day, but in vain for a breeze," hinting at his inability to get the ship moving.

Positive Portrayals of Old Age (10/29, 34%)

Positive age stereotypes covered include being wise, affectionate, and jovial.

Wise

In "A Wise Old Owl," the phrase "the more he saw the less he spoke, the less he spoke the more he heard" conveys that with age comes wisdom and the ability to listen and observe. The concluding line, "why can't we all be like that wise old bird?" demonstrates that the owl's qualities of being observant and thoughtful are worth emulating. Likewise, in "Dance Ter Yer Daddy," old age is celebrated as a stage of life where one bequeaths knowledge and experiences to the next generation. This is evident from the lines "when yer an old man, father to a son, sing to him the old songs, sing of all you've done, pass along the old ways, then let his song begin, dance to your daddy, ma bonnie lamb."

"Manx Lullaby" exalts old age as a time where the accrual of experience and knowledge offers guidance and insight. The lines "Through your life there are many, many, many tales, gems and stories you'll be told. Remember these songs and these rhymes as you grow old; I mean, the truth will never leave you" communicate the idea that the stories and experiences one gathers throughout life should be cherished. "If All the World was Apple Pie" opens with a hypothetical inquiry, "If all the world was apple pie, and all the sea was ink, and all the trees were bread and cheese, what should we have for drink?" The subsequent line, "it's enough to have an old man scratch his head and think," references the intellectual prowess of older individuals by suggesting that such a perplexing question would even stump someone of advanced age.

Affectionate

When a caterpillar crawls on the protagonist's grandmother in "Little Arabella Miller," she proclaims, "Arabella Miller, how I love your caterpillar!" In "Over the River and Through the Woods," the lines "when grandmother sees us come, she will say, "Oh, dear, the children are here, bring a pie for everyone" show a grandmother ever ready to indulge her grandchildren with treats.

Jovial

The central figure in "Old King Cole" is characterized as a "merry old soul." The verse notes that he "called for his pipe and he called for his bowl and he called for his fiddlers three," highlighting his zest for life. In "This Old Man," the refrain "played knick-knack" captures the character's spirited involvement in the world around him as he enthusiastically taps on different objects while engaging with others in a light-hearted manner.

Neutral Portrayals of Old Age (2/29, 7%)

Neutral portrayals depicted old age as a natural part of life. In "Grandfather's Clock," the clock symbolizes the passage of the life of the protagonist's grandfather. Significant life events are recounted, such as "when he entered at the door with a blooming and beautiful bride." The narrative concludes without judgment, stating that the clock "stopped short, never to go again, when the old man died." In "Do Do, Baby Do," the line "daddy old hen dozes over 'neath the roses, tiny chicks she'll have for you" situates old age within the larger context of family life. It suggests that aging is part of a natural process, with one generation giving way to the next.

Discussion

Principal Findings

This study delved into representations of old age in nursery rhymes. We found that only 4% of the nursery rhymes compiled mentioned old age. Of these, over half presented old age negatively, while about a third presented it positively. These findings comport with past literature about age stereotypes being multidimensional, albeit with a tendency toward negativity [14-16,43].

Considering the widespread tendency to overlook the experiences and contributions of older adults, it is unsurprising—though no less concerning—that just 4% of the nursery rhymes mentioned old age. This figure is especially stark given that by 2030, one in 6 people globally will be at least 60 years of age [44]. The issue of underrepresenting or, worse, excluding the older demographic has been flagged in other forms of children's media [9,24-28] as well as popular culture in general [45-48]. This erasure of older adults in the media in turn contributes to their invisibility in wider society.

The presence of negative age stereotypes in more than half of the rhymes raises important concerns about their potential impact on children's beliefs. It has been established that children tend to harbor certain negative stereotypes of older adults [39,40,42]. As per the theory of cultivation, repeated exposure to negative messages about older adults can influence children's perceptions of reality [7-11]. Besides perpetuating ageism and stymying the development of intergenerational solidarity, it also impacts them personally. From the perspective of the communicative ecology model of successful aging [12], negative portrayals of older adults can affect children's self-efficacy regarding their aging process. In addition, consistent with the theory of stereotype embodiment, these narratives can have detrimental effects on their mental and physical health [22].

XSL•FO
RenderX

Old age was cast in a positive light in 34% of the rhymes. These positive depictions offer a much-needed counterbalance to the ageist portrayals replete in popular culture [36,49-52]. In the endeavor to enhance representations of old age, it is crucial to bear in mind that the objective should not be for all rhymes to exclusively endorse positive age stereotypes. Overly romanticized portrayals of old age may wind up creating unrealistic expectations not in sync with the diverse realities of the aging experience [53-56]. Instead, the goal should be to portray old age in a balanced and authentic manner that acknowledges the heterogeneity of the older cohort, as well as the complexities inherent in the aging process [57].

Practical Implications

We propose a set of interventions to improve portrayals of old age in nursery rhymes.

First, new nursery rhymes could be composed to challenge negative age stereotypes. Jan Golden's creation of "Age-Friendly Vibes," a line of greeting cards developed to counter the ageism rampant in birthday cards, is an example of how new forms of expression are necessary to disrupt ageist thinking [58,59]. The creation of new rhymes could involve collaborations among writers, educators, creative professionals, gerontologists, and older adults themselves. These rhymes could be incorporated into educational materials, children's books, and digital platforms to ensure widespread accessibility and exposure. Efforts could also be made to revise existing nursery rhymes to depict the older population more positively, though it is essential to consider how such modifications might be received by educators and parents.

Second, curriculum developers should be mindful not to perpetuate negative attitudes toward older adults. There is evidence that stereotypes often take hold in one's childhood years and carry on into adulthood [29]. Educational materials should therefore be thoughtfully designed to foster understanding toward older individuals.

Third, intergenerational storytelling and performance sessions could be organized in schools, libraries, community centers, or senior living facilities. These sessions would create opportunities for older individuals to share their stories, experiences, and talents with their younger contemporaries. Crucially, these sessions encourage the reciprocal exchange of knowledge and skills while also enhancing the well-being of both groups [60,61].

Fourth, introducing opportunities for collaborative projects across age groups could bridge generational gaps. By encouraging joint artistic endeavors, both generations can contribute their perspectives, talents, and insights, thereby facilitating intergenerational learning [60,61].

Finally, there is a need to provide parents and caregivers with educational resources on ageism. As these individuals usually select the materials children are exposed to, it is crucial that they choose content that advances a more inclusive view of aging. Equipping them with the resources to challenge ageism will create a lasting impact on children's attitudes toward aging.

Limitations and Future Directions

This study has several limitations. First, since most of the rhymes in our dataset were written decades or even centuries ago, the sentiments expressed may be more representative of past attitudes than contemporary ones. Nonetheless, these rhymes warrant scrutiny for their continued relevance today. In addition, we did not manage to locate the country of origin and year of publication for all the rhymes, which limits our ability to fully contextualize them. Second, most, if not all, of the nursery rhymes in our dataset seem to have originated in the West, which means the depictions of old age likely reflect Western perspectives. Since norms of old age vary across cultures [62,63], future studies could investigate the depictions of old age in popular children's poems or songs from other countries. Third, as we were unable to determine authorial intent, our interpretation of each rhyme was inherently subjective. Nonetheless, the high interrater reliability supports the robustness of our conclusions.

To build on the findings of this study, subsequent investigations could dive into the illustrations that accompany nursery rhymes in books or videos. This will generate insights into the visual cues and symbols associated with old age in nursery rhymes. Exploring children's perceptions of depictions of older adults in nursery rhymes is another line of research worth pursuing. It would also be valuable to conduct a historical analysis of rhymes to determine whether newer rhymes contain more negative stereotypes than older ones, for instance. Finally, future research could compare nursery rhymes or other content targeted at children across different societies to examine whether there are cultural differences in the way aging is portrayed.

Conclusion

In the context of an aging population, it is paramount that people embrace a less pessimistic outlook on aging. Although nursery rhymes may seem like mere tales not to be taken seriously, they are powerful cultural artifacts capable of molding thought processes. Our study highlights the need to give children access to more accurate and nuanced stories about older adults. By doing so, society can move beyond passively assimilating negative views of aging to actively fostering healthier ones, thus building a future where all are valued regardless of age.

Abstract

Background: Mental health issues such as depression, loneliness, and cognitive decline are prevalent among older adults. They are particularly pronounced in rural areas due to socioeconomic disadvantages, limited health literacy, and social isolation. These challenges have been exacerbated by the COVID-19 pandemic, highlighting the urgent need for accessible, community-based mental health strategies. Social prescribing—linking individuals to nonmedical community resources—offers a promising model, especially when coupled with culturally relevant and digitally facilitated interventions.

Objective: This study aimed to evaluate the effectiveness of a pilot social prescribing project for individuals aged 65 years and older residing in rural South Korea. Specifically, it examined the changes in social support, loneliness, depression, cognitive function, and life satisfaction among the older adults before and after the intervention and the relationships among these factors.

Methods: A quasi-experimental, nonequivalent control group pretest-posttest design was conducted with 294 participants from Wonju City, Gangwon-do (n=148 in the experimental group, n=146 in the control group). The 8-week intervention featured a community-based music storytelling program incorporating local cultural elements and digital education. Statistical analyses, including *t* tests, difference-in-differences analysis, and structural equation modeling, were conducted to evaluate changes in scores and the effectiveness of the program intervention.

Results: The study confirmed that the social prescribing pilot project effectively reduced depression and increased social support and life satisfaction compared with the control group (P<.05, 95% CI). While cognitive function showed slight improvement, the change was not statistically significant. Social support emerged as a key mediating factor, positively influencing cognitive function and life satisfaction, and was negatively associated with depression. There was no statistically significant direct effect found between loneliness and cognitive function or social support.

Conclusions: This pilot study supports the feasibility and mental health benefits of integrating community and digital support through culturally embedded social prescribing for rural older adults. The findings highlight the importance of leveraging local resources and social networks to address mental health disparities in underserved aging populations, offering valuable insights for policymakers and practitioners developing inclusive aging and health promotion strategies.

Introduction

Developed countries like South Korea (hereafter "Korea") are now experiencing super-aging speed and an increasing number of noncommunicable diseases with long-term conditions [1]. Well-known noncommunicable diseases such as cancer, diabetes, heart disease, Alzheimer disease, dementia, and mental health ailments pose devastating health consequences for individuals, families, and communities and threaten to overwhelm health systems [2]. Disease-related risk factors include age, genes (inherited risks), long-term health conditions, lifestyle factors, sex and gender, cognitive function, and so on. Korea is a "super-aged society," in which over 20% of the total population is 65 years or older [3]. Mental health issues such as depression, loneliness, and suicide ideation have been reported to increase rapidly with soaring cognitive dysfunction among Korean elders. Meanwhile, the older adults have the highest poverty rate, and the suicide rate in South Korea is the highest among Organization for Economic Co-operation and Development countries [4]. This implies that the burden of psychological diseases in older Koreans is rapidly increasing, and the clinical approach alone cannot solve these problems. More innovative interventions should be included in the nonclinical approach to disease prevention and control for a healthier life [5].

Living alone or loneliness and a lack of social support are widely recognized risk factors for psychological disorders such as suicide, depression, and anxiety in later life [6]. These challenges are often exacerbated by life events like retirement or the loss of a loved one, which lead to smaller social networks and increased isolation [7]. The mental health of older individuals living alone is notably worse than that of those who cohabit, and those without spouses are at an even higher risk of depression [8]. During the COVID-19 pandemic, loneliness became more prevalent, with older adults being twice as likely to experience depressive symptoms compared to the prepandemic period, especially among those with lower socioeconomic status or existing health vulnerabilities [9-11]. These conditions not only increase the likelihood of depression and anxiety but also contribute to functional decline, disability, decreased life satisfaction, and even higher mortality rates [12-15]. The COVID-19 pandemic has highlighted the need for robust care support systems and high-quality life for the older adults, especially in addressing issues such as social isolation and loneliness.

Additionally, subjective health status, economic level, and literacy are crucial determinants of psychological health among the older adults. How older adults perceive their health often reflects their mental state, with positive perceptions being linked to better mental well-being and negative ones to poorer outcomes [16]. Economic conditions also play a pivotal role; older individuals with higher subjective economic levels and those receiving financial support from family members report higher levels of life satisfaction and lower risks of depression [17]. Notably, literacy significantly impacts mental health, particularly in rural older populations where low literacy or illiteracy is common. Poor literacy not only limits social participation but also reduces the effectiveness of interventions like social prescribing programs, hindering efforts to improve mental health outcomes in these communities [16]. Addressing these interconnected factors is essential for promoting better mental health among older adults.

Social prescribing originated in the United Kingdom in 2016 as an approach to connect patients or clients with nonclinical services in their local communities, addressing socioeconomic and psychosocial factors that influence health. The social prescribing model enables primary care professionals, particularly general doctors, to refer patients to various community-based activities and services, such as volunteering, gardening, and cooking, which voluntary and community organizations provide [18]. These services are designed to enhance the well-being of individuals, while simultaneously reducing the strain on conventional health care systems. The social prescribing structure has evolved over time. It generally consists of 3 key elements: the health care professional who makes the initial referral, community organizations offering support, and a link worker who facilitates the connection between the patient and the services [19]. The link worker works closely with the patient to identify their needs and goals, offering motivation and support throughout the care process. Recently, social prescribing has expanded internationally and is currently being developed in more than 30 countries and regions [20].

Social prescribing has been shown to benefit older adults [21,22]; however, given the diverse realities of aging, such as bereavement and cognitive decline, personalized interventions are essential [23]. Generic approaches often fail to meet individual needs, highlighting the importance of tailoring community care to specific situations and preferences. Integrating person-centered principles into social prescribing design can enhance intervention effectiveness by co-designing with individuals in ways that honor local culture and increase their sense of control, involvement, and engagement [24]. Around the world, social prescribing models vary but consistently reflect this emphasis on personalized care [25]. In the United Kingdom, social prescribing is integrated into the health care system, linking primary care professionals to community resources for social and psychological support that respect each person's cultural and social context [26]. In Japan, social prescribing initiatives focus on mental health and social isolation, as highlighted in a recent study that implemented social prescribing practices in local settings to improve community mental health and well-being [27]. Research on Canada's social prescribing in rural and underserved communities emphasizes the importance of local partnerships in providing social support and reducing isolation among older adults [28]. These diverse social prescribing approaches, though varying across countries, enhance older adults' well-being by prioritizing person-centered care, fostering greater acceptance and engagement [29].

Adopting the UK's concept at the beginning of 2019, Korea emerged as a notable example of a nongovernment-led program, with social prescribing being tested several times for older adults in a rural area [30]. This pilot project was led by a university and funded by the National School Research Foundation. Based on the special characteristics of the older adults in this rural area, the proportion of older people living alone who are

XSL•FO
RenderX

depressed is relatively high, and a 10-week social prescribing program that includes musical storytelling, community gardening activities [31], and support groups has been developed [32]. Previous qualitative studies reported positive results in reduced depression, improved self-esteem, increased vitality through intergenerational interactions, and expanded social relationships [33]. Reduced loneliness, increased social engagement attitudes and self-esteem [34], and more active social support and life satisfaction were also observed during the COVID-19 pandemic pilot period [35,36].

Despite the considerably high prevalence of chronic conditions, social isolation, loneliness, and mental illness among Korean older adults (prior to the pandemic and exacerbated during this time), social prescribing has not yet been implemented on a national scale. Although there is a growing body of qualitative social prescribing research on a global scale, significant gaps remain in the literature (particularly in quantitative studies). Most notably, how to evaluate the implemented project model with more samples is the priority problem in each region. To address this gap, the present study explores the significant differences in social support, loneliness, depression, cognition, and life satisfaction among rural Korean older adults before and after receiving the pilot social prescribing project intervention, and assesses the effectiveness of the pilot project in which they participated. The findings contribute to the development of social prescribing initiatives that target specific needs, preferences, and expectations of older adults, ultimately enhancing their health, social engagement, and well-being.

Methods

Project Objectives

The pilot project was organized by Yonsei University to achieve two goals: (1) to reduce depression and loneliness in the older population in rural settings in Korea and (2) to help establish city-rural social capital and relationships among older people.

Study Design

Participants were divided into experimental and control groups to evaluate the impact of a social prescribing program on depression, cognitive function, and loneliness among the older adults (April 2022 - December 2022). The design used a nonequivalent control group pretest-posttest model. This approach allowed researchers to compare outcomes before and after the intervention in both the experimental (who received the social prescribing intervention) and control groups (who did not participate in the intervention).

The following are the key steps in the study design:

1. Preliminary survey: Before each intervention, a preliminary survey was conducted to select eligible participants based on set inclusion criteria, such as age, absence of severe depression (as measured by the short form Geriatric Depression Scale-Korean version, GDS-K), and capability for everyday communication.
2. Assignment to groups: Participants were assigned to either the experimental or control group based on their willingness to participate in the social prescribing program.
3. Intervention implementation: The experimental group participated in a 2-month social prescribing program that involved activities designed to reduce isolation and improve mental health.
4. Postintervention assessment: After completing the program, both groups underwent a posttest to assess changes in depression, cognitive function, and loneliness on the final intervention day.

Intervention Programs

Music storytelling (Table 1), self-help groups, community gardening, Kalimba learning, flower tea classes, smartphone education, and COVID-19 prevention sessions were conducted. The related study protocol and research were also published in the previous studies [32,37].

XSL•FO
RenderX

Table . Intervention activities in the social prescribing program.

Intervention	Activities	Location	Time
Music storytelling	• Rhythm for life • Guide image music • Movement improvisation circle	Community library	1 per week (90 min)
Self-help group (School of Hunjang[a])	• Healthy 100-year lecture: fruit • Making natural soup for COVID-19 prevention • Making masks for COVID-19 prevention • Making natural diffuser • Songwriting for the community	Community library	1 per week (60 min)
Community gardening	• Gardening education in the spring and summer	Community library	Community garden 1 per week (30 min)
	• Nursery plant (cherry tomato, sweet potato, corn, and pepper) • Monitoring and managing community garden • Harvesting	Wonju City Agricultural Center	Community garden 1 per week (30 min)
Kalimba class (handheld musical instrument)	• Learning, practice, and public performance	Community library	1 per week (60 min)
Flower tea class (with nutrition facts)	• Learning and flower tea making • Private selling	Community library	1 per week (60 min)
Smartphone education	• Six-week smartphone education intervention for 65 and older people	Community library	1 per week (60 min)
COVID-19 prevention session	• Voluntary visit (per week)	—[b]	3 per week
	• COVID-19 phone call (per week)	—	4 per week
	• Education of healthy nutrition in COVID-19 pandemic	—	1 per week

[a]Hunjang: The teacher or headmaster of the Seodang was called the Hunjang.

[b]Not applicable.

- Music storytelling: Music therapy sessions were the main social program. The intervention was implemented as a multicomponent social prescribing package, with music storytelling as the core component and other activities serving complementary roles to support social engagement, peer support, and accessibility within the social prescribing

XSL•FO
RenderX

framework. Rhythms, group dances, and singing sessions are examples of music therapy. Sessions took place every Thursday for a duration of 10 weeks. Moreover, the team encouraged the participants to exercise while listening to music. Examples include stretching, practicing deep breathing, and joining an indoor walking program (first, the program instructor demonstrated appropriate movements and positions so that participants could easily follow along) [32].

- Self-help groups: Participants gathered at the community library every Friday to make various products using their own hands. The participants made COVID-19 masks, dolls, and soaps. While working on their personal projects, the participants told each other old stories and taught each other how to make the products.
- Community gardening activities, Kalimba class, and flower tea class: Participants and volunteers planted corn, peppers, sweet potatoes, cabbage, and tomatoes during the farming program. Kalimba and flower tea classes were also added to improve older people's hand activities and social contact.
- Smartphone education: Participants were divided into 6 groups to conduct the "smartphone education" session with education instructors and volunteer students. The education plan included basic smartphone operation methods to use apps most commonly used in Korea, such as Naver apps (information search platform) and KakaoTalk (mobile messaging app). Digital support in this study was intentionally designed as a low-threshold and supportive component rather than a technology-intensive intervention. Smartphone-based activities focused on basic functions and were embedded within face-to-face community programs to enhance accessibility and inclusivity among older rural adults. Additionally, every Friday, 2 instructors and a health major researcher shared feedback on the contents of the week's education, adjusting the overall flow of education to be consistent with the difficulty level.

Project Pilot Areas

The pilot areas for this research were Heung-eop-myeon and Munmak-eup in Wonju City, Gangwon Province, Korea. As of August 2022, Gangwon Province ranks fourth nationwide, with a high aging rate (Jeollanam-do 24.9%, Gyeongsangbuk-do 23.5%, Jeollabuk-do 22.9%, and Gangwon-do 22.4%). Both Heung-eop-myeon and Munmak-eup in Wonju City are experiencing high levels of aging with rates of 21.1% and 20.7%, respectively, indicating that both areas have become super-aged societies.

Participant Recruitment

The town office and welfare center of Heungup Town provided a potential participant list and communication support. As detailed below, participants, who were being monitored by the local welfare center, were older than 65 years of age, had mild depression, provided informed consent, and lived within walking distance of the community library were selected for the pilot project:

1. The social welfare officer of the Heungup-myeon Administrative Welfare Center recommended the older participants (age ≥65 y and living alone) living in rural areas, Wonju City, Gangwon-do.
2. First participant selection: The researchers conducted the GDS-K test with the candidates to identify the range of depression and selected those who had mild or moderate symptoms (GDS-K score: 9 - 18).
3. Second participant selection: The researchers selected older people who agreed to participate in the pilot and survey and had no difficulty with daily conversation and physical behavior.
4. Third participant selection (final): Public health doctors conducted an overall health diagnosis. Based on the results, the researchers selected the older adults who had no severe depression as the final participants in the pilot project.

Program Participants Selection

Selection criteria for program participants: The program participants, consisting of experimental and control groups, were residents aged 65 years and older from Heung-eop-myeon and Munmak-eup in Wonju City, Gangwon Province. The other criteria were as follows:

1. The first criterion was that the participants had to be recommended by at least 1 local social worker, primary health care provider (doctor), or community health nurse to have no issues participating in the pilot project.
2. The second criterion was that participants must be capable of everyday communication without hearing or visual impairments.
3. The third criterion was that during the preliminary survey, participants must not have severe depression (normal-0 - 9; mild depressives-10 - 19; and severe depressives-20 - 30), as determined by a score of 16 or lower on the GDS-K, a tool for detecting depression.

Sample Size

The sample size for participants was determined using G*Power 3.1 (Erdfelder, Faul, & Buchner, 1996), with an effect size of 0.5, a power of 0.95, and a significance level of .05, resulting in a minimum sample size of 54. Participants were conveniently sampled from community libraries and senior welfare centers in Wonju City, totaling 294 individuals. Among them, 148 who wanted to participate in the intervention program were designated as the experimental group, and 146 who did not wish to participate were designated as the control group.

Data Collection

Data were collected through one-on-one surveys by seven researchers, including 6 specializing in public health and 1 specializing in preventive medicine. The surveys were administered after explaining them to the participants, ensuring their understanding of the content, and obtaining their consent. The average survey time was approximately 15 - 20 minutes per participant. The surveys conducted before and after the intervention included questions designed to measure sociodemographic indicators, depression, cognitive function, loneliness, social support, and life satisfaction. Data collected from these assessments were analyzed to evaluate the impact of the social prescribing intervention by comparing the preintervention and postintervention results between the

XSL•FO
RenderX

experimental and control groups to determine the program's effectiveness.

Variables and Measurement

Selection of Study Variables

Building on previous research and the opinions of two local experts, this study selected age, sex, literacy, marital status, living alone status, religion, subjective economic level, and subjective health status as control variables. To measure the effectiveness of the pilot project, depression, social support, life satisfaction, cognitive function, and loneliness were selected as dependent variables.

Measurement of Study Variables

The short form GDS-K was used to measure depression among the participants. Higher scores indicated greater depression, with 15 items (15 scores) and a cutoff score of 8 [38]. The 8-item short version of the Perceived Social Support through Others Scale-8 estimated social support levels among these participants, and the highest score was 40 [39]. The Life Satisfaction Scale for Korean older adults was used to measure the index of their life satisfaction, which included 20 items and 3 scores [40]. Cognitive function was assessed using the Mini-Mental State Examination Korean Version (MMSE). For measuring loneliness, the shortened University of California, Los Angeles Loneliness Scale was used [41]. This scale consists of 8 items, with a total possible score of 32, where higher scores indicate greater levels of loneliness.

Statistical Analysis

The collected data were analyzed using SPSS Statistics version 26.0 (IBM Corp), using the following methods:

First, sociodemographic characteristics, depression levels, social support, life satisfaction, cognitive function, and loneliness levels of the participants were analyzed using percentage and frequency analyses.

Second, to verify the homogeneity between the experimental and control groups, *t* tests and Chi-square tests were conducted for all measured variables (including sociodemographic indicators).

Third, paired and independent *t*-tests were conducted to identify significant differences in social support, loneliness, depression, cognitive function, and life satisfaction scores before and after the intervention.

Fourth, to explore significant changes in social support, loneliness, depression, cognitive function, and life satisfaction between the experimental and control groups, simple and multiple difference-in-differences (DID) analyses were performed.

Finally, to examine the direct and indirect relationships between social support, loneliness, and life satisfaction with depression and cognitive function among older individuals, structural equation modeling (SEM) using SPSS Amos (version 23.0, IBM Corp) was conducted. Goodness-of-fit was evaluated using the following indicators: adjusted goodness-of-fit index (≥0.80), comparative fit index (≥0.80), incremental fit index (>0.80) [42,43], and root mean square error of approximation (≤0.80) [44,45].

All statistical significance levels were set at α=.05, and all statistical tests were 2-tailed.

DID analysis is a statistical method that can be applied when there is an experimental group and a control group, and the time point before and after the intervention is divided. This method is widely used to evaluate the effectiveness of health care policies [46-48] and community-based health projects [49,50]. A control group was selected from the same area where the experimental group lived, and presurvey and postsurvey data were collected and analyzed for the same subject in both groups through the same questionnaire. Through this, regional and individual characteristics were controlled, and the effectiveness of the intervention was verified. The amount of change in the effect variable value in the control group from the amount of change in the effect variable value before and after the intervention of the experimental group was used to confirm the effect of the social prescription program intervention. In the United Kingdom, a study using the double-difference analysis was used to assess the effectiveness of social prescription programs for patients with type 2 diabetes [51].

Ethical Considerations

The study was conducted in accordance with the Declaration of Helsinki. Before conducting the survey, the purpose of data collection and use was explained to the participants, and consent was obtained with the promise of maintaining anonymity regarding the use of the research data. Each participant received a small gift (10 $) after each session. All data were deidentified, stored securely, and accessible only to authorized research team members to ensure privacy and confidentiality. This study also received institutional review board approval from the Yonsei University Future Campus Bioethics Committee (1041849 - 202206-SB-105-01).

Results

Participant Characteristics

Results in Table 2 demonstrate the key findings regarding the experimental and control groups' sociodemographic characteristics and changes in the measured variables. The mean age of the 2 groups did not have a statistically significant difference (*P*=.60). A notable difference in gender distribution was found, with a higher proportion of women in the experimental group than in the control group (*P*<.001). Additionally, there were no statistically significant differences in living alone status (*P*=.57) and partner status (*P*=.25), indicating similar living conditions in both groups. Education levels demonstrated that approximately 116 (78.4%) had education and literacy, and 97 (65.5%) to 103 (70.5%) had their own religion in both groups (*P*=.41 and *P*=.36, respectively). Economic levels and subjective health status showed statistically significant differences, with the experimental group having fewer individuals at a high economic level (*P*<.001) and the experimental group reporting worse health (*P*<.001). There were statistically significant differences in social support and life satisfaction between the 2 groups.

[a]DID: difference-in-differences.

For social support, depression, and life satisfaction, the scores in the experimental group showed a statistically significant increase from a premeasure of 22.90, 13.41, and 21.27 to a post measure of 27.02 (*P*<.02), 10.34 (*P*=.009), and 24.75 (*P*=.049). Loneliness scores and cognitive function in both the experimental and control groups showed no statistically significant increase from the post test compared with the pretest. Depression in the experimental group demonstrated a statistically significant decrease, while the control group demonstrated increased depression scores without statistical significance (*P*=.63). Also, similar changes occurred in the control group in terms of social support (1.33) and life satisfaction (opposite, −0.66). Figure 1 shows the pre-post scores change graph in both groups.

P value	<.001	<.001	<.001	<.001	<.001

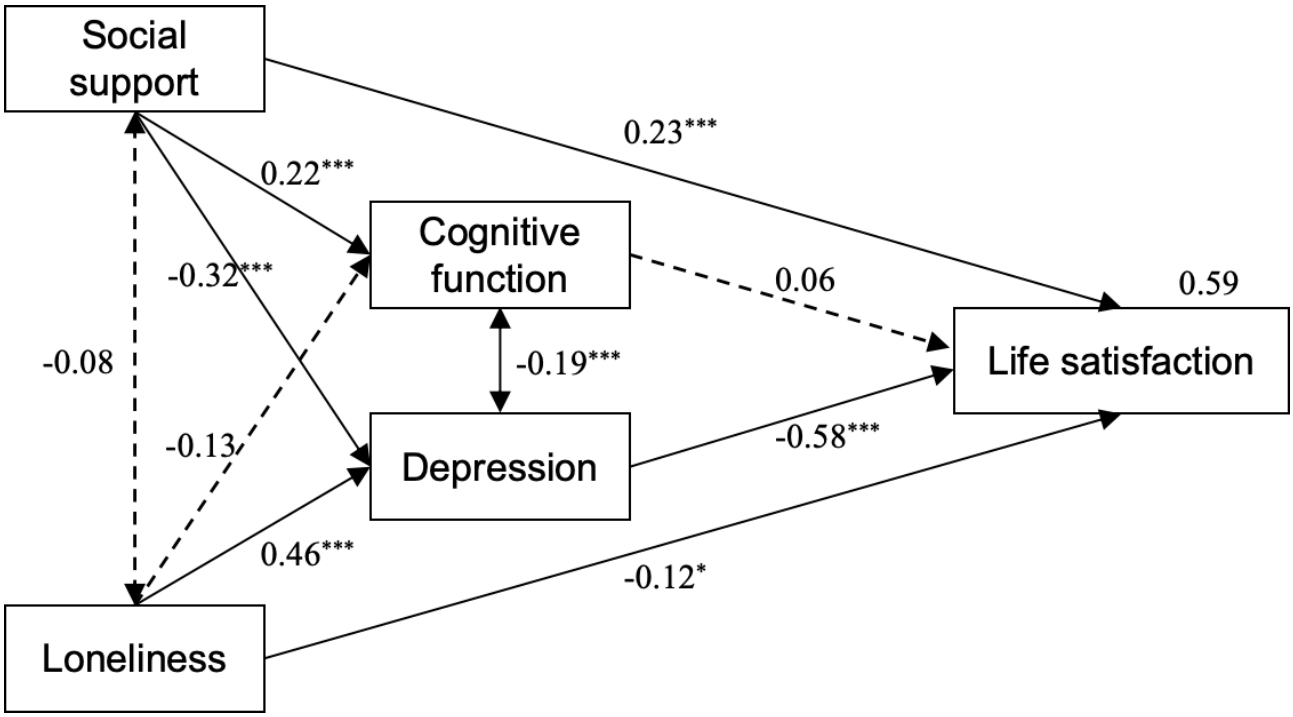
[a]*P*<.05.

[b]*P*<.01.

[c]*P*<.001.

In the analysis of the relationship between these factors and depression scores, group and interaction variables were statistically significant. Comparing the experimental group, the control group showed a higher level of depression (*P*<.05); statistical significance was also found in the negative direction in the interaction variable (β=−4.121, *P*<.01), which confirmed that the intervention effect was found on the change in depression in the experimental group. Moreover, literacy (vs no literacy), having religion (vs no religion), good subjective health status (vs bad subjective health status), and high subjective economic level (vs middle or low subjective economic level) demonstrated a statistically significant negative effect on the depressive condition, indicating that older people who have literacy, specific religion, better subjective health,

XSL•FO
RenderX



and better subjective economic level would have a lower level of depression. Similar results were found in the analysis of life satisfaction. However, no statistically significant relationship was found between literacy and life satisfaction.

Gender differences were apparent in social support, with female participants reporting higher perceived levels of social support than their male counterparts (β=3.201, *P*<.05) in the model of socioeconomic factors and social support. Additionally, social support scores seemed to have no relationship with subjective economic level. As a result of analyzing loneliness and cognitive function as an effect variable, neither the time variable, group variable, nor interaction variable were statistically significant. Surprisingly, statistically significant negative effects of age and subjective health status were reported in the loneliness analysis model; loneliness statistically significantly decreased as age increased (β=−.376, *P*<.05) with a better subjective health status (β=−.734, *P*<.05). However, for cognitive function, it was confirmed that younger persons who did not live alone and had a partner, literacy, better subjective health, and better subjective economic level had higher cognitive function scores.

Impacts of Social Support, Loneliness, Cognition, and Depression on Life Satisfaction Among the Participants

SEM analysis (Figure 2) illustrates the association and standardized effects of social support, loneliness, cognition, and depression on life satisfaction among the participants. The level of social support positively affected cognitive function (β=.22) and life satisfaction (β=.23) and had a negative relationship with depression levels (β=−.32). Additionally, all associations between loneliness, depression, and life satisfaction were statistically significant: loneliness had a positive effect on depression (β=.46), and life satisfaction was negatively impacted by depression (β=−.58) and loneliness (β=−.12), which showed the mediating effect of depression. Surprisingly, no statistically significant relationship was found between loneliness and social support or cognitive function in this study.

Figure 2. Structural equation modeling analysis of the association among social support, loneliness, cognitive function, depression, and life satisfaction. (χ^2=1.50; *P*=.22; comparative fit index=0.99; incremental fit index=0.99; Tucker-Lewis index=0.97; root mean square error of approximation=0.041). Solid lines: significant paths; dotted lines: nonsignificant paths; **P*<.05, ****P*<.001.

Regarding the relationships between cognitive function, depression, and life satisfaction, a statistically significant negative correlation was demonstrated between cognitive scores and depression (*P*<.001), whereas the opposite was observed for the relationship between social support and cognition. Moreover, although there were both negative effects between social support and depression, loneliness and cognitive function, statistical significance was only reported in social support and depression (β=−.32). This indicated that depression was negatively impacted by social support, and that a higher level of social support would result in a lower depressive condition. Fit indices of the SEM model showed an overall goodness of fit for the model: χ^2/df=1.50, root mean square error of approximation =0.041 (95% CI 0.000 - 0.050; *P*=.02), and comparative fit index =0.99.

Discussion

Principal Results

This study assessed the effects of a social prescribing pilot project on the older adults in rural South Korea. The intervention aimed to alleviate depression and loneliness, while fostering cognitive function, social support, and life satisfaction. Consistent with real-world social prescribing practice, this pilot study focused on evaluating the overall effectiveness of an integrated, multicomponent intervention model rather than isolating the relative contribution of individual components.

XSL•FO
RenderX

The results demonstrated statistically significant reductions in depression and improvements in social support and life satisfaction, alongside slight but nonsignificant improvements in cognitive function. SEM analysis further revealed a positive association between social support and life satisfaction, with depression and cognitive function acting as mediating factors, supporting the potential of social prescribing as a nonclinical, community-based approach to improving quality of life among rural older adults.

Research on social prescribing in the United Kingdom has highlighted its role as a valuable complement to clinical treatments for depression, with benefits for both physical and mental health [52,53]. A related study revealed that individuals who engaged more frequently with link workers showed greater improvements in anxiety and depression [54]. Consistent with this evidence, participants in our structured social prescribing program experienced significant reductions in depression and improvements in social support and life satisfaction. Similar positive effects have been observed in global social prescribing studies, particularly in reducing depression through community engagement and personalized support [55].

The differential outcomes observed in this study likely reflect varying responsiveness across outcome domains. Affective and evaluative indicators, such as depression and life satisfaction, appear more sensitive to short-term increases in social engagement and perceived support—core features of the intervention. In contrast, loneliness represents a more deeply rooted subjective experience that may be less responsive to change over a relatively short intervention period, particularly among older adults with long-standing social patterns in rural settings. Although cognitive function showed slight improvement, it did not reach a statistically significant association with the program intervention. This may be partly attributable to the relatively short intervention duration, which was sufficient to influence affective and psychosocial outcomes but may have been inadequate to produce detectable changes in global cognitive function [56]. In addition, cognitive function was assessed using the MMSE, a screening tool with limited sensitivity to short-term or domain-specific cognitive changes [57].

The study also highlighted the role of individual and contextual characteristics in shaping intervention outcomes. Factors such as age, gender, living arrangements, literacy, religion, subjective health, and economic status were associated with variations in social support, depression, cognitive function, and life satisfaction. In rural contexts characterized by long-term residence and stable social ties, older age was associated with lower reported loneliness, consistent with prior evidence suggesting greater emotional regulation, acceptance of social roles, and more selective social networks in later life [58-60]. Gender differences further indicated that women may benefit more readily from social support, aligning with research showing stronger community integration among older women in rural settings [61]. These findings suggest that future social prescribing programs may benefit from gender- and literacy-sensitive designs to enhance inclusivity and effectiveness [62,63].

Living arrangements and social resources also played an important role. Participants who did not live alone nor had a partner demonstrated higher cognitive function, underscoring the role of sustained social and emotional engagement in cognitive health [64], supporting previous studies linking partnership with cognitive resilience [65]. Literacy and religious affiliation were associated with lower depression and higher life satisfaction, highlighting the importance of culturally and cognitively accessible intervention materials and the protective role of spiritual and community support [63,66]. Better subjective health and economic conditions were consistently associated with lower depression and higher life satisfaction, likely reflecting reduced stress and enabling participation in meaningful social activities [25,67]. Conversely, reliance on basic pensions or combined financial and caregiving support from family members was linked to higher depressive symptoms, while informal family care was associated with greater life satisfaction compared with formal long-term or government-provided care [68-70].

The interaction effect between time and group demonstrated that the intervention's structured support and tailored activities effectively influenced mental health trajectories, suggesting that social prescribing interventions may be particularly effective in the older population by providing structured and continuous social engagement and support. These positive shifts emphasize the cumulative benefits of social prescribing, as repeated engagement in meaningful and supportive activities over time appears to foster mental well-being and social connectedness among older participants [71]. It is also possible that the cognitive effects of social prescribing operate indirectly through sustained improvements in social support and depression, suggesting that more pronounced cognitive benefits may emerge with longer engagement and follow-up [56]. This outcome may reflect older participants' established social skills, accumulated life experiences, or resilience, which may make them better equipped to benefit from social prescribing's community-based support, especially in terms of incremental mental health [53].

The results also indicated key relationships among social support, loneliness, depression, cognitive function, and life satisfaction in the older population. Social support had a positive impact on both cognitive function and life satisfaction, while showing a negative association with depression. This finding suggests that social support may serve as a buffer against depressive symptoms, facilitating a more satisfying life experience and supporting cognitive health in older adults. These outcomes are consistent with existing research demonstrating that social support is protective against mental health challenges, helping maintain cognitive function and emotional well-being in aging populations [72,73]. Additionally, loneliness was positively associated with depression, and depression negatively affected life satisfaction, indicating that depression may mediate the relationship between loneliness and life satisfaction [74,75]. This aligns with research indicating that depression is a critical factor in understanding the impact of loneliness on overall well-being, underscoring the importance of addressing both social support and mental health through social prescribing interventions [76].

XSL•FO
RenderX

Moreover, the absence of statistically significant direct associations between loneliness and social support or cognitive function warrants careful interpretation. Loneliness reflects a subjective emotional experience, whereas social support represents perceived or available resources embedded within social structures [77]. In rural communities with relatively stable and enduring social networks, older adults may continue to engage in routine social interactions despite experiencing emotional loneliness, which may attenuate direct associations in short-term analyses [78]. Consistent with this interpretation, our SEM findings indicated that loneliness may primarily influence well-being indirectly through depressive symptoms rather than exerting direct effects on cognitive function or perceived social support. Cultural norms emphasizing emotional restraint and endurance among older adults in rural Korea may further contribute to the underreporting of loneliness, partially explaining the observed pattern [79].

These results further suggest that the cognitive benefits observed in this study are more directly attributable to enhanced social support than to reductions in loneliness per se. Social support appears to play a central role in mental health resilience, as higher levels of social support were associated with lower depression and greater life satisfaction [80]. By strengthening social connections and perceived support, social prescribing interventions may therefore mitigate the negative impact of depressive symptoms on overall well-being, even in the absence of immediate changes in loneliness or cognitive function. This pattern aligns with existing evidence showing that structured social interactions and supportive relationships foster resilience against mental decline and contribute to improved quality of life in later life [81,82].

Taken together, these findings suggest that the mental health benefits of social prescribing in rural older adults are driven primarily by enhanced social support and its downstream effects on depression and life satisfaction, rather than by immediate reductions in loneliness. This highlights social support as a central and actionable mechanism through which community-based, culturally embedded interventions can promote mental health resilience and quality of life in later life. At the same time, the findings underscore the importance of considering contextual and affective pathways—particularly the indirect role of loneliness—when interpreting intervention mechanisms and designing future longitudinal studies to capture longer-term cognitive and psychosocial effects.

Limitations

This study had some limitations. First, the nonrandomized design and participation introduced potential selection bias. Although baseline equivalence was assessed and intervention effects were examined using DID analysis with covariate adjustment, residual confounding cannot be fully excluded. Participants in both the experimental and control groups may have had higher motivation for social engagement and more positive attitudes toward community activities, which could have influenced the observed outcomes. Second, as a real-world pilot study, it was challenging to fully implement all elements recommended by established intervention guidelines [83]. Third, the relatively small sample size and short intervention duration limit the generalizability of the findings and the ability to assess sustained or delayed effects, particularly with respect to cognitive outcomes. The use of the MMSE, while appropriate for screening, may have limited sensitivity to short-term cognitive changes in relatively high-functioning older adults. Future studies with larger samples, extended follow-up, and more sensitive or objective cognitive assessments are therefore warranted.

Conclusions

This pilot study examined the effectiveness of a community-supported and digitally supported social prescribing program in improving mental health and well-being among older adults in rural South Korea. The findings demonstrated that such interventions can significantly reduce depression and enhance social support and life satisfaction, reinforcing the value of integrating community-based resources with culturally relevant digital tools in elder care. These results underscore the incorporation of social prescribing into broader community care strategies to address mental health disparities in underserved aging populations.

The program's effectiveness was driven by culturally tailored activities—such as music sessions, flower tea making, and gardening—implemented through locally accessible and digital supports that promoted sustained engagement. By encouraging collaboration among health care professionals, local facilitators, and residents, social prescribing moves beyond traditional clinical models and toward inclusive, socially grounded care. The study underscores the importance of embedding social prescribing within broader community care and healthy aging strategies, with intermediary roles such as link workers serving as key connectors between digital and local community resources in sustaining and scaling such programs within national mental health and aging policy frameworks.

Implications for Practice and Policy

The findings of this study offer timely and policy-relevant implications for enhancing mental health promotion among older adults in rural and underserved communities. From a sustainability and public health systems perspective, the results suggest that social prescribing interventions can be effectively embedded within broader healthy aging strategies when they leverage existing community infrastructure, such as community libraries, welfare centers, and local volunteer networks. By emphasizing nonclinical, preventive, and person-centered approaches, social prescribing aligns with ongoing shifts toward community-based mental health promotion for aging populations.

In practice and policy, the integration of digitally supported components—implemented as low-threshold, supportive tools embedded within face-to-face community activities—can improve accessibility and continuity of care without exacerbating digital exclusion. At the same time, the institutionalization of intermediary roles, such as link workers or community coordinators, is critical for sustaining and scaling social prescribing frameworks by facilitating needs assessment, navigation of community resources, and coordination between medical and nonclinical services. At the national level, these

XSL•FO
RenderX

findings align with South Korea's priorities to reduce social isolation and promote healthy aging, underscoring the importance of embedding social prescribing within existing mental health and aging policy frameworks and establishing stable funding and governance mechanisms to support sustainable, community-driven mental health promotion.

Acknowledgments

The authors wish to acknowledge the contribution of participants and stakeholders to this program throughout the study process.

Funding

The study was funded by National Research Foundation of Korea, Grant/Award Number: NRF-2018S1A5A2A03039636; Ministry of Education of the Republic of Korea; This work was also supported by the Ph.D. research initiation project of Anhui Medical University (0501054201) and the Youth Social Science Research Program of the Education Department of Anhui Province (2025AHGXSK40223).

Data Availability

Due to ethical reasons, the raw data would remain confidential and would not be shared. The processed data that support the findings of this study are available from the corresponding author, upon reasonable request.

Authors' Contributions

EWN was involved in the design and conceptualization of the study. BZ, JAL, SL, HJY, HKK, SMH, XZ, and EWN were involved in program implementation and data collection. BZ finished data analysis, interpretation, and the initial draft of the manuscript and revised the manuscript. BZ and EWN contributed to funding acquisition, quality control, and reviewing of the final draft of the manuscript. All authors read and approved the final manuscript.

Conflicts of Interest

None declared.

Abstract

Background: Social isolation among older adults is a growing public health concern. While information and communication technologies offer opportunities for social engagement, few studies have examined how video game co-play, a form of interactive digital media, supports intergenerational connection and perceived social support among older adults.

Objective: Guided by uses and gratifications theory, this study investigates whether older adults' online communication attitudes predict video game co-play with younger family members and whether such co-play enhances perceived social support.

Methods: A total of 433 older adults (aged ≥60 years) were recruited using a snowball sampling approach facilitated by undergraduate students. Participants completed an online survey assessing online social connection; online self-disclosure (OSD); video game co-play with younger family members; and perceived informational, instrumental, and emotional support. Regression analyses predicting co-play behavior (H1) were conducted using the full sample (N=433), with participants reporting no co-play coded as 0 to indicate the absence of engagement. Hierarchical regression analyses examining associations between co-play and social support (H2) were restricted to participants reporting video game co-play (n=71). Mediation analyses testing indirect effects (H3-H4) were also conducted among co-players (n=71), controlling for age, gender, and race. Mediation models were estimated using PROCESS Model 4, with 5000 bootstrap samples to generate 95% CIs.

Results: OSD was positively associated with video game co-play behavior (b=0.12, SE=0.03; P<.001), whereas online social connection was not significantly related to co-play (b=0.06, SE=0.03; P=.08). Video game co-play was positively associated with perceived informational (b=0.11, SE=0.04; P=.01) and instrumental (b=0.16, SE=0.04; P<.001) social support but not emotional support (b=0.07, SE=0.04; P=.053). Among 71 participants reporting co-play, mediation analyses indicated that video game co-play mediated the association between OSD and informational support (indirect effect b=0.01, 95% CI .001-0.03) and instrumental support (indirect effect b=0.02, 95% CI 0.005-0.03), with partial mediation for informational support and full mediation for instrumental support.

Conclusions: While not interventional, these findings suggest that video game co-play may function as a culturally relevant, digitally mediated relational practice through which older adults engage in intergenerational connection and perceive informational and instrumental support. The results inform digital health efforts aimed at reducing social isolation and underscore the importance of integrating digital literacy and attitudinal readiness into age-inclusive policy and program design. However, the small subsample of older adults who reported co-play behavior warrants caution in generalizing the findings and highlights the need for broader inclusion in future research.

older adults; video game co-play; digital health; social support; intergenerational communication; online communication attitudes; uses and gratifications theory

Introduction

Background

As the global population ages, addressing social isolation among older adults has become a pressing public health concern. Digital health tools, especially information and communication technologies (ICTs), have emerged as promising means to support emotional well-being and social connectivity [1,2]. Among these tools, video games are increasingly recognized not just as recreational platforms but as interactive environments capable of facilitating intergenerational engagement [3]. As digital connectivity among older adults continues to grow, there is a critical need to examine the psychological drivers that shape their engagement in online activities and evaluate the social and relational benefits that follow [4,5].

XSL•FO
RenderX

Older adults' online communication attitudes, specifically online self-disclosure (OSD) and online social connection (OSC), may influence how they interact with digital platforms [6,7]. OSD refers to the willingness to share personal thoughts and experiences online, while OSC reflects the perception that digital tools help sustain interpersonal bonds [7,8]. These attitudes influence participation in relationship-enhancing digital activities, such as video game co-play.

Video game co-play, which involves collaborative or competitive gaming between older adults and younger family members, enables shared interactive experiences that extend beyond entertainment [3]. Through gameplay, participants engage in storytelling, problem-solving, and coordinated activity, processes that have been shown to strengthen family closeness, shared identity, and intergenerational understanding [9-11]. Prior research also suggests that co-play can foster emotional support and a sense of inclusion in digital spaces, particularly for older adults navigating geographical distance from family members [12,13].

Unlike more passive or asynchronous ICTs, such as text messaging or social media browsing, video game co-play is characterized by real-time interaction, shared goals, and sustained mutual attention [3,11,14]. These affordances create structured opportunities for collaboration, reciprocity, and informal support exchange, making co-play particularly well suited for intergenerational connection [3,11,12]. Focusing on co-play allows this study to isolate a form of digital engagement that is both socially immersive and relationally consequential for older adults [9,12].

To explore these dynamics, this study draws on uses and gratifications theory (UGT) as a foundational framework for understanding older adults' agency in selecting and engaging with digital media [15,16]. While UGT has traditionally been applied to explain media choice and individual-level gratifications, recent scholarship highlights the need to extend the theory to interactive, relational, and socially embedded digital practices [16], particularly in aging populations [2,17]. Within this expanded perspective, older adults' online communication attitudes, such as openness to self-disclosure and perceived importance of online connection, may shape their engagement in interactive activities, such as video game co-play, which offer opportunities for synchronous communication and shared relational experiences across generations.

Social support, including informational, instrumental, and emotional forms, is a key determinant of psychological well-being in later life [18,19]. In digital intergenerational contexts, support may emerge through cooperative gameplay and emotionally resonant exchanges [20,21]. Understanding these relationships provides insight into how digital tools can sustain social bonds and promote resilience among older adults.

By conceptualizing video game co-play as a digitally mediated relational practice rather than a formal intervention, this study highlights a culturally situated pathway through which older adults may sustain intergenerational connection across geographic distance. In doing so, it extends UGT to later life by emphasizing how motivational dispositions translate into interactive relational behaviors, while also acknowledging that access, digital literacy, and cultural norms may shape engagement. These insights provide a theoretically grounded foundation for future research and age-inclusive digital engagement strategies.

Literature Review: Uses and Gratifications Theory

UGT provides a foundational framework for understanding how individuals actively select media to fulfill specific psychological and social needs [15]. Unlike passive models of media effects, UGT emphasizes users' agency in engaging with communication technologies based on anticipated gratifications such as entertainment, escapism, information-seeking, and social connection [22,23]. Although originally developed in the context of mass media, contemporary extensions of UGT emphasize its applicability to interactive, socially embedded, and relational digital practices, moving beyond individual media choice to account for co-use and participatory engagement [16,23]. This approach underscores the functional role of media in addressing users' everyday emotional and relational goals.

For older adults, UGT provides valuable insights into the adoption of digital tools designed to enhance well-being and maintain social relationships. Research has shown that motivations, such as companionship, leisure, and family connection, are central drivers of technology use in aging populations [2,16]. These motivations are especially salient in intergenerational contexts, where digitally mediated shared activities, such as video game co-play, can foster emotional reciprocity and familial closeness.

UGT also emphasizes the significance of individual differences, particularly in attitudes toward digital communication, in determining how and why technologies are utilized. Individuals actively choose media based on psychological and social needs, and these choices vary according to personal dispositions, such as motivation, past experiences, and social context [23]. For older adults, attitudinal orientations, such as openness to self-disclosure or valuing online social connection, may influence not only whether they engage with specific digital platforms but also how effectively those tools meet their evolving social needs. Understanding these motivations is crucial for informing age-appropriate digital engagement strategies that extend beyond usability to foster lasting and meaningful participation. As such, UGT provides a valuable framework for examining how older adults integrate video game co-play into their relational routines, particularly as a means of maintaining connections and reducing isolation in long-distance family relationships. Building on this perspective, this study advances UGT by applying it to intergenerational digital interaction in later life, emphasizing how attitudinal orientations toward online communication shape engagement in interactive, relational media practices rather than passive consumption.

Significance of Video Game Co-Play for Older Adults

Video game co-play has emerged as an innovative and increasingly meaningful form of intergenerational interaction, particularly for older adults seeking to sustain connections with younger family members [3,12]. More than a source of entertainment, co-playing video games provides a structured, immersive experience that fosters real-time engagement,

XSL•FO
RenderX

reciprocal communication, and collaborative problem-solving [3,14]. These interactions can serve as digital pathways for maintaining familial bonds and promoting intergenerational understanding.

For older adults, video game co-play can yield significant emotional and psychosocial benefits. Shared gameplay fosters mutual support and relational closeness, buffering against the health risks of isolation [14,24]. Studies found that older adults who engaged in digital gaming reported significantly higher levels of emotional well-being and reduced depressive symptoms compared to nonplayers [24]. Moreover, social gaming interventions have demonstrated feasibility and effectiveness in promoting intergenerational connection and alleviating loneliness. For example, past study has found that mobile gaming apps designed to facilitate intergenerational interaction can help to increase engagement and reduce social isolation among older participants [25]. These experiences enhance inclusion and self-worth, improving emotional health in later life.

Importantly, video game co-play supports synchronous engagement across physical distances, making it especially relevant for families separated by geography or mobility constraints [12,26]. Unlike more passive forms of communication, such as text messaging or phone calls, gameplay fosters dynamic interaction and shared accomplishment. Through these playful yet meaningful exchanges, older adults and younger relatives can maintain continuity in their relationships despite limited face-to-face contact [27].

In this sense, video game co-play can be understood as a low-barrier, home-based digitally mediated relational practice that holds relevance for digital health and social inclusion efforts. Its accessibility, emotional salience, and interactive format make it a promising tool for enhancing relational satisfaction and psychological well-being among older populations. As such, integrating co-play into broader digital health strategies and aging support programs may offer new avenues to promote social connectedness in aging communities.

Importantly, cross-cultural and comparative research suggests that engagement in intergenerational digital activities is deeply shaped by sociocultural norms related to family obligation, leisure, and emotional expression [28,29]. Prior research indicates that collectivist cultural contexts may place greater emphasis on shared activities and instrumental caregiving, potentially influencing both the adoption of intergenerational co-play and perceptions of its relational value [30,31]. In such contexts, shared digital practices may function as extensions of everyday family caregiving rather than as purely recreational activities [32]. Recognizing these cultural contingencies is essential for interpreting findings related to intergenerational digital engagement and for avoiding overgeneralization across diverse aging populations.

Online Communication Attitudes

Within the UGT framework, online communication attitudes serve as important predictors of media selection and engagement. Drawing on the social influence model of technology use, research shows that individuals' engagement with digital platforms is shaped by their preexisting attitudes toward mediated communication [33,34]. This highlights the central role of attitudinal dispositions, particularly among older adults, in influencing how and why digital tools are used. Attitudes are composed of both affective and cognitive dimensions, which guide individuals' behavioral tendencies [35]. The theory of reasoned action further posits that attitudes and behavioral intentions are key predictors of actual behavior, particularly in contexts that are socially salient, such as maintaining family relationships [36].

Two primary components of online communication attitudes include OSC and OSD [6,8]. OSC refers to the belief that digital technologies are essential for sustaining interpersonal relationships, while OSD reflects one's comfort with sharing personal information in online environments [6,7]. Individuals high in OSC may view digital engagement as a necessary aspect of their social well-being, whereas those high in OSD tend to interact more frequently and meaningfully across digital platforms [6-8]. These dimensions are especially relevant in older populations, as they help explain variability in how digital tools are adopted and used for relationship maintenance.

In the context of aging and family communication, OSC holds particular significance. For older adults with mobility limitations or who are geographically separated from loved ones, maintaining close contact often relies on digital channels [1,37]. Technologies, such as video games, offer new, interactive avenues for sustaining these relationships. Prior studies have shown that older adults who view online platforms as socially vital are more inclined to adopt tools that promote interactive engagement, including video game co-play [2,38]. From this perspective, co-play can be seen as a relational strategy grounded in OSC, a form of active, synchronous interaction that reinforces intergenerational connection.

Similarly, OSD may be a critical enabler of co-play behavior. The willingness to share personal experiences and emotions in digital contexts can deepen relationships and foster more meaningful interactions [7]. In video game environments, where gameplay often involves storytelling, collaboration, and real-time feedback [3], older adults who are comfortable with online self-disclosure may be more inclined to engage. Research has found that individuals high in OSD tend to be more active across various forms of digital media, including those that support emotionally rich exchanges [39,40]. This openness may enhance the depth of intergenerational connection within the gaming context.

Building on these insights, this study predicts that online communication attitudes, specifically OSC and OSD, will significantly influence the extent to which older adults participate in video game co-play with younger family members.

Hypothesis 1 (H1): (a) OSC and (b) OSD will be significantly associated with video game co-play behavior among older adults in the context of long-distance family relationships.

Video Game Co-Play and Perceived Social Support

Building on the understanding that attitudes influence technology adoption and use [39,41,42], the construct of perceived social support is central to evaluating how digital

XSL•FO
RenderX

interaction fosters relational well-being among older adults. Perceived social support encompasses several key dimensions: informational support (eg, sharing advice and guidance), instrumental or tangible support (eg, providing assistance or resources), emotional support (eg, offering empathy and care), social network support (eg, fostering connectedness and belonging), and esteem support (eg, affirming personal worth) [43]. These forms of support collectively contribute to emotional resilience and psychological health in later life.

In intergenerational contexts, family members are typically the primary providers of social support. Emotional support from close relatives is strongly associated with increased life satisfaction and psychological well-being in older adults [44], while instrumental support is essential for navigating health care systems, managing daily tasks, and responding to crises [45]. Informational support, in turn, plays a critical role in promoting autonomy and informed decision-making [46]. These resources support older adults' well-being and integration [47].

When geographic distance limits in-person interaction, digital communication technologies become vital tools for sustaining these support systems. Research indicates that ICTs enable older adults to maintain emotional intimacy and receive both practical and emotional assistance across distances [48,49]. Through interactive platforms, such as video games, older adults can share experiences, collaborate on tasks, and engage in emotionally resonant dialog with younger family members [38,50]. These forms of digital engagement can reinforce a sense of belonging, strengthen emotional ties, and affirm older adults' roles within their family networks.

Empirical studies have documented how ICT engagement improves perceptions of social support and reduces feelings of loneliness [17,51]. In senior living settings, technology use has been linked to enhanced social interaction, community integration, and emotional well-being [1]. Applying these findings to video game co-play, it is reasonable to hypothesize that engaging in shared digital gameplay with younger family members may lead to increased perceptions of informational, instrumental, and emotional support, especially in the context of long-distance relationships.

Hypothesis 2 (H2): Video game co-play will be positively associated with perceived (a) informational, (b) instrumental, and (c) emotional social support among older adults in long-distance relationships.

Mediating Role of Video Game Co-Play

While general ICT use has been shown to mediate the relationship between online communication attitudes and perceived social support [52], video game co-play represents a particularly interactive and emotionally rich form of digital engagement that may offer a stronger pathway to familial bonding [14,27]. Older adults who exhibit positive attitudes toward OSC and OSD are more likely to adopt collaborative digital platforms that enable synchronous, emotionally meaningful interaction [2,7]. Video game co-play exemplifies such a platform, providing not only entertainment but also opportunities for shared achievement, relational expression, and emotional reciprocity [3].

Co-playing video games encourages sustained communication, cooperation, and joint problem-solving, which are core components of emotionally supportive relationships and intergenerational understanding [3,27]. These dynamics are especially salient for older adults seeking to maintain connections with geographically distant family members. The interactive nature of co-play allows older users to both express care and receive encouragement through real-time engagement, reinforcing feelings of value and inclusion within family networks [17]. This process not only enhances emotional closeness but also strengthens perceptions of informational, instrumental, and emotional support [38,51].

Based on this theoretical and empirical foundation, this study examines a mediation model in which video game co-play serves as the mechanism through which online communication attitudes influence perceived social support among older adults. This framework positions co-play not merely as an outcome of digital attitudes but as a critical conduit for transforming psychological dispositions into relational benefits in digitally mediated family interactions.

Hypothesis 3 (H3): Video game co-play will mediate the relationship between OSC and perceived (a) informational, (b) instrumental, and (c) emotional social support among older adults in long-distance family relationships.

Hypothesis 4 (H4): Video game co-play will mediate the relationship between OSD and perceived (a) informational, (b) instrumental, and (c) emotional social support among older adults in long-distance family relationships.

Methods

Participants

Older adults aged 60 years and above were recruited using a snowball sampling approach through undergraduate students at a large West Coast university. Each college-aged participant was instructed to invite 1 older adult family member (aged 60 years or older) who resided in a different geographic location. The long-distance nature of the intergenerational dyads was determined based on participant self-report and supplemented by IP address filtering to reduce the likelihood that dyad members were responding from the same physical location. This recruitment method was incentivized through extra credit for the undergraduate students; no monetary or nonmonetary incentives were provided to older adult participants.

Initially, a total of 1306 older adult participants were recruited (mean age 70.14, SD 7.23 y). To ensure data quality, participants who had excessive missing data or spent insufficient time on the survey (ie, less than 300 s, based on pilot test standards) were excluded, resulting in the removal of 638 cases. An additional 235 participants were excluded due to missing data on the video game co-play measure, defined as incomplete or nonresponse to the co-play items administered to participants who indicated engagement in video game play. The final sample consisted of 433 older adults, ranging in age from 60 to 95 years. Of these 433 participants, 71 reported engaging in video game co-play with their younger family members, whereas 362 reported no co-play engagement. For analyses examining

XSL•FO
RenderX

predictors of co-play behavior (H1), participants who reported no co-play were coded as 0 to indicate the absence of engagement. However, mediation analyses requiring the continuous co-play composite were restricted to participants reporting co-play (n=71). Among these co-players, 41 were female and 30 were male, and the majority were Asian (53/71, 75%), followed by White and Hispanic participants. The gender composition of the full sample was 289 female participants and 144 male participants. In terms of ethnicity, the full sample included 252 Asian participants, 96 White participants, and 85 Hispanic participants.

Ethical Considerations

All procedures were approved by the university's institutional review board (1655269-1). College students were recruited through a study subject pool and received course extra credit for assisting with recruitment. A link to a survey on Qualtrics was provided after each college student gave informed consent; the survey requested the email address of 1 older adult family member aged 60 years or older. The system automatically sent the survey to the electronic address provided by the college student's family member. Older adult participation was voluntary, and no monetary or nonmonetary incentives were provided to older adult participants. The IP address was used as a filter to ensure that respondents were not located at the same physical address and to prevent multiple survey submissions from the same individual, providing supplemental verification of the reported long-distance nature of intergenerational dyads. The web-based survey was administered using a secure online platform between September 2020 and June 2021, and study procedures are reported in accordance with the CHERRIES (Checklist for Reporting Results of Internet E-Surveys) guidelines (Checklist 1). Because the survey was distributed via individualized referral emails rather than a public website, standard web-based response metrics, such as view rate and participation rate, could not be calculated.

Measures

Overview

The survey began with demographic information questions (ie, gender, age, and race). The rest of the survey had items measuring video game co-playing, perceived social support, and online communication attitudes. Participants were instructed to answer the items for their video game co-playing and perceived social support while considering their familial counterparts.

Online Communication Attitudes

This factor was measured with the OSD and OSC subscales [6]. OSD included 7 items, and OSC had 6 items. Both factors were framed as 7-point Likert-type scales (1=strongly disagree and 7=strongly agree). The OSD subscale included statements such as "I feel like I can sometimes be more personal during internet conversations" and "I feel like I can be more open when I am communicating online." The OSC subscale contained items such as "Without the internet, my social life would be drastically different" and "I would communicate less with my friends if I could not talk with them online." OSD (Cronbach α=0.91) and OSC (Cronbach α=0.83) for older adult participants showed good reliability.

Video Game Co-Play

Older adults' engagement in collaborative video game play with younger family members was assessed using 3 items adapted from Wang et al [3]. Participants reported (1) the typical duration of a video game session with a younger family member (eg, "When you play video games with your younger family member, about how long do you play at a time?"), (2) the percentage of their total gaming time spent co-playing with that family member, and (3) the estimated percentage of the younger family member's gaming time spent playing with them. These items captured complementary behavioral and perceptual indicators of co-play frequency and mutual engagement. Only participants who reported engaging in video game co-play completed these items. Participants who indicated no co-play engagement were not administered the follow-up items and were treated as missing for analyses requiring the continuous co-play composite. For analyses examining predictors of co-play behavior (H1), non–co-players were coded as 0 to reflect the absence of engagement. To construct the composite index, each item was standardized (*z*-score) to account for differences in scale and metric and then averaged to form a single co-play score, with higher values indicating greater engagement in intergenerational co-play. The composite demonstrated good internal consistency (Cronbach α=0.83).

Perceived Social Support

This factor was assessed using the UCLA social support inventory [53]. This scale measured informational (5 items), instrumental (5 items), and emotional support (10 items). The items were framed as a 5-point Likert-type scale (1=never to 5=very often). The items were reworded to target intergenerational relationships. Sample items included "how often did your younger/older family member provide assistance to you within the past three months?" and "how satisfied or dissatisfied have you been with the love and caring you've received from your younger/older family member within the past three months?" The scale showed good reliability for the older adult participants (Cronbach α=0.88).

Results

The mean scores for online communication attitudes, video game co-play frequency, and perceived social support were calculated. Descriptive statistics presented in Tables 1 and 2 reflect the full analytic sample (N=433). All regression and mediation analyses controlled for age, gender, and race (with White participants as the reference category) [54,55]. Regression analyses examining predictors of video game co-play behavior (H1) were conducted using the full sample (N=433), with participants who reported no co-play coded as 0 to indicate the absence of engagement. Hierarchical regression analyses were conducted for H2, with age, gender, and race entered in step 1 and video game co-play entered in step 2 to examine its incremental contribution to perceived social support. Mediation analyses (H3 and H4) were conducted using PROCESS Model 4 [56]. Because the continuous co-play composite was calculated only for participants reporting co-play engagement, cases with

XSL•FO
RenderX

missing mediator values were excluded by PROCESS, resulting in a mediation sample of 71 participants. Indirect effects were estimated using 5000 bootstrap samples to generate 95% CIs.

Table . Descriptive statistics among study variables (N=433).

Study variables	Range	Minimum	Maximum	Mean (SD)
Online social connection	6.00	1.00	7.00	2.88 (1.29)
Online self-disclosure	5.57	1.00	6.57	2.72 (1.27)
Video game co-play score[a,b,c]	5.54	−0.32	5.22	−0.00 (0.86)
Perceived informational social support	4.26	1.17	5.43	3.40 (0.74)
Perceived instrumental social support	4.50	1.00	5.50	3.31 (0.80)
Perceived emotional social support	3.75	2.00	5.75	4.05 (0.67)

[a]The video game co-play score is a composite variable derived from 3 standardized items: typical session duration, percentage of the older adult's gaming time spent co-playing, and percentage of the younger relative's gaming time spent with the older adult.

[b]The composite was calculated among participants reporting video game co-play engagement (n=71).

[c]Higher scores indicate greater frequency and intensity of video game co-play.

Table . Pearson correlations among study variables (N=433).

Study variables	1	2	3	4	5	6

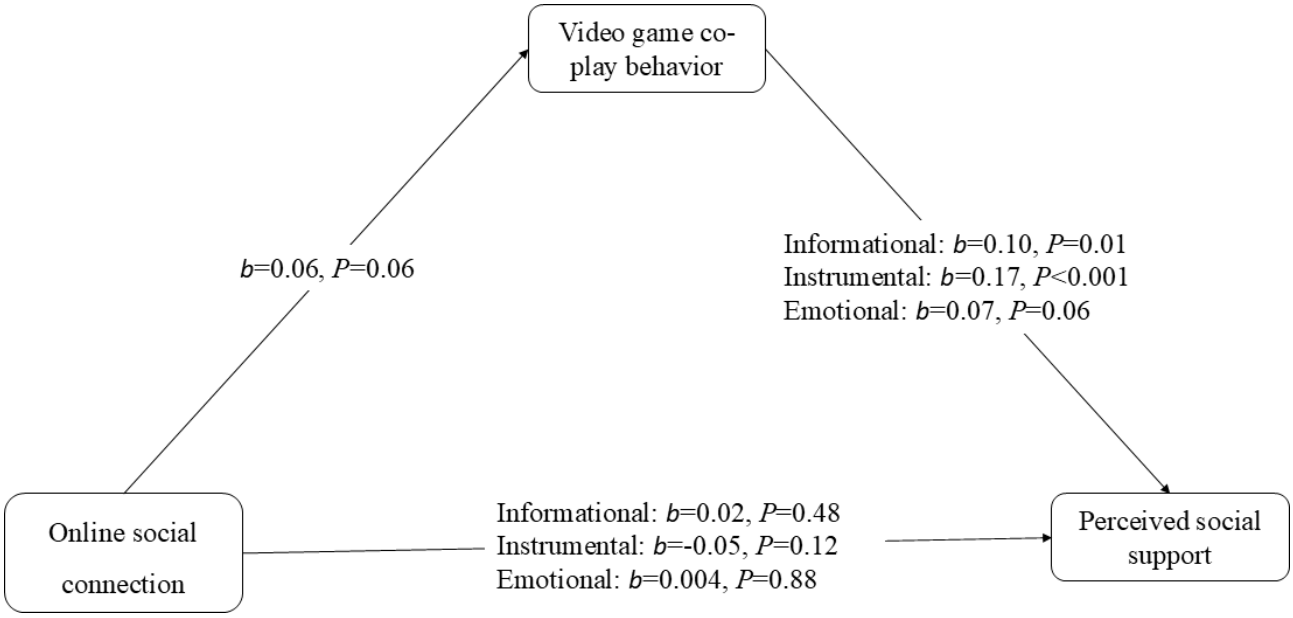
[b]Regression and mediation analyses involving the continuous co-play composite were restricted to participants reporting co-play (n=71).

[c]P<.01.

H1 posits that older adults' online communication attitudes of (a) OSC and (b) OSD would be associated with video game co-play behavior. Hierarchical regression analyses were conducted, with age, gender, and race entered at step 1 and online communication attitudes entered at step 2. For OSC, step 1 model was significant ($F_{3,429}$=3.53; P=.03) and explaining 2% of the variance (R^2=0.02). However, the addition of OSC in step 2 did not significantly improve the model (ΔR^2=0.01, F change$_{1,428}$=3.10; P=.08). The final model was significant ($F_{4,428}$=3.40; P=.02), explaining 3% of the variance (R^2=0.03), but OSC was not significantly associated with video game co-play behavior (b=0.06, SE=0.03, 95% CI −0.01 to 0.12; P=.08). For OSD, step 2 did significantly improve the model (ΔR^2=.04, F change$_{1,428}$=12.85; P<.001). The final model was significant ($F_{4,428}$=6.70; P<.001), explaining 6% of the variance (R^2=0.06). Moreover, OSD was significantly associated with video game co-play behavior (b=0.12, SE=0.03, 95% CI 0.05-0.18; P<.001). CIs were estimated using 5000 bootstrap samples with percentile-based intervals.



H2 posits that video game co-play would be positively associated with perceived (a) informational, (b) instrumental, and (c) emotional social support among older adults in long-distance relationships. Hierarchical regression analyses were conducted, with age, gender, and race entered in step 1 and video game co-play entered in step 2 (n=71). For informational support, the step 1 model was significant ($F_{3,67}$=7.01, R^2=0.06; P<.001). The addition of video game co-play in step 2 significantly improved the model (ΔR^2=0.02,

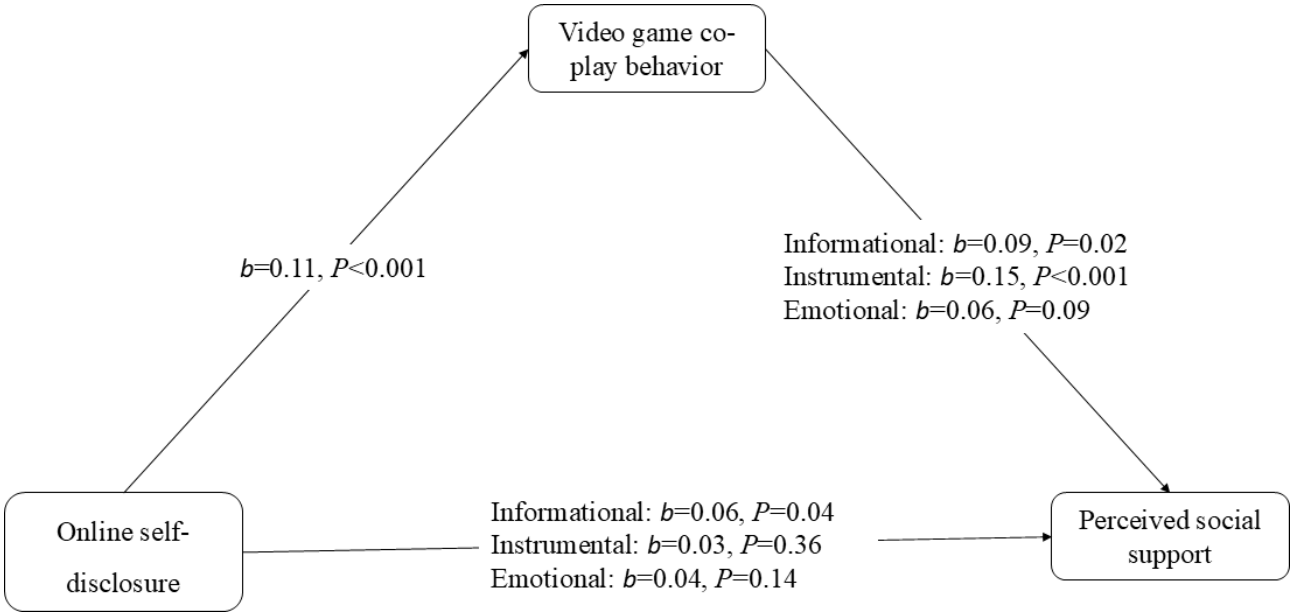
XSL•FO
RenderX

F change$_{1,66}$=7.10; P=.009). The final model was significant ($F_{4,66}$=6.90; P<.001), explaining 8% of the variance (R^2=0.08). Video game co-play was positively associated with informational support (b=0.11, SE=0.04, 95% CI 0.03-0.19; P=.01). For instrumental support, the step 1 model accounted for 11% of the variance (R^2=0.11, $F_{3,67}$=13.15; P<.001). Adding video game co-play significantly increased explained variance (ΔR^2=0.03, F change$_{1,66}$=13.92; P<.001). The final model was significant ($F_{4,66}$=13.62; P<.001), accounting for 14% of the variance (R^2=0.14), and video game co-play was positively associated with instrumental support (b=0.16, SE=.04, 95% CI 0.08-0.24; P<.001). For emotional support, the step 1 model including age, gender, and race was not statistically significant ($F_{3,67}$=1.65; P=.16), explaining 1% of the variance (R^2=0.01). Adding video game co-play in step 2 did not significantly improve the model (ΔR^2=0.01; F change$_{1,66}$=3.76; P=.07). The final model was not statistically significant ($F_{4,66}$=2.07; P=.07), explaining 2% of the variance (R^2=0.02). Consistent with the overall model, video game co-play was not significantly associated with emotional support (b=0.07, SE=.04, 95% CI −0.001 to 0.15; P=.053).

H3 posits that video game co-play will mediate the relationship between OSC and (a) informational, (b) instrumental, and (c) emotional social support among older adults in long-distance family relationships. Mediation analyses (PROCESS Model 4; 5000 bootstrap samples) indicated that the model predicting video game co-play was significant ($F_{4,66}$=4.18; P<.001), explaining 5% of the variance (R^2=0.05). However, because no significant association was found between OSC and video game co-play (b=0.06, SE=0.03, 95% CI −0.001 to 0.13; P=.06), the mediation hypothesis was not supported (Figure 1).

Figure 1. Mediation model of online social connection, video game co-play behavior, and perceived social support. This figure illustrates the mediation model examining the association between online social connection (OSC), video game co-play behavior, and perceived social support among older adults. Values represent unstandardized regression coefficients (b). The association between OSC and video game co-play was not statistically significant (b=0.06, SE=0.03; P=.06). Indirect effects were estimated using 5000 bootstrap samples. All paths were adjusted for age, gender, and race (White as the reference category).

H4 posits that video game co-play mediates the relationship between OSD and (a) informational, (b) instrumental, and (c) emotional social support among older adults in long-distance family relationships. For H4a, mediation analyses (PROCESS Model 4; 5000 bootstrap samples) indicated that the association between OSD and informational support was partially mediated by video game co-play. The model predicting video game co-play was significant ($F_{4,66}$=5.57; P<.001), explaining 6% of the variance (R^2=0.06). Higher OSD was associated with greater video game co-play (b=0.11, SE=0.03, 95% CI 0.04-0.17; P<.001). The overall model predicting informational support was also significant ($F_{5,65}$=6.61; P<.001), accounting for 9% of the variance (R^2=0.09). Video game co-play was positively associated with informational support (b=0.09, SE=0.04, 95% CI 0.01-0.17; P=.02). The direct effect of OSD on informational support remained significant after including video game co-play in the model (b=0.06, SE=0.03, 95% CI 0.001-0.11; P=.04), indicating partial mediation. The indirect effect of OSD on informational support through video game co-play was statistically significant (b=0.01, SE=0.01, 95% CI 0.001-.03).



For H4b, mediation analyses (PROCESS Model 4; 5000 bootstrap samples) supported full mediation of the association between OSD and instrumental support through video game co-play. The model predicting video game co-play was significant ($F_{4,66}$=5.57; P<.001), explaining 6% of the variance (R^2=.06); OSD was positively associated with co-play (b=0.11, SE=.03, 95% CI 0.04-0.17; P<.001). The overall model predicting instrumental support was significant ($F_{5,65}$=11.5; P<.001), accounting for 14% of the variance (R^2=0.14), and co-play was positively associated with instrumental support (b=0.15, SE=0.04, 95% CI 0.07-0.24; P<.001). The indirect effect of OSD on instrumental support through co-play was statistically significant (b=0.02, SE=0.01, 95% CI 0.005-0.03), while the direct effect of OSD on instrumental support was not

XSL•FO
RenderX

significant after including co-play (b=0.03, SE=0.03, 95% CI −0.03 to 0.09; P=.36), consistent with full mediation.

For H4c, mediation analyses (PROCESS Model 4; 5000 bootstrap samples) did not support mediation of the association between OSD and emotional support through video game co-play. The model predicting video game co-play was significant ($F_{4,66}$=5.57; P<.001), explaining 6% of the variance (R^2=0.06). However, the overall model predicting emotional support was not statistically significant ($F_{5,65}$=2.11; P=.051), explaining 3% of the variance (R^2=0.03). Video game co-play was not significantly associated with emotional support (b=0.06, SE=0.04, 95% CI −0.01 to 0.13; P=.09). Consistent with this pattern, the indirect effect of OSD on emotional support through co-play was not statistically significant (b=0.01, SE=0.01, 95% CI −0.001 to 0.02; Figure 2).

Figure 2. Mediation model of online self-disclosure, video game co-play behavior, and perceived social support. Mediation model examining the association between online self-disclosure (OSD) and perceived social support through video game co-play among older adults. Values represent unstandardized regression coefficients (b). OSD was positively associated with video game co-play (b=.11, SE=.03; P<.001). Video game co-play was positively associated with informational support (b=.09, SE=.04; P=.02) and instrumental support (b=.15, SE=.04; P<.001) but not emotional support (b=.06, SE=.04; P=.09). Indirect effects were estimated using 5000 bootstrap samples. All paths were adjusted for age, gender, and race (White as the reference category).

Discussion

Principal Findings

This study advances understanding of how older adults engage with interactive digital platforms to sustain long-distance intergenerational bonds by extending UGT into the context of aging and digitally mediated family relationships. While UGT has traditionally been applied to explain media selection and individual-level gratifications [15], these findings highlight its relevance for understanding how older adults' online communication attitudes translate into interactive, relational digital practices. In particular, OSD emerged as a key motivational driver of video game co-play, which, in turn, was associated with enhanced informational and instrumental social support [7,39]. These findings position video game co-play not as passive media consumption but as an active, socially embedded digital health behavior through which older adults seek connection, reciprocity, and practical support within intergenerational family networks.

Although the findings indicate meaningful associations between video game co-play and perceived social support, only a small proportion of older adults in the sample reported engaging in co-play with younger family members (n=71). This limited prevalence suggests that intergenerational gaming is not yet a normative practice among older adults and may reflect broader barriers related to digital literacy, access, physical ability, or generational perceptions of gaming. The modest size of the co-player subsample necessarily limits statistical power and warrants cautious interpretation of the mediation findings, which should be viewed as exploratory rather than confirmatory. At the same time, the low uptake of co-play itself constitutes an important empirical insight, underscoring the need for targeted digital inclusion strategies that lower entry barriers and expand access to interactive digital activities for aging populations. These structural and attitudinal barriers warrant explicit consideration when interpreting these findings and when evaluating the broader applicability of video game co-play as a digitally mediated practice for aging populations.

Barriers to Access and the Digital Divide

Although the findings suggest that video game co-play may serve as a digitally mediated pathway to informational and instrumental social support among older adults, these benefits are not equally accessible to all aging populations. Structural barriers, such as access to gaming devices, reliable internet connectivity, and appropriate software, remain persistent challenges, particularly for older adults with limited socioeconomic resources [57,58]. In addition, individual-level barriers, including limited prior gaming experience, lower digital confidence, age-related sensory or cognitive limitations, and

XSL•FO
RenderX

the usability demands of commercial video games, may further constrain participation in video game co-play [39,59]. These barriers highlight the uneven distribution of opportunities to engage in interactive digital practices and underscore the importance of considering digital inequities when interpreting these findings [60-62].

Importantly, the current sample likely reflects older adults who already possess a baseline level of digital access and attitudinal readiness, which may partially explain the observed associations between online self-disclosure, co-play behavior, and perceived social support [39,58,59]. Engagement in video game co-play in this context often depended on younger family members initiating, facilitating, or sustaining participation, suggesting that intergenerational support may play a critical role in mitigating aspects of the digital divide [3,11,38]. From a digital health perspective, these findings emphasize the need for age-friendly design, intergenerational scaffolding, and community-based programs that reduce technological complexity and proactively address access barriers rather than assuming universal digital participation among older adults [62,63].

Health Literacy and Culturally Relevant Digital Engagement

Beyond access, effective engagement with digitally mediated practices also requires adequate digital health literacy, including confidence, perceived relevance, and comfort with online interaction [57,58,64]. Although digital health literacy was not directly measured in this study, online communication attitudes function as theoretically meaningful proxies for older adults' readiness to engage with interactive digital tools. In this study, OSD and OSC may be understood as psychosocial indicators of digital engagement readiness rather than measures of technical proficiency alone [8,39,59]. Older adults who feel comfortable sharing personal experiences online and who perceive digital platforms as socially meaningful may be better positioned to engage in interactive digital activities such as video game co-play and derive relational benefits from those interactions [16,41,51]. This interpretation aligns with broader digital health literature, emphasizing that motivation, trust, and perceived usefulness are central components of digital health literacy in later life [41,64].

Cultural context further shapes how older adults engage with digital technologies and how the benefits of such engagement are experienced [28,29,31]. The predominantly Asian composition of the co-playing subsample suggests that intergenerational digital engagement may be embedded within cultural norms, emphasizing family obligation, shared leisure, and instrumental support [30,32,65]. In such contexts, video game co-play may function less as recreational play and more as an extension of everyday family caregiving and relational maintenance [3,12,14]. These findings highlight the importance of culturally relevant digital health strategies that align with older adults' relational values and lived experiences, rather than relying on one-size-fits-all approaches to digital literacy or engagement. Designing inclusive digital programs that recognize cultural variation in communication norms and family roles may enhance both participation and perceived benefits among diverse aging populations [58,63].

Building on these findings, the study contributes theoretically by clarifying how online communication attitudes translate into relational outcomes through specific forms of media co-engagement. Although prior research has broadly documented the role of ICT use in maintaining familial connections [2,60], these findings identify video game co-play as a distinct, immersive activity that mediates the relationship between online self-disclosure and perceived social support. In particular, co-play fully mediated the association between OSD and instrumental support, suggesting that interactive gameplay creates conditions conducive to practical assistance from younger family members. This interpretation aligns with prior evidence that older adults derive both emotional and functional value from collaborative, task-oriented forms of communication [3,27].

This study extends prior research on intergenerational video game co-play, which primarily focused on younger populations and parent-child dynamics within coresiding families [3]. By contrast, this study uniquely focuses on older adults in geographically dispersed families, incorporating a broader age range and explicitly examining long-distance intergenerational ties. Furthermore, while a previous study emphasized family closeness and satisfaction [3], this study disaggregates the social support construct into informational, instrumental, and emotional components, providing a more nuanced understanding of how specific forms of support are cultivated through co-play. In doing so, it reframes video game co-play as a digitally mediated relational practice for aging populations rather than merely a recreational activity.

Drawing on Cutrona and Suhr's [43] social support typology, the results suggest that co-play enhances both informational and instrumental support through real-time problem-solving and skill-sharing. These findings align with prior evidence showing that active ICT engagement enhances the collaborative and cognitive capacities of older adults [17]. Within gameplay contexts, younger relatives may offer advice, guidance, or co-navigate challenges, reinforcing perceptions of competence and shared achievement among older players.

Implications for Policy and Community-Based Digital Programs

Practically, these findings inform the design of family-based digital health programs and future intervention development. They align with aging and digital inclusion frameworks, such as World Health Organization's Age-Friendly Digital Ecosystems and the Centers for Disease Control and Prevention's Healthy Aging initiatives, which emphasize digital equity, intergenerational connection, and inclusive design [62,63,66]. Integrating co-play into these frameworks could inform future health technology policy. Echoing prior research on shared media use and relational bonds, this study shows that video games can support both emotional and task-oriented intergenerational support [14], especially for families separated by distance or mobility constraints. Providers may integrate co-play into care programs to reduce isolation. Structured co-play modules in home or community services could enhance

XSL•FO
RenderX

engagement. Game features that encourage storytelling, collaboration, or personalization may enhance relational outcomes. Designers should prioritize emotional expressiveness and ease of use to maximize accessibility and meaningful interaction. By framing video game co-play as a relational digital health behavior rather than a recreational activity alone, this study aligns with aging-in-place and digital equity initiatives that emphasize socially meaningful technology use to reduce isolation among older adults [38,62,63].

Interestingly, although OSC was expected to predict co-play in video games, this relationship was not statistically significant. One explanation may be the difference between valuing online connections and engaging in specific behaviors, such as gaming. Older adults might appreciate digital connectivity but prefer more familiar tools (eg, email, video calls) over games, which may still seem youth-oriented [67,68]. Measurement limitations or ceiling effects may also have constrained variability in OSC scores, reducing predictive strength. Future research could further explore these dynamics, using qualitative approaches to examine older adults' preferences and comfort levels with various digital platforms.

Notably, video game co-play was more strongly associated with informational and instrumental support than with emotional support. This pattern suggests that structured, goal-oriented digital interactions may be particularly effective for facilitating task-focused assistance, such as problem-solving, guidance, and practical coordination, rather than explicit emotional expression. Emotional support may be communicated through more direct or verbally intimate modalities, such as video calls or messaging [48,49], whereas gameplay contexts emphasize shared activity and collaboration. In addition, cultural norms surrounding emotional expression, especially within collectivist family systems, may privilege instrumental forms of care over overt emotional disclosure [31,32,69]. Thus, the nonsignificant association with emotional support does not imply an absence of affective value but rather highlights the importance of considering how different digital modalities afford distinct types of social support.

These patterns are consistent with cross-cultural research on aging, family interaction, and digital engagement, which demonstrates that cultural norms strongly shape both technology use and expectations of social support in later life [31,58,59]. Comparative studies suggest that, in collectivist cultural contexts, family-based digital activities often emphasize practical assistance, shared responsibility, and instrumental caregiving over explicit emotional disclosure [29,30]. Emotional support may be conveyed implicitly through sustained participation and shared activities rather than through overt verbal expression [31,32]. Viewed through this cross-cultural lens, the observed association between video game co-play and informational and instrumental support, rather than emotional support, aligns with broader evidence on how culturally embedded family practices shape digitally mediated intergenerational relationships.

The predominantly Asian composition of the sample provides an important sociocultural context for interpreting the findings. Cultural values emphasizing familial obligation, interdependence, and instrumental caregiving may shape both engagement in intergenerational co-play and perceptions of support derived from such interactions. In collectivist cultural contexts, shared digital activities may function not only as leisure but also as relational maintenance practices that reinforce family roles and responsibilities [65,70]. While this cultural specificity limits the generalizability of the findings to more individualistic populations, it also offers valuable insight into how culturally embedded family norms intersect with digital media use in later life. Future cross-cultural research is needed to examine how gaming practices and support dynamics vary across cultural, national, and socioeconomic contexts. Although participants were recruited through a US-based university, the national context was not independently verified, and the findings should therefore be interpreted within this institutional and sociocultural setting.

These findings offer practical implications for digital game design and public policy. Developers should design intergenerationally friendly features, such as accessible interfaces, inclusive narratives, and cooperative challenges that foster caregiving dialogue. Policymakers and health professionals can support co-play integration into aging services, including telehealth, community centers, and digital literacy programs. Aging agencies and inclusion initiatives should embed co-play into broader digital engagement strategies, with funding for training and partnerships with libraries, senior centers, and telehealth platforms to pilot intergenerational gaming as a psychosocial support tool. The findings should be interpreted as observational evidence that informs future intervention design rather than as demonstrating causal intervention effects.

As synthesized above, while video game co-play shows promise, equitable implementation requires explicit attention to persistent socioeconomic disparities, digital literacy gaps, and physical or cognitive limitations that constrain older adults' access to interactive digital media [57]. Building on the barriers and literacy considerations discussed above, strategies such as device provision, subsidized internet access, and tailored digital skills training delivered through community-based settings are essential for inclusive adoption.

Intergenerational digital literacy programs, in which younger family members scaffold older adults' engagement in co-play, may simultaneously support skill acquisition and relationship building [71]. To ensure cultural relevance, interventions should incorporate design elements aligned with diverse familial values and communication norms. Multilingual interfaces, culturally familiar imagery, and collaborative mechanics suited to collectivist traditions can enhance engagement.

Age-inclusive policies must move beyond usability to support emotionally resonant, culturally congruent experiences. This study offers empirical grounding for future interventions that design and evaluate digital tools promoting relational well-being. Emphasizing co-play as a vehicle for relational support underscores the need for culturally and socially responsive technology–enabled aging innovation.

Limitations and Future Directions

Several limitations warrant consideration when interpreting this study's findings. First, the study used a cross-sectional design, which limits causal inference regarding the relationships among online communication attitudes, video game co-play, and perceived social support. Although mediation analyses were theoretically grounded, the results should be interpreted as exploratory and hypothesis-generating rather than as evidence of causal mechanisms. Longitudinal or experimental designs are needed to establish temporal ordering and causal direction.

Second, the sampling strategy relied on snowball recruitment facilitated by undergraduate students, which may limit representativeness. While this approach enabled access to geographically dispersed, long-distance intergenerational dyads, a key focus of the study, it may also have introduced selection bias toward families with stronger intergenerational ties or greater digital access. In addition, the sample was predominantly composed of Asian older adults. This ethnic composition likely reflects both institutional recruitment context and cultural norms emphasizing familial obligation and interdependence. Although this provides valuable insight into culturally embedded patterns of intergenerational digital engagement and contributes to theory-building in collectivist family contexts, it constrains the generalizability of the findings to other ethnic or cultural groups. This cultural context likely shapes both the forms of support emphasized and the meanings ascribed to co-play and thus should be understood as an interpretive lens rather than a confounding artifact.

Third, only a small proportion of participants (n=71) reported engaging in video game co-play with younger family members. This limited subsample reduces statistical power and increases the risk of type 2 error, particularly in mediation analyses. As such, null findings, especially regarding emotional support, should be interpreted cautiously. At the same time, the low prevalence of co-play itself represents a meaningful empirical finding, highlighting potential barriers related to digital literacy, access, generational norms, or physical ability that warrant further investigation.

Fourth, measures of video game co-play were based on self-reported estimates of shared gaming time and involvement, which may be subject to recall bias or social desirability effects. This concern may be especially salient among older adults with varying levels of cognitive load or digital familiarity. Future research should consider incorporating objective or behavioral measures, such as gameplay logs, platform-generated usage data, or ecological momentary assessment, to enhance measurement precision.

Fifth, the long-distance nature of intergenerational dyads was based on participant reports and supplemented by IP address filtering to ensure respondents were not located at the same physical address. However, geographic distance was not independently verified, and perceived distance may differ from objective distance. Future studies may benefit from more precise geographic measures to examine how physical separation interacts with digital engagement and support dynamics. Perceived geographic distance may differ from objective distance, and this distinction may influence how intergenerational support is experienced and interpreted, as perceived separation may be more salient for relational dynamics than physical distance alone.

Finally, the study did not directly assess socioeconomic status, national context, or broader structural factors that may shape access to digital technologies and gaming practices. Economic resources, educational background, and cultural exposure to gaming may act as unmeasured confounding variables influencing both co-play behavior and perceived social support. Future research should incorporate more diverse, cross-national samples and explicitly measure socioeconomic and structural determinants of digital engagement in later life.

Conclusion

In conclusion, this study highlights the potential of video game co-play as a meaningful, home-based, digitally mediated relational practice through which older adults may sustain intergenerational relationships across geographic distance. Rather than positioning co-play as an established intervention, the findings suggest that older adults' online communication attitudes, particularly online self-disclosure, are associated with engagement in interactive digital activities, which, in turn, relate to perceptions of informational and instrumental social support. These patterns are consistent with UGT and extend its application to aging populations by illustrating how motivational dispositions translate into relational digital practices in later life. By situating video game co-play within culturally embedded family contexts and acknowledging structural and access-related constraints, this study underscores the importance of age-inclusive, culturally responsive digital engagement strategies for addressing social isolation among older adults.

Abstract

Background: Adult day centers (ADC) are well-positioned to address social isolation among the rapidly growing population of people living with dementia but are underused relative to other forms of long-term care. Mistrust of these centers among family caregivers remains a barrier to their use. Digital health tools offer a promising approach to enhance transparency, improve communication, and build trust between caregivers and ADCs. As such, researchers at New York University (NYU) developed CareMobi, a user-centered mobile app that supports care coordination between ADC, care providers, and caregivers.

Objective: This study aimed to evaluate the real-world usability, acceptability, and feasibility of CareMobi among staff in ADCs and the caregivers of people living with dementia who attend centers.

Methods: Guided by the Goal–Question–Metric (GQM) framework, we conducted a low-burden field usability evaluation of CareMobi in 2 ADCs. Data included baseline caregiver surveys, app usage logs, administration of the **Post-Study System Usability Questionnaire**, and participant interviews. Feasibility benchmarks were established a priori using STOP-AMEND-GO criteria for evaluable retention, usability, satisfaction, engagement, and acceptability. Quantitative analyses summarized demographics, caregiver confidence, and app usability (7-point scale and median scores). Qualitative analyses used thematic coding of interviews and written feedback to identify perceived benefits, barriers, and recommendations for implementation.

Results: Family caregivers (n=15) from 2 ADCs participated in a mixed-methods pilot. Participants were primarily female (87%), non-Hispanic White (93%), and middle-aged or older (67% aged 30-64 years). Most were sole caregivers (80%). Baseline confidence in managing dementia-related care was high, particularly in communication with providers. Of 15 enrolled caregivers, 14 (93%) logged into CareMobi at least once, and the majority “agreed/strongly agreed” that the app was easy to use (6/8, 75%) and easy to learn (7/8, 87.5%); 75% (6/8) of the participants liked the interface and found the information well organized. All staff (n=3) indicated the CareMobi app was easy to use, easy to learn, and well organized (3/3, 100%). Willingness to use the app beyond the study period was high among caregivers (6/8, 75%) and staff (3/3, 100%). Open-ended caregiver responses emphasized reassurance from daily updates, user-friendliness, and time savings. Staff reported reduced “phone tag” streamlining coordination, particularly for new ADC enrollees. However, established caregivers tended to use the app passively, defaulting to phone calls. Themes highlighted the need for structured logging guidance, role-specific templates, and integration with existing systems. Caregivers and staff noted that routine updates fostered trust, improved decision-making about attendance, strengthened communication with health care providers, and provided peace of mind.

Conclusions: CareMobi offers a promising approach to modernizing ADC in ways that respect resource limitations and caregiver needs, through combining digital transparency with low-burden communication. Future efforts should center on equity and focus on linguistic inclusion, infrastructure support, and engagement in underserved communities.

Introduction

Social isolation and loneliness are widely recognized, modifiable social determinants of health in later life. In the United States, approximately one quarter of community-dwelling adults aged ≥65 years are socially isolated and large proportions report loneliness [1]. Social isolation and loneliness are associated with a 32% and 14% increased risk of all-cause mortality, respectively. They are also linked to increased morbidity, including a 29% higher risk of coronary heart disease and a 32% higher risk of stroke [1,2]. These risks are amplified for people living with dementia and their family care partners, for whom shrinking networks, mobility limitations, and caregiver burden compound barriers to engagement in community life [3].

Adult day centers (ADCs) are a cornerstone of community-based long-term care and a promising, equity-oriented platform to counter social disconnection at scale [4], especially for people living with dementia. They represent the most diverse sector of long-term care, serving more than 250,000 predominantly low-income (72%) and ethnically diverse (58%) individuals, who are able to remain in their own homes while receiving daytime care that fosters engagement, health monitoring, and meaningful socialization. By providing structured programming, culturally responsive services, and respite for care partners, ADCs buffer social isolation and loneliness for people living with dementia, and simultaneously reduce caregiver burden [4,5]. Yet, despite the fact that more than 80% of older adults report wanting to remain in their homes [5], and that social engagement is consistently linked to better health outcomes [6], ADCs remain vastly underused compared to other, more costly forms of long-term care that either don't offer socialization or allow people to remain at home. These include home health (serving more than 3 million) or nursing homes (with 1.2 million residents) [7].

There are several barriers that limit uptake of ADCs, including transportation challenges, cost, and limited awareness of services; but one of the most significant is trust. A key relational barrier to ADC use, particularly among socially isolated or underserved families, is mistrust of these facilities and difficulty communicating with center staff about day-to-day care [7]. Family caregivers often report uncertainty about whether staff truly understand their loved one's needs, whether cultural preferences will be respected, and whether information will be shared transparently, all of which cause apprehension and can deter sustained engagement.

Research has consistently highlighted improved information-sharing as crucial to overcoming barriers in the uptake of respite care [8]. While many older adults can articulate their own needs, for those who are unable to do so, like people living with dementia, effective communication often depends on carers and respite staff [8]. Digital health tools, when designed for usability and embedded into real-world workflows, offer a promising strategy to enhance transparency, strengthen bidirectional communication, and improve coordination between families and community providers [9,10]. By providing a lens into the day-to-day care of their loved ones, such tools can reduce caregiver apprehension, build trust in ADCs, and allow people living with dementia to be more socially engaged by attending these centers.

A growing number of mobile health (mHealth) interventions have been developed to support dementia caregiving. such as symptom-monitoring tools, secure messaging platforms, and caregiver education apps, but few are designed for or evaluated within ADC environments, which have distinct documentation practices, staffing structures, and relational communication needs. Existing tools often focus on clinical care coordination or remote monitoring rather than the day-to-day visibility that shapes caregiver trust in ADCs and influences continued attendance. CareMobi is a mHealth app designed to strengthen communication, coordination, and transparency between ADC staff, family caregivers, and health providers. The app allows for real-time updates on daily activities, health status, and logistical information, helping caregivers interpret changes in behavior at home and enhancing continuity of care across settings. CareMobi differs conceptually from prior interventions by centering a digital trust-building approach: it uses real-time, low-burden updates to reduce caregivers' uncertainty, strengthen relational continuity, and support socio-technical alignment between caregivers and ADC workflows. This focus on transparency, role-specific communication, and workflow feasibility represents a novel contribution to the mHealth landscape and addresses known barriers to ADC use [10-12].

We posit that by making ADC-based care more visible to families, through timely updates and low-burden, role-specific interactions, CareMobi can reduce uncertainty, foster trust, and simplify decisions about ADC attendance and sustained participation. Initial interactive prototype testing allowed us to make user-informed modifications that laid the foundation for real-world evaluation [10]. The purpose of this feasibility study was to: (1) evaluate acceptability (perceived usefulness, satisfaction, and burden for caregivers and staff), (2) assess demand (enrollment, uptake, and engagement with core features), and (3) examine implementation and practicality within ADC workflows (resources, role fit, and compatibility with existing communication practices). Our evaluation also sought to understand caregivers' baseline confidence levels and areas where ADCs could provide additional support, as well as the platform's potential impacts on caregivers' overall experience and confidence in the care provided by ADCs.

Methods

Overview and Rationale

CareMobi was developed using a user-centered design process that actively engaged ADS staff, family caregivers, and community stakeholders throughout its development. Iterative feedback was solicited through interviews, focus groups, and usability testing to ensure the tool was feasible to integrate into workflows, responsive to caregiver needs, and adaptable across diverse ADCs. This participatory process emphasized co-design to identify priority features (eg, streamlined messaging, daily activity summaries, and health-related observations) and reduce barriers such as duplicate documentation or technology burden. The full details of CareMobi's design and development process,

XSL•FO
RenderX

including prototype testing, have been reported elsewhere in prior research; here we focus on evaluation of its implementation, usability, and acceptability in practice [10].

Study Framework

We adopted a pragmatic, low-burden field usability evaluation of CareMobi in ADCs, guided by a Goal–Question–Metric (GQM/GAQM) [13] approach. Originally developed for software engineering and adapted for usability research, GQM ensures that data collection remains purposeful, relevant, and aligned with stakeholder needs. In practice, evaluators first articulate the overarching goals (eg, feasibility, usability, and acceptability), then derive key questions that operationalize those goals (eg, "Can caregivers complete core tasks without difficulty?"), and finally specify the metrics that can provide evidence (eg, task completion rates, satisfaction ratings, and interview themes). This hierarchical structure promotes rigor while keeping evaluations pragmatic and low burden, particularly in resource-constrained real-world settings such as ADCs. This allowed us to explicitly tie high-level goals (usability, acceptability, and feasibility) to specific questions and measurable metrics, while respecting constraints of under-resourced ADC settings. We aligned these questions and metrics with the GAQM framework's principle of first defining a goal (conceptual), then attributes (usability dimensions), then operational questions, and finally metrics (quantitative and qualitative). This approach is outlined in Table 1.

Table 1. Goal–questions–metrics framework.

Goal (Usability and implementation focus)	Usability or implementation attribute	Key questions	Metrics and indicators
Assess satisfaction and perceived usability	Perceived usability and satisfaction	How do users rate the app on ease, clarity, and burden?	Likert-scale items (eg, PSSUQ[a])
Understand barriers, user experience, and trust	Qualitative and contextual implementation	What aspects of the app or workflow did users find confusing, burdensome, or trust-enhancing? Where do they feel uncertain?	Thematic codes from semistructured interviews; free-text questionnaire comments
Engagement and uptake in real settings	Implementation and adoption	How many caregivers and staff enroll, how often do they use core features?	Enrollment counts, caregivers who use it at least once

[a]PSSUQ: Post-Study System Usability Questionnaire.

Overall Study Design

The evaluation combined field (in situ) testing, self-user usability (unmoderated use in real settings), post-use questionnaire, and qualitative interviews with staff and family caregivers in ADCs located in rural and underserved communities.

Setting

We partnered with 2 ADC sites primarily serving people living with dementia that were recruited at the Annual Meeting of the National Adult Day Services Association. Within each center, paid staff and family caregivers were recruited to pilot test CareMobi in their real daily workflows (as opposed to a lab setting), over a 12-week period. Our approach was consistent with "field studies" in mobile usability literature, where tasks are executed in the natural environment, and contextual factors (interruptions, real devices, ambient conditions) are preserved [10].

Recruitment and Eligibility

Recruitment occurred over 3 months through center leadership, who distributed study information to eligible caregivers and staff; interested individuals were then contacted by the research team to confirm eligibility and obtain informed consent. Eligible ADC staff included those directly involved in the day-to-day care of people living with dementia and responsible for communicating with family caregivers. Eligible family caregivers were those who identified as the primary caregiver of people living with dementia attending one of the participating ADCs, were aged 18 years or older, and owned a smartphone or tablet capable of running the CareMobi app. Both staff and caregivers were required to speak English and be willing to provide informed consent.

Training and Study Procedures

Prior to deployment, participants received minimal training, an intentional design choice to evaluate how intuitive the CareMobi platform was in real-world use. ADC staff participated in a 30-minute orientation covering the study overview and app functions. Family caregivers were assisted, as needed, in downloading the app using a QR code and were then encouraged to explore it independently. For ongoing support with the app, staff and caregivers were directed to a video library developed by an instructional technologist. Staff and caregivers were also advised to reach out to the study team with any questions or regarding technical issues. This pragmatic, low-burden approach mirrored real-world implementation conditions and aligned with the GQM framework, specifically addressing goals of assessing intuitiveness and efficiency of use with minimal external support.

Staff were instructed to use their discretion and share information through CareMobi that was tailored to each person living with dementia and caregivers' needs, while caregivers were encouraged to use the app as much or as little as they preferred to engage with the ADC. There was no minimum requirement for use in order to reflect real-world engagement patterns. CareMobi uses HIPAA (Health Insurance Portability and Accountability Act)–compliant security protocols, including encrypted data transmission and storage, authenticated user access, and restricted role-based permissions. No identifiable information was shared outside the secure platform, and all study data were deidentified prior to analysis." Following

XSL•FO
RenderX

consent, participants were instructed to download the CareMobi app from their preferred app store, and family caregivers completed a baseline survey. After the 12-week usage period, participants completed a post-use questionnaire assessing perceived usability, satisfaction, burden, and open-ended feedback. We also conducted semistructured interviews with a purposive subset of caregivers and staff, focusing on their experience, trust concerns, communication challenges, and suggestions for improvement. Staggered incentives, in the form of gift cards, were provided upon completion of the baseline survey, usability questionnaire, and interview (US $150 total).

Measures and Instruments

Demographics

We collected self-reported baseline demographic characteristics from family caregivers, including age, gender, role, and caregiving relationship, to contextualize study findings.

Caregiver Confidence

Two validated caregiver-reported instruments were used to assess caregiver experience and confidence. The Caregiver Confidence in Sign/Symptom Management (CCSM) Scale is a 4-item instrument that evaluates caregivers' perceived ability to recognize, monitor, and respond to changes in their care recipient's symptoms [14]. Items are rated on a 5-point Likert scale ranging from not at all confident (1) to extremely confident (5), with higher scores indicating greater confidence in symptom management. Prior research has demonstrated good internal consistency (Cronbach α=0.85) and construct validity, supporting its use in community-based caregiver populations [14].

Usability

To capture perceptions of usability and satisfaction, we administered the Post-Study System Usability Questionnaire (PSSUQ) [15,16], a validated 16-item scale that measures user perceptions across three domains: system usefulness, information quality, and interface quality. Items are rated on a 7-point Likert scale (strongly disagree [1] to strongly agree [7]), with lower scores indicating greater usability. The PSSUQ has been widely applied in digital health research and demonstrates high internal consistency (Cronbach α=0.83-0.96) [15,16].

Satisfaction

Finally, a **semistructured interview guide** was used to explore participants' experiences in greater depth. Interview domains included perceptions of transparency and trust, communication gaps, perceived benefits or frustrations, barriers to engagement, and suggestions for improving design or workflow alignment. Open-ended questions (eg, "Were there any parts of the app that felt confusing, frustrating, or difficult to use?"; "How, if at all, did it impact your experience with the ADC?") elicited participants' reactions to CareMobi, perceptions of usability, potential barriers, and impact on their relationship with the ADC as it pertained to the health of the people living with dementia.

Data Analysis

Quantitative

The pilot was conducted as a feasibility and usability study rather than an efficacy trial, and analyses were therefore descriptive and hypothesis-generating. Quantitative analyses included calculation of descriptive statistics (frequencies, medians, and ranges) for demographic and questionnaire results.

Qualitative

Participant interviews lasted approximately 30 minutes and were conducted by either the principal investigator (TS), who has formal training in mixed-methods research, or a research assistant (LP) with a master's in clinical research. Interviewers used member checking informally during data collection by pausing to confirm interpretations. All interviews were recorded, transcribed, and reviewed for accuracy. Field notes and reflexive journals were maintained to document interviewer observations, decision-making, and potential sources of bias.

Coding focused on domains relevant to the study aims, including trust and transparency, communication barriers, workflow fit, and caregiver confidence. Themes were then triangulated with quantitative findings (eg, task completion and usability scores) to provide a more comprehensive understanding of user experience. Two coders (one PhD, one undergraduate nursing student) independently coded transcripts in Dedoose, with the principal investigator reviewing a 20% subset to ensure reliability. The research team met regularly to discuss coding discrepancies, update the codebook, and validate emerging findings. Saturation was considered reached when no new categories were identified.

Feasibility Benchmarks

To evaluate feasibility, we applied a priori STOP-AMEND-GO [17] criteria across five domains: retention, usability, satisfaction, engagement, and acceptability. **Evaluable retention** was defined as completion of the 3-month follow-up survey, excluding non–study-related attrition (death or transition to a higher level of care); thresholds were STOP if <60%, AMEND if 60-69%, and GO if ≥70%. **Usability** was assessed using the PSSQ, with criteria based on the proportion of participants endorsing "agree" or "strongly agree" for items on ease of use and ease of learning; thresholds were STOP if <60% on any item, AMEND if 60-74%, and GO if >75% on each. **Satisfaction** was measured as the percentage of caregivers and staff endorsing "agree/strongly agree" on overall satisfaction with CareMobi, with thresholds STOP if <60%, AMEND if 60-74%, and GO if >75%. **Engagement** was defined as the proportion of participants who created an account and used the app at least once; thresholds were STOP if <50%, AMEND if 50-69%, and GO if ≥70%. Finally, **acceptability** was measured as the percentage of staff and caregivers expressing willingness to continue using CareMobi beyond the study period, with thresholds STOP if <50%, AMEND if 60-74%, and GO if >75% (Table 2).

XSL•FO
RenderX

Table 2. Study feasibility benchmarks (STOP-AMEND-GO criteria) and results.

Domains	Metric	STOP	AMEND	GO	Study result		
					Caregiver	Staff	Criterion
Evaluable retention	3-month completion of survey excluding nonstudy-related attrition (ie, death)	<60%	60%-69%	≥70%	100%	100%	GO
Usability	% "agree/strongly agree" on easy to use, easy to learn on PSSQ	<60% on any	60%-74% on any	75% on each	75%	100%	GO
Satisfaction	% "agree/strongly agree" on overall satisfaction	<60%	60%-74%	75% on each	>75%	100%	GO
Engagement	% of caregivers who created an account and used the app at least once	<50% any-use	50%-69% any-use	≥70% any-use	93%	100%	GO
Acceptability	% of staff and caregivers expressing that they will continue to use CareMobi beyond study period	<50%	60%-74%	75%	75%	100%	GO

Ethical Considerations

All study procedures were reviewed and approved by the Institutional Review Board at New York University (IRB-FY2023-7509). All participants provided informed consent prior to participation, and all data were deidentified to protect confidentiality. Compensation was US $150 for participation in all phases of the study.

Results

Caregiver Characteristics

In total, 15 caregivers completed baseline surveys (Table 3). Most participants identified as female (13/15, 86.7%), were aged 30-64 years (10/15, 66.7%), and reported some college or higher education (14/15, 93.3%). The sample was predominantly non-Hispanic White (14/15, 93.3% White; 14/15, 93.3% non-Hispanic). Most were married (11/15, 73.3%). Overall, 40% (6/15) were employed full-time and 20% (3/15) part-time; 26.7% (4/15) were retired. All respondents were family caregivers (15/15, 100%); 80% (12/15) identified as the sole caregiver. Relationship to the people living with dementia was most commonly adult child (7/15, 46.7%) or spouse or partner (5/15, 33.3%). Most had been caregiving for ≥1 year (11/15, 73.3%).

Caregiver Confidence With Complex Care

Across 15 respondents, confidence was generally moderate to high for managing common dementia-related challenges (Table 4). For agitation, 10/15 (66.7%) reported being extremely or moderately confident; for mood changes, 10/15 (66.7%); for mental status changes, 12/15 (80%). Confidence in deciding whether to call a provider was high (13/15, 86.7% extremely or moderately). Communication-related competencies were strongest: 14/15 (93.3%) felt extremely or moderately confident talking to a medical provider, and 12/15 (80%) reported they could readily gather information a provider would want. Areas with more dispersion included understanding vital signs (10/15, 66.7% extremely or moderately; 3/15, 20% slightly) and assessing pain (9/15, 60% extremely or moderately).

Table 4. Caregiver confidence: frequency counts and median scores (n=15). Scores are based on a 5-point scale: 5=Extremely, 4=Moderately, 3=Somewhat, 2=Slightly, 1=Not at All. Median scores are reported alongside frequency counts.

Item	Extremely (5), n (%)	Moderately (4), n (%)	Somewhat (3), n (%)	Slightly (2), n (%)	Not at all (1),n (%)	Un-known	Median (IQR; 25th - 75th percentile)

People Living With Dementia Clinical Stage and Health Care Use

Care recipients were primarily in moderate to later stages of dementia: 7/15 (46.7%) had moderately severe cognitive decline, 2/15 (13.3%) severe, and 2/15 (13.3%) very severe. Within the prior 6 months, 6/15 (40%) had at least one emergency department visit, and 4/15 (26.7%) had been hospitalized. Medication burden was substantial: 10/15 (66.7%) were taking ≥5 daily medications and 4/15 (26.7%) were taking 3-5 (Table 5).

Table 5. People living with dementia: disease stage and health care (n=15).

Characteristics	Values, n (%)
Stage of dementia	
Early-stage	4 (26.7)
Moderate-severe cognitive decline	7 (46.7)
Severe cognitive decline	2 (13.3)
Very severe cognitive decline	2 (13.3)
Health care use (past 12 months)	
Mean number of specialists seen	4 (26.7)
Health care use (Past 6 months)	
Emergency department visit	6 (40)
Hospitalization	4 (26.7)
Total daily medications	
1-2 medications	1 (6.7)
3-5 medications	4 (26.7)
>5 medications	10 (66.7)

Attrition and Engagement

Of the 15 caregivers who volunteered for the study, 14 logged into the app at least once, demonstrating high initial engagement. Four participants did not complete the study due to their loved one leaving the center, either due to death or requiring a higher level of care. Of the remaining caregivers, 8/10 completed the usability questionnaire and 6/10 participated in the follow-up interview. Among the 3 staff who participated, all (100%) logged into the app, completed the PSSQ, and completed the follow-up interview.

App Usability and Perceived Impact on Access and Communication

Among the 8 caregivers who completed the application usability questionnaire, perceived usability and satisfaction were high. At least three-quarters “agreed/strongly agreed” that the app was easy to use (6/8, 75%) and easy to learn (7/8, 87.5%); 6/8 (75%) liked the interface and found information well organized. Most felt comfortable using the app in social settings (6/8, 75%) and endorsed appropriate time demands (6/8, 75%). Willingness to use the app beyond the study period was high (6/8, 75%), and overall satisfaction was favorable (6/8, 75% “agree/strongly agree”).

Communication and access benefits were frequently endorsed: 7/8 (87.5%) reported that the app improved access to their loved one at the center, 7/8 (87.5%) said it made communication with the ADC convenient, and 6/8 (75%) felt comfortable communicating with the center via the app. Navigation consistency was also rated positively (7/8, 87.5%) (Table 6).

Staff Usability of the CareMobi App

Staff reported highly favorable usability ratings, with median scores at or near the ceiling across nearly all items (median=7, “strongly agree”). All 3 participants indicated that the CareMobi app was easy to use, easy to learn, and well organized (median=7). Satisfaction was uniformly high (all median=7): staff strongly agreed they would use the app again, that it contained the functions and capabilities expected, and that it provided an acceptable way to communicate with caregivers.

Communication-related items also demonstrated the strongest endorsement. Staff unanimously reported that the app improved access to caregivers, made communication more convenient, and increased opportunities to interact with caregivers (median=7 across items). They also expressed confidence that any information sent would be reliably received (median=7).

Minor variability was observed on a small number of items. For example, one staff member reported difficulty recovering from mistakes, producing a median score of 6 (“agree”) on that item. Another staff member selected “neither agree nor disagree” on certain workflow-related items (eg, time fit and error recovery), though the median across sites still remained 7 (Table 7).

Explanatory Qualitative Findings (Caregivers and Staff)

Consistent with the high ratings for convenient communication and improved access (75-88%), interviews with caregivers and staff, and open-ended written comments, revealed eight major themes that described CareMobi's value and limitations in daily practice.

In general, caregivers expressed strong support for CareMobi in their open-ended survey responses: "CareMobi is very helpful to me." "It is great." "Keep it up :)" "I found the app to be user friendly and easy to communicate to others."

Transparency

Caregivers valued the app's ability to provide "visibility into the day" reducing uncertainty about what occurred at the center and allowing them to interpret behaviors at home. One staff member shared: "If they're acting different, then we may know it's because they didn't get a good night rest." Family caregivers described using updates to understand changes in appetite and weight: "He eats all the stuff at the center he won't touch at home. Seeing that helped me realize the weight loss wasn't from not eating at all." Another wrote, "This app gives caregivers the comfort of knowing they are a tap away from knowing the daily report of their loved ones."

Streamlined Communication and Time Savings

Staff and caregivers highlighted that CareMobi replaced "phone tag" with more efficient messaging. A staff member explained: "Better communication between our center and the families… We can just put it in CareMobi and communicate that way." Staff also emphasized the time saved: "Instead of spending half the morning calling families one by one, I can send the update once in the app." This freed staff to focus more on direct care tasks.

Guidance on What to Track

Both groups requested clearer guidance on what domains to log. Caregivers wanted consistent updates on hydration and bathroom use, saying "It's interesting that we don't track that in here." Staff asked for templates (eg, "Today at a Glance," "Transport Update") to reduce duplication and ensure the right staff member provided the right update. As one caregiver reflected:

Value Across the Care Trajectory

Staff reported the app was particularly helpful for new enrollees, giving families reassurance and setting expectations from the start. One staff member noted: "Really helpful with the new enrollees, because they don't know any different." While families of newly enrolled clients used it to communicate with center staff, established caregivers used it more to maintain daily stability and track ongoing concerns.

Technology Fit and Integration

While usability was generally positive, staff emphasized the need to minimize duplicate data entry and expressed interest in a web or desktop option. One explained: "[Caregivers] have their own portals and our own things you're using." This theme mirrored broader structural challenges, as many ADCs lack interoperable EHRs and rely on paper or billing software.

Operational Constraints

Participation was shaped by staffing capacity and caregiver demands. Rural centers with small teams were able to sustain use; however, caregivers cited competing responsibilities: "I'm juggling work and his appointments, some days I just can't get to it." One caregiver noted they still relied on phone calls for reassurance: "I have great communication with [the center] by phone. If any problems occur I know they will contact me. I also know I can contact them by phone."

Trust, Confidence, and Relationship-Building

Routine updates fostered trust and provided caregivers with peace of mind. One caregiver explained: "The better you know how things are going throughout the day, the better the day is for you both." Importantly, transparency also strengthened caregivers' confidence in communicating with physicians: "When I went to the doctor, I could show them what was happening at the center. I felt more prepared." Multiple caregivers described using CareMobi data to adjust medications: "We actually got him off one of his meds, because I could prove he was eating and drinking fine there." Staff echoed that regular updates improved caregiver satisfaction and contributed to steadier enrollment: "This app will give caregivers the comfort of knowing they are a tap away from knowing the daily report of their loved ones."

Discussion

Principal Findings

This study evaluated the acceptability, demand, and practicality of CareMobi, a mobile platform designed to strengthen communication between ADCs and family caregivers. We posit that by making ADC-based care more transparent to families (through timely updates and role-specific, low-burden interactions), CareMobi, if feasible and acceptable, can reduce uncertainty and build trust among caregivers. This, in turn, can support sustained participation in ADCs and bolster engagement and connectedness for people living with dementia who are at risk of loneliness and social isolation. Our findings provide preliminary support for this proposition.

Acceptability and Satisfaction

CareMobi demonstrated high acceptability among both caregivers and staff, meeting or exceeding all prespecified STOP-AMEND-GO thresholds [17]. Specifically, usability scores surpassed the >75% "agree/strongly agree" criterion across all items, satisfaction levels exceeded benchmarks, and more than 70% of caregivers engaged with the app at least once. Staff usability scores reached ceiling levels, with median ratings of 7 (strongly agree) across nearly all items. Acceptability was also met, with more than three-quarters of participants expressing interest in using CareMobi beyond the study. Caregivers emphasized the platform was "user friendly," "very helpful," and reassured them by being "a tap away from knowing the daily report of their loved ones." Together, these findings provide strong evidence of acceptability and support CareMobi's potential as a low-burden, scalable tool for use in ADCs, and provide robust evidence for moving forward with broader implementation trials.

Demand and Engagement

Technology adoption in dementia caregiving populations has historically been low, with many studies reporting attrition, underuse, or abandonment of digital tools due to steep learning curves, lack of personalization, or misalignment with caregivers' daily realities [18,19]. In contrast, CareMobi achieved high engagement among study volunteers: 93% of caregivers logged into the app at least once, and 75% of caregivers and 100% of staff expressed willingness to continue use beyond the study. This success may be attributed to its co-designed, user-centered development process, which emphasized simplicity. Staff specifically highlighted reduced "phone tag," noting that streamlined messaging saved time and allowed them to redirect effort toward direct care. This represents an important advantage over other health care technologies that inadvertently add to staff burden rather than reducing it [12]. **Staff observed that bidirectional communication via the app was more likely to be achieved with caregivers who were new to the ADC, as they relied on CareMobi as their primary means of communication with staff. In contrast, established caregivers, who were more accustomed to phone-based communication, tended to use the app more passively to track updates. This suggests that** caregivers who have developed routines with staff may perceive less added value in switching.

It is worth noting that our sample was composed of caregivers who reported relatively high baseline confidence in managing their loved ones' needs, which may have facilitated their willingness to engage with a new tool. Many were also sole caregivers, relying on the ADC as an extension of their kinship network. This close relational tie to the center may have further motivated consistent use of CareMobi, as research suggests that engagement is supported not only by the design of the technology but also by the social context in which it was deployed [20].

Implementation and Practicality

ADC staff were able to integrate CareMobi into their workflows, but several refinements were identified. Both caregivers and staff requested more structured guidance on which observations should be logged (eg, hydration, bathroom trips, and mood changes) and templates such as "Today at a Glance" or "Medication Updates" to enhance efficiency. Staff expressed demand for a desktop or web version since most entered data from a computer, as opposed to a smartphone or tablet. Research shows that community-based settings, especially those with limited resources, are often excluded from technological innovation and struggle because of a fragmented digital infrastructure [21,22]. By focusing on low-cost, high-utility design, and implementing requested refinements, CareMobi can help address these structural inequities, ensuring that centers with fewer resources are not left behind in digital health advancement.

Caregiver Confidence and Trust

Another critical finding was CareMobi's impact on caregiver confidence and trust. Families reported using real-time updates to interpret behaviors at home, guide conversations with medical providers, and even advocate for deprescribing when daily logs showed adequate eating and drinking. One caregiver shared: "We actually got him off one of his meds, because I could prove he was eating and drinking fine there." This echoes existing evidence that improved caregiver communication can enhance self-efficacy, reduce decisional conflict, and promote timely care coordination [23,24]. By strengthening transparency, CareMobi appears to foster not only trust in ADCs but also caregiver empowerment in broader health care decision-making. As another caregiver said, "The better you know how things are going throughout the day, the better the day is for you both."

Equity and Representation

Although findings were promising, the sample was predominantly Non-Hispanic White, female, and English-speaking. This does not reflect the broader demographics of ADC families nationally, where approximately 58% of clients identify as racial or ethnic minorities [4]. Language accessibility was a major limitation; CareMobi is not available in Spanish or other languages. This restricted participation for centers serving diverse populations. This represents both a limitation of the current evaluation and a critical direction for future work. Addressing language and cultural tailoring is essential for scaling CareMobi equitably and ensuring its benefits extend to the diverse populations that rely most on adult day services.

XSL•FO
RenderX

Broader Implications

Collectively, these findings suggest that CareMobi can address longstanding barriers to ADC use. By improving "day-visibility," simplifying communication, and providing structured yet flexible updates, the app has the potential to stabilize attendance and support sustained participation, barriers that have historically undermined ADCs' ability to demonstrate value in long-term care [25,26]. This is particularly timely given the underfunding of adult day services and their critical role in providing cost-effective, community-based care for people with dementia [7].

Limitations and Future Directions

While this pilot yielded encouraging results, this study had several limitations. First, although appropriate for a feasibility design, the sample size was small and drawn from 2 centers, limiting generalizability. The sample was also demographically homogenous (ie, primarily Non-Hispanic White, female, and English-speaking) and did not reflect the diversity of families served by ADCs nationally. As participation required English proficiency and smartphone ownership, findings may overrepresent caregivers who were more comfortable with technology and positively predisposed to digital tools. Second, the study duration was relatively short, constraining our ability to draw conclusions about long-term engagement or patient outcomes. Third, while we evaluated usability, satisfaction, and acceptability, we did not measure downstream effects like caregiver burden or health care use. These outcomes will be the focus of future trials.

The findings from this feasibility study will directly inform the next phase of research, which will involve a larger, multisite hybrid effectiveness–implementation trial. Future work will assess whether improved communication and transparency translate into measurable outcomes such as reductions in caregiver burden, improved people living with dementia engagement and quality of life, more consistent ADC attendance, and reduced acute-care use. Recruitment will intentionally prioritize racially, ethnically, and linguistically diverse caregivers and centers, including development of multilingual platform versions and community-engaged recruitment strategies."

Conclusions

By coupling digital transparency with low-burden communication, CareMobi offers a promising approach to modernizing ADCs in ways that respect resource constraints and caregiver realities. In doing so, it reduces caregivers' uncertainty about sending people living with dementia to the ADC, in turn, providing the people living with dementia an opportunity to socialize and engage. To fully realize this potential, future work must prioritize equity, especially linguistic inclusion, infrastructure support, and engagement in under-resourced settings. Ultimately, if scaled thoughtfully, tools like CareMobi may enrich the social fabric of dementia care, increase accessibility of ADCs, and deepen the connection between caregivers, centers, and people living with dementia.

Abstract

Background: Social disparities in oral health persist, disproportionately affecting Indigenous populations.

Objective: This study aims to compare oral health status, dental care access, treatment needs, and social determinants between Mapuche and non-Mapuche older adults in the La Araucanía Region of Chile, within a hybrid dental care model, and to explore whether ethnicity is associated with these outcomes, guided by the World Health Organization (WHO) Commission on Social Determinants of Health (CSDH) framework.

Methods: We conducted a cross-sectional exploratory analytic study using data from 480 adults aged 60 years or older who received dental care through a hybrid teledentistry and mobile clinic model (Geriatric Dental Specialties Tele-Platform [TEGO]) in 4 municipalities of La Araucanía. The analytic sample was restricted to community-dwelling, functionally independent older adults. Outcomes included oral health status (nonfunctional dentition, edentulism, cavitated caries, and periodontitis), dental care access (fixed prosthetic rehabilitation and unmet denture need), and dental treatment needs (restorative and prosthetic). Structural (sex, age, education, rurality, and ethnicity) and intermediary determinants (behavioral, biological, psychosocial, and health system access) were analyzed following the WHO-CSDH framework. Bivariate analyses compared outcomes between Mapuche and non-Mapuche participants. Multivariable logistic regression models examined associations between determinants and outcomes.

Results: A total of 471 older adults (mean age 72.8, SD 7.7 years) were included; 76.9% (362/471) had nonfunctional dentition, 18% (85/471) were edentulous, 25.6% (98/383) had cavitated caries, and 46% (154/335) had periodontitis. In bivariate analyses, Mapuche participants showed lower educational attainment, higher rural residence, poorer oral health, more behavioral risk factors (eg, infrequent toothbrushing and higher sugar intake), greater restorative needs, and reduced access to complex dental care compared with non-Indigenous peers. In multivariable analyses, female sex was associated with increased odds of edentulism but lower odds of periodontitis. Lower education was associated with nonfunctional dentition (odds ratio [OR] 4.28, 95% CI 2.34-7.88; *P*<.001) and edentulism (OR 3.04, 95% CI 1.52-6.09; *P*=.002). Mapuche ethnicity was associated with higher prevalence of cavitated caries (OR 2.40, 95% CI 1.25-4.63; *P*=.009) and periodontitis (OR 2.43, 95% CI 1.21-4.88; *P*=.01). Dental care access was associated with behavioral factors (brushing, interproximal hygiene, and sugar intake) and structural determinants (age, sex, and rurality), while restorative and prosthetic needs were linked to sugar consumption and tobacco use, respectively.

XSL•FO
RenderX

Conclusions: Oral health inequalities among older adults in La Araucanía were associated with both structural and behavioral determinants. Although Mapuche participants exhibited poorer oral health, higher restorative needs, and reduced access to complex dental care in bivariate analyses, ethnicity remained associated only with cavitated caries and periodontitis in adjusted models. These findings underscore the importance of incorporating social determinants into oral health planning for underserved older adults and highlight the potential utility of data generated through digitally supported territorial care models for informing equity-oriented oral health strategies.

delivery of health care; digital health; geriatric dentistry; health inequities; health services accessibility; human rights; Indigenous peoples; rural population

Introduction

Oral health disparities are a persistent global challenge, disproportionately affecting socially marginalized groups, including older adults and Indigenous populations [1-5]. These inequities are shaped by social determinants of health—the conditions in which people live, work, grow, and age [6]. The World Health Organization (WHO) Commission on Social Determinants of Health (CSDH) framework critically distinguishes between structural determinants (eg, socioeconomic position, education, ethnicity, age, and place of residence) and intermediary determinants (material circumstances, biological factors, psychosocial factors, and health system access), which jointly influence oral health outcomes [6-9]. Among older adults, multiple studies have documented robust social gradients in outcomes such as edentulism and oral health–related quality of life [10-15].

Despite global efforts to improve oral health among older adults, progress has been limited, highlighting the need for approaches that account for contextual complexities and structural inequities impacting health outcomes [16,17]. Indigenous populations worldwide experience some of the most persistent and systemic oral health inequities, deeply rooted in historical and structural injustices [2-5,18]. Older Indigenous populations may face compounded barriers to accessing oral health care due to the intersection of age, ethnicity, socioeconomic status, and geographic location [19].

Chile's Indigenous population is among those experiencing the highest levels of aging in the region, with a growing proportion of older adults, including a notably high share of people aged 80 years or older [20]. Approximately 8.8% of the national population self-identifies as Indigenous, and about 16% of this group is aged 60 years or older [21]. Nearly 80% of Indigenous people in Chile belong to the Mapuche, who have historically inhabited Wallmapu, the ancestral territory of the Mapuche people spanning present-day Chile and Argentina; its western portion, Ngulu Mapu, corresponds to what is now south-central Chile [21,22]. In recent decades, a considerable proportion of the Mapuche population has migrated to urban and semiurban areas nationwide, a process associated with longstanding structural inequities, loss of ancestral lands, and limited economic opportunities in rural communities [22,23]. Despite their demographic weight and historical relevance, Mapuche communities continue to experience pronounced health inequities compared with their non-Indigenous peers. At age 60, Mapuche individuals have a life expectancy 7.5 years shorter than their non-Indigenous counterparts, along with lower total and disability-free life expectancy and a greater number of years lived with disability [24,25]. These disparities are also reflected in documented differences in metabolic health, including higher levels of insulin resistance, as well as a greater prevalence of mental and communication impairments compared with non-Mapuche older adults [26,27]. Together, these findings illustrate broader inequalities in general health and aging conditions affecting Mapuche older adults.

Oral health status reflects similar social and health gradients observed among Indigenous populations worldwide. Several studies have documented a high prevalence of untreated dental caries, suboptimal oral hygiene practices, and limited access to preventive oral health services among Chilean Indigenous children and adults [28-31], as well as among Indigenous communities globally [2,3,32]. But despite growing awareness of oral health disparities, research on Indigenous populations in Latin America and Chile remains scarce.

In addressing persistent barriers to oral health care among vulnerable populations, innovative service delivery models, such as telehealth and mobile clinics, have gained traction for their ability to overcome geographic isolation and specialist shortages [33,34]. These approaches have shown considerable promise in expanding access to both general and oral health services, alleviating the burden of chronic diseases, and supporting culturally safe, community-centered models of care for Indigenous populations [34-36]. Such strategies are particularly relevant given the strong preference among many older Indigenous individuals to age in place, often in settings characterized by limited financial resources and scarce health infrastructure [37]. At the global level, digital health research targeting older Indigenous populations is gaining momentum—particularly in high-income countries—through the evaluation of innovations such as wearable technologies, videoconferencing, and mobile telemedicine clinics [38-42]. However, these advances remain less common in low- and middle-income countries, where disparities in technological infrastructure, digital literacy, cultural adaptation, and resource availability pose significant challenges to the implementation and sustainability of culturally appropriate telemedicine and eHealth solutions [20,43].

In response to these challenges, a pilot initiative was implemented in a Mapuche community, introducing a hybrid dental care model designed to reduce territorial barriers to oral

XSL•FO
RenderX

health services. The model integrates outreach clinical services delivered through a mobile unit with digitally supported coordination and remote specialist consultation, linking primary-level care with higher-level clinical expertise. Hybrid care approaches that combine digital and in-person services have been proposed as strategies to improve access and continuity of care in underserved populations [44]. The digital infrastructure supporting this model was provided by the Geriatric Dental Specialties Tele-Platform (TEGO), a web-based system that integrates electronic health records with structured medical-geriatric and odontogeriatric assessment modules and facilitates interdisciplinary collaboration [29,45-47].

Building on this initial experience, the care model was subsequently expanded to rural and urban municipalities across the La Araucanía Region. Although not exclusively targeted at Indigenous populations, the program engaged both Mapuche and non-Mapuche older adults across diverse settings. This broader implementation generated data that enabled the examination of associations between structural and intermediary social determinants of health and oral health outcomes in these populations.

Accordingly, this study aims to compare oral health status, dental care access, treatment needs, and social determinants of health between Mapuche and non-Mapuche older adults in the La Araucanía Region of Chile receiving care through a hybrid dental care model and to explore the association between ethnicity and these outcomes within the WHO-CSDH framework.

Methods

Ethical Considerations

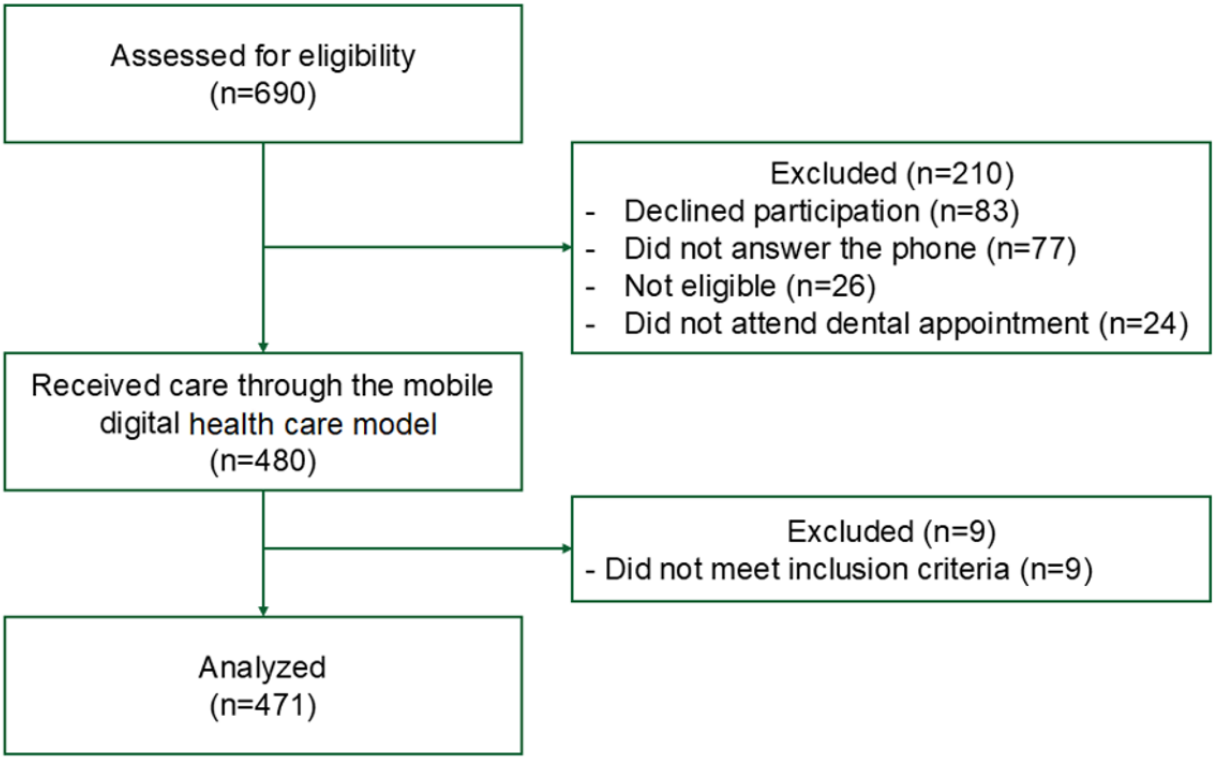
The project was approved by the Ethics Committee of the Universidad de La Frontera (decision 109/22). All participants provided written informed consent, and strict confidentiality protocols were followed, including anonymization prior to analysis.

Overview

This cross-sectional exploratory analytic study is based on the integrated analysis of data collected at the conclusion of a community-based oral health intervention conducted in the La Araucanía Region of Chile. The intervention corresponded to the regional implementation of the previously described hybrid dental care model and was delivered through a mobile clinical unit serving rural and urban municipalities. Services included geriatric dental assessment and treatment, preventive and restorative care, prosthetic evaluation, and referral management according to treatment complexity. Clinical information, coordination of care, and specialist consultation were supported through the TEGO digital platform following standardized protocols described in previous publications [29,45,47,48].

Participants and Setting

The La Araucanía Region is distinguished by its high proportion of Indigenous Mapuche population (34.2%) [21]. The region continues to experience persistent socioeconomic disadvantages, including elevated poverty rates, a predominantly rural context, and pronounced health inequities, particularly reflected in limited access to preventive and routine oral health care services [49,50].



In response to these challenges, a community-based oral health intervention program was implemented with funding from a national Presidential Grant (exempt resolution number 472). Initial recruitment was conducted by telephone using databases provided by the regional branch of the National Senior Citizen Service, in collaboration with local community organizations. Municipalities were selected based on logistical feasibility and implementation criteria rather than probabilistic sampling. Program eligibility included adults aged 60 years or older, residing in the region, and physically and cognitively able to attend dental appointments.

Between January and September 2023, a total of 480 older adults received care through this program, which delivered services through scheduled outreach visits using a mobile dental clinic in 4 municipalities: 2 rural (Cholchol and Los Sauces) and 2 urban (Temuco and Angol). The intervention was implemented in coordination with municipalities and community organizations, including the Araucanía Regional Federation of Older Adults, which brings together municipal-level unions of older adult clubs, as well as local community groups such as church organizations.

This study was based on clinical and assessment data collected during program implementation and recorded through the TEGO digital platform. For the present study, eligibility criteria included being a community-dwelling, functionally independent older adult, defined as a Barthel Index score ≥90. Consequently, 9 institutionalized individuals were excluded, resulting in a final sample of 471 participants. Figure 1 presents the detailed participant flow, including eligibility assessment, application of inclusion and exclusion criteria, and the final analytic sample.

XSL•FO
RenderX

Figure 1. Participant flow diagram.

Conceptual Framework

The WHO-CSDH framework informed the research question, variable selection and classification, and interpretation of findings by conceptualizing oral health as shaped by processes of social stratification and the unequal distribution of power, resources, and opportunities [6]. This framework distinguishes between structural determinants—such as socioeconomic and political context and axes of social stratification, including education, ethnicity, and place of residence—and intermediary determinants, which encompass material conditions, health-related behaviors, psychosocial factors, and access to health systems. Within this framework, ethnicity was conceptualized as a structural determinant reflecting social position, guiding comparisons of oral health outcomes across groups.

The use of the WHO-CSDH framework is particularly relevant in this study context, as it allows oral health inequalities to be examined beyond individual-level risk factors by situating them within broader social and systemic conditions. This is especially important in Indigenous populations, where health disparities are shaped by historical, social, and territorial inequities that are not fully captured by conventional epidemiological approaches focused on proximal determinants [9]. By organizing variables into structural determinants, intermediary determinants, and oral health outcomes, this framework supports a more comprehensive assessment of how health inequalities are patterned across social groups and how different levels of determinants coexist.

Consistent with the WHO-CSDH model, structural and intermediary determinants are theorized to be hierarchically related through pathways linking social position to health outcomes. However, given the cross-sectional design, the present study examines the distribution of these determinants and their associations with oral health outcomes without inferring causal relationships.

Data Collection and Variable Structure

Clinical data were collected by 2 final-year dental interns under direct supervision of 2 experienced dentists (CAA and FM-S), using a standardized clinical protocol under uniform examination conditions. Examinations were conducted by the same team that implemented the initial pilot intervention in the Mapuche community, and the regional phase began 1 month later, maintaining the same examiners, instruments, and diagnostic criteria.

Prior to implementation, examiners underwent structured theoretical and supervised clinical training to apply the complete TEGO clinical record, which includes medical-geriatric, odontogeriatric, behavioral, and prosthodontic assessment modules. Training covered caries detection, periodontal examination, prosthetic evaluation, and standardized collection of self-reported variables (eg, oral hygiene practices and service use).

Formal calibration with assessment of interexaminer and intraexaminer reliability was conducted for dental caries using the International Caries Detection and Assessment System (ICDAS). Interexaminer and intraexaminer κ values were 0.66 and 0.78-0.85, respectively [29]. Periodontal and prosthetic assessments were recorded using standardized objective diagnostic criteria under direct supervision to ensure procedural consistency.

XSL•FO
RenderX

All findings were recorded directly into the TEGO [45,47], ensuring standardized data capture and quality control procedures.

Guided by the WHO-CSDH framework, variables were classified as structural determinants, intermediary determinants, or oral health outcomes.

Structural Determinants

Structural determinants were defined as variables reflecting the broader socioeconomic context that shapes health equity through social stratification. These included: sex (male or female, self-reported); age, recorded as a continuous variable in years and categorized as 60-69 years, 70-79 years, or ≥80 years; and ethnic self-identification, classified as Mapuche (based on self-reported Indigenous affiliation) or non-Mapuche. Educational attainment was dichotomized as no formal or only primary education (≤8 years) vs secondary or higher education (>8 years).

Socioeconomic status was approximated using Chile's Social Registry of Households (RSH), a national administrative classification used to target social programs. The RSH assigns households to 7 socioeconomic percentiles based on an algorithm that integrates income sources, household composition, and indicators of vulnerability (eg, age, disability, and access to goods and services) [51]. For this study, households were dichotomized into the most vulnerable group (0%-40%) vs higher percentiles (>40%).

Additional structural variables included place of residence, classified as urban or rural according to municipality-level administrative definitions [52], and health insurance coverage, categorized according to the Chilean health system as the National Health Fund (FONASA), the health systems for the armed forces and police (National Defense Social Security Fund [CAPREDENA] and Carabineros de Chile Social Security Directorate [DIPRECA]), the Comprehensive Health Care and Reparation Program for Victims of Human Rights Violations (PRAIS), private health insurance institutions (ISAPREs), or no health coverage.

Intermediary Determinants

Overview

These variables represent the mechanisms through which structural determinants influence health, including behavioral, biological, and psychosocial factors and access to care.

Behavioral Factors

Included oral hygiene practices, dietary habits, and smoking behavior, which are known to influence oral and general health [53-56]. Participants reported the frequency of tooth or denture brushing, interproximal hygiene (yes or no), and use of toothpaste (yes or no). Cariogenic dietary patterns were assessed through questions about the consumption of sugary foods and beverages between meals—such as candies, cookies, cakes, soda, sweetened juices, or sugar-added drinks (eg, coffee, tea, mate, or milk; yes or no). Daily water intake was also recorded and categorized as less than or more than 2 liters. Smoking status was documented through a yes or no question regarding current tobacco use.

Biological Factors

Several biological conditions—multimorbidity, polypharmacy, dry mouth, and swallowing disorders—were included as biological factors that may influence oral health, given their established association with impaired oral function, increased risk of caries, periodontal disease, and challenges in maintaining oral hygiene in older adults [57-60]. Multimorbidity and polypharmacy were obtained through self-report. Multimorbidity was defined as the presence of 2 or more chronic conditions, as reported by participants [61], while polypharmacy was defined as the regular use of 5 or more medications per day [62], based on participants' declarations of medication intake. The subjective sensation of dry mouth was recorded, and swallowing disorders were assessed using the Eating Assessment Tool-10 (EAT-10), a validated screening instrument; scores ≥3 indicate a positive screen for swallowing difficulties [63,64].

Psychosocial Factors

Psychosocial factors included variables related to social relationships, used as proxies for social isolation—a recognized risk factor for health in older adults [11]. Living arrangements were recorded and categorized as living alone or living with others. Perceived social support was assessed based on participants' subjective perception of receiving emotional or practical help when needed (yes or no).

Health System Access

Access to oral health services was assessed through various direct and indirect indicators. Self-reported time since last dental visit, categorized as ≤2 years or >2 years, was used as a direct indicator of access. The presence of fixed dental rehabilitation (eg, crowns and fixed bridges) and the presence of dental implants were used as indirect indicators of a history of better access to specialized dental treatment, whereas unmet denture need (absence of a removable dental prosthesis in individuals who were clinically identified as requiring a partial or complete denture) was used as a proxy for barriers to care.

In Chile, treatments such as restorations and removable dentures are commonly provided within primary care, although prosthetic programs do not cover all individuals [65]. In contrast, more advanced treatments, including dental implants and fixed prostheses, are typically available only through secondary care or private services. These indicators therefore reflect not only the availability of services but also the types of services they accessed, going beyond the traditional measure of time since the last dental visit. This approach aligns with previous studies that have used restorative, prosthetic, and visit-related measures as proxies for access to care and oral health inequalities [66,67].

Oral Health Status

Oral health status was assessed through clinical examination and included the number of natural teeth, functional dentition, edentulism, cavitated caries, and periodontal status. The number of natural teeth was recorded as the total count of teeth remaining in the oral cavity, while nonfunctional dentition was defined as the presence of fewer than 20 teeth, regardless of

XSL•FO
RenderX

their location. Edentulism was defined as the complete absence of natural teeth.

Cavitated caries were defined as lesions corresponding to the decayed (D) component of the decayed, missing, and filled teeth (DMFT) index, operationalized as ICDAS codes 4 to 6.

Periodontal status was assessed through a full-mouth periodontal examination, recording plaque levels, probing depth (PD), clinical attachment level (CAL), bleeding on probing, suppuration, and gingival recession at 6 sites per tooth, as well as furcation lesions and tooth mobility [68]. Based on these measures, participants were classified as having gingival health (<10% bleeding sites with PD ≤3 mm [69]), gingivitis (≥10% bleeding sites with PD ≤3 mm), or periodontitis (CAL ≥2 mm on nonadjacent teeth, or buccal/oral CAL ≥3 mm with PD >3 mm on ≥2 teeth [70]). For analytical purposes, periodontal status was dichotomized as presence vs absence of periodontitis.

Treatment Needs

Treatment needs were assessed through clinical examination and included both restorative and prosthetic requirements. Restorative treatment need was defined as the number of teeth requiring intervention due to caries, defective restorations, or other conditions requiring restorative care (eg, fractures or noncarious lesions). Including this measure provides a broader estimate of treatment requirements and supports planning and resource allocation.

Normative prosthetic treatment need was operationalized as a binary variable (presence or absence). Participants were classified as having prosthetic treatment need when clinical examination identified complete edentulism without prosthetic rehabilitation, partial tooth loss requiring prosthetic replacement, or existing removable prostheses in inadequate condition requiring repair or replacement. For participants with removable prostheses (complete or partial), functional adequacy was assessed based on stability, retention, and structural integrity. Stability and retention were evaluated following the Kapur index and the prosthodontic evaluation methods from phase 1 of the Third National Health and Nutrition Examination Survey (NHANES III) [71,72], assessing denture movement under manual lateral and vertical forces. Structural integrity was determined by identifying fractures, missing or chipped teeth, and broken clasps or framework components. Prostheses were classified as requiring repair or not requiring repair according to these criteria.

Statistical Analysis

Descriptive analyses were conducted to characterize the study population. Categorical variables were summarized as frequencies and percentages, and continuous variables as means with SDs or 95% CIs, as appropriate. Bivariate analyses compared structural determinants, intermediary determinants, and oral health indicators by ethnicity (Mapuche vs non-Mapuche). Associations between categorical variables were assessed using the Pearson chi-square test, with *P* values of <.05 considered statistically significant.

Guided by the WHO-CSDH framework, bivariate and multivariable logistic regression analyses were then conducted to examine the associations between structural and intermediary determinants and selected outcomes. Three groups of outcomes were evaluated: clinical oral health outcomes (edentulism, nonfunctional dentition, periodontitis, and caries), access-related outcomes (time since the last dental visit, presence of fixed dental rehabilitation, and clinically unmet denture need), and treatment needs (restorative and prosthetic). Separate multivariable logistic regression models were fitted for each binary outcome (9 models in total) to estimate adjusted associations between structural and intermediary determinants and the outcomes.

Missing data were present in a small proportion of observations for several variables (<10%), and complete-case analysis was therefore considered appropriate given the overall low level of missingness. The proportion of missing data for periodontitis was higher (51/386, 13%). For this outcome, missingness was not significantly associated with most evaluated covariates (all *P*>.05), although excluded participants were older, suggesting a potential age-related component. For all other variables, no substantial differences were observed between included and excluded participants across the evaluated sociodemographic characteristics. Missing periodontal data most likely reflects incomplete clinical examinations rather than item nonresponse, as periodontal assessment requires full-mouth probing in dentate participants. Such incomplete examinations may occur due to participant refusal, logistical constraints during fieldwork, or medical conditions preventing the assessment.

Because some outcomes were only applicable to specific subgroups (eg, dentate individuals or denture users) and some covariates had incomplete observations, the number of observations varied across models; therefore, logistic regression analyses were conducted using complete-case data for each model. Covariates were selected a priori based on the conceptual framework of social determinants of health, rather than through data-driven selection procedures. Indicators of health system access were conceptualized as intermediary determinants; however, in specific models they were also analyzed as outcomes to explore inequalities in access to care. In models examining oral health status outcomes, time since the last dental visit was included as a covariate to account for differential exposure to dental care. Models were also adjusted for the number of natural teeth present, when applicable, given its potential role as a confounder. Results are presented as odds ratios (ORs) with 95% CI, and all analyses were conducted using Stata (version 18; StataCorp LLC).

Results

Sociodemographic Characteristics and Structural Determinants

A total of 471 community-dwelling older adults were included in the analysis (Figure 1). Of these, 24.2% (114/471) self-identified as Mapuche. The mean age of the sample was 72.8 (SD 7.7) years, with Mapuche participants being significantly younger than non-Mapuche counterparts (*P*=.006).

Univariate and bivariate descriptive statistics for the study variables are presented in Table 1. Overall, 59.9% (282/471) of

XSL•FO
RenderX

participants were female, with no significant differences between Mapuche and non-Mapuche participants (*P*=.62). A total of 126 participants were not registered in RSH, as enrollment in this administrative system is voluntary in Chile. Among those registered (n=345 of 471), most (301/345, 87.2%) were classified within the ≤40% bracket, indicating high socioeconomic vulnerability. No significant differences were observed between Mapuche and non-Mapuche participants (*P*=.10). Regarding health coverage, most participants (405/471, 85.9%) were enrolled in FONASA, 9.8% (46/471) had no health insurance, and 4.2% (20/471) were covered by other schemes (ISAPRE, CAPREDENA/DIPRECA, and PRAIS). Coverage differed by ethnicity; nearly all Mapuche participants (111/114, 97.4%) had FONASA, while non-Mapuche participants showed more variation, including a higher proportion without insurance (45/357, 12.6%; χ^2_2=16.6; *P*<.001). Compared with their non-Indigenous counterparts, Mapuche individuals had lower educational attainment and resided predominantly in rural municipalities.

[a]Only dentate participants were considered (n=386).

[b]EAT-10: Eating Assessment Tool-10.

Intermediary Determinants

Behavioral Factors

Regarding behavioral determinants, overall, 85.4% (392/459) of participants reported brushing their teeth or dentures at least twice daily, whereas only 3.4% (16/459) reported never brushing. Among participants who were not completely edentulous, 31.9% (123/386) reported performing interproximal dental hygiene. Cariogenic dietary patterns were common, with 51% (240/471) consuming sugary foods or drinks between meals, with an average frequency of 2.3 (SD 0.9) times per day. Mapuche participants reported lower toothbrushing frequency and higher sugary consumption between meals (*P*<.001). Overall, 9.1% (43/471) of participants were current smokers. No statistically significant differences were observed between Mapuche and non-Mapuche participants in smoking status (*P*=.59) or daily water consumption (*P*=.79; Table 1).

Biological Factors

In terms of biological factors, the mean number of prescription medications per day was 2.63 (95% CI 2.43-2.83), and 16.6% (72/433) of participants met the criteria for polypharmacy. The mean number of chronic conditions was 2.36 (95% CI 2.20-2.51), with 60.7% (286/471) experiencing multimorbidity. Dry mouth was self-reported by 52.2% (246/471) of participants, while 8.1% (38/471) screened positive for swallowing disorders. Only swallowing disorders showed significant differences by ethnicity, being more prevalent among Mapuche participants (*P*=.007; Table 1).

Psychosocial Factors

Overall, perceived social support was high, with 84.7% (399/471) reporting access to emotional or practical help when needed, and 69.8% (329/471) living with family members. Mapuche participants were less likely to live alone compared with non-Mapuche participants (*P*=.008).

Health System Factors

Approximately half of participants (229/467, 49%) reported visiting a dentist within the last 2 years, with no significant differences by ethnicity (Table 1). Overall, 18.6% (70/376) of participants had unmet denture need, with no significant differences by ethnicity (*P*=.44).

More complex rehabilitations were less common. Fixed prosthetic rehabilitation was observed only in 15.9% (75/471) of participants (mean fixed rehabilitation per recipient: 3.63, 95% CI 2.88-4.38), while the presence of dental implants was rare (6/471, 1.3%), with a mean of 2.5 (95% CI 0.77-4.22) implants per recipient. Some participants received both types of treatments.

In the bivariate comparisons by ethnicity, no differences were observed in time since the last dental visit. However, Mapuche participants had a significantly lower prevalence of fixed prostheses (*P*=.003). A lower prevalence of implants was also observed among Mapuche participants, although this difference was not statistically significant (Table 1).

Oral Health Status

Only 4% (19/471) of participants had 28 or more natural teeth. The mean number of natural teeth present was 12.93 (95% CI 12.13-13.72), with no significant differences between Mapuche and non-Mapuche participants (*P*=.86). Nonfunctional dentition was present in 76.9% (362/471) of participants, while 18.1% (85/471) were edentulous; no significant differences were observed by ethnicity (Table 1).

All participants had a history of dental caries. The mean DMFT index was 22.82 (95% CI 22.23-23.42), ranging from 6 to 32. Among participants aged 65 to 74 years, the mean DMFT was 22.03 (95% CI 21.10-22.95). No significant differences were observed between Mapuche participants (mean DMFT 23.12, SD 5.4) and non-Mapuche participants (mean DMFT 21.6, SD 6.5) within this age group (*P*=.14) or overall (*P*=.09). Tooth loss represented the largest component of the index, accounting for 83.6% (mean 19.07), followed by restorations, which accounted for 15% (mean 3.42). Approximately one-quarter of dentate participants (98/383, 25.6%) had cavitated caries, with a significantly higher prevalence among Mapuche participants (*P*<.001).

Among dentate participants, 20.6% (69/335) had periodontal health, 33.4% (112/335) had gingivitis, and 45.9% (154/335) had periodontitis. Significant differences were observed between Mapuche and non-Mapuche participants (*P*<.001; Table 1).

Dental Treatment Needs

Restorative treatment needs were observed in 53.8% (206/383) of participants, and among dentate individuals, the mean number of teeth requiring restorative treatment was 1.25 (95% CI 1.23-2.24). Most participants used dentures (306/470, 65.1%). However, denture repair needs were high: 79.7% (244/306) of denture users required repair or replacement due to poor fit, retention, or structural defects. Overall, normative prosthetic treatment need was 66.8% (314/470). Mapuche participants had significantly greater restorative treatment needs, but prosthetic treatment need did not differ significantly between Mapuche and non-Mapuche participants (Table 1).

Association of Ethnicity and Other Social Determinants With Oral Health Status

After conducting bivariate analyses for all selected outcomes and covariates, multivariable logistic regression models were fitted to estimate the adjusted effect of each independent

XSL•FO
RenderX

variable. Statistically significant bivariate associations are reported in the corresponding table. Given the exploratory nature of the analysis, all predictor variables were included in the multivariable models regardless of their bivariate significance in order to control for potential confounding and obtain adjusted estimates.

In the multivariable logistic regression models, structural determinants exhibited the most consistent associations with oral health outcomes. Age and educational attainment were significantly associated with tooth loss: participants aged 80 years or older had higher odds of nonfunctional dentition (OR 5.55, 95% CI 2.34-13.08; *P*<.001) and complete edentulism (OR 3.75, 95% CI 1.62-8.68; *P*=.002) compared with those aged 60 to 69 years, while ≤8 years of education was linked to increased odds of nonfunctional dentition (OR 4.28, 95% CI 2.34-7.88; *P*<.001) and complete edentulism (OR 3.04, 95% CI 1.52-6.09; *P*=.002). Women had higher odds of edentulism (OR 2.38, 95% CI 1.24-4.58; *P*=.009) but lower odds of periodontitis (OR 0.53, 95% CI 0.31-0.90; *P*=.02). Mapuche ethnicity was associated with higher odds of cavitated caries (OR 2.40, 95% CI 1.25-4.63; *P*=.009) and periodontitis (OR 2.43, 95% CI 1.21-4.88; *P*=.01). Rurality showed no significant associations (Table 2).

XSL•FO
RenderX

Table 2. Adjusted associations between structural and intermediary determinants and oral health status outcomes from multivariable logistic regression models. For each binary outcome, a separate multivariable logistic regression model was fitted, including all structural and intermediary predictors. Categorical predictors with more than 2 levels were entered using dummy coding, and the number of natural teeth was included as a covariate.

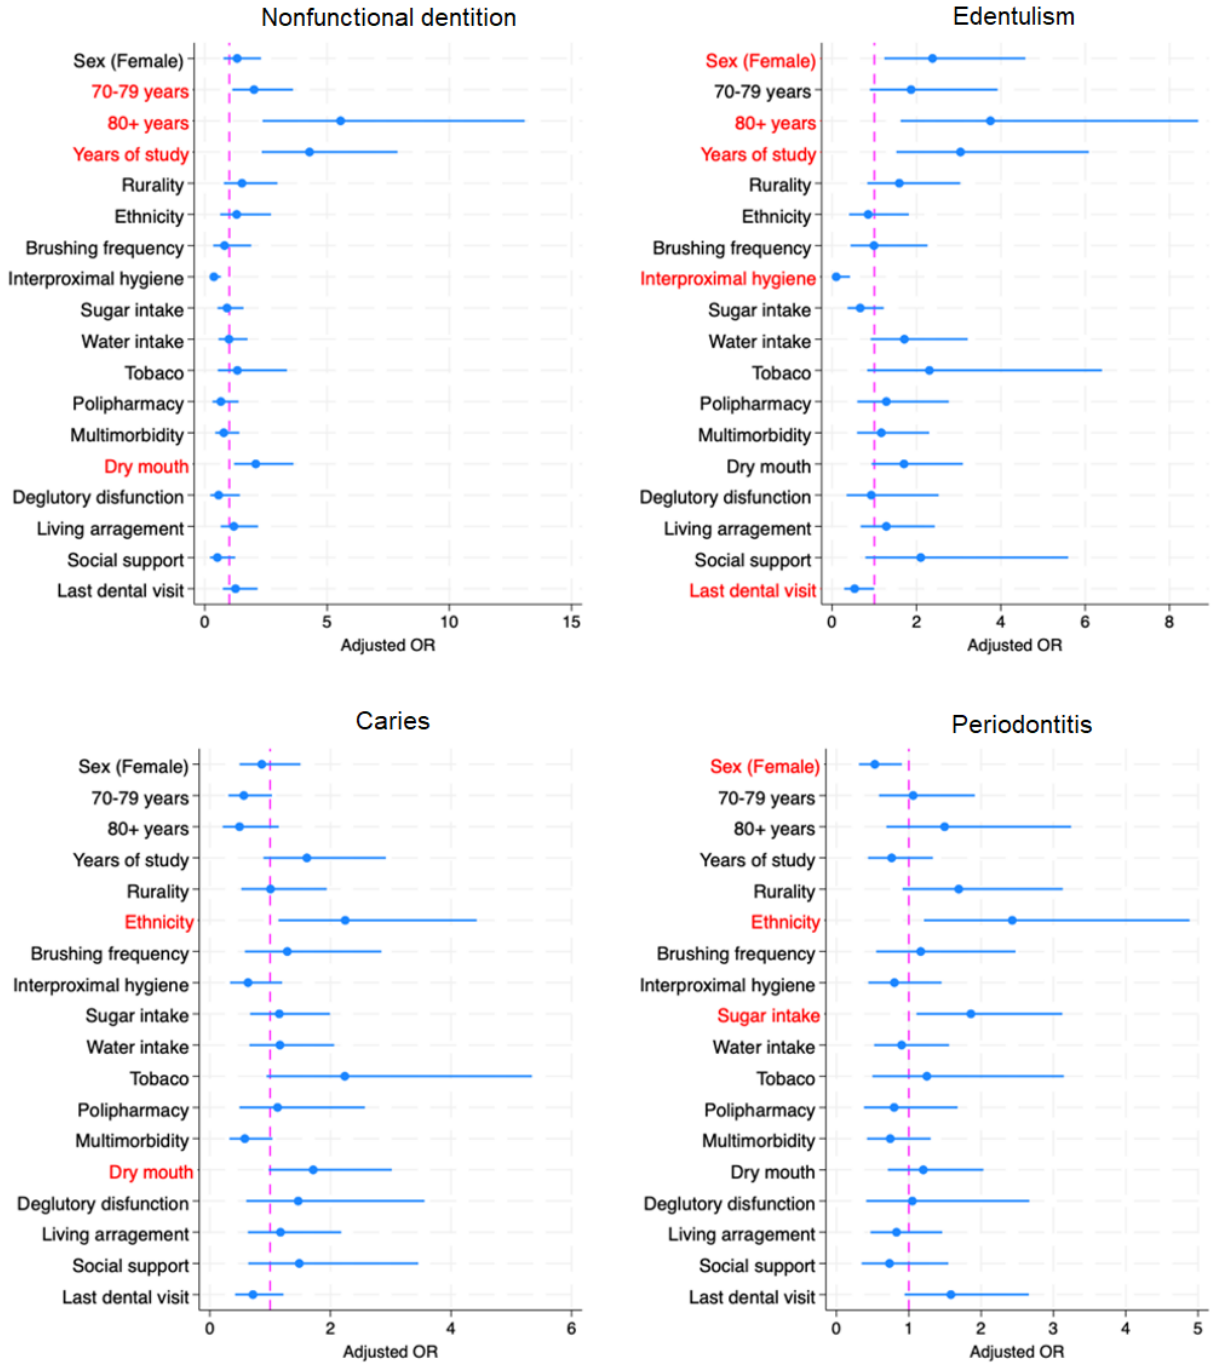
[a]aOR: adjusted odds ratio.

[b]Indicates variables showing significant bivariate associations with edentulism.

[c]Indicates variables showing significant bivariate associations with nonfunctional dentition.

[d]Indicates variables showing significant bivariate associations with periodontitis.

[e]Not applicable.



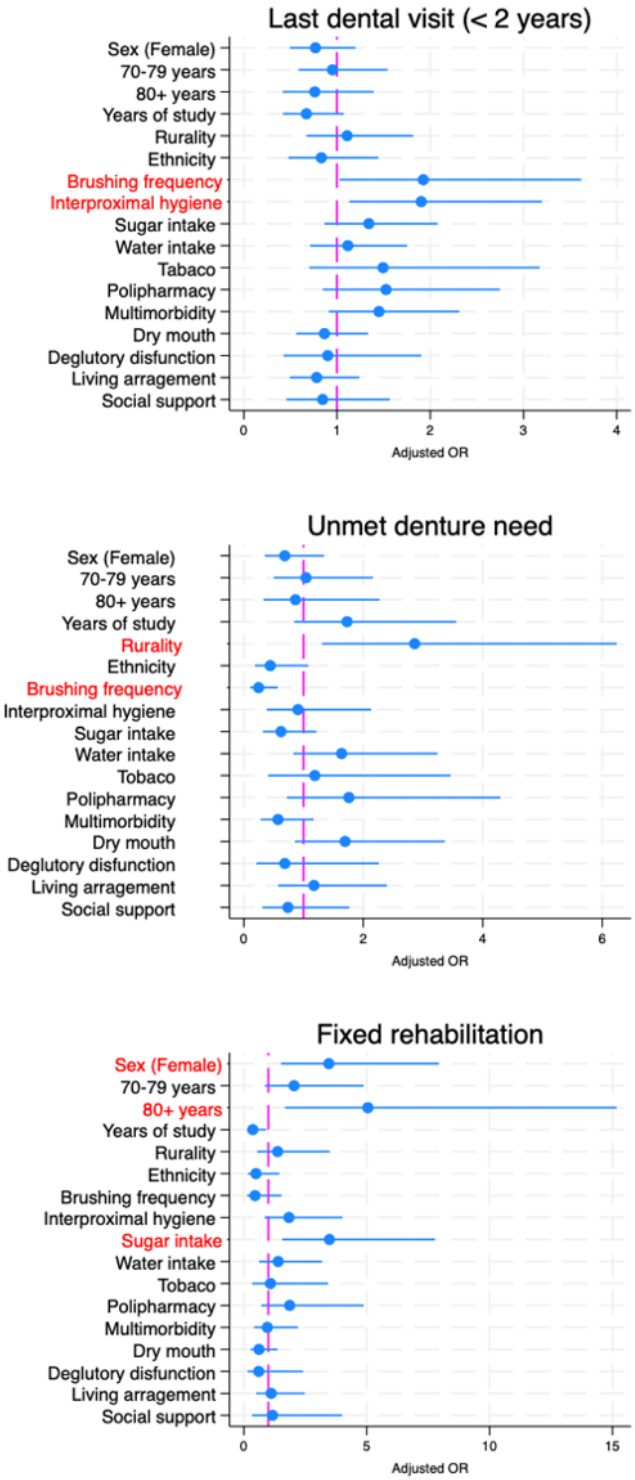
[f]Indicates variables showing significant bivariate associations with caries.

Among intermediary determinants, behavioral factors appeared to be the most relevant. Specifically, lack of interproximal hygiene was linked to tooth loss outcomes, while consumption of sugary snacks was associated with increased odds of periodontitis (OR 1.86, 95% CI 1.11-3.12; *P*=.01; Table 2). Psychosocial factors showed no significant associations, and biological factors had limited associations, with dry mouth linked to nonfunctional dentition (OR 2.08, 95% CI 1.20-3.63;

XSL•FO
RenderX

P=.009) and cavitated caries (OR 1.78, 95% CI 1.02-3.13; *P*=.04). Regarding dental care access, having received care in the past 2 years was associated with lower odds of total edentulism (OR 0.53, 95% CI 0.28-0.99; *P*=.048). These multivariable results, including the 4 oral health outcomes, are summarized in Figure 2.

Figure 2. Adjusted associations between predictor variables and oral health status outcomes. Forest plot showing adjusted odds ratios (aORs) and 95% CIs from separate multivariable logistic regression models for nonfunctional dentition, edentulism, cavitated caries, and periodontitis. Points represent aORs, and horizontal bars represent 95% CIs. The vertical line indicates an odds ratio (OR) of 1 (no association). Statistically significant associations are highlighted in red.



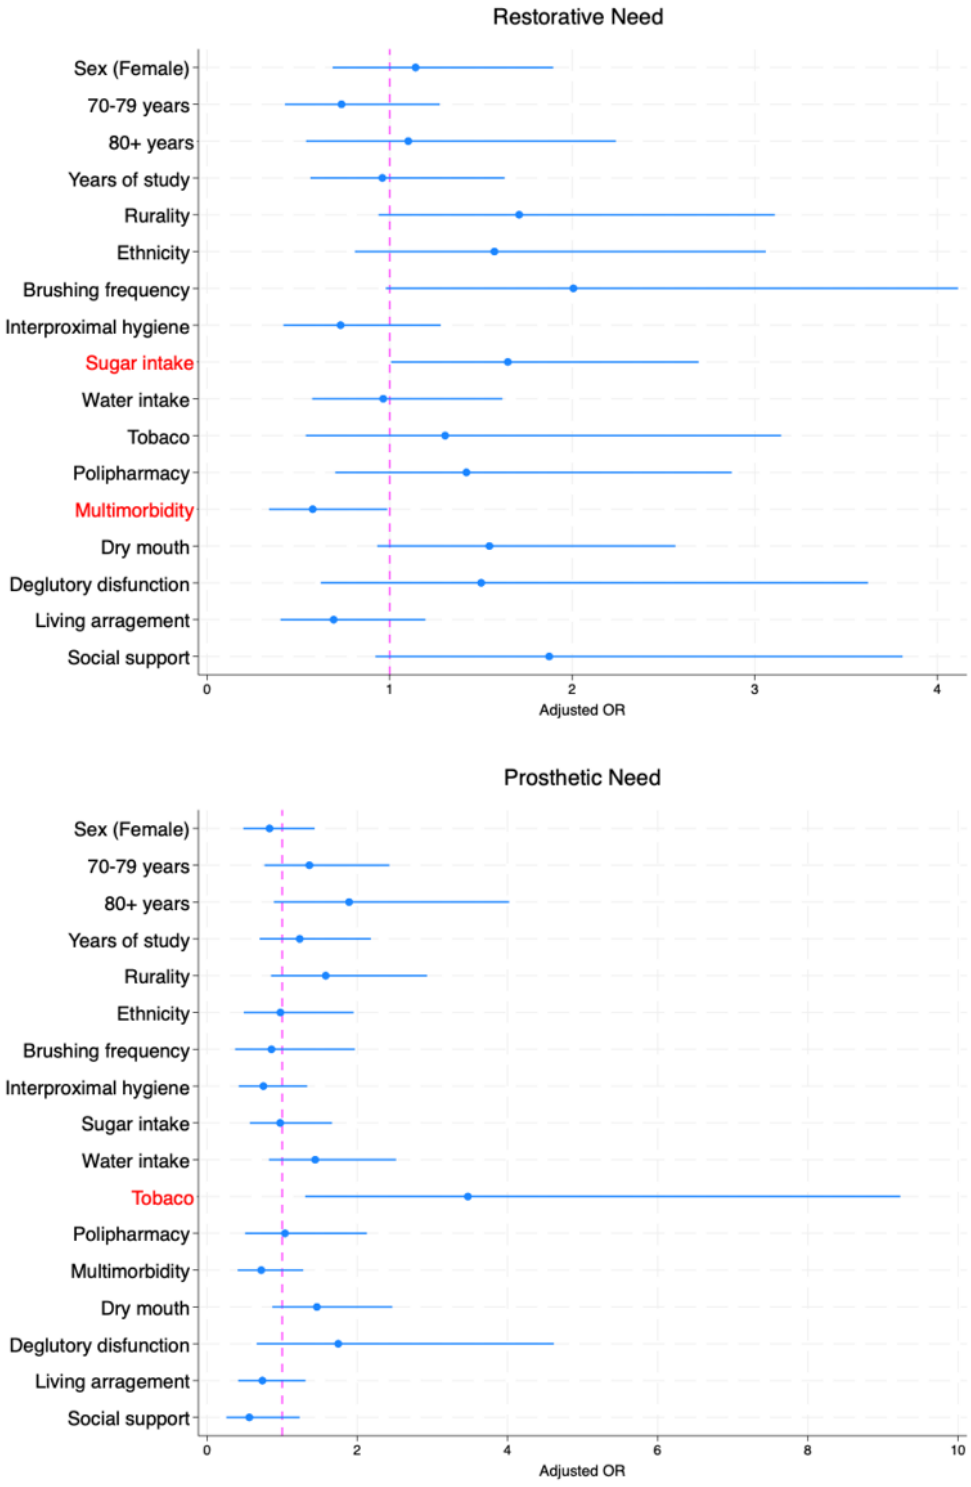
Association of Ethnicity and Other Social Determinants With Access to Dental Care

In the multivariable analysis, variables related to dental care were examined (full results are provided in Multimedia Appendix 1). Time since the last dental visit was associated with toothbrushing frequency (OR 1.92, 95% CI 1.02-3.62; *P*=.04) and interproximal hygiene practices (OR 1.90, 95% CI 1.13-3.19; *P*=.01). Rural residence was associated with higher odds of unmet denture need (OR 2.86, 95% CI 1.31-6.24; *P*=.008), whereas brushing frequency (OR 0.25, 95% CI 0.11-0.57; *P*<.001) was associated with lower odds.

XSL•FO
RenderX

In the adjusted model, women were more likely to have received fixed prostheses (OR 3.46, 95% CI 1.51-7.94; *P*=.003), as were participants aged 80 years or older (OR 5.05, 95% CI 1.68-15.17; *P*=.004). Conversely, participants with ≤8 years of education were less likely to have received fixed prostheses (OR 0.37, 95% CI 0.15-0.91; *P*=.03). Consumption of sugary snacks was also associated with higher odds of having received fixed prosthetic rehabilitation (OR 3.48, 95% CI 1.56-7.78; *P*=.002). Other determinants, including ethnicity, did not show significant associations with this outcome (Figure 3).

Figure 3. Adjusted associations between predictor variables and access to dental care outcomes. Forest plot showing adjusted odds ratios (aORs) and 95% CIs from separate multivariable logistic regression models for last dental visit, unmet denture need, and fixed rehabilitation. Points represent aORs, and horizontal bars represent 95% CIs. The vertical line indicates an odds ratio (OR) of 1 (no association). Statistically significant associations are highlighted in red.



XSL•FO
RenderX

Association of Ethnicity and Other Social Determinants With Treatment Needs

When treatment needs were analyzed, no structural determinants were significantly associated with these outcomes. However, higher consumption of sugary snacks between meals was linked to increased odds of requiring restorative treatment (OR 1.69, 95% CI 1.03-2.77; *P*=.03). In addition, current smoking was associated with higher odds of normative prosthetic treatment need (OR 3.49, 95% CI 1.3-9.31; *P*=.01; Figure 4). Full adjusted model results are presented in Multimedia Appendix 2.

Figure 4. Adjusted associations between predictor variables and dental care needs. Forest plot showing adjusted odds ratios (aORs) and 95% CIs from separate multivariable logistic regression models for restorative treatment need and normative prosthetic treatment need. Points represent aORs, and horizontal bars represent 95% CIs. The vertical line indicates an odds ratio (OR) of 1 (no association). Statistically significant associations are highlighted in red.

Discussion

Principal Findings

This study highlights differences in both structural and intermediary social determinants of health between Indigenous (Mapuche) and non-Indigenous older adults in a sample from the La Araucanía Region of Chile. Compared with non-Indigenous participants, Mapuche individuals had lower educational attainment and were more likely to reside in rural areas. They also showed a higher prevalence of oral diseases, alongside a higher number of risk factors, including less frequent toothbrushing and higher sugar consumption. In addition, they had greater restorative treatment needs and reduced access to complex dental care services.

When examining the independent influence of structural and intermediary determinants on various oral health outcomes, structural factors showed more consistent associations than intermediary ones, in line with the WHO-CSDH framework. The associations observed for these variables may be consistent with the cumulative influence of structural disadvantage across the life course, whereby intermediary determinants in older age could reflect the long-term manifestation of social inequalities. Although our cross-sectional design does not allow direct assessment of life-course processes, longitudinal cohort research has demonstrated that early socioeconomic conditions shape oral health beliefs and behaviors, which subsequently influence adult clinical outcomes and quality of life, supporting the plausibility of cumulative pathways [73].

Notably, the pattern of associations varied depending on the outcome assessed. For instance, female sex was significantly associated with a higher prevalence of edentulism while showing lower odds of periodontitis. Similarly, lower educational attainment was associated with increased prevalence of nonfunctional dentition and edentulism; however, it showed no significant association with caries or periodontitis. For these latter outcomes, ethnicity showed the most consistent association. In particular, Mapuche participants had more than twice the odds of periodontitis compared with non-Mapuche counterparts (OR 2.43, 95% CI 1.21-4.88; *P*=.01). These findings are in line with international evidence reporting a 35% higher prevalence of periodontitis among Indigenous populations compared with non-Indigenous groups [2].

Regarding caries, Chilean adults aged 65 to 74 years exhibit one of the highest burdens worldwide (57,729 per 100,000) [74]. In our sample, all participants had a history of caries experience, and Mapuche participants showed a significantly higher prevalence of untreated (cavitated) caries compared with their non-Indigenous peers. This association remained significant in the multivariable model.

When examining variables related to access to dental care, no significant differences were observed in the frequency of the last dental visit between ethnic groups. However, the lower prevalence of complex treatments, such as dental implants and fixed prosthetic rehabilitations (eg, crowns and bridges), along with higher restorative treatment needs, including active caries and defective restorations, among Indigenous participants suggests a potential disparity in the quality of dental care received.

Ethnicity was significantly associated with 2 of the 9 outcomes in the multivariable models, a pattern similar to that observed for education, sex, and age. Within the WHO-CSDH framework, ethnicity is conceptualized as a structural determinant that interacts with socioeconomic, territorial, and cultural conditions, and is linked to cumulative disadvantages in health [6,9,75]. Historical and structural inequities have been documented as shaping access to services, use of dental prostheses, and the persistence of restorative treatment needs [4,5,76]. These findings highlight that ethnicity, alongside sex, age, and educational attainment, functions as a key axis of social stratification associated with differences in disease distribution and patterns of access and quality of treatment, rather than merely representing background characteristics.

Structural determinants are understood to shape differential exposure to intermediary determinants, including behavioral and biological risk factors [6,75]. In our study, unhealthy lifestyle behaviors, particularly the consumption of sugary snacks between meals, were more prevalent among Mapuche participants and were also linked to periodontitis and restorative treatment needs. These patterns are consistent with broader dietary changes reported in Indigenous populations, where colonization and globalization have contributed to the loss of traditional food systems, with a shift from subsistence diets toward store-bought and processed foods rich in refined sugars [77]. Structural factors, including corporate determinants of health such as the marketing of sugary products, may further reinforce this trend [78]. These dietary changes have been consistently linked with poorer oral health outcomes, including caries and periodontal disease [77]. The higher prevalence of periodontitis and caries in Mapuche participants may be related to a combination of factors, including ethnicity, dietary practices, and a lower brushing frequency, even though brushing frequency was not a significant predictor in the multivariable model. This finding supports the WHO-CSDH framework, which emphasizes the complex and not yet fully understood pathways through which structural determinants translate into biological outcomes [75].

Intermediary determinants played a more limited but still relevant role. Adverse outcomes were associated with dental visits occurring more than 2 years ago, frequent consumption of sugary snacks, and reduced toothbrushing frequency, while dry mouth, a biological factor linked with polypharmacy and aging [79], was also linked to both caries and nonfunctional dentition. Interestingly, better oral hygiene practices were associated with more recent dental visits. Addressing this requires expanding preventive interventions, particularly dietary counseling and management of xerostomia, as well as integrating tailored oral health education at the time of prosthetic delivery to improve long-term outcomes and avoid premature failures.

The Chilean health system, organized under a mixed public-private model, provides coverage to approximately 80% of the national population through its main government-funded scheme, FONASA, which primarily focuses on essential curative oral health care [3-5,80]. In this study, health insurance type

XSL•FO
RenderX

was not included as a covariate since most participants were enrolled in FONASA, resulting in limited variability in coverage. Nevertheless, despite formal insurance coverage, a high burden of oral health problems alongside important gaps in service provision was observed. Although dental visit rates within the past 2 years were comparable across groups, 54% (206/383) of participants required restorative treatment, and a substantial proportion of existing restorations were found to be defective. Access to prosthetic care also showed notable gaps. While the national health guarantee (Explicit Health Guarantees [GES]) provides removable dentures for individuals at age 60 years, and other programs extend this benefit to vulnerable adults aged older than 20 years, important unmet needs persist [65,81-84]. In this study, 2 prosthetic indicators were considered. Unmet prosthetic need referred to individuals requiring a prosthesis but not currently wearing one, serving as a proxy for limited previous access to prosthetic care. In contrast, prosthetic treatment needs included both individuals requiring a new prosthesis and those with existing prostheses requiring repair or replacement, reflecting the overall demand for prosthetic treatment and providing an indicator relevant for service planning. Nearly one-fifth of participants presented unmet denture needs, and among those who already had dentures, almost 80% required repair or replacement. These findings underscore the importance of ensuring the quality of removable dentures provided in both public and private settings, particularly within publicly financed dental care, where more than 300,000 dentures are delivered annually in Chile [65]. A considerable proportion of these prostheses remain unused by patients due to poor fit, discomfort, or insufficient follow-up and adaptation protocols, which are critical to achieving functional rehabilitation and patient adherence [65]. The limited provision of complex treatments, coupled with gender-, education-, and ethnicity-based disparities in the use of fixed prostheses, is indicative of persistent inequalities. Within our sample, access to oral rehabilitation and preventive care appears more limited among older adults characterized by structural disadvantages, including advanced age, lower educational attainment, rural residence, and Indigenous ethnicity. Taken together, these patterns suggest that insurance coverage alone does not guarantee equity in oral health.

An innovative aspect of this study was the implementation of a teledentistry ecosystem (TEGO) supported by a mobile clinic. Although TEGO was designed for the broader older population, its pilot implementation in a Mapuche community demonstrated feasibility, user satisfaction, and a culturally respectful approach through the incorporation of intercultural facilitators, suggesting potential for supporting access to care in underserved communities [29]. Within the WHO-CSDH framework, strategies to reduce health inequities must address both structural and intermediary determinants of health [6,7]. In this context, technology-supported models of care may help mitigate structural barriers related to geographic isolation and limited service availability through remote consultation, screening, and triage, particularly in rural and underserved populations [44,85-88]. At the same time, digital health interventions may also influence intermediary determinants by strengthening oral health literacy, preventive behaviors, and patient engagement [85,89]. In this regard, the TEGO model illustrates a potentially equity-oriented strategy that combines digital tools with mobile service delivery to address barriers across the continuum of care. By facilitating access to primary oral health services (eg, restorative care and repair of removable prostheses) and, in some cases, enabling referral to secondary care for complex treatments such as implants, this approach may help reduce gaps in service use among populations facing structural disadvantages. Such strategies are particularly relevant for older adults living in rural or historically underserved settings and align with broader calls to action aimed at reducing health inequities and expanding access to care, including the objectives of United Nations Sustainable Development Goals, particularly goal 3 (good health and well-being) and goal 10 (reduced inequalities), while also contributing to the growing agenda of digital health equity [35,90-94].

The educational and ethnic inequalities observed in oral disease are consistent with prior evidence and support the need to account for differential disease burden in the design of public health policies [30,67,95]. Ongoing monitoring of these indicators may help identify service gaps and inform more equitable interventions. Even though a “one-size-fits-all” approach focused on individual treatment has done little to improve oral health outcomes at the population level, priority actions should focus on reducing structural disadvantages that influence access to and the cost of dental services, with a strong emphasis on equity [78]. This may include prioritizing socially disadvantaged groups and ensuring that treatments, such as dentures, are provided appropriately to individuals whose anatomical and functional characteristics allow effective use, while simultaneously establishing a subsidized system to improve access to more complex dental treatments for those who require them. Efforts should focus on strengthening the quality and follow-up of dental care, as well as implementing culturally tailored health promotion strategies for Indigenous and rural populations. Additionally, community-based delivery models, including mobile and digitally supported services, may contribute to reducing geographic and social inequities in access to care.

Limitations and Generalizability

Certain limitations should be considered when interpreting these findings. First, the cross-sectional design precludes causal inference. The observed associations reflect patterns of co-occurrence rather than directional relationships, and reverse causation remains plausible. For example, poorer oral health may influence psychosocial domains such as depressive symptoms or social participation in older adults [96]. Accordingly, findings should be interpreted as evidence of social patterning rather than causal pathways.

Second, the sampling strategy and implementation context may have introduced selection bias and limited external validity. Participants were community-dwelling, functionally independent older adults recruited from a publicly funded, mobile, digitally supported care program implemented in municipalities selected for logistical feasibility. Participation required the capacity and willingness to attend scheduled dental visits, which likely underrepresents individuals with greater dependency, mobility limitations, or who are harder to reach—groups that may occupy

XSL•FO
RenderX

more disadvantaged positions within the social gradient. This may have resulted in a healthier or more health-engaged sample, potentially underestimating the magnitude of oral health inequalities. At the same time, as an access-oriented intervention, the program may have attracted individuals with heterogeneous levels of perceived need, including both those seeking care for existing conditions and those engaging in preventive checkups, which may further influence the composition of the analytic sample.

Third, measurement limitations may have affected internal validity. Several intermediary determinants were self-reported, including dental visits, oral hygiene practices, current tobacco use, and chronic conditions used to define multimorbidity. These measures are susceptible to recall and social desirability bias, and the absence of detailed exposure assessment (eg, pack-years of smoking) or verification through clinical records may have introduced measurement error. Clinical outcomes were assessed by trained examiners using standardized protocols and direct supervision; however, periodontal and prosthetic assessments were more susceptible to field variability than caries, which was formally calibrated. These factors may have affected the precision and consistency of associations, particularly for periodontitis and for behavioral and biological variables.

Fourth, residual confounding cannot be excluded. Although the multivariable models were adjusted for the number of natural teeth as a key clinical factor, other potentially relevant confounders may not have been fully captured. In particular, the dataset lacked more granular measures of socioeconomic position (eg, wealth and income) and detailed health system characteristics, limiting the full operationalization of the structural dimension of the WHO-CSDH framework.

Fifth, missing data may have introduced bias. Although missingness was generally low, it was higher for periodontitis and polypharmacy. Incomplete periodontal examinations may occur under field conditions when full assessment is not feasible (eg, due to pain, tooth mobility, or time constraints during clinical evaluation). Missingness was not consistently associated with most measured characteristics, including sex, education, ethnicity, and rurality. However, for periodontitis, excluded participants were older than those included in the analysis, suggesting that examination feasibility may have differed by age. Given the overall low level of missingness and the limited evidence of systematic differences across most covariates, complete-case analysis was considered appropriate. Nonetheless, some degree of bias cannot be entirely excluded.

Finally, the absence of an a priori sample size calculation and the low frequency of some outcomes (eg, implants or complex rehabilitations) resulted in limited statistical precision for certain estimates, as reflected in wide CIs. Also, the study may not have been specifically powered to detect all potential differences between Mapuche and non-Mapuche participants; therefore, subgroup analyses should be interpreted cautiously.

Taken together, these findings are primarily applicable to community-dwelling, functionally independent older adults in rural and urban municipalities of La Araucanía, including both Mapuche and non-Indigenous individuals. Extrapolation to populations with higher levels of dependency or barriers to access, other regions of Chile, larger metropolitan areas, or Indigenous populations with different social or health care contexts should be undertaken cautiously. Moreover, as data were collected within a mobile, digitally supported care model specific to this program, generalizability to older adults receiving standard primary care services may be limited. This program-based implementation reflects real-world conditions of service delivery within its operational context, which may support ecological validity in terms of care processes and service pathways.

Implications and Future Directions

Despite these limitations, this study contributes to the literature by examining oral health outcomes among older adults through a structured social determinants framework that simultaneously models structural determinants, including ethnicity, and intermediary factors. Ethnicity was associated only with cavitated caries and periodontitis. This analytical approach allows observed ethnic differences to be interpreted within broader social and territorial conditions, rather than attributing disparities to ethnic group membership alone. It does not eliminate ethnic gradients but situates them within patterned social conditions that may shape exposure, risk, and access over time [9]. In the Chilean context, national health surveys include self-identified Indigenous affiliation and have examined several social determinants, such as education, income, and insurance status. However, oral health outcomes have rarely been analyzed using multivariable frameworks that incorporate ethnicity alongside other determinants.

The findings further indicate that oral health inequalities in older adults may operate through multiple and outcome-specific pathways. Structural determinants—particularly age and educational attainment—were strongly associated with cumulative indicators of tooth loss, such as nonfunctional dentition and complete edentulism. In contrast, behavioral factors showed closer associations with selected access to dental treatment and treatment needs. This pattern suggests that different levels of determination may be more relevant depending on whether the outcome reflects long-term accumulation of disadvantage (eg, tooth loss) or more proximal conditions and service use patterns.

The inclusion of both rural and urban participants highlights the contextual dimension of these inequalities. While rural residence was not consistently associated with all clinical outcomes, it was linked to selected treatment-related indicators, suggesting that territorial factors may influence patterns of rehabilitation and unmet need even when not uniformly affecting disease prevalence.

Future longitudinal studies incorporating more detailed measures of lifetime exposures, including behavioral factors such as smoking history, as well as health service trajectories and contextual factors, would help clarify the pathways linking structural determinants to oral health outcomes in later life. Research may also benefit from intersectional approaches capable of examining how structural determinants interact to shape oral health disadvantages. Additionally, evaluating the long-term effectiveness and equity of innovative service delivery models, such as teledentistry and mobile dental clinics, may

XSL•FO
RenderX

provide valuable evidence to inform strategies aimed at reducing disparities. Mixed methods studies incorporating qualitative perspectives on social, cultural, and system-level barriers may further contribute to a more comprehensive understanding of the mechanisms underlying the observed patterns.

Conclusions

Oral health inequalities differed between Mapuche and non-Indigenous older adults in La Araucanía and were associated with both structural and behavioral determinants. Structural determinants, particularly lower education, female sex, older age, and ethnicity, showed consistent associations with oral health status, whereas dental care access reflected a combination of structural and behavioral factors. In contrast, current treatment needs were mainly associated with behavioral factors, including sugar consumption and tobacco use. Although Mapuche participants exhibited poorer oral health, higher restorative needs, and reduced access to complex dental care in bivariate analyses, ethnicity remained associated only with cavitated caries and periodontitis in adjusted models.

These findings underscore the importance of incorporating social determinants into oral health planning for underserved older adults, particularly in Indigenous and rural populations experiencing persistent social and territorial inequities. By applying the WHO-CSDH framework within a hybrid teledentistry and mobile clinic model, this study illustrates how digitally supported territorial care programs can generate clinically grounded population health data that help identify inequities in oral health status, access to care, and treatment needs. Integrating these approaches into oral health information systems and service planning may support more equity-oriented prioritization, resource allocation, and delivery of preventive, restorative, and prosthetic care for older adults in underserved territories.

Acknowledgments

The authors thank the Universidad de La Frontera for logistical support and the Inter-University Center of Healthy Aging (CIES) of the Council of Rectors of Chilean Universities (CRUCH) for their collaboration. This study would not have been possible without the support of the FRO2495 MINEDUC-Chile project, “Integrated Technological Ecosystem of Tele-Dentistry to Provide General and Specialized Dental Care for Older Adults,” funded by the Ministry of Education of Chile. The project was awarded to the Universidad de La Frontera under the Plan for Strengthening State Universities, Regional Higher Education (ESR) line.

Data Availability

The datasets analyzed during this study are not publicly available due to privacy restrictions regarding the Indigenous population but are available from the corresponding author on reasonable request, subject to ethical approval.

Funding

This research was funded by the Presidential Grant Project Clinical Center for Innovation in Oral Health of the Elderly in the La Araucanía Region (exempt resolution number 472).
