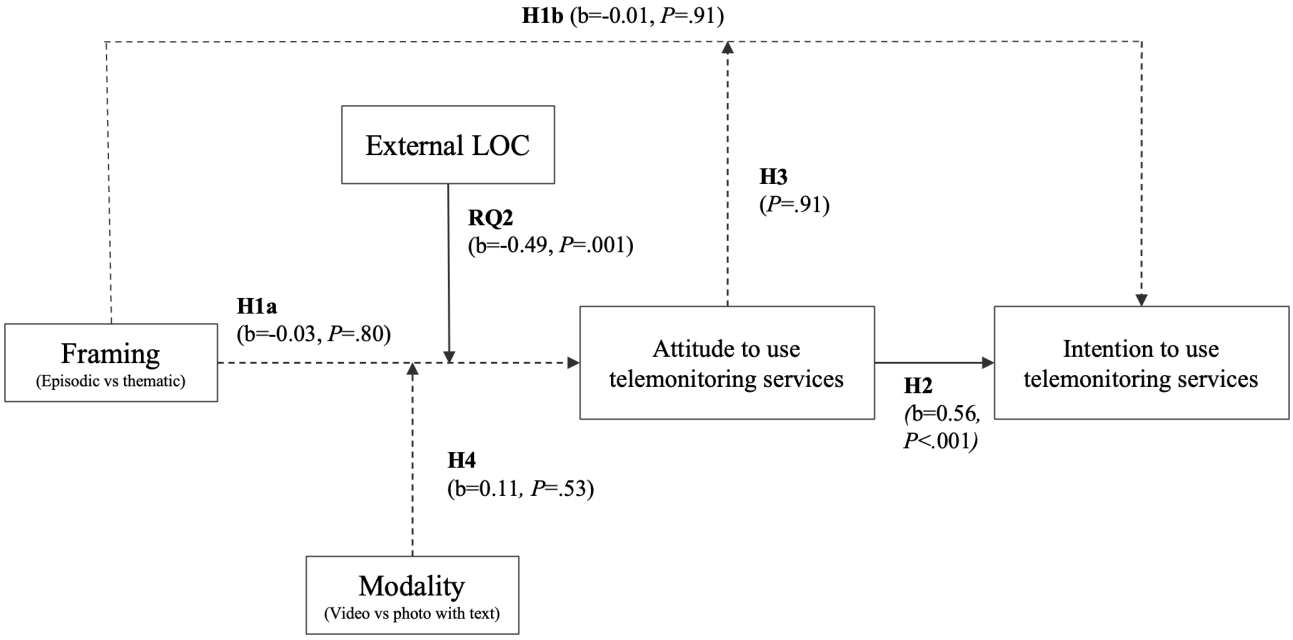
We found a significant positive relationship between attitudes toward using telemonitoring services and intentions to use these services (b=.56, t_{116}=4.47; *P*<.001), supporting the hypothesis that favorable attitudes positively influence usage intentions (H2). Analysis revealed the unconditional indirect effect of message framing on intention through attitude was not significant, regardless of modality (95% bootstrap CI included zero in both cases). However, this indirect effect was conditional on external LOC (Index=−.28, 95% CI −0.52 to −0.08), while the index for modality was not (Index=.06, 95% CI −0.13 to 0.24). At representative levels of the moderators, framing exerted a significant indirect effect via attitude among participants with low external LOC exposed to video (b=.21, 95% CI 0.02-0.44) and among those with high external LOC exposed to photo-text (b=−.18, 95% CI −0.36 to −0.03). H3 was therefore supported only conditionally, through external LOC.

Moderating Effects of Message Modality

Contrary to expectations, the analysis showed no significant interaction effect between modality (video vs photo-text) and message framing on attitudes toward telemonitoring services (b=.11, t_{113}=0.63; *P*=.53). This suggests the modality did not significantly influence how framing affected attitudes in our experimental conditions, indicating that older adults may process different media formats similarly when evaluating health technology information.



Moderating Effects of External LOC

External LOC significantly moderated the effect of message framing on attitudes toward using telemonitoring services (b=−.49, t_{113}=−3.28; *P*=.001). When exposed to episodic framing, participants with lower external LOC showed more positive attitudes (mean 4.21, SD 0.47) compared to those with higher external LOC (mean 3.99, SD 0.47). Conversely, thematic framing resulted in more positive attitudes among participants with higher external LOC (mean 4.15, SD 0.47) compared to those with lower external LOC (mean 3.98, SD 0.47). This finding suggests that individuals' beliefs about health outcome sources play a crucial role in determining the effectiveness of different message framing approaches, reflecting how psychological orientations influence technology adoption decisions in later life.

Figure 5 provides a conceptual summary of the regression paths estimated using Hayes' PROCESS macro (Model 9). The coefficients shown are unstandardized (b) and are taken from the corresponding ordinary least squares regression equations; as noted in the Data Analysis section, global model fit statistics are not applicable.

Discussion

Principal Findings

Our sequential mixed methods study provides valuable insights into factors influencing telemonitoring adoption among socioeconomically disadvantaged older adults in Singapore. By first identifying key motivators and barriers through qualitative methods then experimentally testing communication strategies, we developed a comprehensive understanding of how to effectively promote telemonitoring acceptance. Our qualitative findings, anchored in the SIM, identified 3 key facilitators of telemonitoring adoption: convenience, affordability, and health benefits. These align with prior research [68,69] and underscore how their absence magnifies existing barriers for older adults with lower socioeconomic status.

Affordability and convenience emerged as essential elements, reflecting the structural theories of aging, wherein socioeconomic constraints often intensify in later life [13]. Prohibitive costs and inconvenience of traditional health care services disproportionately affect those with constrained retirement incomes and limited mobility [70], underscoring how economic inequalities accumulated throughout the life course can restrict technology access and adoption [71]. Perceived health benefits of continuous monitoring served as a powerful motivator, suggesting older adults strategically invest in technologies that help manage age-related health changes and maintain independence [72].

The barriers we identified (preference for in-person consultations, perceived limitations of remote monitoring, and diminished information processing abilities) all relate to SIM components while reflecting age-specific considerations. The preference for face-to-face interactions exemplifies embodied knowledge in health care, showing how accumulated physical and relational experiences shape how older adults interact with health care systems [73]. This reflects established patterns of trust and communication developed throughout the life course [74]. The perceived limitations of telemonitoring relate to information exposure and attention, suggesting a need for clearer communication about the proactive monitoring benefits [1]. Perhaps most critically, the challenge of information processing, exacerbated by cognitive changes and socioeconomic factors [75,76], directly relates to the SIM component of information processing.

Message Framing, Modality, and Health LOC in Later Life Technology Decisions

Building on our qualitative findings, our experimental study revealed important insights about effective communication strategies for promoting telemonitoring adoption among older adults. Most notably, episodic framing's persuasive power was conditional on external LOC: our results showed that individuals with lower external LOC responded more favorably to episodic framing, while those with higher external LOC showed greater receptivity to thematic framing. This message-audience matching pattern aligns with a growing body of evidence that dispositional beliefs about control shape which type of health message works [26,55], and a recent systematic review confirms that health LOC systematically conditions how audiences respond to behavioral health interventions more broadly [77]. Substantively, individuals lower in external LOC likely process episodic narratives as personally self-relevant and congruent with their belief that health outcomes are within their own control; individuals higher in external LOC, who attribute health outcomes more to institutions, systems, or chance, may instead find thematic framing more credible and applicable to their own situation, which explicitly foregrounds statistical evidence and institutional infrastructure [34,78,79]. The prevalence of external health LOC aligns with life-span developmental perspectives suggesting that control beliefs often shift toward greater externality with advancing age, reflecting adaptive responses to increasing dependence on health care systems [51]. Older adults' well-documented preference for emotionally meaningful,

XSL•FO
RenderX

narrative information [33] appears to hold most strongly among those who already see themselves as agents in their own health. However, the nuanced interaction between external LOC levels and message framing calls for further exploration, especially to decipher the effects of different dimensions of LOC, such as chance and powerful others, on health communication strategies in diverse aging populations [80].

Contrary to expectations, we found no significant difference in the effectiveness of video versus photo-text modalities in enhancing framing effects on telemonitoring attitudes. This finding diverges from prior research advocating for video's superior persuasive capacity in health communication [47,48] and challenges simplistic notions about age-related preferences for specific media formats. The lack of observed modality impact suggests that individual differences, such as lifelong media habits, might dilute anticipated modality effects [81,82]. Consequently, the choice of modality for telemonitoring communications should be informed by considerations of content complexity and the cognitive and literacy levels of the target audience [83] while recognizing the diversity of media competencies among older adults.

Taken together, these 2 patterns suggest that what is communicated to older adults, and to whom, matters considerably more than the channel through which it is delivered. Through this lens, external LOC may be more than an individual psychological trait: external LOC may reflect in part how individuals perceive influences beyond their personal agency, from message framing to the behavior of trusted others within one's social network. Though in this study, the adapted SIM mainly focused on socioeconomic determinants, social capital mechanisms may operate alongside the socioeconomic pathway examined here. Individuals with higher external LOC may be more attuned to influences beyond their own agency when forming health-related judgments. This interpretation resonates with social capital and network-based perspectives in technology adoption research [84,85].

Digital Inclusion and Aging in Place: Implications for Policy and Practice

Our findings have important implications for inclusive digital health initiatives supporting older adults' aging in place. First, telemonitoring services should prioritize accessibility and affordability, particularly for socioeconomically disadvantaged older adults through free or subsidized community-based services, within walking distance could enhance adoption, aligning with age-friendly community principles [86]. Singapore's mature estates could serve as ideal locations for community-based services. Second, communications should position telemonitoring as complementing rather than replacing in-person care, emphasizing continuous monitoring benefits [16] while respecting established health care relationships. Messages could highlight how it complements and enhances doctor-patient relationships by providing continuous data that makes consultations more effective [87]. Third, the effectiveness of episodic versus thematic framing depends on external LOC. Practical guidance should center on message–audience matching rather than promoting a single "best" frame. Episodic narratives are likely to resonate more with older adults lower in external LOC, who tend to see health outcomes as within their own agency, while thematic messages emphasizing institutional involvement and statistical evidence may better suit those higher in external LOC. Communicators should therefore tailor framing to audience segment rather than defaulting to one universal approach, using simple language and visual aids to enhance accessibility. Finally, older adults should be viewed as active cocreators rather than passive recipients [88]. Their concerns reflect rational evaluations based on lifelong experiences. Involving them in design and implementation could enhance both solutions and acceptance.

Limitations and Future Research

While our study provides valuable insights, several limitations should be noted. First, this study adopted SIM adaptation, which did not incorporate the model's network-level mediating conditions, such as social capital and peer adoption behavior perception. Future research should directly examine whether social network characteristics or social capital account for this pattern, and integrate validated social network measures (eg, network size, tie strength, and peer adoption status). Second, our qualitative sample size was modest, and the convenience sampling approach may limit generalizability. Future research should expand to include more ethnically diverse participants and explore additional framing approaches. Third, our measure of external LOC would benefit from greater dimensionality in future studies. Longitudinal research examining actual telemonitoring adoption behavior would provide valuable insights. Furthermore, statistical power analysis indicates that the study lacked sufficient power to detect small effects (f^2<.07); therefore, the nonsignificant main effects of presentation modality and gender should be interpreted with caution and not viewed as definitive evidence of the absence of an association.

Conclusion

Our research advances understanding of how socioeconomic factors and communication strategies shape telemonitoring adoption among older adults in Singapore. The identified barriers and facilitators illuminate the interplay between aging experiences, health beliefs, and structural inequalities, rather than simple technological resistance. The message–audience matching pattern that episodic framing benefiting participants lower in external LOC, and thematic framing benefiting those higher in external LOC highlights the importance of psychologically tailored communication approaches that recognize older adults' diverse perspectives. This work contributes to both social gerontology and health communication by demonstrating how targeted interventions can bridge digital divides in aging societies. As Singapore and similar nations develop technological solutions to support aging in place, ensuring these innovations enhance rather than diminish equity, autonomy, and well-being for diverse older populations remains paramount, ultimately helping realize the goal of inclusive, technology-supported aging for all.

Abstract

Background: Multidomain dementia-prevention interventions delivered via apps have the potential to reach large populations. However, existing trials have tended to recruit more socioeconomically advantaged participants, raising concerns that the resulting interventions may be less usable for older adults from minority ethnic, lower educational, or lower socioeconomic backgrounds, who are at higher risk of dementia. The Tailored Intervention for Brain Health and Cognitive Enrichment (ENHANCE) app was designed to address this by prioritizing accessibility and engagement across diverse user groups.

Objective: This study evaluated the usability and user experience of the ENHANCE prototype during a 1-week at-home supported-use test and explored factors influencing use and engagement among older adults.

Methods: We purposively recruited adults aged 60 - 80 years without dementia for a 1-week mixed methods usability evaluation through community settings, including groups underrepresented in dementia-prevention trials. Participants had at least 1 of 10 prespecified dementia risk factors, attended a face-to-face onboarding session with a coach, used the app at home for 7 days with ongoing coach support, and completed a posttest interview and satisfaction survey. We analyzed quantitative data, including app usage metrics and survey responses descriptively, and used reflexive thematic analysis of qualitative data from onboarding sessions, posttest interviews, coaching calls, and in-app messages.

Results: Ten participants participated in the study. The mean age was 68 (SD 6) years, and 7 were females. Participants represented a wide range of deprivation (Index of Multiple Deprivation deciles: mean 4, SD 2, range 1 - 8), with 6 from ethnic minority backgrounds. All met prespecified minimum-use targets (watching a module video, completing a check-in, and playing assigned games at least once). Many demonstrated additional voluntary engagement: 5 rewatched the risk factor video, 7 used the in-app messaging feature, and among the 5 participants with the hypertension module, blood pressure was logged on an average of 5 out of 7 days. Survey responses indicated high satisfaction, perceived usefulness, and ease of use; 9 participants intended to continue using the app and would recommend it to peers. Qualitative analysis identified engagement facilitators, including rewarding game design, familiar interfaces, appropriately challenging gameplay, consistent virtual rewards, trusted expert information combined with peer stories, and coach support. Barriers included unclear visual cues, insufficient accommodation of motor or sensory impairments, and visual discomfort in some games.

Conclusions: Older adults found the ENHANCE prototype usable, acceptable, and engaging over 1 week. Human coaching, inclusive design, and integration of expert and peer narratives were highlighted as key engagement drivers. These findings support further feasibility testing to examine longer-term engagement and provide design insights for more inclusive digital health interventions.

KEYWORDS

dementia prevention; older adults; mHealth; underserved populations; usability testing; user experience; cognitive training

Introduction

The number of people with dementia globally is expected to reach 152 million by 2050, posing a major challenge for individuals, families, and health and social care systems [1]. As a result, prevention is a public health priority. The Lancet Commission on dementia prevention, intervention, and care estimates that 45% of cases could be prevented by eliminating 14 potentially modifiable risk factors, including less education, hypertension, diabetes, physical inactivity, smoking, obesity, depression, hearing loss, excessive alcohol, and social isolation [2]. Multidomain interventions addressing several dementia risk factors simultaneously can provide cognitive benefits for older adults at risk, though effects are typically modest [3,4]. For example, a network meta-analysis of over 100 RCTs found small improvements in cognition [3], while the large "Maintain Your Brain" randomized controlled trials (n>6000) reported modest gains over 3 years in the online multidomain lifestyle intervention [4,5].

People with lower socioeconomic status and those from ethnic minority groups are at greater risk of developing dementia likely due to higher risk factor prevalence [6-10]. Despite being at higher risk, these groups are often inadequately represented or reported in prevention trials [11-13]. In the Advanced Cognitive Training for Independent and Vital Elderly (ACTIVE) cognitive training trial (n=2832), participants were disproportionately highly educated (88.6% high school diploma+ vs 67% in the US population aged 65 y and older), healthier (higher health scores in health survey), and less hospitalized than national norms [14]. Similarly, in the Finnish Geriatric Intervention Study to Prevent Cognitive Impairment and Disability (FINGER) trial (a 2-year multidomain intervention; n=1260), participants had higher education levels and were younger or healthier than nonscreened eligible individuals from the same population [15]. These patterns underscore the need for more inclusive dementia prevention strategies that target underserved communities. Given the elevated baseline risk in these populations, even modest improvements in risk factor profiles could yield substantial reductions in dementia incidence at the population level.

In this paper, we use the term "underserved" to refer to groups who may experience higher dementia risk but face barriers to accessing and engaging with prevention interventions and who are often underrepresented in dementia prevention research. This includes (but is not limited to) older adults living in more socioeconomically deprived areas, with lower levels of education, and those from ethnic minority backgrounds.

Digital health interventions, particularly app-based approaches, offer a promising approach to more inclusive dementia prevention as they provide remote access to content, potentially benefiting those with less mobility, in rural areas, or facing financial barriers to in-person programs [16]. Apps can also support multiple languages, improving accessibility for ethnic minority older adults [17].

App use is increasingly common among older adults, including those from low-income groups in high-income countries. In the United Kingdom (2021 - 2022), 81% of adults aged older than 65 years used the internet, with 49% of these older adults accessing it via tablet [18]. Moreover, 67% of individuals from lower socioeconomic backgrounds across all age groups owned a smartphone—a figure likely to have risen due to increased digital adoption during the COVID-19 pandemic [19]. Importantly, a recent study suggests that device access can translate into engagement; individuals from underserved populations use health apps at rates comparable with more advantaged groups and derive similar benefits [20]. However, usability challenges and lower digital confidence remain significant barriers to long-term engagement, especially among this population [21,22]. Addressing these through inclusive design is essential for long-term engagement and use.

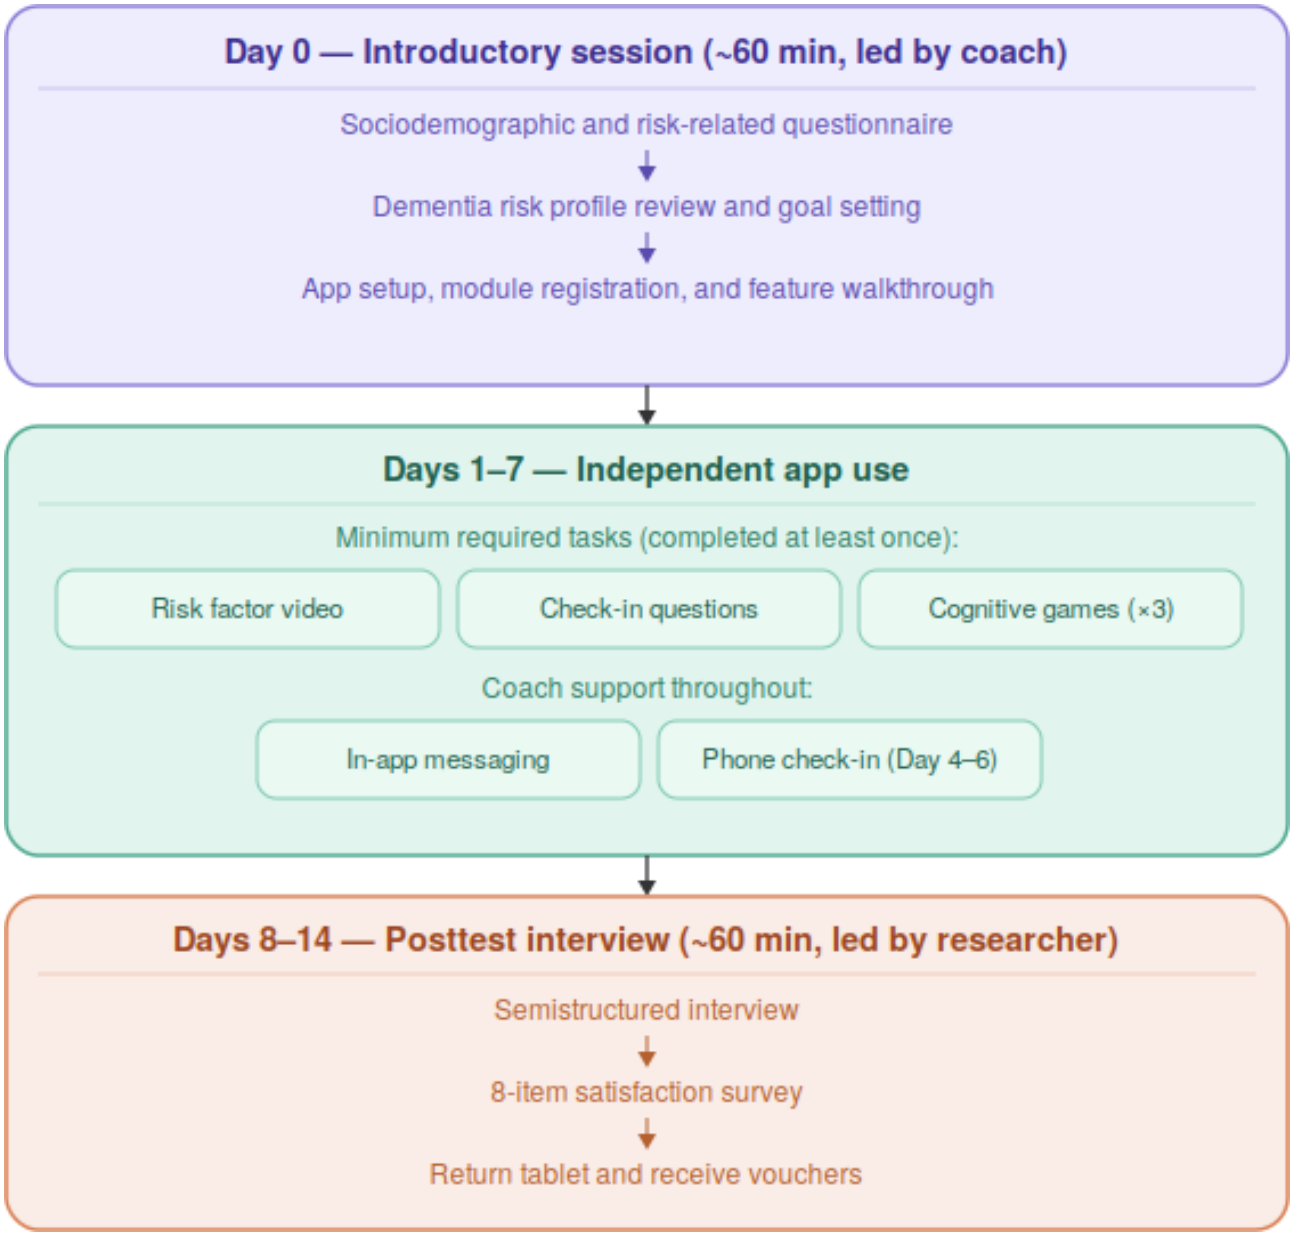
To address these gaps, we developed Tailored Intervention for Brain Health and Cognitive Enrichment (ENHANCE), a theory-informed, coach-supported, app-based intervention targeting modifiable dementia risk factors in older adults. A central aim of ENHANCE was to create an intervention that is accessible and usable across the whole older population, including the underserved people. The development process was centered on co-design with community-recruited participants, with a particular focus on individuals underrepresented in dementia prevention research, including those with lower educational attainment, from ethnic minority backgrounds, and with lower socioeconomic status. We also collaborated closely with patient and public involvement representatives and experts in human-computer interaction. Usability testing and iterative refinement were conducted specifically with older adults with lower education and socioeconomic status (refer to our previous work for detailed description) [23].

This study aims to evaluate user experience with the ENHANCE prototype over a 1-week period, identifying key facilitators and barriers to use.

This study addresses the following research questions:

1. What are the experiences of older adults using ENHANCE over 1 week?
2. What factors facilitate or hinder at-home, 1-week use and engagement with the intervention?

Methods



Overview

We conducted a 1-week usability test of the ENHANCE app prototype with older adults, including individuals from underserved backgrounds in the United Kingdom, using a mixed methods approach. Recruitment and data collection took place in London between November 2024 and February 2025. An overview of the study procedure is presented in Figure 1.

XSL•FO
RenderX

This project is part of the ENHANCE study, which will evaluate the feasibility, acceptability, and effectiveness of the ENHANCE intervention in reducing dementia risk among healthy older adults from underserved backgrounds.

Figure 1. Study's flowchart.

Ethical Considerations

The Institutional Review Board of University College London (ID 24235/001) gave ethical approval on June 19, 2023.

Before enrollment, all participants received a participant information sheet detailing the study purpose, investigator names, study procedures, and the expected time commitment (60-min introductory session, 7 days of independent app use, 60-min posttest interview, and a 5-min satisfaction survey). Participants were informed of their right to withdraw at any time without consequence and gave written informed consent before any data collection. All research participation was voluntary.

We pseudonymized collected data using alphanumeric codes. The code list and consent forms were stored separately from the anonymized data in locked cabinets (paper records) and on a password-protected, encrypted institutional drive (electronic records), accessible only to the core research team. Data are retained for 1 year following completion of the relevant analysis.

Eligibility Criteria and Recruitment

Participants were older adults residing in the United Kingdom. Eligibility criteria were as follows:

- Participants were included if they (1) were aged between 60 and 80 years; (2) had at least 1 dementia risk factor targeted by the ENHANCE intervention (<8 y of full-time education, diagnosed diabetes, hypertension, BMI>30kg/m^2, current smoker, >21 units of alcohol/week, <2.5 h of exercise/week, depressive symptoms identified using 2 adapted screening questions as per Patient Health Questionnaire−2 [PHQ-2] [24], social isolation assessed

XSL•FO
RenderX

with 1 adapted question based on the Lubben Social Network Scale [25], and self-perceived hearing impairment); (3) were able to read and communicate in basic English; and (4) had the mental capacity to provide informed consent.
- Participants were excluded if they reported a dementia diagnosis or any disability that would significantly impact tablet use, both assessed via self-reported screening questions (Multimedia Appendix 1).

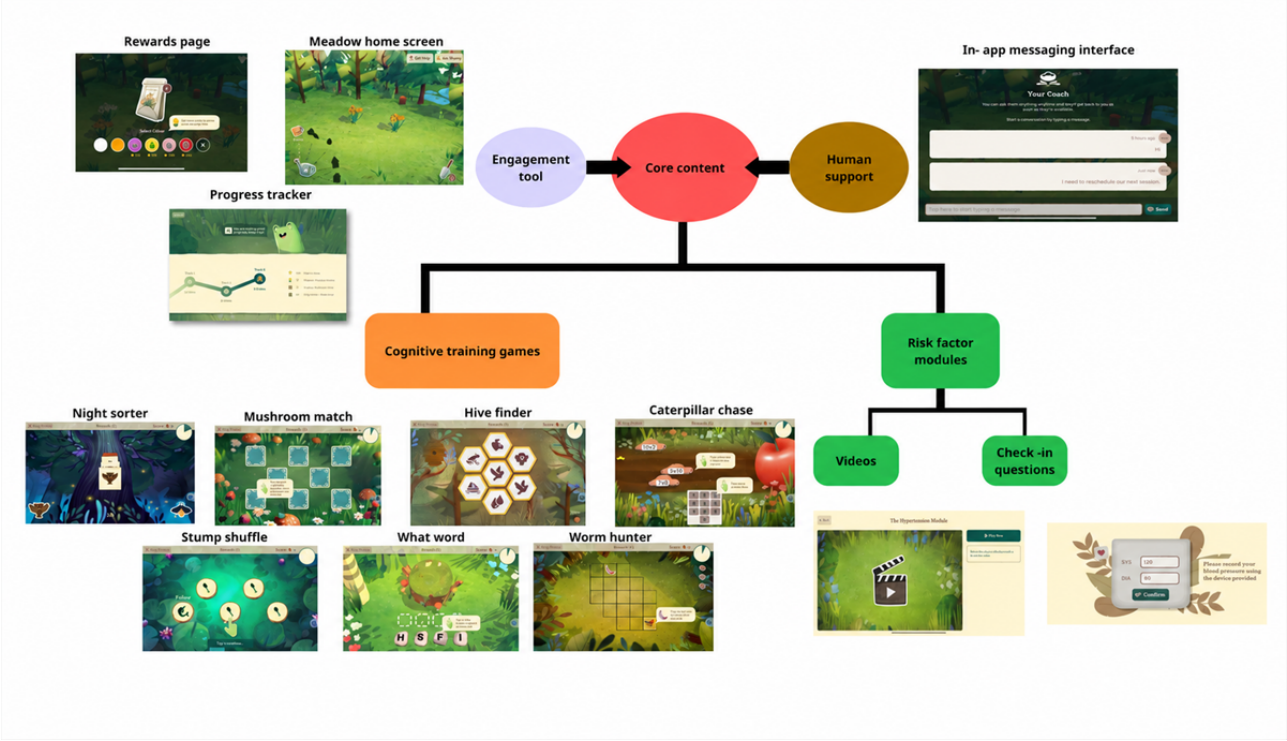
We predetermined a sample size of 10 participants, based on guidance suggesting that this number can identify approximately 95% of major usability issues [26]. We did not set eligibility criteria based on education, ethnicity, or area deprivation; instead, we used a recruitment strategy designed to reach underserved groups. Participants were drawn from a database of over 100 individuals (aged 60 years or older) recruited through community settings serving underserved populations in London, including food banks, neighborhood shopping malls, religious groups, and community organizations supporting low-income and ethnic minority communities. No centers serving people with dementia were included. Participants had previously taken part in ENHANCE coproduction activities [23] and had provided consent to be contacted for future research.

To inform purposive sampling, we extracted participants' age, ethnicity, and Index of Multiple Deprivation (IMD) scores from self-reported data collected in the previous study [23]. The IMD is a UK-based measure of relative deprivation derived from participants' postcodes and divided into deciles, with lower scores indicating higher levels of deprivation [27]. This information was used to purposefully recruit individuals from more deprived areas and non-White backgrounds.

TKCY, a PhD student with 6 years of dementia research experience, recruited potential participants by phone, email, or text. She informed them that no previous digital skills or home access to a tablet were required. Interested individuals completed a brief telephone screening for eligibility, covering age, dementia diagnosis status, as well as dementia health and lifestyle risk factors (Multimedia Appendix 1).

The ENHANCE Intervention

ENHANCE is a coach-supported, app-based intervention designed to help older adults aged from 60 - 80 years, including those from the underserved background, reduce dementia risk by addressing 10 modifiable risk factors—hypertension, diabetes, physical inactivity, obesity, depression, smoking, excessive alcohol use, social isolation, hearing loss, and low education—through lifestyle behavior change and cognitive engagement.



The app's features fall into 3 categories:

- Core content: 7 cognitive training games; modules for 9 other risks which include educational videos and brief weekly check-in questions to support motivation and self-monitoring for lifestyle change tailored to participants' selected risk factors.
- Engagement tools: A unifying "meadow" home screen and rewards page where participants can use virtual seeds to plant flowers in their meadow for playing games, watching videos, and answering check-ins; and a progress tracker showing weekly stars earned from completed activities.
- Human support: Scheduled coaching sessions (45 min in-person onboarding session and fortnightly remote short follow-ups); a coach-only dashboard to monitor participants' activities; in-app messaging with the coach; and optional family involvement.

All participants, regardless of their educational attainment, were given access to the cognitive training games in the ENHANCE intervention as they are rewarding in themselves. For the remaining 9 risk factors, each participant selected 1 risk factor module to focus on during the 1-week testing period. Figure 2 illustrates screenshots from the ENHANCE app. Further details about the app design are reported elsewhere [23].

XSL•FO

Figure 2. Screenshots of the ENHANCE app.

Procedures

Overview

The 1-week usability testing consisted of three components: (1) an introductory session on day 0, (2) independent app use from days 1 to 7, and (3) a posttest feedback interview conducted between days 8 and 14.

Introductory Session (Day 0)

Each participant attended a 60-minute introductory session about the app either at the university or at their home, choosing either. A coach (KF, CL, or VM) with an MSc in Psychology who contributed to the coaching manual development led the session, while the researcher (TKCY), a member of the research team who developed the ENHANCE app, observed participants' engagement with both the app and the coach.

The session began with participants completing a brief sociodemographic and risk-related questionnaire (Multimedia Appendix 2), by answering about age, post code (to derive the IMD to measure socioeconomic status), educational level, and key lifestyle and health factors relevant to dementia risk. Based on responses, the coach reviewed each participant's dementia risk profile, discussed the identified risk factors and which one they wished to target during the 1-week testing, and supported the creation of a SMART (specific, measurable, achievable, relevant, time-bound) goal [28] for positive behavior change related to this risk factor. The coach then guided participants through app setup, registration for the selected module, and key features, encouraging questions throughout.

At the end of the session, participants were given a tablet with the app installed and a SIM card and reminded to complete at least 1 video, 1 check-in tool, and each of the 3 cognitive training games at least once during the week; other activities (eg, additional gameplays and video rewatch) were optional.

The session was audio-recorded, and TKCY took notes on participants' interactions with the app, the coach, and any observed difficulties or misunderstandings.

App Testing Week (Day 1-Day 7)

Participants used the app independently for 7 consecutive days. On the app, each participant received:

- 3 randomly assigned cognitive training games from the games on the app. These covered different areas of cognition and could each be played up to 10 times per week after first completion
- 1 video from their selected module (rewatchable without limits)
- Risk factor–specific weekly check-in questions (eg, number of days exercise was completed in the previous wk, with daily logging enabled only for the blood pressure module).

Minimum required use was defined as completion of three core tasks during the testing period: (1) watching the assigned risk factor video at least once, (2) responding to the check-in question at least once, and (3) playing each of the 3 assigned games at least once.

Coach support was available throughout the testing week. Participants could message their coach via the in-app messaging feature. They also received a phone check-in on days 4 - 6. The check-in call was audio-recorded for further analysis.

Posttest Feedback Interview (Day 8-Day 14)

TKCY conducted and audio-recorded a posttest interview (approximately 60 min) at the same venue as the introductory session, within 1 week after app use, to gather feedback on

XSL•FO
RenderX

participants' experiences with the ENHANCE app and coaching. No previous relationship existed between TKCY and the participants before study commencement. Participants were informed that TKCY was a PhD student involved in the project as part of her doctoral study.

TKCY used a semistructured guide co-developed by the core research team and patient and public involvement representatives (Multimedia Appendix 3). The interview covered participants' general impressions, a section-by-section app review for detailed feedback, reflections on the coaching experience, and any potential barriers. TKCY reviewed app usage data in advance to tailor questions, particularly around unused features.

Immediately following the posttest interview, participants completed an 8-item, 1-page satisfaction survey taking approximately 5 minutes on a laptop preloaded with a direct Qualtrics link. To minimize social desirability bias, participants completed the survey independently, with TKCY briefly demonstrating the navigation and submission and then withdrew. All 8 items were mandatory, and Qualtrics was configured to prevent submission unless all items were completed. Participants then saw a review screen summarizing their responses, allowing them to amend answers if needed.

TKCY developed the satisfaction survey from the Client Satisfaction Questionnaire (CSQ-8) [29]—a validated measure of programs and services satisfaction. She adapted it for ENHANCE as no existing tool adequately captured the app-based gameplay, dedicated risk factor modules, and one-to-one health coaching. SGC and a member of the Patient and Public Involvement team provided feedback on wording, clarity, and coverage of the key ENHANCE components, and TKCY iteratively refined the survey. The final survey assessed app satisfaction, game enjoyment, perceived behavior-change potential of the risk factor modules, and coaching satisfaction using a 5-point Likert scale (Multimedia Appendix 4). Participants then returned the tablet and received £80 (£1=US $1.34) vouchers for their time (£25 for onboarding, £25 for postsession feedback, and £30 for app use).

Analyses

All quantitative data were analyzed using SPSS (version 25; IBM), and qualitative data were analyzed using NVivo 14 (Lumivero).

Demographic Data

Demographic data collected via a brief questionnaire administered during the introductory session were analyzed descriptively, with means, SDs, and range reported for continuous variables and counts for categorical variables.

Quantitative Data

App Use (Minimum and Additional App Use)

App use data were extracted from the backend following the app testing week and analyzed to (1) assess whether participants met prespecified minimum-use targets during the testing period and (2) characterize additional patterns of engagement beyond these targets.

Additional app use was assessed using 4 indicators. First, the number of times the risk factor video was rewatched was obtained from backend logs. Second, only participants assigned to the hypertension module had access to respond to the check-in more than once during the study week. Additional responses to the check-in question=(total number of check-in days÷total days of app use)×7. Third, additional gameplay beyond the minimum requirement=(total number of plays÷total days of app use)×7. The values were then averaged across all participants to yield the mean weekly gameplay frequency for each game. Finally, use of the in-app messaging feature at least once via backend data. Participants were coded as having used the feature if they initiated or responded to at least 1 message with the coach. Those with no interaction were coded as nonusers.

Posttest App Satisfaction Survey

Responses to 8 posttest survey questions were analyzed descriptively and summarized as counts for each response option.

Qualitative Data

All audio recordings were transcribed using data regulation-compliant software (Happy Scribe [Happy Scribe Ltd]) and reviewed by TKCY for accuracy and then imported into NVivo 14. TKCY analyzed the data using 6-step reflexive thematic analysis by Braun and Clarke [30,31]. She also maintained a reflexive journal to consider how her background might have influenced the interviews and analysis. She used the COM-B (capability, opportunity, motivation—behavior) model as a guiding framework to identify facilitators and barriers influencing app engagement [32] to provide a comprehensive overview of internal and external factors influencing behavior. It has been widely applied in studies understanding app use and user engagement [32-35] and aligns well with qualitative interview-based data analysis.

- Capability refers to an individual's ability to carry out the behavior, which includes psychological factors (such as knowledge, memory, and cognitive skills) and physical abilities (such as physical strength or motor skills).
- Opportunity encompasses the external circumstances that facilitate or encourage the behavior. These may be physical (eg, time availability and resources) or social (eg, social support or peer influence).
- Motivation involves the internal processes that initiate or maintain behavior. This includes reflective motivation (like conscious goals, intentions, and evaluations) and automatic motivation (such as emotions, desires, and habits).

She analyzed each qualitative data source separately, generating initial codes and developing them into candidate themes with theme refinement carried out through 5 biweekly meetings between TKCY, A Singh, GL, SGC, and HKP. As consistent patterns emerged, findings from each qualitative data source were integrated into a unified set of themes at the end.

Reflexivity Statement

TKCY is a female PhD student in her 30s from Hong Kong with a background in psychology and research experience in aging and dementia research. She is a core member of the team that co-designed the ENHANCE app. Her role in the project

XSL•FO
RenderX

may have influenced how she conducted interviews and interpreted data. Her familiarity with app usability literature may also have shaped how she identified themes during coding. As a young, educated researcher proficient in technology, she acknowledged a risk that she may underestimate usability challenges and overlook barriers faced by older adults. To mitigate this, she remained open to participants' perspectives, actively probed for any concerns raised by participants during interviews, and regularly discussed her reflections with supervisors throughout the process.

Data Integration Between Quantitative and Qualitative Data

TKCY analyzed quantitative and qualitative data separately, then integrated them through collaborative discussions with the research team of A Singh, GL, SGC, and HKP. These discussions involved comparing and contrasting findings across data sources to identify areas of convergence and divergence.

Results

Overview

All 10 participants completed the introductory session, the 1-week app testing period, telephone follow-up, posttest interview, and the satisfaction survey.

Participants used the app in testing for a mean duration of 9 (SD 3, range 7‐16) days. The participant with the longest testing period (16 d) had a delay in follow-up due to illness, which postponed the follow-up interview.

Demographic Characteristics of Participants

Participants' mean age was 68 (SD 6) years; 7 were female; 4 were White and 6 were non-White (South Asian, East Asian, or Mixed); and 7 had English as a first language. Participants lived in areas spanning a wide range of neighborhood deprivation (mean IMD decile 4, SD 2, range 1‐8). Mean years of full-time education was 14 (SD 3). Refer to Table 1 for full demographic details.

Most had previous experience with technology (smartphone: n=9, computer: n=8, and tablet: n=6); and 5 stated that they were comfortable or highly comfortable using it.

Common dementia risk factors included hypertension and hearing impairment (n=6 each), physical inactivity and depression (n=4 each), and diabetes (n=3). Moreover, 6 participants had 1‐2 risk factors, and 4 participants had 4 or more.

Among participants enrolled in the 1-week testing—5 chose hypertension, 2 hearing impairment, 2 diabetes, and 1 depression.

Quantitative Findings

App Use (Minimum and Additional App Use)

All 10 participants completed and exceeded the minimum required tasks during the first week: watching at least 1 video, answering a check-in question, and playing at least 3 games once. Moreover, 5 participants watched the risk factor video more than once, and 7 participants used the in-app messaging (Table 2). Of the 3 participants who did not use the in-app messaging, 1 reported he did not need it, and 2 said they were unaware of the feature although they had learned how to use this feature as part of the introductory coaching session.

Of the 5 participants who had chosen the hypertension module, which includes a feature allowing for daily blood pressure logging, entries were made on average 5 out of 7 days during the study period, and all participants entered it at least 4 times.

All participants exceeded the minimum required level of gameplay activity. Table 3 presents gameplay data, showing mean plays per game of approximately 5 - 10 times per week, with Caterpillar Chase most frequently played and Mushroom Match least. Worm Hunter was tested by only 1 participant, who played it 6 times during the week.

Table . Additional app use (videos, in-app messaging, and check-in).

Characteristic	Value
Videos rewatch frequency, n	
0	5
1	3

Average weekly check-in frequency (days), mean (SD; range)[b]	5 (1; 4–7)

[a]Participants were coded as having used in-app messaging if they initiated or responded to at least one message with the coach. Those with no interaction were coded as non-users.

[b]*Based on data from 5 participants who are on the hypertension module. Average weekly check-in frequency = (total check-in days ÷ total days of app use)×7.*

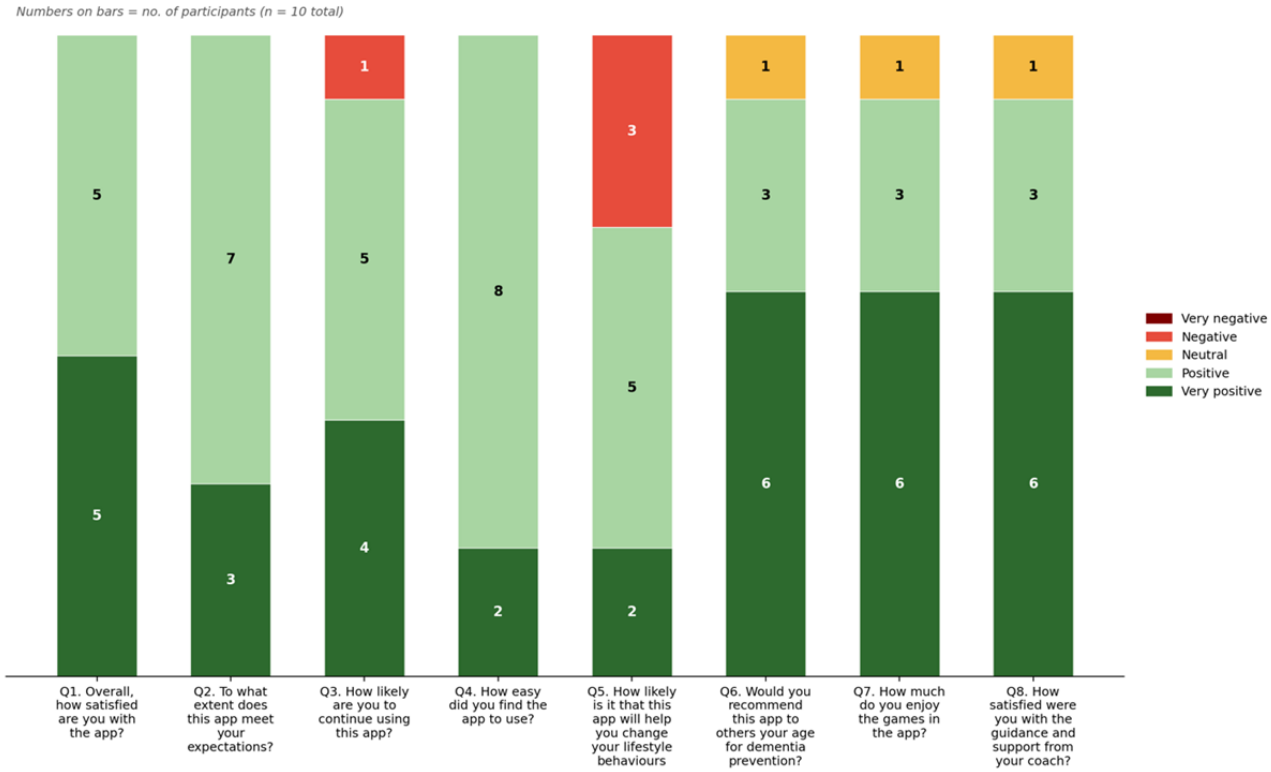
XSL•FO
RenderX

Table . Weekly gameplay frequency for each game among participants (n=10).

Game	Participants assigned[a], n	Plays per week per participant, mean (SD)	Range
Caterpillar Chase	6	10 (5)	6 - 18
Hive Finder	4	7 (3)	4 - 9
What Word	5	7 (3)	3 - 10
Stump Shuffle	6	7 (2)	3 - 9
Night Sorter	4	6 (6)	2 - 15
Mushroom Match	4	5 (2)	3 - 6
Worm Hunter[b]	1	6 (6)	6 - 6

[a]The number of participants assigned to each game varies because the app randomly allocated three games to each participant per week.

[b]Data for Worm Hunter should be interpreted with caution as only one participant was assigned this game.



Posttest App Satisfaction Survey

Figure 3 presents posttest survey results summarizing participants' ratings of the app. Response options differed across survey items (eg, satisfaction, likelihood, ease of use, and enjoyment); however, for visualization purposes, responses were harmonized into a standardized 5-point scale ranging from *very negative* to *very positive* based on semantic equivalence. Full survey questions and response labels are provided in Multimedia Appendix 4.

Using the original item-specific response options, all participants reported being either *satisfied* or *very satisfied* with the app and rated it as *easy* or *very easy* to use. All participants felt the app met or exceeded their expectations. Moreover, 9 participants indicated they were *likely* or *very likely* to continue using the app and to recommend it to others their age for dementia prevention. Similarly, 9 participants reported that they *liked* or *liked a lot* the games, and the same number were *satisfied* or *very satisfied* with support from their coach. Regarding the app's potential to support lifestyle behavior change, 7 participants reported that it was *likely* or *very likely* to help, while 3 reported it was *unlikely*.

No adverse events were reported to the coach or research team during the testing period. However, in posttest interviews, some participants described visual discomfort in relation to rapidly moving or flashing visuals in specific games, which are further described in the qualitative analysis result.

Figure 3. User rating of the app.

RenderX

Qualitative Findings

Overview

Guided by the COM-B model, we identified 6 themes, which are detailed in the further sections. Quotes have age ranges to reduce participant identifiability. The most illustrative quotations are presented in the main text, with additional supporting quotations provided in Multimedia Appendix 5.

Theme 1: Developing Psychological Capability Through Trial-and-Error App Learning

Many participants initially felt uncertain about the unfamiliar interface but gradually gained confidence through trial-and-error app learning. One participant described figuring out *Night Sorter* without initial instructions:

> *I found it [the instructions] a little bit unclear… because it didn't explain what you were trying to do. I had to spend some effort figuring it out myself. But I got a hang of it at last.* [P1, age group 60-69 y, White]

Some app features hindered learning due to competing visual cues. One participant described being confused by the green hand icon in Stump Shuffle until the coach clarified:

> *Because the "hand" is just so overpowering. It was a great big green hand. It's telling you, "Press here." But you're not pressing there—you should be focusing on the odd logo (the target logo; see Multimedia Appendix 6). I didn't get that… I didn't get that at the beginning, but [the coach] explained.* [P4, age group 60-69 y, Asian ethnicity]

App learning also varied depending on participants' previous experience with similar technologies. Familiar interfaces made learning more intuitive. When app visuals mirrored interfaces that participants already knew—such as messaging apps.

> *Yes, for me and I guess most people, the message one [in-app messaging's interface] is intuitive, isn't it? It is like WhatsApp. I thought it pop up the keyboard and everything. That's good.* [P1, age group 60-69 y, White ethnicity]

Theme 2: Drivers of Motivation—Enjoyment and Personal Goal

This theme describes participants' motivation to engage with the ENHANCE app, driven by enjoyment of game challenges, satisfaction from receiving virtual rewards, and desire for self-improvement.

Enjoyment of Game Challenges Boosts Motivation

Many participants described the games as "fun," "exciting," and even said they "got hooked." They especially appreciated games that were mentally stimulating, with just the right level of challenge—difficult enough to engage their thinking, but not so hard as to be discouraging.

> *I think [Hive Finder] is at the right level of challenge because it was pretty challenging for me – I didn't always get it. I'd run out of time sometimes. But it was fun.* [P3, age group 60-69 y, Mixed ethnicity]

Conversely, games perceived as too simple led to disengagement:

> *I don't like this [Night Sorter]. Bosh, bosh, bosh. It's very straightforward. But no, it's not much fun, is it? It's a bit stupid, really, isn't it? Not much thinking needed.* [P1, age group 60-69 y, White]

Participants also valued the adaptive design of some games, where difficulty adjusted based on performance, helping maintain motivation.

> *If you got it wrong, the game [What Word] would give you an easier word to get you more motivated. I like this… Because if it gave me harder ones right after a miss, I'd probably stop and say, "Forget it."* [P3, age group 60-69 y, Mixed ethnicity]

Desire for Self-Improvement Drives Use

Beyond enjoyment, many participants were motivated by a desire to improve their cognitive skills or overall performance, believing that achieving meaningful personal benefits would drive long-term app use.

One participant described the games as a helpful mental exercise:

> *I like games. It's good for me to do it because that's not my strong subject anyway. I regard it as just a good exercise…as an activity which is helpful because it really focuses me on my concentration. So I continued.* [P7, age group 70-79 y, White]

Participants also suggested adding progress visualization features, such as performance trends, believing this would help reinforce personal goals of improving memory and strengthen motivation.

> *Is there anywhere that accumulates those scores to give you, say, a weekly, to show you a weekly, ups and downs or to see whether you've got better during the week or the month? To give you more incentive to keep trying to beat your (game) score.* [P8, age group 70-79 y, White]

Similar progress tracking suggestions extended to other features such as the blood pressure check-in (Multimedia Appendix 5).

In-App Virtual Rewards Reinforce Use

Many participants found the in-game virtual rewards—flowers for completed activities—provided a sense of achievement and encouraged continued participation. One participant described the flower reward as a meaningful achievement:

> *This is a clever idea Yeah. It's accomplishment to me.* [P7, age group 70-79 y, White]

However, when rewards failed to appear due to a bug during testing, motivation declined, leading to frustration and disappointment:

> *Sometimes if I played the game twice in a session, it didn't seem to add, even though it says play for one star, and it didn't, the second time you played it, didn't seem to add the reward to your watering can.…*

XSL•FO
RenderX

> *…This is disappointing. What's the point then?* [P2, age group 60-69 y, White]

Theme 3: Physical Capability Barriers—When Design Overlooks Mobility and Sensory Needs

Some participants with physical or sensory limitations found that certain app features in ENHANCE did not sufficiently support their physical capabilities, creating barriers to engagement. For example, a swipe-based game (*Night Sorter*) was difficult for a participant with reduced movement due to an arm injury. The speed required to play the game interfered with their ability to participate:

> *I've got a problem in my arm because I've had an accident so I can't do fast for this (Night sorter) The swipe thing is kind of like difficult.* [P9, age group 70-79 y, Asian]

Concerns were also raised regarding low-contrast visuals and time constraints (Multimedia Appendix 5).

Theme 4: Discomfort in Gameplay Undermined Motivation

Some participants raised concerns about potential effects from certain games, particularly related to visual discomfort. These experiences undermined motivation and, in some cases, led to disengagement from the games. Some participants reported visual discomfort from specific game elements. For example, *Stump Shuffle*—which involves rapidly moving visuals—was visually demanding:

> *When you had a lot of stumps, and they were moving around… Not just one stump was moving, several of them were moving. I find that…visually quite difficult with flashing numbers, flashing letters, that thing… especially for Epilepsy. That might set you off a bit …* [P2, age group 60-69 y, White]

Similar concerns were raised about Hive Finder due to small, cluttered screen icons (Multimedia Appendix 5).

Theme 5: Enabling Opportunity on App Use—The Role of Coaching and Hands-On Learning

Participants consistently described initial face-to-face coaching as essential, providing real-time support and reassurance.

> *I think it [the introductory session] is very necessary…We can stick to exactly what the coach has shown us. … to have that face-to-face setting up and everything, really.* [P2, age group 60-69 y, White]

Hands-on use during coaching sessions enhanced opportunity to learn by reinforcing understanding. Several participants suggested encouraging users to perform tasks themselves during coaching sessions.

> *[What can be improved in the session?] Yeah, if the coach showed them how to do it once and then had them do it themselves once.* [P3, age group 60-69 y, Mixed ethnicity]

Participants also appreciated ongoing support through phone calls and in-app messaging after the initial session. This helped maintain engagement by providing a sense of personal care and reassurance.

> *I like it [follow-up calls] because you still feel like, oh, somebody really cares.* [P10, age group 60-69 y, White]

Theme 6: Boosting Motivation for Behavior Change: Trusted Experts and Personal Stories

Most participants appreciated the ENHANCE app's educational videos, which combined expert-delivered information with relatable personal stories. This blend of trusted information and real-life experiences encouraged reflection on health behaviors and motivating change.

> *Dr. Sherman [Dr. featured inside the video] is going to be telling the truth because he was going to be real life doctor. It's not like YouTube people… It's going to be true. I was ready and willing to listen carefully and attend.* [P4, age group 60-69 y, Asian]

Practical, actionable advice from professionals also motivated participants to apply recommendations in their daily lives. One participant using the diabetes module appreciated the clear dietary guidance:

> *The video shows me what to do. That's very important…certain foods make the blood sugar go quickly up. If we eat potatoes, they'll make it go up. Glycemic, they call it… That would be really useful and give good tips how to improve it.* [P9, age group 70-79 y, Asian]

Personal stories created emotional resonance that deepened engagement and relevance. One participant expressed a clear preference for human stories over diagrams:

> *I like that it has someone's personal story because it makes it more relatable. personally, I like to see something. I relate more to seeing that human rather than diagrams.* [P1, age group 60-69 y, White]

Furthermore, a participant living with long-term depression found comfort in the simplicity of a story from the "Better Mood" module (Multimedia Appendix 5)

Table 4 summarizes the themes mapped to the COM-B model and their associated design implications, discussed further in the Discussion section.

XSL•FO
RenderX

Table . Design Implications.

COM-B[a] domain and relevant themes	Design implications
Capability	
Theme 1. Developing capability through trial-and-error learning	• Design interfaces that allow users to try, make mistakes, and learn without penalties • Use familiar interface elements and game formats (eg, WhatsApp-style chat, card matching, Sudoku, word games) to support intuitive learning.
Theme 3. When design overlooks mobility and sensory needs	• Use large fonts and high color contrast • Avoid game features that require fine motor skills or fast reactions.
Opportunity	
Theme 5. The role of coaching and hands-on learning	• In-person human coaching is essential to support effective app use. • Introductory sessions should prioritize experiential learning over didactic instruction. • Telephone follow-up coaching is generally preferred over in-app chat, though chat should remain available as an option • Ensure access to a device and reliable internet connectivity. • Family involvement can be beneficial and should remain an optional form of support.
Motivation	
Theme 2. Enjoyment, personal goals, and in-app rewards increase motivation	• Incorporate fun games to boost overall app engagement. • Design games with light problem-solving and adaptive difficulty • Keep games short and update game content regularly • Use consistent virtual rewards linked to personal goals (eg, better brain health) • Use simple, easy-to-understand visual progress tracking linked to users' personal goals.
Theme 4. Visual discomfort in gameplay undermines motivation	• Avoid flashing visuals, rapid motion, or dense layouts. • Offer visually calm alternatives or adjustable display settings. • Test games with users who have sensory sensitivities.
Theme 6. Trusted experts and personal stories increase motivation for behavior change	• Combine trusted expert input with relatable peer narratives • Use clear, actionable health advice • Present information in simple multimedia formats to support reflection and behavior change.

[a]COM-B: capability, opportunity, motivation – behavior.

Discussion

Principal Findings

Our 1-week usability testing suggests that the ENHANCE intervention prototype is acceptable and usable for older adults. All participants met minimum-use targets, with many engaging further, making extensive use of core features (games, videos, and questionnaires). Most also used the in-app messaging feature. All reported high satisfaction with the app and coaching sessions on the postuse survey.

Qualitative interviews identified several facilitators of engagement, such as (1) face-to-face coaching support, (2) appropriately challenging and adaptive games, (3) in-app virtual rewards, (4) visual progress tracking, (5) familiar interface elements, and (6) health information combining expert advice with personal stories. Barriers included unclear interfaces or instructions, design that did not adequately account for users' physical limitations, and visual discomfort linked to specific aspects of game design.

Comparison With Previous Work

Overall, our positive usability and acceptability findings are consistent with the Prevention of Dementia Using Mobile Phone Applications (PRODEMOS) study—the only other UK-based, app-based dementia prevention program targeting underserved populations. The PRODEMOS reported that among its UK participants (n=600), 69% found the app acceptable, 71% considered it feasible, and 77% viewed it as appropriate at 3-month follow-up [36].

While both our study and PRODEMOS included features such as SMART goal setting, educational content, cognitive games, and health tracking, ENHANCE offered more intensive human interaction—including face-to-face onboarding, weekly telephone follow-ups, and in-app messaging with a coach. In contrast, PRODEMOS delivered initial sessions remotely due to COVID-19 restrictions, with follow-up support limited to

XSL•FO
RenderX

asynchronous in-app chat. Participants in PRODEMOS reported difficulties staying engaged, partly attributing this to delays in coach responses [36,37]—a challenge similarly noted in Healthy Ageing Through Internet Counselling in the Elderly (HATICE) internet-based dementia prevention trial [38,39]. .

Our qualitative findings highlighted the value of in-person coaching. Participants described face-to-face onboarding as "necessary" for real-time support and reassurance—echoing findings from the HATICE study [38]. For ongoing support, telephone check-ins were more acceptable than in-app chat: all participants completed phone calls, while only 7 out of 10 used the chat feature. Nonusers tended to be older, less educated, and less familiar with tablets, and were unaware of the chat function despite onboarding demonstrations. This aligns with evidence that human-led approaches—in-person or voice-based coaching—are preferred by older adults and may foster deeper engagement than text-based or AI-driven approaches, such as chatbots [40,41]. In-app chat also posed greater challenges for those with lower digital literacy consistent with evidence that text-based interfaces can present direct barriers when reading or digital skills are limited [42].

While PRODEMOS assessed usability at 3 months, ENHANCE was evaluated after just 1 week, leaving its long-term engagement and feasibility untested. PRODEMOS reported a decline in task completion from 91% in the first 2 weeks to 41% by month 3 [36], reflecting a common pattern of reduced app engagement over time due to loss of novelty and motivation [43,44].

Interpreting Findings Through the COM-B Framework

Using the COM-B framework [32], our qualitative findings can reflect how capability, opportunity, and motivation shaped participants' engagement with the ENHANCE app.

Building Users' Capability Through Effective App Learning

Our findings indicate that trial-and-error learning fostered app engagement by helping users build confidence and skills in using the app (capability). A key facilitator was the use of familiar interface elements—design features similar to those older users already know—which aligns with evidence that recognizable visuals, layouts, and game mechanics reduce cognitive load and enhance usability, particularly for those with limited digital experience [45-48]. In the UK context, games like Scrabble and matching-pair card games are widely recognized by older adults, and several of our games adopted similar mechanics, appearing to lower the cognitive barrier to entry and support a smoother learning curve.

Additionally, we found some app features exceeded users' physical capabilities, reinforcing the need to design in alignment with older adults' motor and visual abilities. Games requiring fine motor skills or fast reactions should be avoided, and interfaces should prioritize large fonts, clear instructions, and limited simultaneous visual cues—consistent with existing recommendations for age-inclusive design that accommodate age-related changes in motor and cognitive function [45-48].

Creating Opportunity Through Coaching

Our study highlights human coaching as a critical factor supporting app engagement, aligning with evidence on blended approaches that combine digital tools with human support, particularly for socioeconomically disadvantaged populations [49]. Personalized coaching can help overcome low digital literacy and complex life challenges (eg, financial barriers to healthy food and poor living conditions) by discussing practical workarounds during sessions [50]. Participants also consistently preferred hands-on, experiential learning during coaching sessions over passive instruction. This supports findings showing that trial-and-error—or "generate-and-correct"—learning enhances recall more effectively than passive study-only approaches [51]. These insights highlight the value of coaching models that emphasize user-led exploration and problem-solving.

Other Opportunities-Related Factors

Our findings partially align with previous research identifying device access, time availability, and family involvement as key opportunity-related factors in app engagement [21,52]. In our study, device and internet barriers were mitigated by providing tablets and connectivity. Time availability, however, did not emerge as a major constraint—possibly reflecting participants' intrinsic motivation or the role of financial incentives in this study.

Although family involvement is often cited as a facilitator [21,34,52], it was notably absent in our findings: despite being asked during onboarding whether they wanted family support, no participant involved family during the testing period, commonly due to living alone or lacking tech-savvy relatives nearby. For older adults from lower socioeconomic or ethnic minority backgrounds, where geographic distance and limited digital literacy within families are common, family support may not be a practical resource [49]. External coaching may therefore serve as a more feasible alternative, with family involvement supplementary where available.

Strengthening Motivation Through App Design

Several app features enhanced both automatic (eg, positive emotional responses) and reflective motivation. These included the games, the combination of professional advice and peer narrative in health information delivery, the desire to improve cognition, and visual feedback and in-app virtual rewards.

The Use of Games

Games were found to be a major source of engagement. Participants enjoyed the cognitive challenge, especially when difficulty was appropriately balanced and adapted to their performance—experiences resembling flow, a state of focused immersion to enhance intrinsic motivation and long-term engagement [53,54]. A meta-analysis found that gamified cognitive training yields greater motivation and engagement than less gamified alternatives [55].

Several design choices likely contributed—games focused on light problem-solving tasks with adaptive difficulty; provided only positive feedback with no penalties, were brief (under 8 min per session); and introduced new games weekly—all

XSL•FO
RenderX

consistent with recommendations for apps or games targeting older adults [46,47]. Competitive elements, such as leaderboards or public performance displays, were deliberately excluded, in line with evidence that these can deter older users [46].

The Use of Expert Guidance and Peer Stories to Deliver Health Information

Our findings suggest that health information was best received when combining expert guidance with peer stories. While older adults tend to trust health care professionals over social media or family and friends [56,57], they also find peer narratives relatable and motivating. Other studies support the value of narrative health communication: personal stories are more emotionally engaging than fact-based messages and are particularly effective at influencing behavioral intentions [58,59]

The Use of Visual Progress Tracking and In-App Virtual Rewards

Participants suggested that visual progress tracking (charts showing improvement in games or behaviors) and in-app virtual rewards (flowers) may support user engagement and health behavior change. Evidence from physical activity apps reinforces this: visual feedback and virtual rewards were the most effective features for predicting actual activity, outperforming elements like leaderboards [60], and rewarding users with virtual currency earned through steps significantly increased activity over 6 months, particularly among sedentary and high-BMI individuals [61]. However, overly complex visualizations of progress tracking can be unclear to older users [62], and extrinsic rewards may undermine long-term motivation once an internally rewarding engagement loop is established [63]. Feedback and rewards should therefore be simple, easy to understand, and aligned with users' personal goals to support long-term motivation.

Strengths and Limitations

This study has several strengths. Recruitment via community settings serving underrepresented groups yielded a sample spanning ethnic minority backgrounds and a wide range of neighborhood deprivation, addressing a key gap in usability evidence for inclusive digital prevention [11]. We used multiple data sources—questionnaires, interviews, and system logs—consistent with the Medical Research Council's guidelines on mixed methods [64] and evidence that combined approaches provide a more comprehensive usability picture than single methods alone [65]. The 1-week testing period captured how user experience evolved across repeated use rather than relying on a single interaction [66], and participants used the app in their natural settings, supporting ecological validity.

Limitations include the 1-week timeframe, which leaves longer-term usability untested, and the small, London-based sample, which limits generalizability to rural areas and other countries. Social desirability bias may have affected interviews, although backend usage data showing use beyond minimum requirements suggests genuine engagement. Despite targeting underserved settings, the sample had relatively high educational attainment; usability barriers may be greater among those with lower literacy. High engagement occurred under supported conditions—device provision, face-to-face onboarding, coach support, and study compensation—which may not reflect real-world implementation. Finally, eligibility relied on not having self-reported dementia without formal clinical assessment. Future studies should incorporate more rigorous eligibility measures.

Conclusion

This study explored how community-recruited older adults, including those underrepresented in dementia prevention trials, engaged with the ENHANCE app over 1 week. The intervention was well-received, with high engagement, positive feedback, and strong usability and acceptability across participants. Key facilitators included face-to-face coaching, familiar interface design, appropriately challenging games, visual progress tracking, and health content that combined expert advice with peer stories. These findings offer practical design insights for developing inclusive digital dementia prevention tools that better accommodate diverse older adults, while future research is needed to evaluate maintained long-term engagement.

Acknowledgments

We thank our research participants and patient and public involvement members for their time, involvement, and valuable feedback.

Funding

This study/project is funded by the NIHR Programme Grant for Applied Research (NIHR203670). The views expressed are those of the authors and not necessarily those of the NIHR. The funder had no role in the study design, data collection, analysis, interpretation of the data, or writing of the manuscript.

Data Availability

The data generated and analyzed during this study are primarily qualitative and include detailed participant accounts. Owing to the risk of re-identification, these data cannot be meaningfully anonymized and are therefore not publicly available. Access to selected, redacted extracts may be considered by the corresponding author on reasonable request, subject to ethical approval and data governance constraints

Authors' Contributions

Conceptualization and methodology: SGC, GL, A Singh, A Sommerlad, HKP, and TKCY formulated the research goals and aims. GL, SGC, and TKCY led the design of the study methodology and selection of testing approaches.
Data collection: TKCY, KF, RB, JJ, CL, and VM
Funding acquisition and supervision: GL and SGC acquired funding. GL, SGC, A Singh, A Sommerlad, and HKP provided oversight and leadership throughout the research activities.
Project administration: JJ
Resources, investigation, and formal analysis: TKCY prepared study materials and performed formal analysis.
Writing: TKCY prepared the initial draft. GL, SGC, A Singh, A Sommerlad, and HKP provided supervisory feedback.
All authors critically reviewed, revised, and approved the final manuscript.

Abstract

Background: Older adults frequently experience cognitive, physical, sensory, motivational, and environmental barriers that affect medication management. Medication adherence technologies (MATs) can support adherence, but their usability varies widely depending on individual abilities and device features. Prior research has largely focused on overall adherence or user experience, providing limited insight into feature-level usability challenges.

Objective: The aim of the study is to develop and internally validate a personalized predictive model to predict the success of MAT subtasks for older adults with diverse cognitive, physical, sensory, motivational, and environmental capabilities.

Methods: A mixed methods approach was used, incorporating the assessment of impairments using various standardized questionnaires, measurement of usability metrics through cognitive walkthroughs, and one-on-one semistructured interviews. For this study, we used "subtasks" as the representative of features of the devices. A subtask is a discrete, individual action that forms part of a larger task, specifically designed to achieve a step in the overall process. Participants tested between 1 and 7 devices from a selection of 13 devices. The proportion of subtask success was taken as the outcome measure. Predictors included demographic, clinical, cognitive, physical, sensory, motivational, and environmental characteristics. Personalized predictive modeling using cosine similarity and generalized linear models were compared with nonpersonalized and naive models. Model performance was evaluated using mean square error (MSE) through cross-validation and held-out validation.

Results: A total of 117 participants (mean age 74.6, SD 7.9 years) were recruited, including 96 participants for usability testing and 21 for the validation, all varying in cognitive, physical, sensory, motivational, and environmental abilities. Both personalized (m=0.25) and nonpersonalized models (m=1.0) outperformed naive predictions (m=1.21), demonstrating that subtask-level success can be predicted using routinely measurable demographic and functional characteristics. During cross-validation, personalized models achieved optimal performance at a matching proportion of m=0.25, with MSEs lower than those observed at higher matching levels, although differences compared with nonpersonalized models were not statistically significant (Self-Medication Assessment Tool [SMAT]: P=.50; Daily Living Tasks Dependent on Vision [DLTV]: P=.43). In the held-out validation cohort, personalized models achieved MSEs of 0.89 (SMAT-based) and 1.16 (DLTV-based) at m=0.20, whereas nonpersonalized models demonstrated better performance with MSEs of 0.726 (SMAT-based) and 0.815 (DLTV-based). Models incorporating performance-based vision measures (SMAT-based) consistently outperformed those using self-reported vision scores (DLTV-based) across both personalized and nonpersonalized settings.

Conclusions: This study demonstrates the feasibility of predicting subtask success of MATs in older adults. While personalization showed limited added benefit in this dataset, the subtask-focused model provides clinically meaningful insights to support

medication adherence; technology; older adults; personalized predictive modeling; usability

Introduction

As the global population ages, the proportion of older adults with chronic health conditions is increasing significantly [1]. According to projections by Statistics Canada, approximately 25% of Canadian people will be older than 65 years of age by 2036, highlighting the importance of creating support systems that allow these individuals to live independently and maintain their quality of life [2]. Chronic health conditions, including heart disease, diabetes, arthritis, and other ailments, are more prevalent in this age group, presenting various challenges that impair their ability to manage daily tasks, including the crucial task of medication management [1]. Complex medication regimens and polypharmacy, a common practice due to multimorbid conditions, introduce additional challenges that often lead to various medication-related problems, such as medication errors, potentially inappropriate medications, adverse drug reactions, and nonadherence, subsequently preventing the achievement of therapeutic outcomes [3-5].

Medication management capacity (MMC) is defined as the "cognitive and functional ability to comply with a medication regimen, when it is the individual's wish or desire to follow a medication regimen as prescribed," and is recognized as an important aspect of adherence [6]. In terms of MMC, deviations from adherence result from a lack of ability and are unintentional [6]. Various challenges associated with aging and chronic conditions can affect medication management, including cognitive, physical, sensory, motivational, and environmental barriers [6-9]. Cognitive decline, often exacerbated by chronic illnesses or age-related conditions such as dementia, presents challenges with memory, spatial orientation, and processing speed, which make it difficult for older adults to follow medication schedules accurately, increasing the possibility of errors and adverse events [9-12]. Physical impairments, such as reduced grip strength, fine motor skills, and hand dexterity, further compromise the self-management of medications. For instance, individuals with rheumatoid arthritis often struggle to open medication packaging due to reduced hand function, which can lead to missed doses and unintentional nonadherence [13,14]. Sensory impairments, including decreased visual acuity and hearing, also hinder medication adherence, as patients may be unable to read labels or hear auditory reminders [9,15-17]. Motivational factors, such as confidence in managing medications and understanding the benefits of adherence, play an important role as well [18-20]. Additionally, environmental factors like inadequate lighting at home, cluttered spaces, and a lack of support from caregivers or family can further complicate effective medication management [21-23].

Addressing these barriers is essential, as medication nonadherence can lead to increased health care costs, hospitalizations, and even preventable deaths [7,8,24,25]. Various studies have explored potential solutions through the development and implementation of assistive technologies to support older adults in managing their medications independently [26-29]. Medication adherence technologies (MATs), such as electronic pill dispensers, ingestible sensors, blister pack systems, and smart medication bottles, have emerged as aids, especially for older adults facing cognitive or physical impairments [26-29]. Research indicates that these technologies could improve adherence by providing alerts, reminders, and dosage tracking to simplify the medication-taking process [30,31]. A mobile health–based medication adherence measurement system using electronic blisters in 53 older adults with increased cardiovascular risk significantly improved adherence to diabetes medication (P=.04) during the monitoring phase. Similarly, another 6-month trial in primary care patients with moderate to severe asthma found that inhaler reminders and feedback significantly improved adherence (73% vs 46%; P<.001). However, how easy MATs are to use and how they appear to the user vary depending on individual user characteristics, impairments, and specific device features [32-36]. For example, individuals who are visually impaired may struggle with devices that rely solely on visual cues, and older adult users may have difficulty opening devices that require a lock and key or are too tight to open due to limited hand dexterity, highlighting the importance of selecting technologies with accessible features that match individual abilities.

Usability focuses on the ease, effectiveness, and efficiency with which users can complete tasks, while user experience (UX) encompasses the overall emotional and psychological interaction with a device, including satisfaction and engagement [37-39]. Both are critical for creating successful technologies, especially for older adults, whose cognitive, sensory, and motor impairments require designs that improve accessibility and independence [37-39]. Previous research on MATs has generally assessed UX without focusing on specific device features or the diverse challenges faced by users with different impairments [35]. Given that each older adult may have unique impairments and that MAT features vary widely, it is crucial to evaluate which specific features facilitate or hinder usability. Personalized predictive modeling (PPM) offers a promising approach by accounting for individual heterogeneity and enabling the prediction of feature-level success based on a user's unique functional profile, thereby supporting more targeted and patient-centered MAT selection [40-42].

Therefore, the objective of this study is to develop and internally validate a personalized predictive model to predict the success of MAT subtasks for older adults with diverse cognitive, physical, sensory, motivational, and environmental capabilities.

XSL•FO
RenderX

For this study, we used "subtasks" as the representative of features of the devices. A subtask is a discrete, individual action that forms part of a larger task, specifically designed to achieve a step in the overall process. It involves precise activities, such as inserting a battery or setting a date, which are essential for the successful operation of a device. By developing a personalized predictive model to predict subtask-level success, this study seeks to guide the selection of more user-friendly MATs that meet the diverse needs of older adults. Ultimately, this tailored approach aims to reduce medication nonadherence, minimize health risks, and support the independence of older adults by ensuring that the technologies they use are accessible and aligned with their unique capabilities.

Methods

This paper adheres to the TRIPOD (Transparent Reporting of a Multivariable Prediction Model for Individual Prognosis or Diagnosis) guidelines for the development of a multivariable prediction model [43]. The TRIPOD checklist was used to ensure complete and transparent reporting of all relevant items (Checklist 1).

Study Design

This study used a prospective mixed methods research design conducted in 2 parts: usability testing and a validation part. Both phases followed the same overall study procedures. This paper focuses specifically on the development and validation of the personalized prediction model. Other outcome variables collected in the study, including additional performance and perception-based measures and qualitative findings from one-on-one interviews, are reported in separate papers.

Eligibility Criteria

Participants were eligible to participate in the study if they were 60 years or older of age and were willing and able to provide informed consent. Participants were excluded from the study if they were unable to speak or read English, were younger than 60 years of age, or were unwilling or unable to provide informed consent. For participants who were unable to provide consent, ones with cognitive impairment, consent was obtained from their caregivers.

Sample and Recruitment

Participants were recruited using purposive and snowball sampling methods to ensure a diverse and representative sample. Initially, we recruited participants and measured their age-related abilities. However, after reaching 50 participants, we encountered challenges in recruiting an adequate number of individuals with diverse impairments. To address this, we modified our recruitment strategy by incorporating screening questions to identify specific symptoms, such as memory problems, hand tremors, limited hand movements, low hand grip strength, low vision, difficulty differentiating colors, blurred vision, low hearing, hand paralysis, and lack of sensation in the hands. Additionally, we included questions assessing medication adherence, such as how often participants skipped their medication due to a lack of motivation or a busy schedule. These modifications allowed us to target participants with specific impairments.

Sample Size

The sample size calculation for the usability study was guided by Green's formula for regression analysis ($n \geq 50+8m$), where m represents the number of independent variables (physical, cognitive, vision, hearing, motivational, and environmental impairments) [44]. Based on this criterion, a minimum sample size of 98 participants was required. Recruitment efforts aimed to ensure that at least 5 participants with each type of impairment tested each of the 13 selected devices, providing a comprehensive and balanced representation across diverse user needs. Recruitment and data collection took place from June 2023 to June 2024.

For internal validation, an increase in sample size by 30% was estimated to be adequate, corresponding to a target of 29 participants. Recruitment and data collection for the validation study took place from May 2025 to August 2025 [45,46].

Study Procedure

An overview of the study procedures followed for the usability and validation phases is provided below. The study procedures remained exactly the same for both phases, with the exception that one-on-one interviews were not conducted during the validation phase.

Step 1: Measurement of Barriers to MMC

The first step involved assessing various barriers to medication self-management, including physical, cognitive, vision, hearing, motivational, and environmental factors. The following tools were used to determine these abilities:

- Self-Medication Assessment Tool (SMAT): Evaluated physical, cognitive, and vision barriers [47,48].
- Daily Living Tasks Dependent on Vision (DLTV) questionnaire: Focused on vision-specific barriers [49,50].
- Whisper test: Measured hearing impairment, categorizing it as 100% impairment if both ears failed, 50% if 1 ear failed, and no impairment if both ears passed [51,52].
- Self-Efficacy for Appropriate Medication Use Scale (SEAMS): Assessed motivational barriers related to confidence in adhering to medication regimens [20,53-55].
- Martin and Park Environmental Demands (MPED) questionnaire: Evaluated environmental challenges that could impact medication management [21].

Step 2: Usability Testing

Overview

After assessing barriers, participants were assigned MATs and performed tasks using these devices following the cognitive walkthrough approach. Two evaluators observed participants' interactions with the devices, systematically documenting task and subtask outcomes, including success, failure, errors, and time taken. The evaluators then reached a consensus regarding the participants' performance on each subtask to ensure consistency and reliability of the observations. More details on the cognitive walkthrough, the devices tested, and the mock medication regimen used in this study are provided below.

XSL•FO
RenderX

Cognitive Walkthrough

The cognitive walkthrough method evaluates how new users interact with a device by simulating their initial experience of exploring its functionality [37-39]. This task-based approach focuses on assessing ease of use and learnability, with the goal of identifying usability challenges that may impede task completion [37-39]. Participants were given a set of predefined tasks outlined in a participant information sheet, designed to evaluate various features and functions of the devices. Tasks ranged from simple actions, such as inserting batteries and unlocking devices, to more complex activities, such as setting alarms, filling medication trays, and retrieving medication after an alert. Each task consisted of smaller, discrete actions called subtasks. For example, in the case of inserting batteries, the subtasks included opening the battery compartment, correctly positioning the batteries, closing the compartment, and ensuring the device was powered on. Across the 13 devices evaluated, 32 subtasks were identified and generalized to ensure broad applicability across devices. The list of subtasks tested in this study is given in Table 1.

Table . Subtasks for using various devices.

Code	Subtask
A1	Locate the battery or cartridge compartment or medication cavity
A2	Put or insert the battery correctly
A3	Lift or close the battery compartment door
A4	Slide in or out the battery compartment door
A5	Slide a tab or button
A6	Check or ensure or verify the device is on or the lock is placed in position or follow instructions or ensure the indicator light flashes for 3 seconds
B1	Flip device
B2	Insert key and rotate
B3	Press and rotate the lid
B4	Open the lid by lifting
C1	Press and hold a button on a device
C2	Press a button on a device
D1	Open the pill box or compartment by rotating the lid
D2	Open the pill box or compartment or tray or door by sliding
D3	Pick up the correct pillbox or pill organizer or open correct compartment
D4	Insert or fill or place medication in the compartment or pillbox or pill organizer
D5	Close lid
D6	Put stickers on pillbox dividers
G1	Remove the medication
G2	Grab or hold the device
G3	Place hand over the open slot
H1	Rotate the carousel 3 days from today’s date
I1	Locate and touch on an icon or button on an app or screen
I2	Enter or type any data in an app or screen
I3	Scroll the screen options
M1	Align and insert the cartridge into the designated slot
P1	Tear the package
R1	Rotate retaining clips at each end of the device in an open or close position
R2	Align connectors to one another and gently push the card into the device
T1	Pierce cavity barrier
T2	Pinch number printed on the card and pull out
U1	Pull the blister packs away from the device

XSL•FO
RenderX

For each device tested, both a participant information sheet and an evaluation sheet were prepared. The information sheet provided instructions for the tasks participants needed to complete, while the evaluation sheet detailed each task and its associated subtasks. The evaluation sheet also recorded key metrics such as time taken for each task, whether each subtask was completed successfully without assistance, with assistance, or failed, and the presence or absence of errors during each subtask.

Device Tested

In this study, 3 smart and 10 electronic MATs were tested for usability and UX. Electronic MATs often include features like multiple compartments and alarms to remind patients to take their medications. In contrast, smart MATs incorporate advanced connectivity features, such as Bluetooth and Wi-Fi, enabling real-time tracking, remote monitoring, and instant feedback between patients, caregivers, and health care providers. These devices frequently include additional capabilities such as audio-visual reminders, adherence data logging, and report generation. The devices to be tested were selected to represent a wide diversity of features, based on a feature-based classification system developed for MATs [56]. Specifically, the selection aimed to include devices with variation across key dimensions of the classification system, including physical features, display, connectivity, system alert, data collection and management, operations, and integration. Devices were purposively chosen to capture differences in compartment design, dispensing and access mechanisms, alert modalities, portability, and levels of automation and connectivity. All selected devices were commercially available and commonly used for medication management. This approach ensured that the sample of MATs reflected a broad range of characteristics and functionalities relevant to older adults and supported a comprehensive testing of usability across diverse MATs. A list of the tested devices is provided in Multimedia Appendix 1. Each participant tested between 1 and 7 devices, with some participants requiring 2 visits to complete their testing. Initially, devices were assigned by the researchers without following specific methods or procedures. However, after testing 50 participants, the assignment strategy was revised to ensure at least 5 participants with each type of impairment tested each device, aiming for balanced representation across 6 types of impairments and devices. No formal training was provided to participants, who relied solely on the instructional materials included with the devices, simulating real-world conditions where users independently learn to use such devices.

Mock Medication Regimen

A simulated medication regimen was designed for this study to replicate the complexity of real-life medication schedules often managed by older adults. Developed in-house, this mock regimen aimed to assess the usability of technologies by mimicking the organization of medications in everyday of MATs while ensuring safety by substituting actual medications with placebo tablets, placebo capsules, and candy.

The mock regimen included placebo equivalents for common medications used to manage chronic conditions, structured as follows:

- Warfarin: 2 mg once daily on Monday, Wednesday, and Friday, and 3 mg once daily on Tuesday, Thursday, Saturday, and Sunday.
- Pantoprazole: 20 mg taken twice daily.
- Phenytoin: 100 mg, with 1 capsule in the morning and 2 capsules in the evening.
- Propranolol: 20 mg, with half a tablet once daily for the first 2 days, followed by 1 full tablet daily.

Step 3: Qualitative One-on-One Interview

Following usability testing, participants engaged in one-on-one interviews to provide feedback on the devices they tested. These interviews explored their experiences, challenges, and perceptions of each device's usability and features, offering qualitative insights to complement the quantitative data.

Outcome Measure—Proportion of Subtask Success

The proportion of subtask success is a measure that shows how often participants successfully completed a specific subtask when using a device. This was calculated using the equation:

(Proportion of subtasks successfully completed by participants using a device / Total number of subtasks attempted by participants using the device)

Data Collection and Statistical Analysis

Data Management and Storage

All collected data from this study were securely managed and organized using the REDCap (Research Electronic Data Capture) platform (version 15.1.2; Vanderbilt University). This included participant demographics, outputs from the tools used to measure barriers to MMC, and the detailed data recorded in the evaluation sheets for each device tested. R Studio (version 4.4.1; Posit Software, PBC) was used to conduct data analysis.

Data Analysis Using PPM

The data analysis methodology used PPM to predict the success rates of subtasks for participants based on their unique characteristics. Unlike traditional modeling, where we use large and heterogeneous data to train the model, with personalized prediction modeling, we identify and analyze the data that are similar to the new participant of interest, whose outcome is to be predicted. By training the model on the subset of the data containing only the participants that are similar to the participant of interest, we aim to provide a customized prediction with improved predictive performance [57]. In other words, a new model is fit for each participant to predict their proportion of success.

There are a few key details of interest when implementing the model with PPM. The first is quantifying how similar one participant is to another participant, and the second is identifying the best subpopulation proportion (denoted as m) to train the unique model for each participant—in other words, how many similar participants do we use to train a predictive model for the participant of interest.

Our approach to measuring similarity is using the cosine similarity metric (CSM). CSM is intuitive to interpret, standardizes the similarity between −1 and 1, and can handle mixed data types that contain both categorical and continuous predictors. The data for each participant, such as their demographic and impairment information, are represented as a

XSL•FO
RenderX

Euclidean vector of predictors in a multidimensional feature space, and CSM is used to measure the angle between the vectors for 2 participants. CSM quantifies the similarity between 2 participants as a cosine of an angle with values between −1 and 1, where −1 represents minimum similarity, and 1 represents maximum similarity [53]. For example, if CSM between participant A and B is −0.1, and CSM between participant A and C is 0.6, then C is more similar to A than B is to A.

With PPM, we train a model on a personalized dataset that contains only the most similar participants to the participant of interest. Then, it is crucial to determine what percentage of the most similar participants from the available data we will use to train the model (denoted as *m*). We find the optimal subproportion of the available data by tuning for this parameter using k-fold cross-validation (CV). The steps are as follows, adapted from previous literature on PPM [57]:

1. Randomly split the available data into 9 folds. The number of folds is 9 to allow the 117 participants to be distributed evenly along all the folds. One of the folds is the test data, and the rest of the data will be the training data.
2. For participant *j* in the test data, calculate CSM between participant j and every participant in the training data. Fit a generalized linear model (GLM) with a binomial logistic framework using the top *m*×100% of the most similar participants in the training data, and calculate the predicted proportion of subtask success for participant *j* using this model. Predictors in this model include demographic and clinical variables such as age, sex, number of medications, cognitive and physical scores, vision metrics (SMAT and DLTV scores), SEAMS scores, and hearing impairment.
3. Repeat step 2 for every participant in the test data. In other words, we are fitting a unique GLM with a logistic model using a tailored dataset containing only the top *m*×100% of the most similar participants from the training data for each participant in the testing data. Then, calculate the mean square error (MSE) to get the predictive performance for this fold. Predictors for each GLM included demographic and clinical variables such as age, sex, number of medications, cognitive and physical scores, vision metrics (SMAT and DLTV scores), SEAMS scores, and hearing impairment. Two models per participant were compared, one using SMAT vision scores and the other using DLTV vision scores, and success probabilities for subtasks were estimated based on model coefficients.
4. Repeat steps 2 - 3 such that each fold becomes the test data, and the rest of the available data becomes the training data. Average over the MSEs calculated to get the predictive performance of the model for a specific *m* value.
5. Repeat steps 1 - 4 for values of *m* ranging from 0.20 to 1.00, in increments of 0.05, to examine the effects of different matching percentages. Smaller subproportions (sub 0.2) were not explored because the resulting dataset would not be heterogeneous enough across all the features to fit the regression model. Note that as *m* increases, we have larger data to train the predictive model, but we also introduce more noise in the data as a trade-off. We denote *m* that gives the smallest MSE value as the optimum subpopulation proportion. When *m*=1, we are using a global (or nonpersonalized) model where we use the exact same data to fit the GLM model for each participant, because we are using all available dataset.

The above CV study can be used to tune for the optimal matching percentage *m* on the combined dataset of 117 participants. The recommended matching subproportion can be used when predicting the proportion of success at a subtask of a new test participant. However, this simulation cannot be used to estimate the generalization performance on unseen data since all of the data appear in at least 1 of the training folds. This is typically why a separate test set is held out from the training process. This is the data that the models have not trained on; hence, the model's performance on this data is a good estimate of the model's accuracy on unseen data. The dataset of 117 participants is split into the 96 participants collected up to 2024, which would be the training dataset, and the 21 participants collected in 2025, which would be the test data. This would give us an estimate of the performance of PPMs on unseen data and also provide us with benchmarks to outperform for newer models.

In both the above simulations (CV and model validation), model performance is quantified by the squared error of the model in predicting the number of successful attempts at a subtask. This evaluation metric allows us to view the problem in the lens of regression rather than as a classification task where area under the curve or F_1-scores would be used. The choice is made because it is challenging to define the threshold for success at a subtask since multiple attempts are being made at subtasks, and an additional threshold hyperparameter that varies by subtask would be necessary.

The GLMs: Logistic Regression

Personalized subsets of participants were used to train GLMs for predicting subtask success rates. Two separate models were developed for each participant: (1) SMAT-based model using SMAT vision scores and (2) DLTV-based model using DLTV summary vision scores.

For each participant, a personalized GLM was fitted to their subset of training data identified via the CSM methodology. Predictors in the logistic regression model included demographics, clinical history, cognitive, physical, sensory, hearing, motivation, and environmental factor scores. Subtask-specific indicators were incorporated as covariates. Task count weights were applied to adjust for variations in subtask performance across participants.

The GLMs were structured as follows.

SMAT-based model:

DLTV-based model:

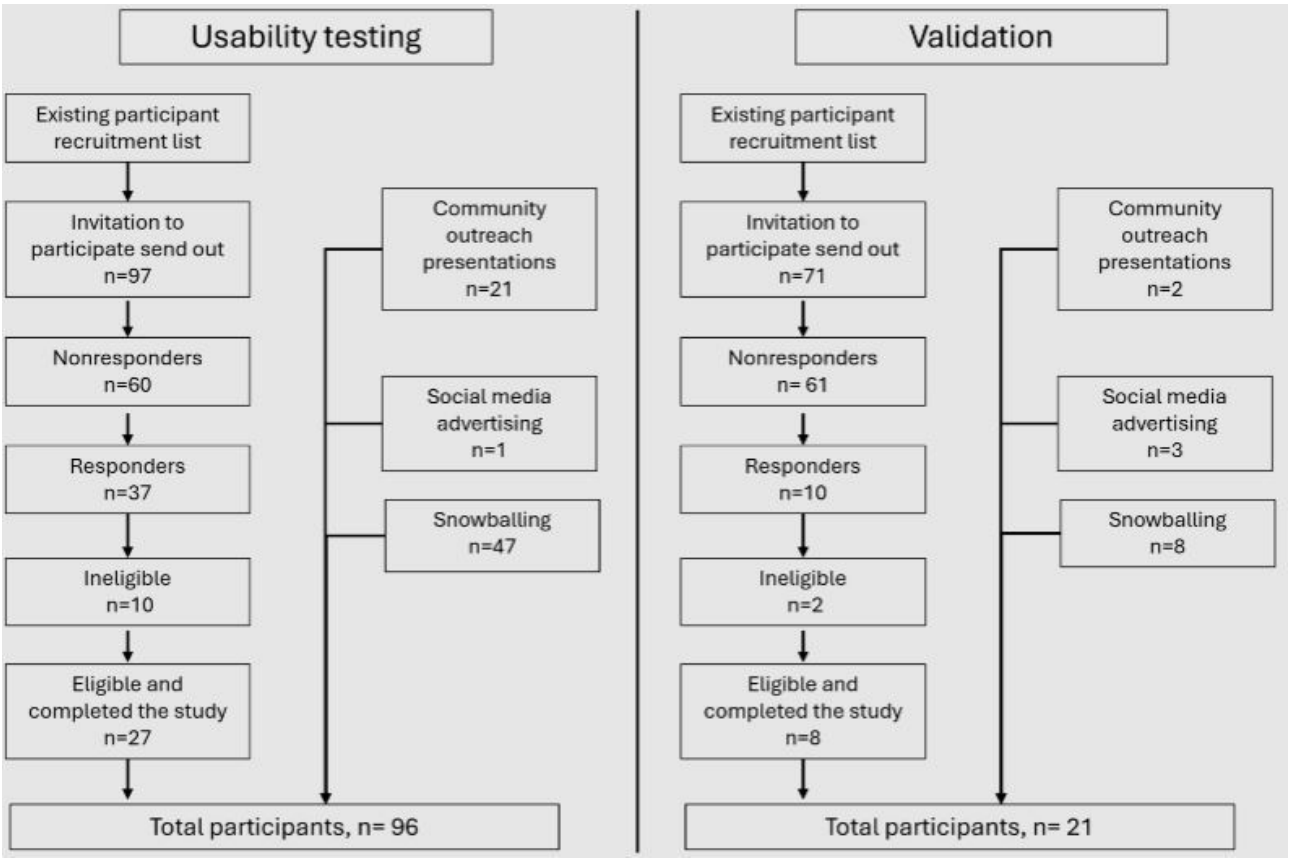
where for a participant *i*, Y_i is the proportion of success of a subtask, age_i is the age, sex_i is the sex, $mednum_i$ is the number of medications, $medhist_i$ is the number of medical history, cog_i is the cognitive score, phy_i is the physical score, $SMATvis_i$ is

XSL•FO
RenderX

the SMAT vision score, $DLTVsumvis_i$ is the DLTV summary vision score, $SEAMS_i$ is the SEAMS score, $MPEDbusy_i$ is the MPED busyness score, $MPEDroutine_i$ is the MPED routine score, $subtask_i$ is a single subtask completed, and $hear_i$ is an indicator variable for hearing impairment.

Ethical Considerations

This study was reviewed by and received approval from the University of Waterloo Office of Research Ethics (ORE##45203). All participants were informed of the study and provided consent before enrolling. Participant confidentiality was maintained by assigning unique participant ID numbers instead of names or identifiable information. All data were deidentified and securely stored. Participants received remuneration for their participation in the study. This study was conducted at multiple locations, including the University of Waterloo School of Pharmacy in Kitchener, Ontario, Canada; various Schlegel Villages across Ontario; and the KW Seniors Day Program in Kitchener, Ontario, Canada.



Results

Participant Demographics Characteristics

The study included a total of 117 participants (mean age SD 74.6, SD 7.9 years), including 96 participants for the usability testing and 21 participants for the validation, all with varying cognitive, physical, sensory, motivational, and environmental abilities.

Although we initially planned to recruit 98 participants for the usability testing and 29 participants for the validation, recruitment and inclusion challenges limited enrollment to 96 and 21 participants, respectively. One of our primary goals while recruiting was to ensure that each of the 13 devices was tested by at least 5 participants from each impairment group, which was achieved with the final usability sample and therefore considered sufficient for this component of the study. Additionally, considering that participants tested up to 7 devices, and that each device was treated as a distinct product with its own subtasks, the resulting dataset provided a sufficiently large number of observations. For validation, although the final sample size was smaller than planned, it allowed for an internal CV of the models. Further validation with larger samples is planned in future studies. Figure 1 presents a flow diagram summarizing participant recruitment and inclusion across the usability testing and validation. As the study involved a single assessment session (with a small number of participants completing 2 sessions), there were no participant attribution or dropouts during the study.

Figure 1. Participant recruitment and inclusion across the usability testing and validation.

Barrier Characteristics of Participants

Among the various barriers identified in the usability study, cognitive barriers, defined as low or moderate cognitive scores, were present in 21.87% (21/96) of participants, as determined using the SMAT. Physical barriers, defined as low or moderate to low physical scores, were observed in 38.54% (37/96) of participants. Vision barriers were also notable, with 23.95% (23/96) scoring low or moderate to low on the SMAT vision

XSL•FO
RenderX

scale, and 38.54% (37/96) reporting impairments in DLTV, as assessed using the DLTV. Hearing barriers, evaluated with the whisper test, were present in 57.29% (55/96) of participants. Additionally, motivation and environmental challenges were reported by 35.41% (34/96) of the group (Table 2).

Someone else reminds me	8 (8.33)	1 (4.76)
Others	3 (3.12)	6 (28.57)
Medication calendar	2 (2.08)	1 (4.76)
Barriers		
Cognitive barrier—Self-Medication Assessment Tool, n (%)		
High cognitive scores (90% or greater)	70 (72.92)	14 (66.67)
Relatively high cognitive score (80% or greater)	5 (5.21)	1 (4.76)
Moderate cognitive score (70% to 80%)	7 (7.29)	2 (9.52)
Low cognitive score (approximately 69% or less)	14 (14.58)	4 (19.05)
Physical barrier—Self-Medication Assessment Tool, n (%)		
High physical scores (90% or greater)	59 (61.46)	15 (71.43)
Moderate to low physical score (76% to 84%)	11 (11.46)	3 (14.28)
Low physical score (approximately 75% or less)	26 (27.08)	3 (14.28)
Vision barrier—Self-Medication Assessment Tool, n (%)		
High vision scores (90% or greater)	73 (76.04)	18 (85.71)
Moderate to low vision score (76% to 84%)	4 (4.17)	1 (4.76)
Low vision score (approximately 75% or less)	19 (19.79)	2 (9.52)
Vision barrier—Daily Living Tasks Dependent on Vision[a], n (%)		
Impairment present	37 (38.54)	10 (47.62)
Hearing barrier—whisper test, n (%)		
Impairment present (both ears)	55 (57.29)	12 (57.14)
Motivation barrier—Self-Efficacy for Appropriate Medication Use Scale[b], n (%)	34 (35.42)	3 (14.28)
Environmental barrier—Martin and Park Environmental Demands[c] questionnaire, n (%)	34 (35.42)	5 (23.81)

[a]Total score <79: vision barrier present.

[b]Total score <40 low self-efficacy: motivational barrier present.

[c]Busyness subscale score ≥15—greater busyness, routine subscale score <16—less routine: environmental barrier present.

In the additional validation sample, similar patterns were observed. Cognitive barriers were present in 28.57% (6/21) of participants, physical barriers in 28.57% (6/21), and vision barriers in 14.28% (3/21) based on SMAT scores. Impairments in vision-dependent daily living tasks were reported by 47.62% (10/21) of participants, and hearing barriers were present in 57.14% (12/21). Motivational and environmental barriers were less prevalent in the validation sample, reported by 14.28% (3/21) and 23.81% (5/21) of participants, respectively (Table 2).

Table 2 presents the demographic, clinical, and barrier-related characteristics of the study participants.

PPM Outcomes

We begin by illustrating our choice of the tuning parameters and how they impact each of the PPMs. Figure 2 indicates that m=0.25 is the optimal matching percentage in this scenario for both the SMAT-based and DLTV-based models. Note that the averaged MSE decreases from m=0.2 to m=0.25 in Figure 2. Therefore, it is not necessary to modify the matching strategy to accommodate PPMs to be trained on the dataset with lower matching percentages (less than 20%) since the optimal matching subproportion as illustrated by Figure 2 is greater than m=0.2. The fairly volatile nature of the trends in Figure 2 suggests that tuning the matching parameter is beneficial, as there is a large difference between the MSE at m=0.25 compared

XSL•FO
RenderX

to the MSE at m=0.95, where performance is even worse than not using any personalization at all (m=1.0).

Figure 2. Mean square error of the DLTV-based and SMAT-based models averaged over all k-iterations of the cross-validation study as a function of the matching percentage m. DLTV: Daily Living Tasks Dependent on Vision; SMAT: Self-Medication Assessment Tool.

Paired 2-sided Wilcoxon signed rank tests were conducted to determine if there is a statistically significant difference in the median MSE values (along the k-folds) between the personalized models at m=0.25 and their nonpersonalized counterparts (m=1.0). These tests (DLTV: P=.43; SMAT: P=.50) do not show statistical significance. Hence, even though 25% matching is optimal in Figure 2, the MSE populations may not be statistically different enough to necessitate tuning for the matching parameter.

If the datasets become large enough that matching each new participant to m×100% of the training dataset and refitting a new model becomes a computational bottleneck, skipping the personalization step should not statistically degrade model performance. However, when computation is not a constraint and PPMs can be used, the optimal matching percentage with respect to the current data is m=0.25.

Model Validation

The CV procedure as described in the previous section was carried out on the 96 participants but with 8 folds instead of 9 folds, and it was found that the optimal matching percentage was 0.2 for both the DLTV-based and SMAT-based models. On the test set, the SMAT-based model with a matching parameter of 0.20 achieves an MSE of 0.89, and the DLTV-based model with a matching parameter of 0.2 achieves an MSE of 1.16. In other words, the SMAT-based model is off by 0.94 subtasks when predicting the correct number of subtasks a participant has successfully completed, while the DLTV-based model with a matching parameter of 0.20 is off by 1.1 subtasks. Note that these results do not reflect the best possible performance of the models on the test set because the matching parameter, while optimal for the training set, is not necessarily optimal for the test set. The nonpersonalized models (m=1.0) perform much better with an MSE of 0.726 and 0.815 for the SMAT and DLTV-based models, respectively. This does raise the question of whether the optimal matching percentage m transfers over to unseen data that might have a different distribution compared to the training data.

To contextualize these results, note that the average proportion of success in the training data collected in 2024 is 0.87. Consider a naive model that always predicts a fixed proportion of success regardless of the participant's features. Due to the left-skewed nature of the success variable, the naive model predicting a success rate of 100% would do much better than a naive model that predicts a fixed success rate of 0%. To be more precise, the naive model that minimizes MSE on a dataset predicts a constant probability equal to the inner product of the success counts and the corresponding number of attempts across subtasks normalized by the squared l^2-norm of the number of attempts at a subtask. Since the test data are unseen, the naive model can instead compute this ratio on the training set and apply it on unseen data. Numerically, this is a prediction of 0.84 resulting in an MSE of 1.21. The optimal naive model is on average 1.1 subtasks off in predicting the correct number of subtasks.

Overall, the SMAT-based model with m=0.2 is on average more accurate by 0.07 subtasks in prediction, while the DLVT-based model with m=0.2 performs similarly to the naive baseline. In contrast, in the nonpersonalized setting (m=1.0), the SMAT-based model improves accuracy by 0.25 subtasks, and

XSL•FO
RenderX

the DLVT-based model by 0.2 subtasks relative to the naive model. The naive model's MSE of approximately 1.1 subtasks serves as a useful benchmark for future model development and validation studies.

It is possible that the training-testing split is suboptimal if participants recruited during the first phase of data collection (2023 - 2024) systematically differ from those recruited during the second phase (2025). To assess this, statistical tests were conducted on all participant features used in the model to evaluate differences between the 2 cohorts. After adjusting for multiple-comparison error, no statistically significant differences were observed for any feature. This finding supports the chosen training-testing split. However, given the unequal and relatively small sample sizes of the 2 cohorts (96 vs 21), these tests may have been underpowered. Consequently, a random partition of the combined dataset (n=117) may have provided a more statistically robust assessment of both the benefits of personalization and the performance of naive models.

Model Specifications

Unlike conventional prediction models that estimate a single set of regression coefficients applicable to all individuals, PPM generates individualized models tailored to each participant. Specifically, each participant's model is trained on a personalized dataset comprising observations most similar to that participant. Consequently, for the 117 participants included in this study, 117 distinct logistic regression models were estimated, each with its own set of regression coefficients and intercept. Because model parameters are individualized by design, there is no single, global set of regression coefficients, odds ratios, or CIs that can be meaningfully reported. Instead, model specification is defined procedurally rather than through fixed parameter estimates.

To generate predictions for a new individual, we first apply steps 1 - 5 of the PPM procedure (see Data Analysis Using PPM section) to the full available dataset to determine the optimal subpopulation proportion, m. This proportion defines the size of the personalized training set. We then identify the m×100% of observations most similar to the new individual according to the predefined similarity metric and fit a logistic regression model on this subset. The resulting personalized model can be used to estimate the probability of subtask success for that individual and to inform individualized recommendations.

Discussion

Principal Findings

This study was conducted to develop and internally validate a personalized predictive model to estimate subtask success of MATs among older adults with diverse cognitive, physical, sensory, motivational, and environmental abilities. Overall, the findings show that it is feasible to predict subtask success of MATs using measurable functional and demographic characteristics, and that such models can perform better than naive prediction models. These results demonstrate that individual differences meaningfully influence how older adults interact with MATs and that these differences can be quantified and modeled.

Research evaluating the usability of MATs for older adults, while considering their specific impairments, remains limited [28,35]. One study by Woo [58] examined usability through a small-scale device trial involving 2 older adult participants who tested a single device over a 2-day period. The study assessed user perceptions, adherence rates, and usability concerns through observations and interviews. In this study, the first participant was an 82-year-old female with mild cognitive impairment, arthritis, osteoporosis, and mobility challenges, requiring the use of a 4-wheeled walker. The second participant was an 84-year-old male with mild to moderate cognitive impairment, hypertension, and mobility impairments. While both achieved high adherence rates (100% and 90%, respectively), they encountered usability challenges. One participant struggled to grasp pills and had to tip the device over to retrieve medication, while the other faced difficulty closing pill compartments due to manual dexterity impairments. This underscores the importance of examining specific interaction failures related to device features and users' functional abilities.

By focusing on subtasks rather than overall device success, this study addresses an important gap in MAT usability research. As we previously noted, subtasks represent features of the device, the specific actions required to use a device, such as pressing buttons, opening compartments, aligning parts, or reading visual indicators. Evaluating success at this level provides a more detailed and clinically meaningful understanding of usability than global device ratings, which may mask specific interaction challenges. This subtask-based approach allows for a clearer link between user abilities and the demands imposed by individual device features. The decision to model success at the subtask level is supported by assistive technology and human factors literature, which emphasizes that devices should be matched to users based on their functional limitations rather than by device type or overall complexity [59,60]. For example, individuals with mild hand weakness may succeed with simple, low-technology solutions, whereas those with more severe impairments may require devices that reduce physical or cognitive effort by automating certain actions [60]. MATs vary widely in the features, functionalities, effort, and understanding they require, and identifying subtask-level success makes it possible to identify which specific features could create barriers for particular users as well as which features are more suitable. Human factors research further shows that usability failures often occur at discrete interaction points, especially as device complexity increases [61-64]. By treating subtasks as representative device features, this study supports a more user-centered approach to MAT selection that recognizes assistive technologies as essential supports that must align closely with users' abilities for successful use, acceptability, and adoption [61-65].

With respect to modeling strategy, both personalized and nonpersonalized GLMs improved prediction accuracy compared to a naive baseline that assumed uniform subtask success across users. This finding suggests that incorporating individual-level characteristics, such as cognitive function, physical ability, vision, hearing, motivation, and environmental factors, adds

XSL•FO
RenderX

meaningful explanatory value when predicting how older adults interact with specific device subtasks. These results support the broader view that usability arises from the interaction between user characteristics and device features rather than by either factor alone. Although PPM is conceptually appealing, its advantages over nonpersonalized (global or broader) models were not statistically significant in this study. Personalized models showed some improvement during CV but did not significantly outperform nonpersonalized models overall, and in the held-out validation cohort, nonpersonalized models demonstrated better performance. Similar patterns have been reported in prior work. Ng et al [66] showed that personalized predictive models can outperform global models when trained on large, dense datasets with sufficient numbers of clinically similar cases, but also emphasized that reliable personalization depends on stable similarity estimates and adequate neighborhood size. When these conditions are not met, global models that leverage the full dataset may generalize more effectively. Evidence from outside health care further supports this interpretation; for example, in sports performance research, Ahsan et al [67] reported that while personalized modeling can offer targeted insights, broader predictive models are often more robust and easier to maintain when data are limited or heterogeneous. Together, these findings suggest that the lack of statistical significance between the models in this study likely reflects constraints related to sample size and population heterogeneity rather than a lack of conceptual value of personalized modeling itself.

The validation results highlight the importance of evaluating model performance beyond internal training. The stronger performance of nonpersonalized models in the validation cohort suggests that matching parameters optimized during training may not fully transfer to unseen data, particularly when sample sizes are small. Although no statistically significant differences were observed between recruitment phases, the smaller validation cohort may have limited the ability to detect subtle differences. These findings underscore the need for external validation in larger and more diverse populations before using PPM approaches in real-world clinical settings.

An additional important finding was that models incorporating SMAT-based (performance-based) vision measures consistently outperformed those using DLTV-based (self-reported) vision scores. This suggests that task-specific functional assessments may be more informative for predicting technology interaction than broader measures of daily living performance. However, at the same time, it is also important to consider the practical advantages of using task-based measures compared with self-reported measures [68].

From a clinical perspective, this modeling framework has the potential to support more informed MAT selection by predicting which device features an older adult is most likely to use successfully or struggle with. By estimating subtask-level success, the model can help clinicians, caregivers, and users anticipate whether specific device features are well matched to an individual's cognitive, physical, sensory, and environmental abilities. This enables more informed decision-making when selecting MATs, particularly by avoiding devices with features that may be difficult or unsafe for a given user. Because medication management is a safety-critical activity, mismatches between user abilities and device demands can increase the risk of medication errors and nonadherence. Selecting technologies that align with users' capabilities may reduce trial-and-error device adoption, minimize frustration, support correct device use, and ultimately could improve medication adherence, safety, and therapeutic outcomes.

Strengths

This study has several strengths, including a diverse sample of 117 older adults with varying cognitive, physical, sensory, motivational, and environmental barriers. Given the exclusion of older adults with impairments in many studies, this inclusion improves the study's relevance and applicability. Additionally, the study tested both electronic and smart MATs, allowing for a comprehensive comparison of their effectiveness. Another key strength is that it addresses multiple barriers affecting medication self-management, beyond just physical or cognitive impairments. The study's use of validated assessment tools (eg, SMAT and whisper test) strengthens its methodological quality, ensuring reliable and meaningful findings. Finally, the subtask-based success approach provided detailed, feature-level insights into usability, supporting more clinically meaningful interpretations of device-user interactions.

Limitations

Despite its strengths, the study has some limitations. Testing environments may not fully replicate real-world conditions, potentially affecting the generalizability of findings. Additionally, while the sample is diverse, it may not fully capture all cultural and socioeconomic factors influencing MAT use. The variability in participants' technological literacy and health status could also introduce biases, impacting the study's applicability to the broader older adult population. A further limitation is related to sample size planning and model complexity. The initial sample size estimation for the usability phase was guided by Green's formula based on 6 primary impairment domains. However, the final predictive models included a larger set of predictors, including demographic, medication-related variables, multiple functional scores, environmental factors, hearing scores, and subtask indicators. While each personalized model was trained on a subset of similar participants (approximately 20% - 25% of the training sample), the ratio of observations to predictors may still be limited, increasing the risk of overfitting and reducing coefficient stability. This constraint likely contributed to the modest performance gains observed for personalized models compared with nonpersonalized models and highlighted the need for larger datasets to fully support more complex personalized modeling approaches.

Future Recommendations

Future research should address these limitations by conducting real-world studies in home and community settings and including a more representative demographic sample. Additionally, developing a standardized, comprehensive assessment tool for measuring all medication management barriers would improve consistency and applicability. Further studies could explore the longitudinal impacts of MATs on

XSL•FO
RenderX

long-term adherence, hospitalization rates, and health care costs. Research should also focus on developing clinical decision-support tools that integrate usability metrics and patient-specific barriers, helping health care providers tailor recommendations. Examining the learnability and long-term engagement of older adults with these technologies is also important, as older adults may experience technology fatigue or changes in ability that affect long-term use. Finally, external validation of the predictive models in larger, independent, and more diverse populations is essential to assess generalizability and robustness. Future work should evaluate model performance across different health care systems, cultural contexts, and device types and examine whether personalized modeling approaches yield greater benefits as datasets grow, and similarity estimates become more stable. Such efforts can be beneficial for translating predictive usability modeling into routine clinical practice.

Conclusions

This study developed and internally validated a personalized predictive model, demonstrating the feasibility of predicting subtask success of MATs among older adults using demographic, clinical, and functional characteristics. Both personalized and nonpersonalized models outperformed the naive model, highlighting the importance of individual differences in technology usability. Although personalization showed limited added benefit in this dataset, the subtask-focused approach offers clinically meaningful findings to support evidence-informed selection of medication technologies and thereby improving adherence outcomes.

Acknowledgments

The authors would like to extend special thanks to Arshia Chauhan, Nischal Ghookal, Prapti Choudhuri, Hawa Patel, Tanaya Sharma, Victoria Nguyen, Karyman Ahmed Fawzy Ghanem, and Sabiha Lakhi for their valuable support with data collection. This work was presented as a poster at the 2025 Annual Scientific Meeting of the American Geriatrics Society.

Funding

This project was funded by Aging in Place program with National Research Council and Canadian Institutes of Health Research (funding reference-184372) with the Government of Canada.

Data Availability

The datasets generated or analyzed during this study are available from the corresponding author on reasonable request.

Authors' Contributions

BB and TP contributed to all aspects of the study, including study concept and design, acquisition of subjects and/or data, analysis and interpretation of data, and preparation of the manuscript. GE contributed to data acquisition and data entry. MK, SB, and JG contributed to data analysis. SP, IH, and RS contributed to the acquisition of data. PKP, AM, SJTG, FC, LL, CB, and RG contributed to the study concept and design. All authors reviewed and approved the final version of the manuscript.

Conflicts of Interest

TP received grants from National Research Council, Canadian Institutes of Health Research, Jones Healthcare Group, and Custom Health; travel support from National Research Council and Canadian Institutes of Health Research; and contribution of medical adherence technology from Jones Healthcare Group and Custom Health. The other authors report no conflicts of interest.

Abstract

Background: With the growing aging population, technology that supports independent living is increasingly important. Web search systems are well established, whereas generative artificial intelligence (Gen-AI; eg, ChatGPT) represents a newer, adaptive tool that could offer personalized information access. However, little is known about how older adults, particularly those with mild cognitive impairment (MCI) or mild dementia, perceive and engage with these systems.

Objective: This study explored the use of and perspectives on web search and Gen-AI in older adults with and without cognitive impairment (including MCI and early-stage dementia).

Methods: A UK-wide mixed methods study was conducted with older adults, including those with MCI or mild dementia. An online survey captured technology use, Likert-scale ratings of web search and Gen-AI, and reasons for nonuse. Follow-up focus groups provided in-depth qualitative perspectives. Quantitative data were analyzed using descriptive and comparative statistics, while qualitative data were thematically analyzed.

Results: Survey findings showed higher use of web search (275/280, 98.2%) compared to Gen-AI (40/286, 14%) within these groups. Web search was rated positively across participants, although challenges were raised regarding the phrasing of queries and commercialization. Gen-AI use was less common, but more than half of nonusers expressed willingness to adopt it in the future. Combined with focus group responses, themes exploring keyword searching, mistrust, lack of knowledge, and willingness to learn were established. Participants also suggested potential applications of Gen-AI, such as supporting independent living through monitoring and simplifying complex searches.

Conclusions: Web search remains the primary method, and participants highlighted both advantages and frustrations with current systems. Gen-AI was underused but seen as promising, with its adoption mainly limited by mistrust and knowledge gaps. Our findings indicate that structured training, early introduction, and user-centered design could encourage adoption, enhance accessibility, and support independent living among older adults with and without MCI.

KEYWORDS

artificial intelligence; dementia; mild cognitive impairment; older adult; generative AI; ChatGPT; search; information retrieval; aging; accessibility

Introduction

Given the rise in the number of people living with dementia worldwide [1], there is an increased demand for technologies that support independent living. In early-stage dementia and mild cognitive impairment (MCI), one potential technology to preserve independence is information retrieval (IR) systems that facilitate access to information. This includes 2 primary areas: web search (eg, Google) and generative artificial intelligence (Gen-AI), such as ChatGPT. In this study, "Gen-AI" refers to text-based conversational artificial intelligence (AI) systems powered by large language models (LLMs), such as ChatGPT. ChatGPT was used illustratively in the survey materials and focus groups, but perceptions of Gen-AI tools were examined more broadly. Much of the existing research on information access via web search has focused on users without impairments [2,3] or younger users [4-6], primarily examining health information seeking rather than broader applications [7-10]. Findings indicate that although health information seeking among older adults is becoming more common, barriers, including digital literacy, stigma, limited support, and information overload, remain [11,12]. Additionally, Gen-AI

XSL•FO
RenderX

systems could serve as a promising tool for information access, enabling independent searches and conversations. Gen-AI's natural language capabilities [13,14] suggest a more adaptable alternative to traditional web search [15], especially beneficial for those with limited digital skills or cognitive impairments.

Recent research suggests that Gen-AI could offer a more personalized and person-centered approach within both new and existing technologies [16], including information search, by simplifying complex information into more accessible formats [17,18]. This indicates that integrating such tools into information access mechanisms could be particularly advantageous in the context of aging [19]. Although many recognize the substantial ethical challenges posed by Gen-AI concerning data management and information sharing, especially given the vulnerability of this population [20,21], it is acknowledged that the potential of Gen-AI, particularly as a means of conversational search, remains significant [20]. Emerging studies have begun to explore older adults' perspectives on LLM-based systems, especially regarding health information seeking and companionship [22], as well as wider AI-driven health technologies [19,23]. These studies suggest that while older adults see potential in these systems, they continue to face barriers such as limited digital literacy, ethical concerns, and persistent ageism in technology design. Yet, despite this growing body of research, little is known about how these tools are experienced by older adults with MCI or dementia, who may have different needs compared to their cognitively healthy peers. Addressing this gap is vital to ensure that future Gen-AI applications support, rather than exclude, those living with cognitive impairments. AI has also been identified as a potential means of enhancing quality of life through informational and social support [24], although studies have noted that responses from Gen-AI can lack the narrative richness and personal experiences often found in peer-to-peer online forums [25]. This highlights the need to balance efficiency with personalization and authenticity valued by older users. Research has begun to investigate their use in this cohort for IR [20], reducing loneliness [26-28], improving mental health [29], and establishing best training practices [30], indicating that the potential for application in the aging population has already been recognized.

Older adults and those with cognitive impairment are often stereotyped as unable or unwilling to use technology [31-33]. This may create a self-fulfilling prophecy [34-37] in which technology is perceived as irrelevant, leading to reluctance, avoidance [38,39], or an underestimation of their abilities. Unfortunately, this stereotype is reflected in some technological developments, which do not attempt to accommodate older populations or are overly simplistic, focusing on skills they have lost rather than retained [37,40]. Additionally, greater emphasis is often placed on young people and their use of technology, which can result in older adults being excluded from its benefits [41]. This "digital ageism" has become an increasingly recognized issue, highlighting how technologies can become misaligned with older adults as age-related changes occur, affecting digital literacy [42] and widening the divide as these groups remain underrepresented in technology development. Beyond equity concerns, reduced digital access has clinical implications, as it may limit autonomy, delay decision-making, or increase dependence on caregivers. More recently, researchers have stressed the importance of addressing this digital divide in relation to Gen-AI specifically, calling for greater attention to accessibility, user-centered design, and inclusivity [43]. Such work demonstrates that while Gen-AI could be transformative for older cohorts, deliberate efforts are necessary to realize these potential benefits. In recent years, the importance of capturing the views of underrepresented groups on AI systems has been increasingly recognized, with older adults identified as a key population whose perspectives should inform the development of these technologies [22]. Therefore, exploring perspectives on information access is vital to understanding how older adults with and without cognitive impairment (including MCI and early-stage dementia) use these technologies and where improvements are needed.

This paper examines usage patterns and perspectives of traditional IR and Gen-AI systems in healthy older adults, those with MCI, and those with early-stage dementia, to characterize current engagement and identify directions for future development. To do so, we ask: How do older adults with and without cognitive impairment (including MCI and early-stage dementia) currently use and perceive traditional web search systems and Gen-AI tools, and what factors shape their engagement with these technologies? To our knowledge, this is the first study to directly compare perspectives on traditional web search and Gen-AI systems across healthy older adults, individuals with MCI, and those with early-stage dementia. In doing so, it provides insights to inform inclusive, clinically relevant design of future information systems.

Methods

Overview

This mixed methods study explored technology use and opinions of older adults with and without MCI or early-stage dementia. The study was conducted in 2 parts: an online survey and follow-up focus groups. The design accounted for heterogeneity in disease and at-risk populations by including participants across the cognitive spectrum, including early-stage dementia, MCI, and cognitively healthy older adults.

Ethical Considerations

The study was given ethical approval by the University of Strathclyde Ethics Committee (UEC24/28). All participants provided informed consent prior to participation. Participants were informed of the nature and purpose of the study and their right to withdraw at any time without penalty. All data were collected and stored in accordance with relevant data protection regulations, and no personally identifiable information was included in the analysis or reporting of results. Participants did not receive compensation for their participation.

Part 1: Online Survey

Participants

The survey gathered a total of 325 responses. As some participants did not go beyond the demographic questions, 39 (12%) responses were excluded before analysis, resulting in

XSL•FO
RenderX

286 (88%) valid responses (162 women, 123 men, and 1 who preferred not to say), with a mean age of 72.87 (SD 5.67) years. Partial responses, where participants completed part of the main survey, were included. Participants were recruited via word of mouth, social networking sites (eg, X and LinkedIn), flyers, and the Join Dementia Research platform, with 272 participants identifying as currently residing in England and 14 in Scotland. Education levels are summarized in Table 1. Participants reported diverse professional and vocational backgrounds, including health care, education, government, engineering, business, and skilled trades. This diversity highlights the varied socioeconomic and professional experiences represented in the sample. They were divided into 3 groups: healthy older adults aged older than 65 years without a neurological diagnosis (n=194, 67.8%, mean 72.38, SD 5.55 y; 119 women and 75 men); adults aged older than 65 years with early-stage or mild dementia or MCI (n=87, 30.4%, mean 74.1, SD 5.62 y; 42 women, 44 men, and 1 who preferred not to say); and caregivers of adults aged older than 65 years with early-stage or mild dementia or MCI, who responded on behalf of the person they cared for, providing their demographics (not their own; n=5, 1.7%, mean 70.4, SD 8.47 y; 1 woman and 4 men). Participants with cognitive impairment included 31 (33.7%) with Alzheimer disease, 44 (47.8%) with MCI, 8 (8.7%) with vascular dementia, 3 (3.3%) with frontotemporal dementia, 2 (2.2%) with Lewy body dementia, and 4 (4.3%) with other or unspecified conditions. Due to the small size of the caregiver group, these responses were combined with those of the dementia and MCI group. Sensitivity analyses excluding caregiver responses showed no meaningful changes in results, justifying their inclusion in the combined cognitive impairment group.

Table . Education level of survey participants[a].

Education level	Response, n (%)
PhD	16 (5.6)
Bachelor's degree	73 (25.5)
Master's degree	31 (10.8)
Some college or further education	88 (30.8)
Secondary school	40 (14)
Other	38 (13.3)

[a]"Other" includes professional, vocational, or partial higher education qualifications not captured by standard degree categories, such as teaching certificates (Postgraduate Certificate in Education), nursing or medical qualifications, engineering or law certifications, postgraduate diplomas, and other professional credentials.

Design

This study was designed as a mixed methods cross-sectional survey using independent samples. The online survey was created and conducted on Qualtrics (Qualtrics International Inc), with questions focusing on respondents' views of online search systems, such as Google, and Gen-AI systems, particularly conversational Gen-AI, such as ChatGPT.

The survey instrument was developed collaboratively by the first author and 2 supervisors to explore awareness, experience, and perceptions of Gen-AI and online search systems in older adults with and without cognitive impairment (including MCI and early-stage dementia). As no existing validated instruments addressed perceptions of conversational Gen-AI in older adults with cognitive impairment, items were created de novo, and established frameworks such as the Technology Acceptance Model (TAM) were not used because they did not capture the specific nuances of these systems in this population. The survey included a combination of Likert-scale and open-ended questions covering prior use, interaction and question phrasing, perceived response relevance, emotional experience, perceived usefulness, and perceived ability for independent use.

For Gen-AI questions, participants were first asked whether they used this technology. Those who said yes were asked about the applications they use, how often, for how long, and through which devices. They responded to questions on a 5-point Likert scale regarding the ease or difficulty of using the applications and the reasons behind their experiences, their usefulness, ease of selecting and writing queries, the relevance of the output, and their experience with the system in terms of boredom, enjoyment, independence, complexity, engagement, and feeling overwhelmed. Those who said no to using Gen-AI tools were asked about their reasons for not using them, what might encourage them to use these tools in the future, and whether they would consider using them in the future. Most Likert-scale questions were rated between "strongly disagree" and "strongly agree." These responses were encoded as integers from 1 through 5 and averaged across groups.

Similarly, participants were asked if they used online search systems. Those who answered yes were also asked about which applications they used (specific to general web search engines), how often, for how long, and through which devices. They were given Likert-scale questions about how easy or difficult the applications were to use and why and questions regarding the overall search process. They were asked about query formulation in terms of phrasing and rephrasing questions and relevance assessment regarding whether the search results were relevant, whether enough relevant information was provided, whether they could decide what information was relevant, and whether results were always relevant to their question. They were also questioned about helpful features, any aspects needing improvement, and their experiences with the system, including memory of their search goals, feelings of being lost, engagement, enjoyment, boredom, independence, complexity,

XSL•FO
RenderX

and feeling overwhelmed. Those who said no to using online search systems were asked about the reasons for not using them, what might encourage them to use these systems, and whether they would consider using them in the future. All participants were asked at the end of the survey what they would like to see in a system they could design themselves and given an opportunity to add any further comments they wished to voice.

Pilot

Five healthy older adults with no cognitive impairments were recruited through the University of Strathclyde Older Adult Research Panel. The pilot sessions were conducted both in person and online. Participants completed the survey with the researcher, providing feedback on the questions, structure, and length of the survey.

Following pilot feedback, minor refinements were made: illustrative images introducing Gen-AI and online search systems were added; it was clarified that "generative AI" referred to conversational, text-based chatbots rather than voice assistants; clarification that questions referred to the search system interface rather than website credibility was included; confusing or redundant response options were removed; and it was more clearly indicated where multiple responses could be selected. Participants reported the survey length and structure to be appropriate, and no major restructuring was required. As the study was exploratory, no formal psychometric validation or reliability testing was conducted.

Procedure

Participants first selected the group they identified with, then filled out the relevant participant information sheet and consent form. If they were interested in joining the focus groups, they had the option to provide their email address for future contact. They received an ID and proceeded to the main questions in the survey, completing the *Generative AI* section followed by the *Online Search System* section. A debrief was then displayed. After the survey recruitment, invitations were sent to those who had expressed willingness to participate in the focus groups. Survey completion times were highly skewed due to a small number of very long durations. The median completion time was 825 (IQR 597.5 - 1223) seconds.

Quantitative Analysis

A series of 2-tailed independent-samples *t* tests were carried out to examine each Likert-scale response between the MCI or dementia and healthy older adult groups. Although Likert-scale data are technically ordinal, independent-samples *t* tests can be considered robust to violations of the interval assumption, particularly for detecting group differences [44]. To account for the small and unequal sample sizes in the Gen-AI comparisons, we conducted supplementary nonparametric analyses using Mann-Whitney *U* tests, which produced results consistent with the *t* tests. Therefore, the reported *t* test results provide a valid representation of group differences.

Part 2: Follow-Up Focus Groups

Focus groups were organized to explore survey results in greater depth.

Participants

Ten survey participants took part in the follow-up focus groups (5 men, 5 women; mean age 73.9, SD 5.67 y). Two (20%) of 10 participants had indicated in the survey that they had used Gen-AI before, and all participants had said yes to having used online search systems. Six (60%) participants identified as healthy older adults, while 4 (40%) had a diagnosis of Alzheimer disease, dysexecutive syndrome due to neurodegeneration, or MCI.

Three focus groups were conducted in total. Group composition was determined based on cognitive status and prior Gen-AI experience: (1) healthy older adults with no prior Gen-AI experience (n=4, 40%), (2) adults with MCI or dementia with no prior Gen-AI experience (n=2, 20%), and (3) a mixed group including both healthy older adults and adults with MCI or dementia, with varying prior Gen-AI experience (n=4, 40%). While group 2 had only 2 participants due to recruitment constraints, their perspectives were included to ensure representation of individuals with cognitive impairment. The characteristics of each group are summarized in Table 2.

Table . Composition of focus groups.

Focus group	Participants, n (%)	Gender (female/male), n	Age, mean (SD)	Diagnosis[a]	Prior Gen-AI[b] use[c]
1	4 (40)	3/1	72.5 (6.56)	No impairments	No
2	2 (20)	0/2	71.5 (6.36)	MCI[d] or dementia	No
3	4 (40)	2/2	76.5 (4.93)	2 MCI or dementia and 2 no impairments	2 yes and 2 no

[a]Diagnosis refers to the self-reported diagnosis provided by participants in the survey demographic questions.

[b]Gen-AI: generative artificial intelligence.

[c]Prior Gen-AI use indicates self-reported experience with Gen-AI tools before completing the survey.

[d]MCI: mild cognitive impairment.

Design

Question topics were informed by initial survey responses, establishing exploration of early patterns, such as trust, which was not questioned in the survey, yet was raised in responses. A semistructured interview guide was used to ensure consistent topic coverage across groups while allowing flexibility for probing and follow-up questions. The full interview guide is provided in Multimedia Appendix 1. To minimize moderator

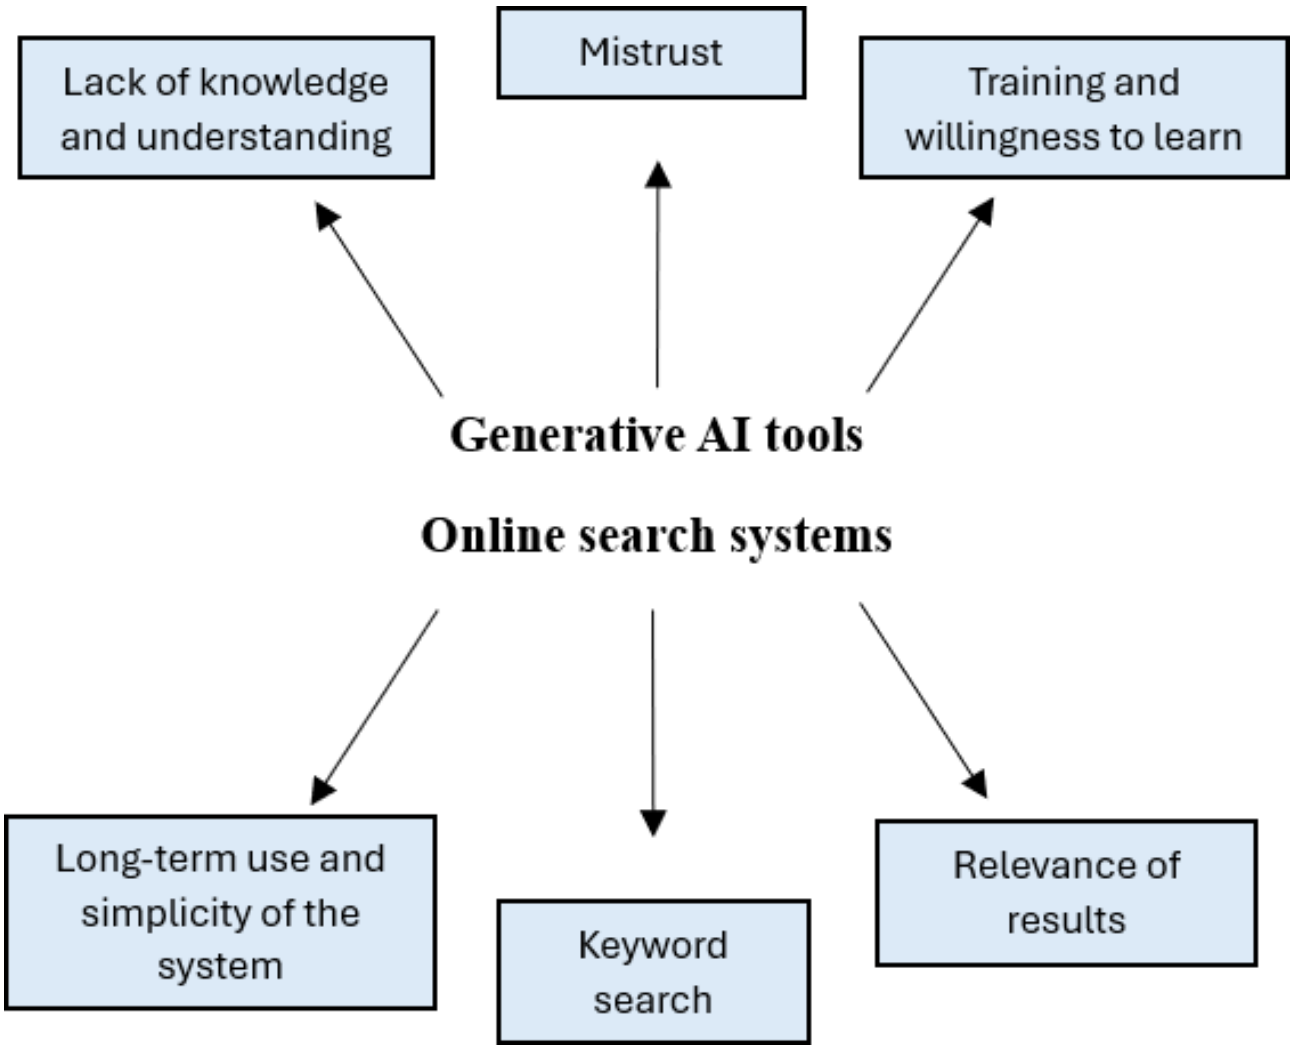
XSL•FO
RenderX

bias, neutral questioning was used, participation from all group members was encouraged, and both positive and negative perspectives were explored. The presence of a second researcher allowed oversight of adherence to the interview guide and provided a reflexive discussion following each session. All sessions were audio recorded and transcribed verbatim, and data collection continued until thematic saturation was reached, ensuring rigor and reliability of qualitative findings. The focus groups were moderated by the lead researcher, with a senior supervising researcher present during each session.

Procedure

Selected participants were contacted by email for the focus group follow-up. Participants read and completed the participant information sheet and consent form before attending the meeting, and focus groups were conducted online via Zoom (Zoom Communications). Each session lasted approximately 80 minutes, including a short mid-session break. Introductions were made, followed by a short demonstration of Gen-AI, particularly ChatGPT (OpenAI), illustrating the basic functions and capabilities of the system. This demonstration lasted approximately 5 to 10 minutes and followed a scripted sequence of predefined prompts to ensure consistency across groups (Multimedia Appendix 1). The main discussion then centered around Gen-AI, covering overall opinions, experience asking questions, its responses to questions, relevance, trust, and training. The same questions were also posed for online search systems. A brief debrief and a question-and-answer session were provided before closing.

Qualitative Analysis



To analyze the qualitative data from both the open-ended survey questions and focus group responses, a reflexive thematic analysis was performed [45]. Themes were iteratively developed and refined across both data sources, allowing the qualitative findings to contextualize and deepen the understanding of the quantitative survey results.

Results

Overview

Thematic analysis of Gen-AI content from the survey open-ended questions and focus groups identified 4 main themes: lack of knowledge about current technologies, mistrust, self-efficacy, and training and willingness to learn. For online search systems, the primary themes were long-term use and simplicity of the system, keyword searching, and relevance of results. Follow-up focus groups explored these themes in more detail, and key findings are presented alongside thematic results (Figure 1).

Figure 1. Final themes developed from qualitative data analysis. AI: artificial intelligence.

XSL•FO
RenderX

Generative AI

Quantitative Data

When asked whether participants currently use a Gen-AI tool, 40 (14%) of 286 participants responded "yes," comprising 27 (13.9%) of 194 older adults and 13 (14.1%) of 92 of those with MCI or dementia, with the most common use being to find information (Table 3). Many participants had heard of this technology, but the reasons given for not having used it varied (Table 4). Despite most participants saying "no" to using Gen-AI, 169 (68.7%) of 246 participants indicated they would consider using Gen-AI tools in the future, highlighting the potential for future adoption. Among those who used these tools, usage was mostly less than monthly, followed by weekly, lasting from a few minutes up to 10 minutes, with ChatGPT being the most frequently used. Thirty-three (94.2%) of 35 Gen-AI users felt that Gen-AI tools could be helpful in their lives. When asked to rate the ease of searching for information using a Gen-AI tool, where 1 was extremely difficult and 5 was extremely easy, the mean rating was 4.15 (SD 0.96).

Table . Uses of generative artificial intelligence (Gen-AI) and web search[a].

Uses	Gen-AI, n (%)	Web search, n (%)
To explore	9 (25.7)	139 (53.7)
To find information	22 (62.9)	257 (99.2)
To learn	20 (57.1)	176 (68)
To socialize	1 (2.9)	20 (7.7)
For entertainment	4 (11.4)	81 (31.3)

[a]Reported use of Gen-AI and web search across participants. N indicates the number of participants who selected each use. Participants could select multiple answers; therefore, totals exceed the number of participants. "Other" and "prefer not to say" were also available options.

Table . Reasons for nonuse[a].

Response option	All groups, n (%)	MCI[b] or dementia, n (%)	Healthy older adults, n (%)
I have heard of it but have never considered using it	113 (45.9)	33 (41.8)	80 (47.9)
I have heard of it but have never had the chance to use it	38 (15.4)	13 (16.5)	25 (15)
I used it and decided to stop using it or didn't like it	8 (3.3)	1 (1.3)	7 (4.2)
I have never heard of it	87 (35.4)	32 (40.5)	55 (32.9)

[a]Participant responses for their reasons behind the nonuse of Gen-AI. Percentages are calculated within participants who reported not using Gen-AI (n=246 total; n=79 MCI or dementia; n=167 healthy older adults).

[b]MCI: mild cognitive impairment.

Independent-samples *t* tests revealed no significant differences between the older adult and MCI or dementia groups, except for independent use of the system, where older adults responded in greater agreement to being able to use Gen-AI independently compared to those with MCI or dementia (Table 5). Nonetheless, there was a noticeable trend of older adults rating items, such as independent use and the ease of use of Gen-AI applications, as more agreeable than the MCI or dementia group. Further investigation through qualitative responses provided additional insights.

XSL•FO
RenderX

Table . Generative artificial intelligence (AI) Likert responses between groups[a].

Question	MCI[b] or dementia, mean (SD)	Healthy older adults, mean (SD)	Significant differences (*P* value)	Effect size (Cohen *d*)
"Generative AI helps me answer my questions". To what extent do you agree with this statement?	3.77 (1.01)	4.18 (0.73)	.17	−0.49
I have to reword my question to get the answer I'm looking for	3.58 (0.9)	3.36 (1.22)	.59	0.2
I find Generative AI tools simple to use	3.69 (1.11)	4.23 (0.87)	.12	−0.56
I can use Generative AI tools independently	4 (1.15)	4.68 (0.65)	.031	−0.79
I feel overwhelmed when using Generative AI tools	1.85 (1.07)	1.5 (0.86)	.30	0.37

[a]Responses from participants who reported that they use Gen-AI applications. Full independent-samples *t* test statistics (*t* values, degrees of freedom, and exact *P* values) for all items are provided in Multimedia Appendix 2. Full Likert-scale response distributions are provided in Multimedia Appendix 3. 1=strongly disagree and 5=strongly agree.

[b]MCI: mild cognitive impairment.

Qualitative Data

Lack of Knowledge and Understanding

When survey participants were asked why they did not use a Gen-AI tool, responses reflected a general lack of knowledge, such as "I don't really understand them," not knowing enough about their potential, such as "don't really know enough about it, its benefits or how to access and use it," and not understanding how to operate it, such as "don't know how to use it." This also extended to the belief that it is solely for education; one survey participant said:

> *...I've read it is used for such things as school/University course work... now I've seen a full explanation... I will investigate further.*

These qualitative responses align with quantitative trends showing that awareness alone does not guarantee confident adoption. For example, the mean ratings for knowing how to phrase their questions were 3.23 (SD 1.3; MCI or dementia) and 3.86 (SD 1.04; healthy older adults), and for understanding when to use Gen-AI, the mean ratings were 3.67 (SD 1.23) and 4.14 (SD 0.89), respectively (Multimedia Appendix 2). This suggests that limited familiarity may restrict effective use, particularly for the MCI or dementia group. Focus groups provided similar insights, with participant 6 (male, aged 69 y, no impairment) stating, "...I didn't know what it was and how to use it," while also expressing interest in using it after hearing about its capabilities.

A minor theme identified in the survey data was the lack of perceived need to use this technology, as reflected by both the MCI or dementia group, "not felt the need," and in the older adult group, "I have no need to generate tracks of commentary or explanation... I feel confident in my ability to read, assess, and formulate written responses." Quantitative data support this: although 68.7% of participants indicated they would consider using Gen-AI tools in the future, current use was only 14%. Older adult survey responses offered more detail, with comments such as "have no need to and don't know enough about it' and "I've not felt a need to use one and I'm not sure how to get started." These insights suggest that perceived lack of need may reflect limited understanding of Gen-AI applications.

Mistrust

A further theme was mistrust. Survey participants who had never used Gen-AI expressed security concerns ("don't trust it. Think it can be used/hacked for nefarious and cruel purposes") and concerns about accuracy ("probably foolishly, I don't feel I can fully trust AI-generated tools or the information they provide"). This aligns with quantitative findings showing lower confidence in independent Gen-AI use (MCI or dementia: mean 4.00, SD 1.15 vs healthy older adults: mean 4.68, SD 0.65; *P*=.03), suggesting that it may limit use. This may relate to limited knowledge about data management.

Survey participants also raised concerns about regulation: "I believe they are dangerous...There is insufficient and inadequate regulation." This aligns with responses from those who had used Gen-AI but stopped or disliked it; when asked what caused this, survey replies included accuracy concerns, ("suspicious of the accuracy of results"), privacy and security ("I need to be absolutely certain that it's secure") and regulation ("better monitoring of these tools by independent third parties"). Quantitative responses showed that although participants generally agreed Gen-AI provides relevant answers (MCI or dementia: mean 3.69, SD 1.32 and healthy older adults: mean 4.09, SD 0.81), lower confidence in phrasing questions (mean 3.23, SD 1.3 vs mean 3.86, SD 1.04) and understanding when to use tools (mean 3.67, SD 1.12, vs mean 4.14, SD 0.89) reflects that mistrust may affect perceived usefulness (Multimedia Appendix 2).

Focus groups discussed trust in more depth. Participants said, "…at the moment I don't trust artificial intelligence," and "…I

XSL•FO
RenderX

actually trust very little of anything." Focus group participants also raised privacy concerns:

> *I think we have enough observation in our lives… from all the CCTVS… a bit of privacy at your own home is quite nice.*
>
> *I'm concerned as well about these algorithms… it gets to know what you like… that worries me too.*

Regulation was also highlighted: "what is being done with social media and how it's abused…we allowed that because nothing was regulated," emphasizing transparency. Participant 3 (female, aged 78 y, no impairment) expressed feeling a lack of control:

> *…I don't know who's feeding it the information…Where's that coming from? Is it coming from one source?*

Survey responses mirrored this cautious use: "if I needed to use AI I would, but I prefer not to increase use of AI until I am sure it is controllable." This mistrust in AI is reflected through sci-fi references by participant 9 (male, aged 74 y, Alzheimer disease), "...these extraordinary machines are not human and all our concerns about sci-fi scenarios in which these machines take over the world," which again mirrors survey responses, "I think they could be dangerous...watch the Terminator films again. If the machines ever become self aware humanity will be in real trouble."

Focus groups also highlighted that trusting Gen-AI depends on the user verifying results. Participant 7 (male, aged 82 y, MCI) said:

> *if I've taken part in history and I quiz the machine... and it responds with a different account... the machine immediately turns around to me and apologizes for providing incorrect facts. So that confuses me a little bit.*

They stressed that their own knowledge is essential:

> *if I hadn't been a witness to the event or taken part in it, I would have believed everything the machine told me...*

Healthy older adults echoed this:

> *…results I get back can be hit and miss and you really have to know what it is you're asking.*
>
> *[Participant 8, female, aged 71 y, no impairment]*
>
> *AI seems to me to be something that just gives you what it thinks you want rather than what you think you want.*
>
> *[Participant 6, male, aged 69 y, no impairment]*

Participant 1 (male, aged 76 y, Alzheimer disease) reinforced this:

> *if you don't have the cognitive ability to be able to discern between fact and fiction, then you're quite likely to be misled, misinformed, or actually harmed.*

These observations help explain why participants reported relevant outputs (MCI or dementia: mean 4.17, SD 0.83), yet lower confidence in independent use, suggesting that mistrust and cognitive concerns influence engagement. Therefore, reliance on the user to identify correct and unbiased information is a significant factor. This was echoed by a participant with MCI or dementia in the survey data, who stated:

> *I'm not a fan of AI. I like to be able to tell the difference between what's real and what's fake... I also don't want to be confused as the disease progresses... I would like all AI generated images and text to have to carry an "AI" generated symbol.*

Thus, mistrust and need for oversight appear linked to lower confidence in independent use shown in the quantitative data, highlighting the importance of distinguishing genuine from AI-generated content.

Perceived Capability and Self-Efficacy

A distinct theme was participants' perceived capability when interacting with Gen-AI, reflecting situational self-efficacy. Some focus group participants reported feeling the need to treat AI as more capable than themselves. For example, participant 7 (male, aged 82 y, MCI) said:

> *...I couldn't treat Gemini or GPI as a machine... For me to relate to them and to use them, I had to treat them as human beings who were more intelligent and more verbal than I was.*

Conversely, focus group participant 8 (female, aged 71 y, no impairment), who uses Gen-AI, offered a contrasting viewpoint, "...I believe I treat it as a machine, as a supercomputer." These perspectives contextualize survey responses reporting discomfort with interactions, "the robotic nature of the exchanges and limitations to interact are uncomfortable to deal with," and may help explain variance in engagement and trust metrics across participants. Although perceived capability was not directly measured, these qualitative insights suggest that participants' situational self-efficacy in using Gen-AI varies depending on how they perceive the AI's abilities relative to their own.

Training and Willingness to Learn

When asked about what would encourage participants to use Gen-AI in the future, survey responses reflected training needs and a general willingness to learn. The MCI or dementia survey group often requested "more knowledge, experience, and training" and "an explanation and teaching of how to do this." Similar responses were given by the older adult survey group, expressing a desire for information on "how it would benefit me followed by training on how to use it," including "a demonstration and practice in using them" and access to "free training sessions possibly at a library." Both survey groups also mentioned the importance of support from others to encourage use, such as "having someone around with the time to explain it and then help me to use it" in the MCI or dementia group, and "recommendation by a friend or family member..." in the healthy older adult group. Quantitative data support this: 68.7% (169/246) of survey respondents indicated they would consider using Gen-AI in the future. Additionally, Likert-scale responses showed moderate agreement that Gen-AI helps answer questions (MCI or dementia: mean 3.77, SD 1.01; and healthy older adults: mean 4.18, SD 0.73) and provides relevant answers (MCI or dementia: mean 4.17, SD 0.83; and healthy older adults: mean

XSL•FO
RenderX

4.18, SD 0.73). This suggests that addressing knowledge gaps and providing transparency could facilitate adoption.

Survey participants also outlined their expectations for training, including desires for "a clear idea of what it can do and be used for," "more information and guidance in how to use and its benefits," and practical examples. Comments also reflected concerns about trust and system performance. The MCI or dementia group mentioned, "only if I could be absolutely assured that what was produced was true and could be collated with other trusted sources of information," while the older adult group expressed concerns about accuracy, stating, "being reassured that they don't make up the answer if they can't find it." These concerns parallel survey Likert items on confidence in independent use, where lower ratings among participants with MCI or dementia (mean 4, SD 1.15 vs 4.68, SD 0.65 in healthy older adults) may reflect caution about trusting outputs and the need for training to build confidence while addressing reliability and accuracy.

Despite encouraging responses, it is important to acknowledge that some reactions showed reluctance to engage. Some participants replied "nothing" when asked what would encourage them to use these systems, while others, such as from the MCI or dementia group, expressed, "I personally don't feel I need anything like this, at the moment," and "Nothing. I do not trust the security of these sites." Older adults also shared perceptions that there is too much technology, with comments such as "I don't want to get involved with anything else," and believed that web search was sufficient, stating "I don't think I need to use such a tool, as I can find most information I need on Google." Willingness to use Gen-AI appears shaped by personal beliefs and experiences, with one noting, "I believe this tool is used to help create content/write something...I have never felt the need to use it." Some responses from the MCI or dementia group cited complexity, "it's too complicated," "I'm not very good with tech stuff," "coping with technology," and "I am a technophobe." These hesitations correspond with quantitative patterns, such as lower confidence in phrasing questions (MCI or dementia: mean 3.23, SD 1.3 vs healthy older adults: mean 3.86, SD 1.04) and understanding when to use Gen-AI (3.67, SD 1.23 vs 4.14, SD 0.89). This indicates that not all barriers can be addressed through training alone.

Both groups also noted ease of use and user-friendliness: "usefulness outweighing frustration." When asked about ease of use, those who used Gen-AI responded positively. The MCI or dementia group said, "...it provides a response that I understand," "it is very responsive to questions posed to it. I often put in further questions...," and "I am just starting with AI as I feel it could be of great help as my condition progresses." Older adults responded similarly, "the info is quite detailed but is easy to query in more detail by using more targeted questions," "no harder than searching in Google," and "a bit better and precise than an internet search." However, some negative points were raised, such as, "with some questions the AI has to be tricked into answering, or will not answer," and concerns about complexity: "I have limited tech" experience and, as I have no family or support network, I can be slow to learn & retain new methods." Overall, these experiences align with Likert-scale ease of use scores (mean 4.15 overall).

The focus group participants expressed varied interest in training. Participant 2 (male, aged 67 y, dysexecutive syndrome) said, "I would go and get that training because I'm curious...the problem is being able to remember... what you've learned," highlighting that training might be most effective early in diagnosis or beforehand. Participant 1 (male, aged 76 y, Alzheimer disease) expressed a preference for being taught by similar individuals, stating:

> *...training would be most effective if- if it was done by people such as myself who were in a MCI state and would have an understanding of what it was that they were talking about…*

Others, who were more skeptical about AI, did not show interest in training, "I just think it's money wasted on me at 80... better given the training to the youngsters so they're prepared for the future rather than me," or simply conveying a lack of interest in attending. Participant 10 (female, aged 79 y, no impairment) expressed a preference to explore it in their own time, stating:

> *I don't think in my case I would need training. I think I would look at it and- and explore it on my own.*

Additionally, it was discussed that targeted training for groups could be most beneficial:

> *I think that training on Gen-AI as a whole for members of the general public would probably possibly not be that useful...*

Despite varied interest, some participants found the focus group demonstration intriguing, saying:

> *when you were givin' the demonstration of ChatGPT, I wanted to start using it myself to, to find some information that I've not been able to get easily from Google.*

Overall, responses highlight that individual experiences, cognitive abilities, and confidence shape willingness to learn, but there is potential for training to help those interested.

Online Search Systems

Quantitative Data

Participants were asked if they currently use an online search system. Of the 286 survey participants, 280 (97.9%) responded to this question, reflecting partial survey completion. Among respondents, 275 (98.2%) of 280 participants responded "yes," with 186 (98.9%) of 188 older adults and 89 (96.7%) of 92 participants in the MCI or dementia group reporting use. Among these users, Google was the most used, and most participants reported using search systems daily and for less than 5 minutes at a time. Participants used these tools primarily to find information and learn (Table 3). When asked how easy they found searching for information using an online search system, where 1 was extremely difficult and 5 was extremely easy, the average response was 4.38 (SD 0.8), indicating generally positive perceptions.

Independent-samples *t* test results reveal significant differences between groups on several survey questions, with the healthy older adult group consistently rating items as more agreeable (Table 6) than the MCI or dementia group. For example, the

XSL•FO
RenderX

MCI or dementia group was more likely to report needing to reword queries, feeling lost, or feeling overwhelmed, whereas healthy older adults more often reported being able to remember what they were searching for, deciding whether information was relevant, and using search systems independently. Survey open-ended questions and focus groups provided additional insight.

Table . Web search Likert responses between groups[a].

Question	MCI[b] or dementia, mean (SD)	Healthy older adults, mean (SD)	Significant differences (*P* value)	Effect size (Cohen *d*)
I have to reword my question to find what I am looking for	3.35 (1.1)	2.94 (1.09)	.005	0.37
I can decide if information is relevant to my question	4.3 (0.74)	4.57 (0.54)	.005	−0.42
I can remember what I was searching for during the search process	4 (1.09)	4.8 (0.44)	<.001	−1.14
I feel lost during the search process	2.39 (1.2)	1.53 (0.85)	<.001	0.88
I can use online search systems independently	4.32 (0.97)	4.67 (0.71)	.003	−0.44
I feel overwhelmed when deciding which information is relevant	2.54 (1.38)	1.7 (1)	<.001	0.74

[a]Responses from participants who reported that they use web search. Full independent-samples *t* test statistics (*t* values, degrees of freedom, and exact *P* values) for all items are provided in Multimedia Appendix 4. Full Likert-scale response distributions are provided in Multimedia Appendix 5. 1=strongly disagree and 5=strongly agree.

[b]MCI: mild cognitive impairment.

Qualitative Data

Long-Term Use and Simplicity of the System

Survey participants were asked about why using these systems was easy or difficult. A prominent response was prior experience, reported by both the MCI or dementia group (“I have a background in IT...”) and the healthy older adult group (“I have used computers in my last job for many years”). Similarly, both survey groups reported personal use, “I have used it for many years, so have been familiar with it for a long time.” These findings align with the quantitative results showing high ease of use (mean 4.38, SD 0.8 overall) and reported high levels of independent use, particularly among healthy older adults (mean 4.67, SD 0.71 vs MCI or dementia mean 4.32, SD 0.97; *P*=.003), suggesting that familiarity underpins perceived ease. Moreover, survey responses often mentioned web search being habitual, “having used various search engines over many years it is almost second nature,” also consistent with quantitative findings of daily use and low feelings of overwhelm when inputting queries (MCI or dementia: mean 2.08, SD 1.24 vs healthy older adults mean 1.34, SD 0.79; *P*<.001). Focus group participants echoed this, noting challenges for learning AI: “I haven’t used it (referring to Gen-AI) because I’m a creature of habit... if I want an answer to something I Google it,” and “one of the necessary keys to people with memory problems in using new technology like AI is that we are people of habit. And that’s going to be the big, the big stumbling block.”

Some survey responses indicated that the enjoyment of discovering information facilitated ease of use, “I enjoy finding things out and have learned how to do this.” Notably, one MCI or dementia survey participant said, “the information is there to be found now that I have learned how to access it. Having family to help me would have been game changing but I have managed. I am acutely aware that as any tech’ ability I have learned… I shall lose these first, so lose this invaluable source of managing my life as Alzheimer’s progresses.” This highlights the impact of IR on independence and daily living and corresponds with survey findings showing lower feelings of being lost among healthy older adults (mean 1.53, SD 0.85) compared with the MCI or dementia group (mean 2.39, SD 1.2; *P*<.001), emphasizing the role of experience in maintaining confidence during searches.

Keyword Searching

Keyword searching was discussed in response to questions about ease of use, with survey participants describing it as both easy and difficult. Some participants with MCI or dementia found it straightforward: “I have always been good at asking questions,” while others found it more challenging: “it depends what I’m looking for. Finding the right words isn’t always easy. The more branches I go down, the more difficult I find it to get back,” and “the most frustrating aspect is when I am unable to select a search term that brings up correct answers... I’m only offered a limited selection of answers and I know there must be more but they don’t appear..." Consequently, some mentioned, “I sometimes have to change my question,” reflecting the quantitative finding that the MCI or dementia group responded

XSL•FO
RenderX

significantly more strongly with needing to reword questions (mean 3.35, SD 1.1) compared to the healthy older adult group (mean 2.94, SD 1.09; *P*=.005; Table 6).

Healthy older adults generally reported less difficulty: "simple to phrase a question," and that rephrasing, if needed, was straightforward: "can usually find what I want quickly but do need to consider how a question is phrased," aligning with quantitative findings that healthy older adults had greater confidence in phrasing questions (mean 4.2, SD 0.73 vs MCI or dementia mean 3.9, SD 1.03; *P*=.02). Both groups highlighted how keywords influence search results, with comments such as "depend on selecting suitable key search words, and the main problem is evaluating the reliability of sources of information..." and "with Google there are a lot of irrelevant web pages returned and it's often necessary to search through the links to find what you are looking for." Overall, there is a contrast between finding keyword searches easy or difficult across both groups, with an acknowledgment that the relevance of results often depends on this.

Focus group participants provided context for these survey patterns. Many participants reported that searching was easy, but occasionally required rephrasing. Participant 5 (female, aged 65 y, no impairment) said:

> *"I think I've always found what I wanted," adding, "...if the results are not relevant... I know I need to rephrase the question..."*

Participant 6 (male, aged 69 y, no impairment) mentioned that their frustration with web search makes Gen-AI appealing:

> *I wanted to start using it myself to- to find some information that I've not been able to get easily from Google...I think it could focus when I want a question answered...*

Overall, survey and focus group data indicate variability in ease of keyword searching, with rephrasing often necessary and keyword selection affecting relevance. Participants with MCI or dementia experienced more difficulty, reflecting quantitative differences.

Relevance of Results

Another identified theme was the relevance of results, particularly concerning advertisements, sponsorships, and location bias. Survey participants highlighted that commercialization reduces relevance, with the MCI or dementia group noting, "it would be easier if the results of searches didn't have such a converging and commercial aspect," and the older adult group stating, "the answers it gives are too random and the paid answers are always crowding out the simple ones." Both groups also reported irrelevant information: "too much irrelevant information given in answers," and "...I am not always convinced by the accuracy or bias in the info I find..." Suggested improvements from survey responses included: "by not showing promoted content first which is irrelevant to my question," "ditch the cookies, by the time I've got through this it's hard to remember what I was thinking about," and "less emphasis on American English terminology, and less bias towards American based info/research." Survey comments also suggested implementing "color-coded hyperlinks" to better distinguish between promoted and relevant results and that "search engines should organize their results so as to assist the searcher rather than according to commercial and financial priorities."

Expanding on the survey concerns, dislike for commercialization was also observed in the focus groups, where participant 5 (female, aged 65 y, no impairment) said, "...the first one that always will come up in the list is sponsored," while participant 3 (female, aged 78 y, no impairment) added, "it disturbs me that...the people who pay most money get up the queue..." This was also linked to trust, with participant 1 (male, aged 76 y, Alzheimer disease) noting that commercial prioritization can facilitate harm:

> *...they will draw revenue from people who are willing to pay to have their entry first in the list... there are a lot of people who get misled.*

Participants also described strategies to reduce risk, such as using privacy-focused browsers, "I use DuckDuckGo because it removes trackers …it just makes me feel more comfortable," although survey responses indicated a knowledge gap: "I wish there was a way of feeling safer when I do the searches."

When survey participants were asked what they would include if they could design their own system, responses addressed relevance filtering, source transparency, and removal of sponsored results, "...A button to click that would identify owners/contributors..," "1. Removal of sponsored responses; 2. Dating of posts to allow disregarding of outdated posts; 3. It may become necessary to identify AI responses derived from old or fake data that should not be relied upon." Interestingly, Gen-AI was suggested as a potential improvement to current systems by the older adult survey group, with comments such as "ChatGPT is useful because you can build a series of questions on a topic to look at different aspects of an issue and then draw on the answers to build a summary," and the MCI or dementia survey group, who said, "I manage my online searches quite easily as long as I am careful with my phrasing. AI is able to help me with that." Others acknowledged that these systems could be improved, stating, "I only know they could be better for me."

Finally, focus group data suggested that the volume of results can affect focus, particularly for participants with MCI or dementia. Participant 7 (male, aged 82 y, MCI) said, "if I ask Google a specific question... I would like a specific answer," whereas participant 3 (female, aged 78 y, no impairment) appreciated the element of choice, saying, "Google gives me choices so I can go in and I consult there." This may be reflected in the survey responses from the MCI or dementia group, which mentioned, "keeping what I am searching for in mind, sometimes I forget mid-search," and "remember what I am doing, short span of concentration, tired easily." The higher volume of results may impose a greater cognitive load or memory pressure when users must determine the most relevant result to select. This may be consistent with quantitative results depicting the MCI or dementia group rating being able to remember what they were searching for as lower (mean 4, SD 1.09) compared to the healthy older adult group (mean 4.8, SD 0.44; *P*<.001).

Participant Perspectives on Future Applications of AI

Building on the survey finding that 68.7% (169/246) of respondents reported openness to using Gen-AI in the future, this theme was explored primarily through qualitative data to understand how participants envisioned AI supporting future daily living needs. Specifically, many envisioned AI systems evolving beyond IR toward proactive monitoring, routine support, and safety. Survey responses acknowledged this:

> *happy with search but still trying to get to grips with AI which I feel has tremendous potential for people with my complaint.*

The MCI or dementia survey group mentioned a monitoring feature:

> *...AI would be ideal to monitor my behaviors...I would be quite happy for my AI to learn all about me and monitor the changes in my behaviors and routine.*

This was taken further in the same response, discussing how their conversational ability could be helpful to them: "...a bit of conversation is helpful when you live on your own!"

These future-oriented applications were not captured in the survey Likert-scale items and were therefore explored in more depth within the focus groups. Participant 4 (female, aged 78 y, no impairment) said, "...I live alone and at the moment I'm hale and hearty but I could have a camera and my daughter could see what I was up to...Things like that I think are good," indicating that monitoring might be accepted as part of a care plan. This was also discussed extensively by participant 1 (male, aged 76 y, Alzheimer disease) who explained:

> *I'm quite happy to share my personal antisocial habits with a computer if it is looking after me...*

This suggests that the potentially adaptable monitoring abilities of AI could be accepted if it improved independent living. However, they also explained that this technology would need to be implemented early in their diagnosis so it could develop alongside them: "...the technology and the help can grow with the disease as it progresses down the step ladder," the step ladder referring to diminishing cognitive decline, "you've got to grow into it... it's got to be led by the individual's needs." Interestingly, this conflicts with concerns about trust and privacy; when asked directly, their perspective on trust was different:

> *by the time my disease develops to the point where I'm going to need AI to look after me, my mind will have degenerated to such a state that I actually don't give two hoots who knows or cares or anything else...I won't have any privacy anyway, so that is really not of a major concern to me.*

A similar stance was taken by participant 5 (female, aged 65 y, no impairment), reflecting on a different meeting about robots used in care:

> *we all went into this meeting saying no way on earth would we have a robot for this. And we all left the meeting saying yes, absolutely, if it meant that we could stay at home...*

Finally, a few notable features were discussed in the focus groups. The first was that AI should learn to forget information, "necessity for AI to learn to forget... when it comes to bank details, jobs in assembly, there are things I think that would be good for AI to recognise it needs to forget…," and proactive autonomy, "AI responds to requests but what AI doesn't do is, is have the autonomous ability to, to, to access prompts ...if AI could be trained to think autonomously about where the needs are and what prompts are—that would be a major step forward in helping people with dementias and brain damage to live independently."

Discussion

Principal Findings

To our knowledge, this is the first study to gather in-depth perspectives of older adults with and without MCI (including MCI and early-stage dementia) on their engagement with and opinions of both traditional IR systems and Gen-AI. This contributes new empirical evidence to the literature on digital engagement in older adults, as most prior studies focus either on younger populations or on health information seeking alone [11,46]. Results show that most participants reported using traditional web search systems, consistent with the understanding that digital literacy in this population is growing [47,48]. Participants were recruited via convenience sampling, which may overrepresent older adults with higher digital literacy or motivation to engage with technology; findings should therefore be interpreted as indicative rather than representative of the broader population. Our findings confirm prior work suggesting that habitual use and familiarity enhance perceived ease of use among older adults [49,50], while also extending this by showing differential experiences in individuals with cognitive impairment. This familiarity likely reflects the long-established nature of web search platforms [12], whereas Gen-AI tools are newer and less commonly adopted, consistent with observations that novelty and lack of exposure limit adoption in older populations [51]. As a result, participants reported greater confidence and skill when using web search compared to Gen-AI. Together, these findings address our aim of examining how these groups use and perceive web search and Gen-AI tools.

Both groups generally found web search helpful, easy to use, and understood when and how to use it. Likert-scale responses showed significant group differences across multiple aspects of the search process, with effect size estimates ranging from moderate to large, indicating meaningful differences in user experience. The MCI or dementia group was more likely to report needing to rephrase questions, feeling lost, and feeling overwhelmed, whereas healthy older adults more often reported knowing how to phrase questions, finding relevant information, remembering search goals, and using systems independently. These findings confirm earlier literature showing that cognitive impairment can increase effort and reduce confidence in information-seeking tasks [52,53] and extend it by quantifying the differences in self-reported behaviors and perceptions. Although overall overwhelm remained low, results suggest that cognitive impairment may increase effort during information

XSL•FO
RenderX

seeking [52]. Despite group differences, quantitative data depicted that web search was generally viewed positively [54], while qualitative data provided deeper insight into these high ratings, highlighting issues such as commercialization, privacy concerns, and keyword selection, which can impact the user experience.

This adds qualitative insight to existing quantitative findings on older adults' web search behavior [52]. Qualitative responses reflect individual struggles based on beliefs and abilities, indicating that cognitive impairment shapes the subjective experience of IR systems [53,55,56]. Participants' proposed solutions indicated that challenges with web search are widespread and may be mitigated through Gen-AI features, with suggestions such as Gen-AI offering more personalized and adaptive responses. These findings complement research on adaptive AI for older adults [57,58] and highlight potential applications supporting independent information access. These findings extend the literature primarily focused on online health information quality [59-61] by highlighting the experiential differences and potential technological improvements for older adults with and without cognitive impairment (including MCI and early-stage dementia). They further suggest that emerging technologies such as Gen-AI may help offset age–related and cognition-related disparities in access [42,62].

Regarding Gen-AI, although reported usage was lower, more than half of nonusers expressed willingness to use these tools in the future, indicating potential uptake if barriers are addressed. Adoption appeared to be influenced by beliefs [51], including mistrust and lack of knowledge, consistent with prior studies showing that trust and perceived knowledge influence technology adoption among older adults [39,63-67]. However, qualitative findings suggest that low engagement cannot be attributed solely to knowledge gaps or mistrust. Some participants reported "no need" for these tools, reflecting perceptions of limited personal utility or preference for existing methods, while others identified practical barriers, such as complexity, navigation difficulties, access limitations, and reliability concerns. These observations extend adoption models [68], suggesting that perceived usefulness and interface design may be equally important in older adult populations.

These findings can be interpreted through the lens of the TAM [69], which proposes perceived usefulness and ease of use as key determinants of adoption. Participants recognized potential usefulness but reported limited adoption due to unfamiliarity and perceived complexity, indicating that both constructs were influential. Applying TAM situates these qualitative insights within an established theoretical framework [19,69]. Together, results suggest that utility, accessibility, design, trust, and perceived relevance interact to shape engagement with Gen-AI among older adults and those with MCI or early-stage dementia. This aligns with established links between technology adoption and trust [39,63-67,70]; however, actual uptake was not measured, and further work is needed to determine whether intentions translate into sustained engagement.

Our findings also highlight an important nuance related to participants' perceived self-efficacy when engaging with Gen-AI. Some focus group participants described feeling less capable than the AI, while others framed their interaction as treating it as a machine. These results extend literature on self-efficacy theory and technology adoption [71-73] by showing that perceived capability may influence engagement, a factor not typically emphasized within TAM. Even when participants recognized usefulness, confidence appeared shaped by perceived competence relative to the AI, particularly among individuals with cognitive impairments, who may already have lower baseline self-efficacy in technology use [72-74]. These perceptions suggest that Gen-AI may unintentionally exacerbate feelings of reduced capability for some users, despite recognized benefits. This highlights the importance of supportive interfaces, gradual exposure, and tailored training to strengthen self-efficacy. Our findings reinforce prior research [19,43] highlighting both barriers and quality of life benefits associated with AI adoption among older adults, while illustrating mechanisms through which Gen-AI may support independent living. Participants' willingness and motivation to learn indicate promise, although prior work shows that intention does not always translate to adoption [51,74,75]; therefore, findings should be interpreted as reflecting potential engagement rather than confirmed behavior change.

Knowledge gaps were common across both groups, indicating that education and training may support adoption. Participants expressed interest in tuition and demonstrations, particularly for ChatGPT [76], aligning with training practices already recognized [30]. However, views were heterogeneous: some participants welcomed structured training, while others viewed it as unnecessary or of limited value. These findings suggest that one-size-fits-all approaches may be ineffective and that training should be flexible and responsive to individual needs and motivation [77,78]. Tailored or optional learning approaches may therefore better support diverse preferences and abilities. Successful interventions may need to balance guidance with autonomy, allowing access to training without assuming universal interest. Structured, transparent education may improve confidence and understanding while complementing web searches and addressing perceived limitations.

Notably, the MCI or dementia group highlighted issues not raised by healthy older adults, including forgetting mid-search, difficulties learning new skills, and challenges in adopting new technologies. They also rated items such as being able to use Gen-AI independently with lower agreement compared to their older adult counterparts. These findings suggest that early introduction of AI and the inclusion of diverse cognitive groups in design processes are crucial. The adaptability and personalization of Gen-AI may help address these challenges [20], potentially supporting independent living outcomes.

Although only one group difference was statistically significant, effect size estimates indicated moderate-to-large differences across measures related to confidence, usability, and independence. This suggests that participants with MCI or dementia may experience greater difficulty when engaging with Gen-AI tools. However, moderate-to-large effect sizes alongside nonsignificant findings likely reflect limited statistical power due to the small number of Gen-AI users, and the observed effect sizes may help inform future power analyses and sample size targets in subsequent studies.

XSL•FO
RenderX

Furthermore, an emerging factor was monitoring, with participants recognizing AI's potential to support daily functioning. This aligns with research showing that chatbots may assist in monitoring and informing care providers about symptom changes [79]. Our findings extend this literature by demonstrating that older adults themselves view monitoring as valuable when independence benefits are clear. Despite privacy concerns, focus group responses expressed willingness to adopt AI if the benefits to independence were substantial. These findings highlight the importance of involving older adults in technology development, especially to address perceptions that AI is unnecessary or irrelevant to them. This is reflected in the theme of "no need," which appears linked to limited awareness of potential benefits [41], yet participants offered clear suggestions for how AI could improve daily life. Therefore, future developments should prioritize early implementation and co-development with older adults and those with cognitive impairment to ensure relevance and utility. Finally, these results complement literature showing that Gen-AI may reduce loneliness, support mental health, and improve person-centered information access, while reinforcing barriers such as ethical concerns, ageism, and digital literacy gaps [17,80]. Our findings demonstrate how these perceptions vary by cognitive status and identify actionable areas for intervention and training.

Limitations

The dementia and MCI groups were smaller than the healthy older adult group, which may limit representativeness. Additionally, one focus group included only 2 participants due to recruitment constraints; although the discussion generated rich data, larger groups may provide broader interactional insights in future research. Furthermore, participants were recruited through convenience sampling, which may overrepresent individuals with higher digital literacy or technology interest. Similarly, the number of current LLM users was small, although this reflects real-world usage patterns. Surveys were conducted online, restricting control over responses and preventing follow-up clarification, although focus groups helped mitigate this.

While demographic information such as age, gender, education level, occupation, and geographic location was collected, ethnicity and detailed socioeconomic indicators were not measured. This limits generalizability, as cultural and socioeconomic factors may influence engagement with web search and Gen-AI tools. Future research should recruit more diverse samples to explore these influences among older adults with and without cognitive impairment (including MCI and early-stage dementia).

Conclusions

Our results provide novel insights into how older adults with and without MCI or early-stage dementia may perceive and engage with web search and Gen-AI tools, addressing an underexplored gap in user experience research [81]. Participants expressed interest in Gen-AI, highlighting areas where training and support may facilitate adoption. While findings reflect perceptions and intentions rather than confirmed behavioral change, they identify factors influencing engagement with Gen-AI. They offer a flexible, personalized approach to information access and conversational search, which may help address limitations identified in web search systems. While web search remains valuable due to its long-standing use, participants highlighted areas for improvement, suggesting that hybrid or complementary approaches with Gen-AI could improve accessibility. The study contributes to an underexplored area of literature where potential applications have been recognized [20,82-84] and aims to inform future technological development grounded in user perspectives.

Future Work

As Gen-AI adoption grows, future research should explore targeted training interventions following best practices [30] to enhance adoption, confidence, and digital literacy among older adults with and without cognitive impairment (including MCI and early-stage dementia). Longitudinal research combining usage tracking and qualitative interviews may clarify evolving perspectives and sustained engagement. Expanding this research to include other underrepresented populations and conditions would be valuable for broadening understanding and assessing the generalizability of the findings. Developers should actively co-design technologies with these groups to combat digital ageism, ensure accessibility, and promote person-centered AI systems. Moreover, effectively evaluating how Gen-AI is integrated into these technologies will be essential to maximize their impact.

Acknowledgments

The authors would like to thank all participants for their time and contributions to this study. The authors also acknowledge the Join Dementia Research platform and the University of Strathclyde Older Adult Research Panel for supporting participant recruitment.

Abstract

Background: Smartphones have become deeply embedded in daily life, supporting a range of social and practical activities. Individuals with dementia can potentially use smartphones to compensate for cognitive decline and maintain independence. However, while smartphones are widely studied in controlled research settings, little is known about how individuals with dementia spontaneously use them in everyday life. Understanding usage patterns and their potential link to social participation could inform strategies to support smartphone use in their social and practical daily activities.

Objective: This study aimed to identify factors associated with spontaneous smartphone use, describe usage patterns, and examine whether smartphone use is associated with participation in social activities.

Methods: In 2024, we conducted a cross-sectional survey among community-dwelling individuals with mild to moderate dementia from 17 medical facilities in Tokyo. Structured questionnaires were completed by the participants, their families, and attending physicians. Participation in social activities was assessed using the “Spending Time with Others” subscale of the Social Functioning in Dementia (SF-DEM) scale. Factors associated with smartphone use were analyzed using multinomial logistic regression. Associations with participation in social activities were assessed via hierarchical linear regression.

Results: Among 151 participants with a mean age of 82.9 (SD 6.6) years, 43 (29%) participants were regular smartphone users. Smartphone use was negatively associated with older age (odds ratio [OR] 0.41, 95% CI 0.21 - 0.80) and positively associated with longer education (OR 1.82, 95% CI 1.00 - 3.30), living alone (OR 3.17, 95% CI 1.08 - 9.31), and better cognitive function (OR 2.14, 95% CI 1.24 - 3.69). Common uses included calling, texting, taking photos and videos, and checking the news and weather. Smartphone users reported marginally more frequent participation in social activities than nonusers did (b=1.41, 95% CI –0.01 to 2.83), particularly visiting the homes of friends or family (b=0.43, 95% CI 0.08 - 0.78) and shopping together (b=0.49, 95% CI 0.15 - 0.83).

Conclusions: Despite their limited use at the time of this writing, commercial-based smartphones have the potential to support participation in social activities among individuals with dementia. Targeted support may help bridge the gap between this usage and the broader capabilities of these devices, enhancing their role in sustaining meaningful social participation.

KEYWORDS

older adults; dementia; smartphone; everyday information and communication technology; social participation

Introduction

Background

Given the global trends in population aging and growth, an estimated 57.4 million people were living with dementia in 2019, and this number is projected to increase to 152.8 million by 2050 [1]. Dementia is characterized by progressive cognitive decline that gradually interferes with daily functioning and independence [2]. While subjective experiences vary, many people with dementia can maintain a good quality of life with appropriate support [3-5]. Participation in social activities is a key contributor to their well-being, particularly in the mild to moderate stages [5,6]. However, individuals with dementia tend to engage less in or withdraw from social activities before and after their diagnosis [7]. Although this decline may reflect a general tendency toward disengagement, many individuals still want to continue participating in activities that they find meaningful [8]. Supporting the well-being of people with dementia may therefore involve not only sustaining overall levels of participation but also enabling continued participation in personally meaningful activities [6].

XSL•FO
RenderX

Assistive technology, which ranges from purpose-built devices to research-based apps installed on everyday information and communication technologies (EICTs), has been widely explored as a support tool for people with dementia. It varies from memory aids and task-prompting systems to GPS tracking and communication technologies, targeting domains such as cognitive stimulation, assistance with daily activities, and social participation [9-11]. However, to date, most studies have been small-scale feasibility trials, and their findings often reveal only modest [10-12] or inconclusive effectiveness [13]. While modest evidence supports the use of assistive technology for memory support [10], task prompting [12], safety monitoring [9], and promoting social participation [11], assistive technology is rarely implemented in practice [14]. Users and caregivers frequently report barriers such as limited usability, low awareness, stigma, low accessibility, and inadequate technical support [15]. These challenges highlight the need to explore more pervasive alternatives to support the daily lives of individuals with dementia [10].

EICTs, particularly smartphones, have become deeply embedded in daily life. In 2022, smartphone ownership among adults ranged from 76% to 98% across 18 countries with available data; even among older adults aged 50 years and older, ownership rates reached 55% - 96% [16]. People increasingly rely on smartphones to engage in a variety of social and practical activities, such as sending messages, making video calls, searching for information, making digital payments, navigation, and booking restaurants [17]. The diversity of use reflects the fact that everyday social infrastructure is increasingly designed with smartphone users in mind. These integrated services facilitate self-initiated engagement and support the continuity of personally meaningful routines.

Importantly, some community-dwelling individuals with dementia spontaneously use smartphones in their daily lives [18,19]. They consider smartphones nonstigmatizing and enjoy exploring innovative ways to tailor them to their lifestyles [20]. Additionally, recent studies focused on training interventions have revealed positive learning effects and improved task performance in this population [21,22]. These findings suggest that smartphones can be commonly used by individuals with dementia and may serve as accessible tools to support autonomy and engagement. However, little is known about whether and how people with dementia spontaneously use smartphones and whether they leverage commercially available, but not research-based, apps and functions to maintain participation in social activities [10,11]. Gaining such insights could inform strategies to support individuals with dementia in effectively using commercially available EICTs to participate in their preferred social activities, thereby enhancing their well-being.

Objectives

In this study, we aimed to explore the role of smartphones in the lives of older adults with mild to moderate dementia. Specifically, we sought to (1) identify factors associated with spontaneous smartphone use, (2) describe these patterns of smartphone use in this population, and (3) examine whether smartphone users engage in more frequent social activities than nonusers do.

Methods

Study Design

We conducted a cross-sectional observational survey to explore smartphone use among individuals with mild to moderate dementia. The survey was carried out at 17 medical facilities where certified dementia support doctors, who have completed a 2-day governmental training course on community-based dementia care [23], provide outpatient dementia services. The study was conducted in collaboration with these doctors, who engaged with potential participants through outpatient services and provided their clinical information.

Study Settings

Between February and August 2024, data were collected from 17 medical facilities in Tokyo, including 4 hospitals and 13 primary care clinics. All participating hospitals were designated medical centers for dementia that provide memory clinic services through their psychiatric departments for outpatients and patients referred from nearby primary care clinics for diagnostic evaluation or management of severe behavioral and psychological symptoms of dementia (BPSD). The 4 hospitals exhibit varied institutional characteristics. They include an acute care hospital, a chronic care hospital, a psychiatric hospital, and a hospital offering a mix of acute and chronic care services, with bed capacities ranging from 126 to 550 beds. This diversity in hospital type and size reflects the heterogeneous nature of medical centers for dementia in Japan and allows inclusion of a range of clinical roles within regional dementia care.

The 13 primary care clinics were generally small, with 1-6 physicians affiliated with each clinic providing outpatient services on a rotating basis. Five clinics with multiple physicians offered dedicated outpatient sessions for dementia care. The remaining clinics provided care for individuals with dementia during general outpatient visits. In both clinic types, certified dementia support doctors typically collaborate with Medical Centers for Dementia to obtain diagnostic consultations and BPSD management. As this collaborative model between medical centers for dementia and primary care clinics is widely implemented throughout Japan under the national dementia policy, our study setting is likely to be representative of outpatient dementia care in other regions [24].

Participants

At the 17 participating medical facilities, the certified dementia support doctors screened individuals for eligibility based on the following criteria: (1) regularly attended medical appointments at the facility for longer than 6 months, (2) a clinical diagnosis of dementia, (3) a stage of mild cognitive impairment, mild dementia, or moderate dementia as determined using the "Functional Assessment Staging of Alzheimer's Disease" [25], and (4) sufficient cognitive capacity to provide informed consent. We excluded individuals with advanced medical conditions associated with comorbid conditions that suggested an end-of-life stage. The certified dementia support doctors screened their outpatients on a rolling basis until they reached a predetermined number of participants, which ranged from 5 to 30 depending on the volume of their outpatient clinic.

XSL•FO
RenderX

Procedure

Data were collected using 2 self-administered questionnaires, one for individuals with dementia (participants) and the other for their family members. Clinical information was recorded on a data sheet by the certified dementia support doctors. The doctors provided the participants and family members with the questionnaires and a return envelope addressed to the first author; the participants were instructed to return the completed questionnaires by postal mail within 2 weeks. The clinical data sheets were returned separately by the doctors via postal mail. A postal reminder was sent to participants if the completed questionnaires were not received within 2 weeks.

Participants were instructed to complete the questionnaires at home, with assistance from their family members only when necessary. To minimize reporting bias, the family members were instructed not to influence the participants' responses. The family members completed their own questionnaires independently and were requested not to discuss or share their responses with the participants. The doctors were blinded to the participants' and families' responses and were instructed to administer the Mini-Mental State Examination (MMSE) based on standardized written guidance.

Instruments

Participant Questionnaire

The participant questionnaire was used to collect the participants' baseline characteristics, including age, sex, years of education, marital status (married, single, divorced, or widowed), living arrangements (cohabiting or living alone), and perceived economic status (very poor, poor, fair, good, or very good). Factual information such as age and sex was cross-verified using the doctors' clinical data sheets as references. Sex was confirmed in 148 out of 151 (98%) cases, with the remaining 3 (2%) cases unverified owing to missing responses. For age, 131 out of 151 (87%) entries corresponded, while 17 (11%) entries differed by approximately 1 year, likely owing to differences in the time of data entry or recall errors. The 3 participants who did not report their sex also did not report their age. For consistency, we used the clinical sheet data for these variables.

The participant questionnaire also included a section on their mobile phone use, including daily use (smartphones, cellphones, or no use) and years of use. We provided smartphone users with a list of 25 general smartphone apps and functions (eg, calling, texting, maps, and videos) and inquired whether they used them weekly, occasionally, or never (Multimedia Appendix 1). The selection and categorization of apps and functions were informed by governmental surveys of the general public and by previously published studies examining tablet use among people with dementia [26,27]. Multinomial logistic regression was conducted with nonusers as the reference category. All independent variables were categorized as shown in the parentheses, with the first category used as the reference group in the regression analysis.

Family Questionnaire

The family questionnaire was used to collect demographic information, including age, sex, family relationship with the participant, and the frequency of time spent together (categorized as daily, weekly, monthly, or yearly). The remaining sections inquired about the individuals with dementia to assess their daily cognitive functioning, BPSD, and daily social functioning.

To measure daily cognitive functioning, the Dementia Assessment Sheet for Community-based Integrated Care System 8-items (DASC-8) was administered [28]. It is a validated tool for use in community and primary care settings [28] and is widely applied in Japan to assess cognitive and functional decline in older adults. It comprises 8 items covering memory, orientation, and basic and instrumental activities of daily living. Each item was rated by the family member on a scale ranging from 0 (independent) to 3 (fully dependent). In the present study, DASC-8 results demonstrated good internal consistency (Cronbach α=0.83).

To measure BPSD, the 5-item short-form version of the Dementia Behavior Disturbance scale (DBD-5) was used [29]. The DBD-5 is a brief caregiver-rated questionnaire developed to screen for BPSD in community and clinical settings; key behavioral issues such as aggression, agitation, and resistance to care are rated on a 5-point Likert scale ranging from 0 (never) to 4 (always). Moderate internal consistency of DBD-5 results was observed in this study (Cronbach α=0.67).

Daily social functioning was measured using the family-rated version of the Japanese Social Functioning in Dementia scale (SF-DEM-J) [30]. We selected its "Spending Time with Others" subscale for the purpose of this study because it captures clearly differentiated types of social activities that are relevant to those potentially supported or facilitated by smartphone functions [31]. This subscale contains 7 items related to social activities with friends or family, which broadly correspond to levels 3 and 4 of Levasseur taxonomy of social activities, encompassing social contact without performing a specific activity and performing an activity with others [32]. We opted for a carer-reported tool, as it has demonstrated higher reliability than patient-reported measures have [33]. Family members rated the social activities of the individuals with dementia over the previous month on a 4-point scale, ranging from 0 (never) to 3 (very often), with acceptable internal consistency (Cronbach α=0.69). Additionally, one question was derived from a different subscale of the SF-DEM-J to confirm that mobile phone use was associated with communication through phones.

Doctor's Data Sheet

The doctors recorded information on participants' dementia etiologies by selecting the following from a predefined list: Alzheimer disease, Lewy body dementia, frontotemporal dementia, vascular dementia, mixed dementia, others, or unknown. They administered the MMSE in accordance with standardized guidance and documented the resulting scores. Participants' comorbidities were selected from a predefined list on the data collection form, and the total number of comorbidities was calculated for each participant.

XSL•FO
RenderX

Data Analysis

The primary outcome of this study was the frequency of social activities, assessed using the "Spending Time with Others" subscale of the SF-DEM-J. The main exposure variable was the type of mobile phone used. Based on their self-reported usage, the participants were categorized into 3 groups, including smartphone users, cellphone users, and nonusers, with "use" defined as operating the device at least once a week. While the original study objective was to examine the association between smartphone use and social activity among individuals with dementia, a substantial portion of the participants reported using cellphones. Including the data of this group in the analysis provided an opportunity to explore a more nuanced gradient of technology use and its potential relationship with social engagement. Nonusers were used as the reference group in all analyses.

For objective (1), frequencies and percentages were calculated for each group (smartphone users, cellphone users, and nonusers) and compared using chi-square tests. Factors associated with the use of each device were modeled using multinomial logistic regression, with nonusers as the reference category. While exploring the most appropriate model using a list of candidate variables, we first eliminated those with weak associations (P<.20) in the chi-square tests. Spearman correlation coefficients were subsequently calculated among the remaining candidate variables. For each pair of variables with a correlation coefficient >0.40, one was considered for elimination. The variables retained in the final model were selected based on logical considerations and prior research evidence [34].

For objective (2), we assessed the descriptive data of 25 general smartphone apps and functions used by smartphone users.

For objective (3), we compared the total score for the frequency of social activities among smartphone or cellphone users with that among nonusers using linear regression analysis. To confirm the robustness of the association, comparisons were made using 3 different models: Crude, Model 1 that was adjusted for selected baseline characteristics, and Model 2 that was additionally adjusted for cognitive function. An item-level analysis of the frequency of each social activity was performed with adjustment for the Model 2 variables.

Missing values in the family-reported scales (ie, DASC-8, DBD-5, and SF-DEM-J subscale) accounted for less than 2% of the responses for each item; hence, they were imputed using the mean value of the family's available responses on the respective scale. Statistical significance was set at P<.05, and the Bonferroni method was applied to adjust for multiple comparisons in the interpretation of P values in the pairwise comparisons. All statistical analyses were performed using R version 4.4.3 (R Foundation for Statistical Computing).

Ethical Considerations

Written informed consent was obtained from the individuals with dementia and their family members to ensure that all parties were fully informed about the study's purpose, procedures, potential risks, and benefits. They were also assured that their participation was entirely voluntary and that they could withdraw at any time without consequences. Their survey responses would remain confidential and neither be shared with their attending physicians nor linked to any clinical evaluations. In addition, data were anonymized and stored securely, with access limited to the research team. Participants received a small token of appreciation for their participation. All the study procedures were approved by the Tokyo Metropolitan Institute for Geriatrics and Gerontology Research Ethics Committee (approval number: R23-090).

Results

Baseline Characteristics

A total of 165 individuals with dementia were screened, among whom 151 participated in the survey (response rate 92%). Their mean age was 82.9 years (SD 6.6), 95 out of 151 (63%) participants were women, and their average MMSE score was 20.9 (SD 4.6). Dementia etiologies were Alzheimer disease (107/151, 71%), Lewy body dementia (17/151, 11%), mixed dementia (17/151, 11%), vascular dementia (3/151, 2%), frontotemporal dementia (1/151, 1%), and other or unknown (6/151, 4%). Out of 151 individuals, 43 were smartphone users (29%), 30 were cellphone users (20%), and 78 were nonusers (52%). The family members had a mean age of 63.9 years (SD 12.8), and out of 151 individuals, 112 (75%) were women. Their relationships with the participants were spouse (53/151, 35%), child (90/151, 60%), son- or daughter-in-law (4/151, 3%), and others (4/151, 3%). The majority (103/151, 68%) lived with the participants, and they spent time together on a daily (112/151, 74%), weekly (27/151, 18%), or monthly (12/151, 8%) basis.

Differences among participants recruited from hospitals and clinics were observed in several socioeconomic and functional characteristics (Multimedia Appendix 2). Participants recruited from the 4 hospitals tended to be younger, more often male, had higher educational attainment, were married, and reported a better perceived economic status than those recruited from the 13 primary care clinics. Participants recruited from hospitals also demonstrated slightly higher levels of cognitive and physical functioning.

Mobile Phone Users

Smartphone users were significantly younger (P=.002), had more years of education (P=.002), and demonstrated better cognitive function (P=.004 for MMSE score and P<.001 for DASC-8 score) than nonusers did (Table 1). The multivariable predictive model (Table 2) confirmed that an older age was associated with a lower likelihood of smartphone use (odds ratio [OR] 0.41, 95% CI 0.21-0.80; P=.009), while more years of education (OR 1.82, 95% CI 1.00-3.30; P=.05) and a higher MMSE score (OR 2.14, 95% CI 1.24-3.69; P=.007) were positively associated with smartphone use. In addition, living alone was significantly associated with a higher likelihood of smartphone use (OR 3.17, 95% CI 1.08-9.31; P=.04).

Table . Factors associated with mobile phone use compared to nonuse.

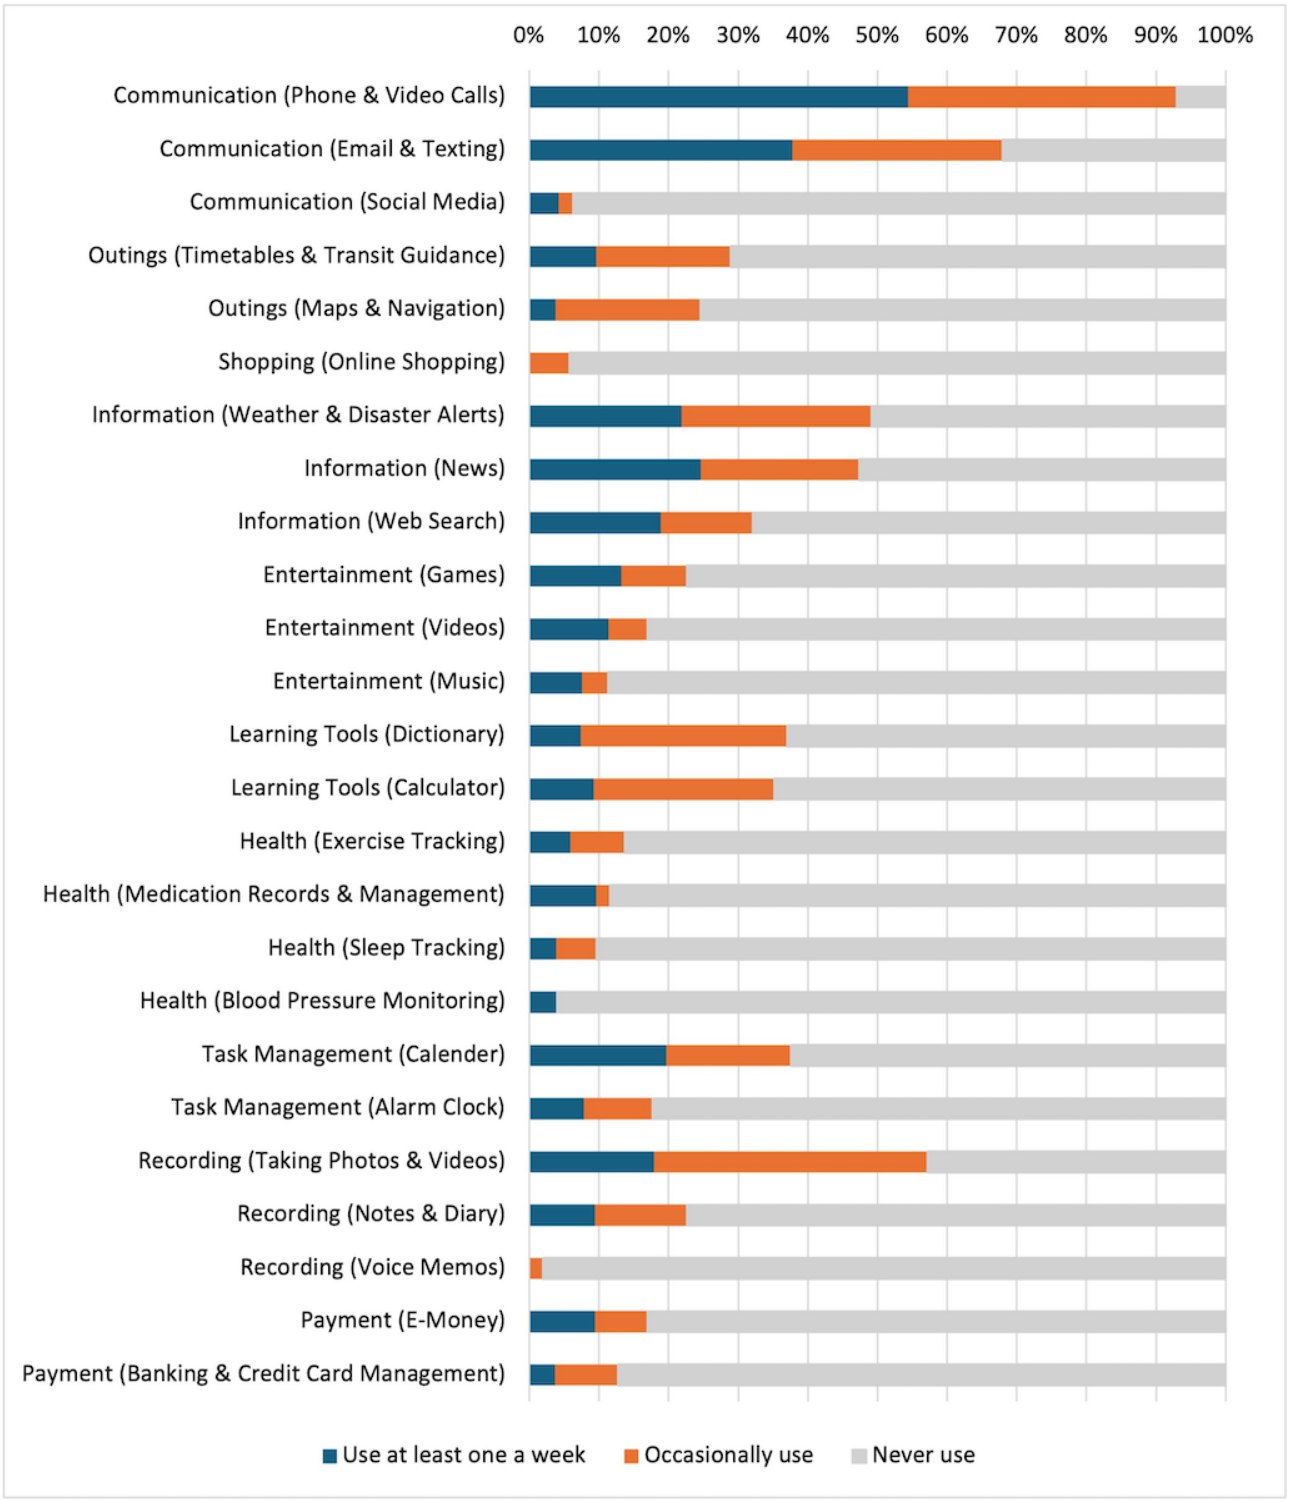
Participant factor[a]	Smartphone use		Cellphone use	
	OR[b] (95% CI)	*P* value	OR (95% CI)	*P* value
Age (years), ≤74, 75-84, and ≥85 (years)	0.41 (0.21-0.80)	.009	0.67 (0.33-1.36)	.26
Gender (men and women)	0.68 (0.26-1.74)	.42	0.43 (0.16-1.17)	.10
Education (years), ≤9, 10-12, and ≥13 (years)	1.82 (1.00-3.30)	.05	1.08 (0.59-1.98)	.80
Living arrangement (cohabiting, living alone)	3.17 (1.08-9.31)	.04	3.37 (1.12-10.13)	.03
MMSE[c] score (8-19, 20-23, 24-30)	2.14 (1.24-3.69)	.007	1.67 (0.94-2.98)	.08

[a]Multinomial logistic regression was conducted with nonusers as the reference category. All independent variables were categorized as shown in the parentheses, with the first category used as the reference group in the regression analysis.

[b]OR: odds ratio.

[c]MMSE: Mini-Mental State Examination.

Cellphone users presented less distinctive characteristics. Age, years of education, and MMSE score were not significantly associated with cellphone use (*P*=.45, *P*=.45, and *P*=.12, respectively; Table 1). In the multivariable predictive model, women were marginally less likely to use cellphones (OR 0.43, 95% CI 0.16-1.17; *P*=.10), and a higher MMSE score was marginally associated with cellphone use (OR 1.67, 95% CI 0.94-2.98; *P*=.08). The only factor that was significantly associated with cellphone use was living arrangements: cellphone users were 3.37 times more likely to live alone (OR 3.37, 95% CI 1.12-10.13; *P*=.03).



Patterns of Smartphone Use

Among the 43 smartphone users, more than 3-quarters had been using a smartphone for longer than 3 years. Specifically, the duration of smartphone use was up to 1 year for 5 out of 43 (11%) individuals, up to 3 years for 5 out of 43 (11%) individuals, up to 5 years for 14 out of 43 (32%) individuals, and up to 10 years for 20 out of 43 (46%) individuals.

Smartphones were used most often for communication, reading the news, and taking photos and videos (Figure 1). Out of 43 smartphone users, 40 (93%) made phone and video calls more than once a week or occasionally, while 27 (63%) used email and texting. Approximately half of the smartphone users used weather and disaster alerts (20/43, 47%), accessed news (20/43, 47%), and took photos and videos (24/43, 56%). However, apps and functions that could assist out-of-home activities were less likely to be used, as only 11 out of 40 (26%) used transit guidance and navigation systems and 7 out of 40 (16%) made digital payments. Regarding cognitive aid features, 16 out of 40 (37%) used calendars, 9 out of 40 (21%) used notes and diaries, and 7 out of 40 (16%) used alarm clocks. Health monitoring or tracking apps (such as for exercise, medication, and sleep) were used by 5 out of 40 (12%) or fewer smartphone users.

XSL•FO
RenderX

Figure 1. Purposes of smartphone use (n=43).

Mobile Phone Use and Participation in Social Activities

The mean scores on the "Spending Time with Others" subscale of the SF-DEM-J were 6.0 (SD 3.6) for smartphone users, 5.1 (SD 4.1) for cellphone users, and 4.4 (SD 3.2) for nonusers. We first confirmed that mobile phone use was associated with more frequent telephonic communication with friends and family members. After adjusting for age, sex, years of education, living arrangements, and MMSE score, both smartphone use (b=1.07, 95% CI 0.73-1.41; *P*<.001) and cellphone use (b=0.73, 95% CI 0.37-1.10; *P*=.001) showed significant associations.

Table 3 shows the results of the stepwise linear regression analyses examining the association between mobile phone use and the frequency of social activities, as measured using the "Spending Time with Others" subscale of the SF-DEM-J, with nonusers as the reference group. In the crude model, smartphone use was significantly associated with higher social activity scores (b=1.55, 95% CI 0.24-2.86; *P*=.02). This association remained marginally significant after adjusting for age, sex, years of education, and living arrangements in Model 1 (b=1.26, 95% CI −0.13 to 2.64; *P*=.07) and additionally for MMSE score

XSL•FO
RenderX

in Model 2 (b=1.41, 95% CI −0.01 to 2.83; *P*=.05). Cellphone use, by contrast, was not significantly associated with social activity levels in any of the models.

Table . Association between mobile phone use and frequency of social activities.

Participant factor	Crude[a]		Model 1[b]		Model 2[c]	
	b (95% CI)	*P* value	b (95% CI)	*P* value	b (95% CI)	*P* value
Smartphone use	1.55 (0.24 to 2.86)	.02	1.26 (–0.13 to 2.64)	.07	1.41 (–0.01 to 2.83)	.05
Cellphone use	.60 (–0.90 to 2.09)	.44	.58 (–0.92 to 2.09)	.45	.68 (–0.83 to 2.20)	.38

[d]MMSE: Mini-Mental State Examination.

[e]Not applicable.

Figure 2 presents the item-level analysis of the association between mobile phone use and the frequency of specific social activities, adjusted for the covariates in Model 2. Smartphone users reported significantly more frequent visits to the homes of friends or family members (b=0.43, 95% CI 0.08-0.78; *P*=.02) and shopping trips with friends or family members (b=0.49, 95% CI 0.15-0.83; *P*=.005) than did nonusers. Most of the other social activities showed nonsignificant but positive associations with smartphone use. In contrast, among cellphone users, none of the individual items reached statistical significance, although many showed positive trends.

All estimates were adjusted for baseline characteristics and cognitive function, including age, sex, education, living arrangements, and MMSE scores.

Discussion

Principal Findings

In this cross-sectional study of community-dwelling older adults with mild to moderate dementia, 29% were regular smartphone users, most for longer than 3 years. Smartphone use was independently associated with a younger age, more years of education, living alone, and better cognitive function. The top five smartphone uses were (1) making phone and video calls, (2) sending emails and texts, (3) taking photos and videos, (4) checking the weather, and (5) reading the news. Functions that could more directly aid cognitive function (eg, notes and alarms) and out-of-home social participation (eg, GPS navigation and digital payments) were not often used. Although both smartphone and cellphone users reported more frequent telephonic communication with their friends or family members, only smartphone use was associated with a higher overall score for participation in social activities after adjusting for demographic and cognitive variables. At the activity level, smartphone users reported significantly more frequent visits to the homes of friends and family members and more frequent shopping trips with friends and family members than did nonusers.

Predictors of Smartphone Use

While our participants used smartphones less often than the general older adult population does, their adoption was observed among a substantial proportion of older adults with dementia in their 70s and 80s (mean age 82.9, SD 6.6 years). In 2023, the rates of smartphone use among the general older adult population in Japan were 71% for those aged 65 - 74 years and 38% for those aged 75 years and older [17]. Among our participants with dementia in the same age groups, the rates were lower at 38% and 23%, respectively. Directly comparable data are limited because most studies on smartphone use among individuals with dementia are feasibility or qualitative studies with small sample sizes [10,20,35]; nevertheless, these studies provide some context. In 2016, 75% of 53 individuals (mean age 64.9, SD 13.3 years) who visited a memory clinic for cognitive evaluation in the United States owned a smartphone [36]. In France (2013 - 2015), 33% of 323 older adults (mean age 75.9, SD 7.0 years) who underwent cognitive assessment at a memory clinic reported the regular use of smartphones or tablets [18]. Considering that these rates are from approximately a decade ago, when smartphone adoption among the general older population was 25% - 55% lower [16], the relatively low use among our participants likely reflects their older age and lower cognitive function rather than a persistent trend among individuals with dementia. As smartphone use has become more widespread among older adults in general [16,17], a similar increase can be expected in individuals with dementia.

XSL•FO
RenderX

Consistent with previous findings, we found that a younger age, higher educational level, and better cognitive function were associated with smartphone use [10]. Notably, living alone emerged as a significant predictor of smartphone use. This trend has rarely been explored [10] but may reflect the increasing number of individuals with dementia who live alone [37] and the heightened risk of loneliness in this group [38]. Smartphones may serve as a compensatory tool for maintaining independent living and social connections among these individuals, and this warrants further investigation [39].

Usage Patterns

Commonly reported smartphone uses included communication, searching for information, and taking photos or videos, while the use of features that could more specifically aid cognitive function and out-of-home activities was limited. Similar trends were reported in a US study conducted in 2016, where social and general-purpose functions (eg, email, photos, and news) were favored over cognitive aids (directions, to-do lists, alarms, and reminders) [36]. However, a more recent UK study (2021), in which 29 younger adults with dementia (aged 56 - 78 years) were interviewed, revealed that they actively explored and enjoyed using various smartphone features, including calendars, reminders, and health-tracking apps [20]. These individuals likely developed smartphone proficiency before cognitive decline, which enabled them to integrate EICTs into their daily lives despite their impairments [39]. Given that cognitive aid features have proven both preferred and effective in prior research [10,14], our findings suggest that older individuals such as those who participated in our study may benefit from additional support to effectively use them [34].

Associations With Participation in Social Activities

Although both smartphone and cellphone use were associated with more frequent phone communication with friends and family members, only smartphone use was associated with greater overall social activity. Prior research has revealed that research-based assistive technologies and EICTs, which typically apply cognitive aid features and are tailored to the needs of individuals with dementia, can supplement daily cognitive functions [10,12] and enhance social participation [11]. Our findings suggest that the benefits of these specialized technologies may also be transferable to commercially available smartphones. However, given the limited usage patterns observed among our participants, there remains untapped potential to expand the impact of smartphones through improved design and tailored support [14,20].

Smartphone use was significantly associated with visiting the homes of friends and family members and shopping together, with a marginal significance also observed for going to cafés, restaurants, pubs, or social clubs. In contrast, no significant association was found for attending community or religious meetings, going on trips, or participating in events. These findings align with those of a multinational study of 163 individuals with mild dementia, in which the authors reported that out-of-home participation was most frequent in familiar, informal activities such as visiting friends and local shopping, whereas engagement in more complex or unfamiliar activities was less common [40]. This pattern suggests that individuals with dementia use smartphones to stay engaged in familiar, emotionally rewarding routines that require minimal cognitive planning [8]. Accordingly, support strategies should be focused on enabling them to sustain meaningful activities with familiar social connections rather than on expanding participation into less familiar domains.

Implications

Our findings suggest that commercially available smartphones can serve as meaningful tools for older adults with dementia to maintain social connections and engage in valued social activities. However, the predominant use of basic communication and information functions indicates a missed opportunity to leverage the full potential of smartphone features that can promote independence and social participation. Given the promise of EICT training interventions [21], tailored strategies are needed to help individuals with dementia to use smartphone functions in personally meaningful ways, focusing on preferred activities and offering training in practical tools such as calendars, reminders, and digital payment systems that can directly support these activities.

Strengths and Limitations

This study has several strengths. First, multisite recruitment reflecting collaborative dementia care systems involving medical centers for dementia and primary care clinics enhanced sample diversity, which improved the robustness of the findings across different care settings. Participants recruited from hospitals and primary care clinics differed in sociodemographic and functional characteristics. Second, the inclusion of both patient- and caregiver-reported data allowed for a more comprehensive understanding of smartphone use and social participation, particularly in cases where cognitive limitations might have affected self-reporting. Third, the item-level analysis of social activities provided more nuanced insights into how smartphone use relates to specific aspects of everyday life.

However, several limitations should also be noted. The cross-sectional design prevents any conclusions about causality between smartphone use and social activity. Additionally, reliance on caregiver-reported outcomes may introduce reporting bias, particularly in cases where caregivers had limited knowledge of the participants' daily routines. Finally, the findings may not be generalizable to individuals with more advanced dementia or those not receiving regular medical care, as this study focused on community-dwelling older adults with mild-to-moderate dementia who were recruited through outpatient dementia services.

Future Research Directions

In the future, researchers should examine how spontaneous smartphone use changes over the course of cognitive decline and whether sustained use contributes to better social and psychosocial outcomes. Longitudinal studies are required to clarify these relationships. Moreover, efforts should be focused on identifying effective ways to support and expand the use of commercially available smartphones among older adults with dementia, particularly to enhance their participation in meaningful social activities. Given the limited use of cognitive aid and out-of-home activity features observed in our study,

XSL•FO
RenderX

targeted training or supportive environments would reduce barriers and facilitate more effective use of these functions. Collaborating with individuals with dementia in the design of such training programs and environments may further enhance their relevance and effectiveness.

Conclusions

Our findings highlight that a substantial proportion of community-dwelling older adults with mild to moderate dementia continue to use smartphones primarily for basic communication and information access. While smartphone use was associated with greater telephonic contact and overall social activity, apps and functions that could support independence and social participation were underused. These findings emphasize the potential of commercially available smartphones as meaningful tools for maintaining social engagement in dementia care. Targeted support may help bridge the gap between current usage and the broader capabilities of these devices, enabling individuals with dementia to sustain valued routines and social participation in daily life.

Acknowledgments

We sincerely thank the doctors at the participating medical facilities for their valuable support in data collection and their contributions to the successful completion of this study.

Abstract

Background: Smart glasses might present a promising solution to support older adults with cognitive impairment in maintaining independence. However, there exists a critical gap in smart glasses research that incorporates recently developed models or directly engages older adults with cognitive impairment.

Objective: This study aimed to use survey and interview techniques to explore the acceptability and usability of smart glasses among older adults with cognitive impairment.

Methods: This explanatory mixed methods descriptive study was conducted at an independent living older adult apartment building among residents with memory complaints or cognitive impairment. This study consisted of a quantitative survey (N=26), followed by smart glasses beta testing with qualitative interviews (n=14).

Results: Overall, older participants with cognitive impairment conveyed a generally positive perception of smart glasses and their potential to support memory in daily life. Results suggest that participants prioritized the following smart glasses functions: audio reminders, phone calls, GPS, and distress signals, with audio reminders emerging as the highest-ranked feature. Additionally, participants emphasized the value of an intuitive and quick interface and a preference for audio, rather than visual, information exchange.

Conclusions: This study supports the development and study of smart glasses for older adults with mild cognitive impairment. Smart glasses developers should place great importance on usability, such as intuitive command interfaces, and equip the smart glasses with functions that are relevant to this population, especially audio reminders. Additionally, future work should examine the integration of smart glasses over a longer period and among a larger sample of older adults with cognitive impairment.

technology; cognitive impairment; smart glasses; dementia; older adults

Introduction

Older Adults With Cognitive Impairment: Prevalence and Burden

Cognitive impairment is a condition associated with a decline in one or more cognitive functions such as memory, attention, reasoning, language, problem-solving, and decision-making [1-3]. The severity of cognitive impairment can range from mild cognitive impairment to more advanced conditions, including severe dementia. In mild cognitive impairment, individuals might struggle with complex tasks such as managing medications and making phone calls, but more basic self-care tasks remain largely preserved [3,4]. The global prevalence of cognitive impairment among community-dwelling older adults is approximately 19%, and this prevalence is expected to rise as the population ages [1,2]. Among older adults who are economically disadvantaged, the onset of cognitive impairment occurs earlier, and the prevalence of cognitive impairment is higher [5,6].

Cognitive impairment is often associated with depression and limitations in activities of daily living, significantly affecting an individual's quality of life [7]. Caregivers of individuals with

XSL•FO
RenderX

cognitive impairment may also experience emotional, physical, or financial strain due to the sequelae of symptoms associated with cognitive impairment [8,9]. While some research indicates that cognitive training, physical activity, and pharmacological interventions can delay the progression of cognitive impairment, no cure currently exists [10-14]. Consequently, innovative solutions are needed to help individuals maintain independence as they live with their cognitive impairment.

Smart Devices to Assist Older Adults With Cognitive Impairment

Smart devices are defined as context-aware electronic tools that are capable of performing autonomous computing and connecting for data exchange [15]. They present innovative solutions to support older adults with cognitive impairment in maintaining independence. For example, researchers have explored smartphones, smart wristwatches, and tablet-based applications to assist with cognitive training or function as an external memory aid [16-19]. Similarly, researchers have investigated virtual assistant smart speakers, such as Google Home or Amazon Alexa, to provide in-home support to older adults living in the community with cognitive impairment [20,21]. While such technologies demonstrate promise in supporting older adults with cognitive impairment in living independently, common acceptability and usability barriers include nonintuitive interfaces, a lack of personalization and accessibility, and technology literacy limitations among older adults [16,20,21]. Over the past decade, a new type of smart device—smart glasses—has emerged as a potential tool to assist individuals with memory-related challenges [22]. Unlike other technological interventions, glasses are a familiar and commonly worn accessory among older adults, potentially making smart glasses a more natural and accepted aid.

The History of Smart Glasses

For the purposes of this paper, smart glasses are defined as an eye-worn device that provides functions similar to a computer to assist and augment the wearer [23]. The release of the Google Glass Explorer Edition from 2013 to 2014 marked the first consumer-grade smart glasses available to the public. However, issues such as unattractive designs, privacy concerns, and high cost led to its limited adoption, and the product was discontinued in 2015 for purchase by general consumers [24-26]. In 2017 and 2019, Google released updated versions, Google Glass Enterprise Edition and Google Glass Enterprise Edition 2, marketed more specifically to businesses; these were discontinued in 2023 [27]. Around this time, the first models of mixed reality headsets were also released, such as the Microsoft HoloLens (2016) [28] and the Magic Leap One (2018) [29]. While at the forefront of innovation in fields such as health care, manufacturing, education, and defense, these devices were still largely considered niche industry products and not marketed to or adopted by general consumers [28-31]. Additionally, their bulky design and lack of portability raise questions about whether the devices should be classified as “smart glasses”—in addition to a headset [22].

In the last 5 years, advancements in features, esthetic, and affordability have led to the growing integration of smart glasses into everyday life, especially among younger individuals [32]. Current models incorporate advanced technologies, including cameras, microphones, GPS, and accelerometers, while maintaining the appearance of regular eyewear [22]. These features enable functionalities such as voice assistance, navigation, reminders, photo live or live stream, and social connection, provided in a more discreet manner. Of note, some commercial smart glasses are becoming powered with advanced artificial intelligence (AI; eg, Ray-Ban Meta) and augmented reality technology (eg, Vuzix V100), defined as digital information overlaid onto the real environment [33]. Given the recent technological and esthetic improvements of commercial smart glasses, alongside the increasing population burden of cognitive impairment, further research is necessary to explore their acceptability and usability among older adults.

Smart Glasses Research and Gap

To contextualize this topic, our research team recently conducted a systematic scoping review on smart glasses for older adults with cognitive impairment [22]. Among the 13 studies identified, only 5 [34-38] involved older adults in hands-on testing of the smart glasses, and only 1 study [37] exclusively recruited older adults living with cognitive impairment, though it was limited by a small sample size (n=6). Additionally, all included studies in the review focused on earlier generations of commercial smart glasses, such as Google Glass and HoloLens, or early-stage rudimentary prototypes (ie, regular glasses with components added to the side arm of the glasses frames). Our review underscores a critical gap in research that incorporates recently developed smart glasses models and directly engages older adults with cognitive impairment. To address this gap, this study aimed to use survey and interview techniques to explore the acceptability and usability of smart glasses among older adults with cognitive impairment. For the purposes of this paper, and consistent with the Sekhon Theoretical Framework of Acceptability, we define acceptability as “the extent to which people delivering or receiving a health care intervention consider it to be appropriate, based on anticipated or experienced cognitive and emotional responses to the intervention” [39]. Next, consistent with the International Organization for Standardization (ISO 9241 - 11), we define usability as “the extent to which a system, product, or service can be used by specified users to achieve specified goals with effectiveness, efficiency, and satisfaction in a specified context of use” [40]. The results from this study will guide researchers in selecting appropriate smart glasses and guide engineers in developing smart glasses that are more accessible and relevant for this population across both research studies and real-world settings.

Methods

Study Design

This was an explanatory mixed methods descriptive study to explore the acceptability and usability of smart glasses among older adults with cognitive impairment and consisted of two phases: (1) a quantitative survey and (2) smart glasses beta testing with qualitative interviews.

XSL•FO
RenderX

Participants

Given the high prevalence and burden of cognitive impairment among economically disadvantaged older adults [5], we recruited participants from an income-controlled independent living older adult apartment building in Baltimore. We recruited participants through flyers posted in the apartment building and a brief on-site presentation about the project. Residents were eligible if they met the following criteria: (1) scored 4 or lower on the Mini-Cog [41] or 3 or higher on the Memory Complaint Scale [42], and (2) passed the Evaluation to Sign Consent Measure [43], which assessed whether participants understood the study purpose, risks, and withdrawal rights. As we specifically invited residents who perceived themselves as having memory problems or forgetfulness, nearly all residents (26/27) who expressed interest in the study were eligible based on the cognitive screening criteria. For phase 1 (surveys), we enrolled all interested residents who met the eligibility criteria. For phase 2 (glasses testing and interviews), we randomly selected phase 1 participants for interviews until we achieved data saturation, defined as redundancy of data with no newly emerged themes [44].

Ethical Considerations

The University of Maryland, Baltimore, Institutional Review Board approved the protocol for this study (HP-00109956). We informed participants of the study procedures, risks, benefits, and withdrawal rights prior to participation. We protected confidentiality by assigning unique study IDs to participants and storing all identifiable data on secure, password-protected servers and in a locked office within a locked cabinet. Participants provided informed consent prior to participation. Participants received a US $30 incentive for completing the survey and interview, respectively.

Procedures

During phase 1, we administered a paper-based quantitative survey, which we read aloud and completed for participants upon request. Once phase 1 was completed for all participants, we purchased 3 different pairs of smart glasses that best aligned with participants' preferences and priorities, as informed by the survey feedback: Ray-Ban Meta smart glasses, Alexa Echo Frames, and Vuzix Blade 2 smart glasses. The 3 pairs of selected smart glasses have many similarities, such as including a speaker and a microphone. One primary distinction is that the Alexa Echo Frames do not have a camera, whereas the other 2 devices do. Additionally, Vuzix Blade 2 smart glasses provide augmented reality functionality, which is not available in the other 2 smart glasses.

During phase 2, a random sample of participants from phase 1 beta-tested these 3 pairs of smart glasses and provided qualitative interview feedback. During beta testing, each participant completed a task list for each pair of glasses, guided by the research assistant, as detailed in Textbox 1. Glasses testing took approximately 20 minutes per pair, for a total of 60 minutes. Participants tested the glasses pairs in a rotating order to minimize order effects. For example, participant 1 tested Ray-Ban Meta smart glasses first, Alexa Echo Frames second, and Vuzix Blade 2 smart glasses third. Alternatively, participant 2 tested Alexa Echo Frames first, Vuzix Blade 2 smart glasses second, and Ray-Ban Meta smart glasses third.

Textbox 1. Participants' beta-testing task list.

Ray-Ban Meta smart glasses

- "Hey Meta, how is the weather outside?"
- "Hey Meta, remember for my shopping list I'll need eggs, milk, and bread."
- "Hey Meta, play [insert favorite music]."
- "Hey Meta, remember that I put my purse/wallet by the door."
- "Hey Meta, remember this book."
- "Hey Meta, remind me in 2 minutes to take my medications."
- "Hey Meta, where is the closest Safeway to me?"
- "Hey Meta, what street am I on?"
- "Hey Meta, look and tell me what this says in English?"
- "Hey Meta, what items are on my shopping list?"
- "Hey Meta, look at this snack and tell me if it's healthy."
- "Hey Meta, look at this cooking tool and tell me what it is called."
- "Hey Meta, look at this recipe and summarize it. Hey Meta, remind me what I do after microwaving the butter."
- "Hey Meta, take a photo now and send it to [research assistant]."
- "Hey Meta, call [research assistant]."
- "Hey Meta, take a picture of this flyer so I can refer to it later."
- "Hey Meta, remind me where I put my purse today. What was the book I wanted to remember?"
- "Hey Meta, play 'Mindfulness for Beginners' on the Calm app."

Alexa Echo Frames

- "Hey Alexa, how is the weather outside?"
- "Hey Alexa, play [insert favorite music]."
- "Hey Alexa, remind me in 2 minutes to take my medications."
- "Hey Alexa, where is the closest Safeway to me?"
- "Hey Alexa, what is the metal tool you use to beat eggs?"
- "Hey Alexa, what items are on my shopping list?"
- "Hey Alexa, are raisins healthy?"
- "Hey Alexa, call [research assistant]."
- "Hey Alexa, what's on my 'to do' list?"
- Participant demonstrates the "find my" function within app (GPS tracking).
- "Hey Alexa, turn off lights."

Vuzix Blade 2 smart glasses

- Scroll through apps with voice: "Hey Vuzix. Move right. Move left."
- Scroll through apps with fingers.
- Select notifications with fingers.
- Select notifications with voice: "Hey Vuzix, notifications."
- Determine preferred method (audio or voice).
- Take a picture with preferred method.
- Take a video with preferred method.
- Navigate to Microsoft Teams and check calendar with preferred method.
- Make a call with preferred method.

XSL•FO
RenderX

Measures

Phase 1

The phase 1 quantitative self-report survey consisted of three sections, which assessed (1) demographics, including age, gender, living alone status, comorbidities, and financial strain; (2) frequency of technology use; and (3) preferred smart glasses functions. To assess the frequency of technology usage, we administered the FACETS (Functional Assessment of Currently Employed Technology Scale) [45], a validated and reliable 10-item questionnaire that measures the frequency of technology use across the following areas: sending emails, accessing files, sending text messages, posting on social media, online banking, online purchases, telehealth, communicating with health insurance online, installing computer components, and resetting a modem or router [45]. We removed the last 2 items, which were less pertinent to those who live in the congregate affordable housing setting, many of whom primarily use smartphones and public building Wi-Fi. Item responses ranged from 0 ("never") to 5 ("daily/prefer"). Thus, total scores ranged from 0 to 40, with higher scores indicating greater technology usage.

As this work is exploratory, no validated survey currently exists that examines the preferred functions of smart glasses. Instead, we developed the "preferred functions" items based on our clinical expertise with this population and dementia-friendly survey guidelines from the Alzheimer's Society [46]. This section contained 17 Likert-style questions in which participants rated smart glasses' potential functions as "not helpful," "slightly helpful," "very helpful," and "most helpful." Participants then reported the 3 "best" smart glasses functions from all listed functions. The survey is provided in Multimedia Appendix 1.

Phase 2

Immediately following the testing of each of the three pairs of glasses, the participants answered five open-ended questions: (1) What did you like best about these glasses? (2) What did you like least about these glasses? (3) What function did you like best for these glasses? (4) What function did you like least for these glasses? (5) Is there anything else you would like to share about these glasses? Upon completing beta testing for all 3 pairs, participants responded to five additional overarching questions: (1) What did you think of the smart glasses overall? (2) Describe the glasses you liked the best and why. (3) Describe the smart glasses functions you liked the best and why. (4) Are there any functions you wish smart glasses could have that these did not? (5) Why or why not do you think smart glasses could be used to help with memory? We intended the questions about participants' likes, dislikes, and overall impressions to capture acceptability, while the questions about specific functions, ease of use, and desired features were intended to capture usability. To maintain consistency, a single interviewer (BFB) with qualitative interviewing expertise conducted all interviews. The interviewer provided assistance as needed, while avoiding leading questions or comments. The interviewer transcribed the feedback verbatim in real time.

Analysis

After collecting phase 1 quantitative surveys, we conducted descriptive statistics and applied data visualization approaches to summarize the quantitative results. Specifically, we obtained mean FACETS results and ranked participants' preferred smart glasses functions based on how frequently each was identified as "the best function" or placed among the top three functions.

One study researcher (BFB) conducted a content analysis to organize and interpret the qualitative data. This process consisted of (1) codebook creation, (2) familiarization with the data, (3) data organization, and (4) data interpretation. First, BFB created the codebook in a deductive manner, based on the topics and questions in the interview guide, reflecting the study aims. This codebook contained the codename, when the code should be used, when the code should not be used, and an example corresponding quotation. Second, and consistent with content analysis, BFB engaged in data familiarization by reading each interview twice. Third, BFB used MaxQDA (VERBI Software), a qualitative data management software, to organize and match segments of text with codes that aligned with them. This coding process was iterative in nature. After coding the first 2 interviews, BFB refined the codebook to capture the advantages and disadvantages of each pair of smart glasses with greater granularity. The finalized code names, subcode names, and their frequency of use are listed in Multimedia Appendix 2. Finally, following the methods outlined by Merriam and Tisdell [47], codes were interpreted so that those with similar concepts were merged into categories, and categories were further integrated into themes.

Once the themes were identified and summarized, a second researcher (NK) independently familiarized herself with the qualitative interview data for the purpose of peer-debriefing. During peer debriefing, BFB and NK met to engage in reflexive dialogue, assess for any themes not expressed within the results, consider alternative interpretations of the data (rival explanations), or identify data that did not align with our current conclusions (negative cases). This collaborative process was conducted to enhance the trustworthiness and credibility of our results. While the peer debriefing did not result in the addition of any new themes, it served as the catalyst for a more detailed explanation of participants' preferred smart glasses functions.

The research team then met to compare survey data results with interview findings, identifying convergent, complementary, and divergent conclusions.

Following triangulation, the research team returned to the older adult apartment building to present results and conduct member checking with available participants (n=18). During this session, participants were asked, as a group, to provide feedback on (1) conclusions that reflected their experience and perspective, (2) conclusions that misrepresented their experience or perspective, and (3) any additional insights that were missing or they wanted to share. In response, participants conveyed that the major conclusions drawn by the research team resonated with their experience and perspective. Of note, 2 small changes were made due to the member checking session; namely, language translation was removed from the list of functions described as least helpful, and facial recognition was added within the "Recommendations for Functions Smart Glasses Should Do" section.

Results

Overview

Among the 26 older adult participants, 16 (61.54%) identified as female, 18 (69.23%) identified as Black or African American, and 14 (53.85%) reported some level of financial strain (Table 1). The participants scored an average of 3.50 (SD 1.42) on the Mini-Cog and 7.62 (SD 3.40) on the Memory Complaint Scale, suggesting that participants overall had an average of mild cognitive impairment, although there was a range of cognition from mild to severe cognitive impairment and memory complaints. Participants scored a mean of 27.88 (SD 13.39) on the modified FACETS, demonstrating moderate technology use across most domains [45]. Participants' frequency of technology use was highest for online banking and SMS text messaging and lowest for social media use and accessing files.

Table . Participant characteristics (N=26).

Characteristics	Values
Comorbidities, mean (SD)	2.3 (2.06)
Mini-Cog, mean (SD)	3.50 (1.42)
Memory Complaint Scale, mean (SD)	7.62 (3.40)
FACETS[a], mean (SD)	27.88 (13.39)
Send email	3.35 (2.06)
Find, open, and close files	2.92 (2.19)
SMS text messaging	4.31 (1.98)
Post on social media	2.11 (1.93)
Manage banking online	4.27 (2.13)
Pay bills and make purchases online	4.15 (2.31)
Communicate with doctor online	3.62 (2.26)
Communicate with health insurance company online	3.15 (2.33)

[a]FACETS: Functional Assessment of Currently Employed Technology Scale.

Quantitative Survey Results

All 26 participants completed the survey with no missing data. Consistently, participants identified audio reminders as the "best" smart glasses function. Specifically, 8 (30.77%) participants ranked audio reminders as the "best" smart glasses function, and 14 (53.85%) participants ranked audio reminders in the top 3 smart glasses functions. Following audio reminders, the following functions were the most valued by participants: phone calls, GPS, so that their loved ones can locate them, and sending distress signals. Conversely, the following functions were reported as least helpful by participants: playing music, cognitive training, subtitles during conversation, companionship and conversation, and providing video or photos for family. All participants (100%) stated that they would be willing to wear smart glasses that assist with memory; however, 6 (23.08%) reported that the glasses *must* look and feel like normal glasses to warrant wear.

RenderX

Qualitative Interview Results

Overview

A random sample of 14 participants beta-tested 3 pairs of smart glasses: Ray-Ban Meta smart glasses, Alexa Echo Frames, and Vuzix Blade 2 smart glasses. We selected these 3 devices because of their capacity to provide reminders, make calls, and provide GPS functionality, consistent with preferences from the quantitative survey results. After beta testing the 3 pairs of smart glasses, the participants provided qualitative feedback. This feedback is described below, consisting of six themes: (1) perceived advantages and disadvantages of Ray-Ban Meta smart glasses, (2) perceived advantages and disadvantages of Amazon Alexa Echo Frames, (3) perceived advantages and disadvantages of Vuzix Blade 2 smart glasses, (4) preferred smart glasses and functions, (5) broad smart glasses concerns, and (6) recommendations for functions smart glasses should do. Additional participant quotations reflecting the themes can be found in Multimedia Appendix 3.

Perceived Advantages and Disadvantages of Ray-Ban Meta Smart Glasses

Participants conveyed the most favorable feedback toward the Ray-Ban Meta smart glasses. These favorable views were due to the following: (1) an intuitive and quick interface, (2) functions that they perceived were relevant to them, and (3) comfort and esthetics. First and foremost, participants overwhelmingly appreciated that the Ray-Ban Meta smart glasses were simple to use and responded clearly, quickly, and precisely to their commands. Participant 4 described:

> *They were just real simple. Not a lot involved just speaking the command and it did what it did.*

Second, participants emphasized that the functions provided by the Ray-Ban Meta smart glasses were helpful and relevant to their lives. Features that the participants highlighted as advantages of the Ray-Ban Meta smart glasses included reminder notifications and serving as a memory aid (eg, “Remember where I put my purse”), GPS navigation, phone call functionality, and the inclusion of a portable charging case. Additionally, participants appreciated how the integration of the camera allows the Ray-Ban Meta smart glasses to require less information input than the Amazon Echo Frames. For example, participant 7 described how they “…like how it can take a picture of the book without me saying the name of it…take a picture of the ingredients and it breaking them down.” Finally, participants appreciated the comfort and esthetics of the Ray-Ban Meta smart glasses. They described the glasses as lightweight, attractive, stylish, comfortable to wear, and fitting well. They highlighted the glasses’ resemblance to conventional eyewear.

Although participants generally perceived the Ray-Ban Meta smart glasses as responsive to user commands, compared to the other models tested, 3 participants noted that the interface could still benefit from improvements in accurately detecting user speech. In particular, 1 participant (participant 11), who was edentulous and identified as having an accent, reported needing to repeat the activation command “Hey Meta” multiple times before receiving a response. While the augmented reality of the Vuzix smart glasses was generally viewed unfavorably among the study participants as described below, 2 participants suggested that integrating augmented reality technology into the Ray-Ban Meta smart glasses could produce a pair of glasses with comprehensive functionality.

Perceived Advantages and Disadvantages of Amazon Alexa Echo Frames

The participants provided generally favorable feedback on the Amazon Alexa Echo Frames, citing various features that they would appreciate integrating into their daily lives. Many such features overlapped with those of the Ray-Ban Meta smart glasses. For example, participants highlighted the reminder notifications, the virtual assistant for answering questions, and the phone call functionality. Participant 2 stated:

> *I liked everything about these glasses. They are right up my alley. The [locating] grocery stores, weather, calling someone, [creating and referring to a] to-do list, locating people.*

Unique to the Amazon Alexa Echo Frames, some participants appreciated how the glasses could sync with other household appliances. In terms of comfort and esthetics, participants generally felt positive toward the lightweight and comfortable frames.

The participants described 3 major disadvantages of the Amazon Alexa Echo Frames. First, some participants emphasized the frequent need to repeat the activation command “Hey Alexa” due to inconsistent voice recognition. Participant 19 explained:

> *You have to pause after “Alexa” but then you have to speak fast for what you want. I wish these could do all the things the first one [Meta] could do. You have to repeat.*

Second, participants noted the absence of a camera as a limitation. In addition to the inability to capture photos and videos, the absence of camera restricts the glasses’ capability to perform object recognition or provide information about objects and the environment through visual analysis. Participant 23 stated:

> *I like these. But if they had a camera… I wish they had a camera so she could see a lot of things that I want to know.*

Third, participants were concerned that the glasses had a tendency to slide down their nose.

Perceived Advantages and Disadvantages of Vuzix Blade 2 Smart Glasses

While feedback on the Vuzix Blade 2 smart glasses was generally negative, some participants described the glasses as interesting and helpful for specific, but limited, situations. Participant 8 stated:

> *It was neat having the experience of seeing something inside your glasses [referring to the augmented reality technology]. But that is sort of a novelty thing.*

Participants envisioned the calendar application within Microsoft Teams as a potentially helpful tool for supporting their daily activities. The participants noted that the Vuzix glasses would

XSL•FO
RenderX

require significant training and might be more helpful for specific populations, such as individuals with high technological literacy who have hearing or visual impairment.

Among the 3 pairs of smart glasses tested, the Vuzix Blade 2 smart glasses were the least favorably received by participants. The participants expressed three main disadvantages: (1) operational complexity; (2) the distracting nature of the augmented reality interface; and (3) a bulky, unattractive design. First, participants described the Vuzix smart glasses as "complicated," "strenuous," and "hard to use." While the participants appreciated the choice between navigating the glasses through touch and audio input, they noted that the glasses did not respond easily to either input. The touch input was overly sensitive, leading participants to inadvertently navigate to incorrect apps. The touch input (eg, long 2-finger touch to return home) was also difficult for the participants to remember, especially among those with more significant cognitive impairment. On the other hand, while "…Voice commands are more intuitive for people with memory problems" (participant 1), the participants collectively noted that the Vuzix smart glasses had a restricted vocabulary and often failed to respond to their verbal prompts. Next, as the only pair of smart glasses to be equipped with augmented reality technology, participants found the projection on the lens distracting and confusing. Participant 9 stated:

> *And the clicking and flashbacks…it's overwhelming to me. It bothers my eyes. It breaks your concentration. Especially if you're sitting here talking. It's flashing and stuff and that bothers me. I'd forget what to do.*

Participants also referred to eye strain and instances of double vision. Finally, there was unanimous agreement that the glasses should be smaller and lighter to improve wearability and transportability. For example, Participant 1 stated:

> *I don't like their look… they are bulky. I mean, what do you put these in? I can't even put these in my purse. They wouldn't fit.*

Participants also complained that the glasses fit incorrectly on their faces, such as being heavy on the bridge of the nose, pushing on the head above the ears, sitting on the cheeks, or being tight around the temples.

Preferred Smart Glasses and Functions

Following beta testing of the 3 models, 11 participants stated that their preferred glasses were the Ray-Ban Meta smart glasses, 3 participants stated that their preferred glasses were the Amazon Alexa Echo Frames, and no participants stated that their preferred glasses were the Vuzix Blade 2 smart glasses. When asked why they preferred the Ray-Ban Meta smart glasses, the participants overwhelmingly described how the glasses were the "easiest to use." Participants also mentioned the comfort, esthetics, and camera function in selecting Ray-Ban Meta glasses as their preferred smart glasses. The few participants who preferred the Amazon Alexa Echo Frames smart glasses referred to the lightweight frame.

When asked about the most important functions that smart glasses can have, the participants mainly discussed two features: (1) reminders and (2) instant hands-free information. First, participants found that smart glasses reminders are critical, such as providing alerts to take medications, remembering grocery lists, and remembering where objects are placed. Participant 17 described the most important glasses feature to them:

> *For me, to remember things. What was I supposed to get at the grocery store? Where was I supposed to go today? What time was I supposed to get there? Just yesterday I got things messed up and I was supposed to have a procedure and I called just to be safe and they said "You don't have a procedure today." So something like this could help prevent these embarrassing moments for someone my age and with my condition.*

The second critical smart glasses function highlighted by participants was instant, hands-free information. Participants stated that smart glasses should provide "clear" and "instant" information through the virtual assistant. Additionally, participants appreciated when the information was delivered through audio feedback, rather than a projection on the lens (augmented reality). Participant 18 described:

> *First off you are not holding anything. That is what I like…hands free…to be able to speak out what you need...*

While not endorsed by any other participants, 1 participant (participant 9) emphatically relayed that smart glasses could significantly improve the lives of older adults through offering social companionship for those who experience social isolation. This participant described how older adults could use the glasses for conversation or calling a support group.

Broad Smart Glasses Concerns

The discussion related to the Ray-Ban Meta smart glasses and Vuzix Blade 2 smart glasses both elicited privacy concerns among 3 participants. Two participants emphasized the ethical responsibility of glasses users to be respectful of others' privacy when capturing photos or audio recordings (participants 8 and 23). Participant 3 advocated for more discreet smart glasses designs (compared to Vuzix glasses) to prevent public apprehension about surveillance or invasive behavior. This participant (participant 3) stated that smart glasses could be useful for people with memory problems but said, "You want to make it so, you know, you have the functions, but you don't want everyone knowing you're getting the help." They suggested that a more subtle design would allow for cognitive support without drawing the attention or discomfort of others.

Generally, participants overwhelmingly affirmed that smart glasses could assist with memory by storing information, stirring memory, offering reminders, recalling appointments, aiding with navigation, and recalling where items were placed. Alternatively, 1 among the 14 participants expressed a negative perception of smart glasses' use for memory within the context of a general overreliance on technology. While this participant (participant 11) believed that smart glasses could be "a potentially useful tool," they stated:

> *I am reluctant to let too much electronics in, myself. I enjoy keeping remembering things myself. Keeping*

XSL•FO
RenderX

> *my memory sharp. Whereas with the glasses, it'll tell me something I don't necessarily need to know. I'd rather remember in my head and exercise my memory.*

Recommendations for Functions Smart Glasses Should Do

After testing the 3 models of smart glasses, the participants provided advice regarding what additional functions smart glasses should provide for older adults who have memory problems. First, participants suggested that smart glasses should identify environmental hazards or dangerous situations, such as recognizing fall risks, dangerous traffic, car accidents, or smoke due to a fire. For example, participant 19 stated:

> *They did not point out danger. Like when you got to the corner: "Don't step down." "Wait till the light changes." Help you be more aware of your surroundings.*

Second, participants also stated that smart glasses should provide health assistance, such as step counts or a medical alert in the event of a medical emergency. Third, participants suggested that smart glasses should provide navigation assistance while shopping. For example, smart glasses could group items from a grocery list while navigating the aisles, help locate items in stores, and provide a price check for grocery items. Finally, participants suggested that smart glasses should provide facial recognition for acquaintances. They expressed how a facial recognition functionality would prevent embarrassing moments, such as forgetting the names of other residents in their building.

Triangulation

The integration of the quantitative and qualitative components of this study revealed convergent and complementary results, strengthening the credibility of the findings. Specifically, both survey and interview results suggest that participants prioritized the following smart glasses functions: audio reminders, phone calls, GPS, and distress signals, with audio reminders emerging as the highest-ranked feature (Table 2). Although participants performed other tasks, such as playing music and sending a photo to family or friends, both the quantitative and qualitative results suggest that these functions were perceived as less essential among older adults with memory problems. In addition to confirming functional priorities, complementary insights emerged from the qualitative interviews. First, following hands-on testing, participants emphasized the value of an intuitive and quick interface. Next, the participants highlighted that audio feedback from the glasses, rather than visual feedback, was the preferred method of information delivery. These complementary qualitative findings reveal that even though certain functions might be perceived as critical, the accessibility of the smart glasses interface is key to participant acceptance.

XSL•FO
RenderX

Table . Favored smart glasses functions.

Favored functions	Participants who selected the function as the "best" function, n (%)	Itemized survey (1="least helpful" to 4="most helpful"), mean (SD)	Example representative quote
Audio reminders	8 (30.77)	3.50 (0.71)	• "You know, unless you write it down, you forget it. It can remind you. It's instant information." [Participant 3] • "Whereas with the others (Meta Ray-Ban smart glasses and Alexa Echo Frames, compared to Vuzix Blade 2), they could function 24/7, you just communicate with it. You don't have the visual to distract you. I'm one of those people, I can't multitask, when I'm on my scooter, I have to watch for curbs and people." [Participant 11]
Phone calls	5 (19.23)	3.38 (0.85)	• "Making a call is handy." [Participant 8] • "A lot of the people in this building have family who don't come see them. These would be beneficial for them. They could sit in their apartment. If they feel lonely or depressed, they could tell the glasses to call a support group or something and it would make the world of difference." [Participant 9]
Distress signals	3 (11.54)	3.54 (0.71)	• "They are going in the right direction with them (smart glasses). If they could do a general programming for them and then customize them to the client's needs, it would be wonderful. If a person can't see very well it could analyze for them. It would need sensors to recognize smoke. It should be able to connect to an ambulance like a medical alert…the person's heart rate and all that good stuff. If the diabetics sugar drops low, it should be able to tell it. It should be able to get it off the phone and help." [Participant 24] • "It would be great if you were stranded…and you could still call someone to save you." [Participant 2]

XSL•FO
RenderX

Favored functions	Participants who selected the function as the "best" function, n (%)	Itemized survey (1="least helpful" to 4="most helpful"), mean (SD)	Example representative quote
GPS	3 (11.54)	3.38 (0.80)	• "The question 'Where am I?' is a big one…Or if you get lost. These things are important to know." (Participant 8) • "For example, I used to live on [redacted street]. When I moved down here, I traveled all the way to go to Giant. But I could have asked the glasses where the closest Giant is. I find it complicated to look up things on phone and computers and it's easier with the glasses to get information." (Participant 23)

Discussion

Principal Findings

This study used surveys and interviews to explore the usability and acceptability of smart glasses among older adults with cognitive impairment. Both survey and interview results suggest that participants prioritized the following smart glasses functions: audio reminders, phone calls, GPS, and distress signals, with audio reminders emerging as the highest-ranked feature. Following beta testing of 3 pairs of commercial smart glasses, interview results suggest that participants prefer the Ray-Ban Meta smart glasses due to their intuitive and quick interface, comfort and esthetics, and functionally relevant features such as audio reminders and instant hands-free information. Overall, participants conveyed a generally positive perception of smart glasses and their potential to support memory in daily life.

This study supports the development and exploration of smart glasses for older adults with cognitive impairment. Some clinicians might question the foundation of such work, believing that smart glasses for older adults with cognitive impairment could be problematic due to low technology literacy and the potential for increased confusion in this population [48]. As an alternative perspective, this work contributes to the previous literature [49,50], which demonstrates that older adults are diverse in technology use and ability, and many are indeed comfortable with technology and view it favorably. Furthermore, all 26 older participants who participated in this study, including those with lower levels of technology comfort, stated that they would be willing to wear smart glasses that assist with memory. One potential explanation is that the potential benefits for supporting independence could outweigh the expected initial usability challenges. This work demonstrated the strength of user-centered research in emerging fields, allowing individuals to articulate their own preferences and needs.

Although participants conveyed a generally positive perception of smart glasses and their potential to support memory in daily life, they also identified some concerns. For instance, 2 participants highlighted the importance of smart glasses users being respectful of others' privacy when capturing photo or audio recordings. While enforcing such boundaries could prove practically difficult, most smart glasses have an indicator light that turns on when photo or video is activated to ensure bystanders are aware of such capture. Additionally, 1 participant expressed concern that ongoing use of smart glasses for cognitive assistance could lead to a reliance on the device and a loss of independent cognitive skills. It would indeed be valuable for future longitudinal work to explore whether the cognitive assistance provided by smart glasses in the short term has a "de-training" effect over the long term.

The results of this study suggest that older adults with cognitive impairment strongly value smart glasses that are easy to activate and equipped with a large vocabulary, thus providing interaction that is intuitive. During the past few years, amidst the proliferation of AI, smart glasses have become more user-friendly. As AI technology continues to advance, it is expected that smart glasses will become even more "intelligent," with improvements in connectivity, data collection and processing, pattern recognition, automation, and adaptability [51]. Over time, as smart glasses require less user input to operate correctly, they could become more appropriate for those with low technology literacy. Going forward, even though the participants verbalized a preference for more polished smart glasses models, older adults with cognitive impairment should still be included in early-stage development research. Including end users in early-stage design of technology helps ensure that the development of technology is applicable and helpful for them and improves the future likelihood of use.

Both survey and interview results suggest that older adults with cognitive impairment perceive audio reminders as the most critical smart glasses function. One of the earliest and most common symptoms of cognitive impairment is episodic memory loss, which is characterized by difficulty in recalling specific personal everyday events and experiences [52]. Audio reminders could help with episodic memory by providing alerts for important upcoming events such as doctor's appointments, medication administration, or social activities. Similarly, individuals with deficiencies in episodic memory may have difficulty navigating to a new place after 1 visit (eg, a parking garage). These deficiencies are consistent with the participants' reports of GPS and navigation as prioritized functions.

XSL•FO
RenderX

The participants' additional preferred smart glasses functions—phone calls and distress signals—reflect the challenges and safety concerns often faced by individuals with cognitive impairment who live alone. Such individuals can experience a sense of uncertainty due to the unpredictable course of symptoms and how these symptoms could negatively impact their lives each day [53]. Especially among this population of economically disadvantaged older adults, many lack adequate home-based services [54]. Smart glasses, equipped with accessible communication features such as phone call capabilities and emergency alerts, may provide older adults with cognitive impairment and their caregivers improved security and assurance that assistance can be readily accessible to the older adult when needed.

Implications

This work provides guidance for smart glasses developers regarding the design and features that are most important for older adults with cognitive impairment. First and foremost, smart glasses developers should place great importance on usability, including straightforward activation and intuitive command interfaces. Developers should also equip the smart glasses with functions that are relevant to this population, especially audio reminders, and ensure that the glasses are minimalistic so that older adults can receive help in a discreet manner. Finally, and contrary to much current development research [22], until augmented reality technology has considerably advanced, this work suggests that developers of smart glasses for older adults with cognitive impairment should prioritize audio rather than visual feedback for assistance with memory and daily tasks.

This work also provides information for researchers of smart glasses for older adults with cognitive impairment. A recent review on smart glasses for older adults with cognitive impairment, conducted by Burch et al [22], found that the current literature focuses either on outdated commercial smart glasses or rudimentary prototypes, such as regular glasses with bulky technology components (eg, cameras) added to the side arm. This study suggests that current commercial smart glasses provide a promising platform for assisting older adults with cognitive impairment, but additional studies are needed to examine the integration of smart glasses into long-term daily life. Additionally, if health researchers collaborate with computer science researchers on the development of future smart glasses, this work could serve as a strong launching pad for informing preferred smart glasses design and functionality.

Although this work does not explicitly assess the acceptability of smart glasses compared to other smart devices, some interpretive insights can be considered as to why smart glasses might be particularly advantageous. First, participants consistently appreciated the hands-free nature of the smart glasses, which allow users to request information while using a walker or performing a task with both hands. Many other wearable smart devices (eg, smartwatches) are not as supportive of hands-free interaction. Additionally, similar to "earables," smart glasses are situated near the ear, allowing for more discreet audio assistance than other smart devices. Another reason smart glasses might stand apart compared to other smart devices is that participants valued that the glasses could "see what they see" and provide relevant information about their environment. Finally, participants appreciated that a device they already carry with them could provide such advanced assistance. As smart glasses naturally travel with the user, they provide more possibilities for assistance compared to stationary technologies such as smart speakers. Notably, the aforementioned points should be considered as thought-launching considerations rather than definitive conclusions, as this study was not designed to compare smart glasses with other smart devices.

Limitations and Strengths

Limitations of this study include a small sample size from a single older adult apartment building, short duration of smart glasses use and testing, and a lack of objective measures. First, the sample size of only 26 participants limits the generalizability of the study results, especially to those with more severe cognitive impairment or those who live in more rural settings. Second, participants beta tested the smart glasses for only 20 minutes per pair. During the testing, the participants could have been influenced by branding, such as associating a particular name brand with quality. Thus, the findings might not translate to long-term preferences and do not reveal information about adherence during everyday life. Finally, no validated survey currently exists that examines the preferred functions of smart glasses. Instead, we developed and used a "preferred functions" survey, which has not been tested for reliability and validity. Responses on this survey during phase 1 informed our selection and purchase of smart glasses for phase 2. As such, participants did not have hands-on experience with the glasses prior to completing the survey.

Study strengths include a user-centered focus, a mixed methods design that included rich interviews, and a sample that reflects older adults who are disproportionately affected by cognitive impairment. Within an emerging field of research, especially those involving new technology, obtaining feedback from intended users is critical to ensure that development and technology selection align well with user needs, thereby increasing the likelihood of adoption. The mixed methodology approach used in this study provided rich insights that numbers alone could not reflect. Finally, we recruited our sample from affordable older adult housing to study a group of older adults who are disproportionately affected by cognitive impairment yet underrepresented in technology research.

Conclusions

This study aimed to use surveys and interviews to explore the usability and acceptability of smart glasses among older adults with cognitive impairment. Overall, participants conveyed a generally positive perception of smart glasses and their potential to support memory in daily life. Both survey and interview results suggest that participants prioritized the following smart glasses functions: audio reminders, phone calls, GPS, and distress signals, with audio reminders emerging as the highest-ranked feature. Additionally, participants highlighted that audio feedback from the glasses, rather than visual feedback, was the preferred method of information delivery and emphasized the value of an intuitive and quick interface. Future work should examine the integration of smart glasses over a

XSL•FO
RenderX

longer period, in a larger sample of older adults with cognitive impairment, and use inferential analytic approaches.

Acknowledgments

During the preparation of this work, the first author (BFB) used Microsoft Copilot and ChatGPT solely for the purpose of editing and improving the readability of sentences. The authors used these artificial intelligence tools consistent with the guidelines outlined in “Best Practices for Using AI as an Author, Peer Reviewer, or Editor” [55]. The authors take full responsibility for the content and references within this publication.

Abstract

Background: Older adults face increased crash risk due to age-related declines in cognitive, visual, and physical functioning; yet, many Australians in their 70s are continuing to drive. Web-based platforms are increasingly used to deliver health and mobility information to older adults and may support safer driving; however, existing online resources on driving safety often lack age-specific guidance, have usability limitations, and may not be designed with older adults in mind.

Objective: This study aimed to explore the information needs, preferences, and experiences of older drivers and general practitioners (GPs) to inform the formative, prelaunch development of a user-centered web-based platform, Ageing Well on the Road. Interviews and focus groups were conducted to gather feedback on content, accessibility, and usability, with data collection guided by the Consolidated Framework for Implementation Research and the Technology Acceptance Model frameworks to explore implementation and technology adoption factors.

Methods: Website development was informed by a review of 26 Australian websites and consultations with stakeholders. Semistructured interviews were conducted with 7 older adults (aged >67 years; one additional participant completed only survey data) and a focus group with 10 GPs experienced in fitness to drive assessments for older drivers. Thematic analysis was used to explore participants' experiences with online driving information and feedback on content, usability, and accessibility. Formative feedback from these users directly informed content and design refinements before public launch.

Results: The website addressed priority topics, including age-related health conditions affecting driving, licensing requirements, vehicle safety features, and strategies for maintaining driving confidence. Older adults valued large fonts, plain language, intuitive navigation, and trustworthy, practical advice. GPs highlighted the website's potential to support clinical discussions around driving capacity and safety. Barriers to engagement included digital literacy limitations, accessibility concerns, and uncertainty about online information credibility.

Conclusions: A co-designed, web-based platform tailored to older adults and clinicians can enhance access to relevant, trustworthy information and support driving self-regulation. Involving end users in the development process is critical to optimize usability and ensure the resource aligns with their needs, highlighting the value of theory-informed, user-guided development for digital health resources.

Introduction

Age-related declines in cognitive, sensory, and motor functions contribute to increased crash risk and driving difficulties among older adults [1,2]. Despite these challenges, over 90% of drivers in their 70s continue to rely on private vehicles, with many expected to drive well into their 80s [3]. Mobility plays a key role in preserving independence and well-being in late life, making it essential to support safe driving practices and provide accessible, evidence-based resources that help older adults make informed decisions about driving safety. However, many existing resources are not tailored to the unique needs of older adults, such as cognitive changes and digital literacy levels, highlighting a gap in accessible, targeted educational tools designed specifically for older drivers.

Web-based platforms have emerged as flexible and cost-effective methods for delivering health interventions, especially as over 75% of older adults now use the internet to seek health and mobility information [4]. While on-road driving assessments have shown effectiveness in evaluating driving ability [5,6], such services are not widely accessible. Older drivers, their family members, and clinicians often report difficulty locating clear, practical guidelines on driving safety, vehicle modifications, and licensing regulations [7,8]. While existing websites about driving safety provide general information, they frequently overlook the unique needs of older users, such as support with age-related decline, planning for driving retirement, and web design accessible to those with reduced physical or cognitive capacity [8].

Although digital health tools can broaden access to information, their effectiveness depends on how well they meet users' expectations regarding usability, accessibility, and content relevance [9]. Older adults may face particular barriers to engaging with digital platforms, such as limited digital literacy, physical impairments, and uncertainty about the credibility of online information [10]. To address these challenges, theoretical frameworks can help guide the design and evaluation of new resources, as we first must understand how older adults search for information and what content they find useful. The Technology Acceptance Model (TAM), which has been applied in studies of older drivers' adoption of advanced driver-assistance systems [11], suggests that perceived ease of use and perceived usefulness are key determinants of whether older adults engage with new technologies. This makes TAM a valuable lens for understanding how older adults evaluate online driving safety tools and identifying features that support or hinder uptake.

This study aimed to explore the information needs, preferences, and experiences of older drivers and general practitioners (GPs) with online driving safety content to inform the development of a user-centered web-based platform. A qualitative approach was used, including a review of existing online resources, consultations with stakeholders, and interviews with older adults (aged ≥67 years) and GPs. GPs play a key role in assessing older drivers' medical fitness to drive (FtD) in Australia, yet often report uncertainty and a lack of appropriate tools to support these discussions [12,13]. These findings underscore the need for clear, accessible resources to support GPs in their decision-making. Given that internet use among older Australians aged >75 years continues to rise, with a sharp increase from 52% in 2019 (before COVID-19–related lockdowns) to 94% in 2022 [14], the development of a tailored web platform, Ageing Well on the Road [15], presents a timely opportunity to improve knowledge, support driving self-regulation, and enhance road safety. Findings from this study contribute formative insights to guide resource refinement and the development of best practice strategies for disseminating online driving safety tools targeted at older drivers.

Methods

Participants and Recruitment

Older adults (aged ≥67 years) were recruited to explore their information-seeking behaviors and perceptions of a newly developed web-based resource on driving safety. Recruitment was conducted via volunteer networks, social media, and partnerships with organizations such as National Seniors Australia. Additionally, participants from the Better Drive Trial and the Community in Health Aging Research Group who had previously consented to research participation were invited. GPs were recruited through the research team's professional network and were eligible to participate if they were currently practicing and had experience conducting FtD assessments with older adults. Eligible participants received a link to an online screening and consent form hosted on REDCap (Research Electronic Data Capture; Vanderbilt University), a secure online survey platform. Those who consented were invited to participate in qualitative interviews or focus groups, where they were shown a prelive version of the website, allowing them to provide feedback on content, design, and usability before public launch, as well as to explore their broader information-seeking behaviors, preferences, and experiences with online driving safety content.

Eight older adults participated in the study, 7 of whom completed semistructured interviews, and 10 GPs participated in a single focus group discussion. Although the total sample size was modest (n=18), this is appropriate for the exploratory and qualitative nature of the study, which aimed to obtain rich, detailed accounts of participants' perspectives rather than statistical generalizability [16]. In usability and user experience research, small samples are widely considered sufficient to identify the majority of issues, with previous studies showing that 5 - 10 participants often reveal key concerns and that additional insights may be gained with up to 20 participants [17]. Recruitment continued until no additional expressions of interest were received, and the research team judged that sufficient feedback had been obtained to inform website development. As a pretesting stage, this sample provided practical insights into user experience, content clarity, and usability. Feedback from participants, together with input from the research team and stakeholders, directly informed iterative refinements to the website. Furthermore, the platform remains open to ongoing feedback via contact details provided on the site, allowing continued updates and improvements post launch.

Website Development

A comprehensive review of 26 Australian websites addressing older driver safety was conducted by a research assistant under the supervision of the project team to assess existing resources, identify content gaps, and inform the development of a new web-based platform. Although not a formal systematic review, this process was guided by content experts, clinicians, stakeholder input, and team discussions, including a meeting with representatives from National Seniors Australia, the Australian Pensioners Insurance Agency (APIA), Suncorp Group, and Transport for NSW to ensure that relevant resources and key perspectives were captured. Websites were identified through targeted Google searches and recommendations from stakeholders.

The review highlighted several consistent patterns and gaps. Most government and national websites provided general information on licensing requirements, legal obligations for drivers with medical conditions, safe driving tips, and alternative transport options. Many included downloadable resources such as fact sheets, PDFs, and videos, and frequently linked to external resources rather than consolidating content in one place. However, few sites offered tailored guidance specifically for older drivers on maintaining driving skills, using vehicle technologies such as advanced driver assistance systems (ADASs), and supporting independence and decision-making around driving retirement. Accessibility features, interactive decision aids, and practical checklists were present in some resources, but not consistently across sites. Table S1 in Multimedia Appendix 1 provides a detailed overview of the content, format, and features of the 26 websites reviewed. Limited information on ADAS, such as lane-keeping assist, adaptive cruise control, and blind spot monitoring, was identified, despite evidence that these technologies can reduce crash risk and improve driving performance among older drivers, particularly when systems are acceptable and usable [18-20].

The resulting website, Ageing Well on the Road [15], was developed through an iterative, user-informed design process that incorporated feedback from older adults, GPs, and key stakeholders. The website design prioritized accessibility features appropriate for older adults, including clear headings, plain language, simple navigation structures, and large easy-to-read fonts. Stakeholder consultations involved representatives from an older adult advocacy group (National Seniors Australia), an older adult's insurance agency (APIA), an insurance group (Suncorp Group), and a government transport authority (Transport for NSW), who emphasized the importance of trustworthy, practical resources that could be easily updated as regulations changed. Interview and focus group data directly informed the structure and content of the website. The resulting platform addressed content gaps identified in the review and reflected user and stakeholder input, with sections focused on maintaining driving skills with age, understanding and using ADAS technologies, planning for driving retirement, navigating licensing and medical requirements, and supporting family and carers. This approach aimed to produce an accessible, evidence-based resource to support safe driving and informed mobility decisions for older adults in Australia. A map of corresponding changes made to the website before launch is available in the Multimedia Appendix 1.

Data Collection

Data were collected using an online questionnaire and through qualitative interviews and focus groups. The questionnaire captured consent, basic demographic information, and participants' driving habits and attitudes toward licensing and safety. It included the participant information statement and consent form, which participants were required to review before proceeding. Consent was recorded electronically, with participants informed of their right to withdraw at any time. Interviews and focus groups were conducted via Microsoft Teams or Zoom (Zoom Communications) and ranged from 30 to 60 minutes in length. A semistructured interview approach was used, combining predetermined open-ended questions with flexibility for participants to elaborate on issues of relevance. The semistructured interview and focus group guides are provided in Multimedia Appendix 1.

Interview guides were informed by the Consolidated Framework for Implementation Research (CFIR), a widely used framework that provides a structured way of identifying the barriers and facilitators influencing the implementation and uptake of health interventions [21,22]. This framework allowed us to systematically design questions that explore contextual factors affecting the adoption of web-based driving safety resources. Specifically, questions about the credibility, usability, and perceived usefulness of the website reflected the domain of intervention characteristics; questions exploring licensing requirements, information sources, and available supports reflected the outer setting; and questions about older adults' motivations, needs, confidence, and comfort with digital tools reflected individual characteristics. By aligning our guide with these domains, we ensured that data captured both personal experiences and broader implementation considerations, providing insights into factors that may support or hinder the uptake of health and safety interventions. This approach also allowed us to capture influences across multiple levels of context. For example, participants' experiences with licensing regulations, access to transport, family involvement, and available community resources reflect the CFIR inner and outer setting domains, highlighting how both organizational and external factors shape engagement with driving safety interventions.

In addition, the TAM [11] guided the design of questions focused on digital engagement. TAM constructs of perceived usefulness and perceived ease of use shaped prompts asking participants to reflect on how straightforward the website was to navigate, whether the information was relevant to their needs, and whether they would recommend the resource to others. For clinicians, TAM principles were reflected in questions about preferred formats for digital screening tools and the likelihood of incorporating these into practice. These links allowed user feedback to be directly interpreted within established theoretical models of technology adoption, particularly for older populations. All sessions were audio-recorded, transcribed, and thematically analyzed. Feedback on user experience and content relevance was reviewed by the research team and stakeholders

XSL•FO
RenderX

and directly informed website revisions to improve clarity, accessibility, and ease of use.

Analysis

Thematic analysis was conducted by 2 researchers using NVivo (QSR International), following the phases described by Braun and Clarke [16,23]. The process involved familiarization with the transcripts, generating initial codes, allocating data segments to the codes, searching for themes, refining themes to ensure they worked in relation to the data, and developing the final thematic framework. Reflexive practices were incorporated throughout, including ongoing consideration of how researcher perspectives shaped coding and interpretation. Two researchers from different disciplinary backgrounds (paramedicine and psychology) independently conducted initial coding of the transcripts. Coding differences and emerging interpretations were discussed collaboratively, and themes were refined iteratively to incorporate multiple perspectives and support reflexivity, producing a more nuanced interpretation of the data [16,23].

Feedback on the website was analyzed primarily deductively, guided by the interview guide and research aim, which were informed by the CFIR and TAM. At the same time, themes related to participants' broader knowledge needs, attitudes toward existing resources, and perceived barriers and facilitators were identified inductively from the data, so unexpected insights could be identified [24]. By combining framework-guided coding with open coding, we were able to use established theory to guide our analysis while also capturing new and unanticipated insights. The coding frameworks are provided in Multimedia Appendix 1.

Participant insights ultimately shaped the content, design, and functionality of the final website. Four main themes from the interviews and focus groups were identified: (1) barriers to accessing information and resources, (2) facilitators of online resource use, (3) driving safety and self-regulation, and (4) motivations and resource needs for information search. Themes were iteratively refined during analysis and further organized into subthemes at the reporting stage to aid clarity. Relevant formative feedback on the prelive website has also been incorporated to illustrate how these insights informed refinements to content, layout, and usability.

Ethical Considerations

This study was approved by the Human Research Ethics Committee at the University of New South Wales (approval no iRECS6396), and participants provided written informed consent. No monetary compensation was provided to participants. Additionally, participants recruited from the Better Drive Trial were originally enrolled under separate approval from the University of New South Wales Human Research Ethics Committee (approval no HC190430) and had previously consented to be contacted for future research. All identifiable information was removed during data collection, and participants were assigned unique codes. The linking file connecting identities to study data was stored separately and was accessible only to the research team. Reidentification was not required, as no participants withdrew their data. Findings are reported in aggregate form to ensure that individual participants cannot be identified.

Results

Characteristics of the Older Adults

Eight older adults consented to participate via the REDCap survey, which collected basic demographics, driving habits, and interview availability. Seven participants completed the interviews. Participants' ages ranged from 67 to 85 years. All were current drivers, with one participant reporting restrictions on their license, requiring spectacles and annual medical reviews. Most participants drove more than half the days of the week, with 3 driving 6 days per week and 3 driving 7 days per week. Weekly driving distances ranged from 31 km to over 150 km. When asked about how many more years they anticipated continuing to drive, the mean number was 17 (SD 6.84) years, with the range spanning from 8 to 30 years. Half of the participants reported having completed a medical review of their FtD by a doctor, while the other half had not.

Confidence in understanding licensing requirements after the age of 75 years was mixed. Three participants expressed high confidence, and 3 expressed low confidence, and the remaining participants reported neutral confidence. Confidence in managing age-related changes affecting driving safety was higher; 4 participants reported high confidence, and 3 reported moderate confidence. Most (n=6) participants also expressed high confidence in managing their own driving safety. Regarding satisfaction with existing information on licensing, aging, and driving safety, participants were generally neutral about both quality (n=4) and quantity (n=5). Common sources of accessing information included family members (n=5), doctors (n=4), and friends (n=2), with online resources being the preferred format for health and driving information (n=6).

Characteristics of GPs

Ten GPs participated in a single focus group. Their ages varied, with 3 participants in their 30s, 2 in their 40s, 2 in their 50s, and 3 in their 60s. Three worked full-time and 7 part-time. Two had joined their practice within the past year, while the others had been with their practice for over 20 years. All GPs held a medical degree and Fellowship of the Royal Australian College of General Practitioners. Two also held PhDs, and 3 held other professional roles, such as being on the board of the Primary Health Network, postgraduate medical education, or running a GP training program.

Barriers to Accessing Information and Resources

Reluctance to Acknowledge Driving Limitations

The older participant group identified a challenge in acknowledging the need for assessment, particularly among long-time drivers. One participant reflected on the difficulty of convincing long-time drivers to recognize when they may no longer be fit to drive, reflecting a broader hesitation in seeking out resources until necessary:

> *The biggest problem all around is persuading people who should be doing something more than an annual test… I think persuading people to use these things*

XSL•FO
RenderX

> *[online resources and tools], is perhaps the key. And perhaps persuading someone who isn't really aware of the difficulties they are having.* [P6, Male, 84]

This reluctance was echoed by the GPs, who noted that older adults typically do not recognize their own limitations when it comes to driving. One GP said:

> *It's pretty rare… when a patient says "maybe I shouldn't be driving." I think that's happened to me once. It may be family members that may say something, but it's rare for the individual to say "no, I'm not good enough."* [GP1]

These observations highlight the challenge both GPs and family members face and suggest the need for resources that help family members recognize signs of potential driving impairment and guide conversations about driving safety.

Reactive Information Seeking

Participants reported that they typically only sought information when it was urgently needed. As one older adult explained, "You're not going to be prompted to go looking for information that you don't need at the moment" (P3, Male, 67). This demonstrates a reactive approach to information-seeking, where older adults may not actively seek driving-related information unless prompted by personal circumstances or external cues such as medical diagnoses or legal requirements.

Skepticism Toward Online Resources

Concerns about the accuracy and reliability of digital tools emerged as another barrier. One older adult expressed doubt about online assessments: "I'm skeptical that a computer questionnaire can actually make an assessment on my ability to drive" (P4, Male, 77). This skepticism was combined with fears regarding privacy and potential misuse of personal data, indicating that trust in online resources remains a significant barrier for older adults, despite the widespread and increasing internet use and online screening tools.

Complexity of Licensing Regulations

Finally, participants highlighted that the complexity of state-by-state licensing regulations can cause confusion, especially for those who regularly travel across Australia. One older adult noted: "The laws are different in every state" (P7, Male, 71), pointing to the need for a centralized, comprehensive resource that consolidates licensing requirements and driving regulations across all states and territories into a single, accessible platform.

Facilitators of Online Use

Accessibility and Convenience

Despite barriers, several factors were identified that could facilitate the use of online resources. Participants highlighted that web-based platforms are appealing because they are quick, easy, and convenient to use. One older adult explained: "It's very quick. It's very easy. It's very comprehensive. You'll get lots more answers" (P4, Male, 77). Similarly, another participant highlighted the convenience of online resources: "Well, it's readily available and easy to access. I don't have to go to the bookshop and look for it or look for a magazine" (P7, Male, 71). These comments underscore that the practical accessibility of online resources is a key facilitator for older adults.

Reducing Anxiety and Stigma

Online resources may also help alleviate the anxiety older adults feel about formal FtD assessments and the potential loss of their license. Participants in the GP focus group noted that many older adults experience significant stress around these assessments: "They get very anxious. Very worried they will fail and their license will be taken away from them, and there's a rapid ball of catastrophising that goes on" (GP). This may discourage older adults from engaging in the process altogether, as one older adult described their personal reaction to medical appointments: "Every time I go to the GP, my blood pressure goes up, because outside the GP's office my blood pressure is normal" (P5, Male, 85). While online resources cannot replace formal assessments, providing clear, transparent, and nonjudgmental information online may reduce the stress associated with seeking information from health care professionals and help individuals feel better prepared before attending in-person assessments. By framing these resources as supportive tools that clarify the process and expectations, they may reduce fear, facilitating greater acceptance and engagement with driving safety information.

Advisory Guidance and Reassurance

Some participants valued online tools that provided guidance rather than a definitive diagnosis, helping them feel more confident about their driving safety. One participant reflected on hesitating to use a potential dementia assessment tool, but noted a different approach for driving:

> *I discovered an online assessment for potential dementia, and I hesitated about doing it. I thought, maybe, I don't want to know. I think that could be less the case in respect to driving. I would want to know, because I'd be putting other people at risk, other than just myself.* [P3, Male, 67]

This highlights how online tools can offer reassurance by helping individuals feel more confident that they are driving safely and not endangering others. Similarly, another participant emphasized the importance of feedback rather than prescriptive outcomes:

> *I wouldn't mind as long as it's a tool that's helping you to determine if you've got some issues or not. But it's not a definitive yes or no. You've got major issues, but something that sort of gives you feedback about how you answer the questions or deal with the online tools would be useful.* [P1, Male, 73]

Participants generally agreed that such tools should be "advisory and not prescriptive" (P2, Male, 74). These findings suggest that online resources can support older adults in managing their driving abilities in a nonthreatening and informative way, providing reassurance and reducing anxiety by framing driving safety as something manageable and shared rather than stigmatizing.

XSL•FO
RenderX

Driving Safety and Self-Regulation

Proactive Approaches to Safety

Some participants took an active role in managing their driving safety by seeking assessments to maintain their driving confidence and reassurance. One participant described:

> *My specialist suggested I have this occupational therapy driving assessment, or something, which I did. I prepared for and did all the reading before that, so that's basically how I got interested and realised that I can still drive properly and safely and confidently.* [P2, Male, 74]

This proactive approach to safety reflects how formal assessments can help older adults make informed decisions and continue driving with confidence, while also acknowledging the need for future adjustments as age-related declines (eg, reduced strength or flexibility) may affect certain driving-related skills, such as towing heavy vehicles.

Social Feedback and Family Influence

Social input was another critical component of driving self-regulation. Participants described relying on their peers or family members for feedback about their driving ability. As P4 (Male, 77) noted, "drivers will always talk to another driver about their ability or a problem." Family concerns also influenced decisions, with one older driver recalling, "At one point, my wife's mum, we were concerned about her driving, and we really didn't want her to drive anymore. It's one of those things—she was mid-80s at that stage" (P4, Male, 77). These examples show that self-regulation often occurs within a broader social context, influenced by both peer discussions and family involvement.

Self-Imposed Driving Restrictions

Self-regulation, including voluntarily limiting driving, was a frequent strategy to maintain safety, shaped by age-related caution or health concerns. For example, one participant explained:

> *My wife says that she isn't going to drive after dark. She didn't go and look and see something somewhere that said "this is how to know whether you can drive after dark or not." She simply just said, "I don't really feel that great driving after dark."* [P6, Male, 84]

This self-imposed restriction was a common behavior among older adults, suggesting that the decision to stop driving may not always be based on formal assessments, but rather personal comfort and awareness of limitations. GPs confirmed this tendency, noting that many older adults consciously restricted their driving to familiar routes or comfortable distances. As one GP stated:

> *I find I have patients who self-restrict their own driving, and say, I only drive where I feel comfortable now…. they've just personally downgraded their driving status within their comfort level.* [GP1]

These findings suggest that self-regulation is a common and pragmatic response, and online tools could help validate these choices by providing reassurance and offering guidance about when to consult with a health care professional.

Access to Alternative Transport

The availability of public transport influenced decisions about driving cessation. Older driver participants living in urban areas reported that giving up driving was more manageable due to better access to amenities and public transport. As P6 (Male, 84) stated, "People in big cities (Melbourne, Sydney, etc) often give up [driving] quite easily as they are near the things they want and the public transport isn't too bad." In contrast, those in rural areas described more difficulty: "Country districts and places like Canberra… it's going to be important and difficult to deal with. If you can't get to the nearest shop" (P6, Male, 84). Limited transport alternatives in these areas make driving cessation more challenging, highlighting the need for tailored resources and support in this area.

Motivations and Resource Needs for Information Search

Health-Related Prompts

Medical diagnoses were a key motivator for seeking information about driving requirements. For example, one older driver participant shared:

> *I've got mild cognitive impairment. And my specialist suggested I complete an occupational therapy assessment…, which I passed with flying colours. And now we're continuing to drive safely and confidently, but it was a good wake-up call.* [P2, Male, 74]

Similarly, GPs noted that new diagnoses such as diabetes, syncope, or stroke often required them to notify licensing authorities, which in turn triggered patients to seek information about driving safety and regulatory requirements.

Family Influence and Forward Planning

Some participants were prompted to search for information because of concerns about their relatives, for example, researching licensing regulations after a relative's dementia diagnosis. One older driver participant explained, "I looked online through the Roads and Traffic Authority, Roads and Maritime Services, and Service NSW websites, and just Googled generally about the issues" (P3, Male, 67). Such examples show how family experiences and concerns can indirectly motivate individuals to seek out resources and prepare for their own future driving needs. In contrast, some participants did not feel an immediate need for information, but acknowledged it would become relevant with age: "The legal requirements for drivers as we get to different ages would be a topic I'd certainly choose to Google" (P1, Male, 73). This reflects a more anticipatory approach, where individuals acknowledge that information will become useful as they age or if their circumstances change.

Preferred Sources of Information

Most participants preferred online resources for accessing driving-related information, with one older driver participant stating, "I prefer to use Google all the time" (P3, Male, 67), while others emphasized the need for these resources to be credible and relevant: "Well, I wouldn't look at anything

XSL•FO
RenderX

American for example, so relevant to my location. But not put there by an insurance company, it's got to be a reputable source" (P7, Male, 71). This emphasis on trustworthiness shows the importance of ensuring that online resources are not only easy to access but also authoritative and specific in their content.

External Prompts and Regulatory Triggers

Despite varied preferences, most participants reported that information-seeking often occurred reactively, in response to external prompts. These included medical advice, legal obligations, family member suggestions, or official reminders. As one GP described:

> *Someone newly diagnosed as a diabetic has to be notified, or a syncope episode or a stroke—those sorts of things—I'll sometimes go and notify the RMS [Roads and Maritime Services] for them, as at least you know that way it's done.* [GP3]

This illustrates how medical diagnoses such as diabetes or syncope can motivate both health care professionals and patients to seek relevant driving safety information and comply with legal requirements. Similarly, one older adult explained, "I got a letter in the mail saying you are due for a check-up… It's a push technique, not a pull" (P6, Male, 84). These examples illustrate how external systems, in addition to personal initiatives, often drive engagement with information about licensing and driving safety.

Preliminary Impressions of the Ageing Well on the Road Website

Participants were invited to review a prerelease version of the Ageing Well on the Road website and provide formative feedback. This input guided refinements to content and design before public launch, as a full usability evaluation was beyond the scope of this study. Older adults described the site as clear, accessible, and easy to navigate. One participant noted: "It wasn't too detailed, and it was in plain English…. I thought it was easy to read, and well presented" (P1, Male, 73), while another commented: "I thought it was easy to navigate, it was broken up into convenient tiles… it included things like technically advanced motor vehicles, and getting cars to assist with lane control etc" (P4, Male, 77). Credibility associated with the university affiliation was also highlighted as supporting trust in the information: "It's got the University of New South Wales symbol... so that gives it some credibility" (P7, Male, 71).

Specific content elements were particularly valued, including state-based licensing information and visual resources. One participant explained: "One aspect I found very good was that you had each state and territory listed, and their licensing requirements" (P4, Male, 77), while another added: "There was a graphic about the blind spots for heavy vehicles, and that was informative to me, because I didn't realize just how blind they are" (P3, Male, 67). Participants indicated they would likely recommend the website to peers, families, and community groups once it is live, noting, "Once it's online, then I'll certainly be promoting it as a good source of information" (P3, Male, 67). Overall, feedback was positive, and participants' broader insights on information needs, preferences, and driving safety concerns were used alongside this input to refine the website before public launch.

GPs also provided positive feedback and highlighted the site's potential use in clinical practice. One GP commented that the site "looks great" and that they would "absolutely refer patients to this." Suggested refinements included adding practical financial guidance for patients retiring from driving, such as demonstrating potential savings from selling a vehicle vs ongoing taxi or ride-share costs, and including information on taxi subsidy schemes. GPs recommended incorporating research-based statistics and evidence on driving frequency and skill decline to support clinical discussions. These suggestions informed adjustments to content and resources before the public launch.

Discussion

Principal Findings

This work represents formative, prelaunch development of the website and aimed to explore how older adults seek information about driving requirements and safety, their motivations and resource needs, and how GPs support older adults in making FtD decisions. Insights on online health-seeking behaviors, information preferences, and driving-related concerns informed the development of the website. Our findings suggest that older adults' information-seeking behaviors are often needs-driven, influenced by personal circumstances, medical conditions, and external prompts, such as family concerns or government notifications, as identified in interviews with older adults and GPs. This aligns with prior research suggesting that older adults often seek information when prompted by a specific need or external factor [25,26].

A key observation was that individuals with existing medical conditions, such as mild cognitive impairment, were more likely to actively seek information. For example, one participant described how a specialist's recommendation for an occupational therapy assessment prompted his search, reinforcing the belief that health-related triggers often lead to increased engagement with driving-related information [3]. Similarly, those with familial experiences of cognitive decline, such as dementia, sought information to better understand the legal and safety implications of continued driving. This finding mirrors studies that emphasize the important role family members and caregivers play in initiating conversations about driving cessation [27]. In contrast, participants who had not yet faced challenges to their driving ability expressed little motivation to seek information. This supports the idea that information-seeking behavior among older adults is often "needs-based" and typically occurs when it becomes personally relevant [26]. However, participants noted that legal requirements would become important over time, indicating they were aware of the information's future relevance even if not immediately needed.

Some participants in the interviews mentioned holding specialized driving licenses, such as for heavy vehicles or trucks. Unsurprisingly, these participants were generally more familiar with regulatory requirements due to the mandatory annual

XSL•FO
RenderX

medical assessments these licenses require. These individuals did not actively seek out additional information, as they felt their licensing processes inherently provided them with updates on medical and cognitive evaluations. This supports the idea that external regulatory frameworks can be effective in disseminating information to older adults, as also found in previous studies focused on policy-driven health behaviors [28].

Regarding preferred information sources, most participants favored online searches, especially Google and government websites. This suggests a need for user-friendly, government-verified online resources tailored to older adults, reflecting other findings from studies that show older adults are increasingly turning to digital platforms for information [29]. Building on these findings, research suggests that internet use can improve the physical and mental health of older adults [30] and that digital literacy is a key factor influencing engagement with online health information. Older adults can be disadvantaged in terms of physiological function, cognitive ability, social status, and economic status, which can limit their use of electronic technology compared with younger individuals [30]. Those with higher digital literacy are more confident navigating websites, evaluating content credibility, and applying information in daily life, whereas those with lower digital literacy may encounter barriers to effectively using digital resources [30,31]. Considering digital literacy and the local sociocultural context when designing a web-based platform could enhance accessibility, usability, and overall engagement, ensuring that the online resource is inclusive for older adults with varying levels of technological skill. When interpreted through the lens of CFIR and TAM, several constructs were particularly relevant in shaping user perceptions. For CFIR, intervention characteristics (such as perceived credibility and usability of the website) and individual characteristics (including confidence and comfort with digital tools) strongly influenced engagement. For TAM, perceived usefulness and perceived ease of use were key determinants of how participants evaluated and were willing to adopt new digital resources [11].

A key theme that emerged was the prevalence of a “push” rather than “pull” approach to information seeking. Many participants reported they did not seek out information unless prompted by an external cue, such as a family intervention or a government letter advising them to go for a medical check-up. This aligns with behavioral models of health communication, which suggest that external cues are often the primary motivators for action [32]. Overall, while some adults proactively sought driving-related information, many reported that they rely on external triggers. To promote safe driving behaviors among aging populations, efforts should leverage these “push” mechanisms to ensure older drivers remain informed and make safe decisions while driving.

In addition to the individual benefits, improving driving safety in older adults has broader societal implications. Older drivers are often overrepresented in crash and injury statistics [11], so supporting safer driving practices through proactive self-regulation and education in later life can contribute to the overall safety of all road users. Therefore, derisking older driver behavior is not only important for maintaining independence and mobility, but also for potentially reducing the public health burden associated with road traffic incidents.

Feedback on the prelive website was constructive and informed content and presentation refinements, providing an initial indication of reach and potential usability. Future research should be conducted to examine longer-term use, gather structured user feedback, and investigate how digital resources can be optimized for this demographic, including strategies to encourage proactive information-seeking. The website does not collect any user data, but visitor metrics, such as the number of views, are monitored monthly to provide ongoing insights into user engagement.

Limitations

This study involved a small, qualitative sample that offers in-depth insights, but limits generalizability to the broader population. The older adult sample was predominantly male and recruited from participants already engaged with research projects, potentially introducing positive bias. Limited demographic information was available for the GP focus group, as the hosting practice did not collect full participant-level data to minimize burden, with only summary information on age ranges, work status, and qualifications available, and sex was not reported. Study findings reflect the Australian licensing and health context and may differ in other jurisdictions. This work was formative and undertaken before the website’s public launch. While participants’ perspectives informed the website design, this study was not a formal usability evaluation. A comprehensive postlaunch evaluation was outside the scope of this project and will require further funding, but would be beneficial, with more diverse users and regions.

Conclusions

This study provides insight into factors influencing older adults’ engagement with driving safety resources. Findings suggest that information-seeking is often reactive, prompted by health issues, family concerns, or legal requirements. Barriers to engagement include skepticism about online resources, the complexity of licensing regulations, and reluctance to acknowledge the need for driving assessments, highlighting the importance of accessible, trustworthy, and user-friendly resources. External cues, such as medical recommendations and family and caregiver input, can encourage engagement with driving safety resources. GPs play a critical role, often serving as the first point of contact for older adults experiencing health issues affecting their driving. Proactive GP involvement, coupled with clear, reliable digital resources, may support older adults in seeking and applying relevant information. Future research should explore how health care professionals, particularly GPs, can be better supported and educated to enhance their role in FtD assessments.

Feedback from older adults, GPs, and stakeholders informed the formative, prelaunch development of the Ageing Well on the Road website [15]. Insights guided the creation of a dedicated clinician section and shaped the site’s plain-language content, intuitive navigation, and additional resources for family members and caregivers, who often play a critical role in initiating conversations about driving safety and helping older

XSL•FO
RenderX

adults navigate relevant information. The multiuser design aims to increase accessibility and promote shared decision-making. Stakeholders involved in the co-design process included representatives from National Seniors Australia, APIA, Suncorp Group, and Transport for NSW, reinforcing the need for accurate, trustworthy, and up-to-date content. Together, these contributions helped create a user-informed, accessible web-based resource tailored to the real-world needs of older adults and clinicians.

Overall, this formative work indicates that a co-designed, web-based platform has the potential to simplify access to essential information, build trust in digital content, and encourage early engagement by older adults and GPs. By addressing key barriers, the platform may contribute to safer driving practices, support independence, and inform broader road safety initiatives. Although developed for an Australian context, the platform's structure could be adapted internationally, with state- or region-specific driving regulations mapped to local legal requirements while maintaining the multiuser design and content approach.

Acknowledgments

The research team would like to thank the research volunteers who contributed to this study.

Funding

We would like to acknowledge the support of the ACT Road Safety Fund (grant reference RSG2023027), which provided funding for this research. We also thank Megan Hiller, Research Assistant, for her contributions to the content development and editing of the website. KJA was funded by an Australian Research Council Laureate Fellowship (FL190100011).

Abstract

Background: Everyday listening ability is essential for individual health and well-being. Age-related hearing loss (ARHL) is associated with reduced communication engagement, social isolation, loneliness, cognitive decline, and increased dementia risk. Interventions that simultaneously target auditory processing and cognitive function, particularly within engaging and ecologically valid contexts, may offer greater benefits than unimodal approaches. However, culturally adapted, web-based, gamified auditory-cognitive dual-task training (ACDT) tailored for older adults with ARHL remains underexplored. At the time of this writing, few auditory or auditory-cognitive training programs are available in Chinese languages, creating linguistic and cultural barriers for older adults.

Objective: This study aimed to (1) assess the feasibility and acceptability of home-based ACDT among older Chinese adults with ARHL and (2) examine its preliminary effects on global cognition, hearing, social engagement, and loneliness. It was hypothesized that the intervention group would demonstrate greater improvements in global cognition, hearing, and social engagement than the control group.

Methods: Sixty community-dwelling older adults with mild-to-moderate ARHL were randomized 1:1 to either the ACDT group or a waitlist control group in a single-blinded pilot randomized controlled trial. Demographic data and outcome measures were collected at baseline, week 6, and week 12. Postintervention interviews were conducted to assess the feasibility and acceptability of ACDT.

Results: A total of 60 participants were randomized (mean age 67.65, SD 4.78 years; 45/60, 75% male). ACDT demonstrated high feasibility and acceptability. The ACDT group showed significant improvements in focused attention (mean change=–0.15; P=.02; d=–0.46) and divided attention (mean change=–0.21; P=.002; d=–0.63). Significant cognitive improvements on the Hong Kong-Montreal Cognitive Assessment were identified in naming (r=0.37; P=.05) and visual cognition (r=0.44; P=.02) in the intervention group, while no significant improvements were found in the control group. Both groups reported significant decreases in emotional hearing handicap, with slightly greater improvement in the intervention group (r=0.39; P=.03) than in the control group (r=0.37; P=.04). Linear mixed model analysis revealed a small to moderate group effect (Cohen d=0.38) for 5-minute delayed recall on the Auditory Verbal Learning Test, with the fixed effects explaining 69% of the variance (marginal R^2=0.69). A significant time×group interaction was observed for left-ear thresholds (P=.01). Qualitative analysis identified three key themes: (1) intervention coherence and participants' affective attitude toward ACDT; (2) perceived benefits in cognition, information acquisition, and self-awareness from ACDT; and (3) perceiving ACDT as less burdensome with enhanced self-efficacy.

Conclusion: Future iterations should incorporate artificial intelligence–enhanced personalization. Large-scale randomized controlled trials involving diverse samples and active control conditions are needed to confirm sustained effects on auditory and cognitive health, dual-task listening-cognitive abilities, and real-world functioning.

Trial Registration: ClinicalTrials.gov NCT06486285; https://clinicaltrials.gov/study/NCT06486285

KEYWORDS

randomized controlled trial; age-related hearing loss; cognitive training; auditory training; gamified; dual-task training

Introduction

Everyday listening ability is essential for individual health and well-being. Age-related hearing loss (ARHL) represents a highly prevalent sensory deficit, affecting approximately one-third of adults aged 60 years or older [1,2]. ARHL is associated with reduced communication engagement, social isolation, and loneliness [3-5]. Beyond these social consequences, ARHL shows consistent associations with cognitive decline and increased risk of dementia [6-8]. Research indicates that even subclinical ARHL may increase the long-term risk of cognitive decline and dementia [9-12], with greater hearing loss severity correlating with poorer performance on memory, executive function, and mental status measures [13,14].

The mechanisms underlying these associations appear multifactorial, involving a complex interplay of sensory deprivation, increased cognitive load during auditory processing, accelerated brain atrophy (particularly in temporal regions), and reduced social-cognitive stimulation leading to neural disuse [15-19]. The sensory deprivation hypothesis suggests that prolonged reductions in sensor input (eg, hearing loss) increase the cognitive effort required for listening, and are subsequently associated with neural atrophy [17-19], while reduced auditory stimulation may cause structural brain changes, such as cortical thinning, reduced gray matter volume, and altered connectivity in auditory and multimodal networks [15,16]. The Cattell-Horn-Carroll theory of cognitive abilities provides a structured framework for describing and classifying the cognitive domains examined in relation to ARHL [20]. For example, increased listening effort may place greater demands on cognitive resources, particularly working memory and processing speed. This chronic reallocation of resources may reduce the capacity available for higher-order cognitive functions, including novel problem-solving, memory retrieval, and the application of acquired knowledge. Thus, hearing loss can cascade into broader cognitive impairment, extending beyond auditory processing alone [20]. Longitudinal evidence indicates that untreated ARHL is associated with a 30% - 50% increased risk of incident dementia and accelerates cognitive decline by 30% - 40% over 6 - 10 years [13,21,22]. Hearing loss treatment in mid-life may reduce dementia risk by 8% [23] with potential benefits in lowering health care use and costs [24,25]. These findings highlight the need for early intervention to mitigate the cognitive risks associated with ARHL.

While hearing aids may help mitigate the risk of cognitive decline [26], adherence challenges persist, and their benefits might be limited primarily to peripheral hearing deficits [27]. However, ARHL also involves central auditory processing difficulties, which appear to be more strongly associated with cognitive impairment than pure tone thresholds. These central deficits place significant demands on cognitive domains that are essential for understanding speech in complex listening environments. Accordingly, interventions that simultaneously target auditory processing and cognitive function [27], particularly in engaging and ecologically valid contexts, may offer greater benefits than unimodal approaches [28,29]. The auditory trainings for older adults with hearing loss mainly focus on speech or word recognition in noise, with auditory processing as the primary outcome [28]. Some studies have expanded these approaches by combining auditory training with cognitive training [30], contextual and visual cues [31], or elements of real-world communication [32]. For example, a randomized controlled trial (RCT) in the United Kingdom used computer-delivered phoneme training with 11 synthesized phoneme continua derived from natural voice recordings and implemented using a 3-interval, 3-alternative forced-choice oddball paradigm. Although the training produced substantial on-task learning effects in older adults with hearing loss, further research is needed to determine which training tasks are most effective, especially given the considerable individual variability in outcomes [30]. Dual-task training approaches, which require participants to perform distinct measurable tasks concurrently or sequentially [33], represent a promising direction for maximizing cognitive benefits [34]. Such training may improve the allocation of limited cognitive resources under challenging listening conditions while also providing repeated stimulation that could support neuroplastic changes in relevant networks [27]. In parallel, web-based cognitive training has shown promise for enhancing cognition [35,36], and gamification may further improve engagement in digital health interventions [37].

However, culturally adapted, web-based, gamified auditory-cognitive dual-task training (ACDT) tailored for older adults with ARHL remains underexplored. At the time of this writing, few auditory or auditory-cognitive trainings are available in Chinese languages, creating linguistic and cultural barriers for older adults. Given evidence that auditory training delivered in one's native language may enhance comprehension, engagement, and listening skill transfer [38], this study aimed to (1) assess the feasibility and acceptability of a web-based, gamified ACDT program performed at home among older Chinese adults with ARHL, and (2) examine its preliminary effects on global cognition, hearing, social engagement, and loneliness. It was hypothesized that the intervention group would demonstrate greater improvements in global cognition, hearing, and social engagement compared with the control group.

Methods

Study Design

A prospective, single-blind, 2-arm parallel pilot RCT, followed by descriptive semistructured individual interviews, was conducted between April 28, 2023, and June 27, 2025. Reporting followed CONSORT (Consolidated Standards of Reporting Trials; Checklist 1) guidelines [39], with the trial protocol available in Multimedia Appendix 1.

Ethical Considerations

The institutional review board of the Hong Kong Polytechnic University (HSEARS20230223006) approved the study. All participants enrolled in this study voluntarily and signed informed consent before the formal start of the assessment after being informed that they could withdraw at any time. Each participant was introduced to the aims and content of the study, potential risks, and benefits. All participants provided written informed consent in accordance with the Declaration of Helsinki. HKD $200 (~US $26; a currency exchange rate on April 28, 2023, is applicable) supermarket vouchers were provided to participants as an incentive to compensate for their time spent on the interview and completion of questionnaires. All data, audio recordings, and written records are stored on a password-protected laptop; only the research team has access to them. In addition, all data were used for research purposes only and could not be disclosed without the participants' consent. To ensure privacy protection, the participants' personal information was anonymized and labeled "P1-P60."

Study Participants

Participants were recruited using convenience sampling through community health centers and advertisements across Hong Kong (eg, social media). Eligibility criteria included (1) aged 60 years or older and living in the community; (2) mild-to-moderate hearing loss, defined as a pure-tone average (PTA) of 20 - 50 dB across octave frequencies from 0.5 to 4 kHz in both ears; (3) no prior use of hearing aids; (4) normal cognitive performance (Montreal Cognitive Assessment score ≥26); and (5) willingness and ability to provide informed consent and comply with study procedures. Exclusion criteria were (1) a history of psychosis, mania, bipolar disorder, substance use disorder, or suicidal ideation; (2) severe or unstable medical illness; (3) significant retrocochlear pathology or an organic lesion causing hearing loss; (4) a diagnosis of probable Alzheimer disease, vascular dementia, frontotemporal dementia, or Parkinson disease; and (5) use of medications, such as antidepressants, sedatives, or antiepileptics, that may affect cognition.

Sample Sizes

This pilot RCT was not designed to definitively test intervention effects, which would require a fully powered trial. Due to the absence of established effect sizes from previous literature, a target sample of 60 participants (30 per arm), allowing for 15% attrition, was determined based on recommendations for pilot RCTs [40,41] and with consideration of the study objectives, timeline, budget, and available tablets.

Interventions

The ACDT training system was co-designed by the research team and older adults with hearing loss, in collaboration with service providers in Hong Kong, and is patented (HK30110757) [42]. The 12-week training intervention consisted of five 60-minute sessions per week [42] and used a sequential dual-task training approach [33]. To enhance engagement, the system incorporates sound effects and interactive gamification elements, including likes, praise, fireworks, and leaderboards (Figure 1). In Figure 1, screenshot 1 illustrates the daily training pathway (only one module is activated per day). Screenshots 2 - 4 show a listening task with background noise, in which the participant listens to a sentence spoken by a male voice, repeats it, and checks whether all words were correctly heard. Screenshots 5 - 8 demonstrate different cognitive training tasks, including indicating a time using hand gestures, identifying locations, counting numbers, and reading Chinese idioms forward and backward. Screenshot 9 shows the scoring system, and Screenshot 10 presents the ranking list. It also offers participants flexibility for individual training while fostering a sense of virtual group participation through the leaderboard.

XSL•FO
RenderX

Figure 1. Screenshot examples of the web-based gamified auditory-cognitive dual-task training (ACDT) system developed by the team.

Each session begins with a 5-minute volume adjustment to establish a comfortable listening level, followed by attention or orientation training exercises where participants answer questions related to person (identifying their name), time (date, month, or year), and place (location at the time of this writing). This was followed by 25 minutes of auditory training based on culturally adapted exercises from the Listening and Communication Enhancement program [43]. The auditory training includes speech-in-noise perception, rapid speech comprehension, and competing speaker discrimination, all contextualized within real-life scenarios such as medical visits or dim sum gatherings. Difficulty hearing a speaker in noisy environments is a common and frustrating consequence of hearing loss. In the training, participants were trained to listen to a medium-length sentence presented in background noise, repeat it aloud, and then see the sentence in writing to confirm whether they understood every word. The difficulty levels of the sentence and background noise are automatically adjusted

XSL•FO
RenderX

based on the participant's performance on the previous sentence. This training enhances the brain's auditory processing by helping participants filter out background noise and focus on the target voice. Understanding rapid speech is another common challenge for older adults with hearing loss. In this training, the system automatically adapts the speed of sentences to help participants focus on fast talkers, aiding in comprehension. Additionally, ARHL makes listening difficult when multiple speakers are talking. During the training, participants listen to one of 3 voices (male, female, or child) as the target voice, while a competing voice is presented at varying volumes to create a challenge. This training teaches the participant's brain to ignore a competing speaker's voice and focus on the conversation they are engaged in. The auditory training was followed by 25 minutes of cognitive training delivered in a game-based format. These activities target executive function (forward/backward serial counting), perceptual-motor ability (arm-clock positioning), memory (forward/backward repetition of numbers/words), and complex attention (forward/backward spelling of Chinese idioms/poetry) using culturally relevant materials. Sessions concluded with a 5-minute wrap-up featuring communication strategy review ("learning classroom") and recall of visuospatial and memory tasks.

Waitlist Control

The waitlist control group received no intervention during the study period but was given access to the ACDT after T2 data collection.

Randomization

Stratified randomization based on key sociodemographic factors (eg, age, gender, and education level) was used to ensure balanced group allocation. An independent statistician assigned participants to either the ACDT or the waitlist control group in a 1:1 ratio using R software (R Core Team). Group assignments were placed in sealed opaque envelopes, and participants were informed of their allocation after completing all baseline assessments.

Study Procedures

After obtaining informed consent, a blinded researcher collected demographic data and administered outcome measures at baseline (T0), week 6 (T1), and week 12 immediately postintervention (T2). The week-6 assessment was included to identify potential early intervention effects, monitor participant attrition patterns, and verify adherence to the intervention dosage. Prior to intervention commencement, participants attended briefing sessions on system operation and received personal accounts with instructional videos. Technical support was available via a hotline.

All the ACDT participants were invited to take part in an individual interview at T2 following a semistructured interview guide (Textbox 1). The interviews were informed by the theoretical framework of acceptability (TFA) [44], which includes 7 constructs, including affective attitude, burden, perceived effectiveness, ethicality, intervention coherence, opportunity costs, and self-efficacy [44]. The TFA was used in the present study to gain a comprehensive understanding of participants' experiences with the ACDT, as well as their perceptions of and acceptability toward the intervention and study design. Interviews were held at community centers or in a university lab and lasted around 45 - 60 minutes. All the interviews were audio recorded to facilitate data analysis. Interview data were reviewed regularly by the study team until no new topics emerged, indicating that data saturation had been reached [45].

Textbox 1. Semistructured interview guide.

Example of questions

- How was your experience of participating in this study?
- Please tell me about your overall experience of attending the auditory-cognitive dual-task training (ACDT) sessions.
- Have you noted any changes in your health/daily life after participating in the ACDT? If so, do you think these changes were related to the training?
- Which ACDT task did you find most helpful, and which did you find least helpful? Please explain your reasons. What made them useful or not useful? How was your experience with the auditory training in this program?
- How was your experience with the cognitive training in this program?
- How was your experience performing the auditory and cognitive trainings simultaneously?
- What difficulties or problems did you experience when using the program?
- Would you like to continue this training at home in the future?
- What did the instructors or facilitators do that was most/least helpful?
- How do you think about the group-based setup of this ACDT program?
- Do you have any suggestions for improving the ACDT program?

XSL•FO
RenderX

Outcome Measures

Primary Outcome

The primary outcome of global cognition was assessed using a neuropsychological battery comprising (1) the Chinese Auditory Verbal Learning Test (AVLT), which assesses multiple cognitive domains including immediate recall, learning efficiency, delayed recall, retention rate, and recognition memory, and has demonstrated high test-retest reliability (intraclass correlation coefficient [ICC]=0.79 - 0.82) and 78% sensitivity; (2) the Chinese Trial Making Test Parts A and B, which measures visual attention, processing speed, and executive function, and has shown strong discriminant validity (Cohen *d*=1.2 for vascular dementia) [46]; and (3) the Hong Kong-Montreal Cognitive Assessment (HK-MoCA), a 30-point cognitive screening tool covering attention, naming, memory, language, visuospatial skills, abstraction, and orientation, with reported sensitivity of 89% and reliability (ICC=0.89 - 0.92) [47]. Alternating versions of HK-MoCA were used to minimize practice effects.

Secondary Outcomes

Secondary outcomes included: (1) hearing, measured by PTA and the Chinese version of the Hearing Handicap Inventory for the Elderly, which has demonstrated strong internal consistency (α=.91) and convergent validity with PTA (*r*=0.74) [48]; (2) social engagement assessed via the validated 6-item Chinese version of the Lubben Social Network Scale, with high test-retest reliability (ICC=0.85) [49]; and (3) loneliness measured by the 6-item Chinese De Jong Gierveld loneliness scale, demonstrating good internal consistency (α=.80) and discriminative validity for social isolation (area under the curve [AUC]=0.79) [50].

Covariates encompassed age, gender, baseline hearing and cognitive function, duration of hearing loss, education level, health status, and psychological well-being.

Feasibility and Acceptability

The feasibility and acceptability of the ACDT were assessed based on qualitative interviews and comprehensive logs documenting recruitment, retention, adherence, participant contacts, implementation challenges, withdrawal reasons, and completion factors (Multimedia Appendix 2). The intervention completion rate was defined as the extent to which participants completed the 60 training modules during the 12-week intervention period. System-generated data (training dates, progress, and performance metrics) were downloaded after the intervention.

Statistical Analysis

Data analyses and plotting were performed using SPSS Statistics (version 29.0.2.0; IBM Corp) and Python (version 3.11; Python Software Foundation). A 2-sided *P*<.05 was set as the predetermined threshold for statistical significance. Missing data (<7% across variables) were imputed using group means to support analyses requiring complete paired observations and to avoid excluding participants due to missing covariates. A natural log transformation was applied to TMT scores at all time points to address skewness. Baseline group equivalence was confirmed via independent *t* tests (continuous variables) and chi-square tests (categorical variables). The primary analysis focused on within-group changes from baseline to T2. Normality of the distribution of outcome change scores was evaluated using the Shapiro–Wilk test. Based on the results, within-group changes for normally distributed variables (*P*≥.05) were analyzed using paired *t* tests, with Cohen *d* calculated to measure effect size. For nonnormally distributed variables (*P*<.05), the nonparametric Wilcoxon signed-rank test was used.

Effect size *r* for the Wilcoxon signed-rank tests was calculated based on the standardized test statistic (*Z*) and the total number of observations. Effect sizes were interpreted using established criteria, with thresholds of 0.1, 0.3, and 0.5 indicating small, medium, and large effects, respectively. Between-group differences across time points (baseline, wk-6, and wk-12) were evaluated using linear mixed effects models. Each model included time (categorical, 3 levels), group, and the time×group interaction as fixed effects, while adjusting for the baseline value of the respective outcome as a covariate. Within-participant correlations across time points were modeled using a first-order autoregressive residual covariance structure. Models were fitted using restricted maximum likelihood. Pairwise comparisons of estimated marginal means for time×group interactions were conducted using the least significant difference adjustment. Given the explorative nature of the study, no adjustment for multiplicity was applied to the multiple comparisons of global cognition scores.

Qualitative data were analyzed using the hybrid thematic analysis approach described by Braun and Clarke [51], combining inductive coding with deductive theme organization guided by the TFA [44]. Two researchers (IYZ and HM) independently analyzed data in Chinese to preserve the original meaning conveyed by participants. Initial codes were generated directly from the transcripts and then mapped onto TFA domains using NVivo (version 14; Lumivero). Codes that did not align with existing TFA domains were used to inform theme refinement or adaptation. All codes and preliminary themes were documented in a spreadsheet, translated into English, and then back-translated into Chinese by HM and verified by IYZ. Any discrepancies were solved with input from the study team.

Results

Participants

A total of 60 participants were randomized. Baseline characteristics were comparable between groups regarding age, gender, education, employment status, marital status, living arrangements, and health status (Table 1). The mean age of the participants was 67.65 years (SD 4.78). Out of 60 participants, the cohort included 45 (75%) men and 15 (25%) women. Most participants (47/60, 78%) were retired and had attained an upper-secondary education or above. Seventy percent were married, while the majority (52/60, 87%) lived with a spouse, family members, or friends. Regarding health status, 42% (25/60) self-reported their health as good to very good, while 52% (31/60) reported their health as normal.

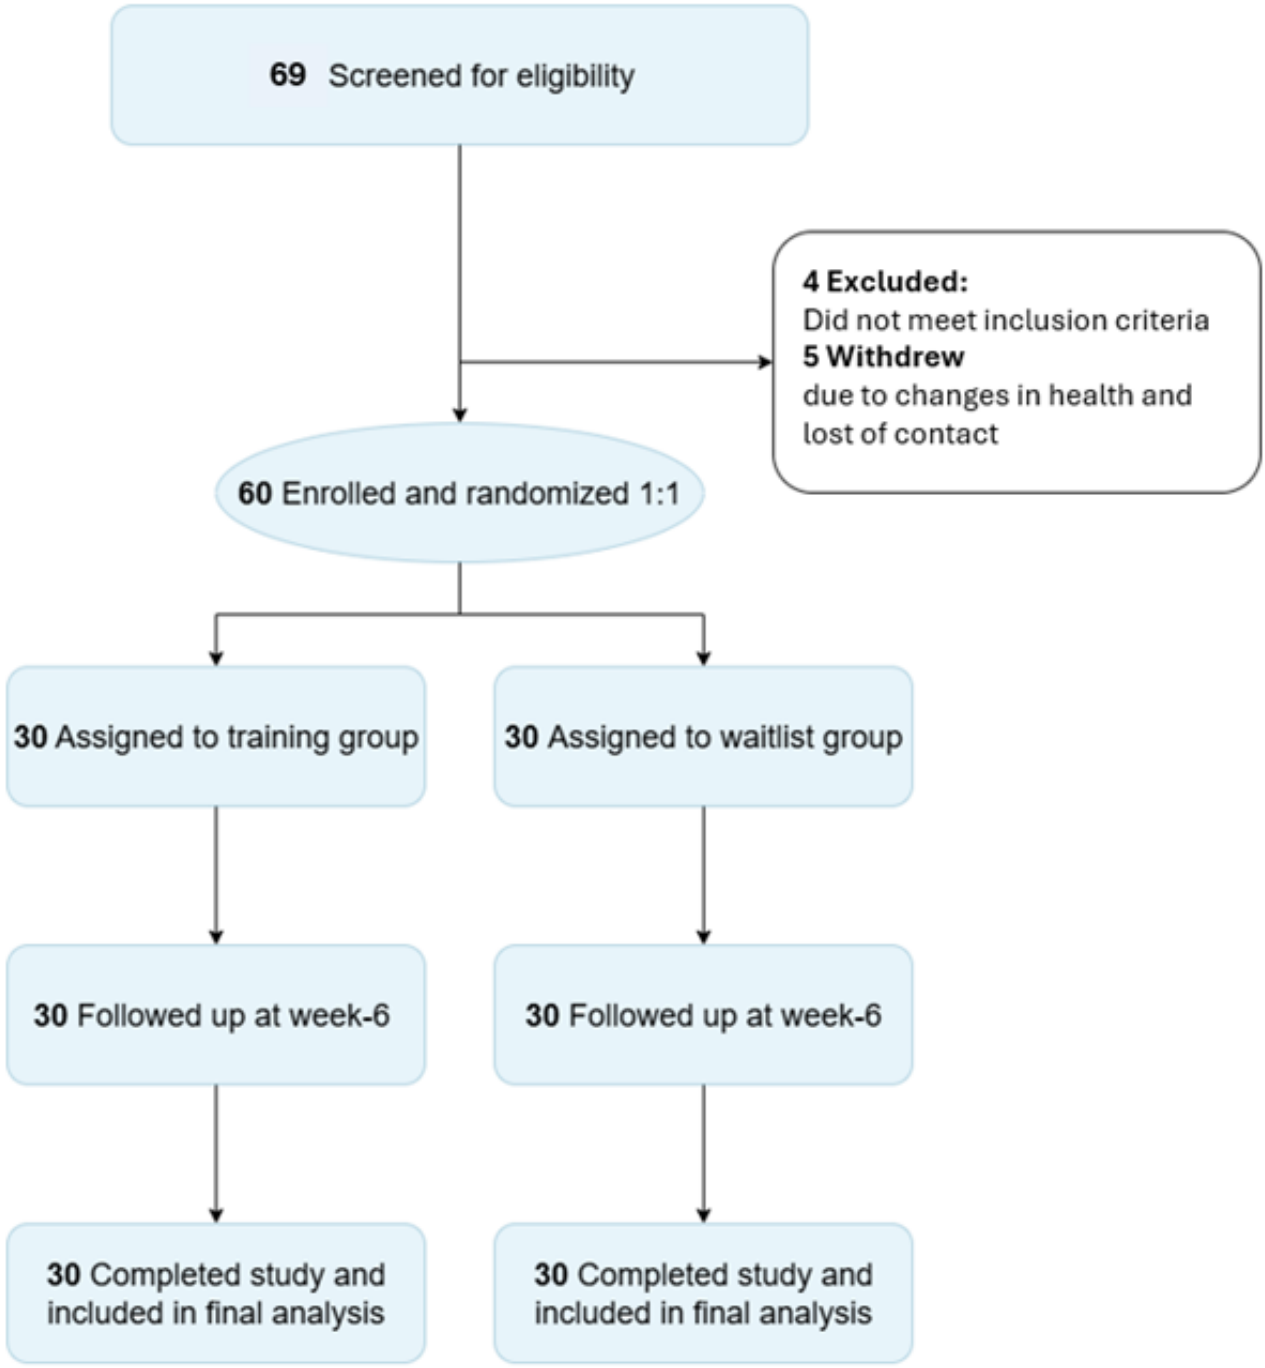
[a]Continuous variable: independent-samples *t* test,

[b]Categorical variables: chi-square test or Fisher exact test.



Feasibility of the Intervention

The trial proceeded according to the protocol without early termination. There were 69 candidates screened for eligibility; 4 were excluded for not meeting the eligibility criteria, and 5 withdrew prior to randomization due to health issues or loss of contact (Figure 2). Of the 60 participants who met the eligibility criteria, 30 were randomized to the ACDT group, and 24 of them completed all 60 training modules, while 6 participants completed 55 modules. The overall intervention completion rate was nearly 98% (1770/1800). At the beginning of the study, our hotline received a small number of calls regarding login issues, primarily from participants who had forgotten their passwords or were unsure how to reset them. This issue was resolved after we improved the study briefing sessions. No

XSL•FO
RenderX

adverse events were reported in either the intervention or control group.

Figure 2. CONSORT (Consolidated Standards of Reporting Trials) diagram.

Quantitative Results

Within-group analyses showed significant decreases in TMT completion times over 12 weeks, reflecting improved performance in focused attention (intervention: mean change=–0.15; *P*=.02; *d*=–0.46; control: mean change=–0.10; *P*=.027; *d*=–0.46), and divided attention (intervention: mean change=–0.21; *P*=.002; *d*=–0.63; control: mean change=–0.11; *P*=.02; *d*=–0.45). The intervention group demonstrated moderately greater improvements than the control group (Table 2). Both groups reported a significant decrease in overall hearing handicap. No statistically significant within-group changes were observed in HK-MoCA total scores or in social relationship and loneliness scores in either group.

[a]TMT-A: Trial Making Test Part A.

[b]TMT-B: Trial Making Test Part B,

[c]HK-MoCA: Hong Kong-Montreal Cognitive Assessment.

[d]HHIE: Hearing Handicap Inventory for the Elderly.

[e]PTA: pure-tone average.

For outcome variables that violated the normality assumptions, Wilcoxon signed-rank tests were conducted separately within each group (Table 3). In the intervention group, significant cognitive improvements were observed in the HK-MoCA subdomains of naming (Z=2.00; P=.05; r=0.37) and visual cognition (Z=2.39; P=.02; r=0.44), while the control group showed no significant within-group changes in these areas. Both groups reported significant decreases in emotional hearing handicap; however, the intervention group demonstrated a larger effect size (Z=2.15; P=.03; r=0.39) than the control group (Z=2.03; P=.04; r=0.37). Similarly, both groups demonstrated significant improvements in 5-min delayed recall on the AVLT, with the intervention group exhibiting greater improvement (Z=4.16; P<.001; r=0.76) than the control group (Z=4.11; P<.001; r=0.75).

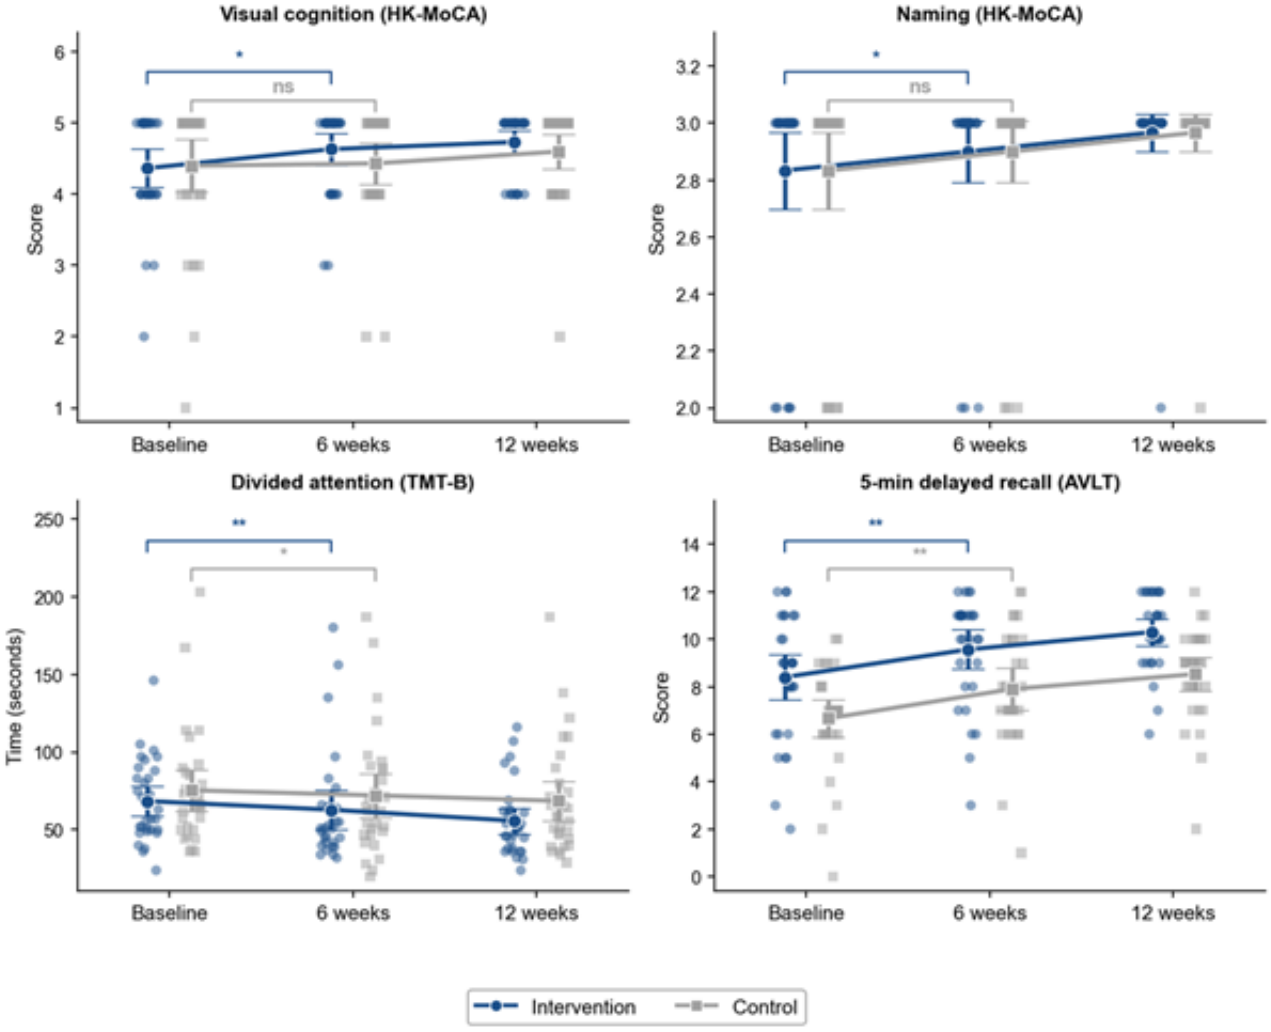
[a]HK-MoCA: Hong Kong-Montreal Cognitive Assessment.

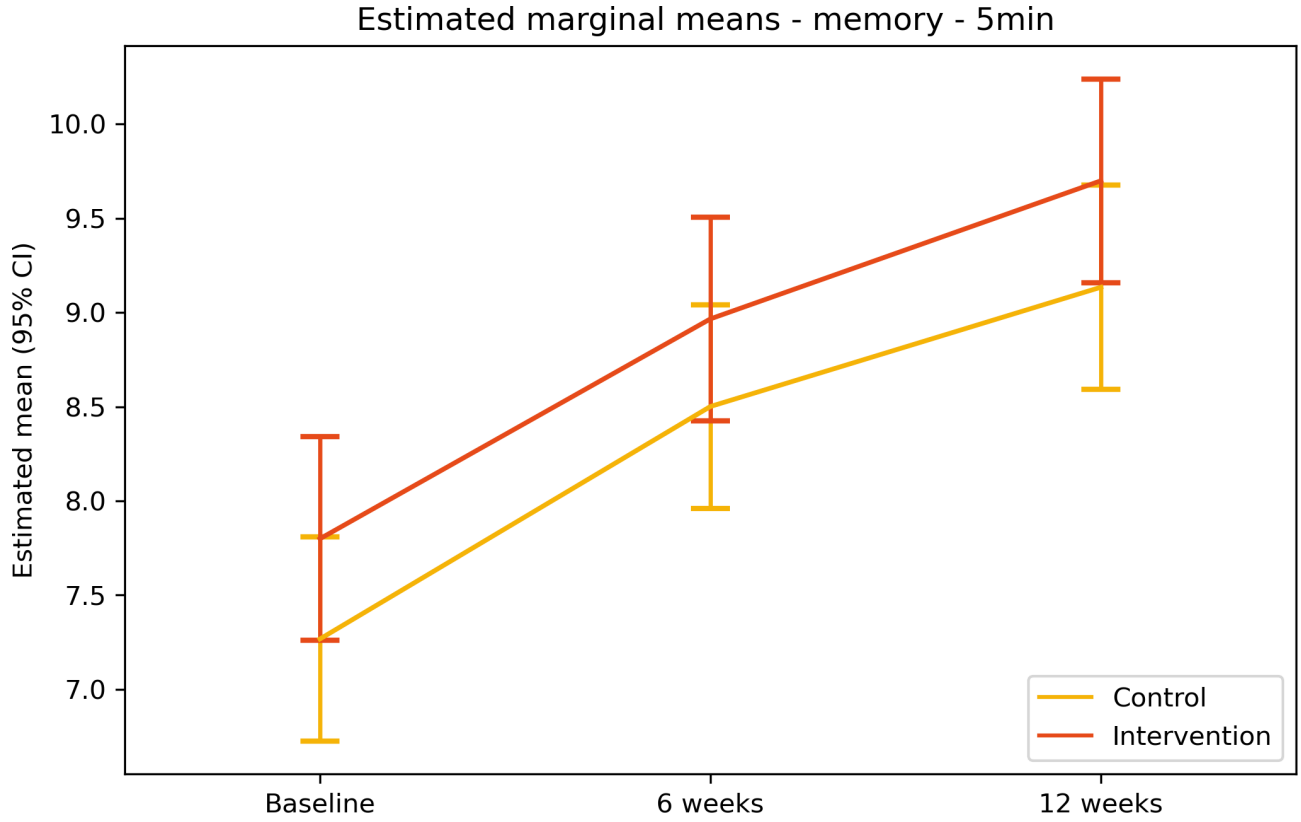
[b]HHIE: Hearing Handicap Inventory for the Elderly.



[c]AVLT: Chinese Auditory Verbal Learning Test.

[d]N/A: not applicable due to zero variance in the difference scores.

Changes in visual cognition, naming, divided attention, and 5-minute delayed recall at baseline, 6 weeks, and 12 weeks are shown in Figure 3 for the intervention group (blue circles) and the control group (gray circles). Each data point represents an individual participant's score, with a horizontal offset added for clarity. Lines connect the group means at each time point, and error bars indicate 95% CIs. The intervention group showed significantly greater improvement than the control group in these functions.

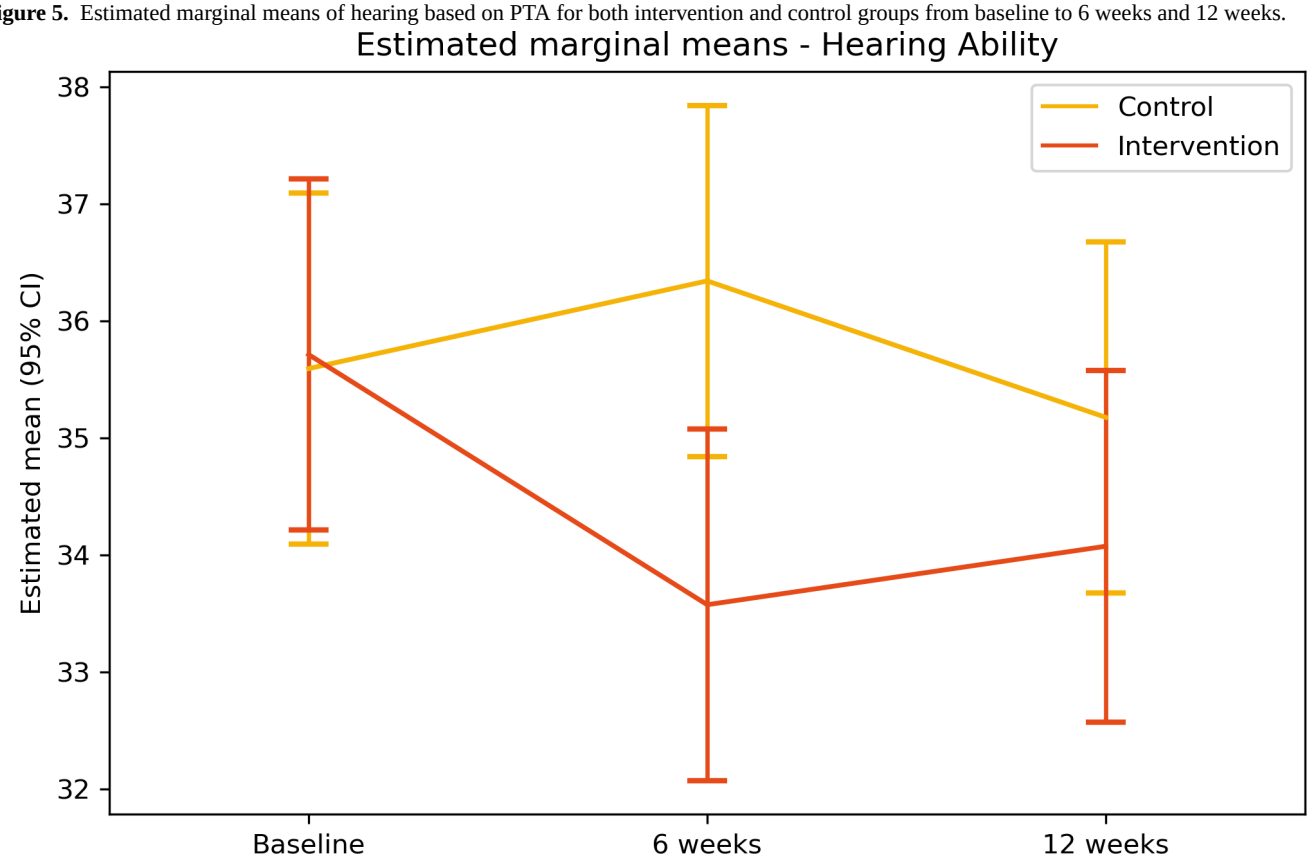


According to the linear mixed effects model analysis, a small to moderate group effect was observed for 5-minute delayed recall on the AVLT (Cohen d=0.38), with the fixed effects explaining 69% of the variance (marginal R^2=0.69). Baseline scores strongly predicted follow-up performance (standardized β=0.78). A significant main effect of time was identified ($F_{2, 129.5}$=25.70; P<.001), along with a significant group difference ($F_{1, 81.2}$=3.997; P=.05), indicating that the intervention group showed better memory scores across visits. The time×group interaction was nonsignificant ($F_{2, 129.5}$=0.022; P=.98; Figure 4).

Figure 3. Trajectories of visual cognition, naming, divided attention, and 5-min delayed recall across the assessment time points. Significance of within-group change from baseline to 6 weeks is indicated above each group's trajectory. AVLT: Auditory Verbal Learning Test; HK-MoCa: Hong Kong-Montreal Cognitive Assessment; TMT-B: Trial Making Test Part. *P<.05, **P<.01, and ***P<.001.

XSL•FO
RenderX

Figure 4. Estimated marginal means of 5-min delayed recall on the auditory verbal learning test (AVLT) for both intervention and control groups from baseline to 6 weeks and 12 weeks.



Cognitive performance was similar between the groups at baseline. Post hoc pairwise comparisons showed that cognitive functions on HK-MoCA total scores in the intervention group increased significantly from baseline to week 6 (P=.03) and were maintained at week 12. In contrast, the control group showed a significant decline from week 6 to week 12 (P=.02) with no net change from baseline.

For hearing thresholds (Figure 5), the standardized baseline coefficient was strong (β=0.88), but the group effect remained minimal (Cohen d=0.17), with a marginal R^2 of 0.67. A significant time×group interaction was observed for left-ear thresholds ($F_{2,\ 117.0}$=4.470; P=.01), indicating improved thresholds in the intervention group.

The Hearing Handicap Inventory for the Elderly total score showed a significant main effect of time ($F_{2,\ 112.6}$=14.69; P<.001), with both groups reporting reduced perceived hearing handicap at weeks 6 and 12 compared with baseline. A significant group main effect was observed for the social subscale ($F_{1,\ 62.1}$=4.81; P=.03), indicating that, on average, the intervention group reported lower perceived social hearing handicap than the control group, independent of time. There was no significant time×group interaction for the social subscale (P=.24).

Figure 5. Estimated marginal means of hearing based on PTA for both intervention and control groups from baseline to 6 weeks and 12 weeks.

Qualitative Results

A total of 30 participants in the ACDT group were interviewed, and 3 key themes were generated based on the TFA [44]. No ethical issues were raised by participants. Opportunity costs refer to the trade-offs users may have to make when engaging with the intervention. None of them explicitly expressed such concerns. Instead, most rearranged daily activities to accommodate the training.

Theme 1: Intervention Coherence and Participants' Affective Attitude Toward ACDT

Intervention coherence refers to the extent to which users understand the intervention, its purpose, and how it fits into their existing routines [44]. Participants generally valued the program's alignment with their cognitive health goals. Daily routines involving auditory-cognitive training were embraced as brain-stimulating activities, with Participant 16 emphasizing, "I value daily hearing and cognition training. The system's varied exercises provide consistent training." Participant 38 similarly stated, "I train seriously to improve memory and hearing." Some participants reported feeling nervous and under pressure when they first began the training, mainly because they were unfamiliar with the content and format. As Participant 35 mentioned, "At first, I was nervous because I had never done this before, but after a few sessions, I became more relaxed as I got used to the process." Over time, most participants integrated ACDT into their daily routines, with Participant 5 reporting, "I do it every morning after I get up; it has become like homework," and Participant 60 adding, "I attend the training every day even when traveling."

Affective attitude focuses on how users feel about using the intervention [44]. Participants generally reported neutral to positive attitudes toward ACDT. Most described their training experience as "acceptable," "quite interesting," and "enjoyable" (Participants 18, 22, and 43). However, some participants felt that certain training components were insufficiently engaging. Participant 13 specifically requested more personalized content with interactive features, noting,

> *For hearing training, I hope the content could be more interesting and personalized. I'm not interested in public transportation. The training should be more interactive, and I'd like immediate feedback.* [Participant 13]

This preference for ecological relevance was further reinforced by reports that tasks involving familiar daily scenarios were easier and more interesting than those involving abstract content. As Participant 14 explained, "Daily activities like going to restaurants or supermarkets are more interesting and easier to remember."

Theme 2: Perceived Benefits in Cognition, Information Acquisition, and Self-Awareness From ACDT

Most participants perceived that ACDT enhanced their abilities, particularly when they observed their own progress over time. Participant 60 described this as a source of motivation:

> *I think I do it happily as it is helpful to me. It turns out that when we see ourselves making progress, we can also challenge the difficulties.* [Participant 60]

Several participants reported improvements in attention and concentration during auditory tasks.

XSL•FO
RenderX

> *I notice the issue of concentration. When I want to learn something, I will know that I need to be more attentive and calm down to listen. This is the influence of the training on me.* [Participant 35]

Others described improvements in memory, mental clarity, and processing speed. Participant 5 observed, "I feel that my memory has improved because when doing math by heart, I often have to calculate the subtrahend and the addend."

Participants also found ACDT informative when integrating real-life scenarios. Participant 4 stated, "Yes, in terms of hearing training, the content can help us. There is some information about healthy or daily life, like when you eat dim sum, or you should not eat fried foods," while Participant 56 similarly described it as "very informative."

Beyond functional improvements, participants demonstrated greater awareness of their hearing and attentional limitations, prompting adaptive changes in communication behaviors. As Participant 18 reflected,

> *Sometimes it is not just about relying on hearing. I begin to realize that many times I cannot do certain things because I suddenly think of something else. So in daily life, I start to understand where my problems lie. [Participant 18]*

Sustainability concerns emerged, with Participant 56 expressing her concern about "maintaining gains after completing of this study."

Theme 3: Perceiving ACDT as Less Burdensome With Enhanced Self-Efficacy

Most participants perceived the training as manageable, with several attributing this to prior life experience or visible self-improvement. As Participant 17 noted, "I don't find it difficult as my previous job was very demanding," while Participant 18 connected manageability to perceived benefits, "I feel no burden because it's a training, where I can manage my own time to complete it." Completing sessions often fostered a sense of accomplishment, as illustrated by Participant 34's comment, "I feel confident after finishing tasks." Participants also described progressive mastery of the auditory exercises, with several individuals (34, 42, and 57) noting "improved processing speed and accuracy." Elements like competing voices were perceived as "both challenging and engaging" (Participants 5 and 34). While task difficulty occasionally prompted frustration, as Participant 55 acknowledged, "There is a sense of success when I answer correctly, but difficult tasks can be frustrating." However, they maintained motivation through perceived utility. Participant 49 articulated this resilience, "The hardest parts are likely most useful; backward counting's challenge makes it interesting."

Discussion

Primary Cognitive Outcomes

This pilot RCT provides preliminary evidence for the feasible, acceptable, and potential efficacy of ACDT for older adults with ARHL. Participants in the ACDT group demonstrated significant improvements in focused attention, divided attention, naming, and visual cognition. However, the control group's improvement in some cognitive measures suggests possible practice effects from repeated testing, highlighting the need for active control conditions in future trials. These findings extend evidence that combined auditory-cognitive training selectively enhances executive functions and visual processing, which are critical domains in dementia risk reduction [52]. This pattern converged with qualitative findings of "enhanced attention and concentration," "improved memory and mental clarity," and "increased processing speed" during daily activities. Mechanistically, results align with previous research that auditory training enhances attention in older adults with hearing loss [53], cognitive training improves domain-specific functions, and dual-task trainings strengthen executive control [34]. The gamified design likely amplified these effects through enhanced engagement and motivation, which is supported by participant feedback and studies showing gamification improves adherence and training outcomes in cognitive interventions [54]. Additionally, further research is warranted to examine the effects of ACDT on dual-task listening-cognitive abilities using an active control group, as poor dual-task performance is recognized as an early indicator of dementia [30].

Notably, the ACDT group exhibited improved 5-minute delayed recall with small-to-moderate group effects and maintained higher average scores across assessments than the control group. This finding is clinically significant given delayed recall is an established early marker for cognitive decline and dementia risk [55]. Furthermore, post hoc pairwise comparisons demonstrated that HK-MoCA total scores significantly increased from baseline to week 6 and were sustained at week 12 in the ACDT group, suggesting that ACDT may help stabilize global cognition over time.

Auditory Threshold Findings and Possible Indicators of Training-Induced Neuroplasticity

Hearing threshold analysis revealed minimal overall between-group differences, which means that ACDT did not produce a significant improvement in PTA compared to the control group, and this finding is consistent with the recognized stability of peripheral hearing loss over short time intervals [56]. While the significant time×group interaction observed for left-ear thresholds may indicate training-induced neuroplasticity in central auditory pathways [57], these preliminary findings warrant confirmation in larger trials. Future studies should investigate whether specific training components can be optimized for bilateral benefits and determine if observed neuroplastic changes translate to measurable functional communication improvements.

Perceived Hearing Handicap and Increased Awareness

Interestingly, the control group reported lower perceived overall hearing handicap but higher emotional hearing handicap than the ACDT group. One possible explanation is that the ACDT participants became more aware of their hearing challenges, leading to more accurate self-reporting. In contrast, the control group may have had lower insight into their hearing limitations, potentially resulting in underreporting. This interpretation aligns with qualitative findings and researcher observations during data collection, wherein ACDT participants frequently described

XSL•FO
RenderX

increased awareness of hearing-related challenges in their daily lives. Previous research also supports that targeted interventions can improve auditory awareness, which may initially increase self-reported handicap but ultimately facilitate adaptive behavior change [58].

In our study, participants reported enhanced recognition of auditory and attentional limitations, which subsequently prompted adaptive modifications in communication behaviors. Many participants described integrating training into their daily routines and adopting compensatory strategies to improve attention and listening engagement, which may reflect a meaningful sign of behavior change. However, longitudinal investigation is required to verify sustainability. ACDT also fostered perceived accomplishment and strengthened self-efficacy, potentially encouraging sustained engagement in beneficial behavior changes. Collectively, these findings position ACDT as a catalyst for positive behavioral adaptations, benefiting not only participants but also their families.

In this study, no statistically significant changes were observed in social relationship or loneliness scores for either group. A possible explanation is that participants were comparatively young, most were married and living with a spouse or other family members, and they demonstrated a positive attitude toward adopting this new training to address their hearing problems. Future studies should test ACDT among individuals at higher risk of loneliness and social isolation.

Enhancing Training Content and Interactivity Using Artificial Intelligence

While the intervention was generally well-received, participant feedback identified opportunities for enhancement through more personalized and interactive training content. Integration of artificial intelligence (AI) can dynamically tailor training modules to individual abilities and progression patterns, with real-time adjustments in difficulty and personalized feedback to optimize training efficacy while maintaining engagement. Machine learning algorithms could further enhance ecological validity by generating complex auditory environments that simulate real-world scenarios, improving training transferability to daily communication challenges. Incorporating AI-powered analytics could continuously monitor user performance trajectories, identify areas for improvement, and deliver targeted interventions to maximize auditory and cognitive gains. Future iterations of ACDT should prioritize the development of AI-enhanced features, including personalized content, interactive feedback, and real-time progress tracking. Engaging users and their families in the co-design process is essential to ensure that the platform meets their needs and preferences.

Strengths and Limitations

This study demonstrates several strengths, including (1) multimodal assessment of auditory and cognitive outcomes, (2) ecologically valid gamified design that could enhance participant engagement, and (3) novel documentation of self-awareness as a facilitator for adaptive behavior change. However, several limitations warrant consideration: (1) the modest sample size and absence of longitudinal follow-up limit detection of subtle neuroplasticity effects, such as the observed hearing threshold trend; (2) the waitlist control design cannot exclude attention bias and isolate the specific efficacy of dual-task training; and (3) although ARHL has been reported to be more common, more severe, and to have an earlier onset in men than in women [59], the homogeneous participant characteristics regarding education level and hearing loss severity, along with a predominance of male participants, may restrict generalizability of our findings to broader ARHL populations.

Conclusions

This pilot RCT suggests that ACDT is feasible and acceptable for older adults with ARHL, with preliminary evidence supporting its potential efficacy. The intervention appeared to benefit both auditory and cognitive domains, as well as self-awareness of hearing loss, which may facilitate adaptive behavioral adjustments. Future development could explore AI-enhanced personalization and interactivity to improve ecological relevance. Further trial with larger, more diverse samples, active control conditions, and longitudinal follow-up would help clarify ACDT's sustained effects on auditory-cognitive health, dual-task listening-cognitive abilities, and real-world functioning.

Abstract

Background: Wearables such as smartwatches can support point-of-care health management for older adults while reducing pressure on health care systems as aging populations grow. Although many studies emphasize technical accuracy, user-centered research on smartwatch adoption among older adults remains limited, particularly in low- and middle-income countries, such as Bangladesh.

Objective: This study evaluated real-world usability, acceptance, and adoption of smartwatches among socioeconomically diverse older adults (aged ≥60 y) in a low- and middle-income country context. It examined how age, education, socioeconomic background, and cultural perceptions influence user experience, and identified barriers and facilitators related to comfort, usability, and long-term engagement. It also explored health-related features that older adults perceived as missing.

Methods: Participants were recruited from older adult communities with diverse socioeconomic and educational backgrounds, and received a commercially available smartwatch. A mixed methods, 3-phase longitudinal design was conducted, including a short-term survey (n=27), 3 long-term survey data points (n=19, 18, and 18), and 2 focus group interviews (n=13 and 12). Quantitative analyses included paired *t* tests across longitudinal data points and chi-square tests for distributional associations, complemented by thematic qualitative analysis.

Results: Comfort improved substantially over time, with participants rating the smartwatch as very comfortable, increasing from 26% (5/19) at baseline to 80% (16/20) at final follow-up. Heart rate monitoring remained the most frequently used feature, rising from 68.42% (13/19) to 75% (15/20). Paired *t* tests showed no significant longitudinal changes in daily usage (t_5=0.00 to 0.22, *P*=.83 to ≥.99), comfort (t_4=−0.07 to 0.30, *P*=.78 to .95), most liked features (t_8=−0.63 to 0.51, *P*=.30 to .62), or clarity of instructions (t_2=0.00 to 0.19, *P*=.87 to ≥.99). Significant increases were observed in feature usage (data point [DP] 2 vs DP3: t_8=−4.16, *P*<.001; DP1 vs DP3: t_8=−2.53, *P*=.03) and perceived difficulty of use (DP2 vs DP3: t_8=−4.29, *P*<.001; DP1 vs DP3: t_8=−2.31, *P*=.05). Chi-square analyses indicated a significant association between study phase and clarity of instructions (χ^2_4=10.3, *P*=.03), with a trend for comfort (χ^2_8=13.8, *P*=.08); other usability dimensions were non-significant (χ^2_{16}=7.1 to 17.5, *P*=.35 to .97). Socioeconomic differences emerged in data-sharing preferences, with higher socioeconomic participants favoring continuous sharing and lower socioeconomic participants preferring emergency-only sharing.

Conclusions: Older adults can adapt to wearable health technologies when given adequate time and support, regardless of education level. Preferences for a limited set of essential health features and faster adoption among participants with lower educational backgrounds highlight the need for simpler smartwatch designs. These findings can guide age-appropriate wearable technologies that prioritize usability, comfort, and familiarity to improve health care access in resource-limited settings.

Introduction

The use of wearables for point-of-care health management has the potential to enhance independence and quality of life among older adults while alleviating pressure on health care systems amid an aging population worldwide [1-3]. While numerous studies have examined the technical accuracy and performance of wearable technologies, significant challenges and limitations remain [4]. Validation studies have assessed wearable activity

XSL•FO
RenderX

trackers in older and clinical populations, supporting measurement reliability while highlighting the need for usability-focused research [5]. Furthermore, user-centered investigations into factors influencing the adoption of wearables among older adults, particularly in low- and middle-income countries (LMICs), such as Bangladesh, are scarce [6].

Wearables have demonstrated benefits in chronic disease management, such as diabetes care, through real-time monitoring and personalized feedback [7]. Wearable sensors and systems have also been extensively explored in rehabilitation and long-term monitoring, demonstrating value for supporting functional health needs [8]. Smartwatches and Internet of Things–based applications can also facilitate independent living by enabling safety monitoring and home health supervision for aging populations [9]. Evidence also suggests that wearable-based interventions can improve physical activity and health outcomes among older adults in community settings [10]. Wearables offer diverse applications, including position and posture tracking, activity recognition, and real-time vital sign monitoring, which are particularly useful in home health care [11].

Despite these advantages, adoption among older adults is inconsistent, and mixed methods studies suggest that usability, contextual, and behavioral factors shape long-term engagement [7]. Design aspects may introduce stigma perceptions, affecting willingness to adopt such devices [12]. Acceptance models further indicate that perceived usefulness and health-monitoring value are central determinants of adoption intention [13].

Older adults may also experience technology anxiety and resistance to change, reducing their readiness to adopt wearable health technologies [14]. Predictive studies suggest that adoption is influenced by multiple interacting antecedents, including behavioral, psychological, and contextual factors [15]. Concurrently, wearable health technologies intersect with artificial intelligence–driven markets, where health consciousness and privacy preferences play important roles in user adoption [16].

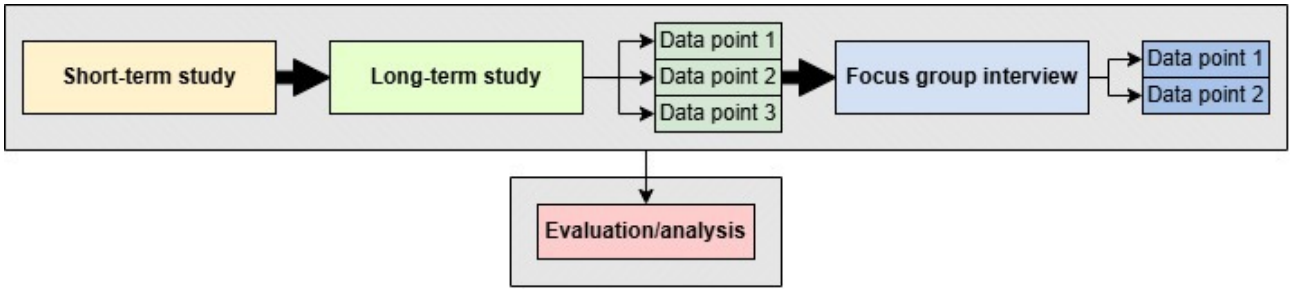
Community-based research indicates that older adults' acceptance of smartwatches is often driven by health and location tracking functions when these align with personal needs [17]. Adoption of fitness technology encourages physical activity and behavioral change, but adoption and long-term engagement are influenced by both perceived usefulness and social visibility, highlighting the interplay between practical value and social context [18,19]. User-centric research from LMIC settings, such as the Philippines, reinforces that real-world adoption depends on usability, perceived value, and local contextual factors [20,21]. At the same time, wearable technology development faces broader challenges, including reliability, battery life, and interface complexity, which can hinder adoption [21].

Older adults often encounter difficulties using smartwatches, including small displays, discomfort, limited battery life, and complex interfaces, making usability evaluation critical [22]. Qualitative studies emphasize that long-term comfort is shaped by interacting human and design factors and strongly influences continued use [23,24]. Focus group research suggests that perceptions, motivators, and barriers influence tracker use during behavior change maintenance, emphasizing the role of perceived value and ongoing support [24]. Technology adoption decisions are further shaped by psychological, social, and situational factors [25].

It is found that qualitative synthesis methods are effective for exploring lived experiences and uncovering usability barriers that quantitative approaches may overlook [26]. Observational studies show that wearable activity trackers can be acceptable for older adults in real-world settings, although practical challenges remain [27]. Systematic reviews highlight that experiences with wearables vary depending on device type, setting, support systems, and integration into daily routines [28,29]. For example, field testing of fall detection wearables demonstrates that real-world deployment can reveal practical challenges not captured in controlled studies [29]. Wearable systems for measuring gait and physical activity in chronic conditions require usability considerations to ensure adherence and data quality [30,31].

Evidence suggests that continued wearable use among older adults is strongly associated with comfort, alignment with daily routines, and perceived value, underscoring the importance of context-sensitive, user-centered design [23,32-38]. Addressing these factors is essential for designing age-appropriate wearable technologies that maximize adoption, usability, and health impact in resource-limited contexts. Hence, in this work, we use a mixed methods study to examine user adoption and reactions to existing smartwatches across diverse older adult populations, and to evaluate age-centric, socioeconomic, and user-focused adoption barriers and facilitators.

Methods



Recruitment

Overview

The core goal of this study is to assess the usability of smartwatches among the older adult communities in an LMIC, like Bangladesh. The first step of the study was to identify interest levels and engage with communities of older adult individuals, as detailed in the following sections. Following that, a survey process of 3 cycles was conducted using purposive sampling techniques by recruiting individuals from different socioeconomic and educational backgrounds, lifestyles, and educational backgrounds. This study cycle includes (1) a short-term survey, (2) a long-term survey with 3 data points (DPs), and (3) a focus group interview with 2 DPs. The final step of the study includes survey analysis and finding key insights from all the cycles for designing a specific older adults–age-centric health monitoring smartwatch. Figure 1 presents a flowchart of the methodological framework of the study.

Participant Demographics and Recruitment

An institutional review board (IRB) was approved by the North South University Scientific Regulatory Committee, and all participants were asked to complete a consent questionnaire. At the start of our study, we surveyed older adult individuals aged 60 years and older from our local community (friends, families, neighbors, and service staff) to understand their interest in using smartwatches for health monitoring. Then we contacted 5 old-age homes in and around Dhaka City and visited them to assess the interest level of participation. Initially, 2 old-age homes and a group of janitors (from residential areas of the authors) agreed and were recruited in the short-term survey study. However, due to internal management issues at one of the old-age homes, the consecutive surveys were conducted with the participants of one old-age home called Probeen Nibash (managed by the Ministry of Social Welfare in Dhaka, Bangladesh). We procured approval from the management of Probeen Nibash to conduct the study at their center and then talked individually to residents to explain the purpose and format of the long-term study. Based on their consent and the inclusion-exclusion criterion, selective participants were recruited from this old-age home. Similarly, several janitors were approached from the authors' local communities, and those who willingly consented were recruited to continue the long-term study. The participants were between 60 and 103 years old, male and female, and purposefully sampled from diverse backgrounds. The participants were divided into 2 groups based on socioeconomic and educational backgrounds.

Inclusion and Exclusion Criteria

Older adults (older than 60 y) who were generally healthy and able to walk >50% time around on their own or with the use of an assistive device (such as a walker) were included. Older adults with restricted mobility (like in a wheelchair >50% time) or conditions that may limit the use of devices, such as blindness and cognitive decline, were excluded.

Survey Method and Participant Demographic Analysis

Overview

Before the first survey, a preliminary questionnaire session was conducted with each participant to collect demographic and baseline health-related information, including age, gender, occupation, educational qualification, and medical history of the past 6 months. The objective of this preliminary questionnaire was to evaluate their eligibility (and health condition) and interest in the study. Older adults (older than 60 y) who are generally healthy and able to walk >50% of the time around on their own or with the use of an assistive device (such as a walker) were included. In contrast, older adults with restricted mobility (like in a wheelchair >50% of the time) or conditions that may limit the use of devices, such as blindness and cognitive decline, were excluded. Aging people with severe cognitive dysfunctions were also excluded. The eligibility criteria included a set of subsectioned questionnaires to assess the participant's health and mental health conditions, technological knowledge, and experience with modern technology to ensure their suitability for our study. From these observations, we found that most participants had no previous experience using technologically advanced devices like any smart wearable, and none had ever used a smartwatch.

Each participant was provided with an Oraimo Watch 4 Plus smartwatch after providing written informed consent to participate in the study. A detailed user guide was also supplied to ensure that participants clearly understood how to operate the device. At the time of the study, the device was commercially available at an approximate cost of US $20.06. The Oraimo Watch 4 Plus was selected due to its affordable price and the availability of standard health-monitoring features commonly found in other commercially available smartwatches.

Short-Term Survey

This survey aimed to determine short-term adherence and compliance to the protocol using the smartwatch device among the participants. Short-term surveys were conducted in 3 places after the participants were distributed the smartwatch for 14 days, with 27 participants from varying socioeconomic and educational backgrounds, as presented in Table 1. Among them, 15 out of 27 (56%) were male participants, and 12 out of 27 (44%) were female, with an average age of 60.55 (SD 7.38) years. In contrast, 13 out of 27 (48%) of participants belonged to a higher socioeconomic background, while 14 out of 27 (52%) belonged to a lower socioeconomic background. This survey involved a comprehensive questionnaire with 19 questions, including 15 multiple-choice and 4 short-answer questions. The following key questions were asked of the participants during the short-term survey:

1. How often do you wear your smartwatch?
2. How comfortable is your smartwatch to wear?
3. Have wearable health technologies helped you in achieving your health goals?
4. Did you find the screen size and text clear and easy to read?
5. Does using a smartwatch present any barriers concerning your religious, social, or cultural beliefs?

XSL•FO
RenderX

6. Did the device provide clear and simple instructions?
7. Did the device feel age-appropriate for you?
8. Have wearable health technologies helped you in achieving your health goals?
9. Which features do you like the best?
10. Which features do you feel uncomfortable with?
11. Which features are important to you in wearable health technology?
12. Would you recommend this device to other older adults?
13. Did you find the device frustrating to use?
14. What challenges do you face when using wearable health technology?
15. What improvements do you expect from this smartwatch?
16. How do you manage and interpret the data collected by your wearable health technology?
17. What kind of support do you expect from smartwatch manufacturers regarding religious use?

Table . Total number of participants, male and female ratio, mean age of participants, percentage of lower socioeconomic class participants, and percentage of higher socioeconomic class participants.

Survey type	Total participants, n	Male, n (%)	Female, n (%)	Age of participants (y), mean (SD)	Participants belonging to lower socioeconomic class, n (%)	Participants belonging to higher socioeconomic class, n (%)
Short-term survey	27	15 (56)	12 (44)	60.55 (7.38)	14 (52)	13 (49)
Long-term survey 1	19	15 (79)	4 (21)	65.00 (8.46)	7 (37)	12 (63)
Long-term survey 2	18	16 (89)	2 (11)	63.11 (5.26)	9 (50)	9 (50)
Long-term survey 3	18	15 (83)	3 (17)	63.16 (5.20)	10 (56)	8 (44)
Focus group interview 1	13	9 (69)	4 (31)	65.08 (9.59)	6 (46)	7 (54)
Focus group interview 2	12	10 (83)	2 (17)	64.75 (8.73)	7 (58)	5 (42)

Long-Term Survey

After completing the short-term survey, the long-term survey had to be proceeded with fewer participants. The participants of one of the old-age homes were excluded from the survey due to internal management issues at the organization, leading us to proceed with just one old-age home's participants and a group of janitors. Also, a few participants from these 2 groups felt disinterested in continuing after the first DP of the long-term survey, primarily due to health issues and inability to adhere to the study guidelines. The first DP, long-term survey-1, was conducted with 19 participants, while long-term survey-2 and long-term survey-3 were conducted with 18 participants due to the sudden death of one of the participants from long-term survey-1. Each long-term survey was conducted at an interval of 10 days. Therefore, this survey section lasted for 30 days. As described in Table 1, the long-term survey-1 was conducted with 15 out of 19 (79%) male and 4 out of 19 (21%) female participants, 12 out of 19 (63%) belonging to a high socioeconomic background, and 7 out of 19 (37%) from a low socioeconomic background. In contrast, long-term survey-2 and long-term survey-3 were conducted with 16 out of 18 (89%) male participants and 2 out of 18 (11%) female participants. Additionally, a minimum of 8 out of 18 (45%) of the participants belonged to high socioeconomic backgrounds, while the other 10 out of 18 (56%) were from low socioeconomic backgrounds. The survey questions of the long-term survey were correlated to the short-term survey, and some variations in question types were used to improve assessment and analysis. The aim of this survey session was to find insights into usability factors of the smartwatch over a long-term period.

The key questions of the long-term survey included:

1. How often do you wear your smartwatch?
2. Which of the following health metrics do you track?
3. Which features do you like the best and are most comfortable with?
4. Which feature of the smartwatch do you find uncomfortable or dislike the most?
5. Rate how comfortable your smartwatch is to wear (out of 5).
6. Does using a smartwatch present any barriers to your religious, social, or cultural beliefs?
7. Did the device provide clear and simple instructions?
8. Has there been any technological challenge in using or understanding the watch?
9. Did the device feel age-appropriate for you?
10. Has the smartwatch helped you in achieving your health goals?
11. What challenges do you face when using the smartwatch?
12. What improvements do you expect from this smartwatch?
13. What health parameters did you collect from the smartwatch?

Focus Group Survey

Based on the socioeconomic background, 2 focus groups were formed among the participants of the long-term survey. However, some participants did not show interest in participating in these sessions due to various reasons. Group A included

XSL•FO
RenderX

participants from higher socioeconomic backgrounds, while group B included participants from lower socioeconomic backgrounds. The first focus group survey was conducted 14 days after completion of the long-term survey (round 3), and the second focus group survey was conducted 14 days after the first focus group survey. These focus groups were repeated in 14-day intervals to investigate if the participants' responses were consistent. More importantly, the focus groups were stratified across socioeconomic backgrounds to understand if and how different backgrounds might influence their experiences with the survey. The first focus group survey was conducted with 13 participants, while group A comprised 7 out of 13 (54%) participants, and group B comprised 6 out of 13 (46%).

In contrast, during the second focus group survey, there was 1 dropout due to illness, consisting of 12 participants, with 5 out of 12 (42%) representing group A and 7 out of 12 (58%) from group B. Each focus group session was conducted for approximately 1 and a half hours at the primary location of the participants to ensure convenience and comfort. Participants were asked structured questions during the sessions, and their responses were collected individually. A casual conversation was facilitated alongside the structured format to explore their thoughts and expectations regarding wearable technologies. The entire session was audio-recorded with participant consent to capture all responses accurately.

Ethical Considerations

This user study or randomized controlled trial to study the adoption behavior of smartwatches among older adults was approved by North South University's IRB and Ethics Review Committee (IRB #2023/OR-NSU/IRB/1231). All the surveys and focus groups described in the study were performed within the guidelines and duration of the approved IRB. A consent form and a baseline health questionnaire were evaluated from each participant before the surveys were conducted. Moreover, participants had the choice to drop out of the study at any time point, which happened over the course of the study. The participants were also provided with contact information of the researcher team for any queries. All data were collected, stored, and analyzed in compliance with HIPAA (Health Insurance Portability and Accountability Act) guidelines and data privacy laws. The participants were recruited by consent on a pro bono basis, although they were gifted the smartwatches at the end of the study.

Results

Short-Term Survey

Overview

The first short-term survey of the study was conducted to determine compliance levels among the participants from varying socioeconomic and educational backgrounds. The survey was designed with a variety of questions mentioned in the short-term survey section. A significant variation in responses was observed.

Responses to the first question, regarding the duration of smartwatch usage, are portrayed in Table 2. Notably, except for 1 individual, all participants used the smartwatch for at least 3 hours daily, with most participants using it for some time (defined as 3 - 4 h), most of the day, and all day, highlighting the interest of the participants in exploring the smartwatch's features and usability.

Table . Daily smartwatch use duration among participants (n=25).

Daily use duration	Participants, n (%)
All the time	7 (28)
Most of the day, except while sleeping	6 (24)
Occasionally	4 (16)
Sometimes	7 (28)
Rarely or never	1 (4)

The second question examined the health features participants tracked. Most of the participants used or tried using multiple features. As illustrated in Table 3, the most frequently tracked features were heart rate monitoring ("Heart Rate"), step counting, and oxygen saturation level monitoring (SpO_2). Less frequently tracked features included sleep quality, calorie burn, respiratory rate monitoring, and stress level monitoring. Participants indicated that "Heart Rate," "Step Count," and "SpO_2" features were easier to access and less complex to use than "Sleep Quality," "Calorie Burn," "Respiratory Rate Monitoring," and "Stress Level Monitoring," which were described as more challenging to understand and monitor effectively.

XSL•FO
RenderX

Table . Participants who reported using each smartwatch feature.

Used feature	Participants, n (%)
Steps	14 (56)
Heart rate	16 (64)
Sleep quality	3 (12)
Calorie, burn	5 (20)
Respiratory rate	3 (12)
Stress	5 (20)
SpO_2[a]	12 (48)
None	4 (16)
Time	4 (16)

[a]SpO_2: oxygen saturation level monitoring.

The third and fourth questions addressed privacy concerns and workplace compatibility. In response to these questions, all participants expressed positive views, indicating comfort in using the smartwatch at their workplaces without privacy concerns.

Questions 5 and 6 explored the features participants liked and disliked. Heart Rate emerged as the most liked feature due to its simplicity and ease of use.

Comfort, addressed in questions 7 and 8, was another key area of investigation. As illustrated in Table 4, most participants reported the smartwatch as "completely comfortable," while a smaller group consisting of 3 (15%) users found it "mostly comfortable," and another group of 4 (20%) users felt "somewhat comfortable," suggesting that participants generally did not encounter significant physiological discomfort while wearing the device.

Table . Number of participants reporting comfort levels during smartwatch use.

Comfortability	Participants, n (%)
Very comfortable	1 (5)
Somewhat comfortable	4 (20)
Mostly comfortable	3 (15)
Completely comfortable	12 (60)

The ninth question examined whether the smartwatch posed religious, social, or cultural barriers for older adult individuals. As illustrated in Table 5, a majority (20 participants) responded "not at all," while 2 participants reported "slight" barriers, and 2 remained neutral. Only 1 participant perceived the watch as a large hindrance while performing religious, social, and cultural activities.

Table . Participant responses regarding barriers.

Response	Participants, n (%)
Very	1 (4)
Slight	2 (8)
Not at all	20 (80)
Neutral	2 (8)

Participants were also asked whether they found the smartwatch age-appropriate and if they would recommend it to others in their age group. As illustrated in Table 6, approximately 52% (n=13) of the participants considered the smartwatch suitable for their age and indicated they would use it for a longer duration in the future. In comparison, 8 (32%) participants expressed neutrality. On the contrary, 2 participants found it very age-inappropriate and declined to use it in the future, citing concerns about advanced technology for older people. Furthermore, 1 female participant (>70 y old) from an old-age home commented:

> *At this age, we cannot use advanced technology like a smartwatch. We are older people, and we believe our instincts suffice to predict physical disorders. I trust natural death will come when it is time. No technology is appropriate to predict diseases early, nor can it serve us with physical complexity.*

XSL•FO
RenderX

Table . Participant responses on whether the smartwatch was compatible with their age.

Response	Participants, n (%)
Yes	13 (52)
No	4 (16)
Neutral	8 (32)

Another question explored whether the smartwatch helped participants achieve health goals. A total of 13 (52%) participants believed it was helpful, while 3 (12%) felt it could not independently establish health goals. Moreover, 9 (36%) participants expressed neutrality. Table 7 presents an analysis of these responses.

Table . Responses from perceptions of whether smartwatch use helped achieve personal health goals.

Response	Participants, n (%)
Yes	13 (52)
No	3 (12)
Neutral	9 (36)

The final question focused on whether participants found the smartwatch frustrating to use. As illustrated in Table 8, 15 (60%) participants responded negatively, 4 (16%) reported frustrations, and 6 (24%) remained neutral. Frustration was reported mostly because of the age-inappropriate user interface.

Table . Responses to whether the device was frustrating to use.

Response	Participants, n (%)
Yes	4 (16)
No	15 (60)
Neutral	6 (24)

Participant Comments and Insights During Short-Term Survey

The survey also captured unique insights from participants, particularly those with lower levels of education. For example, a janitor noted:

> *After using the smartwatch, I often felt hungry and could eat larger portions. This is due to the smartwatch.* [Janitor, 63 y old, primary school graduate]

Similarly, another participant of an old-age home resident noted:

> [I had arthritis, but after using the smartwatch, the pain miraculously healed. I think the device worked like medicine.] [Old-age home resident, 103 y old, with no formal education]

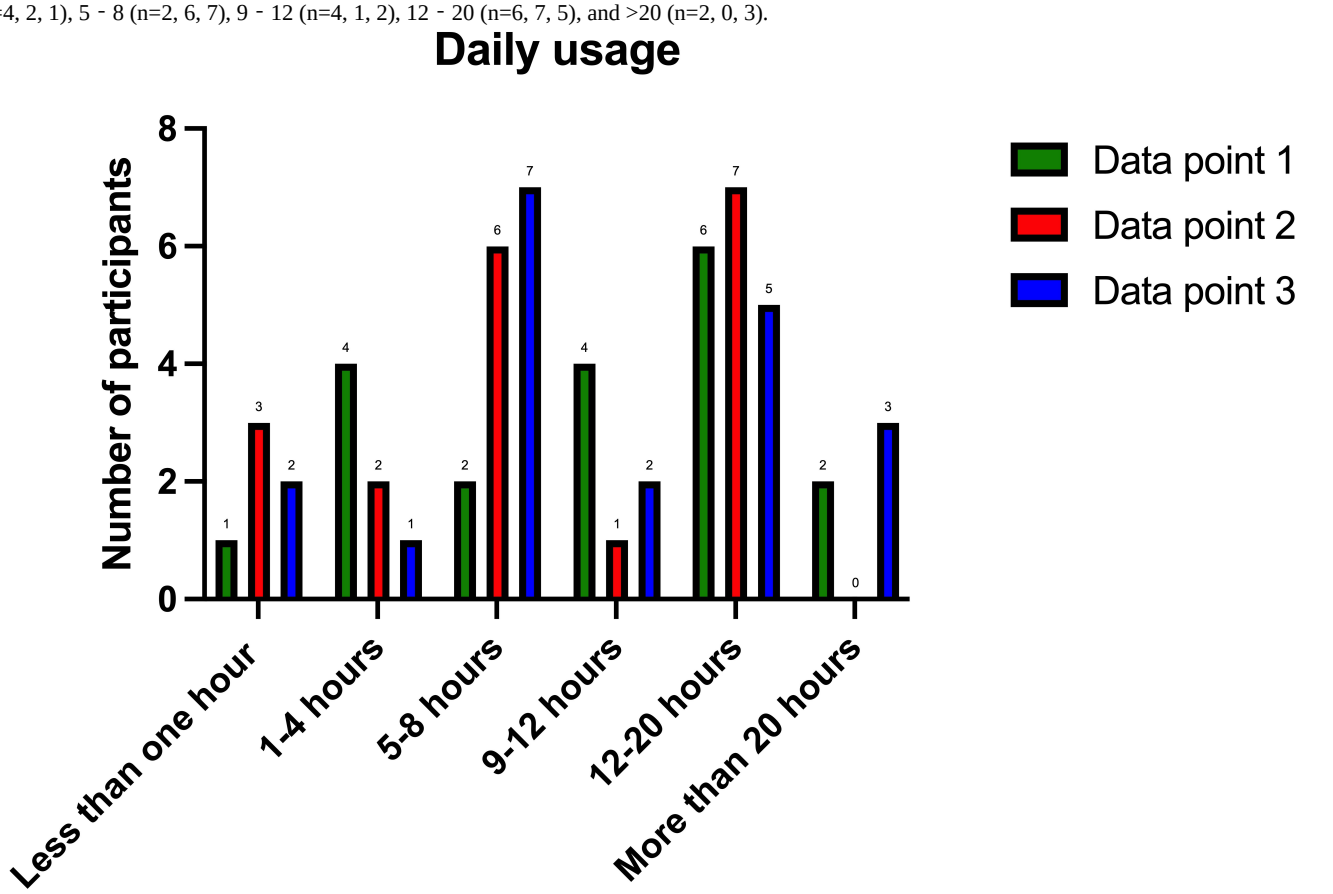
Another female participant (62 y old) from an old-age home reported that she felt nausea, dizziness, and joint pain whenever she used the smartwatch.

The overall responses of this survey phase highlight that both groups of participants were curious about the smartwatch. However, they faced some challenges while using it. According to the responses, Heart Rate, Step Count, and SpO_2 were the easiest features to monitor. Also, the watch was comfortable overall and created no barriers while doing regular activities. However, a few interesting comments were received from participants with lower education and socioeconomic backgrounds. Also, a large portion of the neutrality in the usability of the watch in achieving health goals indicates that a group of participants was confused about the appropriate technical knowledge of using the watch. Many participants shared their complexity in understanding the watch's functionality during the interview. The research team answered that confusion with proper care and ensured clarification about the issues.

Long-Term Study

Overview

The given survey revealed some interesting trends in smartwatch use and responses from participants across 3 phases of the long-term survey. Unlike the former short-term survey, this one included a series of questions categorized into daily usage, comfort level, feature usage patterns, and expected improvements that participants made.



Daily Usage

As Figure 2 illustrates, 31.5% (6/19) of the participants used the smartwatch for 12 - 20 hours daily during the first phase of the survey, thus being the most common usage duration; this was followed by 21% (4/19) of participants who used it from 9 - 12 hours, and exactly the same percentage for those who said they used the smartwatch for 1 - 4 hours daily. Smaller use of the smartwatch (daily periods exceeding 20 h) was reported by 10.5% (2/19), while a single participant reported not using it at all. Usage patterns continued shifting through the second phase, with 31.5% (6/19) of participants using the smartwatch for 5 - 8 hours daily and 36.8% (7/19) for 12 - 20

XSL•FO
RenderX

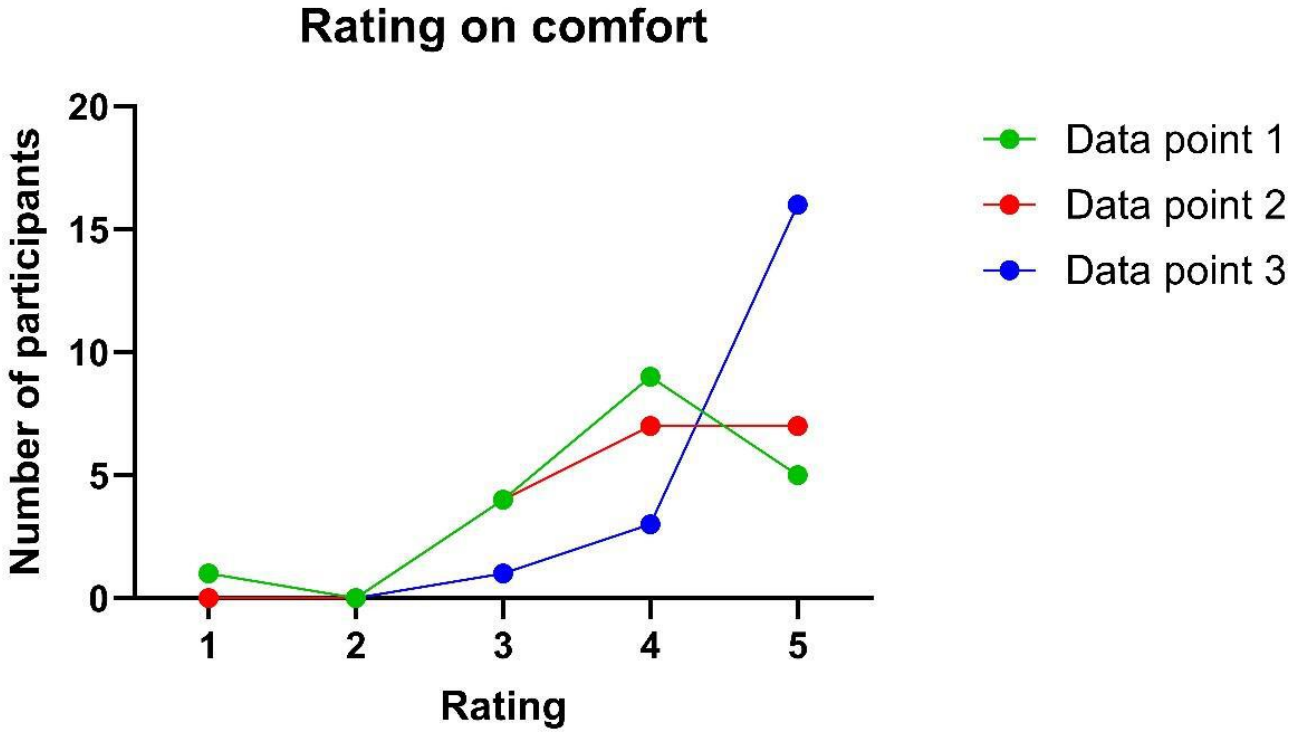
hours. Only 15.7% (3/19) of participants used the watch less than an hour daily, indicating that almost all participants engaged with the device to some degree. Finally, in the third phase, 20% (5/20) of respondents resumed using the smartwatch in the 12 - 20 hours daily category, and 35% (7/20) used it between 5 - 8 hours.

Figure 2. Grouped bar chart showing the number of participants reporting daily smartwatch use across 3 study time points (hours): <1 (n=1, 3, 2), 1 - 4 (n=4, 2, 1), 5 - 8 (n=2, 6, 7), 9 - 12 (n=4, 1, 2), 12 - 20 (n=6, 7, 5), and >20 (n=2, 0, 3).

The results of the *t* test for daily usage, depicted in Table 2, showed a lack of significant variance in usage patterns across all phases; this is evidenced by *P* values ranging from .78 to ≥.99, which reveals that the overall time spent by the participants on the smartwatch remained relatively stable across the course of the study.

XSL•FO
RenderX

Table . Summary of paired *t* tests across 3 long-term study data points.



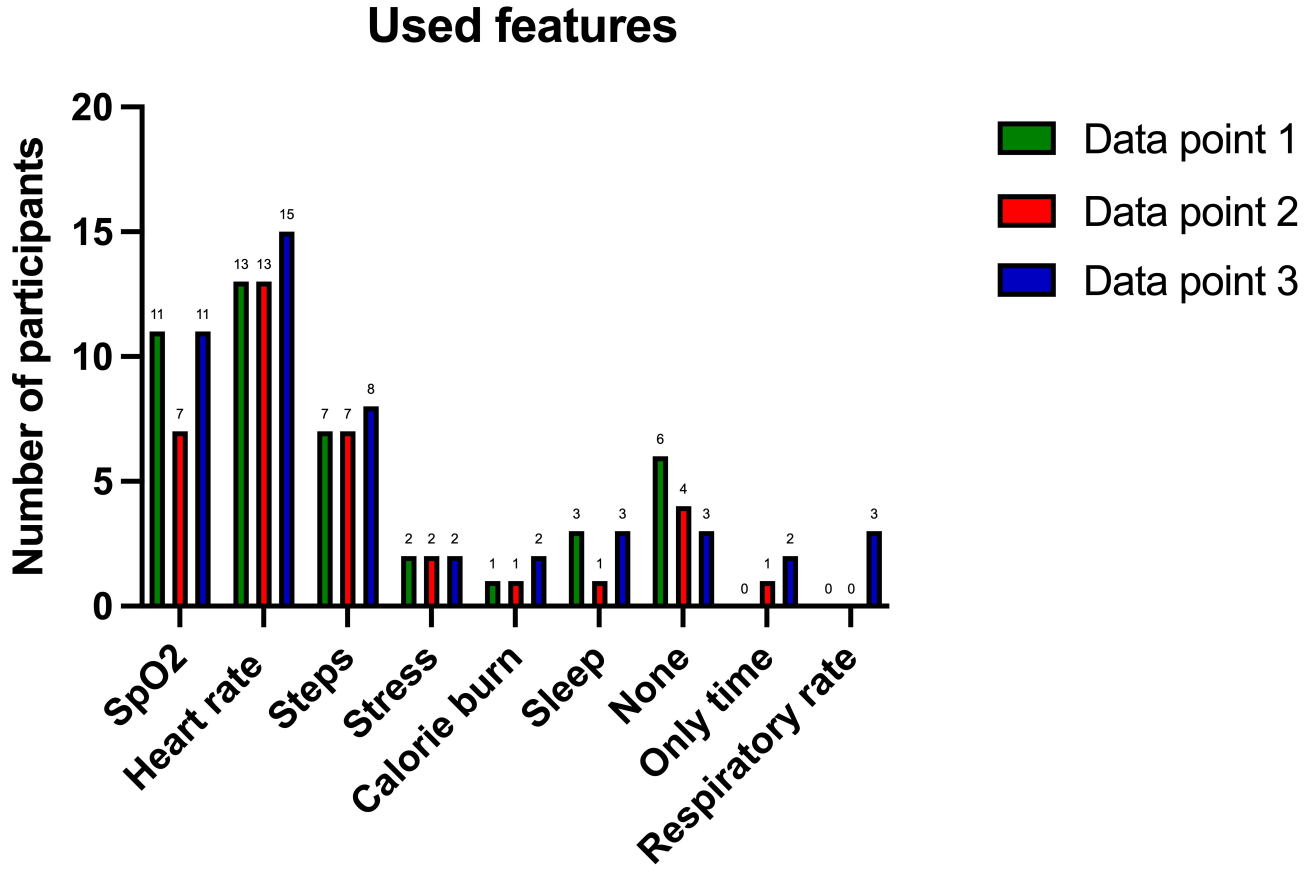
Survey dimension	Comparison	*t* test (*df*)	*P* value	Result
Daily usage	Data point 1 vs data point 2	0.00 (5)	>.99	Not significant
Daily usage	Data point 2 vs data point 3	−0.22 (5)	.83	Not significant
Daily usage	Data point 1 vs data point 3	−0.14 (5)	.89	Not significant
Rating on comfort	Data point 1 vs data point 2	0.30 (4)	.78	Not significant
Rating on comfort	Data point 2 vs data point 3	−0.17 (4)	.87	Not significant
Rating on comfort	Data point 1 vs data point 3	−0.07 (4)	.95	Not significant
Used features	Data point 1 vs data point 2	1.26 (8)	.24	Not significant
Used features	Data point 2 vs data point 3	−4.16 (8)	<.001	Significant
Used features	Data point 1 vs data point 3	−2.53 (8)	.03	Significant
Most liked features	Data point 1 vs data point 2	0.51 (8)	.62	Not significant
Most liked features	Data point 2 vs data point 3	−1.12 (8)	.30	Not significant
Most liked features	Data point 1 vs data point 3	−0.63 (8)	.55	Not significant
Clear instructions	Data point 1 vs data point 2	0.19 (2)	.87	Not significant
Clear instructions	Data point 2 vs data point 3	0.00 (2)	>.99	Not significant
Clear instructions	Data point 1 vs data point 3	0.09 (2)	.94	Not significant
Difficult to use feature	Data point 1 vs data point 2	1.96 (8)	.08	Not significant
Difficult to use feature	Data point 2 vs data point 3	−4.29 (8)	<.001	Significant
Difficult to use feature	Data point 1 vs data point 3	−2.31 (8)	.05	Marginally significant

Comfort Level Investigation

In fact, comfort levels improved a lot in the 3 phases, as portrayed in Figure 3. Initially, 47.3% (9/19) of the participants found the smartwatch comfortable, with only 26.3% (5/19) describing it as very comfortable. A small percentage, 5.3% (1/19), described it as highly uncomfortable since the features were complicated and the users did not have enough knowledge about them. However, in the second phase, no one reported discomfort, while 38.9% (7/18) found the smartwatch very comfortable, which marks the positive shift in user experience. In the third phase, 80% (16/20) rated the smartwatch as very comfortable, while only 1 participant reported it as fairly comfortable, amounting to 5% (1/20).

XSL•FO
RenderX

Figure 3. Line graph showing the distribution of comfort ratings (1=lowest to 5=highest) across 3 data points. The number of participants reporting higher comfort ratings (4-5) increased over time, with rating 5 rising at the final follow-up.



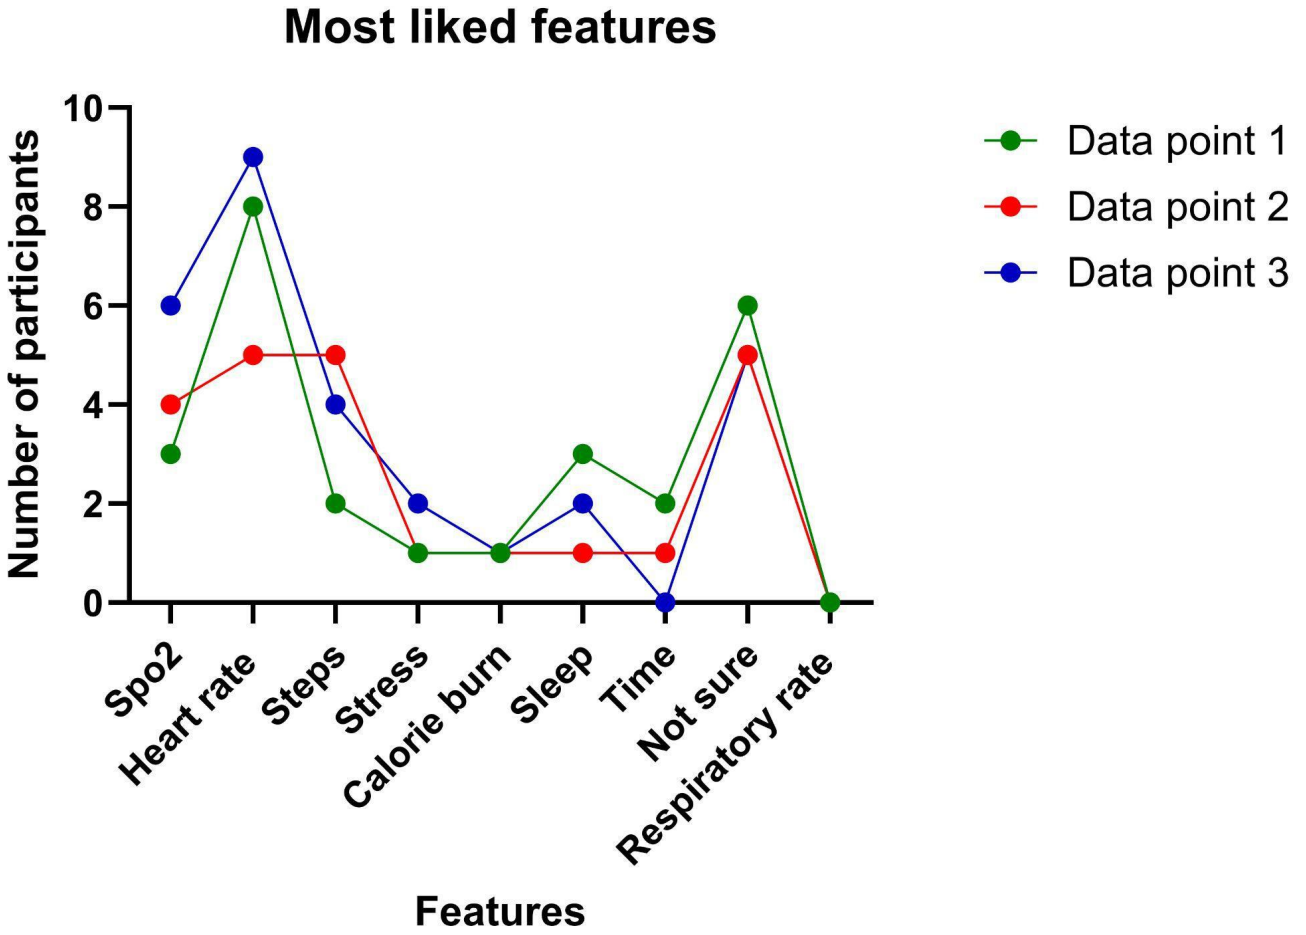
Furthermore, *t* test results of comfort ratings are insignificant among the phases, with *P* values ranging between .78 and .95 (Table 9). However, as revealed by the chi-square test, comfort perception improved dramatically over the survey period (Table 9), with a significant association—namely, *P*=.03 of phases with comfort ratings.

Investigation of Feature Usage Pattern

The usage of the features shows some fixed preferences along with some dynamic behavior, indicated in Figure 4 below. The most used feature in all phases remains heart rate monitoring, which shows an increased usage level from 68.4% (13/19) in phase 1 to 75% (15/20) in phase 3. The participants were primarily using other features such as SpO_2 and Step Count, but with a small fluctuation in them. For example, usage of SpO_2 reduced in phase 2 but increased in phase 3, which shows they were testing different features before making a preference.

XSL•FO
RenderX

Figure 4. Grouped bar chart showing smartwatch feature use across 3 data points. Heart rate and step count were the most used features throughout, while other features were less commonly used and some participants reported using no features.



The respiratory rate function, which had not been used in phases 1 and 2, gained acceptance among 15% (3/18) of participants in phase 3, which indicated increased interest in advanced functions with time as participants got accustomed to using the device.

The results of the *t* test indicated a significant change in used features over time, especially when comparing DP2 and DP3 ($P<.001$) and another significant change when comparing DP1 and DP3 ($P=.03$), which indicated that people have gotten used to using the smartwatch features.

Besides usage, another area that we have explored is the most liked features in each stage of our survey, which can be seen in Figure 5. Heart Rate remains among the most liked features in all phases. As seen in Table 2, *t* test analysis for most liked features did not reach significance in the comparisons of DP1 with DP2 with a *P* value of .62, DP2 with DP3 with a *P* value of .30, and DP1 and DP3 with a *P* value of .55 for Heart Rate.

XSL•FO
RenderX

Figure 5. Line graph showing the number of participants selecting comfort ratings from 1 (lowest) to 5 (highest) at 3 measurement points. Comfort ratings shifted upward over time, with the highest rating (5) becoming most common at the final follow-up.

For example, in an attempt to capture features such as SpO_2, the participants recorded a higher preference in the third phase relative to the first phase, as can be noted by the SD recorded in Table 9, which stood at 1.24722 (mean 4.33). Some of these features, such as SpO_2, were thus better appreciated when participants were more conversant with the device. Other functions, such as tracking and respiratory rate measurement, were well-received but demonstrated inconsistency in preference, especially in the early phases.

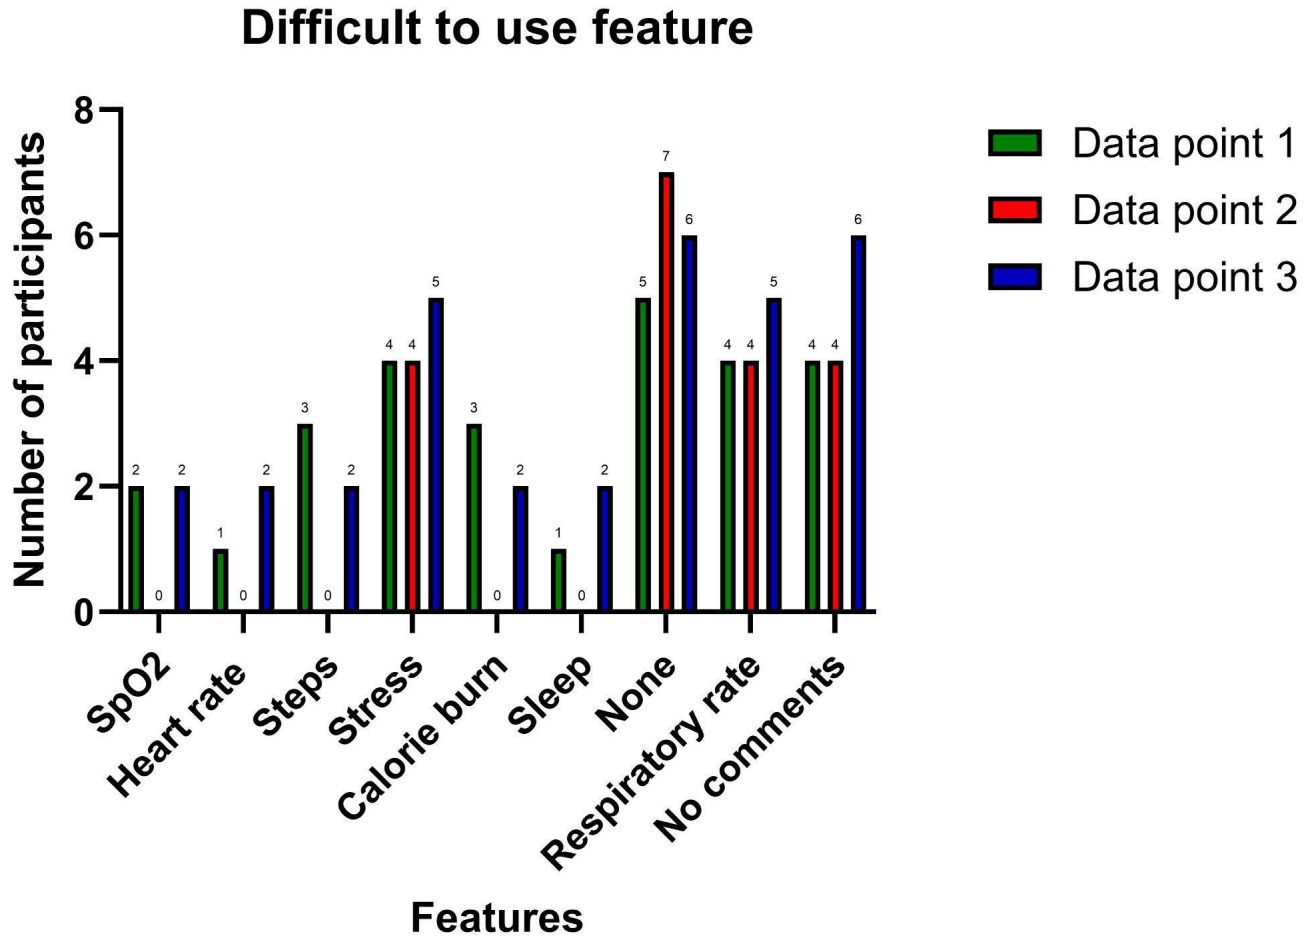
What is interesting, however, is the fact that respiratory rate tracking was considered hard to use but gained acceptance over time, which is in line with the increased usage of advanced functionality in total. The nonuse of some functions in the first phase, with 31.6% (6/19) of participants not using any functions, highlights the learning curve involved in using smartwatches in general, which had declined substantially in phase 3. The above findings indicate how preferences in features change over time, with Heart Rate being a continually popular choice, given other features, such as SpO_2 and respiratory rate monitoring, becoming more popular with increased familiarity.

Clear Instruction

Several trends were observed based on the feedback obtained from the participants with regard to the clarity of instructions, as presented in Table 10. At the beginning, 78.9% (15/19) found it simple and clear; hence, the reason for the easy adoption. This trend flipped as users continued using the application to explore features that became more complicated. In the second and third phases, the participants began to veer toward the neutral side concerning clarity. This is depicted by the high SD obtained in "Yes" (mean 12, SD 2.44) and "Neutral" (mean 4.33, SD 2.86), indicating that respondents do change with increased usage upon exploring more features. These results stress the need for increasing the clarity of instructions as users proceed to more complex features.

Table . Perceptions on clear and simple instructions across data points.

	Data point 1	Data point 2	Data point 3
Yes	15	12	9
No	3	2	1
Neutral	1	4	8



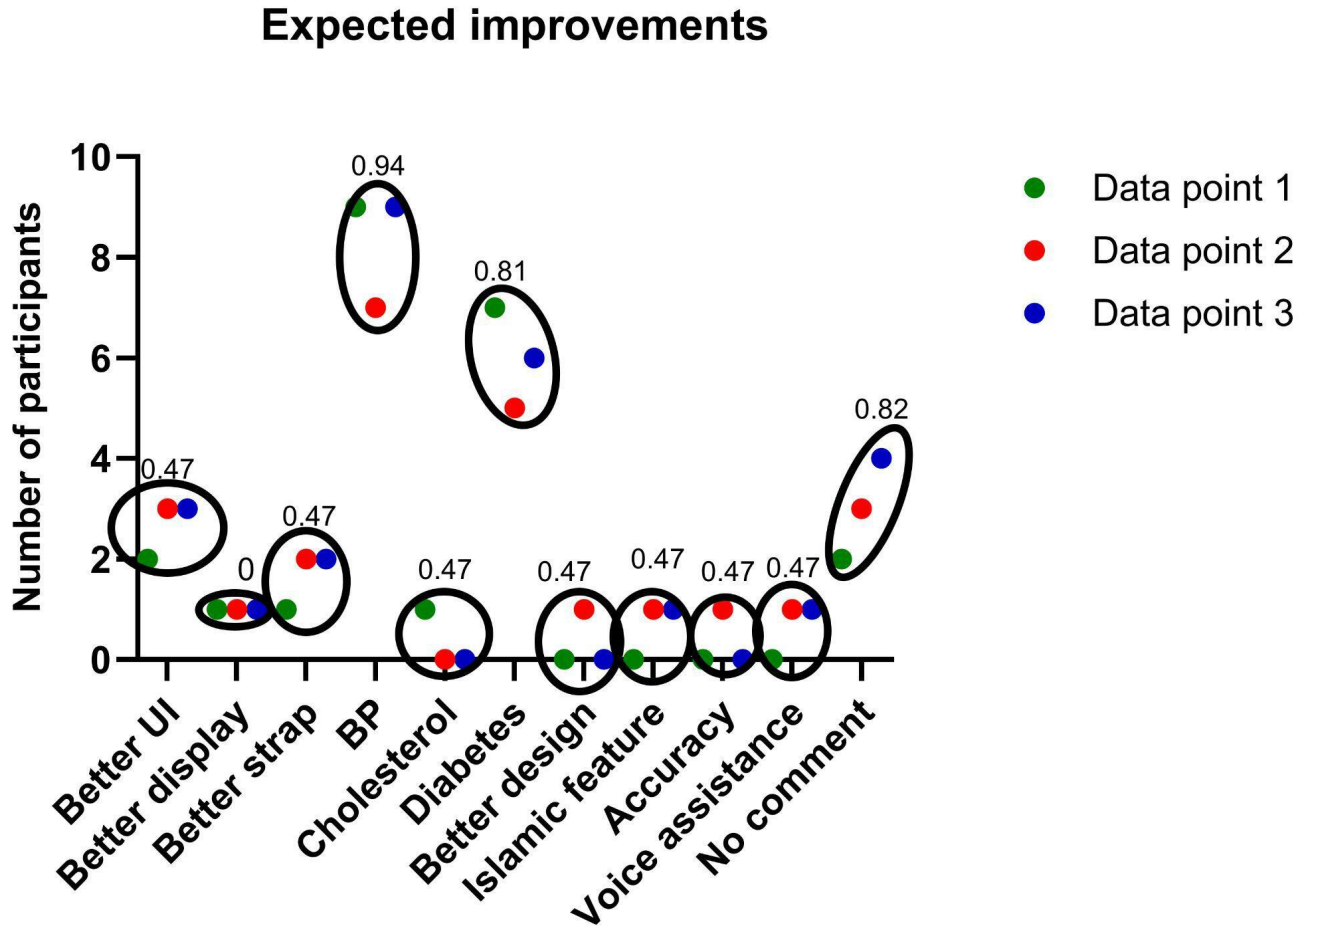
In Table 9, the chi-square test indicates a significant association (P=.04) between survey phase and participants' opinion on instruction clarity, which signals the dynamic user perception as feature complexity increases.

XSL•FO
RenderX

Difficult to Use Features

Figure 6 illustrates that the most difficult feature, especially in the third DP, is stress measurement. This would indicate a possible design or functionality issue with this feature. The same trend occurred for respiratory rate monitoring, which was considered a difficult feature through an increasing number of participants during the course of the experiment. Finally, on the opposite side of the spectrum, Heart Rate was the most favored feature and had no reports of difficulty throughout all points.

Figure 6. Grouped bar chart showing reported difficulty using smartwatch features across 3 data points. Most participants reported no difficulty, while some noted difficulty with specific features.



Furthermore, *t* test results indicate significant changes in the perceptions of difficulty regarding difficult to use features, where $P<.001$ for DP2 versus DP3 and $P=.05$ for DP1 versus DP3 support that design improvements are required in some features, such as stress measurement and respiratory rate.

Investigation of Expected Improvement

After long-term use of the smartwatch, adaptability and comfort were observed among the participants, as illustrated in Figure 7. Alongside, a trend was also observed in the expected improvements from the smartwatch (Figure 7). The data show that the most commonly suggested improvements were blood pressure and diabetes monitoring capabilities from the smartwatch, indicating that older people are mostly interested in critical health monitoring features. Interestingly, some participants initially had no comments on improvements but later suggested new features, though this shift was minimal. The overall low SD across all expected improvements confirms that user needs remained stable, reinforcing the necessity of designing a smartwatch specifically for older adults' health monitoring.

XSL•FO
RenderX

Figure 7. Scatter plot showing participant-suggested smartwatch improvements across 3 study time points (data point 1 - 3). Points represent counts for each suggested feature, and labels indicate variability (SD) over time.

Focus Group Survey

Overview

The focus group interviews constituted the final phase of the study and were designed to provide qualitative insights that contextualize and extend the survey findings. Moreover, 2 rounds of focus group interviews were conducted using identical structured interview guides to enable both cross-group and longitudinal comparisons. Participants were stratified by socioeconomic status and educational background to explore how these factors influenced perceptions, adoption, and experiences of smartwatch-based health monitoring.

Group A comprised older adults residing in an assisted living facility, representing a higher socioeconomic and educational profile; all participants had completed at least a high school education, with the majority holding undergraduate or graduate degrees. Group B consisted of individuals from lower socioeconomic backgrounds with less formal education (below high school level), who were employed in custodial and maintenance roles. This stratification enabled a comparative examination of digital health adoption across differing social and educational contexts.

Qualitative responses were analyzed thematically, with dominant patterns reported alongside illustrative quotations. Descriptive response counts are included to enhance transparency, consistent with *Journal of Medical Internet Research* qualitative reporting guidelines.

Findings of Focus Group Interview 1

The focus group interviews took place in separate locations and under the same setting to gather similar perspectives. A total of 13 participants participated in the study, including 9 males and 4 females. Group A included 7 participants, of whom 4 were female and 3 were male. Group B consisted of 6 male participants. Both focus group interviews followed the same structured questionnaire to examine potential differences in responses and variability across the groups.

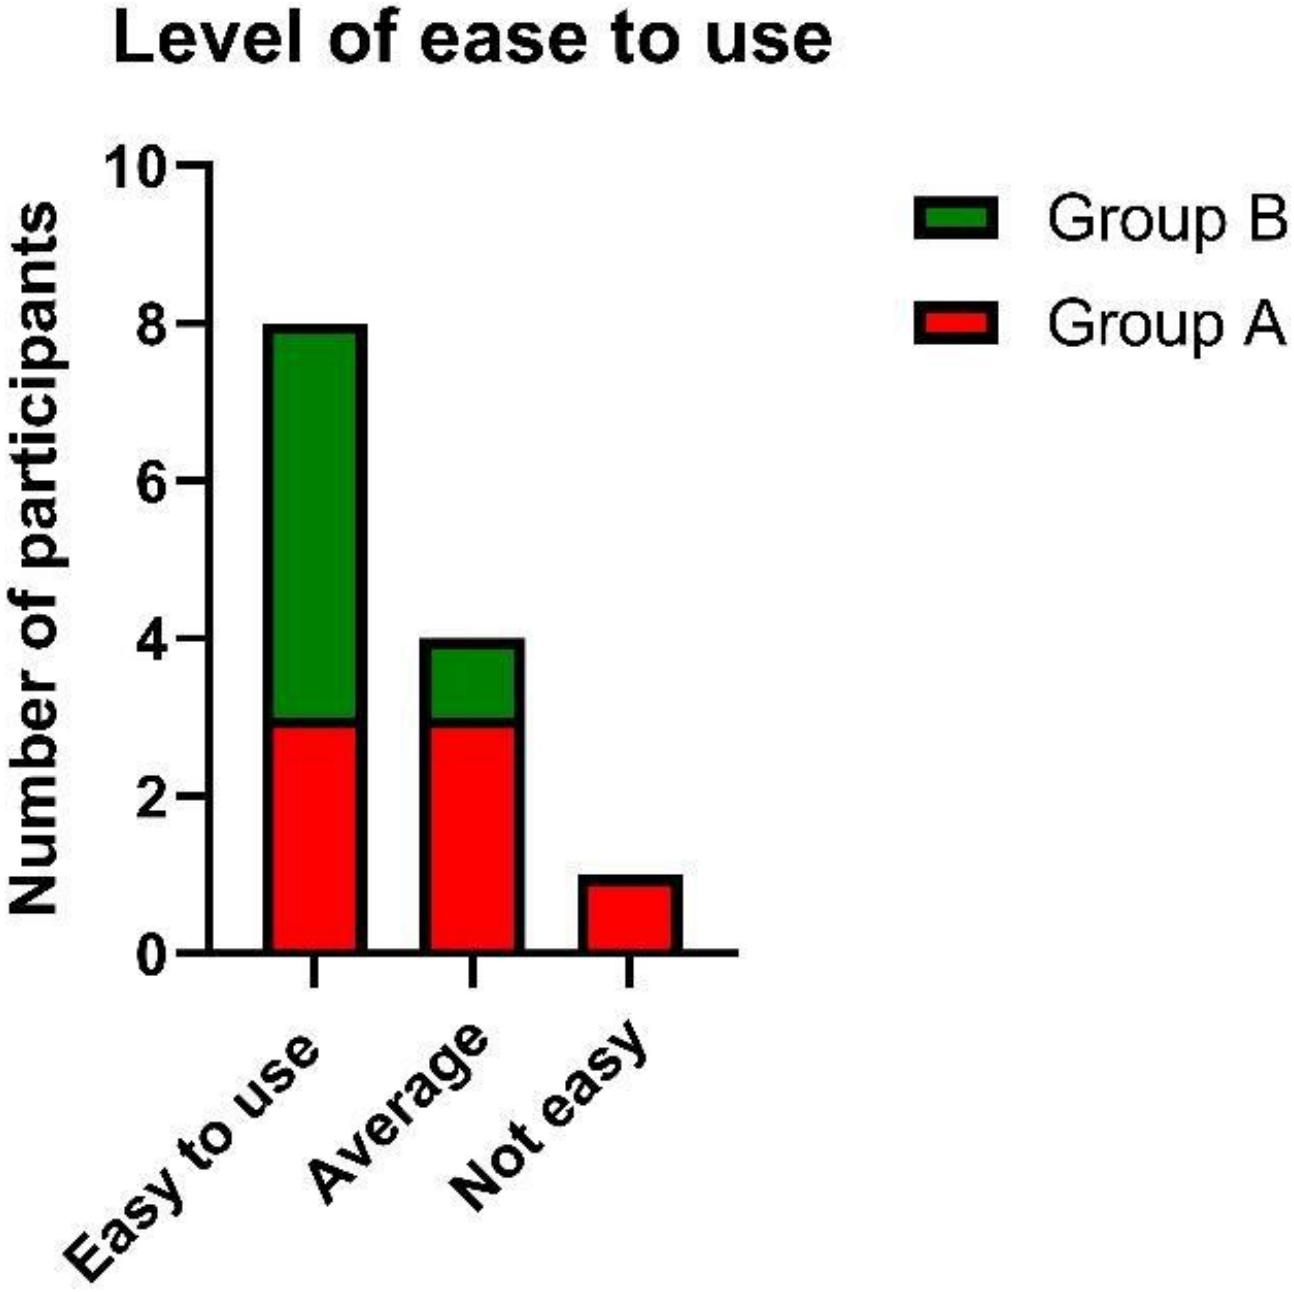
Perception of Smartwatches

Participants' first impressions of smartwatches revealed clear group-level differences. Group A participants predominantly expressed positive attitudes, whereas group B participants more frequently articulated curiosity rather than immediate endorsement. A small subset of participants (2 from group A and 1 from group B) expressed skepticism or negative perceptions.

Qualitative analysis identified three emergent subthemes:

1. Perceived cognitive and physical burden,
2. Concerns about measurement accuracy, and
3. Skepticism toward replacing clinical expertise.

For instance, concerns about language and accessibility were raised by a group B participant ("I cannot read English texts



XSL•FO
RenderX

well"), while doubts regarding clinical validity were voiced primarily by group A participants ("Technology cannot replace doctors"). Notably, these reservations were more pronounced among participants from higher socioeconomic backgrounds, despite their higher educational exposure to technology—implying deeper analysis and more cynicism in technology trust among users with higher education.

Usability of Smartwatches

When asked, "Did you find the smartwatch easy to use?" Most participants rated usability as "easy" or "average," with only 1 participant reporting significant difficulty, as represented in Figure 8. Qualitative responses suggest that initial apprehension transitioned into gradual acclimatization, indicating a learning effect rather than persistent usability barriers. Participants emphasized novelty, visual familiarity with traditional watches, and perceived multifunctionality as positive features.

Figure 8. Stacked bar chart showing the number of participants rating the smartwatch as easy to use, average to use, or not easy to use, stratified by group (group A and group B).

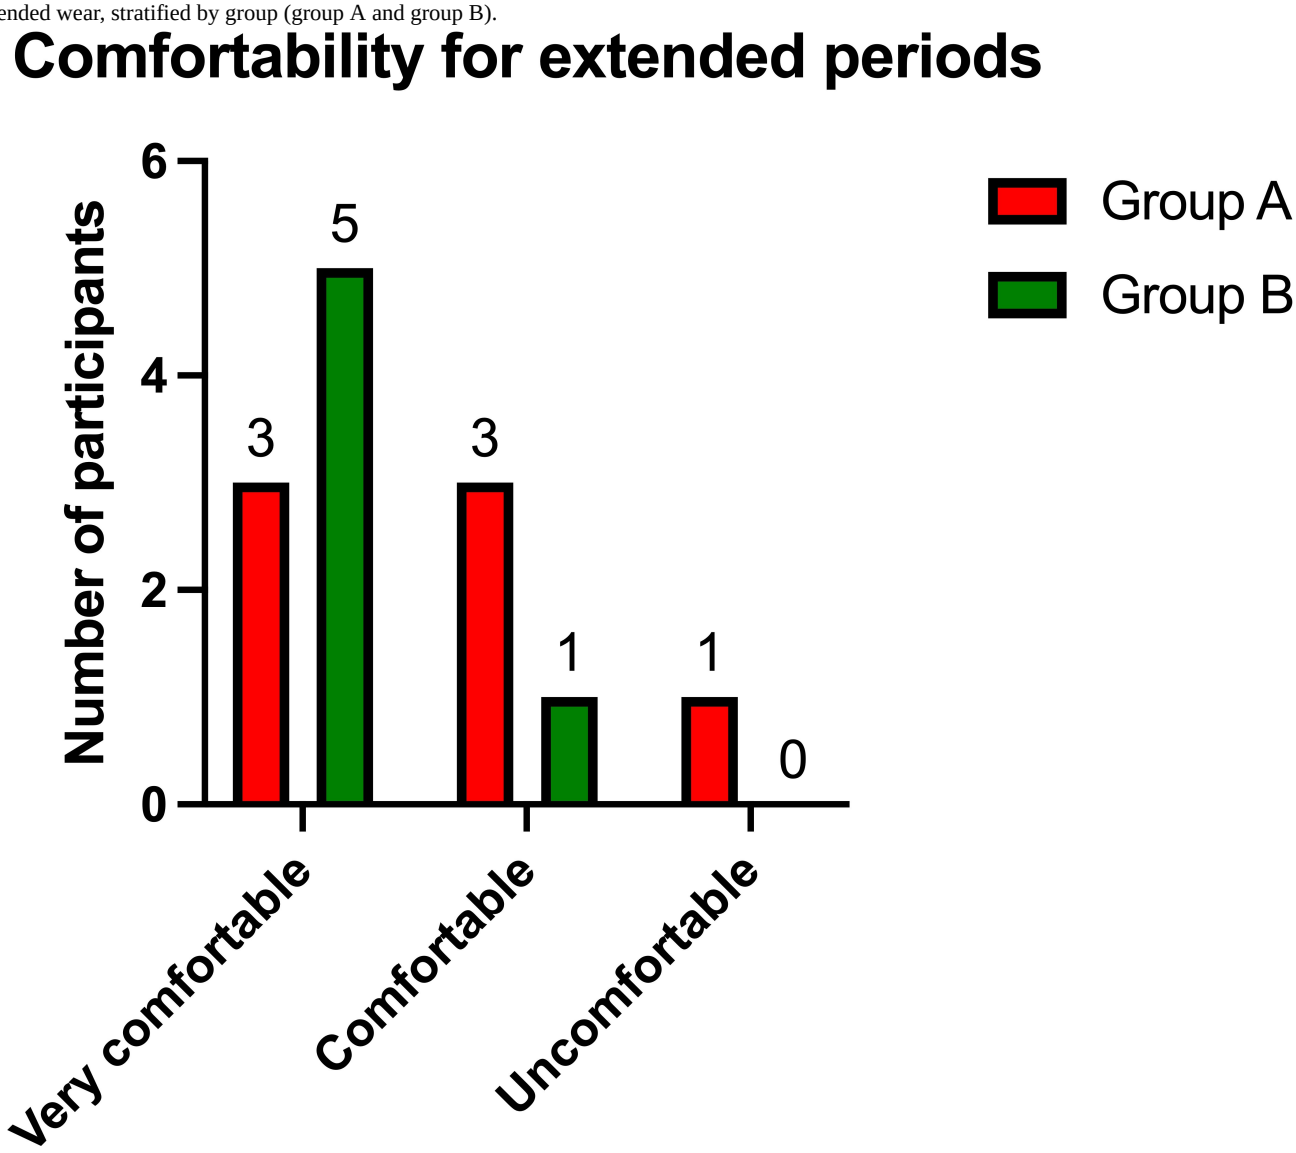
In light of this question, a further question was asked, "What did you love about it?" In response to this question, some participants answered,

> *It is a new invention, and we were new users. At first, we were very excited after learning about such devices, and a positive impression of this device came to our heads. Furthermore, it looks quite similar to a normal watch, so we thought it offers more features than a normal watch; it is a good device.*

A participant from group B answered,

> *I was curious when I found out about this. It looked smart, and I thought I would feel smart if I wore this*

XSL•FO
RenderX



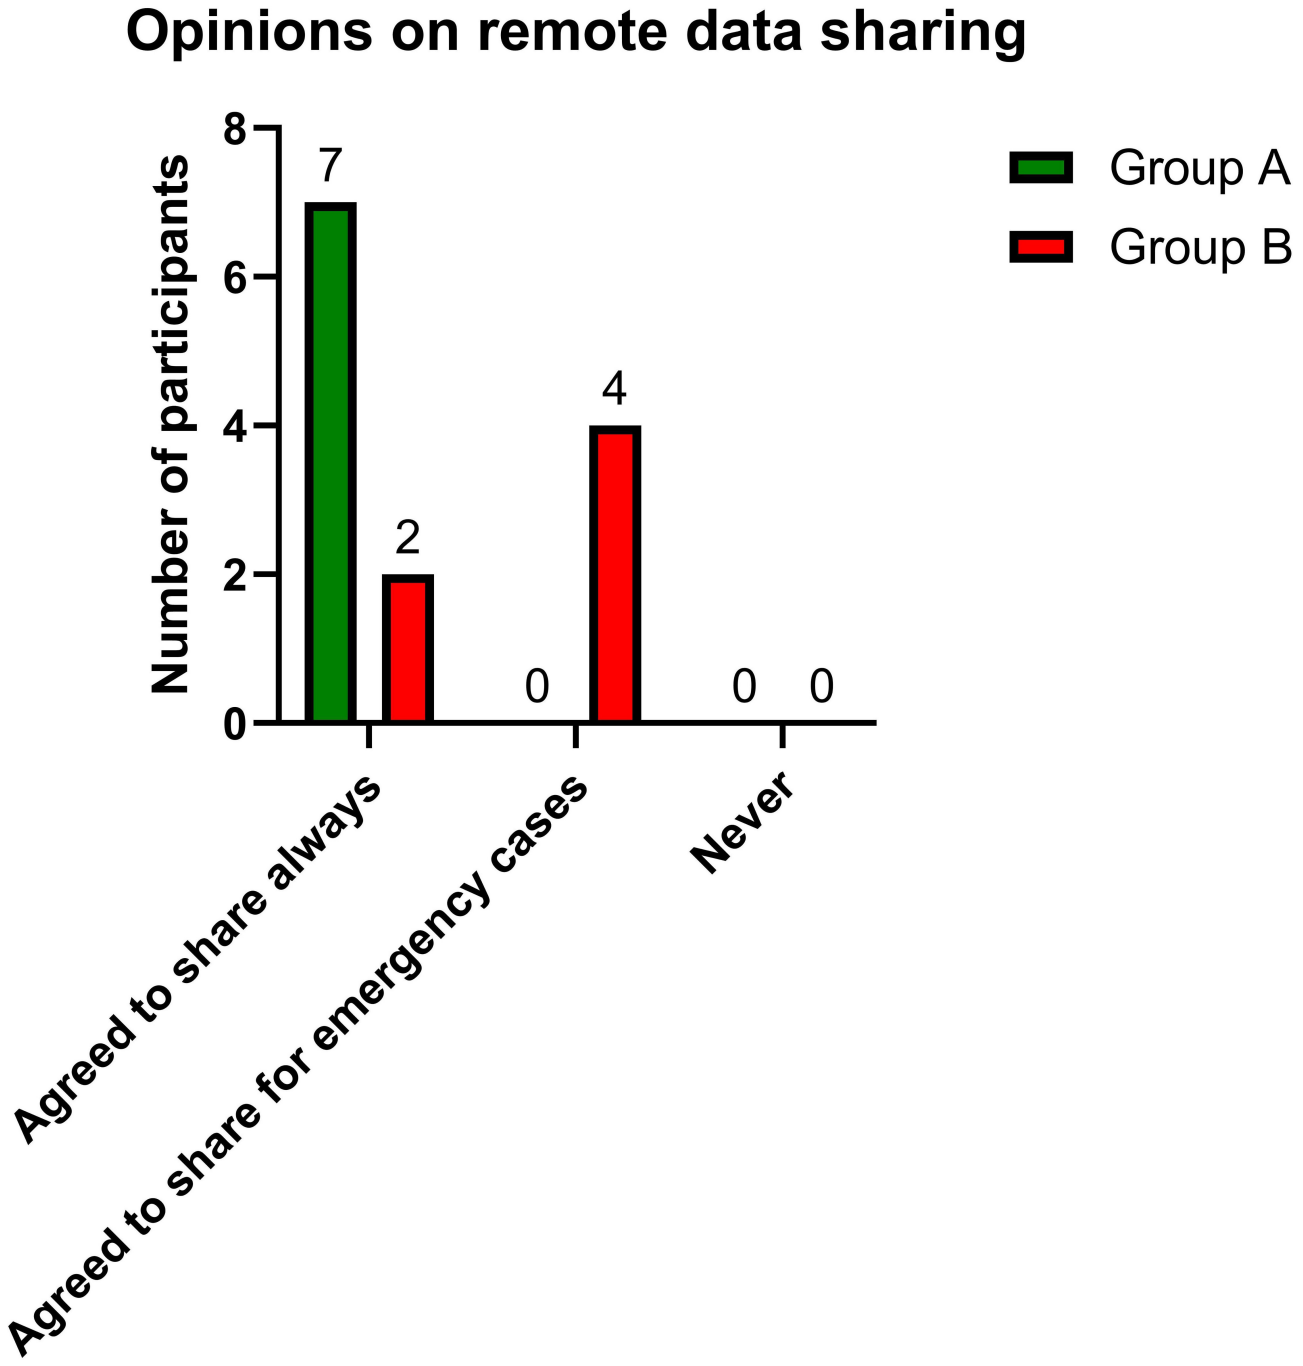
watch. Also, since it offers many health-related topics, it would be a good tool for me.

Therefore, this shows excitement in some older people about using new and "smart" technology, irrespective of their social belonging or understanding of the technology.

Comfort and Design Preferences

While overall comfort ratings were favorable, as illustrated in Figure 9, discomfort related to weight and strap design emerged as a recurring concern, particularly among group A participants. Participants expressed strong preferences for traditional materials (eg, leather or steel straps), suggesting that social acceptability and aesthetic continuity play a role in long-term adoption.

Figure 9. Stacked bar chart showing the number of participants who rated the smartwatch as very comfortable, comfortable, or uncomfortable for extended wear, stratified by group (group A and group B).



Data Sharing Preferences

The question, "Would you like your data to be continuously and automatically shared with family members and/or designated caregivers?" received mostly positive feedback. As illustrated in Figure 10, all participants in group A responded positively. In contrast, 4 out of 16 participants from group B preferred that data sharing be enabled only during emergencies, while 2 participants expressed full support for continuous sharing. This divergence highlights differing expectations regarding privacy and data oversight between the 2 groups, as the less privileged (and less educated) group identified interpretability concerns and seemed more aware of not burdening their family with their health emergencies.

XSL•FO
RenderX

Figure 10. Bar chart showing the number of participants who agreed to share health data always, only in emergency cases, or never, stratified by group (group A and group B).

Perceived Accuracy of Health Metrics

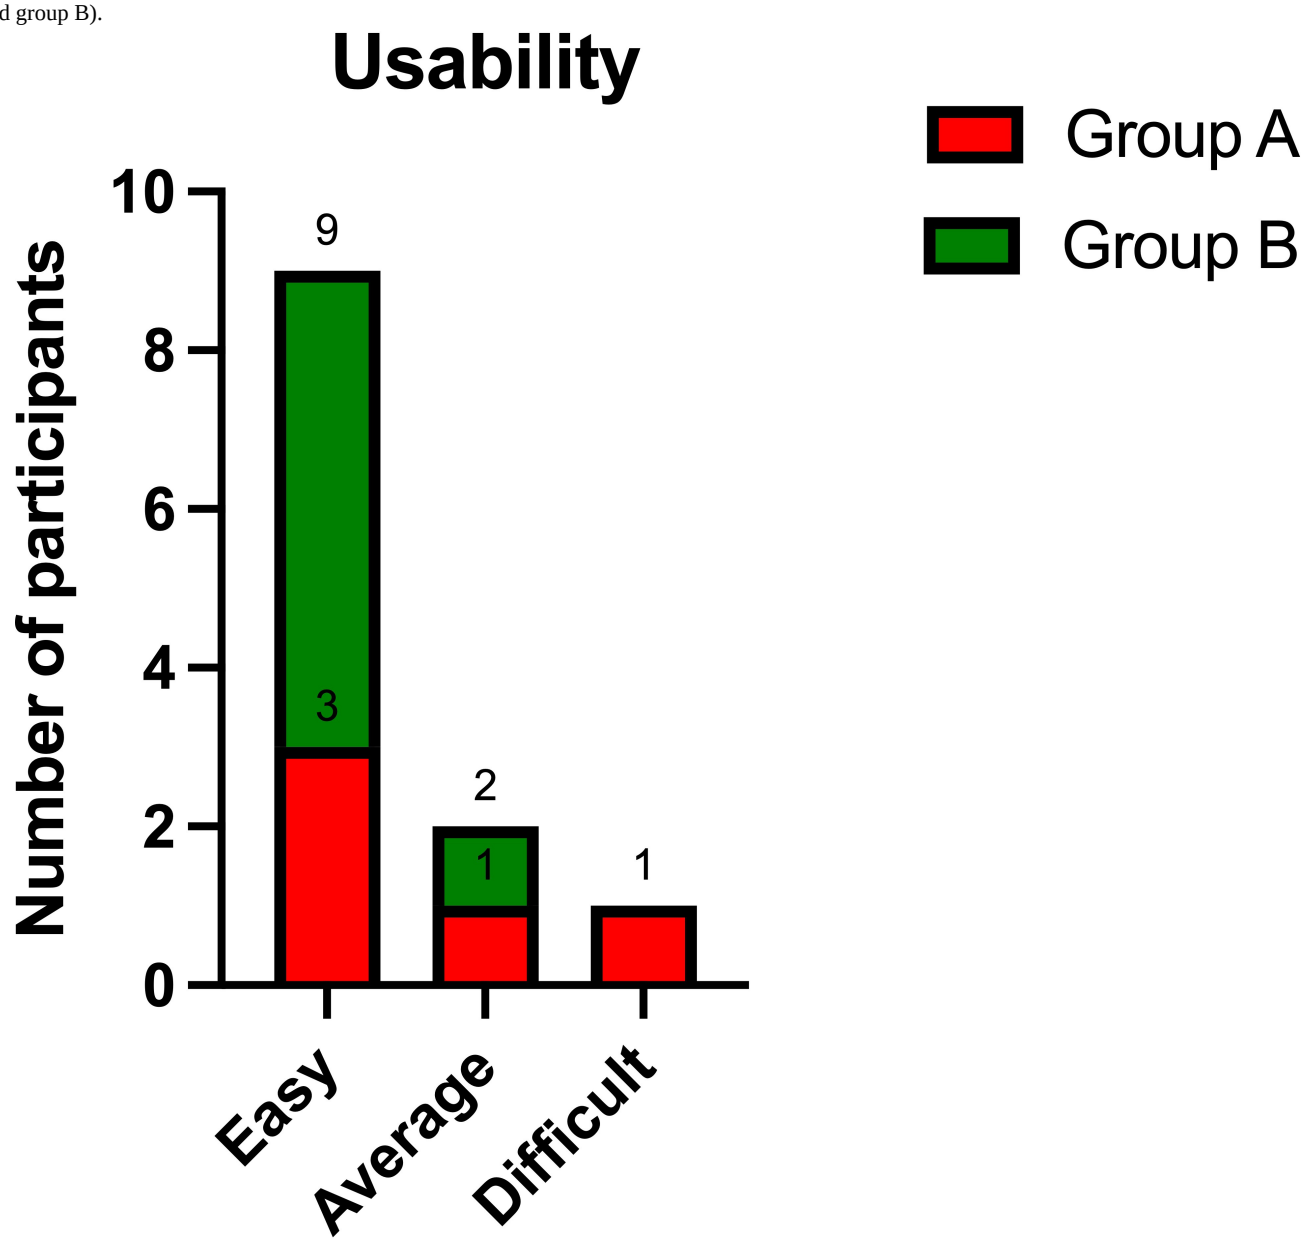
In response to the question, "How accurate did the health metrics seem to you?" participants generally perceived health metrics as reliable. Limited engagement with data—not distrust—explained neutral responses, indicating that attention and interpretation, rather than sensor credibility, influenced perceived accuracy.

Focus Group Interview 2

The second focus group interview involved 12 participants (10 males and 2 females), with 5 participants in group A and 7 in group B. This interview was conducted 14 days after the first, enabling assessment of temporal stability and experiential adaptation.

Evaluation of Smartwatch Perception

Initial impressions in interview 2 closely mirrored those from interview 1, demonstrating thematic consistency over time. However, qualitative depth increased, with participants expressing more experience-based reflections rather than speculative judgments. Curiosity remained dominant in group B, while group A responses polarized slightly between positive endorsement and skepticism.



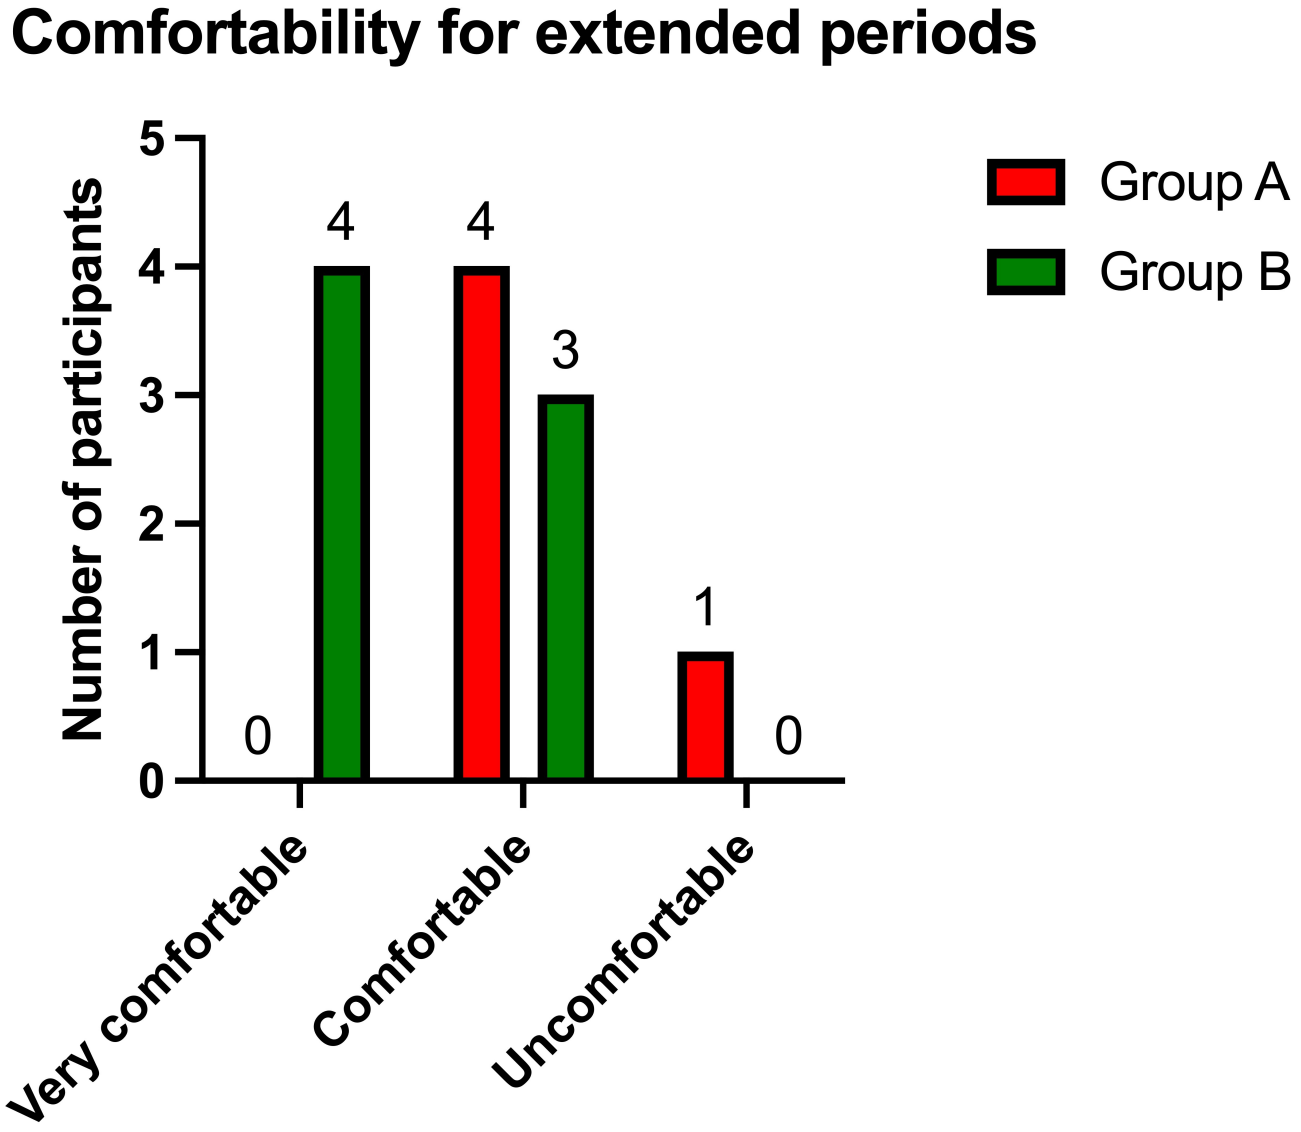
Compared with interview 1, negative perceptions were less frequent and more contextualized, suggesting that prolonged exposure mitigated abstract concerns while amplifying practical considerations.

XSL•FO
RenderX

Ease of Use: Reduced Variability Over Time

Usability ratings improved overall in interview 2, particularly within group B, as depicted in Figure 11. The reduction in "average" or negative usability responses indicates learning consolidation rather than mere tolerance. Difficulty reported by 1 older participant (88 y) underscores the influence of advanced age on interaction with wearable technologies, highlighting the need for age-adaptive interfaces.

Figure 11. Stacked bar chart showing the number of participants who rated smartwatch use as easy, average, or difficult, stratified by group (group A and group B).

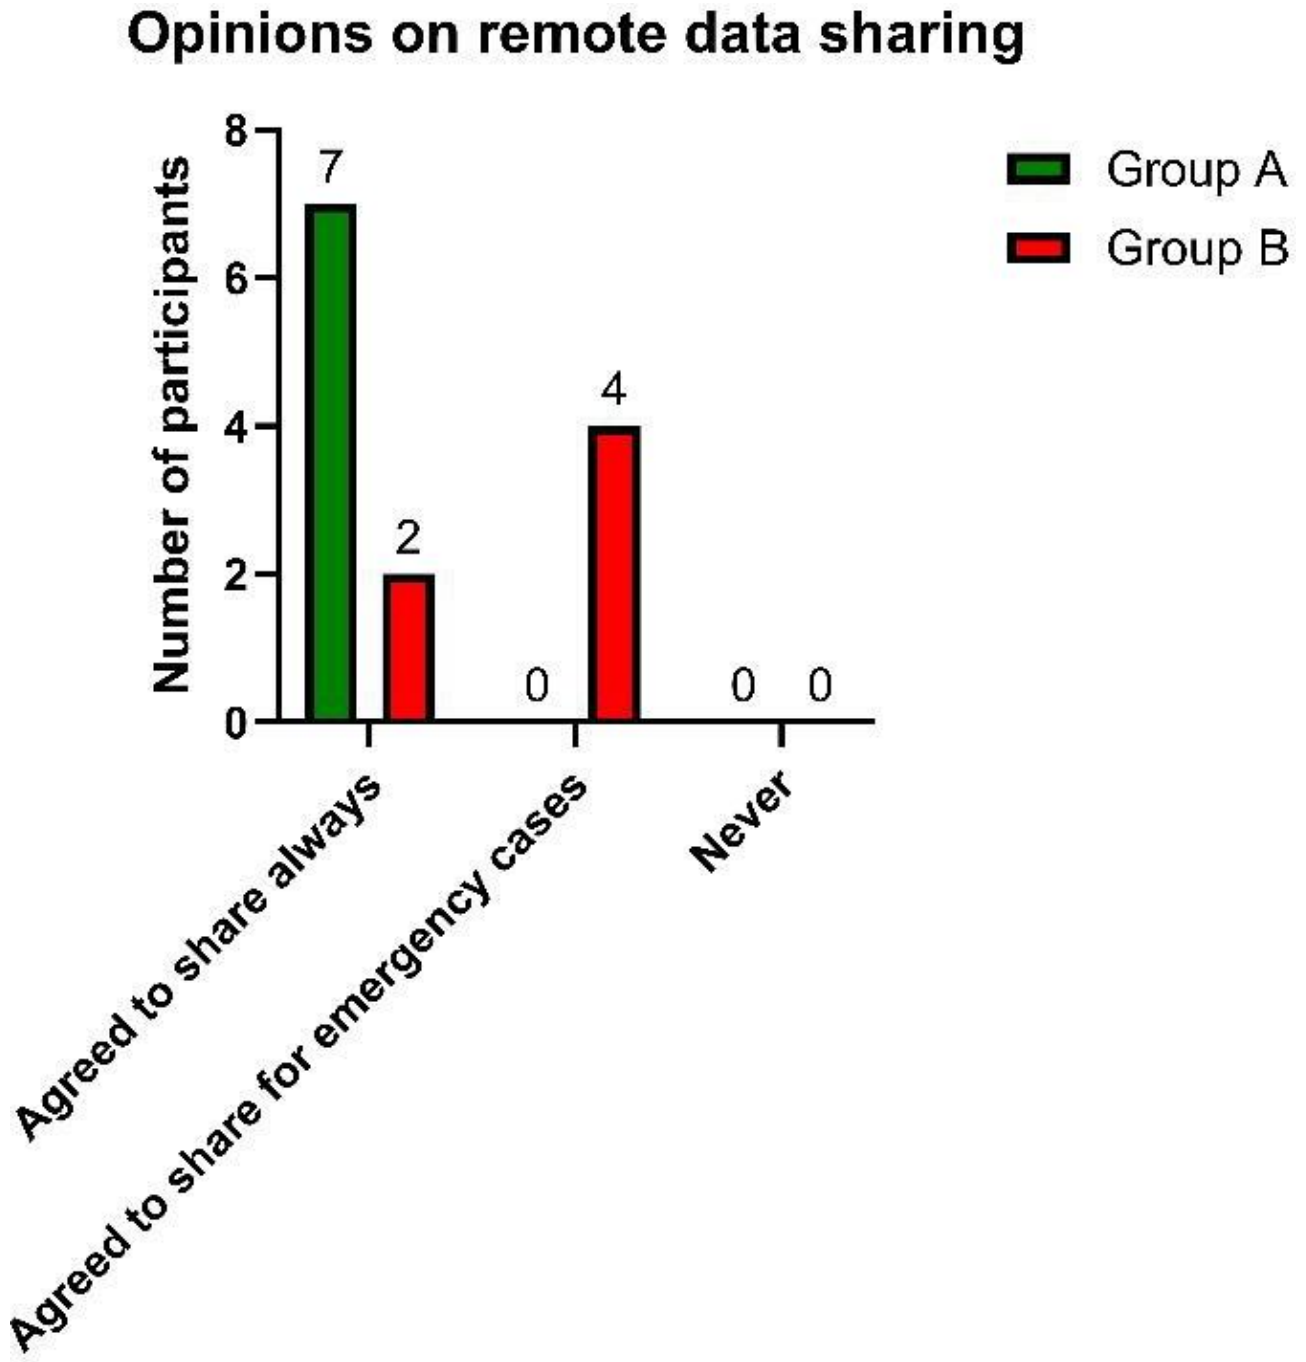


Comfort: Consistency Across Interviews

Figure 12 illustrates that comfort ratings in interview 2 remained stable relative to interview 1, reinforcing the robustness of this finding. Importantly, fewer participants raised new complaints, suggesting that comfort-related perceptions plateaued early and did not deteriorate with extended wear.

XSL•FO
RenderX

Figure 12. Stacked bar chart showing the number of participants who rated the smartwatch as very comfortable, comfortable, or uncomfortable for extended wear, stratified by group (group A and group B).



Data Sharing Preferences: Group Divergence Intensifies

A clearer divergence in data sharing preferences emerged in interview 2, as illustrated in Figure 13. All group A participants supported continuous data sharing, whereas the majority of group B participants favored emergency-only sharing. Compared with interview 1, these preferences were articulated with greater certainty, indicating preference crystallization over time rather than ambivalence.

XSL•FO
RenderX

Figure 13. Bar chart showing the number of participants who agreed to share health data always, agreed to share only in emergency cases, or never agreed to share, stratified by group (group A and group B).

Perceived Accuracy of Health Metrics

Confidence in metric accuracy increased slightly in interview 2, particularly among group B participants. Overall, the responses were mostly neutral and a bit vague at this phase, again reflecting lack of attention rather than distrust, reinforcing findings from interview 1.

Comparative Analysis and Analytical Power Considerations

Cross-Interview Thematic Stability

Across both focus group interviews, dominant themes, including usability adaptation, comfort acceptability, data-sharing conditionality, and perceived metric reliability, remained consistent. The repetition of themes across independent samples and time points supports thematic saturation, enhancing analytical power despite modest sample sizes.

Group-Level Comparative Strength

Although formal statistical power calculations are not applicable to qualitative focus group data, analytical power was strengthened through:

1. Replication of findings across 2 interview rounds,
2. Consistent group-level contrasts (higher vs lower socioeconomic status), and
3. Convergence between qualitative insights and descriptive survey trends.

XSL•FO
RenderX

The observed pattern, where participants from lower socioeconomic backgrounds adopted the smartwatch more readily and expressed fewer aesthetic or conceptual reservations, was robust across both interviews. This repeated contrast increases confidence that the finding reflects a genuine behavioral and perceptual trend rather than sampling variability.

Limitations of Quantitative Inference

While descriptive counts are reported with consistency, the study is not powered for inferential statistical comparisons between groups due to the small number of participants. Group differences should therefore be interpreted as qualitative contrasts supported by frequency patterns, not as statistically generalizable effects.

Implications for Mixed Methods Interpretation

The focus group findings provide explanatory depth for survey results, particularly by uncovering skepticism and aesthetic concerns that were not captured quantitatively. The consistency of these findings across 2 interviews enhances credibility and supports their use in informing design recommendations and future hypothesis-driven studies.

Discussion

Principal Findings

This study was guided by 3 overarching hypotheses. First (hypothesis 1), older adults' smartwatch usage patterns would stabilize over time, with selective increases in feature engagement following continuous support, exposure, and training. Second (hypothesis 2), training and ongoing support would reduce perceived difficulty of use and improve long-term adoption. Third (hypothesis 3), socioeconomic and educational background would significantly shape usability experiences and data-sharing preferences.

Overall, the findings provide strong support for all 3 hypotheses.

First, consistent with hypothesis 1, basic health-monitoring features—particularly heart rate tracking—emerged as the most used and preferred functionality across all study phases, increasing from 68% (13/19) in the first phase to 75% (15/20) in the last phase of the final long-term survey. In contrast, more complex features, such as stress and respiratory rate monitoring, showed persistently lower engagement. This stable preference hierarchy underscores the importance of prioritizing core, easily interpretable health metrics in wearable interfaces for older adults, while introducing advanced features progressively as familiarity increases.

Second, longitudinal statistical analyses partially supported hypothesis 2. Across the 3 long-term study DPs, paired *t* test analyses (Table 2) indicated that most user experience dimensions remained stable over time. No significant differences were observed for daily usage, comfort ratings, most liked features, or clarity of instructions across any pairwise comparisons (all $P>.05$). In contrast, significant temporal changes were detected for feature usage, with increased differentiation between DP2 and DP3 ($t_8=-4.16$, $P<.001$) and between DP1 and DP3 ($t_8=-2.53$, $P=.04$). Perceived difficulty of use also showed change over time, reaching significance between DP2 and DP3 ($t_8=-4.29$, $P=.01$) and marginal significance between DP1 and DP3 ($t_8=-2.31$, $P=.05$). Complementary chi-square analyses (Table 9) largely supported these findings, revealing no significant associations between time point and most survey dimensions, except for clarity of instructions, which demonstrated a significant association with study phase ($\chi^2_4=10.3$, $P=.03$), and a trend toward association for comfort ratings ($\chi^2_8=13.8$, $P=.09$). Together, these results suggest overall stability in usage and satisfaction metrics over time, alongside meaningful evolution in feature engagement and perceived usability as participants gained longer-term experience with the system. Hence, our hypothesis was proved that training and support (as provided by the authors) helped the older participants to adopt and familiarize themselves with the smartwatch.

Third, findings strongly supported hypothesis 3, revealing pronounced socioeconomic differences in data-sharing preferences. Participants from higher socioeconomic and educational backgrounds expressed greater willingness to share health data continuously, whereas participants from lower socioeconomic groups predominantly preferred emergency-only sharing. Notably, reluctance to share data was often motivated not by privacy concerns alone, but by a desire to avoid burdening family members perceived as less technologically or medically informed. This highlights the need for flexible, customizable privacy and data-sharing controls that account for diverse social and familial contexts in LMIC settings.

Beyond these hypotheses, qualitative insights revealed a broader trajectory of adoption. Initial skepticism, particularly regarding accuracy and usefulness, gradually gave way to confidence and routine integration of the smartwatch into daily life. Participants consistently emphasized the importance of familiar physical design elements, such as leather or steel straps, suggesting that aesthetic familiarity plays a critical role in lowering psychological barriers to adoption among older adults.

Key Contributions

This study makes several novel contributions to wearable health technology literature. First, it presents one of the few long-term, mixed methods usability evaluations of smartwatches among older adults in an LMIC context, specifically in Bangladesh. Second, the study uniquely incorporates 3 longitudinal survey cycles and 2 focus group interviews, enabling a nuanced understanding of adaptation over time rather than short-term acceptance alone. Third, by stratifying participants according to socioeconomic and educational background, the study reveals how adoption, usability challenges, and privacy preferences diverge across demographic groups—an aspect largely overlooked in previous work. Finally, the findings extend usability discourse beyond daily use to include cultural norms, family dynamics, and aesthetic preferences, offering a more holistic framework for designing inclusive wearable technologies for aging populations.

Conclusion

This study investigated smartwatch usability, adoption, and perception among older adults through short-term surveys,

XSL•FO
RenderX

long-term follow-up surveys, and focus group interviews. Findings demonstrate that while initial engagement was driven by curiosity and exploration, long-term use depended on comfort, usability, and relevance of features. Core health-monitoring functions, such as heart rate tracking, remained central to adoption, whereas complex features faced usability barriers despite training.

Over time, participants became more comfortable and confident with smartwatch use, validating the importance of continuous exposure, structured support, and intuitive design. Comfort-related concerns—particularly device weight and strap material, along with strong preferences for culturally familiar aesthetics, highlight the need for age- and context-sensitive hardware designs. Participants also expressed demand for features directly aligned with prevalent health concerns, including blood pressure monitoring, diabetes tracking, and caregiver-linked data sharing.

Socioeconomic and educational factors significantly shaped user experiences, particularly in relation to data-sharing preferences and perceived responsibility toward family members. These findings emphasize that successful wearable adoption among older adults, especially in the LMIC context, requires not only technical usability but also sensitivity to social values, privacy expectations, and cultural norms.

In conclusion, this study illustrates the evolving relationship between older adults and wearable health technologies, demonstrating both their promise and their limitations. By foregrounding longitudinal adaptation, socioeconomic diversity, and cultural context, the findings offer actionable design and deployment insights to support more equitable, acceptable, and sustainable adoption of smartwatches among aging populations.

Limitations

A potential limitation of this study lies in the limited size and diversity of the participant sample. A significant proportion of the participants came from similar occupational backgrounds. Although the study targeted individuals from lower-income groups, it did not include any participants who were completely illiterate. Furthermore, due to unavoidable circumstances, such as illness or death, several participants either withdrew from the study or missed certain data collection points, resulting in some discrepancies in the dataset. To maintain data balance, some participants had to be excluded from the focus group sessions. Additionally, the sample exhibited minor gender biases. While the initial male-to-female ratio was satisfactory, a number of female participants later withdrew from the study due to health concerns. The absence of representation from more diverse gender identities and from individuals who are enthusiastic about technology but were not recruited may have impacted the inclusivity of the study. Future research should aim to include participants across a broader spectrum of demographics, regardless of gender, and with varying levels of technological literacy, including individuals who are entirely illiterate.

Acknowledgments

This research project was supported by the North South University (NSU), Office of Research, and Department of Electrical and Computer Engineering. We also thank the North South University Institutional Review Board (IRB) for providing the Ethical approval (IRB 2023/OR- NSU/IRB/1231). We have to mention in acknowledgment that large language model tools were used specifically for bringing more clarity and refinement in writing in some sections, although the results and content were entirely the output of our study. We also sincerely acknowledge and appreciate the guidance and mentorship of Dr Sharifa Sultana, Assistant Professor, Computer Science, University of Illinois Urbana-Champaign, and Dr Syed Ishtiaque Ahmed, Associate Professor, Department of Computer Science, University of Toronto. Finally, we are very thankful to the entire community of older adult study participants from old age homes like Probeen Nibash and neighborhoods.

Funding

This research project was supported by the NSU CTRGC research grant fund CTRG-23-SEPS-18 from North South University.

Authors' Contributions

FM conceived the idea, designed and supervised the study, and contributed to data analysis and manuscript preparation. FR and NM contributed equally to recruitment of participants, data collection, analysis, and manuscript preparation. SAI helped with recruitment of participants and data collection.

Conflicts of Interest

None declared.

Abstract

Background: Nutritional status is an influential factor for functional status and rehabilitation outcomes in patients undergoing geriatric rehabilitation. Although there is evidence for the potential of eHealth interventions in patients undergoing geriatric rehabilitation in general, the evidence for eHealth interventions with a focus on nutrition is scarce. In other target groups with older people, eHealth applications to support nutrition, such as computer-based food records, have been used successfully.

Objective: Therefore, the aim of this study was to verify whether it is feasible for patients undergoing geriatric rehabilitation to independently use a tablet computer−based food record (e-food record) to document their food and beverage intake. The e-food record was developed in advance and tailored to the age- and disease-specific needs of patients undergoing geriatric rehabilitation.

Methods: This prospective pilot study investigated the general feasibility of an e-food record in older adults (≥70 y) in a geriatric rehabilitation center in Germany. It was tested whether the e-food record could be independently used by the participants over 3 days. Furthermore, the usability of the e-food record was assessed by the System Usability Scale (0 - 100 points) after usage. To compare nutritional data, the participants recorded their consumption of food and beverages by the e-food record and by a 24-hour recall for the same time period, and the mean difference was calculated as follows: the value of the 24-hour recall minus the value of the e-food record. As the study was characterized as a pilot, the data analysis was descriptive.

Results: Seventeen out of 25 patients (n=6, 35.3% female, mean age 79.5, SD 3.7 y) maintained the e-food record independently over the study period. The mean System Usability Scale score of the e-food record was 76.0 (SD 11.3) points. Datasets of 9 out of 17 participants (n=5, 55.6% female, mean age 78.2, SD 2.9 y) were analyzed in terms of nutritional data. Mean differences in energy, protein, and fluid intake by the 24-hour recall compared to the e-food record were 4.9 (SD 10.2) kcal/kg body weight (bw), 0.1 (SD 0.3) g/kg bw, and 4.9 (SD 9.4) g/kg bw, respectively.

Conclusions: The use of an e-food record is generally feasible for patients undergoing geriatric rehabilitation characterized by low technical experience, high mean age, and a high rate of functional impairment. Lower intake levels were observed for the e-food record compared to the 24-hour recall with regard to energy, protein, and fluid intake. Aspects for further development of the e-food record were identified to enable evaluation on a larger sample. Following successful evaluation, the e-food record could be used within nutrition therapy in the future to increase the efficiency of the nutritional therapy process.

Introduction

Background

Older people represent a growing population in Western countries due to sociodemographic developments. As a consequence, the number of people who have therapeutic or nursing needs is also increasing sharply [1]. Therefore, geriatric rehabilitation is becoming increasingly important in the medical care of older people. Patients undergoing geriatric rehabilitation are characterized by a reduced functional status due to disabling impairments. These are often combined with the presence of multimorbidity and geriatric syndromes such as sarcopenia or frailty [2-4]. The aim of geriatric rehabilitation is to improve functional resources in order to enable patients to return to their home environments [5].

Nutritional status is a well-known factor that is interrelated with physical function, frailty, and sarcopenia, which are associated with negative effects on functional dependence in patients undergoing geriatric rehabilitation [6-8]. However, malnutrition and the risk of malnutrition are widespread conditions among these patients, with a prevalence of 5% to 20% for malnutrition and 40% to 54% for the risk of malnutrition [8]. Because there is profound evidence, malnutrition is treated as part of the structured rehabilitation program within nutritional therapy [9]. The focus here is on optimizing energy and protein intake and on weight stabilization to generate a positive effect on muscle building and muscle maintenance [10]. The amount of energy and protein intake consumed is determined by the nutritional therapist using the method of a food record. Individual nutritional recommendations for the patient are then derived and communicated on this basis. Due to financial and personnel resources, nutritional therapy is often limited in time during rehabilitation treatment, even if the literature indicates that close-meshed nutritional therapy might achieve greater success [11].

eHealth applications, such as computer-based food records, can be used to provide support by intensifying the nutrition therapy process. The time-consuming processes of recording and analyzing dietary intake data are no longer necessary for the nutrition therapist. Maintaining a computer-based food record regularly enables the diet to be monitored more consistently and proactively. Deviations from the nutrition target can be recognized earlier, and reintervention can be initiated by the nutrition therapist. In addition, maintaining the computer-based food record can increase the patient's awareness of their diet and therefore might lead to higher motivation in achieving nutritional goals. In the context of geriatric rehabilitation, advanced age, limited experience with technology, reduced visual acuity, changes in haptics, cognitive limitations, and fears in dealing with technology are characteristic challenges when using eHealth systems in this target group that must be addressed in the technical development process.

eHealth interventions in geriatric rehabilitation have already been shown to have the potential to improve rehabilitation outcomes. In a meta-analysis, the evidence for feasibility, usability, and effectiveness in the treatment of patients undergoing geriatric rehabilitation was demonstrated. However, the eHealth interventions focused predominantly on activity and physical function. No nutritional interventions were reported [12]. Only Happe et al [13,14] demonstrated in 2022 and 2023 the feasibility and usability of a tablet-based e-coach to improve nutrition and physical activity in patients undergoing geriatric rehabilitation. As far as we know, there is no research data on e-food record methods in the group of patients undergoing geriatric rehabilitation published to date.

Objectives

Therefore, the primary objective of this pilot feasibility study was to verify whether it is fundamentally possible for patients undergoing geriatric rehabilitation with low technical experience and simultaneous high postacute or chronic stress to independently use a tablet computer−based food record (e-food record) over 3 days that has been specially adapted to their needs. Secondary and exploratory objectives included the assessment of usability as well as the analysis of the recorded dietary data. In addition, the recorded food items, food portions, and nutritional intake data of the e-food record are compared to the recorded data of a 24-hour dietary recall, a commonly used reference method in clinical practice. Finally, the study aimed to identify potential areas of improvement to inform further development of the e-food record.

Methods

Participants and Study Design

Patients aged 70 years and older who were consecutively admitted to a geriatric rehabilitation ward of a rehabilitation center in the northwest of Germany were eligible for the present prospective pilot feasibility study. Exclusion criteria were (1) immobility in the sense of confinement to bed, (2) the inability to understand the study content and the course of the study, (3) difficulties in communication in the German language, and (4) participation in another study. Inpatient geriatric rehabilitation in Germany is a structured multidisciplinary program with the goal of regaining independence and functionality in older persons with reduced functional conditions due to acute or chronic medical conditions [15]. Daily therapy is administered for a period of usually 20 days [16], including medical therapy, nursing care, physiotherapy, occupational therapy, neuropsychology and social services, nutritional therapy, and speech therapy [15]. Patients undergoing geriatric rehabilitation represent a highly vulnerable and clinically burdened population, often characterized by multimorbidity, functional limitations, and increased physical and psychological stress following acute or chronic health events. Furthermore, familiarity with and affinity for digital technologies are often limited in this age group. Data for the feasibility study were collected between July and December 2018. All participants took part in the study during the geriatric rehabilitation program. Sex and age were requested from the patients and documented. Due to ethical and data protection regulations, no data were collected from patients who declined participation. Therefore, no systematic information on reasons for nonparticipation is available.

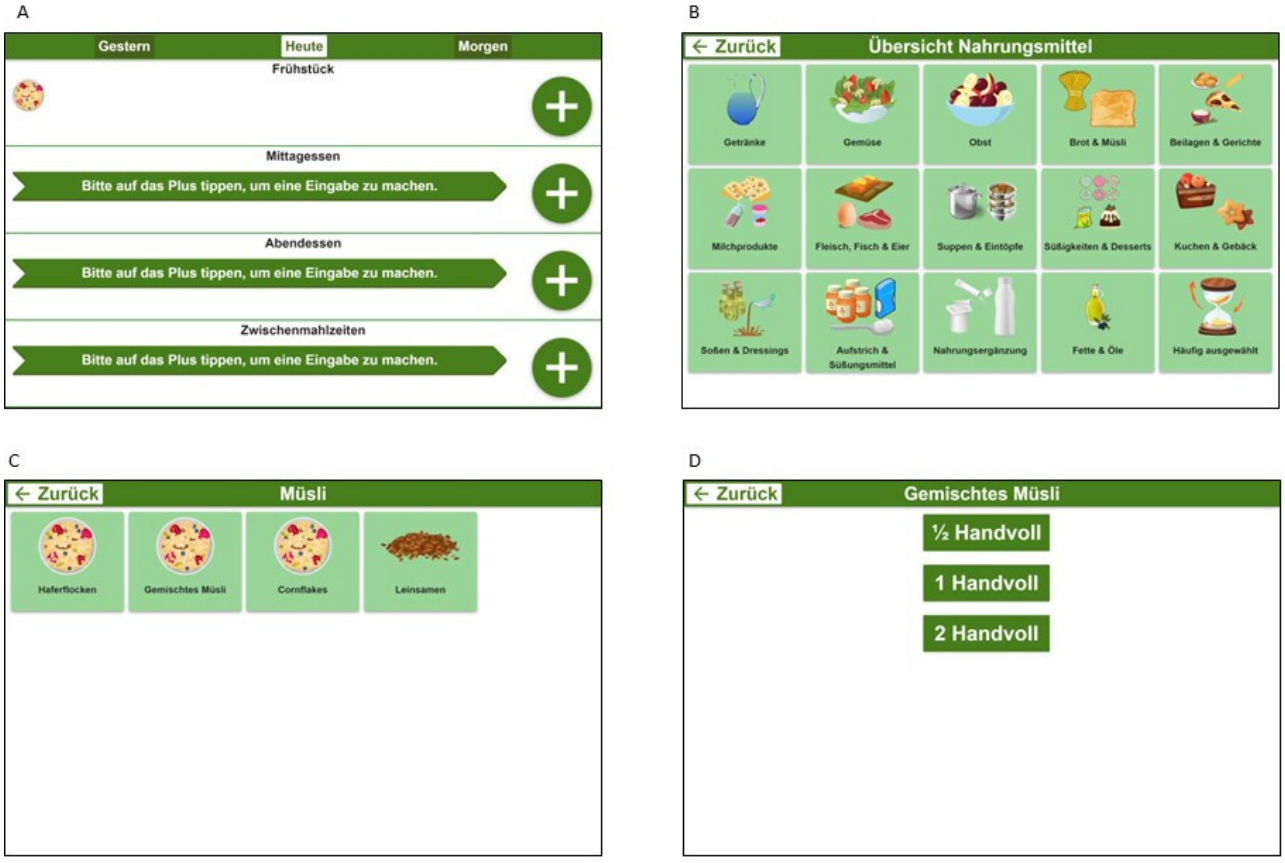
XSL•FO
RenderX

Ethical Considerations

The study was approved by the medical ethics committee of the Carl von Ossietzky Universität Oldenburg (ethical approval code 2018-029). We conducted the study in accordance with the Declaration of Helsinki. The study was a priori registered in the German Clinical Trials Register (DRKS-ID: DRKS 00014370).

Informed consent was obtained from all participants prior to participation. Pseudonymized data were collected and stored on secure, password-protected systems accessible only to the research team. Results are reported in aggregated or anonymized form. Participants did not receive any financial compensation, incentives, or other benefits for their participation in this study.

Study Assessment of Food Records



e-Food Record

The patients' food and beverage consumption was recorded by the patients themselves using an e-food record for 3 days including 2 weekdays and 1 weekend day. The e-food record used was an app-based computer program developed in close cooperation between experts in the field of nutritional counseling and app developers. It was installed on a 10.1-inch tablet Lenovo YOGA Tab 3 Plus in landscape mode. With regard to data protection, all data collected via the e-food record were stored locally on the device and transferred via secure local (offline) data transfer to a university computer after study completion. No cloud-based storage or external data transfer was used. No personal identifying information was stored within the application, and the access to study data was restricted to authorized members of the research team only. Technological aspects and the user-centered development of the e-food record were published by Elfert et al [17,18]. Design guidelines for apps for older people were key components in the development of the e-food record. The start screen of the e-food record was present at the current date and prompted the patients to make an entry for either breakfast, lunch, dinner, or a snack by touching the meal-associated plus signs. In total, 195 food symbols out of 14 food categories (eg, "bread and cereals," "vegetables," "meat, fish, and eggs," and "beverages") and 18 subcategories (eg, "bread," "buns," and "cereal" within the upper category "bread and cereals") could be selected by the patients. The view of the start screen and the selection screen of the food upper categories are shown in Figure 1.

Portions suitable for everyday use were predefined in the e-food record based on the food pyramid of the Federal Center for Nutrition [19] and could be selected as half, 1, or 2 portions. Where possible, the portion sizes referred to an easily manageable hand measure. For example, one portion of bread equaled one slice of bread about the size of the hand, and one portion of cereals, fruits, vegetables, and sweets equaled one handful. Beverages were measured in glasses, cups, or mugs. There was no option for free entries. Before the application test, the participants were given a detailed introduction to the e-food record. For this purpose, they entered a defined sample meal into the e-food record under guidance, whereby open questions regarding the handling were addressed and clarified. All data were stored locally on the tablet computer and downloaded from the device via a cable connection upon successful completion of the study.

Figure 1. Screen views of the e-food record in the original German version according to Elfert [20]. (A) Start screen with an entry of muesli under breakfast and the prompt to make an entry for lunch, dinner, or snacks by tapping on the plus symbol. (B) Screen view for the selection of a food upper group (eg, beverages, fruits, milk products, soup and stew, and fat and oil). (C) Screen view for food selection using the example of muesli. (D) Screen view for portion selection using the example of muesli. English translations are as follows: Gestern: yesterday; Heute: today; Morgen: tomorrow; Frühstück: breakfast; Mittagessen: lunch; Abendessen: dinner; Zwischenmahlzeiten: snacks; Bitte auf das Plus tippen, um eine Eingabe zu machen: Please tap the plus sign to enter an entry; Zurück: back; Übersicht Nahrungsmittel: food overview; Getränke: beverages; Gemüse: vegetables; Obst: fruits; Brot & Müsli: bread & cereals; Beilagen & Gerichte: side dishes; Milchprodukte: dairy products; Fleisch, Fisch & Eier: meat, fish & eggs; Suppen & Eintöpfe: soup & stew; Süßigkeiten & Desserts: sweets; Kuchen & Gebäck: cakes; Soßen & Dressings: sauces; Aufstrich & Süßungsmittel: spreads & sweeteners; Nahrungsergänzung: supplements; Fette & Öle: fat & oil; Häufig ausgewählt: frequently selected; Müsli: cereals; Haferflocken: oatmeal; Gemischtes Müsli: mixed granola; Cornflakes: cornflakes; Leinsamen: flaxseeds; Handvoll: handful.

24-Hour Recall—Paper-Based Food Record

In addition to the e-food record, a 24-hour recall was conducted retrospectively for each day the e-food record was also filled out. For this purpose, a prestructured paper-based template of a 24-hour recall was used to enter all consumed food and beverages of the previous day asked by a nutritionist and a member of the study staff. The prestructured 24 hour recall used here consisted of 18 food categories such as “bread,” “vegetables, salad,” “meat, fish, eggs,” “juices, water, other beverages,” etc. Each upper category contained 4 to 11 single foods. Predefined portions were counted as a tally for each of the 3 days. Food not listed was entered as free input at the end of the 24-hour recall.

Feasibility

Feasibility, defined as the independent use of the e-food record over 3 days, was assessed during a 3-day application test in inpatient geriatric rehabilitation. Feasibility was operationalized by the completion of the recording period and quantified using the dropout rate.

Usability and Technology Commitment

As secondary outcomes, usability and technology commitment were assessed. Following the use of the e-food record, the user experience was reflected upon. Usability was measured using the System Usability Scale (SUS, 0 - 100 points) [21] in its German translation [22], with higher scores indicating better usability. The SUS is a standardized questionnaire with 10 items that are rated on a Likert scale from 1 to 5. A value of over 68 is considered above average. The SUS scores determined were grouped together and classified using adjectives according to Bangor et al [23] as follows: best imaginable (100-84.1 points), excellent (84-80.8 points), good (80.7-71.1 points), okay (71-51.7 points), poor (51.6-25.1 points), and worst imaginable (≤25 points).

Prior to the application test, the technology commitment was assessed according to Neyer et al, with a standardized 12-item questionnaire (12 - 60 points). The items were rated on a 5-point Likert scale and reflect the areas of personal contact, interest, and expectations for the use of technologies [24].

XSL•FO

Exploratory Analysis: Comparison of E-Food Record and 24-Hour Recall

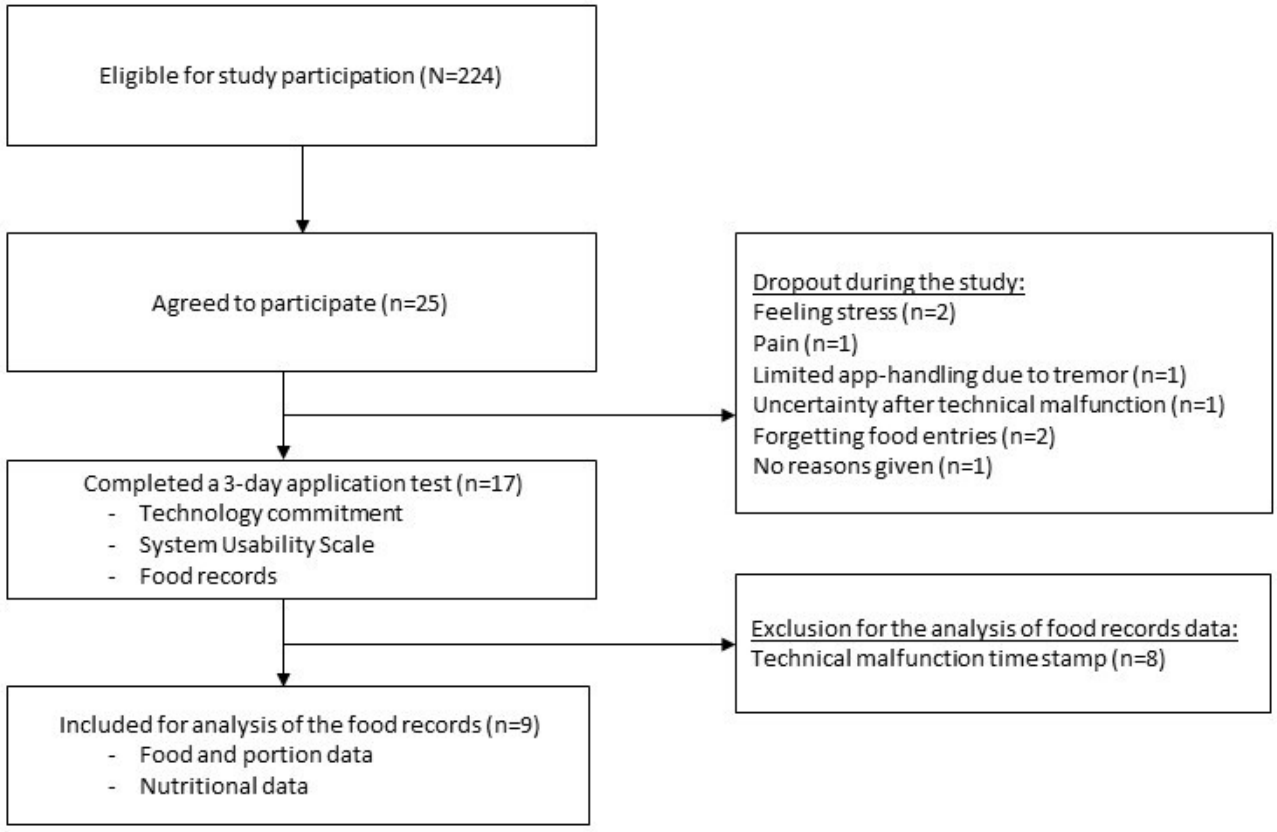
Nutritional Data

As an exploratory objective, dietary data obtained from the e-food record were compared with those from a 24-hour recall. The nutritional values of energy, protein, and fluid intake of the e-food record dataset and the 24-hour recall were adjusted for body weight (bw) and calculated as grams (g) divided by bw (kg) in a comparable manner for both protocol methods on the basis of the German Federal Food Code. Fluid intake was expressed in g/kg bw and not in mL/kg bw, as provided by the nutritional analysis software DGE Expert (version 1.3.14.1, Deutsche Gesellschaft für Ernährung) used in this study. The mean differences of energy, protein, and fluid intake between the e-food record and 24-hour recall were calculated by subtracting the values of the e-food record from the 24-hour recall, respectively. In addition, agreement in recorded food and beverage entries and portion sizes between both methods was explored. For this purpose, entries were grouped into predefined food categories.

Food and Beverage Portion Entries

After the 3-day application test, the entries of the recorded food and beverages along with the corresponding portion entries from the e-food record and the 24-hour recall were extracted. The recorded data of the 2 methods were grouped into the upper food categories of “beverages,” “vegetables,” “fruits,” “meat, fish, and eggs,” “dairy products,” “soup and stew,” “side dishes,” “sauces,” “sweets,” “cakes,” “bread and cereals,” “spreads,” “fat and oil,” “sweeteners,” and “supplements,” respectively.

Statistical Analysis



The statistical analysis was conducted using SPSS Statistics version 29 (IBM SPSS Inc). Descriptive statistics are presented as mean values and SD, median and IQR, or as total numbers and percentages. Due to the pilot characteristics of the study, the statistical analysis refers to an explorative analysis, and no interference statistics were performed.

Results

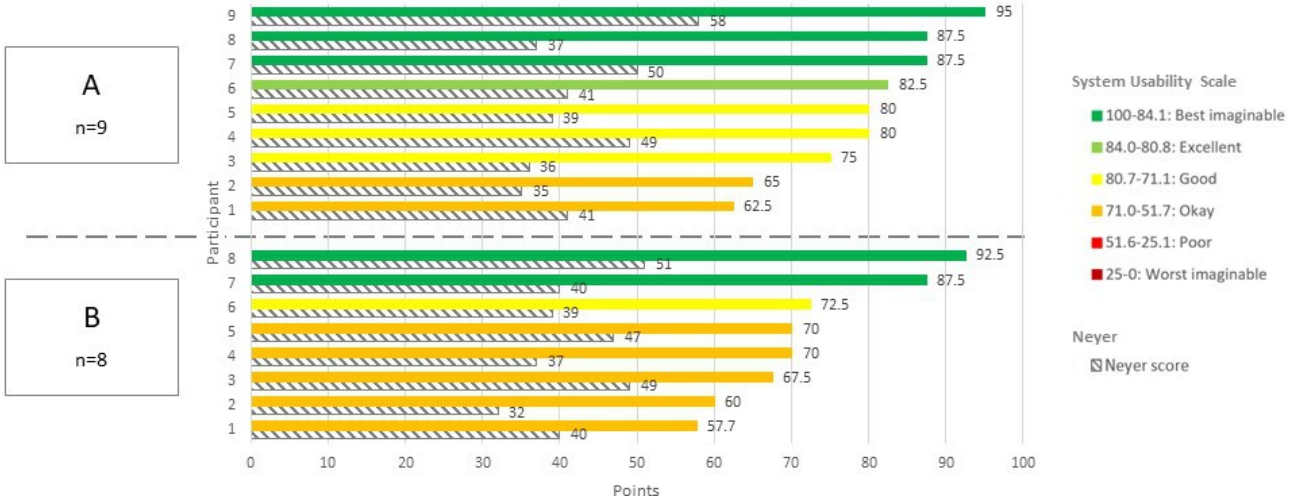
Feasibility

Twenty-five out of 224 (11%) patients who were eligible for inclusion were enrolled in the study. Seventeen out of 25 (68 %) patients completed the study and were included in the analysis of usability and technology commitment, while 8 patients dropped out of the study prematurely. Detailed information about the reasons for dropout is shown in Figure 2. During the study, a technical malfunction occurred in which the day selection did not automatically jump to the current day, contrary to what the study participants were told. As a result, the entries could no longer be validly assigned to the individual protocol days. Due to this, 9 out of 17 datasets were included in the analysis of the nutritional data (group A), while 8 datasets could not be analyzed (group B).

Figure 2. Flowchart for inclusion and dropout of study participants.

XSL•FO
RenderX

Participant Characteristics



The mean age of all participants (n=17) who completed the study was 79.5 (SD 3.7) years. Six (35.3%) of them were female. The mean age of the participants who completed the 3-day application test (group A, n=9) was 78.2 (SD 2.9) years. Five out of 9 (55.6%) participants were female. The average age of the participants whose data were included for the analysis of the food records (group B, n=8) was 81.0 (SD 4.0) years, and 1 (12.5%) participant was female.

Usability and Technology Commitment

The SUS was rated 76.0 (SD 11.3) points on average by all participants. It was higher in participants of group A with a mean score of 79.4 (SD 10.0) points compared to 72.2 (SD 11.4) points in participants of group B.

The mean technology commitment of all participants was 42.4 (SD 6.8) points. For group A, the mean technology commitment was 42.9 (SD 7.3) points compared to group B with 41.9 (SD 6.1) points. The single-item responses of the Likert scale (1 - 5 points) were rated on average with 3.5 (SD 1.8) points (n=17). Detailed information on the values of the SUS and technology commitment per participant are represented in Figure 3.

Figure 3. Usability and technology commitment per participant. Adjectives were used according to Bangor et al [23].

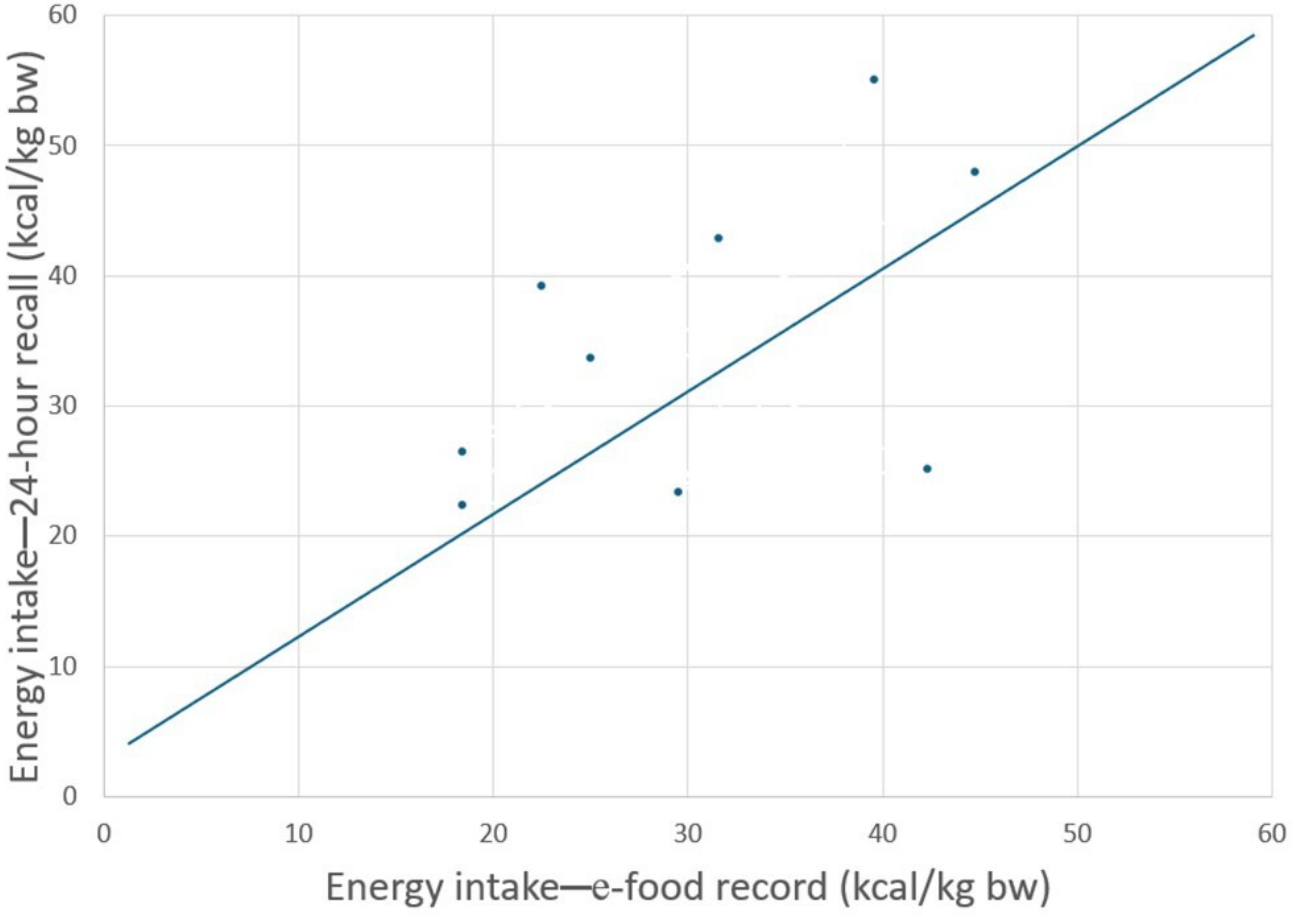
Comparison of e-Food Record and 24-Hour Recall

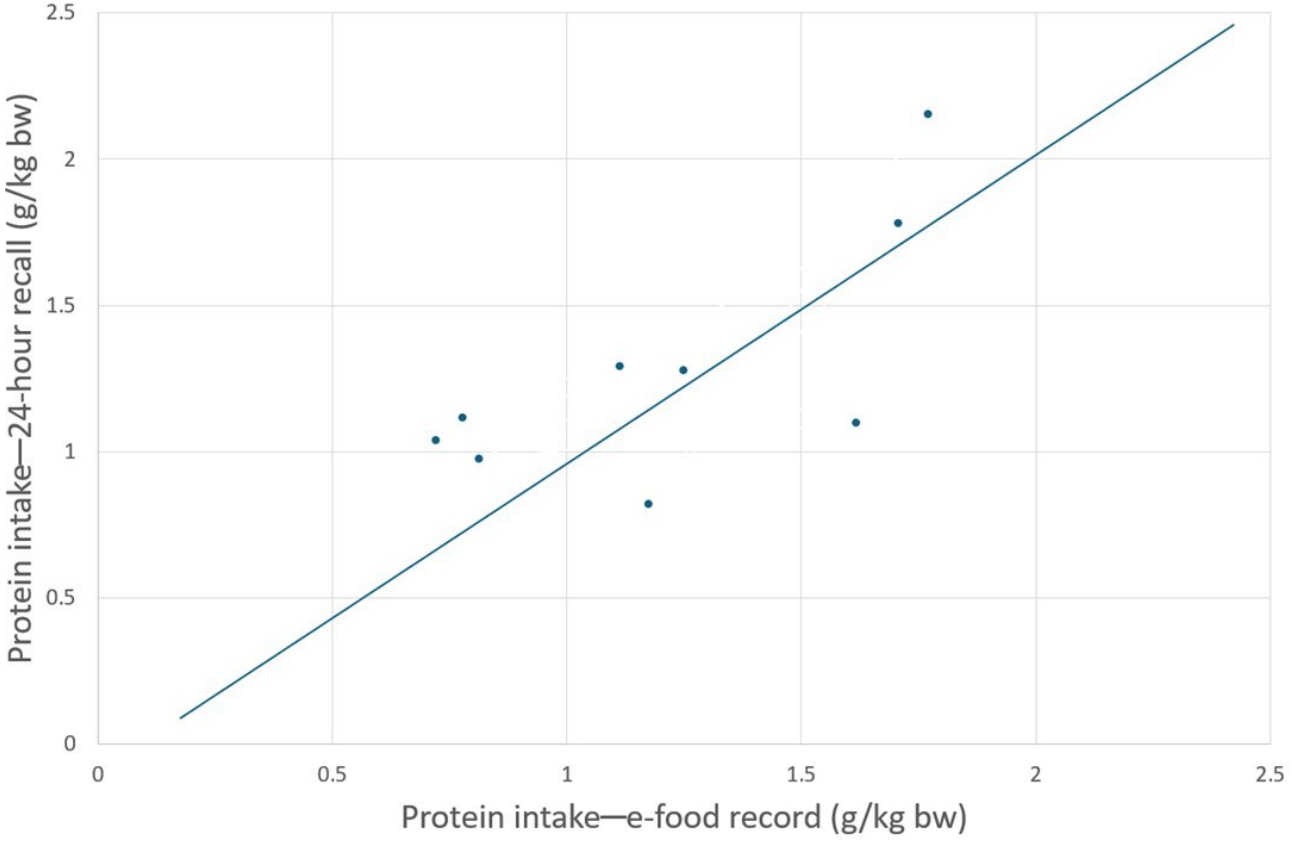
Nutritional Data

The data of 9 participants (group A) were included in the following analysis. The mean energy intake determined with the e-food record was 30.3 (SD 10.2) kcal/kg bw compared to 35.0 (SD 11.0) kcal/kg bw determined with the 24-hour recall. The protein intake determined via the e-food record was 1.2 (SD 0.4) g/kg bw, which was lower than the protein intake determined via the recall at 1.3 (SD 0.4) g/kg bw. Figures 4-6 show the individual participant data of the comparison of the nutritional values for energy, protein, and fluid intake, respectively, according to the e-food record and 24-hour recall. For 7 out of 9 participants, the energy and protein intake determined via the 24-hour recall was higher than that determined via the e-food record. For 6 out of 9 participants, the fluid intake determined via the 24-hour recall was higher than via the e-food record. The mean difference in energy intake between the 24-hour recall and the e-food record was 4.9 (SD 10.2) kcal/kg bw and ranged between −17.2 and 16.7 kcal/kg bw, respectively. For protein intake, the mean difference was 0.1 (SD 0.3) g/kg bw and ranged between −0.5 and 0.4 g of protein/kg bw. Fluid intake differed by 4.9 (SD 9.4) g/kg bw on average and ranged between −13.6 and 18.9 g/kg bw.

XSL•FO
RenderX

Figure 4. Mean energy intake per participant (n=9) over 3 days, recorded by the e-food record and 24-hour recall. bw: body weight.





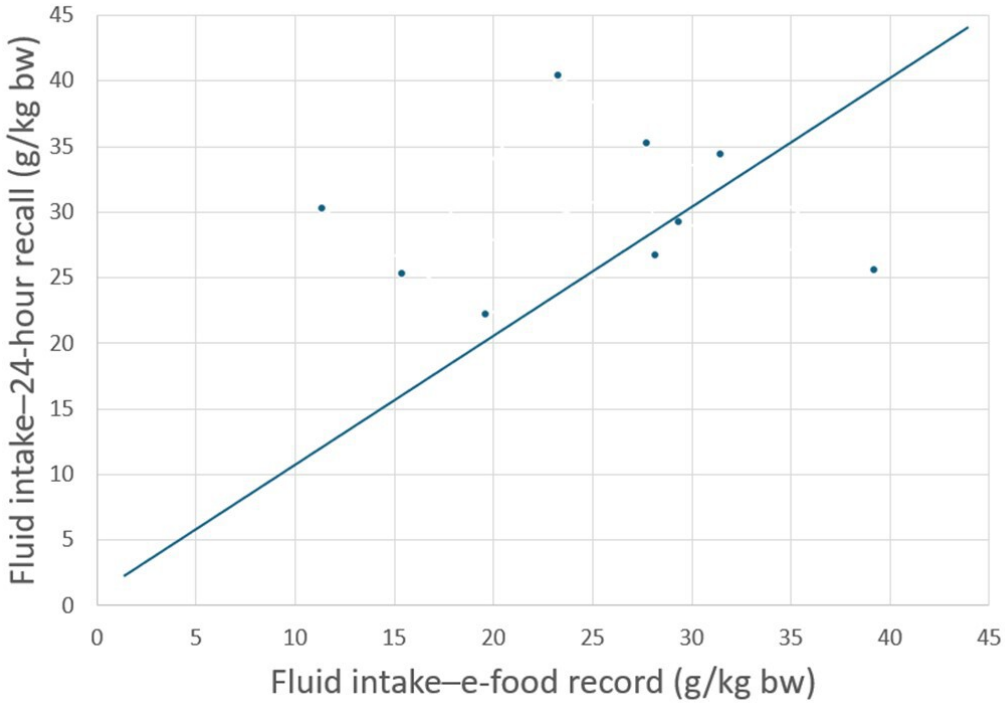


Figure 5. Mean protein intake per participant (n=9) over 3 days, recorded by the e-food record and 24-hour recall. bw: body weight.

XSL•FO
RenderX

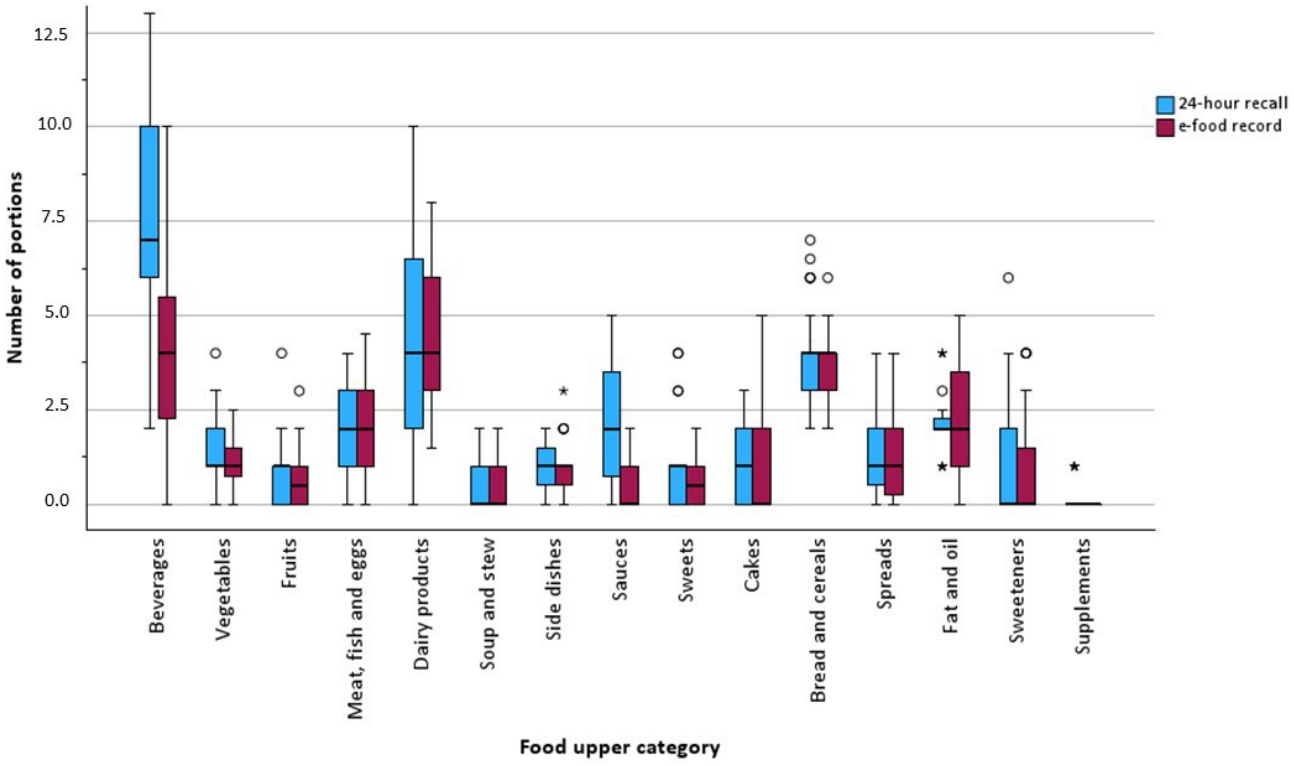

Figure 6. Mean fluid intake per participant (n=9) over 3 days, recorded by the e-food record and 24-hour recall. bw: body weight.

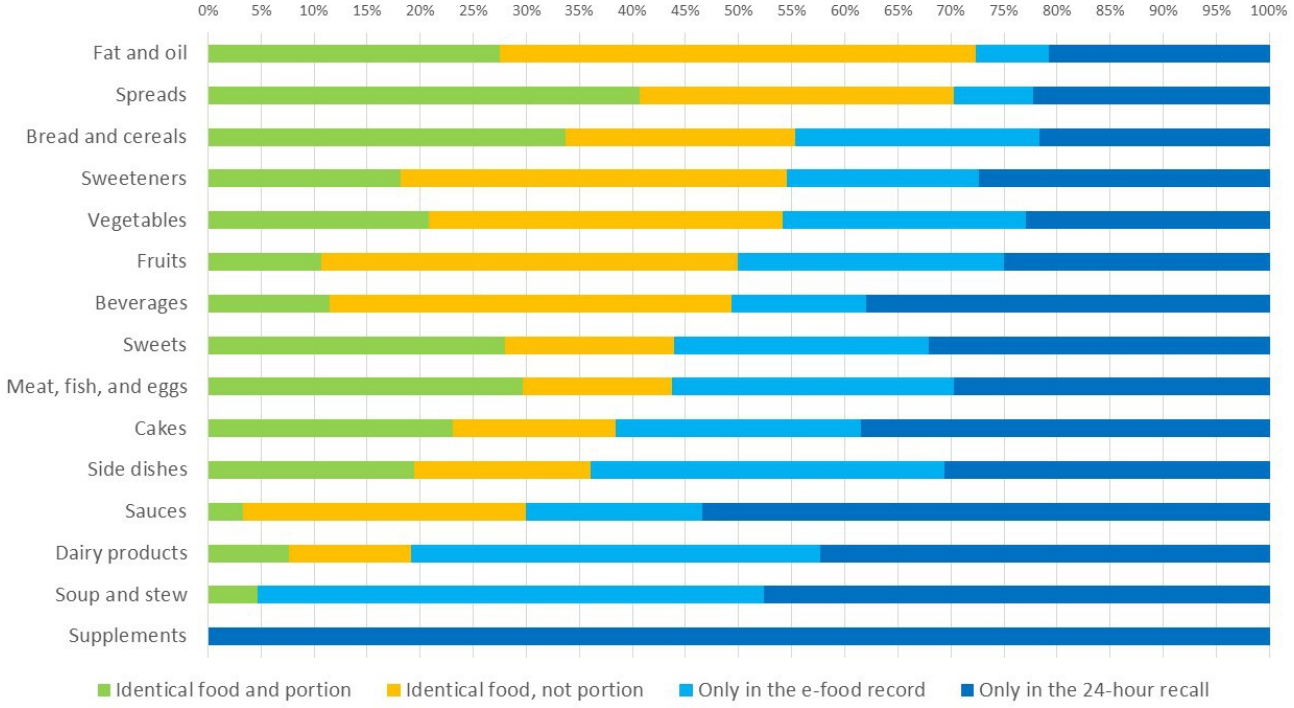
Food and Beverage Portion Entries

Over 3 days and across 9 participants (group A), a total of 625.5 food or beverage portions were recorded by the e-food record and 823.5 food or beverage portions by the 24-hour recall. Per study participant per day, this was an average of 23.9 (SD 5.9) food or beverage portions recorded by the e-food record and 30.8 (SD 6.7) food or beverage portions recorded by the 24-hour recall. On the upper food category level, the median of recorded portions per day was equal for the e-food record and 24-hour recall except for beverages (4, IQR 2-6 vs 7, IQR 6-10.5), fruits (0.5, IQR 0-1 vs 1, IQR 0-1), sauces (0, IQR 0-1 vs 2, IQR 0.5-4), sweets (0.5, IQR 0-1 vs 1, IQR 0-1), and cakes (0, IQR 0-2 vs 1, IQR 0-2), which showed a higher median (IQR) at the 24-hour recall. The results are shown in Figure 7.

Figure 7. Food and beverage portions per protocol day, recorded by the e-food record and by the 24-hour recall.



XSL•FO
RenderX

On the single food level, the portion entries for a corresponding food per day were compared between the e-food record and the 24-hour recall. A consistency was achieved when the same food with the same portion was recorded via the e-food record and the 24-hour recall on the same protocol day. The consistency of the identical portion entries between the e-food record and the 24 h recall was below 30% in 13 out of 15 food categories in relation to all entries in the corresponding food category. The highest correspondence was observed for the food category "spread," in which 40.7% (n=27) of the foods were recorded in both the e-food record and in the 24-hour recall with the same portion size, followed by 33.8% (n=74) in the food category "bread and cereals" and 27.6% (n=29) in the food category "fat and oil." In the food category "supplements," no consistency (0%, n=0) was observed for the portion entries of the e-food record and the 24-hour recall. Further consistency was achieved when the same food, but with a different portion size, was recorded via both the e-food record and the 24-hour recall on the same day. The consistency of food entries with different portion sizes between the e-food record and the 24-hour recall was below 30% in 10 out of 15 food categories in relation to all entries in the corresponding food category. The remaining entries in the food categories were related to foods that were either only recorded via the e-food record or only via the 24-hour recall. The results are shown in Figure 8.

According to the results from Figure 8, a range of food or beverage entries were recorded in only one of the 2 food record methods. In total, 65 different foods or beverages were recorded only via the 24-hour recall by at least 1 participant on at least one of the 3 protocol days. In addition, 48 different foods or beverages were recorded only via the e-food record. Condensed milk, water, and black tea were most often recorded only via the 24-hour recall, and salad and cookies were most often recorded only via the e-food-record. Multimedia Appendices 1 and 2 represent data for the respective protocol method starting with 3 cases per food and upward.

Figure 8. Food and portion entries recorded by the e-food record and 24-hour recall. 100% refers to the total entries of all participants over 3 days.

The explorative analysis of the food and beverage entries with regard to fat content, food variety, and preparation type shows that the same food, but with a different fat level (eg, fruit yogurt with 3.5% fat in dry matter vs fruit yogurt with 10% fat in dry matter), was entered for yogurt, milk and milk drinks, curd, as well as for cold cut and fish. A different type of food (eg, multigrain bread vs wholemeal bread) was entered for cheese, milk and milk drinks, bread, cakes, tea, coffee, fat and oil, vegetables, and fruits. The same dish, but different preparation types, were entered for soup and stew, potato dishes, vegetables, and sauce. Data are represented in Multimedia Appendix 3.

Discussion

Principal Results

This pilot study primarily investigated whether an e-food record is a feasible method for documenting nutritional data in older adults undergoing geriatric rehabilitation. The results of this study demonstrate that the e-food record was successfully used by older adults in geriatric rehabilitation to record their food and beverage intake over a period of 3 days. Secondary and exploratory findings are related to usability and the comparison with a 24-hour recall. The e-food record's usability score (mean 76.0, SD 11.3 points) indicates good acceptability and ease of use. However, the e-food record and the 24-hour recall determined different results in terms of recorded nutrient intake and food portion sizes, indicating possible limitations. These differences should be interpreted with caution, as both methods

XSL•FO
RenderX

are subject to measurement errors. While the 24-hour recall may be affected by recall bias and memory limitations, the e-food record may be influenced by input errors or difficulties in the estimation of portion size. These findings suggest that the e-food record is a promising tool for recording food and beverage intake in older adults, but it currently also has some limitations.

Comparison With Prior Work

With respect to the primary objective of feasibility, this study demonstrated that the target group of patients undergoing geriatric rehabilitation was able to use an e-food record independently during their rehabilitation treatment. A systematic review by Kraaijkamp et al [12] showed that eHealth is feasible, usable, and effective in geriatric rehabilitation. However, none of the 40 included studies were related to nutritional content. A nutrition and exercise e-coach was developed iteratively by Happe et al [13,25] and tested successfully in a piloted application study with a follow-up of 9 weeks among older people during and after geriatric rehabilitation [14]. However, this study was designed for usability testing and user behavior analysis, and the data of the e-food record were not analyzed. A study on community-dwelling older adults with a mean age of 72.2 (range 65-89 y) demonstrated that an e-food record is comparable to a paper-based food record method [26]. During the study, 8 out of 25 participants withdrew prematurely from the study. These results are comparable to the study of Happe et al [14] mentioned above. Here, 8 out of 30 participants dropped out of the study prematurely. In this study, we observed a large difference between the number of patients who were in principle eligible for participation and the number of patients who actually participated (25 out of 224 patients undergoing geriatric rehabilitation).

In contrast, findings related to usability and data comparability should be interpreted as secondary and exploratory, as these aspects were not the primary focus of the study. The usability was rated with a mean score of 76.0 (SD 11.3) points, which reflects a high usability of the e-food record. A score of 82 points is described with the adjective “good” in the evaluation by Bangor et al [23] and is near to the score of 85 from which excellent usability begins. The SUS score is slightly lower than that for a tablet computer−based e-coach to improve nutrition and physical activity in patients undergoing geriatric rehabilitation developed by Happe et al [14] with 78.6 (SD 18.1) points on average. This study was conducted as a 3-day application test that did not contain any increased benefits for the participants (eg, feedback on dietary behavior or dietary recommendations). A higher benefit for the participants and thus a higher willingness to participate could be achieved in future studies by providing feedback on nutritional intake, integrating the e-food record into the nutrition therapy, or extending the study period beyond the rehabilitation program.

Implications for Research

The demonstrated feasibility of independent use of the e-food record provides an important basis for future research in the field of nutritional assessment in geriatric rehabilitation. The e-food record shows potential as a tool for documenting nutritional data in geriatric rehabilitation, which should be emphasized in future research. In order to exploit the full potential of the e-food record in the future, it should be integrated into daily treatment, ideally as part of a randomized and controlled intervention study. A comparison between the e-food record and the recorded nutritional values should be conducted using established reference methods and a larger number of participants to further investigate the validity and reliability of the e-food record in adequately powered studies. In addition, subsequent studies should investigate which factors contribute to the successful use of the e-food record and which barriers exist to use an e-food record among patients undergoing geriatric rehabilitation. Relevant aspects for further development and optimization of the e-food record were identified in this study by comparing the e-food record with the practical method of the 24-hour recall. The data in Figure 8 indicate that the minority of food and beverage entries (<30 % in 13 out of 15 food categories) are consistent between the e-food record and the 24-hour recall. To estimate portions more precisely, images of food items with the corresponding portions could be displayed on the user interface of the e-food record. In literature, there are also attempts to estimate portions using photo documentation and image recognition [27-29]. Furthermore, the data of Figure 8 indicate a relatively large discrepancy between the foods recorded via the e-food record and the 24-hour recall. A confirmation prompt could be added to the end of a meal entry, for example, to detect incorrect entries by the patients and give them the opportunity to correct them. The results represented in Multimedia Appendix 2 indicate that certain foods such as condensed milk, water, black tea, coffee, cookies, and gravy were partly reported only via the 24-hour recall. This might be due to the fact that the 24-hour recall was queried using a predefined list of foods in food or meal groups that possibly counteracted the forgetting of foods and beverages consumed. A structured query of frequently forgotten or often related foods or beverages such as coffee and condensed milk, bread and spreadable fat, or salad and dressing could prevent forgetting of foods and beverages. The results of Multimedia Appendix 3 indicate that participants may have rated the fat content of foods such as yogurt milk drinks, curd cheese, cold cuts, and fish differently in the e-food record and 24-hour recall. A barcode scanner function or letter recognition of the packaging may increase input accuracy. Within the use of the e-food record, it was possible to select both individual foods and entire dishes. Entire dishes could be omitted. They could be replaced by individual foods. If entire dishes are used as an input option, ingredient queries may increase accuracy of, for example, a stew. However, it is important to balance the benefits of additional functionality against the potential increase in complexity to ensure ease of use for patients undergoing geriatric rehabilitation. The exploratory findings of this study, particularly regarding usability and discrepancies with the 24-hour recall, provide important directions for further development and hypothesis generation.

Limitations

This study was aimed at serving as a pilot feasibility test and was, therefore, designed as a short-term observation with only a limited number of participants. This could limit the generalizability of the results. In addition, the study was conducted in a single rehabilitation center, which may limit the

XSL•FO
RenderX

transferability of the results to other settings or patient populations.

Only a small number of eligible patients participated in the study, and even a smaller number contributed analyzable dietary data. This may introduce substantial selection bias and limited generalizability, as participants who agreed to participate may differ systematically from nonparticipants, for example, in terms of motivation, health status, or technology affinity. Due to ethical constraints, no data on nonparticipation were collected, although the characteristics of this highly burdened population undergoing geriatric rehabilitation likely contributed to the low participation rate. As a result, the findings are based on a highly selected subgroup, and their generalizability to the broader population of patients undergoing geriatric rehabilitation is strongly limited.

A technical malfunction occurred during the study, as the automatic navigation to the current day's page did not function as intended. This may have affected user interactions and data quality. Feasibility was operationalized primarily based on the dropout rate. However, more detailed indicators of feasibility, such as the level of assistance required during use or the frequency of user errors, were not systematically recorded. This limits a more comprehensive understanding of independent use.

Furthermore, the cognitive status was not systematically recorded within the study. Cognitive impairment may have influenced both the ability to use the e-food record and the accuracy of the 24-hour recall, for example, due to recall bias or difficulties in reporting. However, patients with inability to understand the study content and procedures were excluded from participation, which may partially reduce the impact of severe cognitive impairment in the study sample.

Differences observed between the e-food record and the 24-hour recall could be interpreted with caution, as both methods are subject to different sources of measurement error. The comparison between the two methods was exploratory and not intended as a validation study. Given the small sample size and exploratory design, no firm conclusions regarding the validity or accuracy of either method can be drawn. In addition, analyses related to usability and comparison with the 24-hour recall were exploratory and not powered for definitive conclusions. These results should therefore be interpreted with caution and require confirmation in larger studies.

Implications for Practice

Effective nutrition therapy is crucial for achieving an optimal nutritional status in patients undergoing geriatric rehabilitation with a reduced nutritional status, as malnutrition is directly linked to physical functionality and rehabilitation outcomes [8]. The e-food record method offers several advantages, including direct access to nutritional information for nutrition therapists. This contributes to the implementation of early and targeted interventions. Traditional food records require manual analysis by nutrition therapists and are often limited to 1-day recalls. With the e-food record method, the patients record their nutritional intake themselves. This reduces personnel resources, which in turn can be used for personalized advice.

By utilizing consumption data, the e-food record can improve nutritional status by providing more intensive and targeted therapy. To date, the detailed data on food and beverage intake over several days are rarely available in clinical practice, although it can enhance counseling. Additionally, nutrition therapists can use the e-food record to monitor the progress of nutrition therapy and introduce new interventions when necessary. This was previously more difficult due to time and financial constraints. This can lead to improved patient outcomes, such as enhanced physical function, reduced hospitalization rates, and better quality of life. Furthermore, an e-food record can facilitate communication between health care professionals, patients, and family members, promoting a more collaborative approach to nutrition therapy. In addition, the use of the e-food record is transferable to patient groups with similar requirements for the use of technology, such as patients in acute geriatric, older patients in neurology, or older people in short-term care facilities. However, given that findings beyond feasibility are exploratory, further validation is required before routine implementation in clinical practice.

Conclusions

This pilot feasibility study of an e-food record in the population of inpatients undergoing geriatric rehabilitation is, to our knowledge, the first of its kind and demonstrated, in general, that patients undergoing geriatric rehabilitation were able to independently record their food and beverage intake using the e-food record over 3 days. The results suggest that app-based food recording can be an integral part of nutrition therapy in the future to improve the medical care of patients undergoing geriatric rehabilitation. However, the findings of this study show that the e-food record and the 24-hour recall provide different results in terms of nutrient intake and food portion sizes. Further research with studies involving larger numbers of participants is needed to draw conclusions regarding data accuracy or validity of the e-food record.

Acknowledgments

We would like to thank all study participants for their engagement. Special thanks are due to Andrea Heinks who supported the study by recruiting participants, entering data, and conducting data analysis and to Louisa Dierkes who conducted a first application test as part of her valuable Bachelor's thesis. We would also like to thank the geriatric rehabilitation department of the Rehabilitation Center Oldenburg for allowing us to conduct our study as well as the DiDiER Consortium, within which fruitful and valuable project work for the development of the e-food record was possible. ChatGPT (GPT-5 and OpenAI) was used solely for language editing of the manuscript. No content ideas or analyses were generated by the tool.

Abstract

Background: Medication adherence technologies (MATs) offer innovative solutions to support older adults in managing complex medication regimens, yet usability challenges can prevent their successful use. Older adults often face cognitive, physical, sensory, motivational, and environmental barriers, which can influence how they interact with these devices. Therefore, performance-based usability testing is essential for identifying usability issues.

Objective: This study aimed to evaluate the performance-based usability and user experience of 13 MATs among older adults with diverse capabilities.

Methods: A prospective mixed methods design was used, with 96 participants aged 60 years and older testing smart and electronic MATs using cognitive walkthroughs and predefined usability tasks without formal training to simulate first-use conditions. This manuscript focuses specifically on the performance-based usability metrics collected as part of the mixed methods study. Validated tools, including the Self-Medication Assessment Tool (SMAT), Daily Living Tasks Dependent on Vision (DLTV), Whisper Test, Self-Efficacy for Appropriate Medication Use Scale (SEAMS), and Martin and Park Environmental Demands (MPED) Questionnaire, were used to assess individual barriers. Poisson generalized estimating equations (GEE) was used to determine predictors of unassisted task success and error rates while accounting for repeated observations.

Results: A total of 96 participants (mean age 75.1, SD 7.7, range 61 - 95 y) were included, with 37.5% (36/96) male and 62.5% (60/96) female. Poisson GEE models identified significant predictors of unassisted task success rate, including cognitive score (P<.001), physical score (P<.001), vision score (P<.001), motivational score (P<.001), and lower environmental busyness (P=.049). Female sex was associated with a 9% lower success rate (P=.002). Predictors of total error rate included age (P=.02), sex (P≤.001), physical score (P≤.001), vision score (P=.004), DLTV vision score (P=.01), MPED routine score (environmental; P=.05), and interaction between physical score and sex (P=.004).

Conclusions: Both device design and user characteristics strongly influence the usability of MATs. Performance-based evaluations provide actionable findings for user-centered design and selection, guiding manufacturers and health care providers toward developing and choosing accessible technologies that could improve medication adherence among older adults.

Introduction

In Canada, the senior population is increasing rapidly and is expected to make up nearly a quarter of the total population by 2040 [1]. As individuals age, their likelihood of developing chronic conditions significantly increases [1-5]. Multimorbidity is associated with polypharmacy, resulting in medication regimen complexity [1-6]. The complexity of such regimens, coupled with age-related cognitive and physical declines, poses significant barriers to medication self-management and adherence [7,8].

For older adults, the ability to manage their own medications is vital to maintaining independence and safety [7-9]. Defined as the ability to organize, take, and adhere to prescribed treatments, self-management requires cognitive functions, such as memory and comprehension, as well as physical capabilities like hand dexterity and visual acuity [8]. Cognitive limitations, such as memory loss and reduced problem-solving abilities, can prevent adherence to prescribed regimens [10,11]. Physical challenges, including arthritis or reduced hand strength, make tasks like opening medication containers difficult [10,12]. Sensory impairments, such as vision loss, can prevent individuals from distinguishing between medications or reading labels accurately [10,13]. Additionally, motivational factors such as low health literacy or reduced confidence, and environmental challenges, such as limited caregiver support or disorganized home environments, can further complicate medication self-management [10,14-16]. These issues often lead to medication nonadherence, resulting in adverse drug events, preventable hospitalizations, and higher health care costs [17,18].

Medication adherence technologies (MATs) offer innovative solutions to support older adults in managing their medications effectively [19,20]. These technologies make use of automation, connectivity, organization, and reminder functions to simplify medication regimens, reduce errors, and improve adherence [19-22]. For example, automated dispensing and reminder systems can reduce cognitive load and support individuals with memory-related challenges, while organized medication compartments and guided workflows may lessen reliance on visual interpretation of labels. While MATs can help address some of the functional challenges encountered by older adults by reducing cognitive load, simplifying medication routines, enabling automated medication dispensing, and facilitating communication between patients, caregivers, and health care providers, they do not eliminate these underlying impairments [21-24]. In fact, these impairments may also influence how effectively individuals interact with these technologies [21,23,25]. Cognitive impairments can limit the ability to understand or operate these devices, while physical difficulties, such as arthritis or tremors, can interfere with interaction with small buttons or complex mechanisms [10,25]. Sensory impairments, including vision and hearing loss, can make it difficult to engage with screens or auditory prompts [10,25]. Moreover, low technology literacy and resistance to adopting unfamiliar tools further restrict MATs' adoption [10,14,25]. The cost of these technologies and limitations in home environments, such as poor internet connectivity, also pose significant barriers [16,26].

The usability of MATs plays an important role in their effectiveness, efficiency, and user satisfaction [27]. Usability is defined as “the extent to which a product can be used by specified users to achieve specified goals with effectiveness, efficiency, and satisfaction in a specified context of use” [28]. For older adults, poor usability can result in medication errors, frustration, device abandonment, and even preventable hospitalizations [27,29]. Usability metrics are vital for evaluating how well users interact with MATs [27]. These metrics can be divided into perception-based and performance-based categories [30-32]. Perception-based metrics focus on users’ subjective satisfaction and feelings about a product’s usability, often captured through standardized tools such as the System Usability Scale (SUS) or the Usefulness, Satisfaction, and Ease of Use (USE) questionnaire [30-32]. Performance-based metrics, in contrast, focus on quantifiable outcomes of user interactions, offering a more objective assessment of usability [30-32]. Key performance metrics include task success, time-on-task, error rates, efficiency, and learnability [30-33]. Unassisted task success evaluates users’ ability to complete specific tasks independently, with lower success rates often reflecting both user-related factors (eg, cognitive, physical, and sensory abilities) as well as potential design-related challenges [30-33]. For example, Ligons et al in a study investigating how cognitive status affects the usability of a medication delivery device (EMMA), found that cognitive impairments reduced success rates for older adults from 69% for individuals with Mini-Mental State Examination (MMSE≥24) to 34.7% for individuals with MMSE<24 [29]. Time-on-task measures the time required to complete tasks, where longer times often indicate inefficiencies in design or difficulties arising from user limitations [30-33]. Error rates, categorized into “slips” and “mistakes,” highlight areas where both interface complexity and user challenges may contribute to confusion [30-33]. Efficiency reflects the effort required to complete tasks, considering both the number of steps and the time spent, and may be influenced by the interaction between device design and user abilities. Learnability assesses how quickly users adapt to a device over time, which can depend on both the intuitiveness of the design and the user’s cognitive and functional capacity [30-33].

By focusing on performance-based metrics, it is possible to pinpoint specific usability problems, such as which features or tasks are most challenging for older adults based on their individual limitations [33]. Barriers to usability, such as confusing interfaces or physically demanding mechanisms, can be identified and addressed to improve functionality, reduce frustration, and improve adoption rates [30-33]. Therefore, the objective of this research is to evaluate the usability and user experience (UX) of 13 different MATs among older adults with diverse physical, cognitive, sensory, motivational, and environmental abilities by examining various performance-based metrics such as unassisted task success rates, total error rates, total task completion time, and efficiency for unassisted tasks. Through comprehensive usability testing, this study aims to identify the design strengths and weaknesses of these devices for older adults with varying limitations, offering actionable

XSL•FO
RenderX

recommendations to improve MATs' usability, functionality, and adoption.

Methods

Study Design

This research used a prospective mixed methods design, integrating both quantitative and qualitative approaches. Quantitative methods included cognitive walkthroughs (refer to Study Procedure section), measurement of various performance-based usability metrics, and assessment of perception-based usability using standardized usability questionnaires. This paper focuses specifically on the performance-based metrics collected in this study.

Recruitment, Eligibility, and Sample Size

Participants aged 60 years and older who were able and willing to provide informed consent were included in the study. Individuals who could not speak or read English were excluded. The sample size for the quantitative analyses was determined by applying Green's formula to ensure sufficient power for regression models, including 6 independent variables (physical, cognitive, vision, hearing, motivational, and environmental limitations). Based on the formula n>50+8 m (where "m" represents the number of independent variables), the recommended sample size was calculated as 98 [34]. In addition, considerations from usability research informed the recruitment strategy. Previous work by Nielsen and Landauer [35] suggests that testing with a small number of users (n=5 approximately) can identify the majority (80% - 85%) of usability issues [35,36]. Accordingly, for each device, we aimed to recruit at least 5 participants representing each type of functional limitation to ensure adequate identification of usability challenges across diverse user groups.

A total of 13 devices were selected for testing. A Microsoft Excel tracking sheet was used to monitor device testing across participants and impairment types, supporting balanced representation across devices. Recruitment targeted a diverse participant pool using convenience, purposive, and snowball sampling methods, with outreach conducted through community organizations, senior fairs, professional networks, and other initiatives. Data collection occurred between June 2023 and June 2024 among older adult residents of Ontario.

MATs Tested

A total of 13 MATs were tested, including three smart devices (SMs) and 10 electronic devices. Electronic MATs typically include features such as multiple compartments, visual or audible alarms, and timers that remind patients when it is time to take their medications [21]. While these devices may operate electronically, they generally do not connect to external networks or systems. Smart MATs incorporate advanced features such as connectivity and automaticity [22]. Connectivity refers to the ability of these devices to connect to other systems or networks using technologies such as Wi-Fi, Bluetooth, or mobile data [22]. This allows smart MATs to synchronize data with health care providers' systems, send reminders to patients via smartphones or other connected devices, and alert caregivers or family members if a dose is missed. Automaticity refers to the device's ability to perform functions without continuous manual input from the user [22]. This may include automatically dispensing medications at scheduled times, recording the timing and quantity of doses taken, and adjusting medication delivery based on real-time data from connected health monitoring devices [22].

These 13 devices were selected for their diversity of features in order to capture the widest range of functionalities and were guided by a taxonomy of MATs based on device features [37]. Participants tested between 1 and 7 devices across multiple sessions, depending on their preference and availability, with some requiring 2 visits to complete the testing. To ensure consistency and minimize potential bias, each device was tested by at least 5 participants representing different types of limitations. Participants were not provided with any formal training; instead, they were instructed to rely solely on the instructional materials provided with the devices, mimicking real-world independent learning scenarios as much as possible in a laboratory setting.

Table 1 provides details of the MATs tested along with their assigned codes, which will be used to refer to the various devices in this paper.

Study Procedure

Upon enrollment, participants provided written informed consent. A structured assessment was then conducted to identify potential barriers to effective medication use, including physical limitations, cognitive challenges, vision and hearing impairments, motivational factors, and environmental influences. Validated tools were used for these assessments: (1) the Self-Medication Assessment Tool (SMAT) [38,39] to measure physical, cognitive, and vision-related barriers; (2) the Daily Living Tasks Dependent on Vision (DLTV) [40,41] for vision-specific challenges; (3) the Whisper Test [42,43] for hearing capabilities; (4) the Self-Efficacy for Appropriate Medication Use Scale (SEAMS) [44-47] to assess motivational factors; and the Martin and Park Environmental Demands (MPED) [48] questionnaire to evaluate environmental factors such as routine complexity and perceived busyness.

Following the barrier assessment, usability testing of the devices was conducted using the cognitive walkthrough method [49]. This is a method used in user interface design to understand how new users interact with a device by simulating the process of exploring its functionality for the first time [49]. It is a task-based approach that focuses on evaluating the device's ease of use and learnability, particularly for users who may not have previous experience or knowledge of the device [49]. The objective is to identify usability issues that could hinder the user's ability to complete tasks efficiently and effectively [30-32]. To conduct a cognitive walkthrough, a participant information sheet and an evaluation sheet were prepared. The participant information sheet outlines specific tasks for users to perform with the devices. These tasks are designed to cover a range of functions and features of various devices, ensuring a comprehensive assessment of their usability. The tasks ranged from basic setup procedures like inserting batteries and unlocking the device to more complex interactions, such as setting up the current time, filling a tray with weekly medication, setting alarms, locking the device, and removing medication after an alarm. The evaluation sheet documented each task's outcome, marking them as unassisted success, assisted success, or failure. Additionally, the sheet recorded task errors, indicating whether multiple attempts were required for a successful completion or if tasks were accomplished on the first try, and the time spent to complete each task. The evaluation sheet was developed based on previous research and expertise in usability testing of similar devices. During the testing sessions, 5 researchers (BB, GE, SP, IH, and RS) were paired in groups of 2 to independently observe participants and simultaneously record task performance. All evaluators received training on the study protocol and data recording procedures to ensure consistency. Training consisted of an initial structured session led by the corresponding author (TP), which lasted 4 hours and introduced all evaluators to the cognitive walkthrough methodology, task procedures, and data recording processes. Mock cognitive walkthroughs were conducted between groups of 3 evaluators to practice observing device testing among participants and recording data. Furthermore, for evaluators who joined the research team after the initial training session, a one-on-one training session was provided by the first author (BB), followed by observation of at least 2 full testing sessions with participants before independently participating in data

XSL•FO
RenderX

collection. Following each session, the researchers reviewed their observations and reached a consensus to ensure accuracy and consistency in the recorded data. A mock medication regimen was developed using placebo medications (eg, candy and inert tablets) to simulate common prescription drugs and dosing schedules. Further details about the regimen are provided in Multimedia Appendix 1.

Outcome Measures

Various outcome measures used in this study, along with their descriptions and the equations used for calculation, are provided in Table 2.

Table . Outcome measures, descriptions, and equations.

Outcome measure	Description and equation
Task success rate (unassisted)	Assesses users' ability to independently complete device-related tasks, reflecting usability and learnability [32]. Task outcomes were categorized as unassisted success, assisted success, or failure based on predefined success criteria [31]. Task success rate unassisted only (%)=Number of tasks completed unassistedTotal number of tasks required to use the device×100
Time on task	The total elapsed time required to complete a task, also referred to as task completion time [32]. Time was recorded from task start to completion using a smartphone clock application.
Efficiency	Measures how effectively users complete tasks by relating unassisted task success to time spent [32]. Efficiency=Number of tasks completed successfully without assistanceTotal number of tasks required to set up the deviceTotal time spent completing the setup steps (minutes)
Error rate	Quantifies unintentional user actions or mistakes made during task performance [31]. Errors were classified as present if additional attempts were required or absent if completed on the first attempt. Error rate (%)=Number of errors encounteredTotal number of tasks required to use the device×100

Data Collection and Statistical Analysis

Data were securely stored and managed using the REDCap platform (REDCap 15.1.2; Vanderbilt University). Descriptive statistics were used to summarize the key variables, and Spearman correlation analyses were performed to examine correlations between outcome measures and predictor variables such as age, number of devices tested, cognitive, physical, vision (SMAT and DLTV), SEAMS, and MPED scores. Product-level outcomes were analyzed using population-averaged generalized estimating equation (GEE) models. The unit of analysis was the individual product tried by a participant (product-level observations), with participants specified as the clustering unit to account for repeated observations within individuals. Models assumed a Poisson distribution with a log link and used an unstructured working correlation structure to account for within-participant correlation. The response variables were the counts of unassisted successes and the counts of errors. To account for variation in the number of subtasks per product, an offset equal to the log of the number of subtasks per product was included, such that model estimates correspond to rates (or percentages) of successes and errors per subtask. Models were fit using the *glmee* function from the *glmtoolbox* R package (version 4.3.3; RStudio). The box plots were created using SAS 9.4 (Enterprise Edition; SAS Institute) on the SAS OnDemand for Academics platform.

Ethical Considerations

This study received ethical approval from the University of Waterloo Office of Research Ethics (ORE #45203). Informed consent was obtained from all participants before study procedures were initiated.

Results

Participant Demographics

A total of 96 individuals participated in the study, with a mean age of 75.1 (SD 7.7; range 61 - 95) years. Among them, 36 (37.5%) were male, and 60 (62.5%) were female. The majority (86/96, 89.6%) reported taking medications regularly. Educational backgrounds varied as follows: 27.1% (26/96) had advanced degrees, 28.1% (27/96) had earned a bachelor's degree, 17.7% (17/96) held diplomas, 17.7% (17/96) had a high school education or lower, and 1% (1/96) had not completed high school or held trade certificates. Most participants (83/96, 86.5%) lived independently in their own homes, while 13.5% (13/96) resided in independent retirement facilities.

Cardiovascular conditions were the most prevalent (56/96, 58.3%), followed by metabolic or endocrine disorders (37/96, 38.5%), musculoskeletal conditions (26/96, 27.1%), and vision-related issues (18/96, 18.8%). Less common health conditions included renal or urogenital disorders (7/96, 7.3%), stroke (5/96, 5.2%), and hematological conditions (4/96, 4.2%). A small proportion (5/96, 5.2%) reported having no significant medical history. Medication management approaches varied: 44.8% (43/96) used pillboxes, 11.5% (11/96) relied on alarm beepers, 10.4% (10/96) used blister packs, 8.3% (8/96) depended on reminders from others, 2.1% (2/96) used calendars, and 3.1% (3/96) reported other methods.

XSL•FO
RenderX

Barriers to Medication Self-Management

Cognitive challenges, defined as low to moderate scores on the SMAT, were observed in 21.9% (21/96) of participants. Physical barriers, also assessed using SMAT, were present in 38.5% (37/96) of participants. Vision-related barriers were also notable, with 24% (23/96) scoring low or moderately low on the SMAT vision scale, and 38.5% (37/96) reporting challenges in vision-dependent tasks as measured by the DLTV scale. Hearing impairments, identified through the Whisper Test, were found in 57.3% (55/96) of participants. Additionally, motivational and environmental barriers, assessed using the SEAMS and the MPED Questionnaire, were each reported by 35.4% (34/96) of participants.

More details on participant demographics and barrier characteristics are provided in Table 3.

[a]SMAT: Self-Medication Assessment Tool; participants categorized as having moderate or low scores were considered to have impairments in cognitive, physical, and vision domains.

[b]DLTV: Daily Living Tasks Dependent on Vision; total score <79 indicates the presence of a vision-related barrier (lower scores reflect greater impairment).

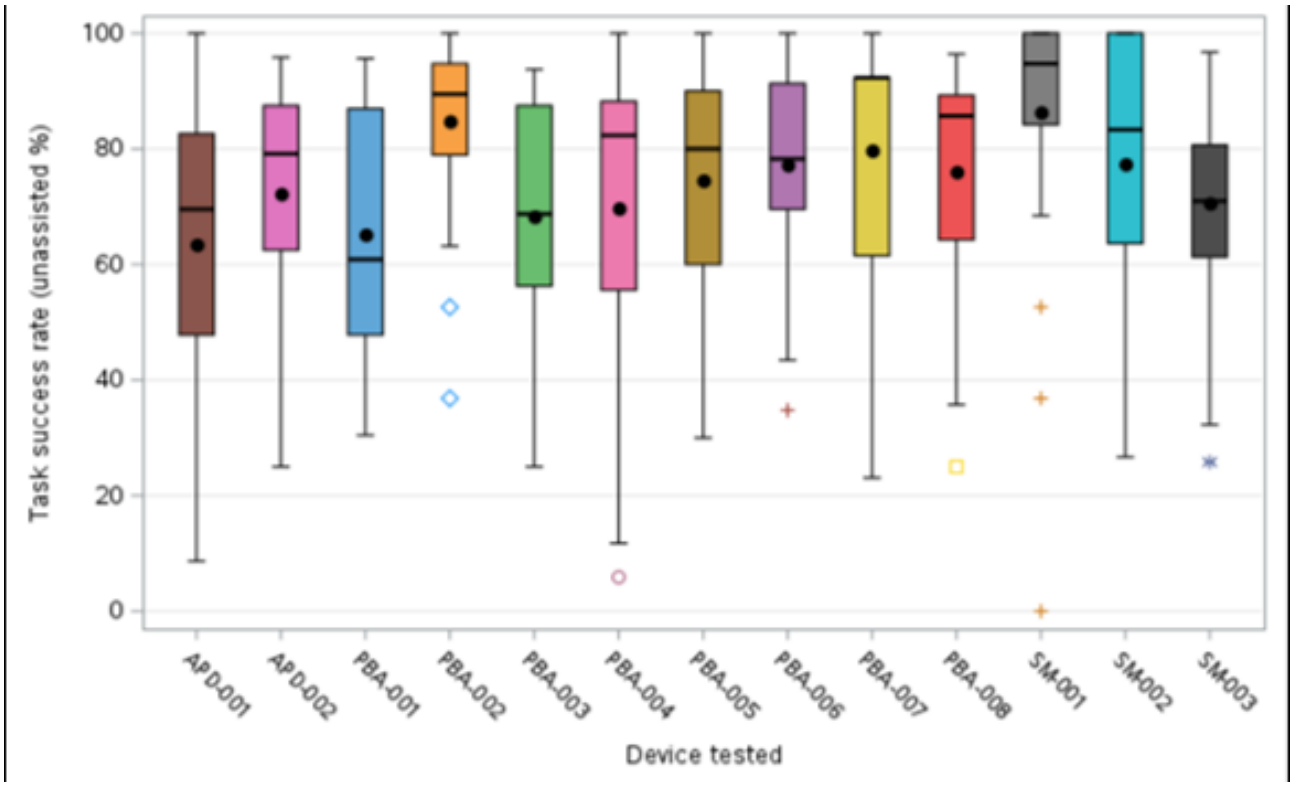
[c]SEAMS: Self-Efficacy for Appropriate Medication Use Scale; total score <40 indicates low self-efficacy (motivational barrier), with lower scores representing reduced confidence in medication use.

[d]MPED: Martin and Park Environmental Demands; an environmental barrier is indicated by a busyness subscale score ≥15 (higher scores reflect greater busyness) and/or a routine subscale score <16 (lower scores reflect less structured routines).

Distribution of product testing by participant impairment type is presented in Multimedia Appendix 2.

Outcome Measures

Observed Usability Performance Across MATs



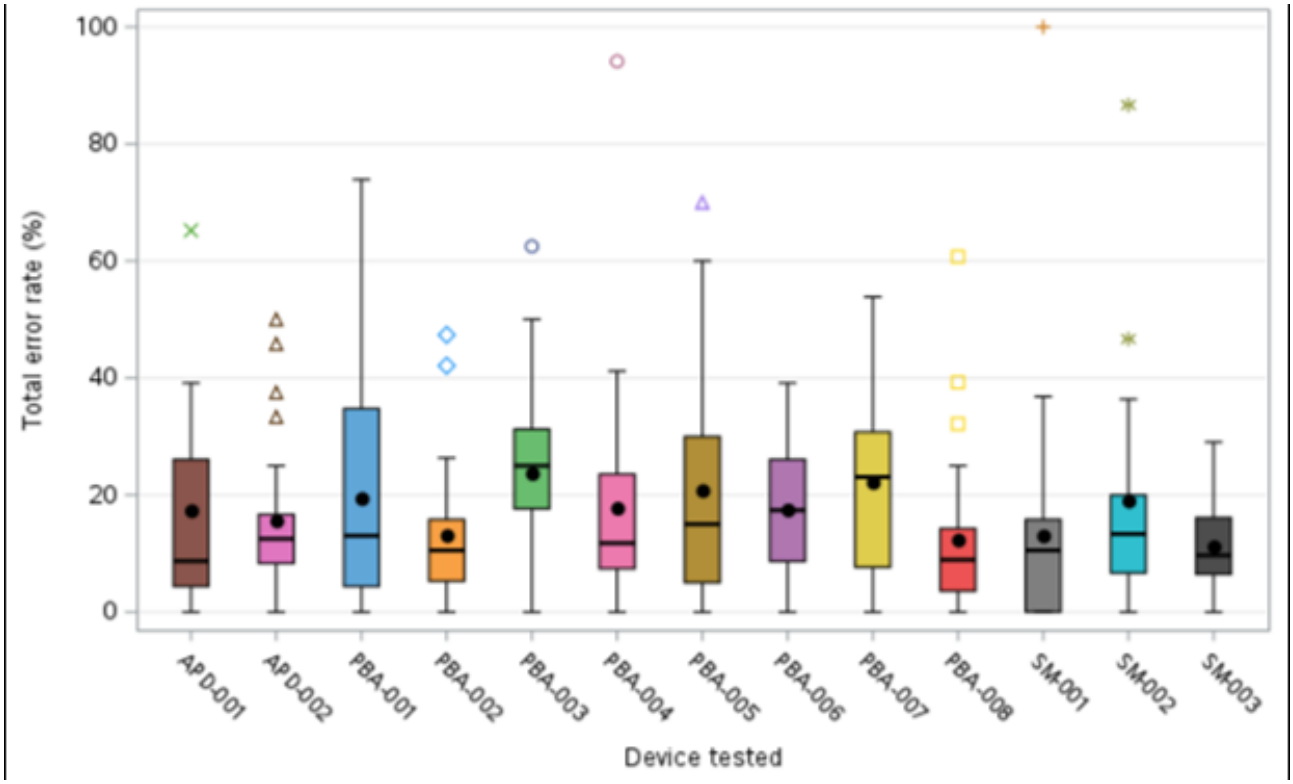
The following section presents observed usability outcomes across the MATs tested in this study, summarizing patterns in average success rate unassisted, total error rate, efficiency for unassisted task success, and total task time.

Average Task Success Rate Unassisted

The overall mean task success rate without assistance across all devices was 74.85% (SD 21.27), with a median of 80% (IQR 61.29-91.30), ranging from 0% to 100%. Smart pill dispensers, including the EllieGrid Smart Pill Organizer (SM-003; EllieGrid), Spencer Automatic Pill Dispenser (SM-001; Custom Health), and Jones Smart Blister Pack (SM-002; Jones Healthcare Group), generally showed higher success rates compared to electronic pill dispensers. Among the SMs, the Spencer Automatic Pill Dispenser (SM-001) had the highest mean success rate of 86.37% (SD 19.98), while the EllieGrid Smart Pill Organizer (SM-003) achieved 70.63% (SD 15.97). Electronic pill dispensers displayed more variability in performance, with success rates ranging from 63.48% to 84.82% (SD 26.42-15.21). The unassisted task success rates of the various tested devices are illustrated in Figure 1.

XSL•FO
RenderX

Figure 1. Unassisted task success rates of the various tested devices (boxes represent the IQR, horizontal lines indicate medians, dots indicate mean values, whiskers represent the spread of the data, and points represent outliers). APD: automated pill dispenser; PBA: pill box with alarm; SM: smart device.



Total Error Rate

The overall mean total error rate across all devices was 16.87% (SD 15.89), with a median of 12.7% (IQR 5.73-23.9), and it ranged from 0% to 100%, indicating considerable variability in user performance. The first quartile (Q1) was 5.73%, while the third quartile (Q3) reached 23.9%, showing that most error rates were clustered within this range. Among the products, the EllieGrid Smart Pill Organizer (SM-003) demonstrated the lowest mean error rate at 11.23% (SD 8.02), with a median of 9.68% (IQR 6.45-16.13), while the highest error rate was observed for the VitaCarry Advanced Pill Case (PBA-003; eNNOVEA Medical, LLC) at 23.76% (SD 14.38). Smart pill dispensers, such as the Spencer Automatic Pill Dispenser (SM-001) and Jones Smart Blister Pack (SM-002), had mixed performance, with Spencer showing a lower mean error rate of 13.09% (SD 18.07) compared with Jones at 19.06% (SD 19.39). The unassisted task error rates of the various tested devices are illustrated in Figure 2.

XSL•FO

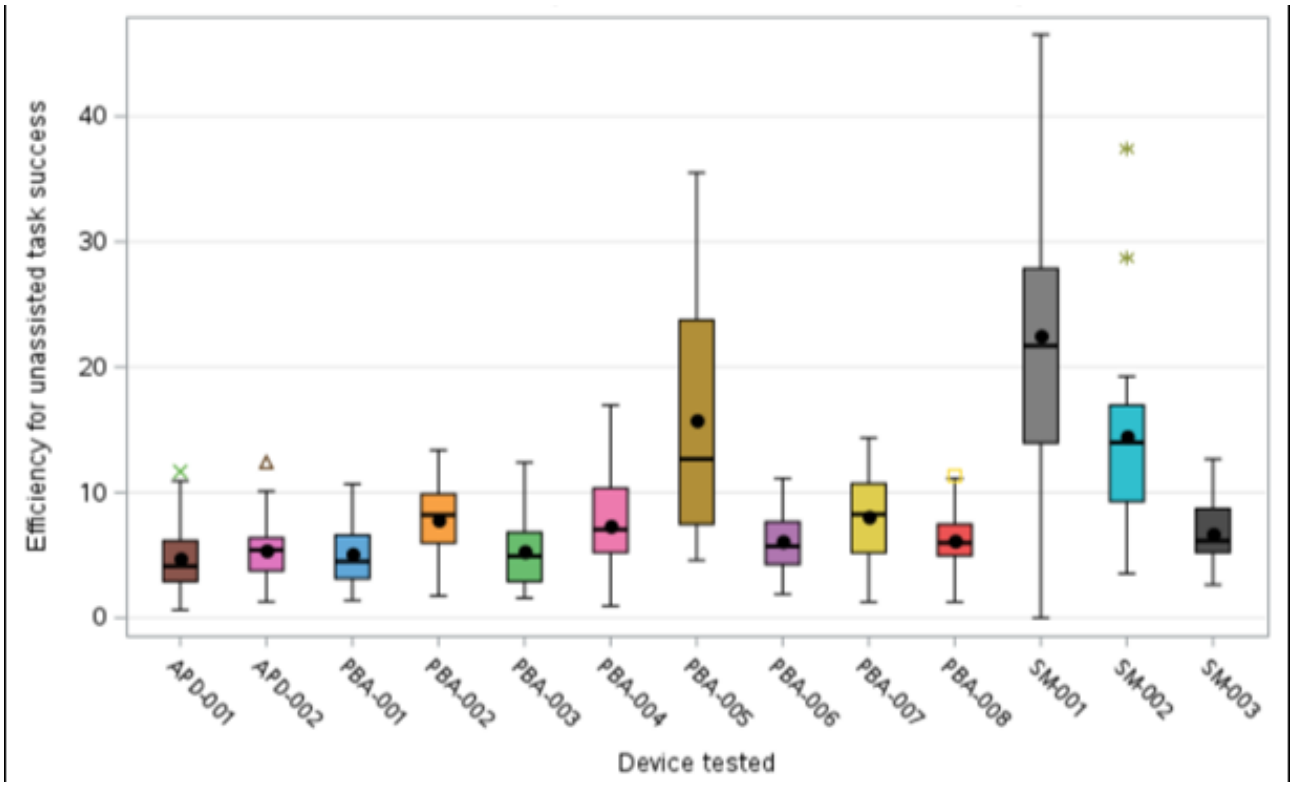
Total task error rates of the various tested devices (boxes represent the IQRs, horizontal lines indicate medians, dots indicate mean values, whiskers represent the spread of the data, and points represent outliers). APD: automated pill dispenser; PBA: pill box with alarm; SM: smart device.



Efficiency for Unassisted Task Success

The overall efficiency for unassisted task success across all devices had a mean of 9.27 (SD 7.87), with a median of 6.83 (IQR 4.67-10.92), and values ranging from 0 to 46.51, indicating significant variability in performance. The highest efficiency unassisted was observed in the Spencer Automatic Pill Dispenser (SM-001), with a mean of 22.51 (SD 11.37) and a median of 21.70 (IQR 14.02-27.15), suggesting that SMs generally outperform electronic dispensers in task efficiency. Among electronic devices, the 100-Hour Pill Reminder (PBA-005; Aidapt) demonstrated relatively high efficiency, with a mean of 15.77 (SD 9.51), while devices such as the MedReady 1700 automated medication dispenser (APD-001; MedReady Inc) had lower efficiency, averaging 4.74 (SD 3.03). Smart pill dispensers, including the Jones Smart Blister Pack (SM-002), also performed well, with a mean efficiency of 14.48 (SD 7.5). The overall efficiency for unassisted task success of the various tested devices is illustrated in Figure 3.

XSL•FO

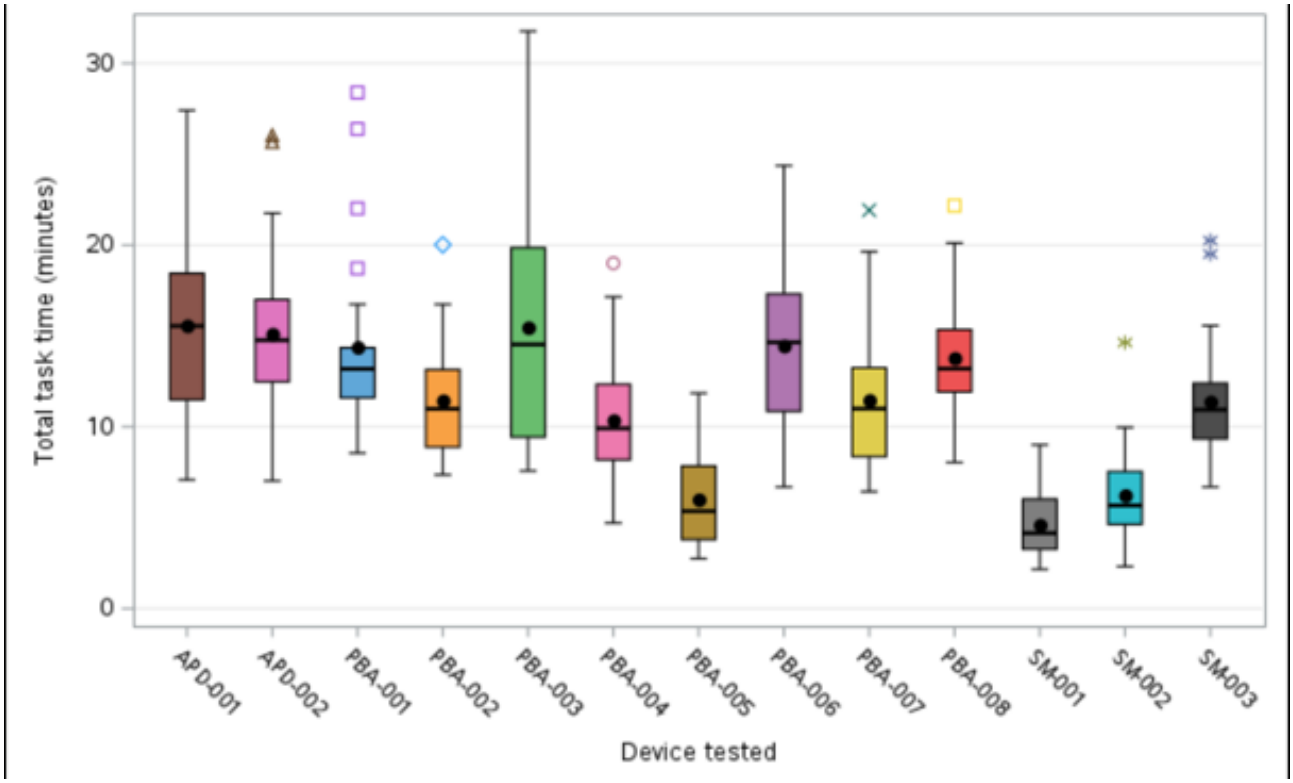
Efficiency for unassisted task success of the various tested devices (boxes represent the IQR, horizontal lines indicate medians, dots indicate mean values, whiskers represent the spread of the data, and points represent outliers). APD: automated pill dispenser; PBA: pill box with alarm; SM: smart device.



Total Task Time

The overall total task time across all devices had a mean of 11.42 (SD 5.48) minutes, with a median of 10.94 (IQR 7.67-14.67) minutes, and ranged from 2.15 to 31.77 minutes, indicating variation in the time required to complete tasks. Smart pill dispensers, such as the Spencer Automatic Pill Dispenser (SM-001) and the Jones Smart Blister Pack (SM-002), demonstrated the shortest task times, with averages of 4.61 (SD 1.83) minutes and 6.24 (SD 2.65) minutes, respectively, possibly suggesting their ease of use and efficiency. In contrast, electronic pill dispensers, such as the MedReady 1700 Automated Medication Dispenser (APD-001), had longer task times, with an average of 15.58 (SD 5.22) minutes, indicating potentially more timely interactions required for operation. Among electronic dispensers, the 100-Hour Pill Reminder (PBA-005) had the shortest average task time at 6.01 (SD 2.64) minutes, showing relatively quicker use. The overall total task time of the various tested devices is illustrated in Figure 4.

Multimedia Appendix 3 provides more details on various outcome measures based on the devices tested and the barriers assessed. Although the data have been presented according to individual impairment categories, these findings should be interpreted carefully, as most participants had multiple coexisting impairments, making it difficult to isolate the effect of any single impairment category. Therefore, these subgroup comparisons are not fully generalizable.

XSL•FO

Significant Predictors of Performance-Based Usability Outcomes

Because participants tested varying numbers of devices and devices were not evaluated an equal number of times across participants, inferential analyses were conducted using Poisson GEE models with a log link, which account for within-participant correlation. This approach accounts for repeated measures within participants, unequal numbers of observations per participant, and variability in device usage, making it well-suited for analyzing correlated outcome data.

The selection of primary outcomes for regression analysis was informed by Spearman correlation analyses examining associations among outcome and predictor variables (Multimedia Appendix 4). Average unassisted task success rate and total error rate were selected as the primary modeled outcomes because they demonstrated meaningful associations with participant characteristics while representing distinct and interpretable dimensions of usability performance. Efficiency for unassisted task success and total task time were not modeled as primary outcomes, as these measures were highly correlated with task success rate and with each other, reflecting overlapping underlying constructs.

Significant Predictors of Average Task Success Rate Unassisted

Poisson GEE model with a log link and within-participant correlation identified several device types and participant characteristics as statistically significant predictors ($P<.05$).

Relative to the reference device (APD-001), success rates were not statistically significantly different for APD-001 ($P=.47$) and PBA-001 ($P=.82$). In contrast, several automated pill dispensers and pill boxes demonstrated higher success rates, ranging from 23.5% (PBA-006; $P=.009$) to 528.5% (PBA-005; $P<.001$). One automated pill dispenser (PBA-008) performed with significantly lower success rates (−28.7%; $P<.001$) in comparison to APD-001. Among SMs, 2 (SM-001 and SM-002) performed with significantly higher success rates (97.2% increase, $P<.001$, and 212.4% increase, $P<.001$, respectively). SM-003 had significantly lower success rates (−39.9%, $P<.001$). Regarding participant characteristics, females had a significantly lower success rate than males (−9.3%, $P=.002$). Higher cognitive (1% increase per unit, $P<.001$), physical (3.8% increase per unit, $P<.001$), and vision scores (3.0% increase per unit, $P<.001$) were all associated with increased success rates. Similarly, higher SEAMS scores were associated with a 1.1% increase in success rate ($P<.001$), while MPED busyness score showed a marginally significant 0.8% increase in success rate ($P=.05$).

Table 4 shows the results of the final Poisson GEE model, showing the estimated effects of device type and participant characteristics on unassisted task success rates.

[a]Estimates (standardized β coefficient) are presented on the log scale from a generalized estimating equations Poisson model with a log link and an unstructured correlation structure. For categorical variables (product tested), estimates represent comparisons relative to the reference category (APD-001).

[b]95% CI for standardized β coefficient were calculated as β±1.96×SE. Percentage change in the expected error rate was computed as (e^β−1)×100.

[c]For continuous variables (eg, age and physical score), percentage change reflects the expected change in error rate per 1-unit increase in the predictor.

[d]Corresponding 95% CIs for percentage change were derived by exponentiating the confidence limits of β, calculated as [(e^(β−1.96×SE)−1)×100, (e^(β+1.96×SE)−1)×100].

[e]Statistical significance was assessed at $P<.05$.

[f]APD: automated pill dispenser.

[g]Not applicable.

[h]PBA: pill box with alarm.

[i]SM: smart device.

[j]SEAMS: Self-Efficacy for Appropriate Medication Use Scale.

[k]MPED: Martin and Park Environmental Demands.

Model diagnostic checks indicated that the final Poisson GEE model fit the data well. The dispersion parameter (0.289) and deviance-to-degrees-of-freedom ratio (1.06) showed no overdispersion, while the Pearson chi-square statistic ($\chi^2_{328}=328$, $P=.49$) confirmed an adequate fit. Residual diagnostics,

XSL•FO
RenderX

including a normal Q-Q plot and residuals versus fitted values plot, showed no major deviations or heteroscedasticity. The diagnostic plots are given in Multimedia Appendix 5.

Significant Predictors of Total Error Rate

Poisson GEE model with a log link and within-participant correlation identified several device types and participant characteristics as statistically significant predictors of total error rate. Relative to APD-001, most devices did not differ significantly in error rates ($P \geq .24$). However, PBA-008 showed a moderately significant lower error rate (−32.6%, $P=.04$). Among SMs, SM-001 showed a nonsignificant trend toward lower error rates (−35.9%, $P=.08$), while SM-002 and SM-003 did not differ significantly from the reference.

Regarding participant characteristics, increasing age was associated with a small but statistically significant increase in error rate (1.9% per unit increase, $P=.02$). Female participants had a significantly higher error rate compared with males (846.2% increase, $P<.001$). Higher physical scores were associated with increased error rates (46.1% increase per unit, $P<.001$), whereas higher vision scores were associated with reduced error rates (−9.9% per unit, $P=.004$). The DLTV summary score was also positively associated with error rate (2.2% increase per unit, $P=.01$). MPED routine score showed a marginally significant association with decreased error rate (−3.7%, $P=.05$). Additionally, there was a significant interaction between sex and physical score (−16.5%, $P=.004$), indicating that the effect of physical score on error rate differed by sex.

Table 5 presents the results of the final Poisson GEE model, showing the estimated effects of device type and participant characteristics on total error rate.

Model diagnostics indicated no evidence of overdispersion (overdispersion ratio=0.96) and an adequate fit (Pearson $\chi^2_{328}=328$, $P=.49$). Residual diagnostics (normal Q-Q plot and residual vs fitted plot) revealed no major violations of model assumptions. The diagnostic plots are given in Multimedia Appendix 4.

[a]Estimates (standardized β coefficient) are presented on the log scale from a generalized estimating equations Poisson model with a log link and an unstructured correlation structure. For categorical variables (product tested), estimates represent comparisons relative to the reference category (APD-001).

[b]95% CI for standardized β coefficient were calculated as β±1.96×SE. Percentage change in the expected error rate was computed as (e^β−1)×100.

[c]For continuous variables (eg, age and physical score), percentage change reflects the expected change in error rate per one-unit increase in the predictor.

[d]Corresponding 95% CIs for percentage change were derived by exponentiating the confidence limits of β, calculated as [(e^(β−1.96×SE)−1)×100, (e^(β+1.96×SE)−1)×100].

[e]Statistical significance was assessed at $P<.05$.

Discussion

Principal Findings

This study tested the usability and UX of 13 MATs among older adults with diverse cognitive, physical, sensory, motivational, and environmental capabilities. By focusing on performance-based usability metrics, such as unassisted task success rate, error rate, task completion time, and efficiency, this research extends previous MAT usability literature by examining not only device-level variability but also how individual user characteristics interact with device design during first-time use. These results are intended to provide an overview of how users interacted with a range of commercially available devices under the study conditions, rather than to rank devices or establish definitive performance comparisons. The devices included vary widely in features, functionality, and required task complexity, reflecting real-world options rather than standardized experimental comparators. Additionally, participants tested differing numbers of devices, and devices were not evaluated an equal number of times across participants.

XSL•FO
RenderX

A key finding was the variability in usability across MATs, regardless of device category or intended function. This indicates that usability cannot be inferred solely from whether a device is "smart" or "electronic," but instead reflects specific design features, interaction complexity, and task demands. These findings align with previous work by Patel et al [27], which reported wide variability in unassisted task success, task time, and workload across electronic medication adherence products, even when devices served similar purposes. This study extends this literature by demonstrating that such variability persists among newer-generation smart MATs and users with diverse functional profiles.

The observed variability reinforces the importance of performance-based usability testing. Although subjective measures such as the SUS capture user perceptions, previous research has shown discrepancies between perceived usability and objective task performance. Consistent with this, participants in this study often rated devices as acceptable despite frequent errors or difficulty completing setup tasks. More broadly, usability research has demonstrated weak correlations between subjective ratings and objective performance measures, particularly for complex or safety-critical technologies [50]. Collectively, these findings highlight the value of performance-based metrics for identifying usability risks that may not be captured through self-report alone, especially for MATs where interaction errors may have clinically significant consequences such as medication-related harm.

Regression analyses showed that cognitive, physical, visual, and motivational (SEAMS) scores were significant predictors of unassisted task success, consistent with previous literature on technology use among older adults [27,29]. Cognitive ability has been consistently linked to successful MAT use, with studies of automated dispensers and reminder systems reporting marked reductions in unassisted success among individuals with lower MMSE scores, even when impairment is mild [29]. Vision also emerged as a significant predictor, with both SMAT vision and DLTV scores associated with usability outcomes, echoing evidence that many technologies impose high visual demands and that inadequate accommodation of vision-specific barriers can compromise safe and effective use among older adults [51,52]. Motivational self-efficacy was likewise associated with higher success rates, consistent with findings that individuals with greater confidence are more likely to persist, implement effective strategies, and achieve better outcomes [53,54].

In contrast, most devices did not differ significantly from the reference device in error-rate models, with only 1 device (PBA 008) showing a statistically significant reduction. This apparent inconsistency reflects an important methodological distinction between task failure and task error. Errors were recorded only when tasks were completed with incorrect actions or multiple attempts, whereas failures were not coded as errors. As a result, devices with lower success rates may also show lower error rates simply because users were unable to progress far enough to generate observable errors. Conversely, devices that allowed task completion often did so with frequent missteps, yielding higher error rates despite greater success. From a medication safety perspective, successful task completion accompanied by repeated errors may pose greater real-world risk than early task abandonment. Similar conclusions have been reported in usability and human-factors research, which emphasizes that usability metrics represent distinct but interdependent constructs and should not be interpreted alone [50].

Some predictors of error rate were less intuitive. Higher physical scores were associated with increased error rates, likely because participants with better physical ability progressed further and interacted more extensively with device features, creating more opportunities for observable errors. Similarly, the positive association between DLTV scores and error rates likely reflects greater task exposure rather than poorer vision, as participants with better vision advanced into more complex interactions. These insights underscore the importance of interpreting error rates alongside task success and engagement measures rather than as standalone indicators [50].

Sex differences were evident across usability outcomes, with female participants demonstrating lower unassisted task success, higher error rates, and a significant interaction between sex and physical ability. These results suggest that sex may moderate how older adults interact with MATs, potentially reflecting differences in confidence, experience, and interaction strategies shaped by historical gender roles [55]. Although gender-related factors were not directly assessed, the consistency of sex effects across success and error outcomes highlights the need for sex-sensitive testing and inclusive design approaches to support safe and effective MAT use among older adults.

All devices were evaluated under untrained, first-use laboratory conditions to approximate real-world initial use. While appropriate for assessing early usability and learnability, laboratory testing cannot capture adaptive behaviors, learning over time, or caregiver involvement that may emerge during long-term home use. Evidence from longitudinal studies indicates that some older adults become more proficient and confident with technology with continued exposure [56]. Accordingly, the performance-based outcomes reported here should be interpreted as indicators of initial usability rather than long-term usability or continued adoption in everyday settings.

Study Strengths, Limitations, and Future Research Directions

A key strength of this study is the inclusion of older adults with multiple barriers, including motivational and environmental challenges, and the evaluation of both smart and electronic MATs. While this study provides valuable insights, several limitations should be acknowledged. Although the inclusion of participants with multiple coexisting impairments improves the real-world application, it may limit the ability to draw conclusions about the effects of a single impairment on the usability of a specific device. Future studies using more controlled designs, such as focusing on participants with a single type of impairment and testing a smaller number of devices, may help provide clearer device-specific conclusions. However, such designs may be less feasible in real-world aging populations, as most older adults experience a combination of impairments rather than a single isolated condition. The sample primarily consisted of Canadian English-speaking older adults, which may limit the generalizability of the findings to non-English speakers who might encounter additional

XSL•FO
RenderX

language-related barriers when using MATs. In addition, the initial sample size estimation was guided by Green's formula based on 6 primary impairment domains. However, the final Poisson GEE models included a broader set of predictors, including demographic variables. In addition, variability in the number of observations per device may result in an uneven distribution of data across predictors. While the overall sample size was adequate, these factors may introduce some risk of overfitting and affect the stability of model estimates.

Future research should explore the usability of these technologies in more diverse populations, including individuals with limited health literacy or linguistic diversity, as well as how device design and instructional materials can be optimized to support individuals with different and multiple barriers in safely and successfully completing tasks. Additionally, longitudinal research is needed to examine the long-term impact of MATs on medication adherence and health outcomes. Understanding how long-term use of these technologies influences adherence behaviors over time can provide valuable insights for health care providers and policymakers. Future studies should also explore how older adults interact with these technologies in real-world settings, including their reliance on instructional materials, learning approaches, and help-seeking behaviors. Moreover, this study only collected information on participants' sex. Future research should include both sex and gender measures to better capture sociocultural and biological influences on technology use.

Conclusion

This study highlights the role of performance-based usability testing in identifying the factors for successful use of MATs among older adults with diverse capabilities. By assessing unassisted task success rates, error rates, task completion times, and efficiency, the findings demonstrate substantial variability in usability across MATs, reflecting differences in device design, task complexity, and interaction demands rather than inherent device superiority.

Cognitive, physical, visual, motivational, and environmental factors were significant predictors of performance, highlighting that successful MAT use depends not only on technological capabilities but also on alignment with age-related abilities and confidence in medication management. The presence of higher error rates even among users who successfully completed tasks further highlights that usability and safety cannot be interpreted from task completion alone. Observed sex differences in performance reinforce the need for inclusive, user-centered design and evaluation approaches that account for diverse interaction styles and experiential backgrounds.

Acknowledgments

The authors would like to extend special thanks to Arshia Chauhan, Nischal Ghookal, Prapti Choudhuri, Hawa Patel, Tanaya Sharma, Victoria Nguyen, Karyman Ahmed Fawzy Ghanem, and Sabiha Lakhi for their valuable support with data collection.

This work was presented as a poster at the Canadian Pharmacy Education and Research Conference (CPERC) 2025.

No Generative AI was used for this manuscript.

Funding

This project was funded by Aging in Place program with National Research Council and Canadian Institutes of Health Research (reference 184372) by the Government of Canada.

Data Availability

The datasets generated or analyzed during this study are available from the corresponding author on reasonable request.

Authors' Contributions

BB and TP contributed to all aspects of the study, including study concept and design, acquisition of participants and/or data, analysis and interpretation of data, and preparation of the manuscript. GE contributed for data acquisition and data entry. DH contributed to data analysis. SP, IH, and RS contributed to the acquisition of data. KP, AM, SJTG, FC, LL, CB, and RG contributed to the study concept and design. All authors reviewed and approved the final version of the manuscript.

Conflicts of Interest

TP received grants from National Research Council (NRC), Canadian Institutes of Health Research, Jones Healthcare Group, and Custom Health; travel support from National Research Council (NRC) and Canadian Institutes of Health Research; and contribution of medical adherence technology from Jones Healthcare Group and Custom Health. The other authors report no conflicts of interests.

Abstract

Background: The therapeutic efficacy of acupuncture in treating Alzheimer disease (AD) largely depends on consistent treatment adherence. Therefore, identifying key factors influencing adherence and developing targeted interventions are crucial for enhancing clinical outcomes.

Objective: This study aims to develop and validate a predictive model for identifying patients with AD who are likely to maintain good adherence to acupuncture treatment.

Methods: This secondary analysis included 108 patients with probable AD, aged 50 to 85 years, from 2 independent randomized controlled trials conducted at Guang'anmen Hospital, China Academy of Chinese Medical Sciences. Of all, 66 patients were assigned to the development cohort and 42 to the external validation cohort. Acupuncture adherence was defined as the proportion of completed sessions relative to scheduled sessions, with good adherence defined as ≥80% completion. Baseline data included demographic, clinical, cognitive, functional, psychological, and caregiving variables. Multivariable logistic regression with backward stepwise selection was used to identify significant predictors, and a nomogram was constructed based on the final model. Model performance was assessed using receiver operating characteristic curves, calibration plots, and decision curve analysis, with external validation performed by receiver operating characteristic analysis. Sensitivity analysis was performed using alternative adherence thresholds of 70% and 90%.

Results: A higher number of treatments during the first month was associated with a significant increase in the odds of good adherence (odds ratio [OR] 3.06, 95% CI 1.68 - 7.01; *P*=.002), while longer disease duration (OR 0.97, 95% CI 0.94 - 1.00; *P*=.049) and receiving care from a part-time caregiver (OR 0.19, 95% CI 0.04 - 0.72; *P*=.022) were associated with lower odds of adherence. Sensitivity analyses further supported the stability and reliability of the model.

Conclusions: This study is the first to develop and validate a predictive model for acupuncture adherence in patients with AD. In clinical research, it can facilitate participant stratification and help identify individuals who may need additional adherence support, thereby reducing bias and enhancing trial quality. In clinical practice, the nomogram enables proactive adherence management by prospectively identifying high-risk patients and guiding targeted strategies to improve adherence and optimize therapeutic outcomes.

alzheimer disease; acupuncture; adherence; nomogram; predictive model

Introduction

Alzheimer disease (AD) is a progressive neurodegenerative disorder primarily characterized by cognitive decline, functional impairment in activities of daily living, and neuropsychiatric symptoms [1]. Acupuncture, given its favorable safety profile and potential for symptomatic improvement [2-4], has been recommended as a promising nonpharmacological long-term

XSL•FO
RenderX

therapy in clinical practice guidelines for the management of AD [5]. However, the therapeutic efficacy of acupuncture for AD remains a subject of ongoing debate [6,7]. This inconsistency in findings may be partially explained by a critical, yet often underinvestigated factor: treatment adherence.

Consistent adherence is crucial to therapeutic efficacy, particularly in chronic disease management and nonpharmacological interventions. At present, adherence has been studied primarily in the context of pharmacotherapy, with reported rates of long-term pharmacological adherence in patients with AD ranging from 16.5% to 51% [8,9]. Some studies have developed models to predict patients' medication adherence [10,11]. In contrast, adherence to nonpharmacological therapies such as acupuncture remains insufficiently explored. This knowledge gap is compounded by the lack of a standardized definition for what constitutes good or poor adherence. This variability in definitions across studies makes it difficult to compare findings and may be a key confounding factor obscuring the true dose-response relationship of acupuncture [12].

Clinical studies have shown that factors influencing acupuncture adherence are multifaceted, encompassing patient subjective norms, perceived behavioral control, and treatment commitment [13]. Specific factors include perceived effectiveness, family support, emotional status, patient recognition and acceptance of acupuncture, and the availability of medical subsidies [14]. Nonetheless, most of these studies have provided only descriptive insights or general recommendations based on literature reviews [15,16], while few have offered quantitative evidence derived from clinical data. Notably, research specifically focusing on acupuncture adherence in individuals with AD is exceedingly scarce. Given the substantial cognitive decline, behavioral symptoms, and caregiver dependence associated with AD, patients in this population may face unique barriers to maintaining adherence. Thus, findings from studies in other populations may not be directly generalizable to patients with AD. Understanding the specific determinants of adherence in this unique population is crucial for optimizing treatment delivery and improving outcomes.

Given the ongoing debate over acupuncture's efficacy and the critical yet poorly understood role of adherence in treatment outcomes, identifying predictors for treatment engagement in a methodologically robust setting is paramount. In this study, we conducted a secondary analysis of data from 2 independent randomized controlled trials (RCTs) previously conducted by our team, with the aim of identifying key predictors of acupuncture adherence among patients with AD and developing a clinically applicable predictive model. By identifying individuals at high risk of poor adherence and enabling the development of targeted intervention strategies, this study seeks to enhance the adherence and efficacy of acupuncture treatment and provide evidence-based support for adherence management in nonpharmacological interventions for AD.

Methods

Study Design and Data Source

This study was a secondary analysis based on data collected from 2 independent RCTs conducted at Guang'anmen Hospital, China Academy of Chinese Medical Sciences (CACMS). Participants were primarily recruited between December 2021 and June 2024. The first RCT, conducted from December 2021 to June 2024, enrolled 66 patients and served as the model development cohort. The second RCT, conducted from June 2022 to November 2022, included 42 patients and served as an external validation cohort for the predictive model.

Eligibility screening and clinical assessments were conducted by licensed physicians from the departments of encephalopathy and neurology. Inclusion criteria and exclusion criteria are present in Textbox 1.

Textbox 1. Inclusion and exclusion criteria.

- **Inclusion criteria:**
  - A diagnosis of probable Alzheimer disease according to the National Institute on Aging–Alzheimer's Association criteria [17]
  - Age between 50 and 85 years
  - A Clinical Dementia Rating score ≥0.5
  - A Mini-Mental State Examination score ≤26
  - A Hachinski Ischemic Scale score ≤4
- **Exclusion criteria:**
  - Other neurological or systemic disorders known to cause progressive cognitive impairment
  - Recent use of medications or exposure to substances known to impair cognition
  - A history of trypanophobia or active skin infections
  - Acupuncture or electroacupuncture treatment within the past 2 weeks
  - Participation in other clinical trials

RenderX

Ethical Considerations

Both studies were conducted in accordance with the ethical principles outlined in the Declaration of Helsinki. This study is a secondary analysis of data derived from 2 RCTs previously conducted at Guang'anmen Hospital, CACMS. Both original trials received independent ethical approval from the ethics committee of Guang'anmen Hospital, CACMS (approval: 2021-056-KY-01 and 2022-087-KY). Written informed consent was obtained from all participants or their legally authorized representatives prior to data collection. Participants did not receive compensation for participation in the original trials. All treatments and assessments were provided free of charge. To protect participant privacy, all data used in this secondary analysis were anonymized and deidentified prior to analysis.

Treatment and Adherence Assessment

Participants received 20-minute acupuncture sessions 3 times per week (on nonconsecutive days) for a total of 12 weeks. Adherence was assessed by calculating the proportion of completed treatment sessions relative to the total number of scheduled sessions during the intervention period. The proportion of days covered (PDC) was used as the adherence metric. In the absence of an established gold standard for adherence in nonpharmacological trials like acupuncture, we adopted the widely accepted threshold of PDC ≥80% from pharmacotherapy research [9]. This threshold is a well-validated proxy for sufficient exposure to treatment in chronic disease management. Participants with a PDC ≥80% were classified as having good adherence, while those with a PDC <80% were categorized as having poor adherence.

Data Collection

The following clinical data were collected: sex, age, disease duration, disease severity, educational level, occupation, history of acupuncture treatment, Mini-Mental State Examination score, Alzheimer's Disease Assessment Scale–Cognitive Subscale score, basic activities of daily living, instrumental activities of daily living, presence of behavioral and psychological symptoms of dementia, Patient Health Questionnaire-9 score for depressive symptoms, caregiving role, number of treatments in the first month, travel time to the hospital, recruitment method, and adherence outcomes.

Screening of Influencing Factors

A linear regression model was used to assess multicollinearity among independent variables. Multicollinearity was quantified by calculating the variance inflation factor and tolerance values. Variables with a variance inflation factor <10 and tolerance >0.1 were considered to have acceptable levels of multicollinearity [18]. Variables meeting these criteria were subsequently included in a multivariable logistic regression model. Variable selection was performed using a backward stepwise regression approach based on the likelihood ratio test, with a significance threshold of $P<.05$ for retention in the model. This data-driven approach was chosen to build a parsimonious model and reduce the risk of overfitting. We also conducted exploratory analyses by forcing clinically relevant but nonsignificant variables into the model, but this did not lead to a significant improvement in model performance and increased model complexity. Therefore, the final model retained only the statistically significant predictors. Final variables were required to meet criteria for statistical significance, low multicollinearity, and satisfactory predictive performance. To improve model interpretability, Shapley Additive Explanations (SHAP) values were calculated to quantify the relative contribution of each predictor to the outcome [19]. SHAP values were visualized using beeswarm plots.

Construction and Evaluation of the Nomogram

A nomogram was developed based on the final multivariable logistic regression model to predict adherence. The nomogram serves as a graphical tool to visualize the relationships between multiple predictors and the outcome, facilitating individualized risk assessment and clinical decision-making. In the nomogram, each predictor is aligned with its corresponding axis; by drawing a vertical line from the predictor's value to the point scale, a score can be assigned. The total score, obtained by summing the individual scores, corresponds to a predicted probability of adherence on the nomogram's outcome axis.

Model performance was assessed through receiver operating characteristic (ROC) curve analysis, calibration plots, the Hosmer-Lemeshow goodness-of-fit test, and decision curve analysis using the development dataset. Internal validation was conducted using the bootstrap method with 1000 resampling iterations. Agreement between predicted and observed outcomes was evaluated using the κ statistic. An area under the ROC curve (AUC) between 0.5 and 0.7 was interpreted as indicating low discrimination, 0.7 to 0.9 as moderate, and >0.9 as high discrimination [20]. The nomogram's robustness was further evaluated by performing ROC analysis in the external validation cohort.

Statistical Methods

Data completeness for the variables included in the final model was assessed prior to analysis. There were no missing values for the variables included in the final model in either the development or validation cohorts, as complete data collection was a requirement for the per-protocol analysis in the 2 RCTs. All statistical analyses were conducted using R software (version 4.4.2; R Foundation for Statistical Computing). Continuous variables with a normal distribution were presented as mean (SD), while nonnormally distributed variables were expressed as median (IQR), with distribution assessed using the Shapiro-Wilk test. Categorical variables were reported as frequencies and percentages. Group comparisons were performed using independent-samples *t* tests for normally distributed continuous variables and the Mann-Whitney *U* test for nonnormally distributed continuous variables. Categorical variables were compared using the chi-square test or the Fisher exact test, as appropriate. All statistical tests were 2-tailed, and a P value <.05 was considered statistically significant. To assess the robustness of our model to the primary adherence definition (PDC ≥80%), a sensitivity analysis was performed by repeating the multivariable logistic regression using alternative thresholds of 70% and 90%.

Results

Baseline Characteristics of the Training Set

The predictive model was developed using data from the development cohort (cohort 1), which comprised 66 patients with AD (Table 1). Participants were stratified by treatment adherence into a good adherence group (n=43) and a poor adherence group (n=23). Of the total participants, 34 (51.5%) were female participants and 32 (48.5%) were male participants. The mean age was 71.8 (SD 7.9) years, and the mean disease duration was 50.0 (SD 26.0) months. Univariate analysis revealed significant differences between the good and poor adherence groups in caregiving status (P=.025) and the number of treatment sessions during the first month (P=.001).

The P values for testing differences between patients with good and poor adherence to acupuncture treatment were derived from independent samples t tests, Mann-Whitney U tests and chi-square tests or the Fisher exact tests.

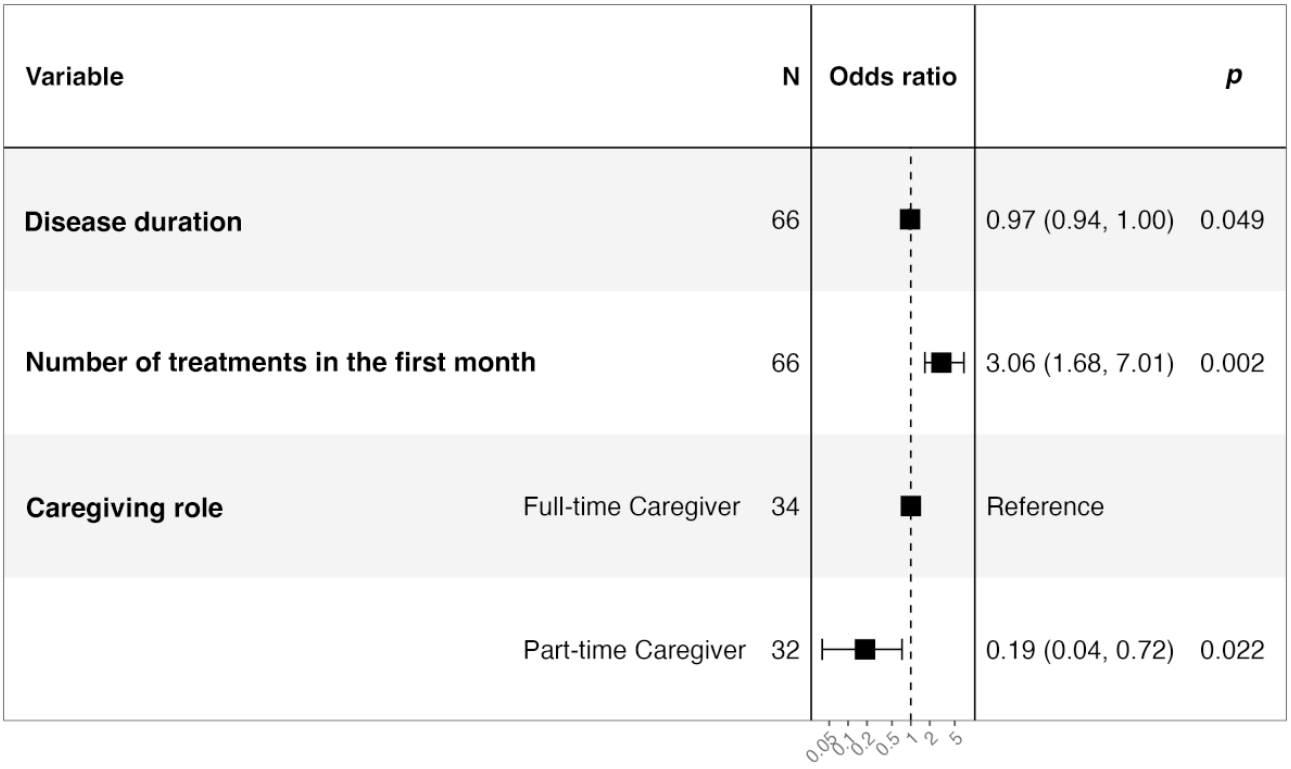
Independent Predictors of Adherence to Acupuncture Treatment Among Patients with AD

Initially, 17 potential predictors of adherence to acupuncture treatment in patients with AD were considered. Following multicollinearity analysis and assessment of clinical relevance, 16 variables were ultimately selected for model construction (Table S1 in Multimedia Appendix 1). Multivariable logistic regression analysis was performed to develop a predictive model of adherence to acupuncture treatment in this population. The final model is represented by the following equation (Figure 1; Table S2 in Multimedia Appendix 1):

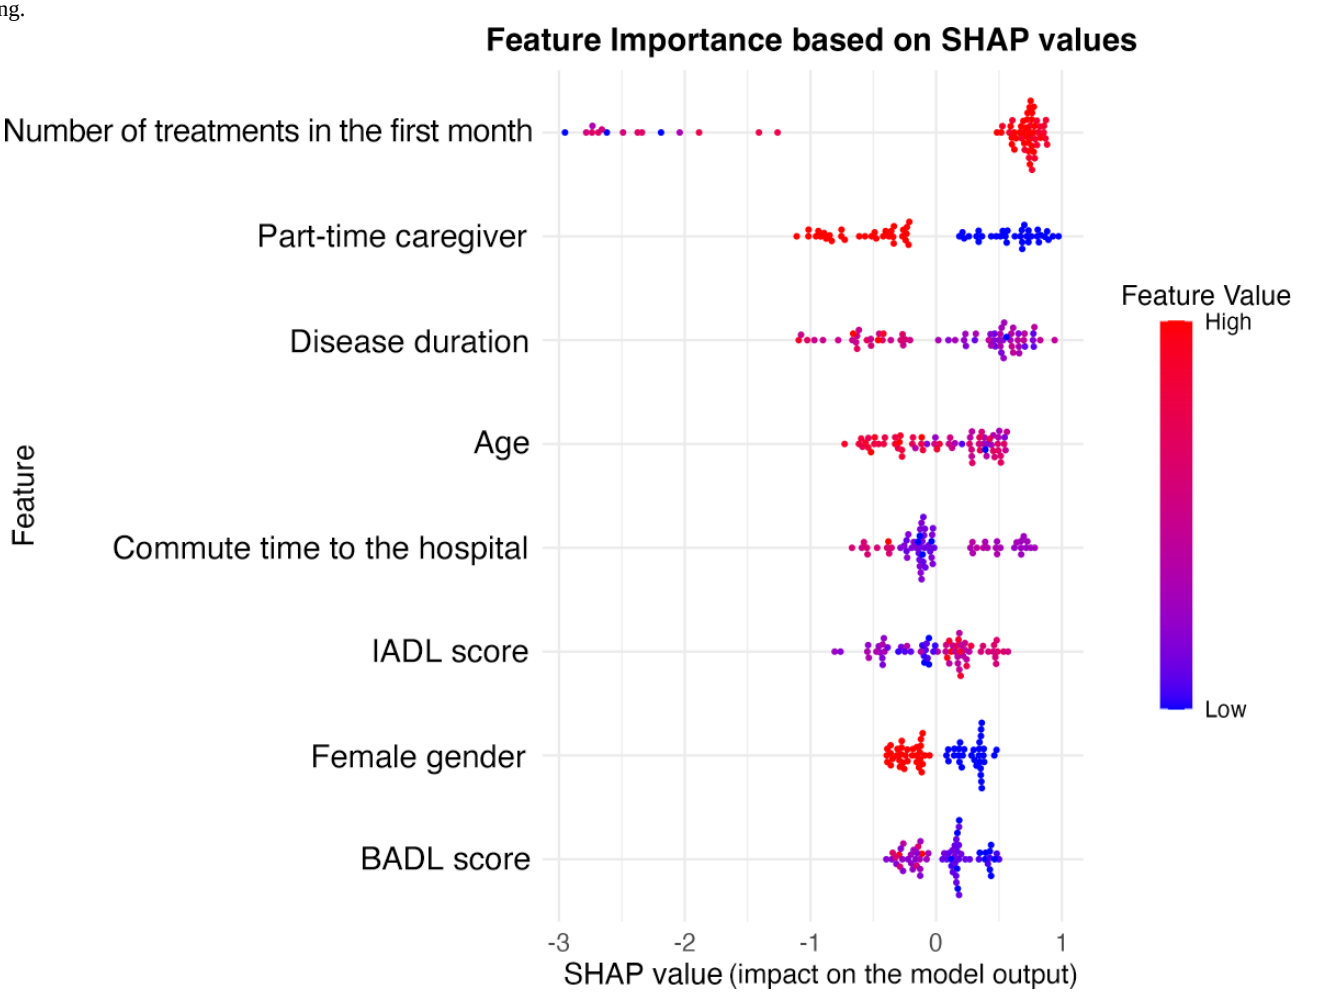
$$\log(p/(1-p)) = 2.24 + 0.12 \times \text{Disease Duration} + 1.20 \times \text{Number of Treatments in First Month} - 1.63 \times \text{Caregiving Role}$$



Disease duration, the number of treatments in the first month, and caregiving role were independent predictors of adherence to acupuncture treatment among patients with AD. A higher number of treatments during the first month was associated with a significant increase in the odds of good adherence (odds ratio [OR] 3.06, 95% CI 1.68 - 7.01; *P*=.002), while longer disease duration (OR 0.97, 95% CI 0.94 - 1.00; *P*=.049) and receiving care from a part-time caregiver (OR 0.19, 95% CI 0.04 - 0.72; *P*=.022) were associated with lower odds of adherence. SHAP analysis quantified the contributions of these predictors, confirming their importance in the model (Figure 2). The SHAP results were consistent with the logistic regression findings, enhancing the interpretability of the model.

The results indicated that the number of treatment sessions during the first month, caregiving role, and disease duration were the 3 most important factors influencing adherence. This ranking was highly consistent with the findings of the logistic regression model, demonstrating the substantial contribution of these variables to the model's predictive performance.

The SHAP summary plot visualizes the impact of each variable on the predicted probability of adherence. Each dot represents the SHAP value of an individual observation, indicating the degree and direction of that variable's influence on the model output. Higher SHAP values correspond to a stronger positive contribution to adherence probability. The color gradient from blue to red indicates the relative value of each variable for that observation (blue =lower value; red =higher value). For example, a higher number of treatments in the first month (red) is associated with higher SHAP values, reflecting its positive impact on adherence.

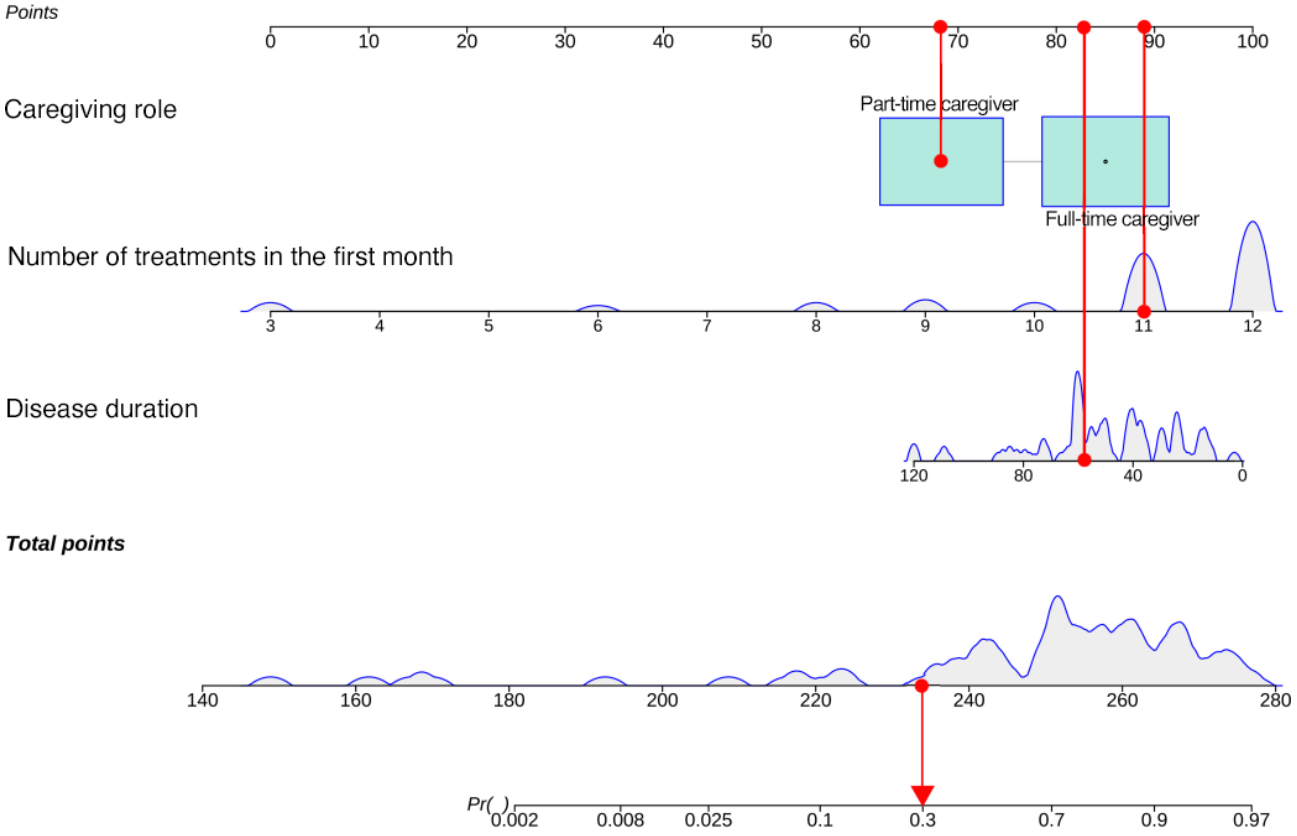


XSL•FO
RenderX

Figure 1. Forest plot of factors influencing adherence to acupuncture treatment among patients with Alzheimer disease based on multivariable logistic regression analysis. Dots represent odds ratios, and horizontal lines indicate 95% CIs. Longer disease duration and care provided by part-time caregivers were associated with lower adherence (odds ratio<1), while a higher number of treatment sessions during the first month significantly increased adherence (odds ratio >1). All variables included in the model were statistically significant (*P*<.05).

XSL•FO
RenderX

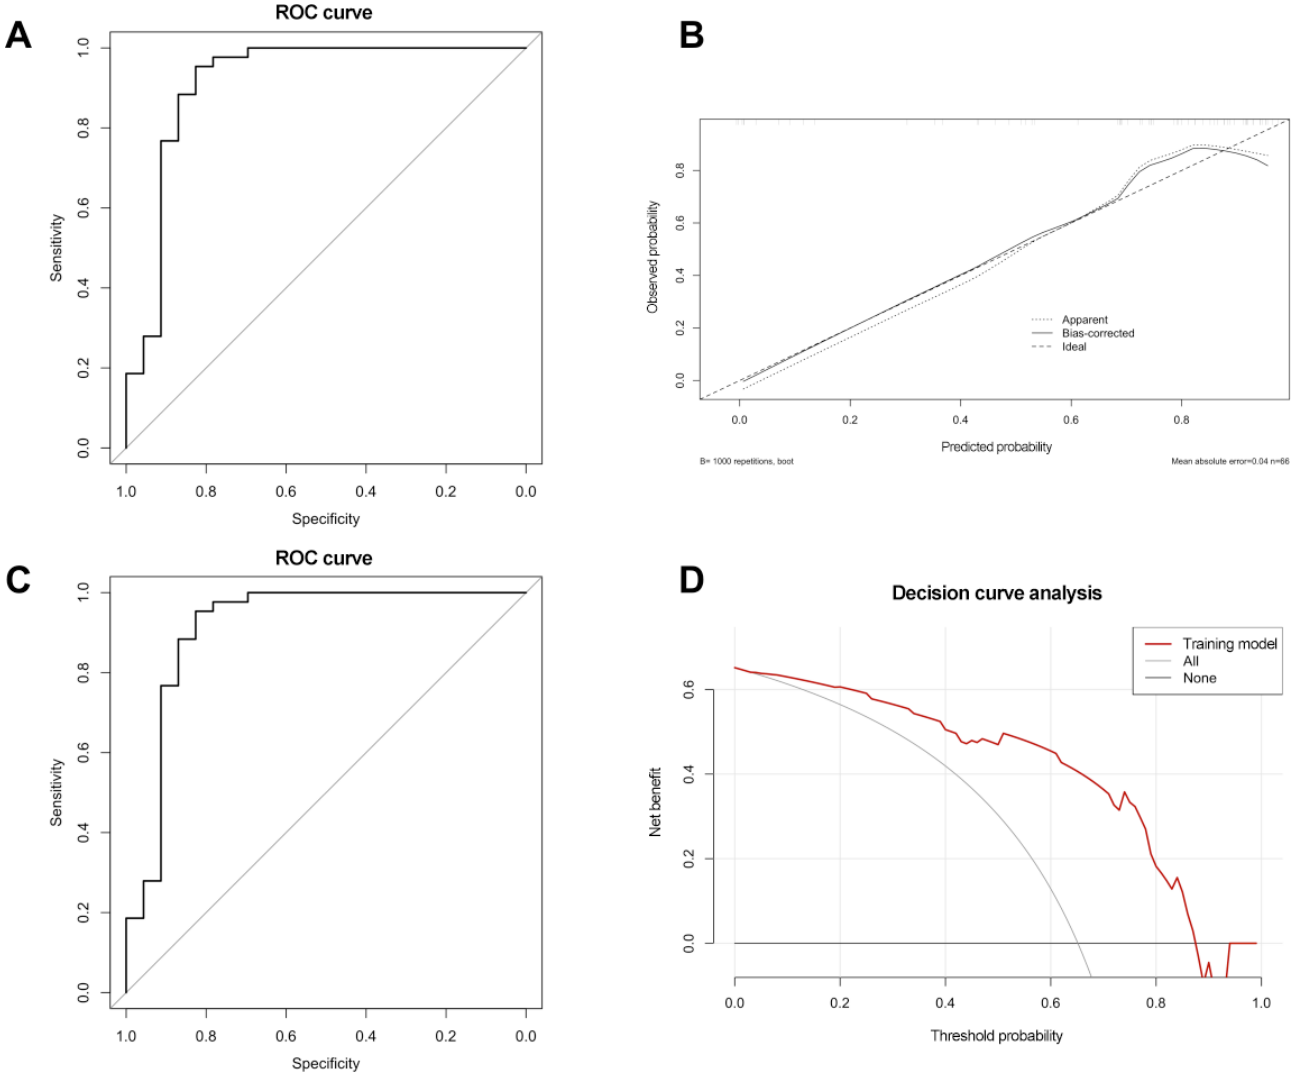
Figure 2. Shapely Additive Explanations (SHAP) summary plot of variable importance for predicting adherence to acupuncture treatment in patients with Alzheimer disease based on multivariable logistic regression analysis. BADL: basic activities of daily living; IADL: instrumental activities of daily living.



Development and Evaluation of the Nomogram

A nomogram was developed based on the final predictive model, incorporating the number of treatments in the first month, disease duration, and caregiving role (Figure 3). The model demonstrated excellent discrimination, with an area under the ROC curve (AUC) of 0.914 (Figure 4A). Validation was performed using cohort 2 (test set), which included 42 patients with AD (Table S3 in Multimedia Appendix 1). The calibration curve from internal validation indicated good agreement between predicted and observed probabilities (mean absolute error =0.04; mean squared error =0.003; 90th quantile absolute error =0.078) (Figure 4B). The Hosmer-Lemeshow goodness-of-fit test showed that the model predictions were well calibrated (χ^2_8=10.9; *P*=0.21). The decision curve analysis showed that the nomogram provided a net clinical benefit across a wide range of threshold probabilities (Figure 4D). Internal validation yielded an overall predictive accuracy of 89.4%, with a κ statistic of 0.759, indicating good consistency and potential clinical utility. Furthermore, the model performed well in the external validation cohort, achieving an AUC of 0.833 (Figure 4C).

For example, a patient with AD with a disease duration of 60 months, part-time caregiving, and 11 acupuncture sessions during the first month would obtain corresponding point values on each variable axis, indicated by red dots on the upper horizontal scales. The points for the 3 variables are summed to yield a total score of approximately 234. On the bottom axis, a total score of 234 corresponds to a predicted adherence probability of approximately 0.30, as marked by the red arrow. This relatively low predicted probability highlights the need for proactive adherence management and targeted interventions in clinical practice.



XSL•FO
RenderX

Figure 3. Nomogram for predicting adherence to acupuncture treatment among patients with Alzheimer disease.

XSL•FO
RenderX

Figure 4. Evaluation and validation of the nomogram model for predicting adherence to acupuncture treatment in patients with Alzheimer disease. (A) Receiver operating characteristic (ROC) curve assessing the discriminative ability of the model, with an area under the ROC curve of 0.914, indicating excellent predictive performance. (B) Calibration curve illustrating agreement between predicted and observed adherence probabilities. The x-axis represents predicted probability, while the y-axis shows the observed probability of adherence. The Ideal line indicates perfect concordance between predicted and actual outcomes. The apparent line reflects model performance in the original sample, and the bias-corrected line shows model performance adjusted for overfitting using the bootstrap method (1000 resamples). The close alignment of the calibration curves with the ideal line demonstrates the high accuracy and reliability of the model. (C) ROC curve of the nomogram model in the validation cohort, with an area under the ROC curve of 0.838. (D) Decision curve analysis of the nomogram model in the training cohort. The x-axis represents the threshold probability, and the y-axis indicates the net clinical benefit across different thresholds.

Sensitivity Analysis

To evaluate the robustness of our model, a sensitivity analysis was performed using alternative adherence thresholds of 70% and 90%. The model's predictive performance remained strong across all definitions, with an area under the ROC curve (AUC) of 0.892 for the 70% threshold and 0.860 for the 90% threshold. The statistical significance of the number of treatments in the first month (P=.01 at 70%; P=.05 at 90%), caregiving role (P=.03 at 90%), and disease duration (P=.08 at 70%; P=.09 at 90%) fluctuated near the P=.05 cutoff; this could be caused by the dataset size. Overall, these findings support the stability of our model. Detailed results of the sensitivity analysis are provided in the supplementary materials (Figure S1 in Multimedia Appendix 1).

Adverse Events

Safety monitoring was conducted throughout both RCTs. No serious adverse events related to acupuncture treatment were reported in either the development cohort or the validation cohort. Adverse events unrelated to the intervention are summarized in Table S4 in Multimedia Appendix 1.

Discussion

Predictors of Treatment Adherence in Patients with AD

This study identified the number of treatments in the first month, caregiving role, and disease duration as significant predictors of adherence to acupuncture treatment among patients with AD. The predictive nomogram constructed with these 3 variables demonstrated excellent discrimination in the development cohort (AUC=0.914) and acceptable performance in the external

XSL•FO
RenderX

validation cohort (AUC=0.838). With its simplicity, interpretability, and ease of application, the nomogram may serve as a practical tool to assist clinicians in identifying patients at risk of poor adherence and tailor intervention strategies accordingly.

To understand the clinical implications of these predictors, it is useful to interpret them through the established framework of intentional versus unintentional nonadherence. Unintentional nonadherence typically arises from practical barriers, which can be internal to the patient's condition (eg, forgetfulness and functional limitations) or external and situational (eg, transportation difficulties, inclement weather, and systemic disruptions like a pandemic). In contrast, intentional nonadherence involves a deliberate decision to cancel the treatment plan, often driven by subjective factors such as a perceived lack of efficacy, treatment fatigue, or shifting personal priorities. Our findings suggest that the identified predictors likely influence adherence through mechanisms related to both categories.

Increasing the Number of Treatments in the First Month May Improve Adherence

A key finding of this study is that a higher number of treatments during the first month was a powerful predictor of adherence. This suggests that early and intensive engagement is critical for establishing sustained treatment behaviors. From the perspective of unintentional nonadherence, a structured, frequent schedule in the initial phase may help patients and caregivers with cognitive and organizational deficits to more quickly accept the therapeutic routine, making it a habitual part of their lives [21].

This intensive approach can also mitigate intentional nonadherence through two possible ways. First, given that the therapeutic effect of acupuncture is often cumulative [22], increasing treatment frequency may accelerate the perception of clinical benefits [23,24]. When patients and caregivers observe an improvement early on, their motivation and belief in the treatment's value are naturally reinforced [25]. Second, frequent sessions offer more opportunities for communication among patients, caregivers, and clinicians, enabling the early detection and management of emerging issues. However, this approach requires careful consideration. It is important to acknowledge that a higher treatment frequency does not universally guarantee improved clinical outcomes [26] and may increase the treatment burden on families. The optimal number and timing of sessions may vary depending on disease severity, stage, and individual patient needs [27]. In conclusion, tailoring the intensity of acupuncture interventions to individual profiles remains a key consideration for future research and clinical practice for patients with AD, balancing clinical benefit and treatment burden.

Caregiver Capacity Is a Critical Determinant of Adherence

Our finding that patients supported by part-time caregivers (defined as providing fewer than 41 h of care per week [28]) were significantly less likely to adhere underscores the critical role of caregiver capacity in treatment engagement. This highlights a powerful driver of unintentional nonadherence, as dementia caregiving is a long-term, high-burden undertaking [29-31]. In advanced stages, care demands can often exceed 100 hours per week [32]. This presents formidable logistical barriers for part-time caregivers, who are typically adult children trying to balance employment, their own household duties, and the challenge of not living with the person they care for. These challenges frequently limit their ability to schedule and accompany patients to appointments, provide consistent emotional support, or respond to emergent care needs, thereby compromising adherence despite their best intentions [29].

This relentless demand also takes a significant physical and psychological toll, leading to caregiver burden and fatigue that can further diminish the capacity to support treatment [33-37]. These inherent difficulties are often compounded by unpredictable external factors, such as sudden illness or bad weather, which can disproportionately disrupt the routines of caregivers with less flexibility. A more subtle yet powerful factor is a form of intentional nonadherence driven by altruism, where patients may forgo appointments out of a desire not to burden their children, ultimately leading to treatment discontinuation.

In contrast, spouses often serve as full-time caregivers (≥41 h/wk) [38,39] and are typically more emotionally invested and committed to maintaining treatment routines. Some may even retire early to provide round-the-clock care [40]. Our study also found that professional caregiving within institutional settings can offer stable, structured, and high-quality care, which may facilitate better adherence. To enhance adherence in clinical practice, health care providers should actively involve caregivers in treatment planning and offer tailored education to improve their understanding of disease progression, treatment goals, and the importance of adherence [41,42]. Such interventions can mitigate both unintentional nonadherence (by improving scheduling and problem-solving skills) and intentional nonadherence (by reinforcing the perceived value of the treatment). Strengthening caregivers' motivation and capacity to support treatment is essential. When informal caregiving resources are insufficient, incorporating professional home care services or transitioning to institutional care may help ensure treatment continuity and effectiveness. Notably, countries such as Denmark and the Netherlands have developed comprehensive formal care systems for dementia that integrate medical and social support services [30,43]. These models may provide valuable reference points for improving dementia care infrastructure in China.

Early Detection, Prevention, and Intervention Still Key to Treating AD

Our study found that longer disease duration was associated with poorer adherence to acupuncture treatment. Primarily, this is a form of unintentional nonadherence driven by the patient's own progressive cognitive and functional decline, which impairs their capacity to independently manage appointments [44]. A higher prevalence of neuropsychiatric symptoms can reduce patient cooperation, while accumulating physical comorbidities and mobility limitations create new logistical hurdles. As the disease advances, a cascade of factors converges to further undermine adherence. This decline simultaneously increases

XSL•FO
RenderX

the burden on caregivers, who may experience emotional exhaustion and a deterioration in their own health, diminishing their ability to provide consistent support [45]. The combination of increasing patient dependency, rising caregiver exhaustion, and mounting logistical obstacles creates a formidable barrier to sustained treatment in the later stages of the disease.

This underscores the critical importance of a proactive and early approach to management. Our findings emphasize that the timing of intervention is paramount. Initiating treatment when patients retain greater cognitive and functional capacity offers a crucial window of opportunity. Early initiation of acupuncture may help establish regular treatment routines, foster therapeutic rapport, and enhance patient motivation. Moreover, health care providers should prioritize early education and ongoing support for both patients and caregivers. This includes training in caregiving skills, psychological counseling, and practical strategies to reduce caregiver burden and enhance quality of life [46]. These factors can contribute not only to improved adherence but also to more favorable long-term outcomes by potentially slowing the trajectory of disease progression.

Limitations

This study has limitations. First, although this study suggests that early, intensive treatment may enhance adherence, the optimal frequency and total number of acupuncture sessions for patients with AD remain undetermined. In real-world settings, increasing treatment frequency may impose greater transportation, time, and financial burdens on both patients and caregivers, potentially reducing their motivation and adherence. Second, our analysis was based on data from previous RCTs that were provided free of charge. Consequently, we could not assess the influence of crucial socioeconomic factors, such as treatment costs, or household income, which are known to be factors of health care engagement. Their influence on adherence may have been underestimated. Third, our sample size (N=108) was adequate for the primary analysis; it may be underpowered to detect predictors with more subtle effects. Finally, although we performed external validation, both cohorts were recruited from a single hospital. This shared clinical and demographic context limits the generalizability of our nomogram. Studies are needed to validate our model in multicenter or community-based cohorts to confirm its broader applicability.

Conclusions

In conclusion, this study is the first to develop and validate a predictive model for acupuncture treatment adherence in patients with AD, offering a novel, evidence-based tool for both clinical research and practice. For clinical research, this model provides a method to stratify enrollment or identify participants who may require enhanced adherence support, thereby reducing bias and improving the integrity of future trials. In clinical practice, the nomogram enables a shift from reactive problem-solving to proactive adherence management. By prospectively identifying patients at high risk, clinicians can address specific barriers and implement targeted strategies to improve adherence and, ultimately, enhance therapeutic outcomes.

Acknowledgments

The authors extend their heartfelt gratitude to all patients with Alzheimer disease and their family members for their participation in this study, without whom this research would not have been possible. During the preparation of this work, the authors used ChatGPT to improve the language. After using this tool, the authors reviewed and edited the content as needed and take full responsibility for the final content of the publication.

Abstract

Background: Conventional methods of functional assessment include subjective self- or informant report, which may be biased by personal characteristics, cognitive abilities, and lack of standardization (eg, influence of idiosyncratic task demands). Traditional performance-based assessments offer some advantages over self- or informant reports but are time-consuming to administer and score.

Objective: This study aims to evaluate the validity and reliability of the Virtual Kitchen Challenge—Version 2 (VKC-2), an objective, standardized, and highly efficient alternative to current functional assessments for older adults across the spectrum of cognitive aging, from preclinical to mild dementia.

Methods: A total of 236 community-dwelling, diverse older adults completed a comprehensive neuropsychological evaluation to classify cognitive status as healthy, mild cognitive impairment, or mild dementia, after adjustment for demographic variables (age, education, sex, and estimated IQ). Participants completed 2 everyday tasks (breakfast and lunch) in a virtual kitchen (VKC-2) using a touchscreen interface to select objects and sequence steps. Automated scoring reflected completion time and performance efficiency (eg, number of screen interactions, percentage of time spent off-screen, interactions with distractor objects). Participants also completed the VKC-2 tasks using real objects (Real Kitchen). All participants and informants for 219 participants completed questionnaires regarding everyday function. A subsample of participants (n=143) performed the VKC-2 again in a second session, 4-6 weeks after the baseline, for retest analyses. Analyses evaluated construct and convergent validity, as well as retest and internal reliability, of VKC-2 automated scores.

Results: A principal component analysis showed that the primary VKC-2 automated scores captured a single dimension and could be combined into a composite score reflecting task efficiency. Construct validity was supported by analyses of covariance results showing that participants with healthy cognition obtained significantly better VKC-2 scores than participants with cognitive impairment (all *Ps*<.001), even after controlling for demographics and general computer visuomotor dexterity. Convergent validity was supported by significant correlations between VKC-2 scores and performance on the Real Kitchen (r=−0.58 to 0.64, *Ps*<.001), conventional cognitive test scores (r=−0.50 to −0.22, *Ps*<.001), and self- and informant report questionnaires evaluating everyday

XSL•FO
RenderX

function (r=0.25 to 0.43, *Ps*<.001). Intraclass correlation coefficients (ICCs) indicated moderate to excellent retest reliability (ICC=0.70-0.90) for VKC-2 scores after 4-6 weeks. Reliability improved in analyses including only participants who reported no change in cognitive status between time 1 and time 2 (n=123). Spearman-Brown correlations showed acceptable to good internal consistency between the VKC-2 tasks (breakfast and lunch) for all scores (0.77-0.84), supporting the use of total scores.

Conclusions: The VKC-2 is an efficient, valid, and sensitive measure of everyday function for diverse older adults and holds promise to improve the status quo of functional assessment in aging, particularly when informants are unavailable or unreliable.

Introduction

As the US population ages and interventions for Alzheimer disease and Alzheimer disease–related dementias become available [1], highly sensitive, objective, and efficient measures of functional abilities are needed for multiple purposes. Mild functional difficulties are among the strongest predictors of future cognitive decline and dementia [2-5]; thus, accurate measurement of functional ability will improve prognostic prediction and help identify the need for early intervention. Given that functional ability level is often the criterion that distinguishes mild cognitive impairment (MCI) from mild dementia, accurate assessment is critical for diagnostic decision-making [6,7]. According to the Food and Drug Administration, the approval of pharmacological treatments for dementia, even at the very early, presymptomatic stage, is contingent on demonstrating gains on meaningful measures of functioning [8]. Recently approved treatments have relied on composite measures such as the Clinical Dementia Rating-Sum of Boxes and the integrated Alzheimer's Disease Rating Scale, but these measures require specialized training, are not readily deployable in typical clinical settings, and lack sensitivity to the earliest functional changes [9,10]. There exists a critical need for sensitive and efficient functional assessment tools that are clinically meaningful, psychometrically sound, and practically implementable across diverse health care settings [11,12]. We developed a nonimmersive virtual reality (VR) measure, the Virtual Kitchen Challenge—Version 2 (VKC-2), an objective, sensitive, efficient, and theoretically based tool for assessing everyday function in older adults to address the gaps in current functional assessments. Here we report results on VKC-2 validity and reliability in racially diverse, community-dwelling older adults with healthy cognition, MCI, or mild dementia.

Self/informant reports of everyday function, which are easy to administer and score, are the current standard method for functional assessment. When used with reliable, observant, and knowledgeable reporters, they generate useful information about how a person is functioning in everyday life [13-15]. In many circumstances, however, the accuracy of self and informant reports is uncertain. Their subjective nature makes them prone to over- or underreporting due to faulty cognitive abilities, psychological factors (eg, denial, depression, burden), or cultural beliefs [16]. Informant reports are often unavailable, as many older adults do not have a living spouse, nearby family members, or close friends. Even when available and willing, informants may have limited opportunities to observe daily functioning and may lack knowledge, particularly when functional difficulties are mild and may be masked by compensatory behaviors [17,18].

Another limitation of questionnaires is that older adults vary widely in the activities they perform and the contexts in which they perform them. For example, informant-reported difficulties with medication management may be profoundly different for an older adult managing a single prescription while residing in a small, highly organized home with her spouse versus an older adult taking dozens of medications while living alone in a large, cluttered house [19]. However, given identical clinical presentations and cognitive test scores suggesting mild cognitive decline, the latter patient would likely be diagnosed with clinical dementia if she were unable to independently manage her medications. Failure to account for context and task complexity confounds the informant report of everyday function and precludes clear comparisons of functional abilities across individuals.

Further, many questionnaires do not distinguish difficulties due to physical versus cognitive limitations [14], and if they do, it may be difficult for an informant to fully understand the nature of the functional difficulties, particularly because physical and cognitive limitations often co-occur [20-22]. Informant and self-reports also do not offer a detailed characterization of types of functional difficulties arising from different underlying cognitive problems (eg, slowing, disorganized actions vs omission of crucial task steps), which could offer insights into interventions for improving function and reducing the risk of future functional disability [23,24].

Performance-based measures of function address many of the limitations of questionnaires; they are objective, standardize task complexity and context, and allow for detailed analysis of behavior and systematic comparison across individuals. The Naturalistic Action Test (NAT), for example, is a performance-based test of everyday function with strong psychometric properties, normative data, and suggested cut scores for healthy cognition versus MCI versus mild dementia [23,25-35]. Scoring NAT performance for subtle inefficient errors, called micro-errors, has increased the sensitivity of NAT tasks for detecting mild difficulties with everyday tasks [35-38]. Results from performance-based tests, such as the NAT, with added sensitive scoring procedures, have demonstrated that (1)

XSL•FO
RenderX

healthy older adults make more errors and require more time to complete everyday tasks than younger adults [36,37,39-43]; (2) people with MCI make more errors than healthy controls but fewer errors than individuals with dementia [32,35,44-46]; and (3) the ability to accurately and efficiently perform everyday tasks is moderately correlated with performance on cognitive tests [27,28,35,37,47] and informant report of everyday function [27,29,31,35,48]. Together, these findings and others [37,49-52] suggest that standardized performance-based assessment of function is valid and reliable.

Despite their objectivity, validity, and potential for rich characterizations of function, current performance-based tests require extraordinary effort, limiting their implementation and scalability. Scoring, particularly scoring for subtle errors and inefficiencies, is time-intensive and requires video recording, detailed scoring instructions, and trained coders. Although some performance-based tests may be scored quickly as pass/fail without video recording [40,53], such gross measures are less sensitive to mild difficulties (ie, MCI) [54], do not advance our understanding of the nature of functional problems [5,55,56], or still require considerable effort to administer. To streamline administration and scoring, a nonimmersive VR task called the Virtual Kitchen, modeled after the NAT, was developed. The original version of the Virtual Kitchen [57] required a mouse to move objects on a computer screen to complete a coffee-making task. Results showed that people with dementia accomplished fewer steps and made more errors than healthy controls on the Virtual Kitchen. Validity was also supported by significant correlations between Virtual Kitchen scores and performance of real tasks, cognitive tests, and informant reports of functioning [57].

Our team revised the original Virtual Kitchen [57] by implementing the following updates: (1) expanding the coffee task to include a more extensive breakfast; (2) adding a lunch task; (3) updating the graphics; and (4) transitioning from a mouse to a computer touchscreen to make interactions more natural [39]. We also added a brief training task to familiarize participants with the touchscreen interface. Automated scores were expanded to include measures computed based on interactions with the touchscreen to increase sensitivity (ie, number of screen interactions). Preliminary results from the revised task, which we called the Virtual Kitchen Challenge (VKC), demonstrated validity and good internal consistency [39]. The VKC automated scores have been validated against conventional cognitive tests in young adults [52] and against neuroimaging markers of cerebral vascular disease (white matter hyperintensities) in a small sample of community-dwelling older adults [48].

In this paper, we present the psychometric properties of the automated scores from the most recent revision of the Virtual Kitchen, the VKC-2. This version includes enhanced graphics and a more extensive basic familiarization task for practice and to obtain a score of participants' digital visuomotor dexterity that may be used as a control measure. We evaluated construct and convergent validity as well as retest and internal reliability in a large, community-based sample of racially diverse older adults with healthy cognition, MCI, or mild dementia. Construct validity of the VKC-2 automated scores was evaluated in a known-group comparison (healthy cognition vs MCI vs mild dementia). Convergent validity was evaluated with correlations between automated VKC-2 measures and performance on the real versions of the VKC-2 tasks (Real Kitchen), demographically adjusted cognitive test scores, and conventional self/informant questionnaires of everyday function. Retest reliability was evaluated over a period of 4-6 weeks. Internal consistency was evaluated for the 2 VKC-2 tasks (breakfast and lunch).

Methods

Participants

Participants were recruited for an observational, longitudinal psychometric study designed to evaluate the psychometric properties of the VKC-2 (n=217; grant R01AG062503) or for a separate, smaller study on activity tracking (n=20; grant F31AG089944). Procedures for the baseline visit of both studies were the same, designed and conducted in accordance with the Helsinki Declaration, and approved by the Institutional Review Board at Temple University (institutional review board protocols 23116 and 29712). All participants and a knowledgeable informant signed informed consent forms, were compensated for their participation (US $50 for participants per session and US $25 for informants per session), and were assigned study numbers to protect their privacy when storing research records. At the end of the study, participants were also offered a research report with their cognitive test scores, if interested.

All participants were recruited from community outreach events, fliers, and referrals from neurology departments in Philadelphia, Pennsylvania, from September 2020 to June 2025. Inclusion and exclusion criteria were screened by phone, with only minor differences between the 2 studies. In both studies, participants were excluded for the following reasons: lifetime history of severe psychiatric disorder (eg, schizophrenia, bipolar disorder); nervous system infections or disorders (eg, epilepsy, brain tumor); current metabolic or systemic disorders (eg, B_{12} deficiency, renal failure, cancer); current moderate-severe depression; current moderate-severe anxiety symptoms; severe sensory deficits that would preclude visual detection or identification of common everyday objects used in the study or the ability to hear task directions (eg, blindness, total hearing loss); severe motor weakness that would preclude the use of everyday objects (eg, severe deformities or paralysis of both upper extremities); intellectual disability; and not being a fluent English speaker. The inclusion criteria for the larger study required participants to be at least 65 years old and have an available informant who could serve as a study partner. Informants were screened by phone for the following eligibility criteria: 18 years of age or older; fluent English speaker; available and willing to complete study questionnaires in person, by phone, or online; has daily contact with the participant; and reports knowledge of the participant's daily functioning. Inclusion criteria for the second, smaller study required participants to be at least 55 years old and did not require a study informant/partner.

XSL•FO
RenderX

Procedures

At the baseline visit (session 1), participants (N=237) completed informed consent, cognitive testing, the VKC-2, the real version of the VKC-2 tasks (ie, Real Kitchen), and questionnaires regarding demographic information, familiarity with the tasks used in the VKC-2, and their ability to perform activities in everyday life. The order of the Real Kitchen and VKC-2 was counterbalanced across participants to control for order effects. At session 1, informants completed questionnaires in person, online, or at home by mail. After reaching our target sample size (n=140) for retest reliability analyses (June 2024), participants were no longer requested to return for a second session 4-6 weeks after session 1 [58]. A total of 143 participants completed session 2, which included a brief interview (for both the participant and informant) regarding changes in cognition or health status (eg, medication changes, falls, illnesses, hospitalizations) since session 1, as well as repeat administration of the VKC-2 and Real Kitchen.

Measures

Conventional Cognitive Tests

Cognitive tests were administered to characterize the sample, classify participants according to their cognitive status, and evaluate the convergent validity of the VKC-2. The cognitive testing protocol is described in Table 1. The protocol included 2 tests from 4 different cognitive domains to classify participants according to Jak/Bondi actuarial criteria [59,60] and clinical criteria originally proposed by Petersen [6] and McKhann [61]. Normative data from the Calibrated Neuropsychological Normative System [62] were used to enable raw score adjustments for sex, age, education, and IQ estimated by a test of reading/vocabulary. Such demographic adjustments are critical for confirming group membership in a diverse sample of older adults [63,64]. Further details on how tests were used for classifying cognitive abilities are provided in Multimedia Appendix 1.

Table 1. Cognitive tests administered at session 1.

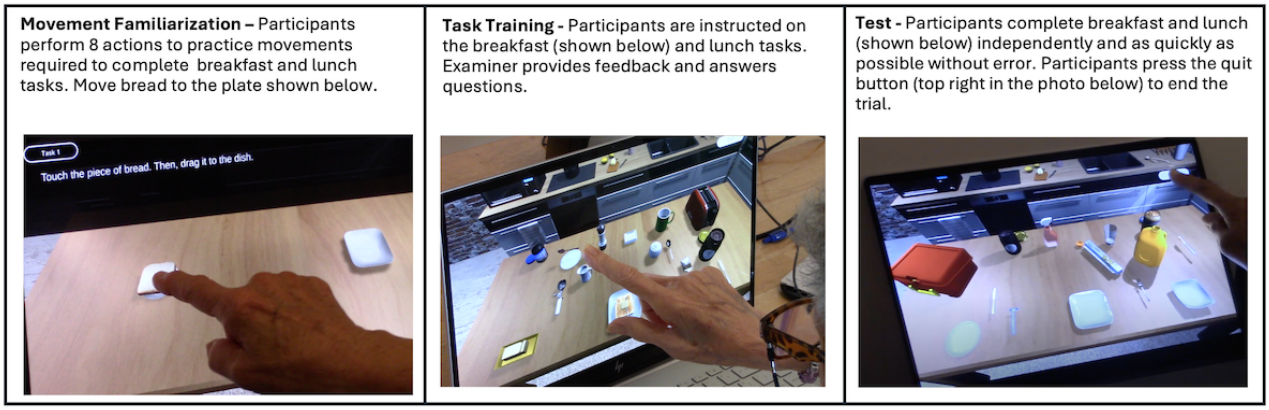
Cognitive domain and test	Score(s)	Reference
Premorbid intellectual functioning (IQ)		
Hopkins Reading Test	Estimated IQ	Schretlen et al [65]
Global cognitive status		
Mini-Mental State Examination	Total correct	Folstein et al [66]
Episodic memory		
Hopkins Verbal Learning Test—Revised[a,b]	Delayed free recall total correct	Brandt and Benedict [67]
Brief Visual Memory Test—Revised[a]	Delayed free recall total correct	Benedict et al [68]
Language		
Category (Animal) Fluency[a,b]	Total correct	Schretlen et al [62]
Boston Naming Test—30 item[a]	Total correct	Goodglass and Kaplan [69]
Executive function		
Trail Making Test—Part B[a,b]	Completion time	Reitan [70]
Digit Span Backward[a]	Longest span	Wechsler [71]
Processing speed		
Salthouse Letter Comparison[a,b]	Total correct	Salthouse [72]
Salthouse Pattern Comparison[a,b]	Total correct	Salthouse [72]
Attention		
Digit Span Forward[a]	Longest span	Wechsler [71]
Trail Making Test A[a]	Completion time	Reitan [70]

[a]*t* scores from these tests were used for healthy versus mild cognitive impairment versus dementia classification.

[b]*t* scores from these tests were averaged to compute the modified Knight-Preclinical Alzheimer Cognitive Composite.

For the analysis of VKC-2 convergent validity, composite scores were computed by averaging demographically adjusted *t* scores from tests within each domain (eg, Episodic Memory, Language). A global cognitive composite was modeled after the Knight-Preclinical Alzheimer Cognitive Composite (modified [m]Knight-PACC) [73], which has been validated as a sensitive measure of early cognitive change due to neurodegenerative disease.

Virtual Kitchen Challenge-Version 2



The VKC-2 is a nonimmersive VR test of everyday function that requires participants to complete 2 everyday tasks (breakfast

XSL•FO
RenderX

and lunch) by moving virtual objects using a touchscreen [39,57]. The VKC-2 tasks and objects were modeled after the NAT [25], an extensively studied and theoretically based performance-based test of everyday function that involves completion of familiar everyday tasks using real objects. The VKC-2 breakfast and lunch tasks were designed to be of comparable complexity and difficulty, with each task including 13 target objects and 4 distractor objects. For this study, the VKC-2 was administered on an MSI Creator Z16-A12UET laptop (12th Gen Intel Core i9 Processor) with a 16″ QHD+ (Quad High Definition Plus) (2560 × 1600), 120 Hz, IPS (In-Plane Switching)-level touchscreen display to maximize visibility and portability. Participants were instructed to use the index finger of their dominant hand to move and manipulate objects on the touchscreen.

The VKC-2 included 3 phases: Movement Familiarization, Task Training, and Test. See Figure 1 and the text below for more details.

Figure 1. Photos of participants completing each phase of the VKC-2.

VKC-2 Movement Familiarization

Participants were directed to perform 8 basic touchscreen actions (eg, tap, drag) to complete the following task steps: (1) move bread to dish, (2) stir mug with spoon, (3) pour juice, (4) place thermos in lunch box, (5) spread jelly on bread, (6) wrap cookies in foil, (7) place bread in toaster, and (8) add sugar to mug. Participants first performed all basic touchscreen actions with guidance from the examiner and had the opportunity to ask questions and repeat each action as needed. Next, participants were asked to complete all 8 trials independently as quickly and efficiently as possible. Completion time of the second, independent trial was computed as a measure of basic digital visuomotor dexterity (Digital Dexterity Score).

VKC-2 Task Training

The examiner reviewed the written instructions presented on the computer screen for each task. Participants were asked to point to each of the target objects needed for the task. For example, training for the breakfast task included the direction to “point to all of the objects you will need for the toast” while the examiner named each object out loud (eg, “bread,” “toaster”). Participants were also asked to point to each of the distractor objects and were told that they would not need to touch or use those objects. Participants then proceeded to practice trials, making breakfast and lunch with prompting, cues, and error correction from the examiner. The examiner also answered questions to ensure that participants fully understood each task.

VKC-2 Test

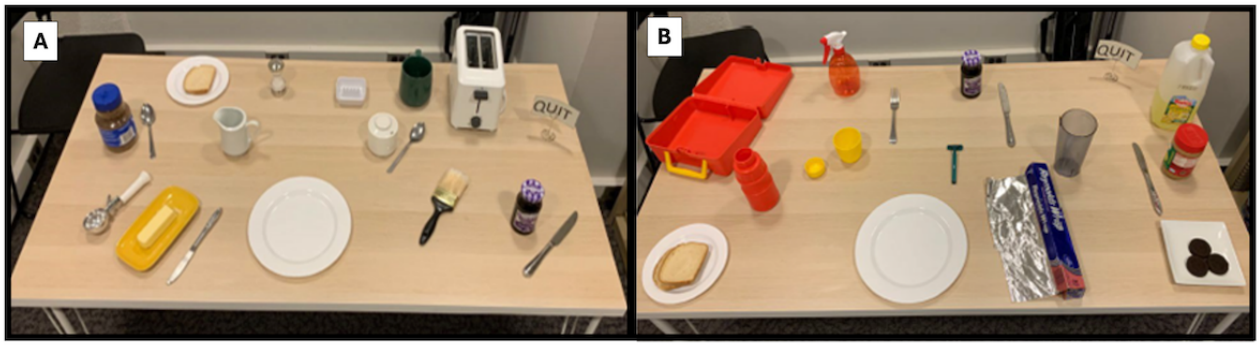
Breakfast and lunch tasks were completed independently without feedback. Instructions regarding the task objectives, which were reviewed during the practice trials, were repeated (eg, “pack a lunch for someone who wants a sandwich, snack, and a drink”). Participants were also instructed to complete test trials as quickly as possible, without making errors, and using clear and precise movements. They were told to touch the quit button at the top right of the screen to end the trial (see Figure 1). Participants were asked to verbally repeat the directions before each task to ensure comprehension; instructions were repeated as often as needed before the participant initiated the task.

VKC-2 Test Automated Scores

Performance on the VKC-2 Test tasks (breakfast and lunch) was scored using data from the touchscreen, as described and validated in our pilot work with the original version of the VKC [39,48,52]:

- Completion time (time) was recorded in seconds from the moment the virtual kitchen screen appeared (after instructions) until the participant pressed the quit button. Results from prior studies of the original VKC indicate that completion time differed significantly between older and younger participants and correlated with completion time on the Real Kitchen, cognitive tests of executive function and episodic memory [39], and neuroimaging markers of cerebrovascular disease [48].
- The number of screen interactions (touches) included the number of discrete instances the participant made contact with the computer touchscreen. Touches were collected as a measure of performance efficiency, with fewer screen interactions reflecting more precise and deliberate actions. Results from the original VKC showed that older adults made significantly more touches than younger adults, with additional touches by older adults including both inefficient correct actions and errors. A higher number of touches was significantly associated with more total errors scored by trained coders who watched video recordings of VKC

XSL•FO
RenderX



performance. Additionally, screen touches were significantly associated with performance on the Real Kitchen and cognitive tests of executive function and episodic memory [39].

- The percentage of time off-screen (%off-screen) was the percentage of time spent working on the VKC-2 when the participant was not touching the screen. It was computed by subtracting the time spent touching the screen from the completion time, dividing by the completion time, and multiplying by 100. The percentage of time off-screen also reflects performance efficiency. Pilot data from the original VKC [39] indicated that older adults spent a significantly higher percentage of their total time off-screen than younger adults. Correlations between %off-screen and human codes of VKC performance suggested that higher %off-screen times were due to multiple factors, including slower planning, difficulties locating target objects, difficulty resolving competition for object selection, and misreaching toward the computer screen (ie, micro-errors). Higher %off-screen times were significantly associated with more errors on the Real Kitchen, poorer scores on tests of executive function [52] and episodic memory [39], and neuroimaging markers of cerebrovascular disease [48].
- The number of distractor object interactions (distractor interactions) included instances when a distractor object was touched or moved. Our pilot work in a sample of healthy older and younger adults indicated that distractor interactions occurred too infrequently for analysis [39], but they have not been studied in participants with cognitive impairment.

Real Kitchen

The Real Kitchen required participants to complete the breakfast and lunch tasks using real objects placed on a table (Figure 2). Instructions for the Real Kitchen were identical to those for the VKC-2, including the instruction to "press the quit button when finished." In the Real Kitchen, the Quit Button was a piece of paper on the right side of the table labeled "QUIT." Real task objects were similar in appearance (color and shape) to the simulated objects in the VKC-2. Participants repeated the directions before each test trial to ensure comprehension; instructions were repeated as often as needed. Participants were video recorded, and recordings were labeled using a code so that human coders were unaware of participant classification and study session.

Figure 2. Real Kitchen breakfast (A) and lunch (B) tasks.

Real Kitchen performance was scored according to detailed instructions using validated scores and procedures. Real Kitchen scores from a subset of the current sample have been published and show strong interrater reliability, significant differences between participants with healthy cognition versus cognitive impairment, and correlations with cognitive tests and self/informant reports of everyday function [35]. For our current study, the following Real Kitchen scores were used to validate (convergent validity) the VKC-2 automated measures:

- Real Kitchen completion time was recorded in seconds and reliably coded by starting the timer when the first step was initiated and ending when the participant touched the quit button. Prior work shows that participants with greater cognitive impairment demonstrate longer completion times than participants with healthy cognition [35].
- Accomplishment was coded for each completed step and scored from 0 to 13 for the breakfast task and 0 to 20 for the lunch task. A total accomplishment score was computed (0-33), with higher scores reflecting a greater number of task steps accomplished.
- Total errors were coded according to a taxonomy studied in a range of clinical populations [25,74], showing validity and strong interrater reliability in people with stroke [75,76], dementia [27,28,30,47], MCI [26,32,33], and healthy controls [37,38,49], as well as a subset of participants from this sample [35]. The error taxonomy (see Multimedia Appendix 1) includes overt errors (eg, performing task steps in the wrong sequence) and micro-errors (eg, reaching toward a distractor object). In studies of participants with dementia, total overt errors correlate with cognitive tests and informant reports of function. The micro-error category was added to improve detection of subtle, inefficient behaviors in healthy and MCI participants [35,37,38,49]. As overt errors occur with relatively low frequency, they were combined with micro-errors to compute a total error score [35].
- Motor errors were tracked separately from total errors. Motor errors involved instances in which a corrective action was performed with motor or spatial imprecision (eg, spilling coffee grounds, dropping a knife).

XSL•FO
RenderX

Participant Questionnaires

Participants completed a demographic form assessing age, sex, race, ethnicity, income, and education level, as well as the following questionnaires.

The Past Experience Scale [45,77] assessed familiarity with the breakfast and lunch subtasks that comprise the VKC/Real Kitchen. The scale included 4 items (toast, coffee, sandwich, and thermos), each rated from 0 (not at all familiar) to 4 (very familiar). The total familiarity score ranged from 0 to 16, with higher scores reflecting greater familiarity. Participants also rated the frequency with which they had completed each subtask in their day-to-day life over the past 5-10 years, using a scale from 0 (never) to 4 (just about every day), with total scores ranging from 0 (never performed any of the tasks) to 16 (performed each task just about every day).

Functional Activity Questionnaire (FAQ) [14] instructions were modified to reflect only difficulties due to cognitive problems (not physical problems, fatigue, etc) for 10 activities (eg, preparing a balanced meal). Each activity is rated on a scale from 0 (performs normally) to 3 (dependent). Total FAQ scores range from 0 to 30, with higher scores reflecting greater dependence on others in everyday tasks due to cognitive difficulties.

The 12-item Everyday Cognition Scale (ECog-12) [13,78] measures decline over the past 10 years in 12 everyday cognitive abilities (eg, remembering where you have placed objects) on a scale from 1 (better or no change) to 4 (much worse all the time). Total scores reflect an average across all completed items and range from 1 to 4, with higher scores indicating greater decline in everyday cognition.

The Instrumental Activities of Daily Living—Compensation (IADL-C) [15] scale measures the need for assistance and compensatory strategies when performing 27 daily activities (eg, preparing one's own meals). Each activity is rated on a scale from 1 (independent, no aid) to 8 (not able to complete the activity anymore). The total score is the sum of all item responses, with a possible range from 27 (completely independent, no aid needed for any tasks) to 216 (no longer able to perform any task).

Informant Questionnaires

Informants completed questionnaires regarding their demographic information (eg, age, education), their relationship with the participant (eg, cohabitation, years known, hours in contact with the participant), and the participants' everyday function, including the ECog-12 [13,78], FAQ [14], and IADL-C [15]. Instructions and scoring for each questionnaire were the same as those for the participant versions described above.

Analysis Plan

Preliminary Analysis

Analyses were conducted using SPSS version 29.0 (IBM Corp) [79]. VKC-2 automated scores were examined for outliers and Winsorized at the first and ninety-ninth percentiles. The VKC-2 distractor interaction score was dichotomized because a few participants interacted with distractor objects (0=no interactions; 1=at least one interaction with a distractor object during completion of the VKC-2). Relations among VKC-2 scores were evaluated using bivariate correlations. Additionally, a principal component analysis (PCA) was conducted, including the 3 primary VKC-2 variables (time, touches, and %off-screen), to determine whether the dimensional VKC-2 automated scores could be combined into a single composite score. The Digital Dexterity score was not included in the PCA because it is derived from a separate condition intended to be used as a control for basic visuomotor skills. The distractor interaction score was not included because dichotomous variables are not appropriate for PCA. The suitability of the data for PCA was evaluated using the Kaiser-Meyer-Olkin measure of sampling adequacy and the Bartlett test of sphericity.

Construct Validity

VKC-2 automated scores were compared across groups known to differ in functional ability level: healthy cognition, MCI, and mild dementia. As the size of the dementia subgroup was relatively small (n=16), statistical analyses focused on differences between participants with healthy cognition and those with MCI. Participants with dementia were included for descriptive comparisons. One-way analyses of covariance (ANCOVA) were used to test group differences for each VKC-2 automated score (digital dexterity, time, touches, %off-screen, and VKC-2 composite) after controlling for demographics. Group differences were also evaluated in ANCOVA models that controlled for the digital dexterity score to determine whether significant group differences were explained by differences in basic visuomotor or computer abilities. Group differences on the dichotomized VKC-2 distractor interaction score were evaluated using chi-square tests. Significant between-group differences with at least small effect sizes (ie, partial η^2>.01; phi [ϕ] coefficient>.30) were interpreted as supporting the construct validity of the VKC-2 automated scores.

Receiver operating characteristic analyses comparing participant groups (healthy cognition vs impaired cognition [MCI + dementia]; healthy cognition vs MCI) were performed to identify cutoff values for each of the VKC-2 automated scores. Youden indices were used to identify cutoff scores that optimized sensitivity and specificity [80].

Convergent Validity

Correlations between the VKC-2 automated measures and the ability to perform tasks with real objects (Real Kitchen), demographically adjusted cognitive test scores of overall cognition and specific cognitive abilities, and self/informant reports of everyday functioning were performed to evaluate convergent validity. Pearson correlation coefficients were computed using the full sample. Spearman rank-order correlations were also performed and are included in Tables S3-S5 in Multimedia Appendix 1. Significant and moderate-level relationships were interpreted as supporting the convergent validity of the VKC-2 automated scores.

Reliability

Retest reliability was assessed using intraclass correlation coefficients (ICCs), calculated with a 2-way mixed-effects model based on absolute agreement and average measures [81].

XSL•FO
RenderX

ICC values range from 0 to 1, with values above 0.75 generally indicating good reliability and values above 0.90 considered excellent [82]. 95% CIs were computed for each ICC, and significance was determined using *F* tests. Retest reliability for the distractor interaction score (dichotomous variable) was examined using Cohen κ [83]. Retest reliability was evaluated for the full sample who completed session 2 (n=143) and for a subsample that reported no change in cognitive abilities since session 1 (123/143). Internal consistency between the 2 VKC-2 tasks (breakfast and lunch) was tested using the Spearman-Brown formula (*r*), with coefficients>0.70 interpreted as evidence of strong internal consistency [84].

Results

Participant Characteristics

A total of 237 participants were recruited from June 2021 to June 2025 for studies on everyday function. One participant with mild dementia refused to complete the study tasks; thus, the final analytic sample included 236 participants, of whom 172 were classified as having healthy cognition, 48 as having MCI, and 16 as having mild dementia. On average, participants were 72 years old and had completed 15 years of education; of the 236 participants, 156 (66.1%) were women, and nearly equal numbers identified as Black (n=106, 44.9%) and White (n=113, 47.9%). Demographic characteristics of the groups are reported in Table 2. The groups differed in age and education, but post hoc comparisons did not reach statistical significance (*P*>.051 for all). There were no group differences in estimated IQ or in the distributions of sex, Black/African American versus White race, or ethnicity.

Table 2. Demographic and descriptive characteristics by group.

Variable	Healthy (n=172)	Mild cognitive impairment (n=48)	Mild dementia (n=16)	*F* test (*df*) or chi-square (*df*)	*P* value
Age, mean (SD); range	71.95 (6.56); 58-94	74.54 (7.27); 61-98	74.50 (8.70); 55-91	3.30 (2, 235)	.04
Education (years), mean (SD); range	16.06 (2.51); 10-20	15.40 (3.25); 10-20	14.06 (3.04); 10-20	4.64 (2, 235)	.01
Estimated IQ, mean (SD); range	112.44 (11.73); 87-139	112.06 (13.30); 88-138	108.25 (13.19); 88-139	0.87 (2, 235)	.42
Sex: women, n (%)	114 (66.3)	33 (68.8)	9 (56.3)	0.85 (2)	.67
Race				3.53 (2)	.17

White	89 (51.7)	17 (35.4)	7 (43.8)		
Asian	5 (2.9)	3 (6.3)	1 (6.3)		
Pacific Islander/Hawaiian	2 (1.2)	0 (0)	0 (0)		
American Indian	0 (0)	1 (2.1)	0 (0)		
Multiracial	3 (1.7)	1 (2.1)	0 (0)		
Not reported	1 (0.6)	0 (0)	0 (0)		
Latino/Hispanic Ethnicity	2 (1.2)	0 (0)	0 (0)	0.75 (2)	.69
Past Experience Scale					
Familiarity rating, mean (SD); range	14.20 (2.44); 6-16	13.45 (3.27); 3-16	10.80 (4.44); 4-16	10.69 (2, 235)	<.001
Frequency rating, mean (SD); range	7.87 (2.82); 0-16	7.89 (3.27); 2-13	8.27 (1.62); 5-11	1.11 (2, 235)	.87

Results from the Past Experience Scale showed that task familiarity ratings were generally high, indicating that, on average, the breakfast and lunch tasks were “pretty” to “very” familiar. The groups differed on the familiarity rating, with post hoc tests indicating that the dementia group reported significantly lower task familiarity than the healthy cognition group (*P*<.001) and the MCI group (*P*=.005); however, the healthy cognition group and the MCI group did not differ (*P*=.32). According to the frequency ratings, participants reported that, on average, they had performed the VKC-2 tasks about once per month over the past 5-10 years. Frequency ratings did not differ across groups.

Demographic characteristics of participants who returned for session 2 and were included in the retest reliability analysis are reported in Table S1 in Multimedia Appendix 1. Compared with participants who did not return, the returning participants had completed significantly more years of education, obtained higher estimated IQ scores, and included a greater proportion of White participants.

XSL•FO
RenderX

Informant Characteristics

A total of 219 informants participated in the study. On average, informants were 63.97 years old (SD 13.99 years; range 20-90 years) and had completed 15.73 years of education (SD 2.43 years; range 10-21 years). Informants included spouses (95/219, 43.4%), children (60/219, 27.4%), friends (41/219, 18.7%), and other family members (23/219, 10.5%).

Correlations Among VKC-2 Scores and Principal Component Analysis

Average VKC-2 scores and their bivariate correlations indicate significant, moderate associations among all scores (Table 3). The relationship between VKC-2 time and touches was particularly strong, reflecting nearly overlapping scores, with more touches associated with longer completion times.

Table 3. VKC-2[a] scores and correlation coefficients in the full sample (N=236).

VKC-2 score	Digital dexterity	Time	Touches	%Off-screen
Time	0.67[b]	N/A[c]	N/A	N/A
Touches	0.51[b]	0.83[b]	N/A	N/A
%Off-screen	0.49[b]	0.42[b]	0.34[b]	N/A
Distractor interactions	0.34[b]	0.39[b]	0.42[b]	0.26[b]
Mean	86.76	197.47	67.82	0.48
SD	27.47	111.57	50.59	0.09

[a]VKC-2: Virtual Kitchen Challenge—Version 2.

[b]*P*<.001 (2-tailed). A total of 21 (8.9%) participants interacted with distractor objects; the mean and SD for the distractor interactions score are not reported because it was dichotomized.

[c]N/A: not applicable.

According to the Kaiser-Meyer-Olkin measure of sampling adequacy (0.579) and the significant Bartlett test of sphericity (χ^2_3=311.45, *P*<.001), there was a modest but acceptable level of shared variance among variables and a suitable correlation matrix for factor analysis. PCA results showed that only 1 component was extracted (eigenvalue=2.09), accounting for 69.74% of the total variance. All variables loaded positively on this component (time=0.930, touches=0.905, and %off-screen=0.639), suggesting a single underlying factor representing a common dimension. Thus, a VKC-2 composite score was computed by averaging sample-based *z* scores for time, touches, and %off-screen, with higher scores reflecting worse (ie, more inefficient) performance.

Construct Validity

The construct validity of the VKC-2 automated scores was evaluated by assessing differences among groups known to differ in functional abilities: healthy, MCI, and mild dementia. As shown in Figure 3, average scores on each VKC-2 measure were consistently worse for the dementia group. The same pattern was observed in the VKC-2 composite score (healthy: mean –0.22, SD 0.49; MCI: mean 0.43, SD 1.07; and dementia: mean 1.27, SD 1.36). Statistical analyses focused on differences between the healthy and MCI groups due to the relatively small number of participants with dementia. ANCOVA results comparing healthy versus participants with MCI are reported in Tables 4 and 5 and showed significant group differences (*P*<.001) in all measures after controlling for age. After controlling for the digital dexterity score and age (see Tables 4 and 5), the difference in the time score was no longer significant (*P*=.06), suggesting that the difference in completion time could be explained by low-level visuomotor skill differences between the MCI and healthy groups. By contrast, after controlling for digital dexterity and age, the differences in touches (*P*=.004), %off-screen (*P*=.01), and the VKC-2 (*P*<.001) composite score remained statistically significant, indicating that these between-group differences could not be explained by basic visuomotor skills. Thus, aside from time, the VKC-2 scores—particularly the composite score, which showed the strongest effect size after controlling for digital dexterity and age—likely reflect more than simple visuomotor abilities and capture the cognitive processes required to perform everyday tasks (ie, goal maintenance and control over task goals for the efficient execution of multistep everyday tasks).

RenderX

Figure 3. Unadjusted VKC-2 mean scores by group.

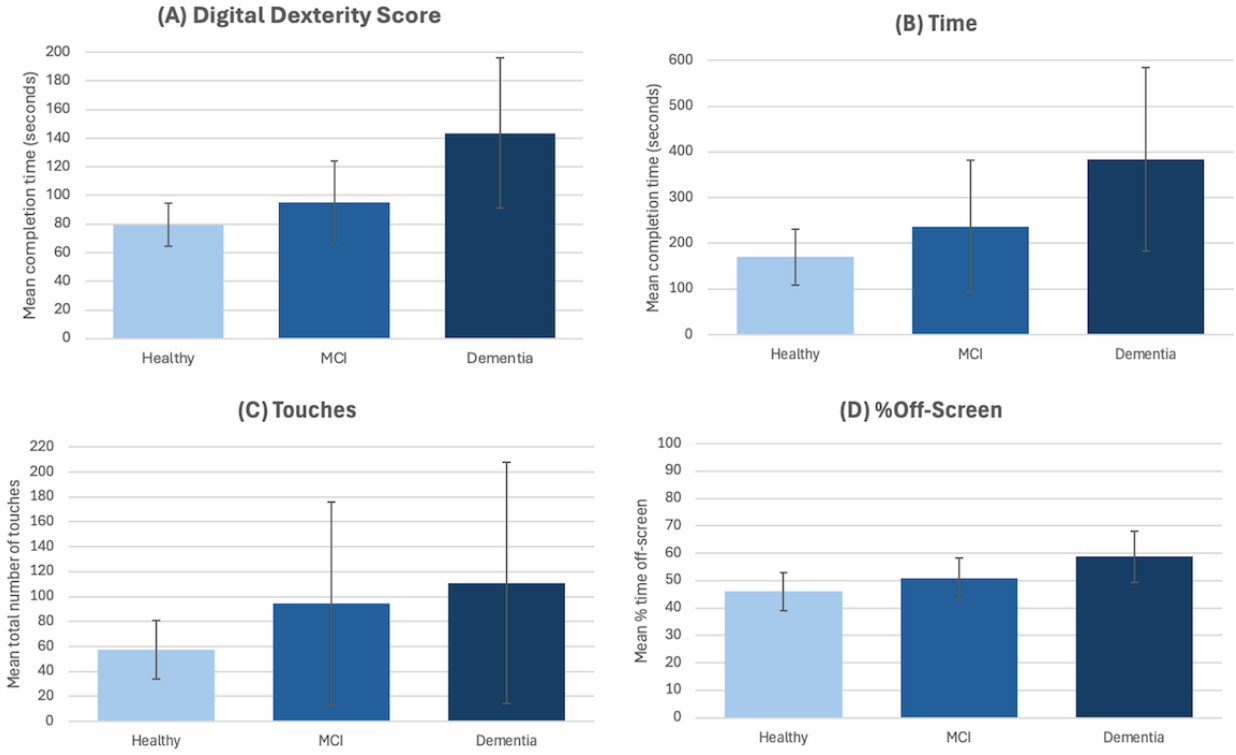

Table 4. Analysis of covariance results comparing participants with healthy cognition (n=172) versus those with mild cognitive impairment (n=48) on all VKC-2[a] automated scores: controlling for age.[b]

VKC-2 score	*F* test (*df*)	*P* value	η^2 (partial eta^2)	Effect size
Digital dexterity	20.68 (2, 219)	<.001	0.087	Medium to large
Time	17.54 (2, 219)	<.001	0.075	Medium
Touches	23.35 (2, 219)	<.001	0.097	Large
%Off-screen	12.71 (2, 219)	<.001	0.055	Medium
VKC-2 composite	29.70 (2, 219)	<.001	0.120	Medium to large

[a]VKC-2: Virtual Kitchen Challenge—Version 2.

[b]Effect sizes (η^2) are interpreted as follows: small=0.01, medium=0.06, and large=0.14.

Table 5. Analysis of covariance results comparing participants with healthy cognition (n=172) versus those with mild cognitive impairment (n=48) on all VKC-2[a] automated scores: controlling for age and digital dexterity.[b]

VKC-2 score	*F* test (*df*)	*P* value	η^2 (partial eta^2)	Effect size
Time	3.47 (3, 219)	.06	0.016	Small
Touches	8.60 (3, 219)	.004	0.038	Small to medium
%Off-screen	6.42 (3, 219)	.01	0.029	Small to medium
VKC-2 composite	11.68 (3, 219)	<.001	0.051	Medium

[a]VKC-2: Virtual Kitchen Challenge—Version 2.

[b]Effect sizes (η^2) are interpreted as follows: small=0.01, medium=0.06, and large=0.14.

The distributions of the distractor interaction score across the 3 groups (not reported in Figure 3) indicated a higher percentage of participants interacting with distractors in the groups with cognitive impairment (dementia: 5/16, 31%; MCI: 8/48, 17%; and healthy: 5/114, 4.3%). The difference in distractor interactions between the MCI and healthy groups was statistically significant (χ^2_1=8.03, *P*=.005; ϕ=0.191, small-to-medium effect size).

Classification Analyses

Classification analyses for distinguishing participants with healthy cognition from those with cognitive impairment (MCI

XSL•FO
RenderX

+ mild dementia combined) are reported in Table 6. All predictors showed statistically significant areas under the curve (AUCs; *P*<.001 for all), indicating that they were better than chance at predicting impaired group status. Time and the VKC-2 composite score were the strongest predictors, as indicated by their high AUCs and sensitivity. Time demonstrated particularly high sensitivity, making it useful for maximizing the identification of participants with impairment for early detection. By contrast, the %off-screen score showed the highest specificity, suggesting it may be more useful for ruling out individuals with healthy cognition during diagnostic confirmation. As expected, scores that increase sensitivity reduce specificity, reflecting the inherent trade-off between identifying true positives and minimizing false positives. Analyses distinguishing participants with healthy cognition versus those with MCI demonstrated similar AUCs (0.68-0.74), cutoff scores, and patterns of sensitivity and specificity, and are reported in Table S2 in Multimedia Appendix 1.

Table 6. Area under the curve values, optimal cutoffs, and specificity/sensitivity for predicting cognitive impairment from VKC-2[a] scores (N=236).

VKC-2 score	AUC[b]	95% CI	SE	*P* value	Optimal cutoff	Sensitivity	Specificity

[b]AUC: area under the curve.

Convergent Validity Against Real Kitchen Scores

Bivariate correlations between VKC-2 scores and Real Kitchen scores are reported in Table 7. Correlations with Real Kitchen completion time, accomplishment, and total errors were consistently significant (*P*<.001 for all) and moderate to strong, supporting the convergent validity of the VKC-2 scores against the real versions of the VKC-2 tasks. Relations between VKC-2 measures and motor errors on the Real Kitchen were relatively weaker and not consistently significant (*P* values ranged from <.001 to .08), suggesting that VKC-2 scores correspond more strongly with the cognitive aspects of Real Kitchen performance rather than visuomotor errors made with the real tasks (Table 7). Spearman rank-order correlations showed the same pattern of results and are reported in Table S3 in Multimedia Appendix 1.

Table 7. Correlation coefficients (and P values) between VKC-2[a] scores and Real Kitchen scores (n=201).

VKC-2 score	Completion time	Accomplishment score	Total errors	Motor errors
Digital dexterity	0.59[b]	–0.58[b]	0.50[b]	0.13 (*P*=.08)
Time	0.58[b]	–0.53[b]	0.64[b]	0.22 (*P*=.004)
Touches	0.38[b]	–0.26[b]	0.53[b]	0.30[b]
%Off-screen	0.44[b]	–0.44[b]	0.40[b]	0.15 (*P*=.057)
VKC-2 composite	0.56[b]	–0.48[b]	0.62[b]	0.27[b]

[b]*P*<.001 (2-tailed).

Convergent Validity Against Conventional Cognitive Tests

Bivariate correlations between VKC-2 scores and demographically adjusted cognitive test scores are reported in Table 8. The coefficients were statistically significant (*P* values ranged from <.001 to .03), indicating that participants with higher cognitive test scores completed the VKC-2 tasks more quickly and efficiently, supporting the convergent validity of the VKC-2 scores. Spearman rank-order correlations showed the same pattern of results and are reported in Table S4 in Multimedia Appendix 1.

[c]*P*<.001 (2-tailed).

Convergent Validity Against Self/Informant Questionnaires of Everyday Function

Table 9 shows the relationships between VKC-2 scores and questionnaires assessing everyday function completed by participants and informants. Results from participant questionnaires indicated that the associations between VKC-2 scores and the IADL-C and FAQ, which assess current functional abilities, were statistically significant (*P* values ranged from <.001 to .02) and in the expected direction. That is, participants who reported greater current functional difficulties (IADL-C and FAQ) also performed the VKC-2 tasks less quickly and efficiently. The relationship between VKC-2 scores and participants' reports of functional decline (ECog-12) was not significant (*P* values ranged from .21 to .55). By contrast, informant reports of both current functional difficulties (IADL-C and FAQ) and functional decline (ECog-12) were significantly associated with lower VKC-2 scores. Overall, correlations between the VKC-2 and participant/informant questionnaires support the validity of the VKC-2 and are comparable to or stronger than the relationships reported between conventional performance-based tests and questionnaires in the literature [43]. Spearman rank-order correlations showed a similar pattern of results and are reported in Table S5 in Multimedia Appendix 1.

Table 9. Correlation coefficients (and P values) between VKC-2[a] scores and questionnaires.

VKC-2 score	Participant questionnaires (n=236)			Informant questionnaires (n=194)

Retest Reliability

ICCs are reported in Table 10 and indicate moderate to excellent reliability for the VKC-2 automated scores. Cohen κ, used to assess agreement between distractor interaction scores at time 1 and time 2, showed only fair agreement (κ=0.27, *P*<.001), indicating limited but statistically significant consistency over time. When ICCs were rerun, including only participants who reported no change in their cognitive status from session 1 (123/143, 86%), results yielded comparable or slightly improved coefficients relative to the full sample (see Table S6 in Multimedia Appendix 1).

XSL•FO
RenderX

Table 10. Intraclass correlation coefficients for VKC-2[a] scores over time (n=143).

VKC-2 score	Intraclass correlation coefficient[b] (average measures)	95% CI	*F* test (*df*)	*P* value
Digital dexterity	0.844	0.766-0.893	6.965 (142, 142)	<.001

%Off-screen	0.703	0.523-0.806	3.837 (140, 140)	<.001
VKC-2 composite	0.899	0.860-0.923	9.965 (140, 140)	<.001

[a]VKC-2: Virtual Kitchen Challenge—Version 2.

[b]Type A using an absolute agreement definition.

Internal Reliability

Internal consistency between the VKC-2 breakfast and lunch tasks at time 1 was evaluated using Spearman-Brown coefficients in the full sample (N=236). Results indicated acceptable to good internal consistency for all scores (time: 0.81; touches: 0.81; %off-screen: 0.77; and VKC-2 composite score: 0.84).

Discussion

Results of this study support the validity and reliability of the VKC-2 automated scores as measures of everyday function in older adults. As predicted, VKC-2 scores differed significantly between groups known to vary in functional ability (healthy vs MCI vs mild dementia), supporting the construct validity of the VKC-2. Convergent validity was further supported by significant correlations between VKC-2 scores and performance on the real versions of the VKC-2 tasks (Real Kitchen), conventional cognitive test scores, and self/informant questionnaires assessing everyday functioning. Retest reliability analyses showed fair to excellent reliability for the VKC-2 automated scores over 4-6 weeks. Internal consistency between the 2 VKC-2 tasks (breakfast and lunch) was also good. Additionally, participants reported that the tasks included in the VKC-2 were highly familiar (Past Experience Questionnaire). These findings suggest that the VKC-2 automated scores hold strong potential for addressing critical gaps in functional assessment across multiple contexts, including screening older adults at risk for decline in meaningful everyday activities in primary care and serving as a functional end point in clinical trials of Alzheimer disease/Alzheimer disease–related disorder treatments.

To our knowledge, this is the first study to demonstrate significant differences between older adults with healthy cognition and those with MCI on the VKC-2 automated scores. Group differences in all scores except time persisted even after controlling for the digital dexterity score, a novel feature of the updated VKC-2. Thus, differences between MCI and healthy participants on the VKC-2 cannot be attributed solely to differences in digital visuomotor skills or touchscreen accuracy, but rather reflect the additional cognitive demands required to perform everyday tasks accurately and efficiently (eg, accurate object selection, sequencing of task steps, performance monitoring [74,85,86]). This conclusion is further supported by significant correlations with Real Kitchen scores (see also [57,87]) and by the fact that differences between participants with MCI and healthy participants on the VKC-2 mirror those observed on performance-based tasks with real objects in previous studies [26,32,33,35,45]. Significant associations with cognitive tests of episodic memory and language, which do not primarily measure motor skills or processing speed, provide additional evidence that the automated VKC-2 scores reflect cognitive abilities. Collectively, these results strongly support the construct validity of the VKC-2, offering a novel approach to identify everyday task difficulties without the need for video recording or trained coders—a major advantage over traditional performance-based tests—providing a highly efficient, scalable, and sensitive measure of everyday functioning.

It is important to acknowledge that some VKC-2 scores reflect visuomotor skills more than others. For example, the completion time (time) score did not remain significantly different between participants with MCI and those with healthy cognition after controlling for the digital dexterity score. This should not be viewed as a limitation, as mild upper motor dexterity difficulties contribute to functional impairments in people with MCI [20], and mild upper and lower limb difficulties are significantly associated with cognitive challenges in older adults without MCI [21,22,88]. Indeed, the VKC-2 digital dexterity score, as well as VKC-2 measures of efficiency, were associated with a measure of global cognitive abilities (mKnight-PACC) that is sensitive to preclinical Alzheimer disease. Thus, mild motor difficulties may serve as important early indicators of Alzheimer disease/Alzheimer disease–related disorder risk that could be missed by conventional cognitive tests. Additional studies, including longitudinal follow-up, are needed to identify the optimal combination of VKC-2 scores to maximize early detection of functional difficulties and risk.

Correlation analyses with conventional self- and informant-report questionnaires of everyday function provided additional support for the validity of the VKC-2 automated measures as indicators of processes that influence real-world functioning. The strength and pattern of correlations between VKC-2 scores and conventional questionnaires were similar to those reported for validated performance-based tests and questionnaires of everyday function in the existing literature [89,90]. Correlations were stronger and more consistent with informant reports than with self-reports, particularly for the questionnaire assessing cognitive/functional decline (ECog-12 [13]); this pattern has been reported in previous studies [56]

XSL•FO
RenderX

and aligns with our conceptualization of the constructs measured by performance-based tests versus questionnaires. We view the VKC-2, like other performance-based tests, as a measure of everyday functional capacity, making it well-suited for between-participant comparisons, staging, and tracking change over time. Questionnaires assess real-world functioning, which is highly unconstrained, with task demands, motivation, economic resources, social support, and other factors varying widely. Thus, in clinical practice, the VKC-2 could be used alongside questionnaires to provide a comprehensive evaluation of everyday function across contexts.

Significant associations between VKC-2 scores and conventional questionnaires of everyday function support the clinical relevance of the VKC-2 measures. Differences between participants with healthy cognition and those with MCI were small to moderate, with absolute differences amounting to only a few seconds on some scores. Such differences may reflect subtle processing difficulties that lead to inefficiency and increased cognitive load, which could accumulate over the course of a day. We acknowledge, however, that direct evidence that the mild cognitive difficulties captured by the VKC-2 translate to meaningful impacts on everyday tasks is currently lacking. Further validation using ecological momentary assessment or digital phenotyping via wearables (or both) would provide more direct evidence of the VKC-2 as a measure of real-world everyday function.

In addition to validity analyses, the reliability of the VKC-2 represents an important novel contribution of this study. To our knowledge, reliability has not been examined for any prior version of the Virtual Kitchen. Retest reliability estimates (ICC) showed that the automated VKC-2 scores—except for distractor interactions, which occurred very infrequently—were highly stable over a 4-6-week period. ICCs were even stronger when participants who reported notable changes in cognitive abilities were excluded. Strong retest reliability is critical for using the VKC-2 to evaluate meaningful change over time and for clinical trial applications. The VKC-2 tasks (breakfast and lunch) also demonstrated strong internal consistency, supporting the coherence of the combined total VKC-2 scores. Furthermore, correlations and PCA indicate that VKC-2 automated scores reflect a single underlying dimension and can be combined into a composite score representing task efficiency.

Several strengths of the study are worth noting. First, the sample size and inclusion of a substantial proportion of participants (106/236, 44.9%) identifying as Black or African American addresses a critical gap in cognitive assessment research and enhances the generalizability of our findings across the US population. Second, the VKC-2's portability, automated scoring, and standardized administration protocol offer clear advantages over current functional measures and existing regulatory-approved outcome measures for clinical trials, which often require specialized training, lengthy administration times, and access to informants. The VKC-2 does not require Wi-Fi and can be administered on any commercially available, budget-friendly touchscreen computer. Finally, the efficiency of the VKC-2 compared with conventional cognitive test batteries makes it particularly suitable for busy clinical settings where comprehensive neuropsychological assessments are impractical.

Study limitations also warrant consideration. First, although our sample included substantial racial diversity, the predominance of highly educated participants (mean 15.7 years of education) may limit generalizability to populations with lower educational attainment. Additionally, the sample was majority female (156/236, 66.1%), and participants from racial groups other than Black/African American or White or diverse ethnicities were underrepresented. Second, the community-based sample primarily included older adults with healthy cognition, with only 64 of 236 (27.1%) participants meeting criteria for cognitive impairment. The imbalance in subgroup sizes between participants with healthy versus those with impaired cognition limited statistical power for between-group comparisons and AUC/classification analyses. Therefore, additional studies are needed to replicate these findings in samples with larger groups of individuals with MCI or mild dementia. Third, although the virtual task environment is ecologically valid, it may not capture all real-world functional demands, such as physical fatigue, environmental distractions, or competing task requirements. Fourth, the cross-sectional design limits conclusions about the VKC-2's ability to detect meaningful change over time or predict clinical outcomes (predictive validity). Finally, direct validation against regulatory outcome measures is necessary before the VKC-2 can be considered an alternative end point in clinical trials.

As noted, future research on the VKC-2 should include longitudinal studies to determine the predictive validity of its scores. It will be important to evaluate whether the VKC-2 outperforms conventional measures in identifying individuals at risk for cognitive and functional decline. However, even if the VKC-2 performs comparably to traditional cognitive tests or questionnaires, it offers important advantages, including greater efficiency and independence from the need for a reliable informant. Another important future direction is validation of the VKC-2 against biomarkers of neurodegenerative disease. Holmqvist and colleagues [48] demonstrated strong correlations between VKC-2 scores and magnetic resonance imaging–derived measures of cerebral white matter hyperintensities, a biomarker of small vessel disease associated with brain aging and neurodegeneration. Ongoing studies are examining associations between VKC-2 scores and additional biomarkers, including Alzheimer disease–specific positron emission tomography and blood markers. Finally, automated VKC-2 scores that capture task accomplishment are under development, which will further enhance the utility of the VKC-2 by providing a detailed characterization of everyday task performance patterns [85]. Future implementation research should examine and address potential barriers to VKC-2 adoption, including variability in technology literacy, digital skill levels, and computer-related anxiety among diverse older adults [91], as well as strategies for seamless integration into existing clinical workflows.

In conclusion, there is growing interest in the development of digital assessments of cognition, including digitized versions of traditional cognitive tests, smartphone- and tablet-based cognitive assessments, and VR [92]. Digital, performance-based

XSL•FO
RenderX

assessments of everyday tasks, such as the VKC-2, extend this trend to meaningful measures of everyday function. The VKC was designed to address weaknesses of conventional functional measures by providing an objective, standardized, and highly efficient assessment that does not rely on informant reports. The VKC-2 requires approximately 15-20 minutes to administer, is suitable for the full spectrum of cognitive aging—from healthy aging to mild dementia—and includes tasks (breakfast and lunch) that have been extensively studied and shown to be highly familiar to older adults [27,28,32,47,93]. The VKC-2 can be administered on a portable laptop without the need for additional objects or supplies, including a VR headset, avoiding limitations associated with cybersickness and confusion. The touchscreen interface provides a more natural interaction than a mouse or joystick for older adults [94]. Finally, the VKC-2 provides sensitive and detailed performance analysis, including time to completion and measures of performance efficiency derived from the touchscreen, eliminating the need for video recording and human coders. Older adult participants in this study were able to use the touchscreen interface, understood the instructions, did not require extensive training, and performed the tasks consistently with expectations based on data from the Real Kitchen [35]. The VKC-2 shows strong potential as an ecologically valid and scalable tool for capturing everyday functional capabilities in people with healthy cognition, MCI, and mild dementia across various settings, including large longitudinal studies, health clinics, and clinical trials.

Acknowledgments

The authors acknowledge Anna Callahan, Julina Hossfeld, Nicole Lloyd, Julia Manganti, Shrey Patel, Emma Pinsky, and Yuki Tsuchiya for their contributions to the Virtual Kitchen Challenge Project, including participant recruitment, assistance with data collection, and database management. The authors also thank Ms. Sherry Hill, Director of the Community Engagement Fitness Network, for her support with community outreach and participant recruitment. Generative artificial intelligence was not used in the creation of this manuscript.

Funding

This study was funded by grants from the National Institute on Aging (R01AG062503 to TG; F31AG089944 to SH).

Data Availability

The dataset analyzed for this study will be made available in the Virtual Kitchen Challenge Repository. In the interim, data requests may be sent to the corresponding author (TG).

Authors' Contributions

Conceptualization: TG (lead), TY (equal)
Data curation: TG (lead), MK (equal), MM (equal)
Formal analysis: TG (lead), DAGD (equal)

Abstract

Background: Remote health care delivery, including the use of digital health interventions, is emerging as a tool for assessing and managing physical function, but its design and implementation often overlook the needs and preferences of older adult end users.

Objective: The primary aim of this modified Delphi process was to develop consumer consensus on preferences for remote assessment and management of physical function in older adults.

Methods: Research and consumer experts of the Remote Assessment and Management of Physical Function in Older Adults (RAMP) Working Group co-developed the Round 1 Delphi survey, which was advertised to consumers (adults aged ≥60 years) via international clinical and research networks and social media between August and November 2023. The online survey presented 23 Delphi statements for which respondents reported their level of agreement using an 11-point Likert scale (0-10; scores ≥7 indicated agreement). Statements were classified as having "strong agreement" and achieving consensus if ≥80% of participants indicated agreement. Statements classified as having "moderate" (70%-80% of participants indicated agreement) or "low" (<70% of participants indicated agreement) agreement were revised or rejected. Revised statements were presented to participants in Round 2 (January to February 2024), and the final consensus statements were consolidated into recommendations.

Results: A total of 654 consumers (75.7% female) with a mean age of 69.0 (SD 6.0) years from 15 countries (5 continents) were included in analyses in Round 1. Of 23 statements, 13 achieved consensus, with the strongest agreement observed for statements relating to the importance of physical function for quality of life and performing activities of daily living (6 statements; agreement 97.6%-99.5%). Two statements regarding privacy and security concerns when using technology (agreement 20.8%) and the inability to perform physical function assessments or exercise at home (agreement 15.5%) were rejected with low agreement. The remaining 8 statements (agreement 49.5%-79.5%) were modified into 7 new statements for the Round 2 survey, which was completed by 526 (80.4%) respondents from Round 1. Five of seven Round 2 statements were accepted with strong agreement (agreement 80%-82.7%), including the importance of addressing personal preferences for self- versus clinician-led remote interventions, group versus individual exercise, and availability of necessary resources (eg, technology and exercise equipment).

Conclusions: Eighteen statements achieved consensus and were translated into 7 recommendations highlighting that older adults recognize physical function as a health priority, would value more information about it, and are willing to participate in remote assessment and management interventions (including via digital health) to maintain or improve it. These recommendations also reinforce that interventions should be easily accessible and meet individual preferences of consumers.

KEYWORDS

aged; Delphi technique; exercise; remote consultation; digital health; physical function

Introduction

Maintaining physical function is crucial for older adults to live independently and maintain a good quality of life [1]. Depending on the task examined, up to 50% of older adults may report difficulty with physical function, and more than 10% use walking aids, with an increasing prevalence of functional limitation in older age (eg, ≥80 years) [2]. Older adults with functional limitations are half as likely to engage with their communities, family, and friends [3] and have significantly increased health care costs compared to those without functional limitations [4]. However, assessment and management of physical function receive limited attention in many clinical settings [5-7]. While multimodal exercise is recommended for improving physical function [8], older adults report that lack of access to interventions, facilities, and relevant health care professionals are barriers to participation [9].

Remote health care services enable patient assessment and monitoring without physical co-location [10] and, especially since the COVID-19 pandemic, have been commonly used by older adults [11]. Emerging evidence suggests digital health interventions using technologies such as telephone calls, videoconferencing, wearable devices, and web applications are feasible and effective for supporting older adults to maintain or

XSL•FO
RenderX

improve their physical function [12-14]. However, both consumers (ie, older adult end users) and health care professionals face barriers to engagement with digital health interventions, such as low digital literacy, lack of equipment, and unsatisfactory social interactions [15,16]. Furthermore, the design and implementation of digital health technologies for remote care have largely failed to consider the perceptions and experiences of consumers in their design and implementation, impeding large-scale sustained adoption [17].

The Delphi method, a rigorous consensus-building approach [18], is effective for developing recommendations for the delivery of care related to maintaining and improving physical function in older adults based on the insights of both experts and consumers (ie, older adults themselves) [19,20]. Incorporating consumer participation in consensus-building processes helps ensure that subsequent recommendations address end users' priorities, maximizing the potential for wide adoption and adherence among consumers in health care and community settings [21]. However, no consumer-focused consensus Delphi process has explored the priorities, acceptability, enablers, and barriers for remote assessment and management of physical function from older adults' perspectives, and there are no consensus guidelines on the delivery of remote care in older adult populations. Thus, this study aimed to develop consumer-informed recommendations for remote assessment and management of physical function in older adults via a modified Delphi process.

Methods

Study Design and Population

The Remote Assessment and Management of Physical Function in Older Adults (RAMP) International Consumer Delphi Process was a modified (2-round) Delphi study. Eligible participants were aged 60 years and older with internet access, residing in any country, and able to complete the survey in the English language.

RAMP was advertised to potential participants via email (consumer mailing lists of the RAMP Working Group), direct invitations (investigator-led conversations with consumers), and social media (Facebook [Meta Platforms, Inc] advertisements; posts on X [X Corp] and LinkedIn [LinkedIn Corp]) between August and November 2023.

Delphi Process

This study's methodology adhered to that of a previous modified Delphi process where 2 rounds, as demonstrated by common practice in previous Delphi studies [22,23], were sufficient to reach consensus on sarcopenia management [19]. Multimedia Appendix 1 summarizes the study timeline. The Round 1 survey (Multimedia Appendix 2) was co-developed by RAMP Working Group research experts (DS, CH, JF, PJ, and RMD) and consumer experts (RD and PK) and included questions on demographics, health status (including the SARC-F questionnaire [24]), and health care experiences, plus 23 Delphi statements related to physical function and its assessment and management. The first 13 statements relate to physical function generally, while the latter 10 statements refer to remote provision of health care related to physical function. Respondents were asked to report their level of agreement with each Delphi statement via an 11-point Likert scale (0=Strongly disagree, 10=Strongly agree) and could optionally provide a free-text comment explaining their response to each statement.

Round 1 survey responses were analyzed by DS, and the results and proposed Round 2 survey were shared with RAMP Working Group members for feedback. In January 2024, an invitation to participate in the Round 2 survey, which included seven new or modified statements, was emailed to respondents who completed Round 1, along with a summary of the Round 1 results and an explanation of decisions taken in developing the Round 2 statements (Multimedia Appendix 3). Further details on reasons for low or moderate agreement to Round 1 statements and decisions taken are provided in Multimedia Appendix 4. Upon completion of the Round 2 survey (Multimedia Appendix 5), DS analyzed the results, and ED and DS initially developed the final recommendations. Finally, this manuscript, including the developed recommendations, was revised (2 rounds of revisions) and approved by RAMP Working Group members.

Statistical Analyses

Survey data were assessed for completeness, and all respondents who completed ≥50% of survey questions were included in analyses. Where duplicate responses were identified, the most complete and/or first response was included. Descriptive characteristics were reported as frequencies or percentages for categorical variables and means and SDs or medians and IQR for continuous variables.

Participants with a response ≥7 out of 10 were considered to have agreed with a given statement, and the level of consensus was determined by the proportion of participants who agreed. Round 1 and 2 Delphi statements were classified as having "strong agreement" if ≥80% of participants responded with a score ≥7 out of 10 [19]. These statements were considered to have achieved consensus and were not further modified. In Round 1 only, statements with "moderate" (70%-80% of participants responded ≥7) or "low" (<70% of participants responded ≥7) agreement were revised or rejected. DS reviewed the associated free-text comments and revised the statements based on common reasons for lack of agreement. The revised statements were shared with the RAMP Working Group for approval. In Round 2, all statements that did not achieve "strong agreement" were rejected. All analyses were performed using SPSS Statistics 28 (IBM Corp).

Ethical Considerations

The study was approved by the Deakin University Human Ethics Advisory Group (Reference number: HEAG-H 111_2023) and complied with the Declaration of Helsinki. Potential participants were directed to an online plain language statement defining physical function (ie, "the ability of a person to perform everyday activities"), as well as the study aims and methods. Potential participants provided an electronic signature confirming their informed consent. Those who consented were subsequently emailed a link to the Round 1 Delphi survey (hosted by Qualtrics XM). Participants who completed the Round 1 survey were invited to participate in the Round 2 survey

XSL•FO
RenderX

between January and February 2024. Participants who consented but had not completed the Round 1 and 2 surveys were sent a reminder 2 weeks prior to the closing date. Participation was voluntary, and respondents did not receive any form of reimbursement.

Results

Round 1

A total of 861 complete consent forms were received, and the Round 1 Delphi survey subsequently received 716 responses during the Round 1 survey period. Of these responses, 50 (7%) completed less than 50% of the survey, and 12 (2%) were duplicate responses. Thus, 654 of 861 (76%) consented consumers were included in the Round 1 survey analyses. Most of the included respondents (n=644, 98%) completed the entire Round 1 survey, while 10 respondents rated their agreement with the first 13 statements only. Respondents' mean age was 69.0 (SD 6.0) years, and three-quarters were female (Table 1). Respondents were residing in 15 countries across 5 continents (Australia, Africa, Asia, Europe, and North America), although the majority (81.5%) were from Australia and the United Kingdom. Three-quarters of respondents had completed higher education and around 70% were retired. Over 87% rated their health as good to excellent, but more than 70% perceived their current physical function was "somewhat worse" or "much worse" than when they were 40 years old. The SARC-F instrument demonstrated that approximately 54% of respondents had some functional limitation, and around one-quarter had experienced at least one fall in the past year (Multimedia Appendix 6).

Characteristic	All respondents (n=654)
SARC-F score, median (IQR)	1 (0-2)

Less than one-third of respondents reported that a health care professional had started a conversation with them about their physical function in the past 5 years, while 38% had initiated a conversation themselves (Table 2). More than 60% had sought information on physical function from sources other than a health care professional. Around 40% of respondents reported having ever completed a physical function assessment with a health care professional, and almost 50% had commenced a supervised exercise program aimed at improving their physical function. The majority of respondents (>60%) had commenced an unsupervised exercise program aimed at improving their physical function.

Table 2. Health care experiences related to physical function for Remote Assessment and Management of Physical (RAMP) participants in Round 1 (n= 654).

Question	Yes, n (%)	No, n (%)	Don't Know, n (%)
In the past five years, have you started a conversation with a health professional (eg, doctor, physiotherapist, and nurse) about your physical function (eg, asking how you can continue to stay independent as you get older, or why you might not be as strong as you were when you were younger)?	245 (37.5)	399 (61)	9 (1.4)
In the past 5 years, has a health professional (eg, doctor, physiotherapist, and nurse) started a conversation with you about your physical function?	209 (32)	436 (66.7)	7 (1.1)
Have you ever tried to find information about physical function from sources other than a health professional (eg, by asking a friend or family member, visiting a website, or reading a book or magazine)?	395 (60.4)	255 (39)	3 (0.5)
Have you ever completed a physical function test (eg, walking speed test, hand grip strength test, and chair stand test) under the supervision of a health professional (eg, where a health professional asked you to perform a specific test while under their supervision to determine whether your physical function was poor)?	270 (41.3)	376 (57.5)	7 (1.1)
Have you ever completed a physical function test (eg, walking speed test, hand grip strength test, and chair stand test) while NOT under the supervision of a health professional (eg, performing a specific test designed to determine whether your physical function is poor after you read or viewed instructions in a document or online)?	101 (15.4)	543 (83)	9 (1.4)
Has a health professional ever prescribed you an exercise program aimed at improving your physical function?	315 (48.2)	333 (50.9)	5 (0.8)
Have you ever commenced an exercise program aimed at improving your physical function while NOT under the supervision of a health professional (eg, an exercise program that you created for yourself, with or without the help of a friend or family member, or using a website/book/magazine)?	402 (61.5)	245 (37.5)	6 (0.9)

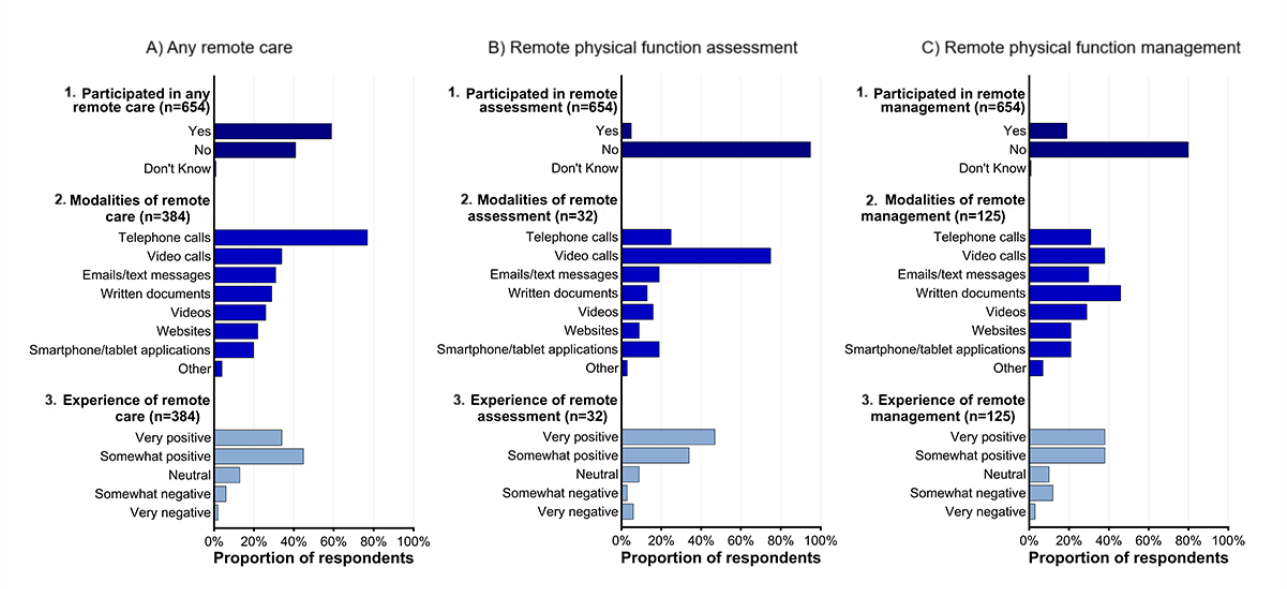
Over 58% of respondents had participated in a remote health care service, while less than 5% had participated in a remote physical function test, and less than 20% had engaged in remote physical function management such as an exercise program (Figure 1). For respondents who had participated in any form of remote care, telephone calls were most commonly used (77%), with video calls and emails/text messages each used by over 30% of respondents. For respondents who had participated in a remote physical function assessment, video calls were most commonly used (75%), followed by telephone calls (25%). For respondents who had participated in a remote treatment for their physical function, written documents (eg, flyers, brochures, magazines, and books) were most common (46%), followed by video calls (38%) and telephone calls (31%). Regardless of the type of remote care, respondents generally reported positive experiences; 75%-81% rated their experience as somewhat or very positive.

Only 5% of respondents reported that they would not be willing to participate in remote physical function tests and treatments (Multimedia Appendix 7), with optional comments indicating that this was due to concerns regarding lack of supervision, safety, lack of necessary technologies and technological familiarity, data privacy, hearing and visual problems, potential costs, and insufficient space in the home. Amongst those willing to participate in such interventions, videos (eg, on a website or DVD) were the most preferred delivery method (78%). Approximately 4% were willing to use other approaches; free-text comments indicated that these could include digital voice assistants, wearable devices, webinars, smart televisions, and wall charts. The most common perceived positives of remote tests and treatments, selected by over 80% of respondents, were the convenience of not needing to travel to appointments and the flexibility to perform assessments and exercises when suitable. Some (<4%) respondents nominated other positives in free-text comments, including avoiding body shaming or embarrassment when exercising, self-motivation, empowerment and autonomy for managing exercise, and better use of health care professionals' time. Regarding negatives of remote care, the lack of personalized guidance during exercises was reported by half (51%) of respondents, and concerns regarding the potential ineffectiveness of interventions and a lack of social interaction and motivation were each reported by more than

XSL•FO
RenderX

40%. Approximately 14% of respondents cited other potential negatives, including costs and/or lack of access to necessary equipment and technological devices, lack of confidence in performing exercises correctly, low motivation to exercise, lack of engagement with programs and health care professionals, and insufficient space to perform exercises at home.

Figure 1. Remote health care experiences of RAMP participants in Round 1, related to (A) any type of remote care, (B) remote care to assess physical function, and (C) remote care to manage physical function. Sublabels (1) describe the proportion of respondents who reported having participated in that type of remote care, (2) report the modalities by which respondents engaged with that type of remote care, and (3) report the perceived experience of respondents participating in that type of remote care. Questions 2 and 3 were only asked to participants who responded yes to having participated in that type of remote care. For question 2, participants could choose multiple responses, so the total does not equal 100%.



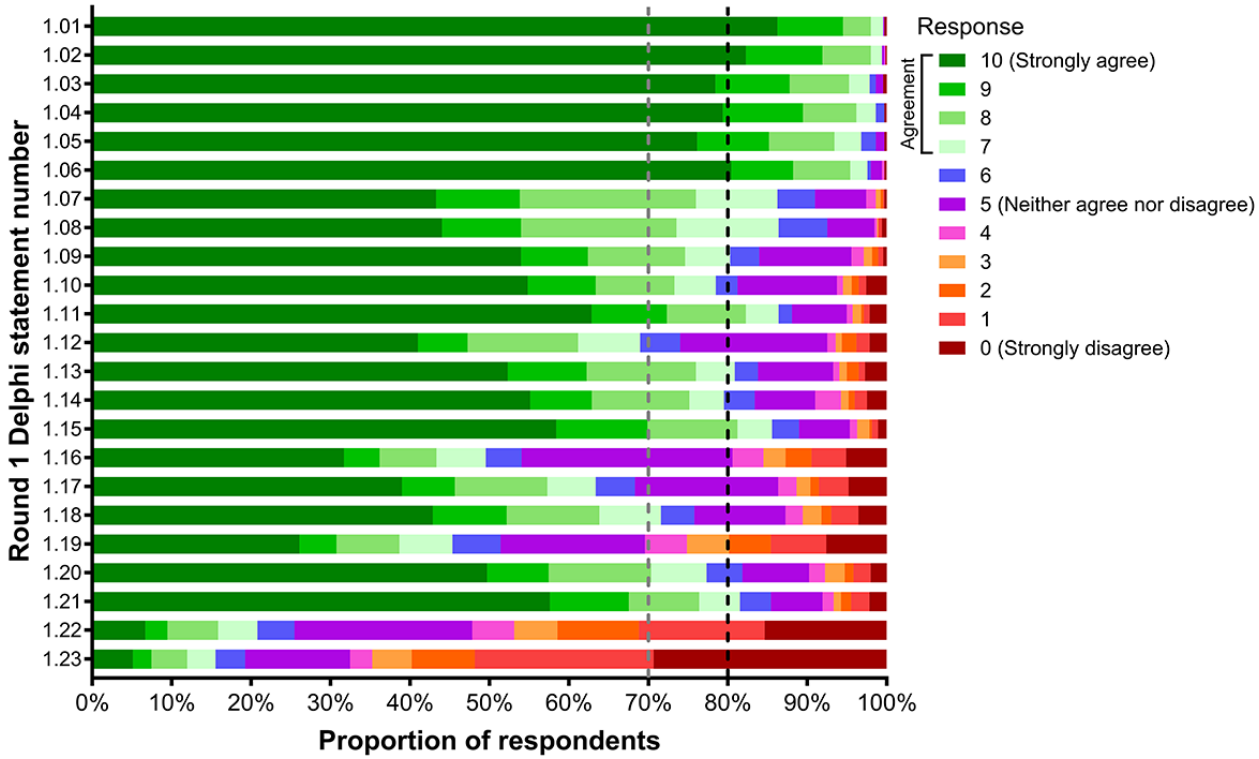


Figure 2 and Table 3 present respondents' reported agreement with the 23 Delphi statements from Round 1. Statements related to the importance of physical function for maintaining overall quality of life, participating in activities in the community and home, and engaging with family and friends (Statements 1.01-1.06) had the highest proportion (97%-100%) of respondents who reported agreement (response ≥7 out of 10) in this round and were accepted. Consensus was also achieved that poor physical function can be prevented and reversed (Statements 1.07 and 1.08; both 86% agreement) and that respondents would discuss with their health care professionals if concerned about their physical function (Statement 1.09; 80% agreement). There was moderate agreement that respondents would like access to information on how to test their physical function (Statement 1.10; 78% agreement) and low agreement that having better access to information would assist in conversations with health care professionals (Statement 1.12; 69% agreement). However, there was strong agreement that respondents would like access to information on how to improve their physical function (Statement 1.11; 86% agreement) and that having better access to information would assist in managing their physical function independently (Statement 1.13; 81% agreement).

Regarding remote provision of health care, almost 80% of respondents agreed that they would be willing to participate in remote physical function tests, but this statement (Statement 1.14) did not meet the criterion for consensus. There was strong agreement that physical function tests would be safe to perform without direct supervision (Statement 1.15; 86% agreement) but only low agreement that respondents would be willing to participate in a remote exercise program that was always (Statement 1.16; 50% agreement) or sometimes (Statement 1.17; 63% agreement) supervised, and moderate agreement that they would be willing to participate in an unsupervised exercise program (Statement 1.18; 72% agreement). There was also low or moderate agreement that respondents would be happy to participate in a remote exercise program in a group setting (Statement 1.19; 45% agreement) or individually (Statement 1.20; 77% agreement). Finally, low proportions of respondents agreed that they would be concerned about their privacy and security when using technology to participate in remote care (Statement 1.22; 21% agreement) or that remote physical function tests or exercise programs would be difficult to perform in their home (Statement 1.23; 16% agreement).

Table 3. List of Round 1 Delphi statements with levels of agreement and outcome decisions.

Statement number	Statement	Agreement (%)[a]	Agreement rating[b]	Outcome
1.01	Having good physical function is important to the overall quality of life of older adults	99.5	Strong agreement	Accept
1.02	Having good physical function is important for activities involving moving around the community (eg, going shopping or to a restaurant or cafe, visiting your neighbors, friends and family, or the doctor)	99.4	Strong agreement	Accept
1.03	Having good physical function is important for participating in activities with family and friends (eg, playing with grandchildren)	97.9	Strong agreement	Accept
1.04	Having good physical function is important for participating in activities like work, household duties (eg, cooking, cleaning, and gardening), and volunteering	98.6	Strong agreement	Accept
1.05	Having good physical function is important for participating in hygiene activities (eg, showering, dressing, and using the toilet)	96.8	Strong agreement	Accept
1.06	Having good physical function is important for participating in exercise (eg, walking, swimming, dancing, golf, and other types of physical activity)	97.6	Strong agreement	Accept
1.07	It is possible to slow down or prevent poor physical function that occurs as we get older	86.2	Strong agreement	Accept
1.08	If someone already has poor physical function, it is possible to improve it	86.4	Strong agreement	Accept
1.09	If I was concerned about my physical function, I would discuss it with my health professional	80.3	Strong agreement	Accept
1.10	I would like access to information about how to test my physical function myself to determine if it is poor	78.4	Moderate agreement	Modify statement for Round 2
1.11	I would like access to information about things that I can do myself to improve my physical function	86.4	Strong agreement	Accept
1.12	Having better access to information on physical function would help me to have conversations about this with health professionals	69.0	Low agreement	Modify statement for Round 2
1.13	Having better access to information on physical function would help me to take care of my own physical function	80.9	Strong agreement	Accept
1.14	I would be willing to participate in remote tests of my physical function (eg, on a video call with a health professional, or by myself using written instructions and/or video demonstrations provided to me)	79.5	Moderate agreement	Modify statement for Round 2
1.15	I am confident that it would be safe for me to perform physical function tests at home without direct supervision by a health professional if I was provided with instructions (eg, written information or video demonstrations)	85.6	Strong agreement	Accept
1.16	I would be willing to participate in a remote exercise program to improve my physical function if it was ALWAYS supervised (eg, exercising while on a live video call with a health professional for all exercise sessions)	49.5	Low agreement	Modify statement for Round 2
1.17	I would be willing to participate in a remote exercise program if it was SOMETIMES supervised (eg, exercising on a live video call with a health professional for some exercise sessions, but exercising by myself unsupervised using instructions provided by the health professional for other sessions)	63.4	Low agreement	Modify statement for Round 2
1.18	I would be willing to participate in a remote exercise program if it was NOT supervised (eg, exercising by myself unsupervised using instructions provided by a health professional)	71.6	Moderate agreement	Modify statement for Round 2

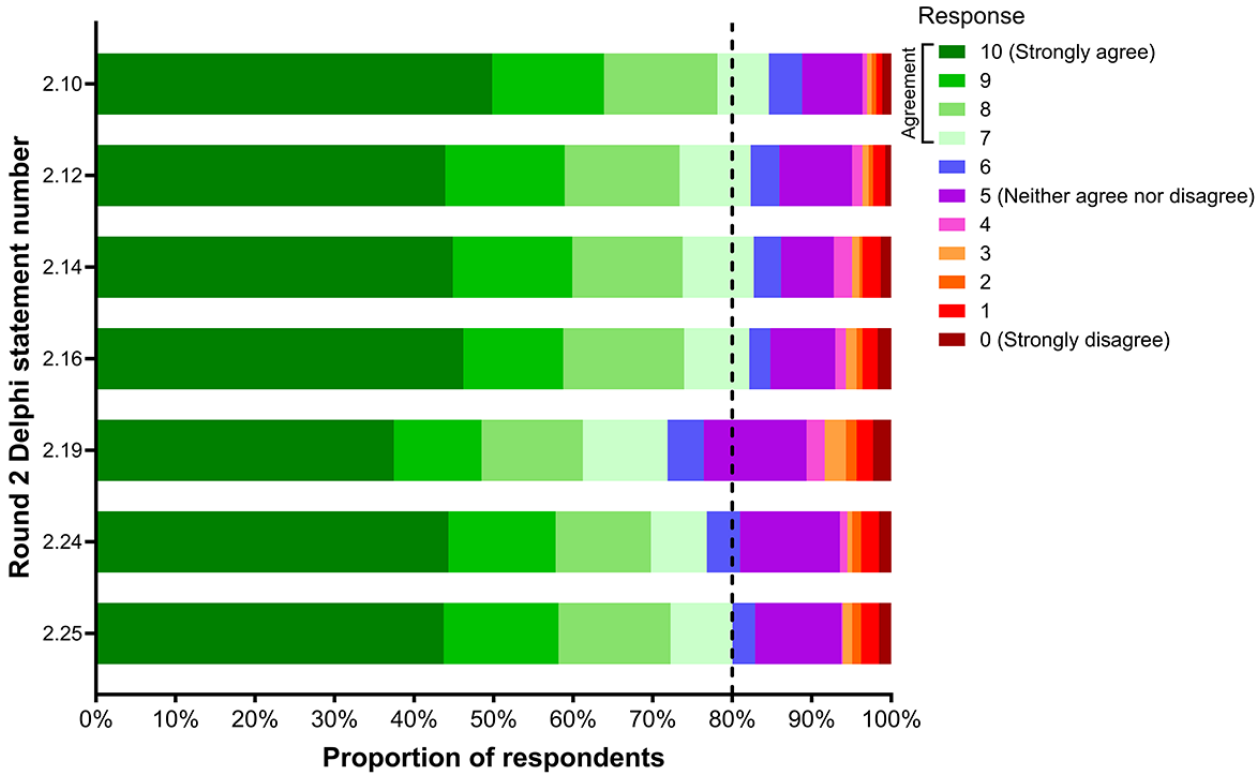
XSL•FO
RenderX

Statement number	Statement	Agreement (%)[a]	Agreement rating[b]	Outcome
1.19	If I was to participate in a remote exercise program I would be happy to do so with a group (eg, exercising by myself at home but while on a video call with other people like me who are also exercising at home, with or without the supervision of a health professional)	45.3	Low agreement	Modify statement for Round 2
1.20	If I was to participate in a remote exercise program to improve my physical function, I would be happy to do so alone without other people like me involved in the exercise sessions (eg, exercising by myself at home with or without supervision by a health professional)	77.3	Moderate agreement	Modify statement for Round 2
1.21	I would be comfortable using technology (eg, computers, smartphones, and tablets) to participate in remote tests and treatments for my physical function	81.5	Strong agreement	Accept
1.22	I would be concerned about the privacy and security of my personal information when participating in remote tests and treatments for physical function using technology (eg, computer, smartphone, or tablet)	20.8	Low agreement	Reject
1.23	Remote physical function tests or exercise programs would be difficult to perform in my home (eg, because there is limited space)	15.5	Low agreement	Reject

[a]Proportion of participants who rated statement ≥7 out of 10.

[b]Statement classification based on the following criteria: Strong agreement (>80% of respondents rated statement ≥7 out of 10); Moderate agreement (70% to 80% of respondents rated statement ≥7 out of 10); Low agreement (<70% of respondents rated statement ≥7 out of 10).

Round 2



Following Round 1, 13 of 23 statements were accepted to have achieved consensus with strong agreement. It was determined that statements 1.22 and 1.23 had such low agreement that they should be rejected rather than modified and presented again in Round 2. Other statements that achieved moderate or low agreement (Statements 1.10, 1.12, 1.14, 1.16, 1.17, 1.18, 1.19, and 1.20) were modified. In brief, Statements 1.10, 1.12, and 1.14 were revised into Statements 2.10, 2.12, and 2.14, respectively. Statements 1.16, 1.17, and 1.18, which covered similar concepts regarding remote exercise supervision, were merged into a single revised statement (Statement 2.16). Statements 1.19 and 1.20 covered similar concepts regarding preferences for participating in remote exercise individually or in a group setting and were revised into a single statement (Statement 2.19). Finally, based on common themes identified in free-text responses to several statements across Round 1, 2 new statements were introduced for Round 2: Statement 2.24 explored the importance for consumers that remote physical function tests have been demonstrated to be safe and accurate, and Statement 2.25 explored the importance of having access to necessary information and resources to support participation in remote exercise programs. Multimedia Appendices 3 and 4 provide further details on the development of Round 2 Delphi statements.

Among participants who completed Round 1, 526 (80%) completed Round 2. No notable differences were observed between the Round 2 and Round 1 respondents, respectively, for age (mean = 69.3, SD 5.7 vs 69.0, SD 6.0 years) or SARC-F score (median 1.0, IQR 0.0-2.0 vs median 1.0, IQR 0.0-2.0). In Round 2, respondents were asked to rate their physical function compared with when they completed the Round 1 survey (mean interval between survey completions was 117.2, SD 21.5 days). The majority (68%) reported that their physical function was neither better nor worse, while 13% reported their physical function was somewhat or much better, and 19% reported that it was somewhat or much worse.

Figure 3 and Table 4 summarize participant responses to the Round 2 Delphi statements. Respondents strongly agreed that they would like access to instructions on how to test their own physical function and monitor changes (Statement 2.10; 85% agreement) and that having access to information on physical function would allow them to have more informed conversations with health care professionals (Statement 2.12; 82% agreement). Respondents also strongly agreed they would be willing to participate in a remote test of their physical function (Statement 2.14; 83% agreement) and to participate in a remote exercise program suited to their preferences at the time (Statement 2.16; 82% agreement). However, there was only moderate agreement that respondents would be willing to participate in remote exercise programs with a group or individually (Statement 2.19; 72% agreement) and that they would be more likely to participate in a remote physical function test if they were confident that the test was safe and accurate to perform alone (Statement 2.24; 77% agreement). Finally, there was strong agreement that respondents would be more likely to participate in a remote exercise program if they had access to necessary information and resources, including technology and exercise equipment (Statement 2.25; 80% agreement).

Table 4. List of Round 2 Delphi statements with levels of agreement and outcome decisions.

Statement Number	Statement	Agreement (%)[a]	Agreement Rating[b]	Outcome
2.10	I would like access to simple and reliable instructions on how to test my physical function myself so that I can monitor how it changes over time	84.6	Strong agreement	Accept
2.12	If I felt I needed help to improve or maintain my physical function, having access to simple information about this (including advice on appropriate health professionals to discuss it with) would help me to have more informed conversations with health professionals about my physical function	82.3	Strong agreement	Accept
2.14	If I felt I needed help to improve or maintain my physical function, I would be willing to participate in a remote test (eg, supervised on a live video call with a health professional or unsupervised using printed instructions and/or video demonstrations provided to me)	82.7	Strong agreement	Accept
2.16	If I felt I needed help to improve or maintain my physical function, I would be willing to participate in a remote exercise program suited to my preferences at the time which may include exercise supervised by a health professional, and/or exercise led by myself	82.1	Strong agreement	Accept
2.19	If I felt I needed help to maintain or improve my physical function, I would be willing to participate in a remote exercise program suited to my preferences at the time which may include exercise performed by myself, and/or exercise performed with a group of people	71.9	Moderate agreement	Reject
2.24	I would be more likely to participate in a remote test of physical function if I was confident that the test was safe and accurate to perform by myself, and I had access to the necessary information and resources, including technology and equipment, to perform the test myself	76.8	Moderate agreement	Reject
2.25	I would be more likely to participate in a remote exercise program if I was confident that I had access to the necessary information and resources, including technology and exercise equipment, to exercise safely and effectively	80.0	Strong agreement	Accept

[a]Proportion of participants who rated statement ≥7 out of 10.

[b]Statement classification based on the following criteria: Strong agreement (>80% of respondents rated statement ≥7 out of 10); Moderate agreement (70% to 80% of respondents rated statement ≥7 out of 10); Low agreement (<70% of respondents rated statement ≥7 out of 10).

Summary of Delphi Outcomes and Recommendations

Five of seven Round 2 statements achieved consensus (ie, ≥80% agreement), and 2 (2.19 and 2.24) were rejected with moderate agreement. Thus, including the 13 statements accepted in Round 1, a total of 18 statements achieved consensus in this Delphi process and provided a basis for the 7 recommendations relevant to health care professionals, researchers, and policymakers developed by the RAMP Working Group and presented in Table 5.

Table 5. Recommendations for remote assessment and management of physical function in older adults.

Recommendation number	Recommendation	Supporting Delphi statements
1	Recognize that physical function is an important health priority for older adults	1.01, 1.02, 1.03, 1.04, 1.05, 1.06
2	Recognize that older adults are aware that it is possible to prevent, delay, and reverse declines in physical function	1.07, 1.08
3	Regularly engage older adults in discussions about their physical function	1.09, 2.12
4	Provide older adults with accessible and reliable information on how to monitor and maintain their physical function	1.11, 1.13, 2.10
5	For older adults who have concerns about their physical function, facilitate physical function assessments in-person and/or remotely considering feasibility and consumer preferences	2.14
6	Facilitate in-person and/or remote exercise programs for improving older adults' physical function considering feasibility, consumer preferences, and supervision requirements	2.16
7	Ensure that older adults participating in remote assessments or exercise for physical function have access to, or are provided with, appropriate support, technology, and/or equipment to perform assessments and exercises safely and effectively	1.15, 1.21, 2.25

RenderX

Discussion

Principal Results

The World Health Organization's global strategy on digital health stresses the importance of person-centered approaches where end users are engaged in the design and development phases of digital health approaches [25]. This consumer-focused Delphi process demonstrated that older adults recognize physical function as a health priority and are generally accepting of remote assessment and management, including the use of digital health approaches. Based on these findings, the RAMP Working Group has developed 7 recommendations for researchers, health care professionals, and policymakers to guide remote assessment and management of physical function.

Comparison with Prior Work

Consistent with previous health care professional surveys showing that assessment and management of physical function are infrequently performed in clinical settings [7], our Round 1 survey demonstrated less than half of older adult respondents had received any health care professional-led assessment or intervention for physical function. Even fewer had participated in a remote physical function assessment (<5%) or intervention (<20%). This is despite almost 60% of respondents having participated in some form of remote care, likely due to increased general digital health use during and since the COVID-19 pandemic [11]. For those respondents who had participated in remote physical function care, several methods were reported, likely influenced by their appropriateness for the desired outcome. For example, video calls were most commonly used for remote physical function assessments whereas written documents were most commonly used for remote interventions. Respondents reported receptiveness to a range of different remote care approaches, and less than 5% stated they would not be willing to participate in any remote care for physical function. Key facilitators for remote care included convenience and flexibility in scheduling, while barriers included lack of guidance and motivation as reported previously [26]. Based on the Delphi statements that achieved consensus, seven recommendations for remote care of physical function in older adults were developed. The above barriers and facilitators should be considered when seeking to implement these recommendations in research, clinical care, and policy. Our findings are consistent with a recent position statement on telehealth policy for older adults, which highlights the need for dedicated policies to address common barriers to telehealth among older adults [27].

Recommendations for Researchers, Health Care Professionals, and Policymakers

Recognize That Physical Function Is an Important Health Priority for Older Adults

Over 97% of respondents strongly agreed physical function was integral to their overall quality of life and their ability to participate in activities with family and friends and in the community, to exercise, and to complete self-care tasks. This recommendation is in line with the World Report on Ageing and Health [28], which emphasizes that maximizing functional ability is a priority for older adults.

Recognize That Older Adults are Aware it Is Possible to Prevent, Delay, and Reverse Declines in Physical Function

Over 86% of respondents strongly agreed that it is possible to slow down or prevent poor physical function and that if someone already has poor physical function, it is possible to improve it. This knowledge may encourage older adults to engage in physical function care [29] and health care professionals should leverage it to promote and implement individually tailored strategies to maintain or improve physical function.

Regularly Engage Older Adults in Discussions About Their Physical Function

Respondents strongly agreed that they would raise concerns about their physical function with health care professionals and that access to information about physical function would help them initiate these conversations. Previous research has highlighted the importance that older adults place on mutual goal setting with health care professionals regarding their physical function [29], and that aligning care with patient priorities can lead to better health outcomes [30]. Health care professionals may require upskilling to ensure effective collaboration with consumers on identifying causes and symptoms of poor physical function and promoting benefits and strategies for maintaining physical function [8].

Provide Older Adults With Accessible and Reliable Information on How to Monitor and Maintain Their Physical Function

In addition to conversations with health care professionals, respondents reported a desire for information on how to independently monitor and maintain their physical function. Previous research has highlighted the importance of providing physical function information and advice to patients [30]. It is necessary to develop and promote appropriate resources that empower older adults to monitor and maintain their physical function.

For Older Adults Who Have Concerns About Their Physical Function, Facilitate Physical Function Assessments In-Person and/or Remotely Considering Feasibility and Consumer Preferences

There is a lack of data on the acceptability and appropriateness of remote physical function assessment [31]. In this study, however, respondents agreed they would be willing to participate in a remote physical function assessment if they were concerned about it. Remote assessment of physical function for older adults can be as reliable as face-to-face assessments [32,33] although further research is required to identify the most appropriate physical function tests, protocols, and communication platforms to support reliable remote physical function assessment, as well as facilitators and barriers to implementation in home and community settings.

Facilitate In-Person and/or Remote Exercise Programs for Improving Older Adults' Physical Function

XSL•FO
RenderX

Considering Feasibility, Consumer Preferences, and Supervision Requirements

Round 1 statements regarding remote exercise programs with set levels of supervision (ie, always, sometimes, or not supervised) or a set format (ie, individual or group-based) achieved only low to moderate agreement, reflecting the varied preferences for exercise among older adults [34]. Remotely delivered exercise programs with varying levels of synchronous and asynchronous exercise may be beneficial for community-dwelling older adults who do not have access to exercise facilities or prefer exercising alone and/or at home [35]. Remote programs can support novel and engaging exercise approaches such as integrating exercise into everyday activities [36], "exercise snacking" [12,13] and gamification [37], and may also incorporate other behavioral and educational interventions such as nutrition counseling [38].

Many medical professionals lack knowledge on exercise prescription [39]. Referral of patients to an exercise professional with experience in supporting older adults to exercise via remote care should be a consideration for clinicians who do not feel qualified to prescribe exercise. Upskilling exercise professionals in effectively delivering exercise via remote care and providing access to requisite resources and equipment is also important to build capacity for remote management of physical function.

Ensure That Older Adults Participating in Remote Assessments or Exercise for Physical Function Have Access to, or Are Provided With, Appropriate Support, Technology, and/or Equipment

Respondents believed it was safe and feasible for them to perform remote physical function assessments and exercise programs, and contrary to previous research [40], had relatively low agreement (<21%) that privacy was a concern. Nevertheless, ensuring remote care is administered by secure technologies and adheres to privacy laws is an important consideration for health care professionals to reduce barriers for those who do have concerns. Most of our respondents strongly agreed that they were comfortable using technology to participate in remote tests and treatments for their physical function. Technological literacy can be a barrier to participation in remote health assessments [26] and further research is required to identify approaches to overcoming technological barriers to remote care. Our results demonstrate that older adults agree that access to appropriate instructions, technology, and equipment would increase the likelihood of participation in remote programs. These findings suggest that older adults can successfully participate in remotely delivered exercise programs if appropriate support is provided. This can include standby technical assistance and technology orientation sessions, especially in the early stages of the program [41]. This support can potentially be integrated into existing funding models to support remote care which have increased internationally, particularly following the COVID-19 pandemic, although further development of policy and reimbursement mechanisms is needed for sustainable integration [42].

Recommendations for Future Studies

Based on the current results, it is recommended that future research, informed by collaboration with consumers, caregivers, health care professionals, and policymakers should focus on, but not be limited to, the following outcomes:

- Identifying and addressing barriers to accessibility of remote physical function assessment and management for older populations, particularly in culturally and linguistically diverse populations, those with socioeconomic disadvantage, those from low-middle-income countries, and/or those with low technology literacy or with limited access to technology
- Determining optimal approaches (including protocols and technologies) to delivering remote care for physical function to ensure validity and reliability of assessments and effectiveness and safety of interventions
- Exploring cost-effectiveness and implementation processes to embed remote care for physical function across varying levels of health care internationally
- Developing evidence-based guidelines and health promotion strategies for remote physical function assessment and management in older adults

Strengths and Limitations

Our modified Delphi study was co-developed with health care consumers and incorporated 2 rounds of iterative and anonymous questionnaires and controlled feedback to create consensus. Our study adhered to quality evaluation metrics for Delphi methodology [22] and included an international population of older adults. A high level of agreement (80%) was set a priori for acceptance of statements. There was low attrition of participants between Delphi rounds (<20%), suggesting the respondents were engaged and interested in sharing their views on physical function assessment and management.

Despite these strengths, there were limitations to our study. Given our survey was electronic, the participants required internet access and were likely technologically savvy, and thus a selection bias may be present. Respondents were from 15 generally high-income countries, with the majority residing in Australia and the United Kingdom, a large proportion (76%) were tertiary-educated, and all were English-speaking. It is not known if results are generalizable to those with lower socioeconomic status and/or non–English-speaking individuals. Our respondents also included a large proportion of women (76%), so it may not accurately reflect the views and experiences of older men. Similarly, less than 5% of respondents were aged 80 years or older, and less than 7% had a SARC-F score ≥4 (symptomatic of poor physical function) [24]. However, comparable SARC-F data in our study (median 1, IQR 0-2, proportion with score ≥4=7%) and other similar cohorts (median 0, IQR 1-2, proportion with score ≥4=6%-15%) [24] suggests the level of poor physical function in our sample is generally representative of community-dwelling older adults. Overall, further research investigating remote physical function care preferences in more diverse populations is required to understand the unique and common barriers, enablers, and needs, which would help to enable more widespread adoption of remote

XSL•FO
RenderX

methods. This should include research in men, non–English speakers, the oldest old, those with poorer health and/or digital literacy, those with poorer access to health care and/or technology, and those with poor physical function. Furthermore, effective strategies to address technology access, digital literacy, and support needs for these vulnerable populations need to be explored. This may include reducing access barriers through device and internet connectivity provision, improving digital health literacy through ongoing human coaching and troubleshooting support, and co-designing content, interfaces, and delivery models with underserved communities [43].

The current study captures respondents' preferences and intentions, but not their behaviors or health outcomes. Future research is therefore needed to evaluate engagement with remote physical function interventions among older adults in the real world, as well as the effectiveness of such interventions for relevant health outcomes. The study was also focused on consumer perspectives and does not capture the perspectives of other stakeholders involved in delivering care to older adults (eg, health care professionals and policymakers), which are critical to translating research into practice. To address this, the RAMP working group has recently completed a Delphi process investigating the views of experts involved in the care of older adults (manuscript under review).

Conclusions

This international consumer Delphi process achieved consensus on 18 Delphi statements, which were synthesized into 7 recommendations for health care professionals, researchers, and policymakers to inform remote assessment and management of physical function in older adults. Further research on the feasibility and integration of remote delivery of physical function assessment and exercise programs is required, and this should be co-designed with older adults and other relevant stakeholders. Furthermore, given the recommendations reflect the sample of predominantly highly educated and digitally literate volunteers from high-income countries, further research is also required to explore their generalizability to more diverse older adult populations.

Acknowledgments

The Remote Assessment and Management of Physical Function in Older Adults Working Group gratefully acknowledges the contributions of all consumer participants of this Delphi process.

Abstract

Background: Aging is a phenomenon accompanied by declines in attention and emotional well-being. Exposure to natural environments has been shown to support cognitive and psychological restoration; however, many older adults face barriers to accessing authentic natural environments. Virtual natural environments may offer an accessible alternative, but evidence from community-dwelling older adults remains limited.

Objective: This study examined the immediate effects of a single-session virtual or actual-nature exposure on attention, mood, and physiological indicators of stress among community-dwelling older adults compared with actual-nature and urban environments.

Methods: A randomized controlled trial with a 3-group, pre-post design was conducted among 120 community-dwelling adults aged 65 years and older in northern Taiwan. Participants were randomly assigned to 1 of 3 groups: a virtual-nature group, an actual-nature group, or an actual-urban environment group. Then, they completed a single 20-minute exposure session. Attentional performance, mood, and physiological indicators were assessed before and immediately after the intervention. Intervention effects were analyzed using generalized estimating equations, focusing on group-by-time interaction effects.

Results: Compared with the urban environment group, the virtual-nature group demonstrated a significantly greater improvement in attentional capacity, as measured by the digit span test (B=1.00, 95% CI 0.19-1.80; *P*=.02), and significant improvements in both positive affect (B=2.82, 95% CI 0.02-5.62; *P*=.048) and negative affect (B=–2.22, 95% CI –4.05 to –0.39; *P*=.02). The actual-nature group showed a significant improvement in positive affect compared with the urban group (B=3.92, 95% CI 1.65-6.19; *P*=.001) but did not demonstrate a significant improvement in attention. No significant group-by-time interaction effects were observed for physiological indicators. No adverse events were reported.

Conclusions: A single 20-minute virtual-nature exposure was associated with immediate improvements in attention and mood among community-dwelling older adults, whereas physiological effects were not detected. These findings suggest that virtual nature may serve as an accessible, short-term restorative strategy, particularly when access to real nature is limited. Larger,

XSL•FO
RenderX

multisession trials with longer follow-ups are needed to evaluate the sustained effects of virtual-nature interventions for mental well-being in older populations.

Introduction

Population Aging and Mental Health Challenges

Population aging is a global phenomenon with profound implications for public health. As life expectancy continues to increase worldwide, a growing proportion of older adults experience age-related declines in cognitive functioning and emotional well-being [1,2]. Even among community-dwelling older adults who do not meet diagnostic criteria for cognitive impairment, subtle reductions in attention and mood are common and may precede more pronounced cognitive decline [3,4]. Consequently, identifying accessible and nonpharmacological strategies to support cognitive and emotional well-being has become a key priority for promoting healthy aging [5]. Although aging-related challenges are shared globally, contextual factors, such as urbanization, living environments, and health care infrastructure, substantially shape older adults' daily experiences [6], underscoring the need for feasible interventions that can be integrated into everyday living contexts [7].

Attention Decline and Attention Restoration Theory

Attention is a fundamental cognitive process that supports goal-directed behavior, information processing, and safe engagement in daily activities [8]. Age-related changes in attentional capacity, particularly those involving frontal brain networks, may compromise older adults' ability to sustain attention and manage competing demands [9,10]. Because attention is essential for overall cognitive functioning, attentional impairments can adversely affect daily activities and social behavior, thereby increasing the risk of falls, unsafe driving, and accidental injuries [11,12]. Natural environments are recognized for providing restorative experiences that promote cognitive, psychological, and physiological well-being, particularly by facilitating attentional recovery [13,14]. Attention restoration theory (ART) provides a theoretical framework that explains how exposure to natural environments may facilitate attentional recovery [15,16]. According to ART, natural environments evoke "soft fascination," allowing directed attention resources to rest and replenish [15]. Empirical studies have shown that exposure to natural settings is associated with improved attentional performance; however, findings remain mixed, particularly in studies using brief exposure durations or heterogeneous attentional measures [16,17]. These inconsistencies underscore the need for carefully designed trials that specifically examine attentional outcomes in older populations.

Mood, Stress, and Stress Reduction Theory

Mood, defined as an individual's emotional state, is a core component of psychological well-being and daily functioning [18]. In addition to attentional changes, older adults frequently experience emotional stress, anxiety, and depressive symptoms, which can negatively affect quality of life and may interact with cognitive decline [19,20]. In a community-based health survey, 36.9% of the adults aged more than 65 years exhibited anxiety symptoms, and 12.1% exhibited depressive symptoms [21]. Stress reduction theory suggests that natural environments elicit an affective response that promotes emotional calm and physiological relaxation through the regulation of the autonomic nervous system [22]. Empirical evidence from systematic reviews shows that exposure to natural or simulated natural environments is associated with reduced psychological distress, increased positive affect, and enhanced mood states [23,24].

Barriers to Real-Nature Exposure and Virtual Nature as an Alternative

Despite the potential benefits of real-world natural environments, many older adults face barriers to accessing nature, including physical limitations, mobility constraints, transportation difficulties, urban density, and public health restrictions [25,26]. These barriers have prompted an increasing interest in virtual-nature interventions, which use immersive technologies to simulate natural environments in accessible, indoor settings [23]. Virtual-nature interventions use immersive digital simulations to recreate natural environments and elicit restorative effects comparable to those of real-world nature [27]. Systematic reviews have demonstrated that virtual-nature exposure can improve attention, cognitive performance, mood, and stress regulation [27,28]. Emerging evidence further suggests that even a single session of simulated nature exposure, lasting between 6 and 20 minutes, may reduce stress and enhance positive emotions and attentional restoration [29-32]. However, most previous studies have focused on younger or middle-aged adults, and evidence regarding the effectiveness of virtual-nature interventions among older adults remains limited [27,28]. In addition, the immediate effects of a single-session virtual-nature exposure on attention, mood, and physiological indicators in older populations are not well established. Moreover, few randomized controlled trials have directly compared virtual nature, actual nature, and urban environments within the same experimental framework among community-dwelling older adults.

To address these gaps, this study aimed to examine the immediate effects of a single-session virtual-nature intervention on attention and mood among community-dwelling older adults in Taiwan. Specifically, we investigated whether virtual or actual-nature exposure would produce greater improvements than exposure to an urban environment. We hypothesized that a single session of virtual or actual-nature exposure would lead

XSL•FO
RenderX

to immediate improvements in attention, mood, and physiological outcomes.

Methods

Study Design

This study used a randomized controlled trial with a 3-group, pre-post design to examine the immediate effects of environmental exposure. The trial was registered at ClinicalTrials.gov (NCT05803460). Participants were randomly allocated to 1 of the 3 conditions: virtual nature, actual nature, or actual urban. Each participant completed a single 20-minute exposure session. Outcome measures were collected at baseline and immediately after the intervention to evaluate changes in attention, mood, and physiological responses.

Participants

Participants were recruited from 6 community care centers in Taipei, Taiwan, between April and October 2023. Eligible participants were aged 65 years or older, had intact global cognitive function as assessed by the Short Portable Mental Status Questionnaire (>8), and were able to communicate in Mandarin Chinese and complete study procedures. Individuals were excluded if they had a diagnosed psychiatric disorder or medical condition that could interfere with study outcomes, severe visual or hearing impairments that would impede participation, or active ocular or dermatologic infectious diseases. The required sample size was determined using G*Power statistical software. Given the repeated-measures design and the primary interest in detecting group-by-time interaction effects, a small-to-medium effect size (Cohen *f*=0.20) was assumed based on an *F* test for ANOVA, as no previous studies using a comparable virtual-nature intervention design were available [33]. The significance level was set at an α of .05, with statistical power of 0.90. On the basis of these parameters, a total sample size of 84 participants was considered sufficient to detect overall intervention effects. After accounting for an anticipated 20% attrition rate, the minimum required sample size was increased to 105 participants; ultimately, 120 participants were enrolled.

This randomized controlled trial used computer-generated block randomization with a block size of 6. The allocation sequence was generated by a research team member who was not involved in participant recruitment or assessment. As participants were enrolled, the corresponding sequence numbers were placed individually into opaque, sealed envelopes to ensure allocation concealment. A separate research team member opened each envelope sequentially to assign participants to 1 of the 3 groups: the virtual-nature group, the actual-nature group, or the actual-urban group, with 40 participants allocated to each group.

Intervention

Participants assigned to the virtual-nature group viewed a 20-minute immersive video of a natural environment filmed by the research team. This duration was selected based on previous evidence indicating that 10 to 20 minutes of virtual-nature exposure can improve attention and emotional outcomes in older adults [29,31]. The 360° panoramic video was recorded in a natural park in Taipei, a location commonly visited by older adults for its safe walking paths. Filming was conducted under stable weather conditions to minimize visual distractions and ensure ecological validity. The footage was captured using an Insta360 ONE R dual-lens camera, edited using standard audiovisual software, and structured into two 10-minute segments. In line with previous virtual-nature protocols for older adults, no interactive features were included to maintain a passive, restorative experience [34]. The video was delivered using a lightweight head-mounted display (HTC VIVE Flow). Before the session, participants received brief instructions encouraging them to observe in a relaxed manner. Each participant remained seated throughout the 20-minute exposure. For hygiene and safety, all equipment was disinfected after use, and disposable virtual reality (VR) face pads were provided.

Participants in the actual-nature group completed a 20-minute real-world exposure session at the same natural park featured in the virtual intervention. Upon arrival, participants rested for 10 to 15 minutes to acclimate. They were then seated in a safe, shaded location and instructed to observe their surroundings in a calm and relaxed manner.

Participants in the actual-urban group underwent a 20-minute observation session in a nearby urban area selected for safety and accessibility. As with the other groups, participants rested for 10 to 15 minutes before beginning the session and were seated during the exposure period, observing the environment in a relaxed state.

Outcomes

Overview

At baseline, participants completed a questionnaire assessing demographic characteristics (age, sex, years of education, and marital status); health-related variables (BMI, blood pressure, exercise habits, sleep quality, and comorbidities); and time spent in natural environments. Additionally, perceived restorativeness was assessed after the intervention using the Perceived Restorativeness Scale [35]. The primary outcomes were attention and mood. The secondary outcomes were physiological indicators of stress.

Attention

Attention was assessed using the digit span test (DS) and the trail making test (TMT), which capture multiple dimensions of attentional functioning, including attentional span, orienting, and sustained attention. The DS includes 2 subtests: digit span forward (DSF) and digit span backward (DSB). In both tasks, participants were asked to immediately repeat digit sequences read aloud by the assessor, with testing discontinued after 2 consecutive errors. A total DS score was calculated by summing DSF (range 0-16) and DSB (range 0-14), with higher scores indicating better attentional capacity. The Chinese versions of DSF and DSB demonstrate acceptable sensitivity (0.62 and 0.77) and specificity (0.65 and 0.78), respectively [36]. The TMT assessed orienting and sustained attention and consisted of 2 parts. In part A, participants connected numbered circles (1-25) in ascending order, and in part B, they alternated between numbers (1-13) and letters. Performance was scored based on completion time, with longer times indicating poorer attention.

XSL•FO
RenderX

The TMT has demonstrated strong reliability and validity as a measure of attentional processes [37].

Mood

Mood was assessed using the Positive and Negative Affect Schedule (PANAS), which evaluates 2 dimensions of affective states: positive affect (eg, enthusiasm and alertness) and negative affect (eg, distress and fear). The PANAS consists of 20 items, each rated on a 5-point Likert scale ranging from 1 ("very slightly or not at all") to 5 ("extremely"). Higher scores indicated greater intensity of the respective affective states. The PANAS has demonstrated high internal consistency, with Cronbach α coefficients ranging from 0.86 to 0.90 for positive affect and 0.84 to 0.87 for negative affect [38].

Physiological Indicators of Stress

Physiological parameters were assessed using a wrist-worn autonomic monitoring device (ANSWatch, Taiwan Scientific Corporation; approved by the Taiwan Ministry of Health and Welfare, medical device permit number 001525). The device measured heart rate (HR), systolic blood pressure (SBP), diastolic blood pressure (DBP), and indices of sympathetic nervous system and parasympathetic nervous system activity. HR variability (HRV) indices were derived from normal-to-normal RR intervals. High-frequency (HF) power was used as an indicator of parasympathetic activity, whereas low-frequency (LF) power reflects combined autonomic influences. The LF/HF ratio was reported as an index of autonomic balance [31]. To reduce potential confounding, participants were instructed to avoid stimulant beverages (eg, tea or coffee) for at least 2 hours before measurement. All assessments were conducted while participants were seated comfortably in a relaxed position. Each HRV measurement required approximately 6 minutes.

Procedure

Following approval from the institutional review board, community-dwelling older adults were recruited from 6 community health stations in Taipei City from April 2023 to October 2023. Station staff first identified and approached potential participants. Individuals who expressed interest were contacted by the research team for eligibility screening. After written informed consent was obtained, baseline assessments were conducted, including attention tests, mood questionnaires, and physiological measurements (HR, SBP, DBP, and HRV).

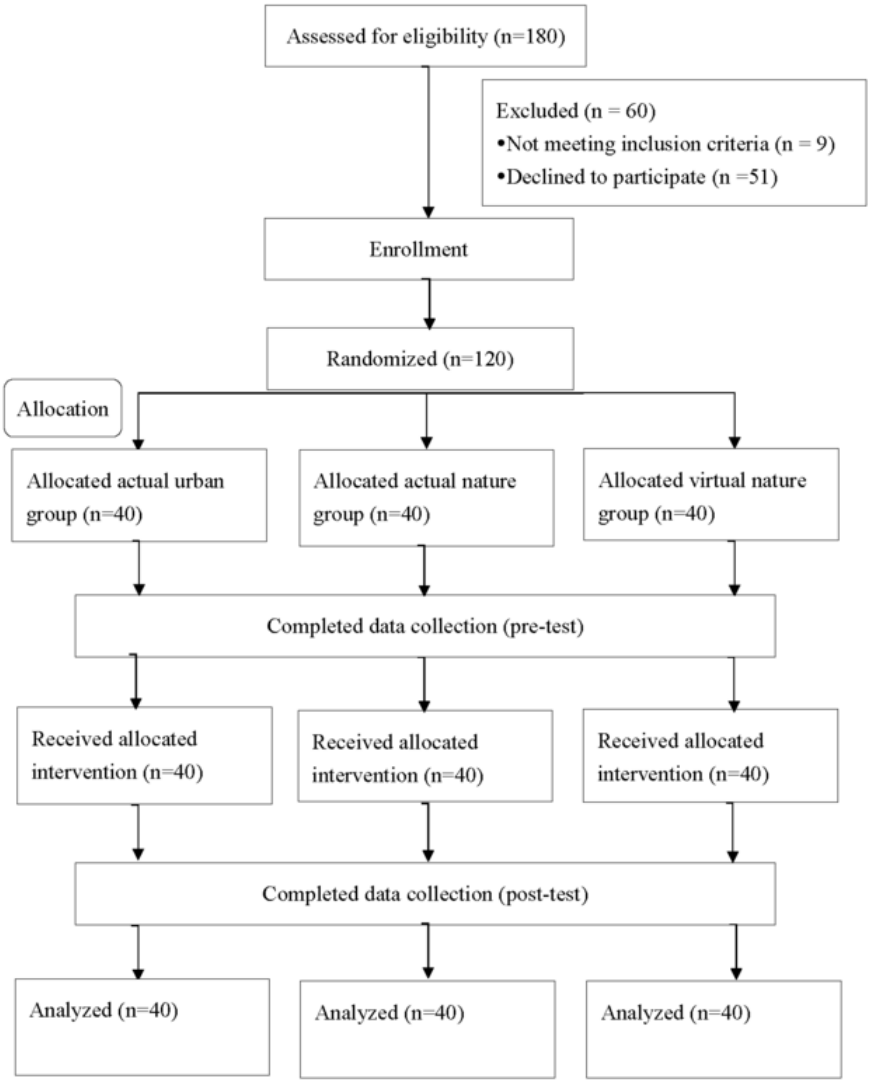
Participants were then exposed to 1 of the 3 assigned conditions (virtual nature, actual nature, or actual-urban environment) according to the randomized allocation sequence. A trained research assistant provided standardized instructions and supervised the 20-minute exposure session. Immediately after the intervention, participants completed the posttest assessments, which included physiological measurements, attention tests, and questionnaires. Participants were monitored for discomfort before the posttest assessment was initiated. The entire procedure required approximately 60 minutes per participant. All data were collected by a trained research assistant to ensure standardized administration of assessments and measurement reliability.

Ethical Considerations

The study protocol was reviewed and approved by the institutional review board at National Yang Ming Chiao Tung University (YM111067). Written informed consent was obtained from all participants after they received a full explanation of the study purpose, procedures, potential risks, and expected benefits. Participants were informed that their involvement was voluntary and that they could withdraw from the study at any time without consequence. All members of the research team completed the required human participant protection training and certification before data collection began. A small gift was provided as appreciation for participation.

Data Analysis

Data were analyzed using SPSS (version 25.0; IBM Corp). Descriptive statistics (means, SDs, frequencies, and percentages) were used to summarize participant characteristics and baseline variables. Intervention effects over time were analyzed using generalized estimating equations (GEEs) with an exchangeable working correlation structure and robust SEs. Group-by-time interaction effects were examined. In accordance with the CONSORT (Consolidated Standards of Reporting Trials) 2010 extension for multiarm randomized controlled trials (item 12a) [39], exploratory pairwise comparisons between each of the 2 intervention groups (virtual nature and actual nature) and the control group (urban environment) were conducted without adjustment for multiple comparisons. Baseline group differences and postintervention perceived restorativeness were examined using One-way ANOVA for continuous variables and the chi-square test for categorical variables. One-way ANOVA revealed a significant difference in postintervention perceived restorativeness scores among the 3 groups (P<.05). Post hoc analyses using the Tukey honestly significant difference test indicated significant between-group differences. A 2-tailed P value <.05 was considered statistically significant.



Results

Overview

A total of 180 invitation letters were distributed to community-dwelling older adults. Of these, 9 (5%) individuals did not meet the inclusion criteria, and 51 (28.3%) declined to participate. A total of 120 (66.7%) older adults agreed to participate, completed the study procedures, and were included in the final analysis (Figure 1). No adverse events or intervention-related discomfort was reported during the study.

XSL•FO
RenderX

Figure 1. Flow diagram of the study.

Sample Characteristics

A total of 120 community-dwelling older adults participated in this study. The mean age was 72.6 (SD 4.1) years, and most were female (n=97, 80.8%). Participants had an average of 10.2 (SD 2.8) years of formal education, and 79 (65.8%) were married. The mean BMI was 23.1 (SD 3.4) kg/m^2. Most participants reported regular exercise (n=103, 85.8%), and more than half (n=70, 58.3%) perceived their sleep quality as poor. The most common chronic conditions were hypertension (n=49, 40.8%), hyperlipidemia (n=50, 41.7%), and diabetes (n=33, 27.5%). Regarding exposure to natural environments, 83 (69.2%) participants reported spending less than 1 hour per month in natural settings. Group comparisons showed no significant baseline differences in demographic or health-related characteristics, including age, sex, education, marital status, BMI, blood pressure, exercise habits, number of chronic conditions, or monthly nature exposure. However, a significant between-group difference was observed in perceived restorativeness. Post hoc analyses indicated that the virtual-nature group (P=.01) and the actual-nature group (P=.001) both reported significantly higher restorativeness scores than the actual-urban group (Table 1).

Attention

GEE analyses revealed a significant overall group-by-time interaction for total DS scores (Wald χ^2_2=6.28; *P*=.04). Specifically, the pre-post improvement in attentional capacity was significantly greater in the virtual-nature group than in the actual-urban group (B=1.00, 95% CI 0.19-1.80; *P*=.02), indicating a greater increase in DS performance following exposure to virtual nature. The corresponding contrast between the actual-nature and actual-urban groups was not statistically significant. No significant overall group-by-time interaction effects were observed for performance on the TMT Part A (Wald χ^2_2=2.07; *P*=.36) or TMT Part B (Wald χ^2_2=1.90; *P*=.39) between the virtual-nature and actual-urban groups. Additionally, neither the virtual-nature group nor the actual-nature group showed significant improvements in attentional performance compared with the actual-urban group following the intervention (Table 2).

[a]The generalized estimating equation analysis was conducted using the actual-urban group as the reference group; an omnibus Wald χ^2_2 test was first conducted for each outcome to evaluate the overall group-by-time interaction. Wald χ^2_1 tests were subsequently used to estimate individual group-by-time contrasts (virtual nature vs actual urban and actual nature vs actual urban).

[b]Not applicable.

[c]TMT: trail making test.

[d]PANAS: Positive and Negative Affect Schedule.

Mood

Significant overall group-by-time interaction effects were observed for both positive affect (Wald χ^2_2=11.46; *P*=.003) and negative affect (Wald χ^2_2=6.05; *P*=.049). Compared with the urban environment group, the virtual-nature group demonstrated significantly greater improvements in both positive affect (B=2.82, 95% CI 0.02-5.62; *P*=.048) and negative affect (B=–2.22, 95% CI –4.05 to –0.39; *P*=.02). These findings indicate that exposure to virtual nature produced more pronounced mood-enhancing effects than the urban condition. In addition, the actual-nature group showed a significantly greater improvement in positive affect compared with the urban environment group (B=3.92, 95% CI 1.65-6.19; *P*=.001), whereas changes in negative affect did not reach statistical significance.

Physiological Variables

GEEs analyses indicated that no significant overall group-by-time interaction effects were observed for any physiological indicators, including HR, SBP, DBP, LF, HF, or the LF/HF ratio (all omnibus Wald χ^2_2 tests; *P*>.05). Consistent with these findings, pairwise group-by-time contrasts showed no significant differences in pre-post changes between the virtual-nature and actual-urban groups or between the actual-nature and actual-urban groups (all Wald χ^2_1 tests; *P*>.05; Table 3).

Discussion

Principal Findings

This randomized controlled trial examined the immediate effects of a single-session virtual-nature exposure on attention, mood, and physiological indicators among community-dwelling older adults. The preliminary findings suggest that, compared to an urban environment, a single 20-minute exposure to virtual nature is associated with greater short-term improvements in attentional capacity and mood. Actual-nature exposure was associated with improved positive affect but did not produce significant attentional benefits. No significant physiological changes were observed across groups. These findings suggest that virtual nature may provide immediate cognitive and emotional benefits in older adults, particularly when access to real-world nature is limited. However, the observed effects were task and domain specific and should be interpreted cautiously within the context of a brief, single-session intervention.

Participants in the virtual-nature group demonstrated a statistically significant improvement in attentional span compared with those in the urban group. This result differed from several previous studies that reported nonsignificant effects of virtual-nature exposure on attention [31,40]. Differences in study design, attention assessments, sample characteristics, intervention duration, and limited statistical power may explain these inconsistent findings. Previous studies often relied on a single attention measure, such as the Sustained Attention to Response Test, which may not adequately capture the

XSL•FO
RenderX

multifaceted nature of attention across environmental contexts [31]. Because distinct environments may engage different attentional components, the use of a single tool may limit sensitivity to change. This study used a multidimensional assessment approach, including the DS and TMT, to evaluate selective attention, sustained attention, and attentional span. This comprehensive measurement strategy may have enhanced the ability to detect subtle yet meaningful changes in attention following environmental exposure [14].

Improvements in attention were observed only in the DS and not in the TMT. This task-specific pattern may reflect differences in cognitive demands and sensitivity to short-term restorative effects. The DS primarily assesses attentional capacity and working memory [36], which may be more responsive to brief environmental restoration. In contrast, the TMT involves additional components, such as visual scanning, psychomotor speed, and executive control [37], which may require longer or repeated interventions to demonstrate measurable change. It is also noteworthy that the virtual-nature group had slightly lower baseline DS scores than the other groups, raising the possibility of a ceiling effect in the comparison groups [41]. Although the analyses focused on group-by-time interaction effects, baseline differences in performance may have influenced responsiveness to the intervention. Practice effects may also contribute to the absence of significant between-group differences in TMT performance [42]. Together, these findings highlight the importance of considering task characteristics and baseline performance when interpreting attention outcomes in environmental intervention studies.

Another explanation for the divergent findings may relate to differences in intervention duration and participant characteristics. This study used a single 20-minute session, whereas previous studies typically administered shorter 10-minute exposures in middle-aged and older adults [31] and younger adult samples [43]. Variations in exposure duration may influence the extent of attentional restoration achieved. In addition, because participants in this study were all aged 65 years or older, they may have been more responsive to restorative stimulation, as age-related declines in attentional capacity could increase susceptibility to the benefits of natural environments [44].

Both virtual and actual-nature exposure were associated with improvements in positive affect, with virtual nature additionally demonstrating reductions in negative affect. These results are consistent with previous research involving mixed middle-aged and older populations [31,45] and extend existing evidence by demonstrating similar effects in community-dwelling adults aged 65 years and older. These findings are broadly consistent with stress reduction theory, which posits that natural environments elicit affective responses that promote emotional calm and psychological well-being [22]. The emotional benefits observed following a single session suggest that even brief exposure to nature-related stimuli may have a positive influence on mood in older adults. The concurrent improvement in attention and mood in the virtual-nature group also aligns with ART [15,16], as emotional relaxation may facilitate the recovery of attentional resources. However, the absence of attentional benefits in the actual-nature group suggests that the relationship between environmental exposure and cognitive outcomes may depend on contextual factors, such as environmental familiarity, attentional engagement, and individual expectations.

A unique strength of this study was the use of locally familiar natural settings, which may have enhanced both the ecological relevance and acceptability of the intervention. Although most participants had no previous experience with VR, previous research suggests that Taiwanese older adults generally perceive VR as useful, enjoyable, and easy to use for supporting active aging [46]. Such positive attitudes may have facilitated greater immersion and engagement with the virtual natural environment.

Contrary to the initial hypothesis, no significant changes in physiological indicators of stress, including HRV and blood pressure, were observed over time between the virtual-nature and urban groups or between the actual-nature and urban groups. Thus, the findings are consistent with previous research reporting similar null effects [31,45]. Several factors may account for these results. First, the single 20-minute intervention may have been insufficient to elicit detectable changes in the autonomic nervous system, particularly in older adults. Second, most participants (102/120, 85%) had no previous experience with VR, and novelty-induced arousal associated with first-time VR exposure may have transiently increased sympathetic activation [47,48], potentially masking relaxation-related physiological responses.

Limitations

Several limitations should be acknowledged. First, the sample comprised predominantly female, community-dwelling older adults recruited from urban areas in northern Taiwan. This demographic profile may limit the generalizability of the findings to male older adults, individuals living in rural settings, those with mobility limitations or limited familiarity with technology, and older adults from different cultural contexts. Future research should explicitly examine the feasibility and effectiveness of the intervention in more diverse and vulnerable older populations. Second, this study was designed as a preliminary, exploratory investigation of immediate effects. Guided by feasibility considerations and real-world conditions, this study used a single-session intervention design and included an urban environment as a comparison group. Future research is recommended to conduct larger-scale trials with multiple intervention sessions and to incorporate additional no-exposure control conditions to further validate the findings. Third, most (102/120, 85%) participants in this study had no previous experience with VR. As a result, the observed effects may partially reflect VR-related factors, such as novelty or immersion, rather than the natural content alone, particularly with respect to physiological outcomes (eg, HRV). In addition, this study included only a single VR condition and did not incorporate formal measures of presence or engagement, which limits the interpretation of the underlying mechanisms of the observed effects. Future research should use multiple VR control conditions and incorporate validated measures of presence or immersion to strengthen the evidential support for the validity of the intervention. Finally, the study sample consisted of older adults who were able to participate in community activities,

XSL•FO
RenderX

excluding those with limited mobility. Future studies should include mobility-impaired older adults to further evaluate the feasibility, accessibility, and effectiveness of virtual-nature interventions in broader older populations.

Conclusions

The findings of this study provide evidence that a single 20-minute virtual-nature exposure can yield immediate improvements in attention and mood among community-dwelling older adults, whereas physiological effects were not detected. Virtual nature may represent a feasible and accessible short-term restorative strategy, particularly for older adults facing barriers to accessing real-world natural environments. Future research using multisession interventions, larger and more diverse samples, additional control conditions, and longitudinal follow-up is needed to clarify sustained effects and underlying mechanisms.

Abstract

Background: Aging is a pressing global issue, and older adults need to build up their knowledge to manage their health. Insufficient self-efficacy and low acceptance of technology hinder their ability to use emerging technologies for self-management.

Objective: This study explored the potential of generative artificial intelligence (GenAI) videos in the health management of older adults.

Methods: We developed a video-based GenAI prototype, AIHealthV. This study used a mixed methods approach, enrolling 20 older adult participants (aged 60 to 80 years) in 3 rounds of iterative workshops. Data collection included pre- and postquestionnaires, in-depth interviews, prompt text records, and the generated video content. Qualitative data were analyzed using the 6-stage reflexivity thematic analysis method by Braun and Clarke, and quantitative data were analyzed using the Wilcoxon signed-rank test.

Results: The findings revealed that GenAI videos can enhance older adults' self-efficacy and technology acceptance, reduce cognitive load, and simultaneously meet their health management needs. The multimodal content generated by GenAI makes health information more comprehensible and thus improves the accessibility of health knowledge. Following the workshop, the interaction between older adults and AIHealthV exhibits a trend of exploration, adaptation, and verification.

Conclusions: Despite ethical, privacy, and usability concerns, AIHealthV has been proven to be beneficial in improving the health management capabilities of older adults. This paper also provides practical insights for developing artificial intelligence health tools tailored to older adults as GenAI tools continue to prevail.

KEYWORDS

generative AI; GenAI videos; older adults; health self-management; mobile phone

Introduction

With the acceleration of global aging, the World Health Organization projects that the worldwide population aged 65 years and older will increase to 1.5 billion by 2050 [1]. Physiological declines associated with aging, including deteriorating physical functions, sensory impairments, and memory loss, alongside this increase, have increased older adults' needs for self-health management, particularly in disease prevention, health monitoring, and chronic disease management [1]. Technology offers opportunities to support self-management; however, research has found that older adults encounter significant difficulties in accessing printed or online health information, particularly in technologically complex and information-overloaded environments [2]. Technology-enabled precision health information, for example, on-demand generation

XSL•FO
RenderX

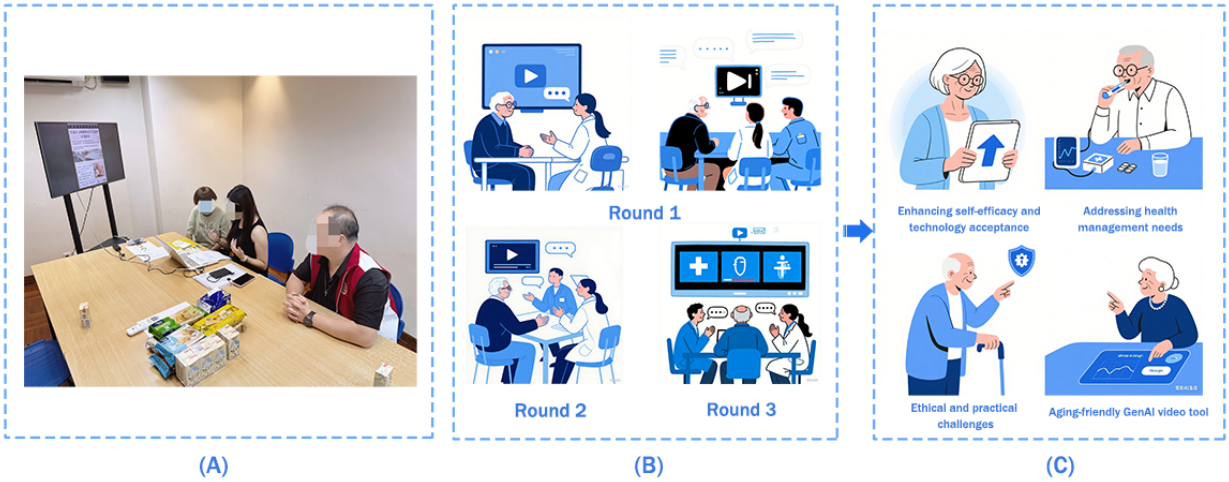
of health educational content, can improve older adults' health management and decision-making abilities [3]. The rapid development of artificial intelligence (AI) sheds light on the generation of tailor-made information for older adults' self-health management.

Older adults are gradually emerging as a significant user group of digital health technologies, which enable them to access health-related information and resources on time, thereby facilitating better health management and chronic disease control [4]. Accessing health knowledge through digital technologies not only enhances older adults' health management capabilities but also strengthens their sense of technological control [5]. However, their persistent reliance on traditional health knowledge acquisition channels (eg, printed materials, doctor visits, or face-to-face classes) also limits the potential of digital technologies in this domain [6]. Studies indicate that some seniors use AI voice assistants (eg, Amazon Echo and Google Home) to access health information [7]. In contrast, others rely on AI conversational agents and robotic systems for health-related queries [8]. Despite their potential, text- or image-based health AI applications often present interaction challenges for older users due to limited comprehension abilities or complex interfaces [9]. Complicated operations and navigation structures further hinder adoption [2]. Additionally, concerns about data privacy and security are prevalent among older adults when using AI [10], with technological distrust potentially reducing acceptance [11].

The capabilities of generative artificial intelligence (GenAI) to create on-demand informational material in a variety of formats, including text, video, or images, offer new opportunities for tailored digital education [12]. The emergence of GenAI has opened new avenues for efficient health knowledge dissemination and precision personalized education [13]. Furthermore, GenAI's capacity for dynamic content modification and optimization enhances the quality and user adaptability of health knowledge outputs through iterative refinement [14]. AI-generated health videos offer high flexibility and adaptability, enabling the creation of personalized video content based on user backgrounds, such as educational level and health needs, such as disease prevention or treatment decision-making [15].

GenAI is revolutionizing the creation and dissemination of health information, particularly in producing high-quality, dynamic content. Personalized health videos generated by GenAI have been preliminarily applied in patient education and health promotion, such as disease-specific tutorials [16]. GenAI technologies can dynamically generate personalized, easily comprehensible health information, particularly through video, a visually rich medium that compensates for the interpretive challenges of text-based content [17]. These videos dynamically tailor information to user needs, outperforming static content in engagement. Videos as a form of educational materials can improve adults' self-efficacy and reflect their critical thinking skills [18], but this is not necessarily true for older adults. Beyond dynamic generation, GenAI's capacity for scenario-specific personalization enhances its utility in health education [19]. Furthermore, generative models integrated with sentiment analysis (eg, detecting user satisfaction or confusion) can swiftly identify older adults' preferences for video design and functionality, optimizing information delivery [20]. GenAI's capacity for dynamic content modification and optimization enhances the quality and user adaptability of health knowledge outputs through iterative refinement [14]. By combining GenAI with user-driven optimization, health communication strategies for older adults can be refined more effectively [21].

While technology offers many opportunities, declines in information processing speed, sensory functions, and memory capacity create numerous barriers for older adults in accessing and comprehending health information via digital technologies [2]. Additionally, research reveals that older adults exhibit deeper fears regarding data security and potential privacy breaches, which further hinder their access to and use of emerging internet-based digital health management tools [22]. Technophobia and heightened concerns about usability and privacy issues represent significant barriers to the adoption of digital health among older adults [12]. These factors contribute to the challenges of promoting the use of AI technologies in general.



Self-efficacy plays a fundamental role in older adults' use of digital health technologies. According to the social cognitive theory by Bandura [23], an individual's belief in their ability to perform specific tasks influences their willingness to try and persist with new behaviors. In the context of technology adoption, Kim [24] found that older adults with higher technological self-efficacy showed greater persistence when facing initial usage difficulties. The development of technological self-efficacy in older adults follows unique patterns. Unlike younger users who typically acquire digital skills through independent exploration, older adults usually benefit more from organized, guided learning experiences [25]. Schroeder et al [26] emphasized that successful skill-building interventions for this population should include progressive challenge advancement, immediate feedback mechanisms, and opportunities for mastery experiences, which have been proven to enhance self-efficacy [27]. This self-efficacy then becomes a key determinant of technology acceptance. The perceived ease of use (PEOU) influences adoption decisions, especially for older adults who may view technological interfaces as complex [28]. Research by Malureanu et al [29] shows that enhanced self-efficacy directly improves perceived usefulness (PU) and ease of use, the 2 core elements of technology acceptance. This relationship creates a positive feedback loop: as older adults gain confidence through successful experiences, their willingness to adopt more advanced features increases [30]. The interaction between self-efficacy and acceptance has important practical implications. GenAI offers the potential for high self-efficacy, through simple interaction, for older adults, a potential that merits further exploration.

Static output modes in video generation tools neglect user feedback, failing to adapt interactively for maximal information retention. While this approach has theoretical benefits for older adults, these benefits warrant empirical analysis as in this paper. In this paper, we use "GenAI" to refer specifically to its use in creating health promotion videos. The usefulness of this application in supporting health education for older adults is currently underexplored. Figure 1 is a summary of this paper:

XSL•FO
RenderX

Figure 1A shows that workshops were implemented through the following process to obtain requirements from the participants. Prompts and health videos were generated collaboratively between participants and researchers. Figure 1B shows that 3 rounds of videos were generated in a session. Videos were regenerated, discussed, and evaluated in each round. Figure 1C shows key research findings.

Figure 1. Summary of this paper. GenAI: generative artificial intelligence.

To systematically explore the potential of GenAI videos in supporting older adults' health management, this study addresses three key research questions: (1) How can AI-generated videos create an impact on older adults' health management? (2) What is the role of AI-generated videos in the health management processes of older adults? (3) What are the issues and concerns faced by older adults when using GenAI technologies?

Methods

Ethical Considerations

This study was approved by the Human Ethics Committee of Macao Polytechnic University (HEA006-FCA-2025). All procedures followed the guidelines of the principles of the World Medical Association Declaration of Helsinki. All participants provided written explicit informed consent before participation. All data were deidentified. Before the data collection began, the consent form was obtained through an offline paper-based method, and participants were informed about the voluntary nature of this study and their right to withdraw at any time without penalty or loss of benefits. All participant data and visual materials (including figures, video samples, and prototype interface screenshots) in this manuscript have been fully deidentified to eliminate any identifiable personal information, strictly adhering to privacy and confidentiality protection requirements. To ensure the accuracy and safety of generated content, community workers who worked at the community center where this study was conducted were invited to the workshops. They conducted manual reviews of GenAI-generated videos, focusing on verifying the accuracy of health information and mitigating the risk of misleading information. Specifically, these reviews occurred at two critical checkpoints: (1) immediately after the initial script and plot generation to flag potential medical inaccuracies, and (2) after the final video rendering to ensure visual-audio alignment and content safety. All videos required confirmation by community workers to ensure that they did not violate any scientific medical knowledge before they were presented to participants. Additionally, before the workshops, participants were explicitly informed that "AI-generated content should be used in conjunction with professional advice," and the consent form emphasized the limitations of GenAI and the potential of inaccurate information. Participants voluntarily signed up for the workshops and chose a suitable timeslot. They did not receive any additional compensation, but snacks and drinks were provided in the workshop.

Prototype Development

We developed a prototype of a GenAI video tool tailored to older adults, named AIHealthV. This prototype allowed us to customize GenAI for better meeting older adults' needs for health management. For example, AIHealthV integrated voice input and keyword suggestions to reduce the barrier for content creation, as many older adults were reluctant to type; video outputs supported adjustments, including playback speed and voice selection, as well as subtitle fine-tuning with adjustable font sizes. These usability considerations were considered crucial for carrying out our study successfully with the older adult cohort.

For the technical implementation of this prototype, we integrated different software libraries as they have separate functions. The video generation application was built using Python (version 3.12; Python Software Foundation; for the backend) and React (version 18.2; Meta Platforms, Inc; for the frontend), which interconnects with SiliconFlow AI services for image and video generation. The default video length was set to 3-5 minutes, with output parameters optimized for high-contrast mobile viewing to suit the visual needs of older users. The prototype also featured a prompt generator embedded with preloaded health templates (eg, hypertension management and sleep improvement), which leveraged the GPT-4o (OpenAI) model for script generation.

The prompt template followed the structure with content of the role, background, health issue, and constraint, for example, "I

XSL•FO
RenderX

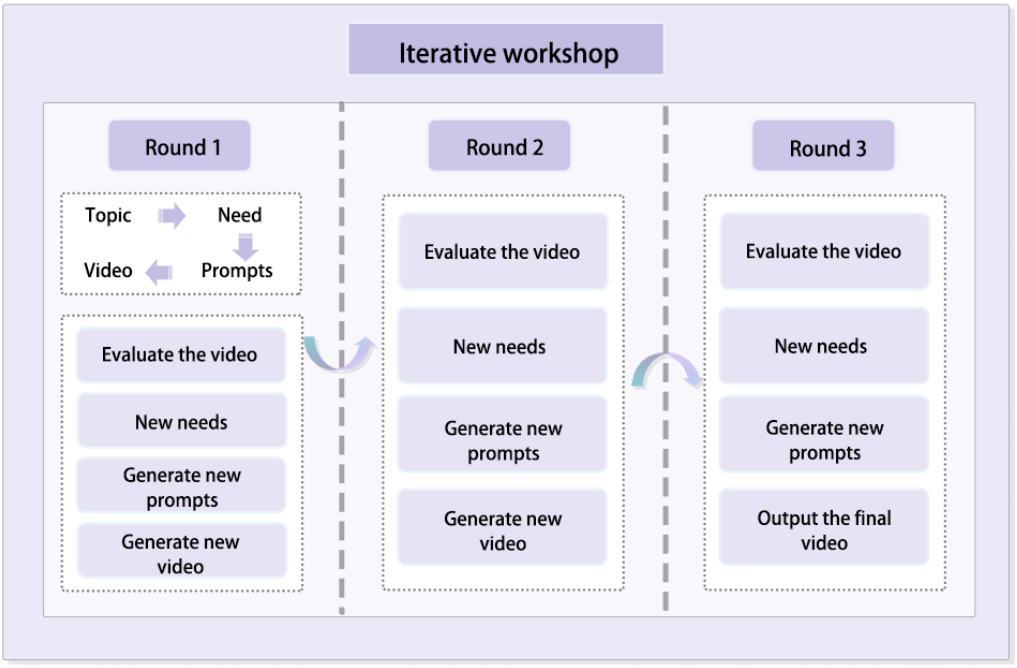
am 70 years old with diabetes and want to learn about a sugar-controlled healthy diet, focusing on [specific constraint].” In this way, the video plots and transcripts generated by the prototype were more health-related and accurate. Furthermore, to make the prototype more trustworthy and encourage older adults to share their health concerns, we used a friendly, human-like voice for feedback with a simplified and conversational interface instead of a technical one. These human-centric design elements help reduce the anxiety that older adults might feel when using the new technology, making them more willing to “talk” to the AI and disclose their real health needs [31].

The user interface design adopts a step-by-step guidance process: (1) a multimodal interactive input area supporting voice and text input, which is used to generate video plots; (2) the output of video plots which are used for video generations, and the content can be modified for fine-tuning video output; (3) a video preview area including multiple alternative videos; (4) features for adjusting elements such as voice, speed, volume, and subtitle size; and (5) generic functions such as settings, saving, and sharing. Figure 2 demonstrates the design of AIHealthV.

Figure 2. The prototype for generating health-related videos with GenAI. GenAI: generative artificial intelligence.

Participant Recruitment

With the assistance of community partners, we recruited 24 older adults aged 60 years and older from nearby communities through offline posters to participate in an iterative workshop. The inclusion criteria used were that participants were 60 years of age or older and had the basic operational ability to use smart devices such as smartphones and tablets. Of the 24 recruited participants, 4 were excluded from the final analysis: 3 withdrew before the pretest due to sudden scheduling conflicts, and 1 failed to complete the full iterative workshop rounds due to physical fatigue. Ultimately, results from 20 participants were included in this study. The purpose of this sample selection is to consciously focus on different population characteristics, such as the different levels of education, living conditions, and health needs (such as high blood pressure, joint health, and sleep disorder) of participants, to maximize the reliability of the information. All participants expressed motivation and a need to use GenAI and health videos for better self-health management. Participants had a range of health conditions (chronic disease, good health, and mild illness) and lived in a variety of residential situations (eg, living alone, with family, or in a nursing facility). In addition, community workers also participated in this study. They worked in community-based health, had a basic understanding of personal health management, and had experience assisting older adults with technology tools. It is the role of community workers to professionally review the content generated by GenAI to effectively circumvent the risk of AI generating erroneous or inaccurate medical information, thereby ensuring the safety and reliability of all discussed information.



Procedure

Each workshop lasted for about an hour for a single participant and consisted of three phases: (1) pretest, (2) iterative workshop, and (3) posttest. The pretest phase (about 20 minutes) used questionnaires and interviews to collect participants’ subjective evaluations regarding health knowledge needs, technological proficiency, and self-efficacy. In addition, each participant received a 15-minute introduction to the fundamental principles of GenAI and our prototype for video generation. Then, the iterative workshop was carried out with the following procedure

XSL•FO
RenderX

(Figure 3). First, participants identified health topics based on personal interests and articulated their requirements across 5 video dimensions (visual, auditory, narrative, cognitive, and emotional) [32], which were then translated into prompts for video generation by the researcher to produce the first video. Second, after each video generation, community workers reviewed the content and flagged potential issues in the video (eg, incorrect medical advice or misleading claims) if there were any. This step was put in place to ensure discussions were grounded in reliable information. Finally, participants then reviewed the initial video generated by AI, discussed their experiences, provided feedback, and proposed new requirements, which were refined into a revised version of prompts for the generation of the second video.

Figure 3. The procedure of workshop implementation.

This iterative process was repeated for a total of 3 cycles, resulting in a final video incorporating the feedback from all rounds.

The posttest phase (about 20 minutes) involved another series of questionnaires and interviews to evaluate participants' satisfaction with the final video, as well as the changes in self-efficacy and technology acceptance. The entire research process emphasized iterative improvements to the generated videos to ensure progressive alignment between participant needs and the capabilities of the GenAI technology.

Data Collection and Analysis

This study adopts a mixed methods approach, integrating both qualitative and quantitative data for analysis. Data were primarily collected from two sources: (1) pretest and posttest questionnaires, along with interview transcripts from the iterative workshops, and (2) prompts and generated videos recorded in the system. To mitigate potential social-desirability effects stemming from the workshop setting, interviews were conducted by researchers in a neutral community environment, with a strong emphasis to participants that their negative feedback was essential for system improvement.

Interview transcripts were analyzed using the 6-phase reflexive thematic analysis (RTA) by Braun and Clarke [33]. RTA was specifically chosen for this qualitative inquiry due to its emphasis on the researcher's subjective and reflexive involvement in meaning-making, allowing us to generate rich, interpretative themes beyond simple data summation, focusing on "what is said and why" in the context of emerging GenAI technology. The RTA process involved: (1) familiarization (transcribing all interviews and reading the data for initial immersion); (2) generating initial codes (identifying semantic and latent features across the dataset); (3) searching for themes (grouping codes into meaningful broader categories); (4) reviewing themes (checking themes against the coded extracts and the entire dataset to ensure internal consistency and external heterogeneity); (5) defining and naming themes (creating clear, concise, and academically rigorous themes, as presented in Table 1); and (6) producing the report. The coding process was performed collaboratively by two researchers to ensure analytical rigor through constant comparison and to minimize individual bias.

XSL•FO
RenderX

Table 1. Theoretical dimensions and thematic coding.

Theoretical dimension and theme	Sample quotations
Self-efficacy	
Gaining confidence using GenAI[a] videos	• "I believe I can complete the operation with guidance." (E1) • "I am capable of learning as long as someone teaches me." (E6)
Instructions needed for using GenAI videos	• "I need step-by-step instructions to use it." (E4) • "I need specialized guidance on using GenAI." (E7)
Ease of use	• "This video generation process feels simpler than other mobile apps I use." (E3) • "The operation feels as simple as using WeChat." (E2)
Technology acceptance	
Perceived usefulness	• "The generated video effectively explains hypertension symptoms, which is very useful for me." (E1) • "The health videos help address my medical concerns." (E5)
User-friendliness	• "The interface is more user-friendly than expected."(E8)
Intention to use	• "I hold an open attitude toward learning GenAI and creating videos, and I'm willing to try." (E3) • "Gradual adoption is needed." (E9)
Perceived risks	• "I worry about privacy breaches when using GenAI." (E15) • "GenAI outputs require human review." (E19)
Health management	
Ways of understanding information	• "Dynamic visuals are more intuitive than static images or text." (E1) • "Animated video explanations are clearer than doctors' charts." (E3)
Providing personalized information	• "It can provide personalized dietary recommendations." (E4) • "GenAI gives exercise guidance tailored to my current physical condition." (E7)
Needs of management plans	• "I hope GenAI can help me develop fitness plans." (E1) • "I want GenAI to provide sleep improvement plans." (E12)
Requiring further medical or professional advice	• "I'll consult doctors before adopting GenAI suggestions." (E5) • "Family or professionals should review certain content." (E9)

[a]GenAI: generative artificial intelligence.

The coding process was performed collaboratively by 2 researchers who independently coded the data before holding coordination meetings to refine reflexive interpretations and ensure coding consistency. This methodical approach adheres to the standards for reporting qualitative research guidelines. The research team was external to the community center, maintaining a critical distance to minimize potential bias. Thematic saturation was determined when no new codes or subthemes emerged during the analysis of the final 3 participant interviews. We analyzed interview transcripts from all 20 participants, reaching thematic saturation where no new themes related to self-efficacy, acceptance, or concerns emerged in the final interviews. Thematic saturation was determined when no new codes or subthemes emerged during the analysis of the final 3 interviews.

Prompts and videos were analyzed using an inductive content analysis [34] to categorize the evolution of user requests and the content sophistication across the 3 rounds. In addition, comparative analysis was conducted to assess the iterative evolution of prompts and videos.

For quantitative analysis, the pretest and posttest questionnaires were designed to be relatively short and included only a few dimensions, so that older adults could complete them without difficulties. As older adults' needs and preferences for using technologies can be unique, we chose usability dimensions that focus on aging [26]. For this reason, we referred to the literature studying older adults' acceptance of technologies in health care to select appropriate dimensions for our questionnaire. As suggested by recent research and meta-analysis [24,28], we included the following constructs in our study: PU (3 items) refers to the perceived improvement in health management; PEOU (3 items) assesses the effort required; and behavioral intention (BI, 2 items) measures the future usage likelihood. In addition, to gauge the effectiveness and efficacy of older adults in adopting GenAI for health management, we included additional measurements of technology confidence (TechConf,

XSL•FO
RenderX

4 items) [35], task mastery (TaskMastery, 2 items) [25], and the learning of health information (HealthLearn, 3 items) [36]. Internal consistency for these scales was verified, with all constructs demonstrating acceptable reliability (Cronbach α>0.70). The questions were presented to the participants in the pre- and postphases, then Wilcoxon signed-rank tests were used to examine significant differences between pretest and posttest questionnaire results. To evaluate effect sizes, we computed Cohen *d* and additionally reported the Wilcoxon-compatible effect size *r* (calculated as Z divided by the square root of the sample size). In this study, items within core dimensions showed substantial effect sizes; for instance, Cohen *d* values for PEOU items ranged from 0.96 to 1.53 (*r*=0.75-0.86), and the BI items reached a Cohen *d* of 1.05 (*r*=0.81). The full list of questions can be found in Multimedia Appendix 1.

Sample

We recruited 20 older adults residing in nearby communities to participate in iterative workshops of GenAI videos. The participants were aged 60-84 (mean 70.15, SD 6.90) years, possessed basic skills of using smartphones, but had no experience with GenAI. This inclusion criterion ensures that their initial attitudes and user acceptance toward GenAI were not influenced by previous exposure. To enhance the heterogeneity of our sample, the participants reported diverse health statuses (eg, healthy, with chronic or mild conditions), living arrangements (eg, living alone or with family), and educational background (from primary school to university). They were also interested in a wide range of health topics, such as the 3 hyper-conditions, cardiovascular health, sleep disorders, and exercise-related topics. Table 2 lists the demographic information of the participants.

Table 2. Demographic information of our sample.

ID	Age (years)	Gender	Self-reported health status	Living arrangement	Education level	Health topics of concern
E1	60	Woman	Healthy	Alone	High school	Hypertension, hyperlipidemia, and hyperglycemia
E2	80	Woman	Chronic condition	Alone	Primary school	Sleep disorders
E3	78	Woman	Healthy	Living with family	Junior high school	Cardiovascular health
E4	77	Men	Chronic Condition	Living with family	High school	Hypertension, hyperlipidemia, and hyperglycemia
E5	72	Woman	Chronic condition	Living with family	Primary school	Healthy diet
E6	61	Woman	Chronic condition	Living with family	University	Physical wellness
E7	69	Woman	Chronic condition	Living with family	Junior high school	Obesity
E8	73	Woman	Chronic condition	Alone	Primary school	Healthy diet
E9	67	Woman	Healthy	Living with family	High school	Joint health
E10	76	Woman	Healthy	Alone	Primary school	Joint health
E11	74	Men	Mild condition	Living with family	Junior high school	Exercises
E12	69	Men	Chronic condition	Alone	Junior high school	Healthy diet
E13	73	Woman	Chronic condition	Living with family	Primary school	Joint health
E14	62	Woman	Mild condition	Living with family	University	Thyroid issues
E15	84	Woman	Chronic condition	Alone	College diploma	Sleep disorders
E16	67	Woman	Healthy	Alone	Junior high school	Joint health
E17	62	Woman	Healthy	Lives with family	Primary school	Hypertension, hyperlipidemia, and hyperglycemia
E18	72	Woman	Healthy	Lives with family	High school	Healthy diet
E19	62	Woman	Healthy	Alone	Primary school	Joint health
E20	65	Men	Chronic disease	Alone	University	Sleep disorders

Results

Quantitative Impact on Confidence and Learning

Through Wilcoxon signed-rank tests, we analyzed the impact of workshops on multiple dimensions among older adults. The results demonstrated consistently positive mean differences across all dimensions (ranging from 0.375, SD 0.582, to 0.917, SD 0.571) after the workshops, with all reaching statistical significance ($P \leq .01$). Notably, PEOU, PU, BI, technical confidence (TechConf), and the influence on health information learning (HealthLearn) exhibited substantial mean increases. Table 3 shows the results of the Wilcoxon signed-rank tests.

XSL•FO
RenderX

Table 3. Summary of Wilcoxon signed-rank test results.

Item	Mean difference (SD)	Wilcoxon statistic	*P* value
PU[a]	0.867 (0.652)	0	.001[b]
PEOU[c]	0.917 (0.571)	0	.001[b]
BI[d]	0.575 (0.712)	12	.003[b]
TechConf[e]	0.65 (0.455)	0	.001[b]
TaskMastery[f]	0.375 (0.582)	13.5	.01[b]
HealthLearn[g]	0.717 (0.544)	0	.001[b]

[a]PU: perceived usefulness.

[b]Statistically significant.

[c]PEOU: perceived ease of use.

[d]BI: behavioral intention.

[e]TechConf: technical confidence.

[f]TaskMastery: task mastery.

[g]HealthLearn: health information learning.

To evaluate the practical significance of these changes, Cohen *d* was calculated. The results showed large effect sizes for PEOU (*d*=1.61), PU (*d*=1.33), and the influence of health information learning (*d*=1.32). Medium to large effects were also found in technical confidence (*d*=1.43), BI (*d*=0.81), and task mastery (*d*=0.64). These results indicated that these improvements were not only statistically significant but also practically meaningful. Table 4 lists the results of each item and its Cohen *d* tests.

XSL•FO
RenderX

Table 4. Wilcoxon signed-rank test and Cohen *d*.

Item	Mean difference (SD)	Wilcoxon statistic	*P* value	Cohen *d*
PU1[a]	0.75 (0.79)	0	.002[b]	0.95
PU2	1 (1.03)	0	.002[b]	0.97
PU3	0.85 (0.81)	0	.002[b]	1.05
PEOU1[c]	1.1 (0.72)	0	.001[b]	1.53
PEOU2	0.85 (0.81)	0	.002[b]	1.05
PEOU3	0.8 (0.83)	7	.001[b]	0.96
BI1[d]	0.3 (0.92)	37.5	.16	0.32
BI2	0.85 (0.81)	0	.001[b]	1.05
TechConf1[e]	0.5 (0.51)	0	.002[b]	0.97
TechConf2	0.75 (0.79)	0	.002[b]	0.95
TechConf3	0.7 (0.86)	0	.004[b]	0.81
TechConf4	0.65 (0.75)	0	.004[b]	0.87
TaskMastery1[f]	0.35 (0.75)	10	.05	0.47
TaskMastery2	0.4 (0.75)	11	.03[b]	0.53
HealthLearn1[g]	0.8 (1.06)	4.5	.005[b]	0.76
HealthLearn2	0.6 (0.6)	0	.001[b]	1
HealthLearn3	0.75 (0.72)	0	.001[b]	1.05

[a]PU: perceived usefulness.

[b]Statistically significant.

[c]PEOU: perceived ease of use.

[d]BI: behavioral intention.

[f]TaskMastery: task mastery.

[g]HealthLearn: health information learning.

Older Adults' Experiences of Technology

Overview

We qualitatively analyzed the interview transcripts of 20 participants as data saturation was reached, and identified themes around self-efficacy, technology acceptance, and health information comprehension. Data analysis followed the 6-phase method for RTA by Braun and Clarke [33]. RTA emphasizes the researcher's reflexive involvement in the data analysis process, where subjective interpretation is central to understanding and generating meaning from qualitative data [37]. In terms of the changes in self-efficacy, we found that older adults gained confidence using GenAI from the workshops. Meanwhile, they expressed the need for more instructions on using GenAI. The ease of use of the GenAI video technology under simple and clear instructions also contributed to the improvement in self-efficacy.

Another category of emerging themes was related to technology acceptance. Participants perceived that AI-generated videos were useful, and the GenAI tool was user-friendly. The workshops demonstrated the applications of GenAI videos in health management, and participants tended to use them in the future after witnessing the positive side of GenAI. At the same time, they pointed out the potential risks of such AI tools.

From a health management perspective, older adults found that GenAI videos changed their ways of understanding health information and allowed them to retrieve personalized information. However, the AI tool warranted more improvements, such as providing health management plans and integrating validation or reviews from medical and professional experts to ensure the accuracy and reliability of content. Table 1 summarizes the theoretical dimensions, themes, and sample quotations to support the findings. We use the following subsections to offer further insight into each theme.

Improvements in Self-Efficacy

Through content analysis of interview transcripts, it was found that the self-efficacy of participants exhibited a significant upward trend after engaging with the GenAI video tool. Before the workshops, 12 (60%) participants explicitly expressed concerns about the difficulties of GenAI technologies because

XSL•FO
RenderX

of their ages. Many participants mentioned concerns such as, "my memory has deteriorated, and I can't learn new things as quickly as before" (E4), and "I need my children's guidance to operate these new technologies" (E8). This low confidence stemmed from doubts about their digital capabilities and fear of complicated user interfaces. After the workshop, 14 (70%) participants reported that the iterative workshops helped them to use GenAI. For instance, participants noted, "by following your instructions and prompts step by step, I was able to complete the task" (E3) and "I could better understand the content [after the workshop]" (E12).

In the initial workshop stage, many participants demonstrated a strong reliance on external support, which meant that they hoped to complete learning through vocal guidance or assistance from other people. After the workshop, 12 (60%) participants reported that they could independently use our GenAI tool to generate videos or adjust various settings. As 1 participant stated, "[other people's] guidance when making mistakes enables success" (E5).

Before the workshops, 8 (40%) participants perceived GenAI video generation as a highly challenging task. The workshop helped to mitigate cognitive load through template-based prompt designs (eg, preset health-related prompting templates) and video revisions with feedback iterations. The postworkshop interviews showed that 16 (80%) participants expressed the ease of use of GenAI tasks. For example, "after the entire process, I [have] found [that] GenAI video generation simpler than I originally imagined" (E11) and "I now believe I can attempt creating my health videos" (E14).

Increase in Technology Acceptance

After the workshops, 18 (90%) participants emphasized the PU of the generated content was useful for them to manage their health, for example, "the GenAI-generated health video comprehensively explains hypertension knowledge and the content is practical" (E1) and "my legs are weak and I don't know what exercises suit me. GenAI recommended exercises tailored to my condition" (E5).

Many participants commented on the user-friendliness of GenAI features. Among them, 16 (80%) participants mentioned the advantages of adaptable user interfaces (such as adjustable subtitle sizes) and the obvious design for specific functions (such as dedicated buttons for AI interaction). Other participants compared the GenAI with other commonly used mobile phone apps, for instance, "the operations are simple and similar to WeChat" (E2), which further contributed to the intention of using the technology.

While sentiment was generally positive, 5 (25%) participants expressed privacy concerns, including the possible leaks of personal data and the incorrect information provided by GenAI. For example, a participant said, "I worry about privacy breaches when using GenAI" (E15), while others suggested, "GenAI outputs require human review" (E19) or "professionals should review certain content" (E9).

Meeting Health Management Needs

GenAI videos were reported to help older adults better understand health information. A total of 15 (75%) participants described that AI-generated videos were a better way to present health knowledge, for example, "videos explain health knowledge better" (E3), and 11 (55%) participants mentioned that self-caring demonstrations generated by the GenAI were better, for example, "scenario-based demos in videos are more lively than [the demos from] medical experts" (E11).

Furthermore, at least 12 (60%) participants mentioned that GenAI video tools could provide personalized information, for instance, E12 reflected that the AI-generated video "taught how to do daily calorie calculations [for myself]," while many others mentioned that the GenAI could offer information about "healthy diets" and "hypertension control."

Despite the positive feedback, participants highlighted the need for the GenAI to generate health management plans for older adults saying, "I hope GenAI can help me develop fitness plans" (E1), and "I want GenAI to provide sleep improvement plans" (E12). In addition, some participants suggested that they would not rely solely on the information provided by the GenAI. Instead, they will "consult doctors before adopting GenAI's suggestions" (E5).

Interaction Changes With Experience: Prompt Analysis

Overview

With the analysis of a total of 60 prompts collected in all workshops, the changes of prompts across 3 rounds of video generation demonstrated the progressive trajectory of older adult–AI interaction from exploration to decision-making support. The details in each round are shown below.

First Round

In the first round, older adults demonstrated an exploratory attitude toward AI-generated videos. Their understanding of GenAI began at an early stage, and their core concerns centered on exploring the basic capacities of the GenAI tool. Their prompts contained questions about privacy concerns and the accuracy of answers to explore the accuracy and reliability levels of the GenAI tool. Below are examples of this category of prompts:

> *I'm 77 years old. I have Hypertension, Hyperlipidemia, and Hyperglycemia. I want to know how diabetes can be prevented. Will my personal information be disclosed?* [E4]
>
> *I was 62. I lumped my thyroid. I want to know if there is a risk. Is the health video content [that] you provide correct?* [E17]

Second Round

In the second round, older adults focused on functional adaptation, and the prompts were changed accordingly. With a preliminary understanding of the technology, their focus shifted toward whether GenAI could precisely satisfy individual needs and whether the information was simple enough to understand. Prompts emphasizing personalized recommendations and

XSL•FO
RenderX

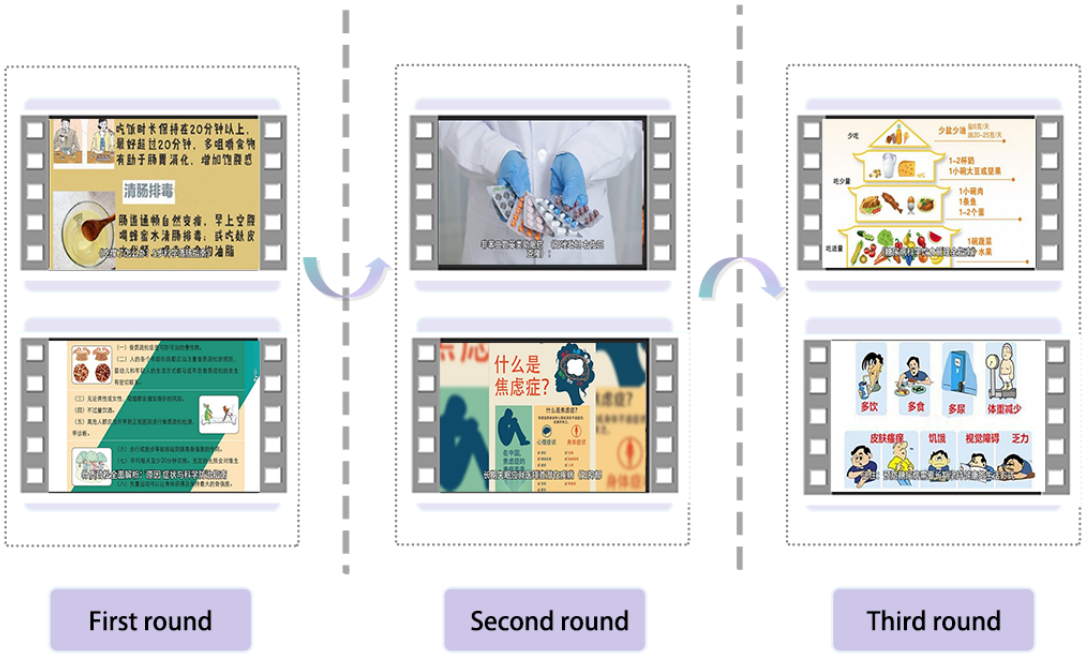
requiring easy-to-understand information revealed their needs. The following are samples of the prompts:

> *Help me generate a video about joint health care. This video is a bit complicated. Please make it simpler and more understandable.* [E16]

> *I want to know how to lose weight healthily. Please recommend some diet and exercise videos that are suitable for my specific health condition.* [E18]

Third Round

In the final round, after asking the GenAI to provide personalization, older adults escalated to the level of asking for information to support decision-making. For instance, older adults asked for the content to support the discussion during consultations, or the content reviewed by human experts that could be shown to family members. The following shows the excerpts from such prompts:



> *I want to know about the issue of obesity among the elderly. Which method is better for losing weight, traditional Chinese medicine or Western medicine? … Are the suggestions you gave me the result of a review by relevant experts?* [E7]

> *I want to know about digestive problems in the elderly. My stomach often feels uncomfortable after eating. … Can dizziness only be caused by low blood sugar? Please help me make a detailed video about a healthy diet and lifestyle. Please provide some health suggestions that experts have reviewed.* [E5]

Results of Generated Videos' Analysis

The analysis of 60 videos produced across 3 rounds of workshops revealed the patterns evolving from vague to concrete. In the first round, participants engaged in exploratory attempts with ambiguous needs. At this stage, most videos consisted solely of text-based captions with static images. Then, the second round saw participants, who had gained preliminary experience with the GenAI tool, begin proposing more concrete demands. The video content at this stage started incorporating scenario-based plots, with a significant portion focusing on specific topics such as health management and medication reminders. However, the explanations about these topics remained vague. In the final iteration, the videos became more sophisticated, with most presenting comprehensive health solutions with the customization of target audiences, content formats, and risk management strategies. Figure 4 shows the video samples in 3 rounds of iterations. Chinese is displayed because the screenshots are captured from the original video clips.

Figure 4. Sample videos in different rounds of the workshops.

Discussion

Principal Findings

This study systematically investigates the application and potential of GenAI video technologies and our prototype AIHealthV in older adults' health management. The research captures the dynamic evolution of older adults' interactions with GenAI and reveals how their needs progress from basic exploration to sophisticated decision-making support. Our findings provide novel insights into the role of AI-generated videos in reducing cognitive load and enhancing health information comprehension among older populations, while highlighting the importance of understanding their concerns in using GenAI technologies.

Interaction and Multimodality: Cognitive Accessibility and Self-Efficacy

The research indicated an improvement in older adults' self-efficacy and confidence, which may be viewed in alignment with the core principles of social cognitive theory. Self-efficacy suggests that individuals' beliefs in their capabilities can be

XSL•FO
RenderX

progressively strengthened [38]. As our GenAI prototype was structured with phased task decomposition, for example, preloaded health templates, and provided immediate feedback mechanisms, for example, step-by-step prompt guidance, these factors likely contributed to older adults building confidence during the experience. Older adults' belief in technological efficacy may be reinforced through gradual, experience-based accumulation when technological interactions are tailored to their cognitive capacities [39].

GenAI health videos offer a personalized visualization of health information that is often complex or difficult to access. This capability has the potential to enhance the PU of the technology, a factor that is widely understood to influence BI. Beyond mere information delivery, our findings suggest that multimodal GenAI content plays a crucial role in satisfying the emotional and cultural needs of older users. This resonance is vital for sustained engagement, as multimodal learning is most effective when it addresses the user's underlying emotional context, a pattern also observed in how younger generations engage with multimodal platforms such as Douyin (ByteDance) for skill learning [40]. Observations suggest that while some participants initially expressed reservations about the complexity of the tools, their acceptance and willingness to use the technology appeared to increase alongside a progressive learning curve [41]. The unified theory of acceptance and use of technology, where experience acts as a critical moderating variable, posits that accumulated familiarity with technologies can substantially improve users' attitudes [42]. Our work proposes that encouraging older adults to adopt GenAI for personal health purposes may necessitate continuous guidance and support, as well as patience, to help them cultivate confidence and practical experience. This further suggests that GenAI functions should be considered as part of a sociotechnical intervention strategy that supports older adults' digital capabilities through both social and technical means. The multimodality of GenAI videos is also thought to contribute to technological confidence and adoption. The media richness theory by Sun and Cheng [43] proposes that high-richness media, such as animation and voice interaction, may be better suited to meet older adults' cognitive needs. While textual data remains the dominant GenAI modality, the maturation of AI-supported interactive technologies, for example, video generation, multimodal fusion, and adaptive learning algorithms, is expected to lead to the increased application of multimodal GenAI in older adults' health education and management.

GenAI Videos as a Potential Virtual Companion and Access to Health Experts

As global aging intensifies, we can witness the potential of GenAI video tools as a potential virtual companion, while the prevalence of older adults living alone has risen markedly [44]. These individuals often face greater challenges in accessing health knowledge through digital technologies due to the absence of familial or societal support networks [45]. GenAI technologies may help mitigate this gap by providing algorithm-driven personalized health guidance, partially substituting traditional interpersonal support functions [46].

However, the sociotechnical implications of GenAI present a paradoxical duality. From a positive perspective, it helps address immediate gaps in health service accessibility for older adults living alone by providing basic health information and guidance when human support is unavailable. While not a complete replacement for professional care or family support, these GenAI tools can serve as a temporary solution that enables older adults to access health knowledge and manage certain aspects of their well-being independently [47]. The research by Niehaves and Plattfaut [48] suggests that digital technologies can compensate for social support deficits. Similarly, the work by Satariano and Scharlach [49] highlights how technology enhances older adults' autonomy. The interaction between older adults and GenAI tools can be further understood through the lens of "reverse generative learning." This approach emphasizes that intergenerational digital inclusion can be reconstructed when technology serves as a bridge, allowing older adults to develop digital readiness through creative engagement with AI [50]. Dynamic video tutorials generated by GenAI tools enable independent completion of health management tasks (such as medication management), reducing reliance on community clinics and the younger generation. On the other hand, prolonged overreliance on virtual interactions may erode real-world social connections and exacerbate emotional isolation risks [51]. Longitudinal studies reveal that while technological interventions improve functional autonomy (eg, self-management capabilities), they cannot replicate the emotional resonance of human care and potentially lead to digital isolation [52]. Recent observations indicate that some older adults living alone have reduced their frequency of visiting community health centers after adapting to GenAI, which further substantiates the contradiction [53].

To this end, technological design should adhere to the complementary principle, for example, integrating AI health videos with community volunteer service networks to provide human-based support, and at the same time, it can sustain emotional bonds with people. Cross-generational digital inclusion strategies (eg, encouraging grandchildren to participate in technology learning) could further supplement this approach, reconstructing social support networks through intergenerational interaction. These findings can underscore the necessity of embedding technological interventions within social ecosystems to avoid the pitfalls.

While older adults appreciate the value of addressing health and lifestyle issues brought by GenAI videos, they have concerns about privacy and highlight the need for human content review. These clearly reflect their uncertainty about the technology while balancing expectations for convenience against fears of misinformation or privacy violations. Finally, GenAI videos present a unique opportunity to bridge the gap between older adults and reliable health information sources. By incorporating verification mechanisms that connect AI-generated content with certified medical expertise, these tools can serve as a gateway to professional health resources. For instance, videos could include prompts encouraging users to discuss the information with their doctors or provide direct links to schedule consultations with health care providers, such as real health experts. This approach not only enhances the credibility of

XSL•FO
RenderX

AI-generated content but also fosters more informed conversations between older adults and medical professionals, ultimately leading to better health outcomes.

Ethical, Privacy, and Usability Concerns for Older Adults to Use GenAI Videos

Older adult users' ethical concerns regarding GenAI health videos reflect profound tensions between digital-era health rights and privacy rights. Despite being aware of risks, participants still tend to accept the use of these technologies, driven by anticipated health benefits. This replicates the view of the risk perception theory by Slovic [54], wherein individuals tolerate higher risks when potential benefits are sufficiently significant. However, the "black box" nature of AI algorithms renders trust establishment that is heavily dependent on external authorities (eg, the guidance from community workers), which exposes the gap in older adults' algorithmic interpretability rights [55]. Intergenerational differences further complicate the ethical issues. Older adults who are living alone exhibit different risk perceptions when compared to those cohabiting with family members, which prompts the necessity of the development of participatory governance frameworks [56].

Our study found that older adults' acceptance of GenAI is influenced by privacy concerns. These concerns mainly stem from worries about personal data security, particularly regarding the storage and potential misuse of sensitive health information, which are consistent with recent findings [57]. Many older users distrust algorithmic systems, fearing accidental data leaks and questioning the reliability of AI-generated health advice. These concerns are further exacerbated by potential algorithmic biases. To address these challenges, GenAI can enhance older adults' trust by establishing transparent data governance frameworks that clearly explain how personal information is collected, processed, and protected.

On the other hand, our findings demonstrate that older adults' use of GenAI video tools follows a process of constructing cognitive perceptions of technological controllability, for example, the needs of adjusting playback speed and the verbal language used in narratives. The interactions between seniors and the GenAI should balance between features and aging-friendly design; for instance, step-by-step guidance, visual support, and accessible user interfaces are crucial for older adults to gain momentum in learning AI tools. In practice, the transition from passive experimentation to active cocreation can be facilitated to inform better design.

Health videos generated by GenAI may contain misleading or inaccurate information, which could disproportionately affect older adults with lower digital literacy [57]. This phenomenon is often associated with GenAI's hallucinations, which may lead to outdated or inaccurate information. Such risks can be mitigated through the implementation of expert validation systems, where health care professionals review AI outputs. In addition, older adults should be educated to understand the limitations of AI-generated advice, and therefore, older adults' AI literacy will be an important topic for reducing the impact of misinformation provided by GenAI.

Limitations and Future Work

This study has several limitations. First, the urban community-focused sample may not capture access disparities of AI among rural or cross-border older adult populations, potentially limiting the generalizability of findings. Second, the short intervention period restricts the observation of long-term dynamics in technological usage. Third, reliance on self-reported data may introduce social desirability bias, possibly overestimating actual technology acceptance levels. Future work should expand to urban-rural and cross-border contexts to enhance sample diversity and use a longitudinal research design, for example, using diary methods and behavioral logs to track long-term usage patterns. The integration of multimodal data (eg, eye-tracking and physiological measurements) can be alternatives to measure the use of GenAI by this cohort.

Conclusions

Our work makes a unique contribution to older adults' health by examining the potential of GenAI videos in supporting older adults' self-management and highlighting important considerations for future implementation. Currently, AI-generated videos show a promising future of empowering older adults to take an active role in managing their health despite several concerns. As AI technologies continue to advance, their thoughtful applications in aging populations can create new possibilities for accessible, personalized, and effective health education while respecting older adults' unique needs and preferences. Future research should explore the longitudinal effects of AI-generated videos on older adults' health outcomes, as well as the feasibility of better integrating these tools with health care systems and social support networks. It is also crucial to reduce hallucinations and misinformation in GenAI, especially for older adults with limited AI literacy. The use of GenAI videos as a learning resource for older adults in other contexts also remains a rich area of exploration for future work in older adults' health, as do the ethicolegal implications of this kind of AI use.

Acknowledgments

We are grateful to the Macao Federation of Trade Unions (FAOM) for their assistance in this research.

Data Availability

The author confirms that all data generated or analyzed during this study are included in this published paper. Furthermore, primary and secondary sources and data supporting the findings of this study were all publicly available at the time of submission.

Abstract

Background: Evidence suggests that older adults can improve dual-task (DT) performance through specific motor-cognitive training programs. Recent technological advancements have facilitated the development of novel rehabilitative DT methodologies. In particular, the DUAL-REHAB project exploits 360° technology to develop ecological, cost-effective DT exercises for clinical and home settings.

Objective: This study aimed to comprehensively understand the DUAL-REHAB project's end users (older adults with subjective memory complaints [SMC] and mild cognitive impairment [MCI]) and obtain feedback on an initial DUAL-REHAB mobile app prototype using a user-centered design approach.

Methods: The study used a 2-phase procedure. In the first phase (user requirements), we investigated end users' lifestyles, habits, perceived well-being, technology adoption, and cognitive and cognitive-motor DT training expectations. In the second phase (prototype evaluation), we developed and tested a DUAL-REHAB mobile app prototype to assess its functionality with end users.

Results: Overall, 14 participants were initially recruited for the study. The sample included 7 women with a mean age of 79 (SD 3.79) years and 7 men with a mean age of 82.43 (SD 5.65) years. One female participant was excluded for not meeting the criteria for either group; accordingly, the final sample study included 13 participants, with 8 categorized as MCI and 5 categorized as SMC. Participants reported structured daily routines with high autonomy, although some faced challenges with social connections. Perceived well-being was moderate across physical (mean 2.79, SD 0.97), psychological (mean 3.14, SD 0.86), and cognitive (mean 3.14, SD 0.53) domains. The perceived technology skills were low (mean 2.57, SD 0.94), with low digital literacy (mean 2.21, SD 0.89). Interest in cognitive training was high, with 92.31% (12/13) participants aware of its benefits and demonstrating strong interest (mean 4.15, SD 1.34) and perceived use (mean 4.15, SD 1.28). While only 46.15% (6/13) were aware of the possibility of DT training with technology, 92.31% (12/13) were willing to participate, and 84.61% (11/13) were open to home-based training. The preferred frequency was 2-3 days per week (63.64%, 7/11), with 10-20 minute sessions (8/11, 72.72%). Prototype evaluation revealed specific usability issues related to icon identification, device interaction, and navigation between training days.

Conclusions: We obtained valuable insights into the lifestyles, habits, and technological needs of older adults with MCI and SMC, which will guide DUAL-REHAB training development to align with user needs and capabilities. Our findings emphasize

XSL•FO
RenderX

the importance of simplified technological processes with intuitive interfaces. Additionally, structured interaction opportunities during clinical and at-home training could enhance motivation, facilitate timely problem resolution, and address participants' social needs.

KEYWORDS

dual task; user centered; aging; usability; technology; cognitive-motor training

Introduction

Background

In recent decades, a growing focus has been on developing and testing effective strategies to mitigate cognitive decline associated with physiological and pathological aging [1]. The global population of older adults (65 years and older) is projected to reach 1.5 billion by 2050 [2], while Alzheimer disease prevalence may exceed 152 million cases [3]. These conditions significantly impact autonomy through various cognitive, behavioral, and motor symptoms [4-6], including deficits in dual-task (DT) performance, namely the ability to perform 2 tasks simultaneously. The DUAL-REHAB project uses 360° technology to address these challenges and develop ecological training environments for cognitive-motor exercises. Our approach is based on a user-centered design (UCD), prioritizing end user involvement throughout the design and development process. Accordingly, this study explores the needs of older adults with mild cognitive impairment (MCI) and subjective memory complaints (SMC) by investigating their lifestyles, habits, perceived well-being, technology adoption, and expectations regarding cognitive and cognitive-motor DT training, while also gathering their feedback through interaction with a prototype mobile app designed for home-based training.

Cognitive-Motor DT Training: State-of-the-Art and Current Challenges

Deficits in the ability to divide attention, or to perform 2 tasks simultaneously, referred to as DT performance, are early symptoms of dementia that evolve as the disease progresses [7,8]. An interplay exists between motor skills and cognition, with shared brain areas involved in attention, executive functions, and motor control, particularly in the prefrontal and temporal regions [9]. It is suggested that these networks can either process 1 task at a time [10] or that simultaneous engagement in a motor task and a cognitive task could result in interference caused by competing demands for attentional resources [11]. Despite different theoretical accounts, the effect appears to be more pronounced in individuals with cognitive impairments [12], leading to a deterioration in performance. Several studies have highlighted the close relationship between DT impairment alterations and motor dysfunction [13-15], falls [16-18], and a decline in daily activities observed in both normal and pathological aging [13,19]. Additionally, literature indicates that DT impairments could be considered a clinical marker of progression from cognitive impairment to dementia [9,20-22], underscoring the importance of DT skills for both daily functioning and clinical relevance.

There is convincing evidence suggesting that both older adults with Alzheimer disease and MCI can enhance their DT performance, motor skills, and cognitive abilities through specific DT motor-cognitive training programs [23-26]. Moreover, the recent advancements in technological tools have facilitated the development and implementation of novel rehabilitative DT methodologies [27-30]. A recent systematic review [30] indicated that an increasing body of evidence suggested the potential of exploiting technological devices to enhance DT skills across various age-related chronic conditions. Using motion-tracking systems, it is possible to reproduce users' movements within immersive virtual reality (VR) environments or on computer screens while participants are engaged in cognitive tasks. VR platforms offer realistic and immersive cognitive challenges and multisensory stimulation, enriching the interactive experience [31,32], also in home settings. For instance, Downey et al [33] recently exploited the potential of semi-immersive VR for older adults' rehabilitation, specifically targeting executive functions. This protocol used both laboratory and simulated real-world conditions to deliver at-home cognitive training focused on DT performance for both adults with normal-hearing and older adults who use hearing aids.

UCD: A Critical Approach for Effective Technology-Based Interventions

To ensure that technological interventions effectively meet the needs and capabilities of older adults, adopting a UCD approach is essential [34,35]. This methodological framework places end users at the core of the design and development process, systematically incorporating their perspectives, capabilities, and limitations at every stage. The basic premise of UCD is to directly involve end users in shaping the technology-based solutions they will ultimately use, to make them more easily adopted and effective. For instance, Hassandra et al [36] specifically investigated the acceptability, usability, and tolerability of using the VRADA (VR Exercise App for Dementia and Alzheimer's Patients) system compared to standard care physical and cognitive training. In another study by Nayak et al [37], 4 feasibility themes emerged from qualitative analyses: reasons for participation, difficulties using the technologies, engagement, and motivational values. UCD shares principles with related approaches like human-centered design and design thinking, emphasizing active user involvement, iterative design processes, and multidisciplinary collaboration to develop effective technological solutions through different techniques such as participatory design and rapid prototyping [38,39]. The adoption of UCD approaches for developing digital solutions in older adults has been extensively explored [40-43] and is even more crucial for individuals with cognitive decline [44-46]. Standard design

XSL•FO
RenderX

approaches often fall short when developing interventions for these populations because they fail to account for specific cognitive limitations and needs, reduced technology familiarity, and unique user contexts [47-49]. UCD addresses these challenges through structured, iterative cycles that follow 4 key stages: understanding the context of use, specifying user requirements, producing design solutions, and evaluating designs against requirements. When applied to older adults, as suggested by Nimmanterdwong et al [49], this process requires recruiting older participants, identifying their specific needs, incorporating measurable goals, creating rapidly testable prototypes, and adapting usability techniques to accommodate age-related limitations. In particular, UCD becomes particularly relevant for home-based interventions, as these solutions should be integrated into users' daily routines without direct professional support. Without careful consideration of user experience, even evidence-based interventions may fail due to incorrect use or poor adherence. For instance, Mehra et al [43] applied UCD methods to develop a tablet-based exercise app for older adults, revealing that iterative testing with end users was crucial for identifying unexpected interaction barriers and designing appropriate solutions.

The DUAL-REHAB Training: Addressing Research Gaps Through 360° Technology

Despite promising advancements in technology-enhanced DT training [27], several significant research gaps remain unaddressed. First, it remains less investigated whether training gains can be effectively transferred to novel contexts [50], particularly in daily life settings. Most training interventions were conducted in laboratory settings or using commercially available video games, limiting the possibility of generalizing the acquired skills to real-life contexts [29,51]. Second, due to potential mobility and/or physical constraints, transportation limitations, or insufficient facilities in nearby communities, older adults still face significant challenges accessing cognitive training programs. From this perspective, further exploitation of technological innovations could solve the challenges associated with traditional face-to-face interventions. Third, it is crucial to note that controlled randomized trials for older adults with SMCs are rarely included in DT research [21], despite facing a higher risk of developing MCI or dementia compared to those without such disorders [52-54]. To address these research gaps, the DUAL-REHAB project [55] aimed to exploit the potential of 360° technology, which is increasingly being adopted in assessment and cognitive training contexts [56-61]. 360° video represents a particularly accessible technology, offering significant advantages over other VR-based approaches. Since 360° cameras can easily capture real-life environments, they provide a practical solution for generating immersive and realistic scenarios where older adults can actively participate in cognitive-motor exercises, thus providing enhanced opportunities for transferring skills to real-life contexts. Regarding accessibility challenges, 360° content can be easily integrated into high-end applications for in-hospital sessions with therapists. The same format could be delivered through mobile apps and tablets for home sessions, overcoming transportation and facility access barriers. The DUAL-REHAB project will investigate the efficacy of this novel approach with both SMC and MCI populations, specifically including the underrepresented group of older adults with SMCs. The program's structure includes 10 days of training, each featuring approximately 10 DT exercises replicating real-life scenarios, implemented through both an immersive modality in clinical settings (using a head-mounted display and cycle ergometer) and a nonimmersive version for at-home use (via tablet app and portable cycle ergometer).

Study Objectives

To ensure that the DUAL-REHAB training program meets the needs and expectations of end users, as explained before, a UCD approach was adopted throughout the design and development process. This study represents the initial phases of a comprehensive UCD process, and it was designed with two primary objectives: (1) to obtain a comprehensive understanding of the end users of the DUAL-REHAB project, specifically targeting older individuals with SMC and older adults with MCI. This involved exploring various aspects, such as their lifestyles, habits, perceived well-being, technology adoption, and their needs and expectations regarding cognitive training and technologies for cognitive-motor DT training; and (2) to obtain feedback on an initial functional prototype of the DUAL-REHAB mobile app, specifically evaluating its overall functionality from the perspective of the target end users.

By systematically incorporating user perspectives throughout the development process, this study aims to ensure that the resulting training not only addresses clinical objectives but also aligns with the capabilities, preferences, and contexts of its intended users, potentially enhancing engagement, usability, and clinical outcomes.

Methods

Overview

A 2-step procedure was implemented to achieve our objectives. Phase 1 (user requirements) investigated end users' lifestyles, habits, well-being, technology adoption, and expectations regarding cognitive-motor DT training. Phase 2 (prototype evaluation) tested a DUAL-REHAB mobile app prototype with end users. We used semistructured interviews with open-ended and multiple-choice questions, and a think-aloud method to evaluate user-prototype interaction (Multimedia Appendix 1).

Participants and Recruitment

Overall, 14 participants were initially recruited for the study. The sample included 7 women with a mean age of 79 (SD 3.79) years and 7 men with a mean age of 82.43 (SD 5.65) years. Participants were recruited from patients and outpatients of the Department of Medicine, Neurology and Rehabilitation, Istituto di Ricovero e Cura a Carattere Scientifico Istituto Auxologico Italiano, Milan, Italy. In accordance with UCD principles, we recruited participants who represent our intended end users. Researchers contacted potential participants who met the following inclusion criteria: (1) age ≥60 years (no maximum age limit) to target the demographic most affected by age-related cognitive changes, (2) normal or corrected-to-normal vision to ensure participants could adequately view and interact with the visual elements of the technology, and (3) self-reported or

XSL•FO
RenderX

caregiver-reported cognitive concerns or memory complaints. Exclusion criteria were (1) debilitating medical, psychiatric, or neurological conditions that could affect performance; and (2) severe cognitive impairments indicated by a score <24 on the Italian version of the Mini-Mental State Examination [62,63].

To determine participants' cognitive status and establish diagnostic categories, an expert neuropsychologist conducted a comprehensive assessment using a battery of Italian-validated tests, including:

1. The Addenbrooke's Cognitive Examination III [64]
2. The forward version of Digit Span and Corsi Span [65]
3. The phonemic/semantic alternate fluency test [66]
4. The Short-Story Recall and Rey figure task [67]
5. The Frontal Assessment Battery [68]
6. The Trail Making Test [69]

These neuropsychological tests were used only for diagnostic purposes and were not used for analyses in any other part of the study.

MCI participants were identified based on self-reported or caregiver-reported cognitive decline, objective impairment in one or more cognitive domains, preserved functional abilities, and absence of dementia diagnosis [70,71], as documented in hospital medical records. SMC participants were identified based on self-reported memory complaints without objective cognitive decline [52], assessed through an ad hoc qualitative interview using established criteria [72].

Of the 14 initially recruited participants, 13 met the criteria for inclusion: 8 participants (3 women and 5 men) were categorized as MCI, and 5 participants (3 women and 2 men) as SMC. One female participant was excluded because she did not meet the criteria for either group.

Materials and Procedure

Phase 1: User Requirements

A semistructured interview with both open-ended and multiple-choice questions was developed specifically for this study to address the research objectives of the DUAL-REHAB project. Following UCD principles [34,35], both open-ended and multiple-choice questions were developed based on literature on technology acceptance in older adults [47,48], cognitive training preferences [23-26], and UCD approaches for older adults with cognitive impairments [44-46]. The content was subsequently reviewed by the multidisciplinary research team, including neuropsychologists and UCD experts, specifically considering the unique needs of older adults with MCI and SMC [49]. The procedure consisted of a semistructured interview administered by 1 experimenter, with a second experimenter observing and taking notes, conducted in a research room at the Department of Geriatrics and Cardiovascular Medicine of IRCCS – Istituto Auxologico Italiano in Milan. The interview comprised 2 parts: open-ended questions exploring lifestyles, habits, and socio-demographic details, followed by a questionnaire with multiple-choice responses covering perceived well-being, digital habits and skills, cognitive training knowledge, and DT cognitive-motor training expectations. While designed for independent completion, the interviewer assisted when needed or verbally administered questions in cases of fatigue to optimize time and resources. All multiple-choice questions used 5-point Likert scales ranging from "not at all" to "very much," "poor" to "excellent," or "never" to "every day." Each participant was welcomed inside the room with his or her companion, who was dismissed after explaining the procedure. The interview administration lasted between half an hour and 1 hour, depending on participants' reading speed, comprehension, response time, and the extent of their conversational digressions. Experimenters remained flexible regarding digressions as these could provide valuable information and help participants feel comfortable.

Phase 2: Prototype Evaluation

For Phase 2, a prototype of the DUAL-REHAB mobile app designed for DT motor-cognitive training was developed. It included DT exercises planned over 10 days in the final version. The experimenters created a Microsoft PowerPoint presentation displayed on an 11.2-inch iPad (A1566) and administered it to the participants. The presentation slides simulated the user journey from the home screen to the screen displaying DT exercises. The prototype was meticulously designed to ensure an optimal user experience, considering elements such as graphics, colors, user-system dialogue, and text adherence to International Organization for Standardization 9241 guidelines (ISO [International Organization for Standardization] 9241-11:2018, 2018). While the prototype was primarily based on established usability guidelines, some initial considerations from Phase 1 (see Phase 1: user requirements) informed basic design decisions, such as interface simplification and clear visual hierarchy.

Participants were instructed to interact with the slides, following written instructions in a binder. The instructions directed individuals to simulate starting the app and completing exercises scheduled for the first and second training days. The instructions provided were as follows:

Simulation of the first day of rehabilitation

1. Open and enter the app.
2. Launch the first day of exercises.
3. Select the first exercise of the day.
4. Listen to the exercise instructions.
5. Launch the exercise.

Simulation of the second day of rehabilitation

1. Open and enter the app.
2. Launch the second day of exercises.
3. Select the first exercise of the day.
4. Listen to the exercise instructions.
5. Listen to the instructions again.
6. Launch the exercise.

Each exercise was designed with the option to relisten to the instructions if a specific button was selected. Participants were instructed to listen again to the instructions of the exercise, even if they understood them initially, to evaluate whether they could successfully interact with this feature when experiencing comprehension difficulties. According to the think-aloud method

XSL•FO
RenderX

[73], participants were explicitly instructed to verbalize their thoughts and decision-making while interacting with the prototype. This cognitive verbalization technique requires participants to continuously "think aloud" by speaking everything that comes to mind during task completion, without filtering or interpreting their thoughts. This approach provides direct access to participants' cognitive processes and immediate reactions to the interface, capturing usability issues and misunderstandings as they occur rather than relying on retrospective reports that might be affected by memory limitations or post-hoc rationalizations. During the observation, researchers documented participants' verbalizations, hesitations, mistakes, and questions, along with their ability to complete tasks independently or with assistance. This real-time data collection method is particularly valuable for identifying specific interface elements that cause confusion or difficulty.

Ethical Considerations

The study was approved by the Ethics Committee of IRCCS – Istituto Auxologico Italiano, with protocol number approval 2023_01_31_10. All participants provided informed written consent before enrollment in the study. To ensure privacy, all potentially identifying information was removed, and data were kept strictly confidential. Participants received no financial compensation.

Results

Participants Characteristics

Selected participants were the same for this study's Phase 1 and Phase 2. The main socio-demographic information is presented in Table 1.

[a]MCI: mild cognitive impairment.

[b]SMC: subjective memory complaints.

Phase 1: User Requirements

Overview

This section presents findings from our semistructured interviews examining user characteristics, needs, and preferences. We systematically analyze different components of the interview data to understand potential users of the DUAL-REHAB training.

Lifestyle and Habits

In the initial interview phase, participants were presented with an open-ended question to investigate their lifestyle and habits: "Describe a typical day from waking up until going to bed, without unexpected or extraordinary events."

A structured checklist guided the interviewer in systematically collecting information across multiple domains, such as family and social relationships, leisure activities, daily habits, nutritional patterns, sleep quality, and physical activity levels.

Participants typically reported waking up around 7 AM; primary meals (lunch and dinner) were predominantly prepared and consumed at home. Between meals, participants are commonly engaged in activities including walking, reading, television viewing, or resting periods. Household management tasks and fulfillment of daily responsibilities were consistently reported. In total, 5 participants specifically noted attending to

XSL•FO
RenderX

health-related needs, either their own or their spouses', through medication management or attendance at medical appointments for more intensive therapeutic interventions.

Overall, participants demonstrated adequate cognitive and motor autonomy levels for daily functioning, with occasional exceptions due to specific conditions such as temporary limitations following falls or chronic pain. While social relationships were universally identified as fundamental, many participants reported challenges maintaining social connections due to diminished friendship networks or geographical separation from family members with competing obligations. Nevertheless, 7 participants specifically identified interactions with children and grandchildren as significant protective factors for emotional well-being.

These insights informed the development of 2 distinct "personas" (Multimedia Appendices 2 and 3), a UCD technique that synthesizes representative user behaviors and needs [74].

Perceived Well-Being

Participants' perception of well-being appeared moderate, as indicated by mean scores of 2.79 (SD 0.97) for physical health, 3.14 (SD 0.86) for psychological health, and 3.14 (SD 0.53) for cognitive health on a Likert scale ranging from 1 to 5.

Habits and Digital Skills

On a Likert scale ranging from 1 ("very bad") to 5 ("excellent"), participants demonstrated a relatively poor relationship with technology, as evidenced by a mean score of 2.57 (SD 0.94). Moreover, their perception of personal digital literacy (the ability to interact with digital tools) was even lower, with a mean score of 2.21 (SD 0.89).

Tables 2-4 present the frequency distributions for technological assistance received, device use (tablets, smartphones, smart televisions, and PCs), and digital service use (health, shopping, administrative, and entertainment), respectively.

XSL•FO
RenderX

Overall, findings suggested that smartphones dominated daily use, with 7 out of 13 participants (53.85%) using them every day. However, other devices show more sporadic patterns, with tablets and laptops being the least frequently used among our participants. On the other hand, it is interesting to note a strong heterogeneity across service categories. Health services showed the lowest penetration (10/13, 76.92% reported never using them), while email services, audio or video streaming, and social networks demonstrate more distributed use.

Two general evaluation parameters were considered in assessing technology: curiosity and use. While participants did not perceive themselves as particularly curious about technology (mean 2.71, SD 1.54, with 3 indicating "neutral"), they did recognize its usefulness in daily life (mean 3.57, SD 1.28).

Cognitive Training

Regarding cognitive training, we aimed to explore the end users' prior knowledge of the feasibility and methodologies involved in training cognitive functions and their level of interest in this area. Twelve participants demonstrated awareness of the potential for cognitive training to improve mental health, encompassing memory, attention, and perception. Eleven individuals also acknowledged the feasibility of incorporating cognitive and motor exercises. At the same time, 12 recognized that the objective of such training could be to enhance cognitive functions or impede their decline.

Interest in improving cognitive abilities was substantial, with a mean rating of 4.15 (SD 1.34), on a Likert scale from 1 to 5. Similarly, participants perceived the personal use of cognitive training, with a mean rating of 4.15 (SD 1.28). Only 1 participant expressed no interest in cognitive training. Furthermore, an interesting finding concerned participants' willingness to recommend cognitive training to others, with 11 individuals expressing readiness to endorse such training. Qualitative analysis of these responses revealed diverse recommendations for peers and younger generations, including children and grandchildren, underscoring the perceived value and broad applicability of cognitive training across age groups.

Cognitive-Motor DT Training With Technology

In implementing integrated DT cognitive-motor training programs, this section explored participants' knowledge and expectations regarding using technology, including tablets, smartphones, and laptops.

Among the participants, 6 individuals (approximately half of the sample) were aware of the possibility of performing cognitive-motor training with the support of technological tools. Despite this limited awareness, 12 participants expressed their willingness to participate in this type of training. However, when asked if they would also perform the training independently at home, the number of willing participants decreased slightly to 11.

Those willing to engage in home-based training were then asked to envision how much time they would dedicate to such a protocol, including weekly frequency, session duration, and overall training period. The results of these 3 questions are reported in Table 5.

Table 5. Time willing to dedicate to cognitive-motor dual task training at home with technology (N=11).

Home training time	Values (N=11), n (%)
Days per week	
1 day	1 (9.09)
2-3 days	7 (63.64)
3-4 days	3 (27.27)
5-6 days	0 (0)
7 days	0 (0)
Time per day	
10-15 minutes	4 (36.36)
15-20 minutes	4 (36.36)
20-30 minutes	1 (9.10)
30-45 minutes	0 (0)
45-60 minutes	2 (18.18)
Overall duration	
1 week	0 (0)
2 weeks	4 (36.36)
3-4 weeks	3 (27.28)
5 weeks	0 (0)
6 weeks	4 (36.36)

XSL•FO
RenderX

Overall, participants showed moderate willingness to dedicate time to home-based DT training. While daily and weekly commitment tended to range from moderate to low, the total duration indicated considerable availability, ranging from medium to high. Further analysis revealed that all 11 older adults would engage in the training for a maximum of 4 days per week. A total of 9 individuals would participate for 30 minutes daily, with the other 2 willing to extend it to 60 minutes. Additionally, 7 participants would undergo training for 2 to 4 weeks, with 4 participants willing to extend it to 6 weeks.

Overall, participants perceived using technology or performing cognitive-motor training with DT exercises as very useful (mean 4.31, SD 0.85) and moderately simple (mean 3.31, SD 1.38). We explored the participants' positive expectations and primary concerns regarding a technology-supported cognitive-motor training protocol. The summarized results are presented in Tables 6 and 7. As participants could provide multiple responses, the total frequencies may exceed the number of interviewees.

Table 6. The most common positive expectations regarding a cognitive-motor training protocol using technological tools at home (N=13).

Positive expectations	Values (N=13), n (%)
Enhanced autonomy	8 (61.54)
Improved self-esteem and self-efficacy	6 (46.15)
Cognitive function enhancement	11 (84.61)
Improved physical health status	3 (23.08)
Enhanced self-care capabilities and awareness	6 (46.15)
Reduced frequency of medical consultations	0 (0)
Improved social interaction	1 (7.69)
Time efficiency benefits	3 (23.08)
Financial benefits	2 (15.39)
Improved daily routines and lifestyle	2 (15.39)

Table 7. The most common concerns regarding a cognitive-motor training protocol using technological tools at home (N=13).

Concerns	Values (N=13), n (%)
Privacy concerns	5 (38.46)
Adaptation to new routines	2 (15.39)
User errors in technology operation	8 (61.54)
Technical difficulties with devices	7 (53.85)
Exercise adherence challenges	4 (30.77)
Increased stress levels	3 (23.08)
Training requirements	4 (30.77)
Need for technical assistance	5 (38.46)
None of the previous answers	1 (7.69)
Other	0 (0)

Phase 2: Prototype Evaluation

Using an observation grid during prototype evaluation, all verbalizations were documented, including (1) comments, (2) complaints, or (3) direct requests for help, as well as observable behaviors such as (1) hesitations or (2) errors that indicated the participant's inability to complete the tasks independently. During the data collection, only inputs regarding the system characteristics were documented.

Data collected for each participant were compared to identify tasks causing the most significant difficulties. For each critical task, we determined whether others shared similar challenges. Identifying the most problematic tasks and system characteristics would provide valuable guidance for modifications in the final app version. This comparative analysis is represented in Table 8, which specifies the most critical tasks (and their instructions), synthesizes issues preventing task completion, indicates the number of participants encountering each difficulty, and presents potential solutions.

XSL•FO
RenderX

Table 8. Most critical tasks and respective instructions, problems, and solutions for the think-aloud protocol of the DUAL-REHAB prototype in mild cognitive impairment and subjective memory complaints participants.

Instructions, critical tasks, and problems	Solutions	Participants, n
Open the app		
Device interaction		
Excessive pressure during screen interaction	Implementation of device familiarization sessions for participants without prior touchscreen experience	1
Difficulty identifying the app icon	Elimination of extraneous visual elements from the home screen interface	3
Execution of instructions		
Protocol execution only following researcher's prompting	Development of an interactive tutorial for home screen navigation	1
Launch day 1		
Execution		
Day selection errors due to participants' tendency to search for calendar dates rather than ordinal day numbers in the training sequence	Consideration of replacing numerical day identifiers with calendar dates to align with participants' expectations	1
Proper interaction with the device		
Attentional dispersion due to interface complexity (eg, several buttons on the screen layout)	Reduction of interface elements to minimize cognitive load	1
Launch day 2		
Comprehension of the instructions		
Erroneous day selection	Provision of a tutorial or additional information on the appropriate protocol sequence navigation across different training days	1

Discussion

Principal Findings

The DUAL-REHAB project represents an innovative approach to cognitive-motor rehabilitation that exploits the potential of 360° technology to develop a novel DT training program specifically designed for older adults with SMC and MCI. Following UCD principles, this study revealed important insights about our target users and prototype functionality. Participants demonstrated high autonomy in daily activities and strong motivation to maintain independence despite reduced social interactions. They reported moderate satisfaction with their well-being across physical, psychological, and cognitive domains, with physical health rated lower than cognitive health. Participants expressed strong belief in cognitive training's potential and high interest in enhancing cognitive functions, with expected outcomes primarily focused on autonomy and self-care improvements.

Despite low self-reported technology proficiency, they showed a high willingness to participate in technology-based interventions and perceived such tools as valuable for cognitive-motor training. Participants preferred moderate training frequency (2-3 days/week) and shorter sessions (10-20 minutes). The prototype evaluation revealed some usability issues, with challenges primarily related to basic tablet interaction and navigation understanding. Key design improvements needed include simplifying the interface, redesigning icons, and implementing familiar temporal references for training day selection.

One of the main risks associated with an aging population and increased life expectancy is that older people may lose their autonomy and independence [75], requiring more assistance for longer periods. However, the target population we interviewed demonstrated a high degree of autonomy in daily activities and a strong desire to maintain independence, care for themselves, and improve their well-being. Participants maintained structured daily routines, primarily self-managed their meals, and engaged in various daily activities. This high level of autonomy could benefit the DUAL-REHAB training program, potentially facilitating the implementation of at-home training sessions where participants will access a nonimmersive version of the DT exercises via a tablet app combined with a portable cycle ergometer.

Despite this autonomy, a deeper look into participants' lifestyles showed fewer social interactions than expected, with boredom and loneliness frequently mentioned as negative aspects of their lives. This aligns with previous research identifying social isolation as a significant risk factor for cognitive decline [76]. Interestingly, health maintenance emerged as a meaningful activity for many participants, often becoming time-consuming but purposeful. This finding suggests that framing the DUAL-REHAB program as a health-promoting activity could leverage existing motivational patterns to enhance compliance. Given that 7 participants specifically identified interactions with

XSL•FO
RenderX

children and grandchildren as protective factors for emotional well-being, and 5 participants were already managing health-related needs within their family context, the training program could capitalize on these existing dynamics by incorporating caregivers as "active supporters." This approach would potentially address both training goals and social connection needs simultaneously. For our target populations specifically, family members should serve not merely as technical support but as cognitive scaffolding, a design consideration that might extend beyond the general principle for designing technologies for older adults.

Participants' self-perceptions of well-being deserve careful attention. Despite meeting clinical criteria for MCI or SMC, they reported moderate satisfaction with their cognitive health. Participants reported moderate levels across physical, psychological, and cognitive health domains when assessing their perceived well-being. Even if everyone included in the study is categorized according to MCI or SMC criteria, they feel quite satisfied with their cognitive well-being. It can be interpreted in 2 ways: a lack of self-awareness [77] or psychological acceptance that cognitive decline is inevitable. Notably, participants rated their physical well-being lower than their cognitive health, suggesting potential opportunities for interventions addressing both domains simultaneously, as the DUAL-REHAB approach aimed. Another aspect worth mentioning is their strong belief in the potential of cognitive training. Additionally, participants acknowledged the existence and the potential of motor-cognitive training. Consistently, they also expressed great interest in enhancing their cognitive functions. When discussing expected positive outcomes, our sample most frequently mentioned self-care-related aspects: autonomy, improvement in self-efficacy, cognitive improvements, self-awareness, and self-care.

Technology is the most delicate aspect investigated in this study. While participants reported low technology proficiency, digital literacy, and limited awareness of technology-based cognitive training possibilities, they simultaneously demonstrated high willingness to participate in such interventions (12 out of 13 participants). This apparent contradiction is coupled with their high perceived usefulness of technology for cognitive-motor training, suggesting that older adults' limited technology use likely might derive from motivational barriers rather than a lack of interest, in line with Lee and Coughlin [47], who established perceived value as a key factor in technology adoption. These findings suggest the opportunity to frame technology as a mean to maintain cognitive health could provide sufficient motivation to overcome initial resistance, a strategy supported by Wildenbos et al [48], who found that health-related technologies achieve higher adoption rates when they address specific health concerns valued by older adults.

Finally, it is interesting to highlight that the specific training preferences expressed by participants, favoring moderate frequency (2-3 days/week) and shorter sessions (10-20 minutes), align with typical training guidelines for older adults. These parameters should inform the DUAL-REHAB implementation strategy, as they represent a self-identified sustainable level of engagement that could optimize adherence while minimizing the burden on participants.

Regarding mobile app prototype and tablet use, testing revealed fewer problems than anticipated despite the participants' limited technological skills. Most issues were related to interaction with the tablet touchscreen (eg, pressure calibration), suggesting that the prototype design achieved appropriate simplicity for the target population. A brief training session on tablet interaction fundamentals could effectively address these basic usability barriers.

The 2 key navigation challenges emerged that require design modification. First, participants struggled to recognize the app icon, a finding consistent with research showing that older adults often have difficulty with abstract icons [78]. This necessitates redesigning icons and reducing competing visual elements on the home screen. Second, and more notably, participants had trouble selecting the correct training day, frequently defaulting to "day 1" when attempting subsequent sessions. This conceptual navigation barrier suggests that sequential numbering systems may be cognitively demanding for this population, particularly for individuals with MCI and SMC who may experience episodic memory difficulties and challenges with abstract sequencing. This supports the implementation of familiar temporal references (calendar dates) rather than abstract ordinal numbering. These findings inform some critical design decisions for the DUAL-REHAB: (1) implementing intuitive navigation with familiar conceptual models that accommodate cognitive limitations, and (2) developing a comprehensive initial training phase focusing on basic tablet interaction skills tailored to the cognitive profile of end users.

Finally, the personas developed from our interview data (Multimedia Appendices 2 and 3) will guide future design decisions for the DUAL-REHAB app. These personas reflect key patterns from our study: participants showed technological curiosity alongside dependency concerns, strong motivation for health maintenance, and clear preferences for structured training approaches. The personas will inform design decisions, such as balancing user independence with appropriate support features and involving family members as cognitive support rather than just technical help.

Conclusions

In conclusion, this study successfully addressed its primary objectives by adopting a UCD approach for the development of DUAL-REHAB training. We used 2 methods (a semistructured interview and the think-aloud method) to obtain valuable insights into the lifestyles, habits, and technological needs of older adults with MCI and SMC, as well as crucial feedback on the initial prototype of the DUAL-REHAB mobile app. Our findings will inform the further design and development of the training program, ensuring alignment with user expectations and technological capabilities. A critical need emerged for simplifying technological processes with intuitive and user-friendly interfaces. The importance of a comprehensive pretraining or familiarization phase to prepare participants for using the app was also highlighted. Furthermore, the necessity to consider and monitor participants' engagement and motivation levels throughout the training became evident. Sociality, well-being, and self-care were key areas for implementing and framing the training. Establishing opportunities for interaction

XSL•FO
RenderX

(in particular, with caregivers and family members) during clinical sessions and at-home training could help maintain motivation, promptly solve potential problems, and satisfy participants' need for social engagement. This approach could effectively address the participants' desire for social interactions and feeling supported in managing their well-being.

However, this study has several limitations. First, we did not collect data about the app from experts or caregivers [79]. Future studies should incorporate such feedback to comprehensively evaluate the DUAL-REHAB app's functionality and end users' expectations and lifestyles. This is particularly important considering the social needs that emerged from our findings. Moreover, our sample size represents a methodological limitation. While we followed established usability testing guidelines suggesting that 4-5 participants can identify most major usability issues [80,81], the specific cognitive characteristics of our population warrant consideration. Participants with MCI and SMC may experience varying cognitive difficulties that affect their technology interaction patterns, potentially requiring larger samples to capture the full spectrum of user experiences. Individual usability issues were often identified by small numbers of participants (n=1-3), but these findings align with established usability principles where even single-user observations can reveal critical design flaws. However, we recognize that the cognitive heterogeneity within our target populations limits the generalizability of these specific findings, and larger-scale usability testing would be essential to establish the prevalence and priority of identified issues before final implementation. In addition, it is crucial to note that although the semistructured interview protocol was developed based on existing literature and expert review, the absence of pilot testing represents another limitation. To address potential comprehension issues, interviewers assisted when participants encountered difficulties or fatigue, for example, by providing clarification or reading the multiple-choice questions aloud. Moreover, they allowed for spontaneous digressions that could yield valuable insights. Finally, another limitation of our usability testing regards the use of an initial prototype created with Microsoft PowerPoint rather than a fully functional application. This solution might have affected the ecological validity of our findings, and future testing of DUAL-REHAB solutions should involve more advanced technological prototypes, including, for example, interactive elements, to fully capture potential difficulties in interacting with the training application.

By addressing these limitations and building on the insights gained, future iterations of the DUAL-REHAB project can better address the needs of older adults with MCI and SMC, potentially improving their cognitive function and overall quality of life. Integrating UCD principles throughout development will allow a more effective and engaging cognitive training program tailored to its target users' unique needs and capabilities.

Funding

This work was supported by the Italian Ministry of Health - Ricerca Finalizzata (GR-2021-12374204).

Authors' Contributions

Francesco Bigotto and SS conceptualized the study and prepared the interview procedure. Francesca Bruni, JP, and EP prepared the study prototype of the app. Francesco Bigotto and JP administered the procedures and elaborated the collected data. Francesco Bigotto and SS proceeded with the first draft of the manuscript. Francesco Bigotto, JP, and SS wrote and edited the manuscript. MSB, EP, and SS contributed to the reviewed version of the manuscript. SS and EP supervised the study.

Abstract

Background: Smart home technologies are often promoted as a means to support independent living and alleviate pressure on health and care systems. However, adoption among older adults remains low, and little is known about how passive, ambient technologies are experienced over time.

Objective: This study aimed to examine the adoption of a Connected Care System among older adults and their caregivers in a real-world deployment, testing the applicability of the Unified Theory of Acceptance and Use of Technology model and identifying design considerations for future systems.

Methods: A mixed methods study was conducted with 91 older adults who used the Connected Care System for approximately 6 months. Quantitative survey data were analyzed using structural equation modeling to assess predictors of behavior intention. Thematic analysis of open-ended survey responses was used to explore participants' experiences and perceptions of the system.

Results: Perceived ease of use (β=0.075; *P*=.02) and facilitating conditions (β=0.232; *P*<.001) were significant predictors of behavior intention, while perceived usefulness and social influence were not. Thematic analysis revealed that older adults often conceptualized usefulness in emotional and relational terms, such as peace of mind and caregiver reassurance. Adoption was frequently described as a shared process involving family members. Key barriers included low confidence in setup and reliability concerns, while valued features included passive monitoring, increased independence, and reduced caregiver burden.

Conclusions: The findings suggest that conventional adoption models require adaptation to account for passive, caregiver-mediated smart home systems. Emotional and relational benefits, rather than task efficiency, drive perceived usefulness. Design recommendations are offered to support user-friendly, personalized, and relationally aware smart home technologies that align with the realities of aging in place.

Introduction

Background

Smart home technologies are often positioned as part of the solution to the global challenges of population aging, supporting not only older adults but also family members who provide informal care [1]. As the proportion of older adults continues to grow, there is an urgent need for innovative solutions that promote independent living while reducing the emotional and financial pressures on caregivers, who already bear substantial—yet often underreported—burdens [2-4]. Projections indicate that by 2050, one in four people in the United Kingdom will be aged 65 years or older, compared with one in five in 2019 [5]. This demographic shift is expected to place increasing

XSL•FO
RenderX

strain on health and social care systems, reinforcing the need to investigate technology-enabled models of care. Within this context, smart home technologies such as the Connected Care System (CCS) developed by a major UK telecommunications company offer a practical example of how digital infrastructure could be leveraged to support aging in place.

Despite their potential, the uptake of smart home technologies remains relatively low among older adults [6-8]. Recent reports show that only 54% of adults over the age of 75 years in the United Kingdom use the internet regularly [9], reflecting broader barriers to digital inclusion. This gap between the growing need for scalable care solutions and the slow adoption of digital technologies underscores the importance of examining how integrated systems, such as the CCS, can address barriers while supporting aging in place. In this study, the CCS consisted of a mobile app used by the informal caregiver, an Amazon Alexa device, and several plug-in motion detector sensors placed in the older adult's home. The sensors captured patterns of movement and relayed this information through the mobile app, enabling caregivers to receive notifications as the older adult moved about their house. The inclusion of a voice assistant also provided a familiar interface for interaction, while the mobile app acted as the main point of access for caregivers to monitor activity. Unlike professionally monitored telecare systems, the CCS was designed for informal caregiving contexts, where family members received the notifications directly and used them to support independent living. It also supports daily activity tracking, providing caregivers with insights into routines and well-being over time. These functionalities align with ongoing policy and practice goals to extend independent living while addressing the costs associated with formal care provision [10].

However, existing research on smart home technologies for older adults has significant limitations. Much of the evidence comes from laboratory settings or short-term deployments [11], leaving open questions about sustained use in everyday life. For example, the SmartSenior project evaluated a 36-device smart home system over an average of 45 days, finding that acceptance improved once initial technical issues were resolved [12]. Similarly, a 2-year study in a care home context showed that older adults' attitudes became more positive over time [13]. More recent studies highlight the importance of trust and perceptions of security in influencing adoption [14]. Yet, long-term, real-world evaluations of smart home systems in private households remain rare. This study addresses this gap by examining the adoption and sustained use of the CCS in older adults' own homes over an extended period, offering novel insights into how these systems function beyond pilot or institutional settings.

This study makes several contributions to the field of technology adoption and smart home system design. First, it evaluates theoretical adoption constructs in the context of passive, ambient smart home technologies, identifying potential gaps where traditional models fail to capture the unique dynamics of older adult users. Second, by integrating qualitative insights, the study refines existing adoption frameworks, offering a more holistic understanding of the interplay between behavior intention, perceived usefulness (PU), social influence, and ease of use [15]. A key practical contribution of this research is the development of 6 design requirements based on empirical findings. These requirements provide actionable insights for technology developers, health care providers, and policymakers seeking to design more accessible, personalized, and user-friendly smart home systems. By bridging the gap between technological potential and real-world adoption, this study supports the broader goal of enabling older adults to maintain independence, improve well-being, and enhance quality of life while aging in place.

Theoretical Framework

The Unified Theory of Acceptance and Use of Technology (UTAUT) model [15] is often used to predict technology adoption, but it mainly focuses on task-oriented use rather than on in-home or passive use by older adults [16]. While the UTAUT model has been applied to various groups, studies focusing on older adults are scarce [17,18]. When applied, UTAUT has been found sufficient to explain older adults' technology use [19]. The limited research may be due to the unique needs of older adults, such as physical or cognitive limitations, which can alter the relevance of the model's core constructs [20,21]. For example, older adults may prioritize ease of use and immediate utility [22] more than younger users. Findings regarding the influence of social factors are also inconsistent [11,23], with some research suggesting a strong influence from family and peers, while other studies find it less significant. Empirical findings also point to mixed results when UTAUT is applied to smart technologies with older adults; for example, one study found that performance expectancy strongly predicted intention to use, but effort expectancy, social influence, and facilitating conditions were not significant, despite being core constructs of the model [24]. However, in other cases, social influence has growing importance due to extra reliance on caregivers [25,26]. These inconsistencies highlight the need for more nuanced research on this demographic. This paper also responds to a call for more thorough research using the UTAUT model that also incorporates qualitative data through a longitudinal study [27].

Objective

The objective of this study is to investigate the adoption and use of the CCS among older adults during a 6-month real-world deployment. Specifically, we examine the key factors that shape adoption behavior and assess how well-established constructs from the UTAUT explain technology engagement in this context. In addition, this study seeks to identify the perceived benefits and barriers experienced by both older adults and their caregivers. By integrating quantitative measures with qualitative insights, the research provides a nuanced understanding of how smart home technologies are taken up in everyday life and highlights design implications for systems that aim to support independent living and aging in place.

Research Model and Hypotheses

This study tested the UTAUT model [28] in the context of older adults who had used the CCS for 6 months. The model examines the key determinants influencing older adults' behavior intention to adopt and use smart home technologies.

XSL•FO
RenderX

Behavior intention refers to an individual's readiness to perform a specific behavior—in this case, the intention to use smart home technologies [29]. The model includes 4 independent constructs: perceived ease of use (PEOU), PU, social influence, and facilitating conditions. PEOU is defined as the degree to which an individual believes that using a system is free from effort [11]. PU refers to the extent to which a person believes that using the system will enhance their performance or daily living [28]. Together, these constructs capture both the effort and value components of technology acceptance. Social influence reflects the extent to which individuals perceive that people important to them think they should use a technology [28]. This factor is particularly relevant in the context of older adults, whose technology decisions are often shaped by family members and caregivers. Facilitating conditions refer to the degree to which individuals believe that adequate organizational and technical support exists to enable system use [28]. For older adults, these conditions include access to digital infrastructure, such as Wi-Fi, and availability of guidance or assistance during setup [30].

Based on the UTAUT model and the context of this study, the following hypotheses were proposed:

Hypothesis 1: Perceived ease of use positively influences behavior intention to use a smart home system.

Hypothesis 2: Perceived usefulness positively influences behavior intention to use a smart home system.

Hypothesis 3: Social influence positively influences behavior intention to use a smart home system.

Hypothesis 4: Facilitating Conditions positively influence behavior intention to use a smart home system.

Methods

Research Design

This study used a longitudinal observational design to examine older adults' adoption and use of smart home technologies within the context of a real-world deployment. The trial was designed and conducted by a UK telecommunications company, which managed all aspects of recruitment, technology deployment, and data collection. Recruitment was open to households in the United Kingdom that included an older adult receiving informal care from a family member, friend, or neighbor. No other eligibility restrictions were applied. The study commenced in October 2020 but experienced delays due to the COVID-19 pandemic, which influenced the timing and logistics of technology setup in participants' homes.

A total of 393 participants took part in the trial, with survey completion being entirely voluntary. The smart home technology, the CCS, was installed in participants' homes with only remote support provided by the telecommunications company. The system included an Amazon Alexa device, motion-detecting smart plugs, and a mobile app that enabled informal caregivers to receive notifications and monitor household activity.

All survey data were anonymized prior to being shared with the researchers. The only information available to the researcher was an overview of participants' ages, unlinked to any survey responses.

Ethical Considerations

The data analyzed in this study were collected as part of a trial conducted by a large technology company in the United Kingdom. Ethical approval for the original data collection was obtained through the company's internal ethics and governance review processes, in accordance with national regulations for industry-led research involving noninvasive technologies. All participants in the original trial provided informed consent to participate. Participation in the survey component was voluntary. This study involved secondary analysis of fully anonymized survey data. No personally identifiable information was available to the research team. In line with UK Health Research Authority guidance on Research Ethics Committee review, research limited to the secondary use of previously collected, non-identifiable information is generally excluded from NHS/HSC REC review where participants are not identifiable to the research team [31]. The authors had permission from the telecommunications company to access and analyze the anonymized dataset.

Instrument Development

The researcher involved in this study played a pivotal role in designing the survey questionnaire tailored to meet the trial's specific objectives. Subsequently, the questionnaire was handed over to the organization, the study's industry partner, for further refinement to ensure alignment with their requirements. Following this collaborative effort in questionnaire design, the researcher's involvement with the trial concluded, with no direct participation in the trial's administration. The survey was developed using pre-existing surveys from already recognized models of technology adoption. Constructs selected to be included were primarily based on the UTAUT model [28]. In our instrument development, we opted for the inclusion of open-ended survey questions to provide participants with a platform to articulate their experiences with the CCS. These can also be seen in Multimedia Appendix 1. This design enabled the collection of both quantitative and qualitative data regarding participants' interactions with the CCS, providing a naturalistic view of technology adoption behavior among older adults.

Qualitative Analysis

The results reported in this study were derived from an inductive thematic analysis following the 6-stage reflexive approach proposed by Braun and Clarke [32,33]. The analysis used an open-coding strategy, in which participants' excerpts were first coded line by line and then iteratively grouped into broader categories and overarching themes. This process was conducted using NVivo (version 12, QSR International) software to assist in organizing, coding, and managing the data while enabling the identification of recurring patterns and relationships within the dataset.

The thematic analysis involved the following six stages: (1) becoming familiar with the data through repeated reading and annotation, (2) generating initial codes through open coding of

XSL•FO
RenderX

participant excerpts, (3) collating related codes into potential themes, (4) reviewing and refining these themes against the coded data and entire dataset, (5) defining and naming the final set of themes to ensure clarity and distinctiveness, and (6) producing the analytic narrative and selecting illustrative extracts for reporting. Thematic analysis, as a structured and methodical yet flexible approach, was particularly suited to analyzing the open-ended survey responses, allowing for both depth and breadth in interpreting participants' experiences with the CCS [34].

Quantitative Analysis

Structural equation modeling (SEM) was used as a social science tool to examine complex relationships among latent constructs and observed variables [35]. In this research, SEM was applied to explore factors influencing attitudes and behaviors towards technology adoption. By combining measurement and structural models, SEM validated instruments and tested causal relationships, making it suitable for small sample sizes like this study's 91 participants. SEM allowed for efficient analysis by integrating multiple relationships within one model, enhancing reliability despite limited data. The analysis followed standard operational steps: (1) data screening for missing values and outliers; (2) evaluation of the measurement model using Cronbach α and composite reliability (>0.70), average variance extracted (AVE) (>0.50), and discriminant validity via Fornell–Larcker and Heterotrait-Monotrait ratio criteria; and (3) estimation of the structural model using bootstrapping (5000 resamples) to assess path coefficients, *t* values, and *P* values. Model fit was assessed using SRMR, d_ULS, d_G, and NFI indices, which are appropriate for partial least squares SEM. Predictive accuracy was examined through R^2 values of endogenous constructs. To address limitations, qualitative findings were used to complement SEM results, offering a nuanced view of attitudes towards smart home technologies and balancing potential dataset shortcomings.

Mixed Methods Analysis

This research used a mixed method approach where quantitative and qualitative research methods were used concurrently, taking an exploratory approach. This research compared the findings of the quantitative and qualitative data collected [15,36]. By comparing and contrasting results from different data sources, triangulation enabled researchers to corroborate findings and uncover nuances that may not have been apparent with either method alone [37].

Results

Overview

A total of 91 participants responded to the survey between October 15, 2021, and October 29, 2021. A total of 14% of the participants were younger than 65 years, 16% between the ages of 65 and 75 years, 43% were aged between 75 and 85 years, and finally 27% were older than 85 years across the whole of the study. Additional demographic data were not reported, as only an anonymous dataset was shared.

Quantitative Analysis

The results of the UTAUT model are shown in Figure 1 and Table 1. PU, PEOU, facilitating conditions, and social influence explained 67% of the variance in behavior intention.

XSL•FO
RenderX

Figure 1. Results of Connected Care System data within the Unified Theory of Acceptance and Use of Technology model of technology adoption. BI: behavior intention; FC: facilitating condition; PEOU: perceived ease of use; PU: perceived usefulness; SI: social influence.

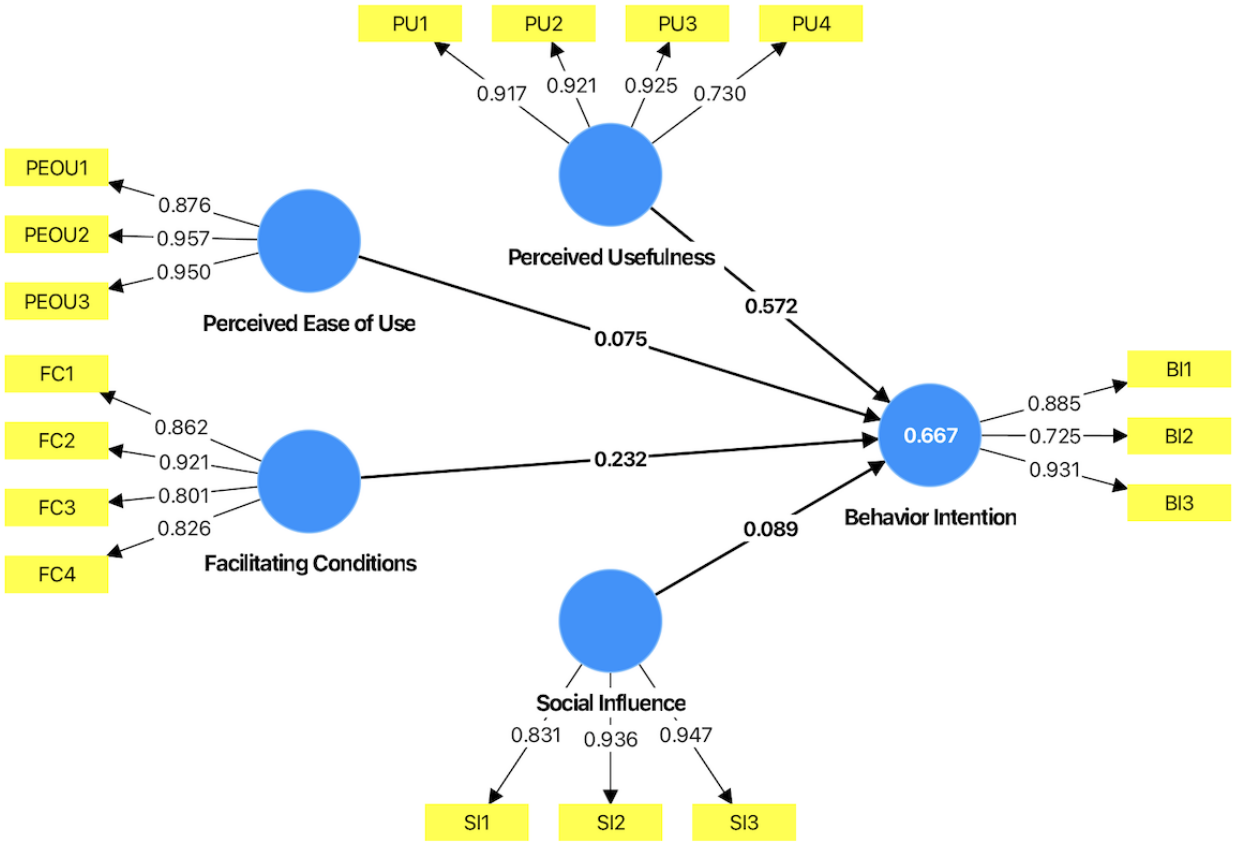

Table 1. Unified Theory of Acceptance and Use of Technology model results (P<.05 and T>1.96).

	Path coefficients	Sample, mean (SD)	Bootstrapped T value	*P* value	Hypothesis
Hypothesis 1	0.075	0.243 (0.095)	2.441	.02	Supported
Hypothesis 2	0.572	0.071 (0.111)	0.673	.50	Not supported
Hypothesis 3	0.089	0.101 (0.075)	1.186	.24	Not supported
Hypothesis 4	0.232	0.561 (0.099)	5.764	<.001	Supported

When measuring for discriminant validity of the model, we completed 2 separate tests of this. First, by considering the latent variable correlations (Table 2), and second, by considering the Heterotrait-Monotrait ratio ratios (Table 3). The recommended threshold for measuring the latent variable correlations is that all values should be below 0.85 [38]. Values above this can indicate that the constructs are too similar and do not measure distinct enough concepts.

Table 2. Unified Theory of Acceptance and Use of Technology latent variable correlations.

	Behavior intention	Facilitating conditions	Perceived ease of use	Perceived usefulness
Facilitating conditions	0.614	—[a]	—	—
Perceived ease of use	0.548	0.697	—	—
Perceived usefulness	0.766	0.502	0.471	—
Social influence	0.507	0.473	0.467	0.477

Table 3. Unified Theory of Acceptance and Use of Technology model discriminant validity (Heterotrait-Monotrait ratio matrix).

	Behavior intention	Facilitating conditions	Perceived ease of use	Perceived usefulness
Facilitating conditions	0.675	__[a]	—	—
Perceived ease of use	0.622	0.768	—	—
Perceived usefulness	0.890	0.520	0.506	—
Social influence	0.570	0.485	0.503	0.524

[a]Not applicable.

The study also tested for construct reliability measures such as Cronbach α and composite reliability (Table 4). The reliability coefficients are all above the recommended threshold of 0.70 [39], indicating satisfactory reliability. AVE assesses the amount of variance captured by the latent variables relative to measurement error. AVE values above 0.50 are generally considered acceptable [40], indicating that constructs explain more variance than measurement error.

Table 4. Construct reliability.

	Cronbach α	Composite reliability (rho_a)	Composite reliability (rho_c)	Average variance extracted
Behavior intention	0.808	0.844	0.887	0.726
Facilitating conditions	0.880	0.923	0.915	0.729
Perceived ease of use	0.919	0.940	0.949	0.861
Perceived usefulness	0.897	0.910	0.930	0.769
Social influence	0.891	0.914	0.932	0.821

Qualitative Results

This results section will describe the most relevant themes found in the thematic analysis, but a full breakdown of themes, including excerpts and frequency counts, is included in Multimedia Appendix 1.

Acquiring Technology

The largest theme emphasized the significant effort required for technology acquisition (n=46), with participants expressing that they would need substantial support, as one participant explained, “Too much/not capable by myself” (ID74).

Followed by participants’ desire for effortless technology acquisition (n=33), highlighting how important it was that the process of obtaining the CCS felt straightforward. Some participants described the experience as smooth and independent, for example, “It would be pretty straightforward to purchase this product” (ID84). A related theme was the desire to improve knowledge and understanding of the technology (n=37). Participants wanted to make more informed and autonomous decisions. For example, one noted simply, “Understanding of devices” (ID35), pointing to the value of accessible information during the acquisition stage. Transparency of cost information also emerged as a recurring concern (n=30). Participants wanted clarity about setup and ongoing costs to support their decision-making. One participant explained, “I need a simple one price for set up and then one monthly price please, nothing for extras” (ID25). Finally, family advice and support played a key role in acquisition processes (n=23). Many participants relied on family members’ expertise and guidance. As one participant put it, “My nephew as he is very good at explaining how to use the technology in a way I understand” (ID3). In several cases, decisions were made jointly, with either the older adult or the caregiver leading the practical acquisition.

Attitude to Technology

A prominent theme to emerge was exposure to the latest technology (n=39), which reflected participants’ curiosity and enthusiasm for innovation. Many were eager to explore and keep up with new technological developments, positioning themselves as proactive users. As one participant explained, “To know what new technologies are available and their potential” (ID72). Another described their involvement in testing initiatives: “I wanted to test the new innovation solution from … and wanted to see the latest and be part of the testing. I really enjoyed it” (ID25). This theme highlights how engagement with emerging technology is not solely the domain of younger groups; some older adults also actively seek new experiences.

Closely linked to this was a positive perception of technology (n=34), with participants frequently describing technology as beneficial, particularly for safety and well-being. For instance, one participant stated, “It won’t be going anywhere. It’s been great and I feel much safer” (ID17), while another simply noted “excellent” (ID15). These accounts illustrate the positive value placed on technology as part of everyday life. By contrast, a theme of neutral perception of technology (n=26) was also evident. Here, participants described the technology as “ok,” reflecting moderate satisfaction or indifference rather than enthusiasm or resistance. This suggests a pragmatic stance, where technology is seen as functional but not transformative.

A further theme concerned the role of technology in everyday life (n=24). Participants emphasized the significance of technology in supporting independence and enabling aging in place. For example, one participant noted, “I think it will play

XSL•FO
RenderX

an important role in allowing older people to live independent lives in their own homes rather than going into care" (ID22), while another commented, "It will play an effective role in keeping me independent but safe" (ID52). These perspectives position technology as an important, sometimes essential, element of daily living for older adults.

Not all participants, however, saw technology as necessary. The theme of limited need for new technology (n=16) captured participants who stated that they did not perceive a need for the system, suggesting varying levels of perceived necessity based on individual circumstances. A smaller but noteworthy theme was updating current technology systems (n=4), where participants discussed adopting new systems as a way to replace or integrate with their existing devices. Finally, some participants expressed uncertainty about the role of technology (n=15), revealing ambivalence and mixed views. For example, one participant commented, "not too keen" (ID10), while another remarked, "It's not really impinged on my life. It's more for the kids" (ID29). These accounts reflect uncertainty about both the relevance and impact of the technology.

Older Adults' Perspective

A central theme concerns mobility decline (n=53), which emerged as one of the most significant challenges for participants. Many described increasing difficulties in moving around their homes, particularly for essential activities such as eating or using the bathroom. As one participant put it, "Getting around the house for food, toilet, etc" (ID52). Another noted, "I need a walking aid as I'm not good on my feet and can't walk far" (ID64). This theme underscores the ways in which declining mobility shapes daily routines and heightens vulnerability. Several participants expressed concerns about falls (n=15), including fears of collapsing alone at home, as one participant put it, "fear of failing" (ID29). Linked to this were concerns around memory decline (n=14), with participants describing difficulties remembering tasks, appointments, or daily routines. For example, one participant said, "My memory isn't so good so it's not so easy for me to remember what I'm supposed to be doing and when" (ID22). Closely related to this was the theme of health decline (n=25), which captured broader concerns about deteriorating physical capacities, including sight and general health. For example, one participant noted, "Further deterioration in my sight" (ID36), reflecting a heightened awareness of age-related change and its implications for independence.

Alongside these physical changes, participants also described challenges with solo tasks and chore difficulty (n=22), highlighting the impact of functional decline on everyday activities. For instance, one participant referred to a "decline in day to day functioning" (ID28), while another noted difficulties with "carrying things around house safely" (ID39). Emotional and social dimensions were also prominent. The theme of loneliness and isolation (n=18) revealed feelings of spending much of the day alone and a desire for companionship. One participant described, "feel lonely at times" (ID41), and another emphasized, "The ability to be able to have human interaction and company" (ID20). Similarly, mental health decline (n=9) captured experiences of boredom, demotivation, and low mood, as in the comment, "Boredom, not seeing anybody" (ID80).

A smaller theme captured older adults' reluctance to rely on assistive systems (n=13). Some participants articulated a preference for maintaining autonomy, for example: "but I want to be able to do things myself and ask for help if needed not rely on it" (ID25). This theme points to the tension between independence and technological support. Another theme, growing need for emergency response (n=8), reflected participants' recognition of the benefits of continuous monitoring and rapid assistance. As one participant explained, "Need more monitoring / access to immediate help" (ID70). These accounts illustrate the desire for reassurance that support is available in emergencies. Finally, the theme of reduced frequency of welfare checks (n=7) highlighted the perceived value of technology in supporting independent living while easing caregiver burden. One participant commented, "Less calls from relatives checking on me as they can see from the app I'm moving" (ID43). This was seen to benefit both older adults, who experienced fewer interruptions, and caregivers, who could monitor well-being remotely.

System Benefits

Participants described multiple benefits of the CCS, particularly in enhancing well-being and quality of life. A prominent theme was the older person's peace of mind (n=45), reflecting reassurance from knowing that assistance is available in case of emergencies. One participant explained, "I am always seeking ways of giving me more peace of mind that if something happens to me, I won't be alone" (ID68), while another noted, "have some relief knowing that my family are able to be notified if something happens" (ID86). Similarly, the theme of caregiver's peace of mind (n=26) highlighted how the system alleviates family concerns: "it stops my family worrying about me, knowing where I am or if I am alright" (ID25).

The CCS also supported enhanced independence (n=26), empowering older adults to live autonomously at home. Participants emphasized this benefit, as one stated, "Being able to live alone longer" (ID45), and another added, "I want to stay in my own home and live independently and these solutions will help me do that" (ID64). Complementing this was the theme of feelings of connectedness (n=13), illustrating how the system fosters familial bonds: "secure I know my daughter is looking after me" (ID10) and "Knowing my family are feeling more connected to me" (ID7).

Practical utility was also emphasized through the theme of usefulness (n=20). Participants described how the system supported daily activities and safety, for instance: "it is like the front door lock, I can't do without, even if I think I am safe!!" (ID25). Relatedly, caregiver support (n=16) reflected how the CCS facilitates informal caregiving by providing monitoring and communication: "It's just used by my family to watch over me" (ID64). Improved communication (n=15) further emphasized connectivity and prompt response in emergencies, as one participant noted, "Confidence there is a way of contacting people and being monitored in case I have issues" (ID28). Several participants valued discreet monitoring and devices (n=34 and n=11, respectively), highlighting unobtrusive

XSL•FO
RenderX

design and passive oversight: “I know that I can be seen to be active without feeling like I’m being watched” (ID60) and “I think the devices all look very smart and fit into my home nicely” (ID68). Finally, ease of use (n=5) and reminders (n=4) were seen as additional benefits, with participants describing the system as simple and supportive: “Very simple” (ID70) and “Little reminders are great” (ID3).

System Issues

The most prevalent theme concerned the reliability of the emergency support system (n=49). Participants consistently expressed worries about their ability to contact someone in case of emergencies, highlighting the need for a dependable and responsive system. One participant stated, “Making sure I can contact someone if I need to” (ID40), while another emphasized, “Fear of not being able to contact someone in the event of emergency” (ID6). These concerns underline that the perceived trustworthiness of emergency support is central to adoption and continued use.

Closely related was the theme of requiring additional and properly functioning devices (n=20). Participants highlighted the importance of reliable call buttons and integrated devices to enhance system effectiveness. As one participant noted, “Our call button never worked and we would definitely want one of those” (ID74), while another commented, “More but needs greater integration with other devices” (ID78). This theme reflects broader concerns about technology reliability and the need for well-functioning, complementary devices. The theme of assistance with setup and maintenance (n=9) captured participants’ need for practical support when installing or maintaining the system. Many reported struggling with new technology or complex setup procedures. For example, one participant explained, “Simple advice as I do not understand new technology” (ID61), and another stated, “I would not understand it or be able to do it without the help of others” (ID37). These accounts highlight that effective user support is critical for ensuring proper use.

Participants also emphasized dependence on additional services or devices (n=7), reflecting a desire for customizable solutions that meet individual needs and preferences. One participant noted, “Video system is likely to be more useful” (ID6), while another stated, “Also if additional types of device become available, they would be considered” (ID74). This theme underscores the value of flexibility in system design to accommodate varying requirements. Smaller themes included financial aid (n=14), with participants recognizing that affordability may influence adoption, and adjustment periods required to trust technology (n=3), exemplified by a participant remarking, “It took a bit of time for me to trust it wasn’t watching everything I do” (ID60). These reflect practical and psychological considerations that can affect engagement with the system.

Discussion

Principal Findings

This study examined how older adults perceive and engage with the CCS, a passive smart home technology designed to support well-being through ambient monitoring. Using a mixed methods approach, we identified several insights that extend existing theoretical models and carry implications for the design, implementation, and policy contexts of care technologies. Notably, our findings suggest that UTAUT [28] requires adaptation when applied to ambient systems. For older adults who engage with the system indirectly, the boundary between PU and behavior intention becomes less meaningful. Consistent with prior research [16,41-44], PU and social influence did not reach statistical significance, highlighting the complexity of measuring technology adoption in this demographic. This finding suggests that PU may require reconceptualization in the context of passive or ambient smart home technologies. For older adults, usefulness may not be derived from direct task performance or system efficiency—as traditionally defined in UTAUT—but from indirect, emotional, and relational benefits, such as reassurance, safety, and reduced caregiver burden. Redefining PU to incorporate these affective and social dimensions may therefore provide a more accurate representation of technology value in aging in place contexts.

A key factor shaping these findings is the passive nature of the CCS. Unlike technologies used actively on a day-to-day basis, participants rarely interacted directly with the system or the data it collected. Instead, benefits were realized indirectly through caregivers or family members, who could monitor the older adult’s well-being without interrupting their daily routines. Consequently, participants’ perceptions of usefulness were primarily emotional rather than functional [14], encompassing peace of mind, reassurance, and ease of access to safety information. As one participant noted, the comfort provided by the system is valuable even if it is not actively used. This underscores the importance of evaluating technology not only in terms of functional outcomes but also in terms of emotional and relational value.

The study also highlights the critical role of social influence and caregiver mediation in technology adoption. Although quantitative analysis found no significant link between social influence and behavior intention, qualitative findings emphasized that family and caregivers play a central role in adoption and ongoing use. This reflects prior research in health settings that integrates social, emotional, and contextual factors into technology acceptance models [45] and suggests that adoption should be conceptualized as a relational process involving shared decision-making and co-dependency within household care arrangements. These dynamics raise broader concerns about digital equity, particularly in how older adults rely on others to access and benefit from smart home technologies.

It is important to acknowledge the potential impact of the small sample size (n=91) on the statistical power of the SEM and the generalizability of the findings. While SEM provides a robust framework for evaluating complex relationships, smaller sample sizes can increase the risk of Type II errors, potentially obscuring significant effects and limiting the reliability of path estimates. In this study, the limited sample may have contributed to the nonsignificant relationships observed between PU, social influence, and behavior intention. Furthermore, the participant pool reflects a specific demographic context—older adults

XSL•FO
RenderX

engaged with a passive smart home system—which may not capture the full diversity of older populations in different care settings or cultural contexts. These considerations highlight that, while the findings provide meaningful insights into the relational and emotional dimensions of technology adoption, caution is warranted in extrapolating the results beyond this sample. Future research should aim to replicate these analyses with larger and more diverse cohorts to confirm the robustness of the observed patterns.

Furthermore, this study contributes to methodological advancements in technology adoption research by demonstrating the value of mixed methods approaches. While UTAUT has been widely applied using survey-based models [46], our research underscores the necessity of integrating qualitative thematic analysis to contextualize adoption behaviors [45]. The discrepancies between quantitative and qualitative findings, particularly regarding PU and social influence, highlight the limitations of relying solely on numerical measures to understand technology adoption in aging populations. By combining statistical modeling with in-depth user perspectives, this study provides a richer, more nuanced understanding of technology adoption, reinforcing the importance of mixed methods research in studying complex user interactions with emerging technologies [23,47].

Ultimately, this research contributes to ongoing debates about how emerging technologies are transforming domestic life and care infrastructures. By integrating qualitative thematic analysis with a widely used adoption model, the study provides a socially embedded account of technology uptake—reflecting the realities of aging, caregiving, and digital participation. The findings highlight the importance of designing technologies not only for individual users but also for the networks and systems that support them, with consideration for emotional reassurance, relational dynamics, and passive engagement.

Comparison With Prior Work

The joint table developed from the mixed method analysis can be seen in Multimedia Appendix 1 [36]. The table presents the qualitative and quantitative findings alongside the construct relationships found in our CC model. The final column of the table presents the meta inference, and the distinction of each inference as being in discordance, expansion or confirmation [48].

Behavior Intention

The quantitative findings of this study provide strong evidence that behavior intention is a significant driver of technology adoption among older adults, as indicated by the high explanatory power in our UTAUT model. This suggests that older adults are not only receptive to smart home technologies like the CCS but also actively recognize their potential to enhance quality of life, increase independence, and provide peace of mind. These findings align with previous studies demonstrating that when technology addresses key psychological and emotional needs, older adults are more willing to adopt and use it [11,49]. The qualitative data further support this conclusion, revealing a strong enthusiasm for continued use of the CCS. Participants particularly valued the peace of mind, security, and independence it provided, not just for themselves but also for their caregivers. However, while the overall attitude toward adoption was positive, qualitative insights also highlight key challenges and barriers that must be addressed to ensure sustained, reliable, and comfortable usage. These include concerns about reliability, usability, and the role of caregivers in facilitating technology adoption. This suggests that technology adoption among older adults is not simply a matter of willingness—rather, it is shaped by contextual factors, such as how well the system integrates into their existing support networks and whether it is perceived as empowering rather than burdensome.

Perceived Ease of Use

Our quantitative findings confirm that PEOU is a significant predictor of behavior intention. This aligns with the technology acceptance model, reinforcing the well-established importance of usability in driving technology adoption among older adults [29]. High outer loadings for PEOU indicators suggest that participants consistently found the CCS to be intuitive and learnable, supporting the need for simplified and user-friendly interfaces. The qualitative findings, however, provide additional depth to this perspective. While participants acknowledged that the system was relatively easy to use, they also emphasized the importance of customizability and flexibility. Many older adults desired the ability to mix and match features based on their individual needs, which were largely influenced by health status, mobility, and caregiving arrangements [50]. This suggests that ease of use is not a one-size-fits-all construct—rather, it should be viewed as a dynamic, individualized factor that varies based on personal circumstances and support systems. A notable insight from the qualitative data is that older adults often rely on caregivers or family members for technology setup, troubleshooting, and maintenance. This highlights an important but underexplored dimension of PEOU: the role of the caregiver in facilitating ease of use. Some participants saw the caregiver as the primary user, while they themselves merely benefited from the system's presence. This raises a critical question: how does ease of use function in systems with shared users, particularly when the technology benefits both the caregiver and the older adult?

Perceived Usefulness

The qualitative data strongly emphasized the usefulness of the CCS, with participants highlighting key benefits such as peace of mind, safety, and independence. These benefits were not just functional but also emotional, reinforcing findings that technology for older adults often plays a psychosocial role beyond simple task efficiency [11,49]. However, the quantitative results indicate that PU did not significantly predict behavior intention. This discrepancy suggests that the traditional conceptualization of PU in technology adoption models may not fully capture its meaning for older adults. Specifically, usefulness in this context extends beyond functionality—it encompasses emotional security, social connectedness, and caregiver support. Furthermore, the qualitative findings suggest that customizability plays a key role in perceptions of usefulness. Older adults highly valued the ability to tailor the system to

XSL•FO
RenderX

their specific needs, which were highly individualized based on health, mobility, and social support structures [50].

Social Influence

The relationship between social influence and behavior intention was the weakest in our model, a finding that aligns with previous studies questioning the role of social influence in older adults' technology adoption [23,47]. This suggests that broader social networks (eg, friends, community) have minimal impact on adoption decisions, while immediate family and caregivers play a much more significant role [49,51]. The qualitative findings reinforce this idea, revealing that older adults primarily rely on caregivers and family members for support, setup, and decision-making. Interestingly, participants often saw the caregiver as the true decision-maker, which may explain the weak correlation between social influence and behavior intention—older adults do not see the choice as their own, but rather as a necessity dictated by their caregivers. This suggests a reconceptualization of social influence is needed in models of technology adoption for older adults, particularly when technology is used collaboratively.

Facilitating Conditions

The quantitative findings confirm that facilitating conditions are a strong predictor of behavior intention, reinforcing existing literature that emphasizes the importance of external support in technology adoption [52]. However, our qualitative findings reveal a more complex picture of facilitating conditions. The moderate positive correlation between facilitating conditions and PEOU (0.697) suggests that the availability of resources and support contributes to users' perceptions of how easy the system is to use. This underscores the importance of providing adequate support structures, clear instructions, and accessible help resources to enhance the PEOU of smart home systems for older adults. Particularly in the case of older adults, who may be starting their adoption process from a point of less knowledge than younger users of smart home systems. A key theme emerging from the data is that older adults perceive facilitating conditions as external rather than internal. Many participants felt that they did not need personal knowledge of the system, as they relied on family members to provide expertise and manage technology-related tasks. This suggests that the traditional framing of facilitating conditions in UTAUT may need revision—rather than measuring an individual's perceived ability to use technology, future models should account for interdependent technology adoption, where one party (the caregiver) facilitates access for another (the older adult). Additionally, the qualitative data highlight the importance of knowledge acquisition—older adults expressed a need for better education and guidance on how to use CCS effectively. This aligns with prior research indicating that older adults require ongoing education and training to improve confidence in new technology [52].

Implications for Design and Practice

The findings from this study inform a set of 6 interrelated design requirements that enhance the adoption, usability, and effectiveness of smart home technologies such as the CCS for older adults and their caregivers. Together, these requirements highlight the importance of designing systems that are not only technically reliable and easy to use but also emotionally supportive, socially connected, and adaptable to users' evolving needs. They address key adoption factors, including behavior intention, facilitating conditions, social influence, PU, and ease of use. Table 5 summarizes how each construct informed specific design requirements, linking empirical insights to actionable design guidance.

Table 5. Design requirements showing the meta inference made across each of the constructs, the system adaptation required to fit in the smart home context, and the requirements.

UTAUT[a] construct	Meta-inference	Requirement based on adaptation
Perceived usefulness	Older adults and caregivers value peace of mind, security, and independence provided by CCS[b]. High behavior intention indicates a strong interest in adoption.	RQ1: Provide clear and tangible benefits emphasizing safety, independence, and emotional reassurance.
Perceived ease of use	Older adults often lack confidence and require structured onboarding to navigate the system effectively.	RQ2: Implement an intuitive, guided onboarding process with tutorials and voice navigation. RQ3: Develop a minimalist, senior-friendly UI with large fonts, voice controls, and simple navigation.
Social influence	Immediate family plays a crucial role in adoption, highlighting the need for real-time shared insights into user well-being.	RQ4: Include a "Shared Dashboard" for real-time well-being monitoring by family members.
Facilitating conditions	Concerns about reliability affect perceived usefulness; trust-building measures can increase confidence in the system.	RQ5: Emphasize trust-building features (fail-safe mechanisms, backup options, transparent logs); provide a dual-interface option with "Essential Mode" and "Full Feature Mode", allowing users to customize their experience based on their comfort level.
Behavior intention	Older adults have varying comfort levels with technology; dual-interface options allow for gradual adaptation and personalized interaction.	RQ6: Provide dual-interface options to allow gradual adaptation and personalized interaction, supporting both mediated and autonomous use.

[a]UTAUT: Unified Theory of Acceptance and Use of Technology.

[b]CCS: Connected Care System.

XSL•FO
RenderX

A central design priority is to ensure that smart home technologies deliver clear and tangible benefits (RQ1). The findings show that both older adults and caregivers highly value peace of mind, safety, and independence, making these factors essential in encouraging adoption. To reinforce behavior intention, systems should communicate emotional and practical benefits early and consistently, for example, through onboarding materials, real-life success stories, and user testimonials that illustrate improvements in daily life and well-being. Integrating real-time feedback, alerts, and status updates can further build confidence and demonstrate reliability, reassuring users that the system is functioning as intended [11].

For many older adults, low digital confidence remains a significant barrier to adoption. A structured onboarding process that includes step-by-step tutorials, voice-assisted navigation, and simplified instructions can help users build comfort and familiarity (RQ2). Importantly, training should not target the older adult alone. Because family members and caregivers often play a central role in setup and troubleshooting, implementing a "Family Support Mode" would allow them to provide remote assistance when needed. To maintain inclusivity, designers should also offer multiple access pathways, such as an on-demand helpline, chatbot, or low-tech phone-based interfaces, ensuring that support is available for users who struggle with app-based interactions [52].

Ease of use also depends on minimizing cognitive load and supporting habitual use. A senior-friendly interface with large fonts, voice commands, and clear navigation can make the system more accessible (RQ3). Compatibility with smart assistants such as Alexa or Google Home would reduce interaction complexity and align with technologies many users already know. Personalized automation features—such as preset routines and scheduled alerts—can further reduce manual adjustments and promote effortless engagement. These design strategies together enhance usability and sustain engagement over time, reinforcing the link between ease of use and adoption [23].

Equally important is recognizing that adoption and use are shared experiences rather than solitary ones. A "Shared Dashboard" can enable caregivers to remotely monitor well-being while preserving older adults' autonomy (RQ4). Multiuser support and customizable permission settings allow older adults to determine what data are visible and to whom, maintaining control and privacy within supportive relationships. These features echo evidence that family involvement—rather than peer influence—is the strongest predictor of adoption among older adults [50,51]. To further enhance trust, fail-safe mechanisms, transparent data logs, and customizable alerts (eg, emergency notifications, wellness check-ins, or reminders) should be integrated. A non-intrusive "Check-in" feature can also allow caregivers to confirm safety in a way that is supportive rather than surveillant [49].

Beyond interpersonal support, the system itself must feel dependable and seamlessly embedded in daily life. Smart home interfaces should be transparent, intuitive, and designed for users with differing levels of digital experience (RQ5). Because many participants preferred minimal engagement, passive monitoring functions should operate quietly in the background, providing meaningful support without creating a sense of constant observation or disruption [45]. This principle extends beyond product design to service delivery, offering guidance for housing providers, health and social care organizations, and policymakers seeking to integrate smart home systems into aging in place strategies [53].

Finally, long-term adoption depends on flexibility and personalization. Older adults' needs and comfort levels change over time, meaning that a single interface or configuration is unlikely to suit all users indefinitely. A dual-interface option, allowing users to switch between a simplified Essential Mode and a more advanced Full Feature Mode, supports gradual learning and adaptation (RQ6). Customization features—such as adjustable settings, notification preferences, and tailored prompts—ensure that technology remains user-centric and empowering. Such personalization not only promotes sustained engagement but also helps mitigate feelings of surveillance or dependency, reinforcing autonomy and dignity in everyday use [30,50]. In this way, personalization and emotional reassurance become mutually reinforcing elements of inclusive smart-home design. This form of personalization enhances usability while helping to reduce perceptions of surveillance or disruption, especially in multiuser households [54].

Taken together, these design implications emphasize that effective smart home technologies for aging populations must integrate emotional reassurance, shared use, and adaptability into their core functionality—not as optional features but as central principles. Doing so will enable systems like the CCS to support aging in place while strengthening trust, confidence, and connectedness between older adults and their caregivers [55].

Limitations and Future Research

Building on the contributions of this study, future researchers should rethink traditional approaches to technology adoption in aging populations by incorporating training interventions and structured support systems that better address older adults' needs. This study highlights the importance of customization and personalization, suggesting that future research should move beyond generic usability considerations and instead investigate which specific customization features are most effective in promoting long-term engagement with smart home and health care technologies.

Additionally, this study challenges the conventional social influence construct in technology adoption models. Future researchers should redefine social influence by considering how shared-use systems operate when one user group (eg, caregivers) has more agency in adoption decisions than the other (older adults). Researchers should explore family dynamics in adoption processes, shifting focus from broad social influence on immediate social networks, particularly how family members shape adoption and continued use. Future studies should explore how caregiver involvement modifies traditional adoption pathways, particularly in health, caregiving, and assistive technologies [52]. A key limitation of this study is that data were collected solely from older adults, without corresponding input from their caregivers. As a result, the findings reflect older

XSL•FO
RenderX

adults' perceptions of caregiver involvement rather than caregivers' own experiences and perspectives.

Furthermore, this work calls for a broader conceptualization of PU in aging populations. Future adaptations of UTAUT should refine the PU construct to better capture indirect, relational, and emotional benefits, rather than relying solely on task efficiency-based measures [11,49]. Last, researchers should integrate care models with technology acceptance frameworks, recognizing that smart home technologies are often collaborative rather than individualistic, requiring a more nuanced understanding of adoption behaviors across multiple stakeholders.

The methodology used in this study was subject to several noteworthy limitations, which significantly impacted the results and constrained the interpretation of the data. The lack of control over participants' access to technology introduced variability in their technological usage throughout the experiment. This may have confounded the results, particularly affecting the PEOU construct. By not having an in-depth understanding of the user's existing experience and self-efficacy with computer use, the results and their interpretation have assumed minimal experience and knowledge regarding computer skills. Despite these limitations, the study's strength lies in its use of real participants who used a real system for a minimum of 6 months. This real-world usage provides valuable practical insights, reflected in the strong relationship between facilitating conditions and behavior intentions. However, the methodological constraints may have led to an incomplete picture of the adoption process, particularly in understanding the temporal aspects of adoption and the evolving perceptions of usefulness over time.

Conclusions

This study sought to examine the adoption and use of the CCS among older adults over a 6-month period, addressing a critical research gap in understanding how this population interacts with smart home technologies in real-world settings. By using both quantitative and qualitative methods, the study offers a more nuanced perspective on the factors influencing the adoption of these technologies. The research contributes to the existing literature by testing the applicability of preexisting adoption constructs, particularly those from the UTAUT model, while also revealing insights that may challenge or extend these frameworks when applied to older adults. Findings indicate that PU in passive smart home technologies must be redefined to include emotional and relational benefits, rather than focusing solely on task efficiency. The role of caregivers as facilitators in adoption decisions emerged as crucial, necessitating a more relational approach to social influence.

Furthermore, personalization and adaptability were identified as key factors in sustained engagement. These insights have practical implications for system design, emphasizing the need for user-friendly, customizable, and caregiver-supported technologies. Future research should further explore caregiver involvement, shared-use adoption models, and long-term engagement strategies to ensure that smart home technologies effectively support aging in place, balancing independence, usability, and support structures.

Acknowledgments

The authors would like to thank all participants for their patience and openness to share opinions on a novel assistive technology. This study was supported by funding from the Engineering and Physical Sciences Research Council (EPSRC) through an Industrial CASE Award, with additional support provided by a large telecommunications organization in the United Kingdom.

Conflicts of Interest

Abstract

Background: By 2050, 22% of the global population will be aged 60 years or older, with Europe experiencing rapid aging. This increase in chronic diseases and functional decline demands a shift from fragmented, hospital-centric care to continuous care models. The World Health Organization's healthy aging framework prioritizes intrinsic capacity (IC)—defined as physical and mental abilities across the locomotion, vitality, sensory, cognition, and psychology domains. Digital health solutions enable remote monitoring but face barriers, such as low digital literacy and usability challenges among older adults.

Objective: This study evaluates the impact of a multidimensional, artificial intelligence–driven digital health platform (CAREUP) on the dynamic monitoring and personalized enhancement of IC in community-dwelling older adults through the integration of real-time physiological, cognitive, and behavioral data streams.

Methods: This pilot feasibility study was conducted from September to December 2024 in Italy, Romania, and Austria. It involved 66 older adults as primary users and 17 caregivers as secondary users. The CAREUP system included Android apps (Careplan and Positive Health), smart devices, and a dashboard. Users followed a 2-month plan. We assessed usability (System Usability Scale [SUS]), user experience (User Experience Questionnaire short version [UEQ-S]), and acceptance (qualitative) at 3 time points (T0, T1, and T2), along with health and quality-of-life measures.

Results: Of the 66 enrolled participants, 61 primary users (37 women and 24 men; mean age 73.9 years) completed the study. The overall SUS score was 68, indicating acceptable but improvable usability, with significant variation across countries. The UEQ-S score of 1.45 indicated a good overall user experience, with high Hedonic Quality (1.66) suggesting strong emotional appeal and Pragmatic Quality (1.23) reflecting above-average usability. Most participants (49/61, 80%) rated the platform as interesting, helpful, and efficient, and 48 out of 61 (79%) were willing to recommend it to friends. Secondary outcomes demonstrated stable physical and mental health and maintained independence in daily activities. Technical connectivity issues and device complexity emerged as the primary barriers to adoption.

Conclusions: CAREUP demonstrated feasibility for IC monitoring, with acceptable usability and a positive user experience. However, technical challenges and cross-country variations indicate a need for adaptations to address cultural differences and

XSL•FO
RenderX

varying levels of digital literacy. Prioritizing reliability, simplifying the system, and providing user support will be essential to enhance broader adoption.

Introduction

Background

By 2050, nearly 22% of the global population will be aged 60 years or older, with Europe experiencing a particularly rapid demographic shift in which those aged over 65 years will outnumber children aged under 15 years [1,2]. This aging trend is accompanied by a rise in chronic diseases, as aging is a primary risk factor for many health conditions [3,4]. Age-related chronic diseases often lead to functional decline and social isolation, making it difficult for older adults to maintain independence and quality of life.

To shift away from a disease-centered model of aging, the World Health Organization introduced the concept of healthy aging, which focuses on preserving functional abilities through the optimization of intrinsic capacity (IC) alongside environmental support. IC encompasses the core physical and mental abilities individuals have at different stages of life, which are influenced by environmental factors and naturally decline with age. It includes 5 key domains: locomotion, vitality, sensory function, cognition, and psychological health [5-7].

Preventing chronic diseases and improving the lives of older adults require care models that focus on maintaining IC. The World Health Organization's Integrated Care for Older People framework recommends an integrative, long-term, multidisciplinary approach centered on person-focused care [8]. However, these complex care needs place significant strain on health care and social systems that are already facing resource shortages, compounded by a limited supply of formal and informal caregivers [9-11].

Digital technologies present promising solutions to support this challenging landscape. Remote monitoring and digital health platforms can streamline and integrate the management of chronic conditions, enhancing older adults' independence while reducing health care costs. Collectively referred to as digital health solutions, these technologies require users to have varying levels of health and digital literacy, which must be considered to ensure accessibility and adoption, especially among older adults with frailty and chronic disability [12-16]. Given the wide variability in digital skills among seniors and their preference for personal contact with health care providers, digital tools must be tailored to be simple, intuitive, and user-friendly—for example, by employing large fonts, minimal button use, and straightforward interactions [17-19].

Knowledge Gap

Many digital platforms targeting healthy aging have been developed in both commercial and research settings, as summarized in Table 1. Most health monitoring platforms collect data using sensors, such as blood pressure monitors, thermometers, oximeters, smartwatches, and activity trackers, as well as digital questionnaires assessing mental well-being and social engagement. These data are typically uploaded via a gateway device, such as a tablet or smartphone, and processed in the cloud. The outcomes are usually accessible through web- or mobile-based interfaces.

Table 1. Exemplary health monitoring platforms.

Platform name	Target	Data sources	Interface	Additional features	Trials	Usability
Comarch HomeHealth 2.0 [20]	Patients and medical professionals	Sensors and questionnaires	Web and mobile	Alerts of parameters outside of predefined scope and virtual visits	Not reported	Not reported
RO-SmartAgeing [21,22]	Patients and medical professionals	Sensors	Web and mobile	Alarms for unusual parameter values	Laboratory tested	High (laboratory tested)
InnoWell [23]	Patients and medical professionals	Sensors, medical records, and questionnaires	Web	No	Not yet reported; protocol available	Low
My AHA [24]	Patients and medical professionals	Sensors and other platforms (acts as middleware)	Web and mobile	Personalized care plan and fall and dementia risk	20 adults (alpha wave)	Not reported directly; platform revised after alpha wave
GER-e-TEC [25,26]	Older adults	Sensors and questionnaires	Web	Alerts of warning signs leading to hospitalization	36 adults monitored for 2 months; specificity could be higher	Not reported
FRAIL [27]	Patients with prefrailty and frailty	Sensors (including custom vest)	Web	Gamification system	40 adults recruited to test the devices	Medium usability of the custom sensors
CAREPATH [28,29]	Older adults	Sensors and questionnaires	Web and mobile	Personalized care plan and physical exercises plan	11 project team members	Good to excellent according to the project team members
HOPES [30,31]	Patients and medical professionals	Sensors and smartphone	Web and mobile	Anomaly detection	100 patients with schizophrenia	Not reported
Vivify +Home [32]	Patients and medical professionals	Sensors and smartphone	Web and mobile	Health tips and virtual visits	Not reported	Not reported
NESTORE [33]	Older adults	Sensors, questionnaires, and location data	Web and mobile	Personalized care plan, social platform, and chatbot	10 older adults	Reported issues with software usability
CAREUP [34]	Older adults	Sensors, questionnaires, and games	Web and mobile	Personalized care plan, intrinsic capacity monitoring, intrinsic capacity prediction, and games	66 older adults and 17 caregivers in 2 months	See the "Usability" section

The platforms differ primarily in how they process data and the services they offer. Medical system–connected platforms often alert caregivers or clinicians to abnormal physiological readings and may provide online consultation features. Home-use platforms tend to focus on personalized care plans that adapt based on the user's current status. More advanced solutions incorporate predictive analytics to estimate the risk of future health problems or declines in capacity.

As maintaining user engagement is crucial for platform success, features such as social networking and gamification are commonly added to enhance adherence. However, usability remains a pervasive and critical challenge. Many platforms incorporate wearables, mobile apps, and surveys to cover all IC domains, but often neglect the linguistic, educational, and social diversity of older adults. This oversight results in low user acceptance and limited engagement [23,35-40]. Reported challenges include difficulties with navigation, lack of personalized experiences, software bugs, and hardware integration issues [27,33]. These barriers are frequently observed in newly developed platforms within research projects.

Caring for an aging population within the healthy aging framework requires supporting residual IC and compensating for its decline. Technology designed specifically for older adults may facilitate integrated and continuous care, thereby addressing physical and psychosocial needs more effectively.

Study Objectives

The CAREUP project introduced an innovative digital platform for the remote monitoring of older individuals' IC to promote inclusive health. It integrates real-time physiological, cognitive, and behavioral data, aiming to slow IC decline and support caregiver-assisted care. This paper reports on a pilot feasibility study detailing the study design and user interactions with the CAREUP platform across Italy, Romania, and Austria. The results focus on usability, acceptance, and the platform's impact on quality of life, cognition, and physical activity. In line with current reporting standards for digital health implementations, this work was structured according to the iCHECK-DH (Guidelines and Checklist for the Reporting on Digital Health Implementations) to enhance completeness, transparency, and

XSL•FO
RenderX

reproducibility of the implementation description. The completed iCHECK-DH checklist is provided as Multimedia Appendix 1.

Methods

Study Design

The pilot feasibility study was one of the main objectives of the CAREUP project, aimed at evaluating the platform in a real-life environment and collecting feedback from actual users. A mixed methods design was used to collect data from primary (older adults) and secondary users (formal or informal caregivers). End users (primary and secondary) were enrolled by project partners in 3 European countries (Austria, Italy, and Romania) from September 2024 to December 2024.

Ethical Considerations

The research protocol was approved by the Ethics Committee of IRCCS INRCA (Istituto Nazionale di Ricovero e Cura per Anziani) on March 30, 2023 (approval number D/GEN 91).

CAREUP Platform Technical Description

The CAREUP platform integrates Android apps installed on a tablet (Careplan and Positive Health [PH]), smart devices, and an online dashboard (CAREUP's Portal Web Interface). The CAREUP platform concept is presented in Figure 1, and a brief description of the platform components is provided in Table 2. The technical aspects of the platform and the implemented algorithms are described in more detail elsewhere [34].

Figure 1. The CAREUP platform concept. AI: artificial intelligence; IC: intrinsic capacity; ICT: information and communications technology.

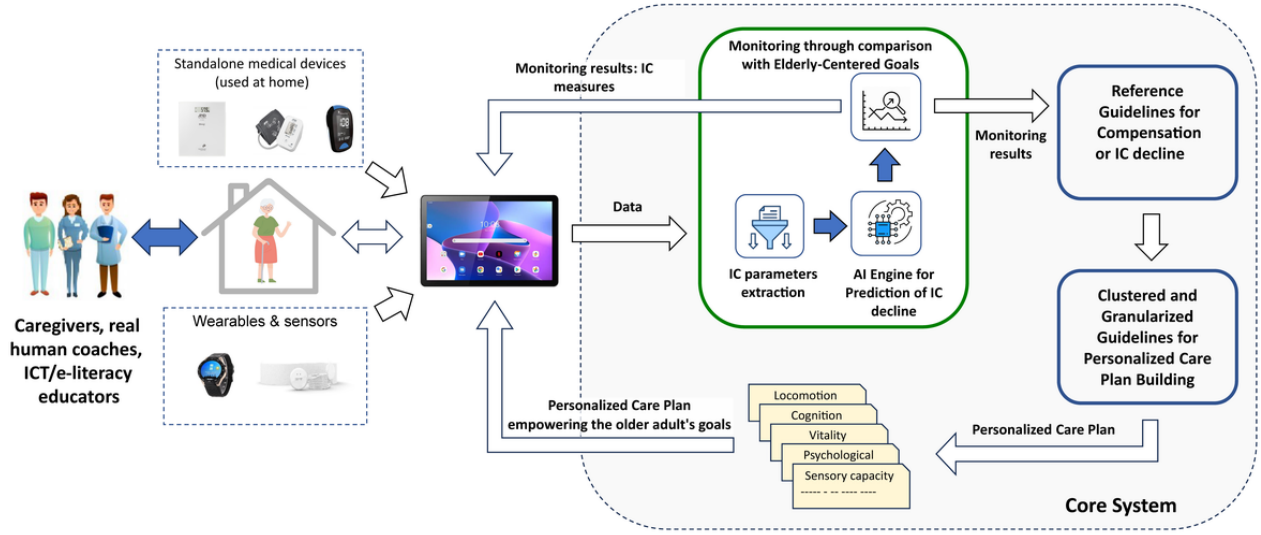

Table 2. CAREUP platform: components and functions.

Component type and the respective component	Function
Android tablet apps	
Careplan app	• Health parameters scan and report • Access to cognitive games apps
Positive Health app	• Health questionnaires and locomotion test
Devices	
Smartwatch (Starmax WS50)	• Step number acquisition
Blood pressure monitor (iHealth track)	• Blood pressure measurement
Weight scale (iHealth weight scale)	• Weight measurements
Oximeter (iHealth PO3M)	• Saturation measurement
Glucometer (iHealth glucometer)	• Blood glucose measurement
Handgrip strength meter (GRIPX Digital Hand Dynamometer Grip Strength Measurement Meter)	• Grip strength measurement
Online dashboard	
CAREUP's Portal Web Interface	• Monitoring of health parameters and intrinsic capacity values

XSL•FO
RenderX

The platform operation follows a common pattern in which primary users, using the platform devices, collect multimodal health data, such as the number of steps taken per day, blood pressure, oxygen saturation, body weight, and sleep quality. The core platform app is the Careplan app, which acts as the entry point to all platform apps. Its main purpose is to collect data from the medical devices. For supported Bluetooth-enabled devices, data are transferred and uploaded automatically using standard, secure protocols; for others, results can be entered manually. The Careplan app presents users with a personalized care plan, including tips for maintaining their IC at the required levels. Users can also access the PH app and the game section through provided links, featuring cognitive games selectable from both commercial and CAREUP-specific options.

The PH app is designed to collect health data that cannot be captured with smart devices. It includes digital health questionnaires to gather information on aspects such as well-being, emotions, and social activities, as well as 2 locomotion tests to assess physical performance. The PH app questionnaires are brief and consist of 3-4 closed-ended questions selected from a pool of 89 items derived from standardized and ad hoc reference questionnaires (Table 3). To reduce respondent burden, the PH app questionnaires do not address family situation, cognition, religion, or instrumental activities of daily living. A questionnaire for a given day is generated according to a predefined 4-week cycle, during which each question is asked at least once. Questions from specific reference questionnaires are distributed throughout the cycle to avoid monotony and maintain user engagement. If a user forgets to complete the PH app on a given day, the prepared questions are presented the following day. The questionnaire generation cycle is described in detail in Multimedia Appendix 2.

Table 3. Reference list of health questionnaires.

Standardized questionnaires	Assessment area
EQ-5D-5L [41]	Quality of life
15-item Geriatric Depression Scale [42]	Depression level
Health Status 12-Item Short Form version 2 [43]	Quality of life
Instrumental Activities of Daily Living scale [44]	Overall well-being
Loneliness Scale version 3 [45]	Perceived social isolation
Lubben Social Network Scale—Revised [46]	Social isolation
Mini Nutritional Assessment [47]	Overall nutritional status
Montreal Cognitive Assessment [48]	Mild cognitive impairment
Patient Health Questionnaire [49]	Depression level
Sensory domain (ad hoc questionnaire)	Sensory system
Short Physical Performance Battery [50]	Functional mobility in older adults
Sleep Quality Scale [51]	Sleep quality
Spiritual Well-Being scale [52]	Perceived spiritual quality of life
User-Centered Goals (ad hoc questionnaire)	User's goals/needs
Locomotion test	
30-second chair stand test [53]	Leg strength and endurance
Balance test [54]	Balance

The app's locomotion tests implemented selected components of the Short Physical Performance Battery, specifically the chair stand and balance tests. The PH app also provides users with appropriate instructions to enable them to perform the tests at home.

Results from device measurements and from the PH app's questionnaires and tests are uploaded to the platform via a Representational State Transfer (REST) application programming interface using the secure HTTPS protocol. In addition, any application programming interface operation requires a valid token to be provided with the request. Tokens are generated only for logged-in users and have an expiration date. After a prolonged break of a few days in platform use, the user must log in again.

The results are stored in a secure database in the CAREUP cloud. For additional data security, they are pseudonymized, and they cannot be directly linked to users' personal information without access to additional data. The collected results are used for weekly assessments of primary users' health status and IC. They also serve as the basis for preparing personalized care plans and IC prognoses.

Summaries and graphs of the analysis results are automatically generated and presented in the CAREUP Portal Web Interface, the online dashboard of the CAREUP platform. This browser-based interface can be accessed by both primary and secondary users using personal credentials to review health status and monitor changes in IC among older adults. In addition, the Web Portal provides access to results from medical

XSL•FO
RenderX

devices and outcomes of game sessions completed by the primary user.

Outcomes Measures

Data collection was conducted at 3 time points: the baseline evaluation (T0), the intermediate evaluation (T1), and the final evaluation (T2).

The primary outcomes, assessed at T1 and T2, aimed to evaluate the system's usability, user experience, and acceptance. Perceived usability of the platform (mobile apps, devices, and online dashboard) was assessed using the System Usability Scale (SUS) [55]; user experience was assessed using the User Experience Questionnaire short version (UEQ-S) [56]; and acceptance was evaluated using an ad hoc qualitative questionnaire consisting of open-ended questions.

The SUS score indicates excellent usability if it is over 80.3 (grade A), good usability from 68 to 80.3 (grade B), and poor or unacceptable usability if it is less than 51 (grade F). The UEQ-S focuses on pragmatic quality (usability-related aspects such as efficiency, clarity, and task support) and hedonic quality (emotional and aesthetic appeal, excitement, and innovation). Its score ranges from –3 to +3 and represents a very bad (–3.00 to –0.81), neutral (–0.80 to 0.80), good (0.81-1.40), excellent (1.41-2.00), or outstanding (2.01-3.00) experience. Acceptance refers to the degree to which users are willing to use a form of technology and was assessed using ad hoc open-ended questions.

The secondary outcomes included various health variables evaluated at T0, T1, and T2. Physical health was assessed using the 12-Item Short Form version 2 (SF-12 v2) survey [43] and the Instrumental Activities of Daily Living (IADL) scale [44]. Perceived loneliness was assessed using the UCLA Loneliness Scale (UCLA version 3 [UCLA v3]) [45], and social interaction was assessed using the Lubben Social Network Scale—Revised (LSNS-R) [46]. Quality of life was assessed using the EQ-5D-5L [41]. Cognitive and mood health were assessed using the Montreal Cognitive Assessment (MOCA) [48] and the 15-item Geriatric Depression Scale (GDS-15) [42], respectively. Spiritual well-being was assessed using the Spiritual Well-Being Scale score [52], and cognitive game experience was assessed using the Game Experience Questionnaire [57]. In addition, care workload among secondary users was assessed as a secondary outcome using ad hoc questions.

The SF-12 [43] provides 2 summary scores: 1 for the physical component summary and 1 for the mental component summary. The UCLA v3 [45] score can range from 20 to 80, with higher scores indicating greater feelings of loneliness and isolation (scores: 20-30, low loneliness; 31-50, moderate loneliness; and 51-80, high loneliness). The LSNS-R [46] focuses on the quality and quantity of social relationships; higher scores indicate a wider and more supportive social network (scores: 12-30, low social support; 31-44, satisfactory network with room for improvement; and 45-60, strong and supportive social network). The GDS-15 [42] score ranges from 0 to 15. Values up to 5 indicate a normal condition, while scores from 5 to 10 indicate moderate depression and scores from 11 to 15 indicate severe depression. The Spiritual Well-Being Scale [52] total score ranges from 20 to 120, with higher scores indicating greater spiritual well-being. The EQ-5D-5L [41] measures health-related quality of life using 5 items, and the Visual Analogue Scale, with values ranging from 0 to 100, measures the person's perceived state of health. The MOCA [48] has a maximum score of 30 points and generally indicates the presence of cognitive impairment when the score is 26 or lower. The Game Experience Questionnaire [57] measures the player's emotional and cognitive status after playing games, and its score follows a 5-point Likert scale ranging from 0 (not at all) to 4 (extremely).

Participants

Overview

During the study, data were collected from both primary and secondary users according to predefined inclusion and exclusion criteria. The primary users were older adults, whereas the secondary users were their formal or informal caregivers.

Inclusion Criteria

Primary users were deemed eligible for the pilot if they (1) were aged 65 years or older; (2) lived independently in their homes in rural or urban areas; (3) had the capacity to provide consent and were available to sign the informed consent form; and (4) were willing to participate voluntarily in the pilot.

Exclusion Criteria

The exclusion criteria were as follows: (1) failure to meet the inclusion criteria; (2) use of active implantable or nonimplantable medical devices; (3) allergy to nickel components; (4) concomitant participation in other studies; (5) lack of written informed consent; (6) acute or untreated medical problems, such as a history of syncopal episodes, epilepsy, or pharmacologically uncontrolled vertigo; serious dysfunction of the autonomic system; severe behavioral syndromes not compensated by medication; concurrent neurological diseases; or severe systemic diseases with a life expectancy of less than 1 year; (7) myocardial infarction or stroke within the previous 6 months; (8) uncontrolled hypertension; (9) pacemaker or implantable cardioverter-defibrillator; (10) advanced Parkinson disease or other neuromuscular disorders; (11) metastatic cancer or immunosuppressive therapy; and (12) significant visual or hearing impairment. No inclusion or exclusion criteria were applied for secondary users.

Recruitment Strategy

Recruitment was multicenter and multinational, involving sites in Italy (n=30), Romania (n=23), and Austria (n=8) from September to December 2024. Participants were recruited through collaborating clinics, local outreach, and direct invitations and were representative of both rural and urban populations. Each site provided local training and support.

Sample Size Rationale

As a pilot study, the sample size (n=66) was determined to enroll a sufficient number of participants to capture usability barriers, acceptance issues, and preliminary outcomes across diverse cultural contexts. No formal power calculation was performed, as the primary aims were formative rather than confirmatory [58]. Although the sample size was limited, the study was explicitly designed as an exploratory feasibility investigation

XSL•FO
RenderX

to evaluate the usability, acceptance, and preliminary impact of the CAREUP platform.

Procedure

At T0, the primary and secondary users were asked to sign the informed consent form. Sociodemographic data were then collected from all participants. The initial evaluation of the primary users also included the MOCA [48] assessment to evaluate cognitive status and the User-Centered Goals questionnaire to define personal health goals and ambitions. Each primary user was provided, on a free-loan basis for the entire duration of the study, with all necessary equipment, including a tablet equipped with a SIM card for internet access and a selection of smart medical devices. Through the tablet, users could access the CAREUP platform apps and the online dashboard. Users were asked to select the smart devices they wished to test, and only the selected devices were provided. Participants received detailed explanations on how to use the system and its role in supporting and monitoring their health and IC. An introductory training phase was also conducted at the start of the pilot at each study site. During this phase, users received a manual in their native language along with recommendations for system use. Participants were instructed to access the tablet apps at least once a week; use the devices at least 2-3 times per week; complete the questionnaires and locomotion test once a week; and play the games as desired. All collected data (measurement values and IC graphs) could be checked daily or weekly by both primary and secondary users through the web portal (online dashboard).

Primary users were invited to use the platform according to these recommendations from T0 to T2, covering the entire pilot period of approximately 2 months. Details of the assessments conducted at T0, T1, and T2 are summarized in Table 4.

Table 4. List of tests and measurements for the pilot.

Dimension	Scale	Type of out-come	Type of end user	Timing of data collection
Socio Demo Data	N/A[a]	N/A	Primary and secondary	T0
User-Centered Goals	N/A	N/A	Primary	T0
Usability and User Experience	SUS[b] and UEQ-S[c]	Primary	Primary and secondary	T1 and T2 (for both)
Acceptance	Qualitative items	Primary	Primary and secondary	T1 and T2 (for both)
Cognitive Status	MOCA[d]	Secondary	Primary user	T0 and T2
Physical Health	SF-12[e] version 2 and IADL[f]	Secondary	Primary user	T0, T1, and T2
Perceived Loneliness	UCLA version 3	Secondary	Primary user	T0, T1, and T2
Social Interaction	LSNS-R[g]	Secondary	Primary user	T0, T1, and T2
Quality of Life	EQ-5D-5L	Secondary	Primary user	T0, T1, and T2
Mental Health	GDS-15[h]	Secondary	Primary user	T0, T1, and T2
Game Experience Questionnaire, part 3 postgame module	Game Experience Questionnaire	Secondary	Primary user	T1 and T2
Privacy and Stigma	Qualitative items	Secondary	Primary and secondary	T1 and T2 (for both)
Care Workload	Qualitative items	Secondary	Secondary user	T1 and T2
Willingness to Pay	Qualitative online questionnaire	Secondary	Primary and secondary	T2

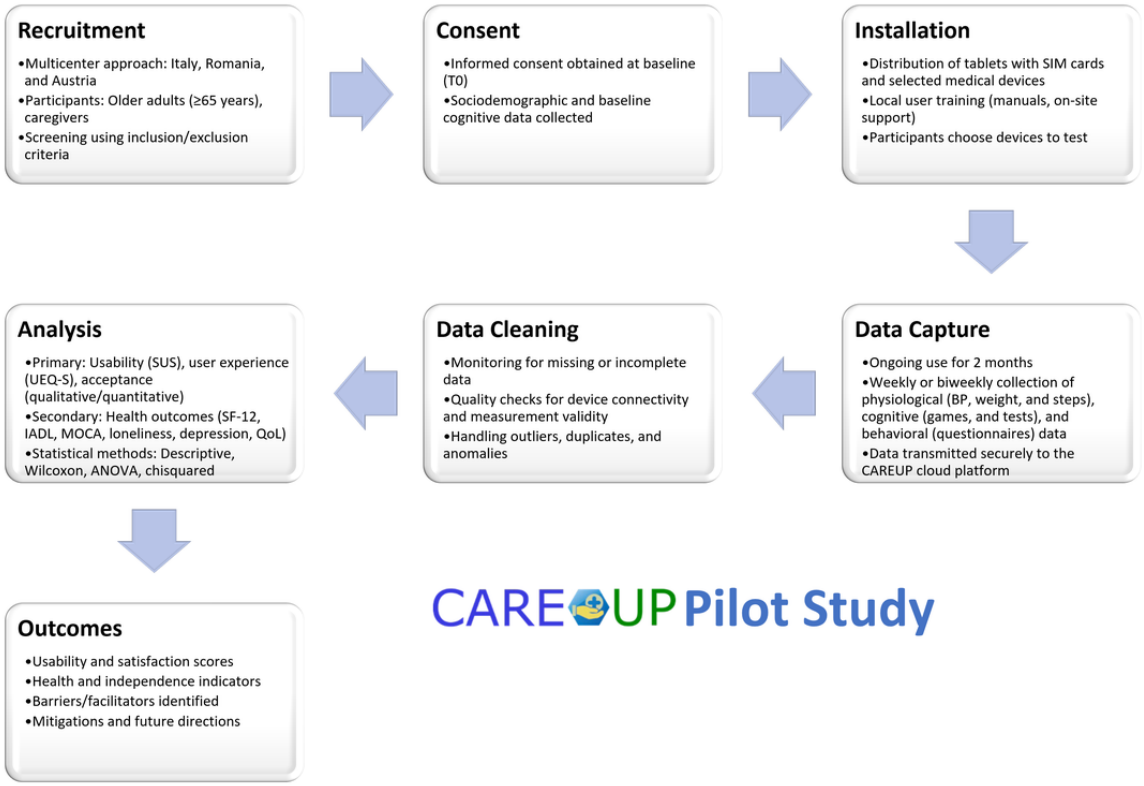
[h]GDS-15: 15-item Geriatric Depression Scale.

Statistical Analysis

The following section describes the outcomes of the pilot study. The pilot study data were uploaded to the Zenodo repository and are publicly available [59]. The dataset includes the results of the T0, T1, and T2 assessments; physiological measurements performed using the medical devices; and responses to the PH app questionnaires. The data are accompanied by anonymized demographic information for the users.



The dataset was curated at the end of the pilot study, and all data were cleaned and encoded using Python (Python Foundation) and the pandas package. The data are stored in standard CSV format. Instructions for dataset use, including a description of the file structure and variable dictionary, are

XSL•FO
RenderX

available in the dataset description PDF file. The repository also includes exemplary Python code for dataset loading and visualization.

In the following analysis, data are reported using mean values (a measure of central tendency representing the typical value of the dataset), frequencies (indicating how often a particular value or category appears in the dataset), and *P* values (used to determine whether observed differences or associations in the data are statistically significant). Statistical analyses included the Wilcoxon test and ANOVA for continuous variables, whereas the chi-square test was used for categorical variables. These analyses were conducted using Python (version 3.11), leveraging libraries such as SciPy for statistical testing, pandas for data handling, and Seaborn for visualization. A descriptive flowchart of all study stages is presented in Figure 2.

Figure 2. Study flowchart. IADL: Instrumental Activities of Daily Living scale; MOCA: Montreal Cognitive Assessment; QoL: quality of life; SF-12: 12-Item Short Form; SUS: System Usability Scale; UEQ-S: User Experience Questionnaire short version;.

Results

User Statistics

A total of 66 older adults participated as primary users: 30 were enrolled in Italy, 25 in Romania, and 11 in Austria. Their caregivers were involved as secondary users (7 in Romania, 5 in Austria, and 5 in Italy).

In Romania, 2 primary users (who enrolled without caregivers) withdrew after the first week of the pilot because they considered the platform too difficult to use and requiring IT knowledge that they did not have. There were also 3 primary user dropouts in Austria: 2 withdrew during the first week after recruitment, and 1 withdrew after the T1 phase. These users did not perceive any benefit from using the system. The pilot was therefore completed by 61 primary users and 17 secondary users. Not every primary user (older adult) was assigned a secondary user (caregiver), as the inclusion criteria for primary users required them to be in good health and not in need of caregiver support for daily activities.

The primary users included 37 women and 24 men, with a mean age of 73.9 years. Most participants were married (n=36), whereas 14 were widowed, 4 divorced, 3 separated, 2 single, and 2 in a full-time relationship. Regarding education level, 27 older adults had a secondary education, 28 had a tertiary education (university or further education), 5 had a primary education, and 1 had no formal education. Most participants (n=54) lived in urban areas, whereas 7 lived in rural areas.

The secondary users included 10 men and 7 women, with a mean age of 47.5 years. All were informal caregivers except for 1 formal caregiver from Italy. Full sociodemographic details are presented in Table 5.

Adherence to platform use was defined as the proportion of days between the first and last app use relative to the individual study period, whereas app usage referred to the total number of distinct days on which the app was used (Figure 3).

Figure 3. Platform use. (A) Adherence and (B) usage.

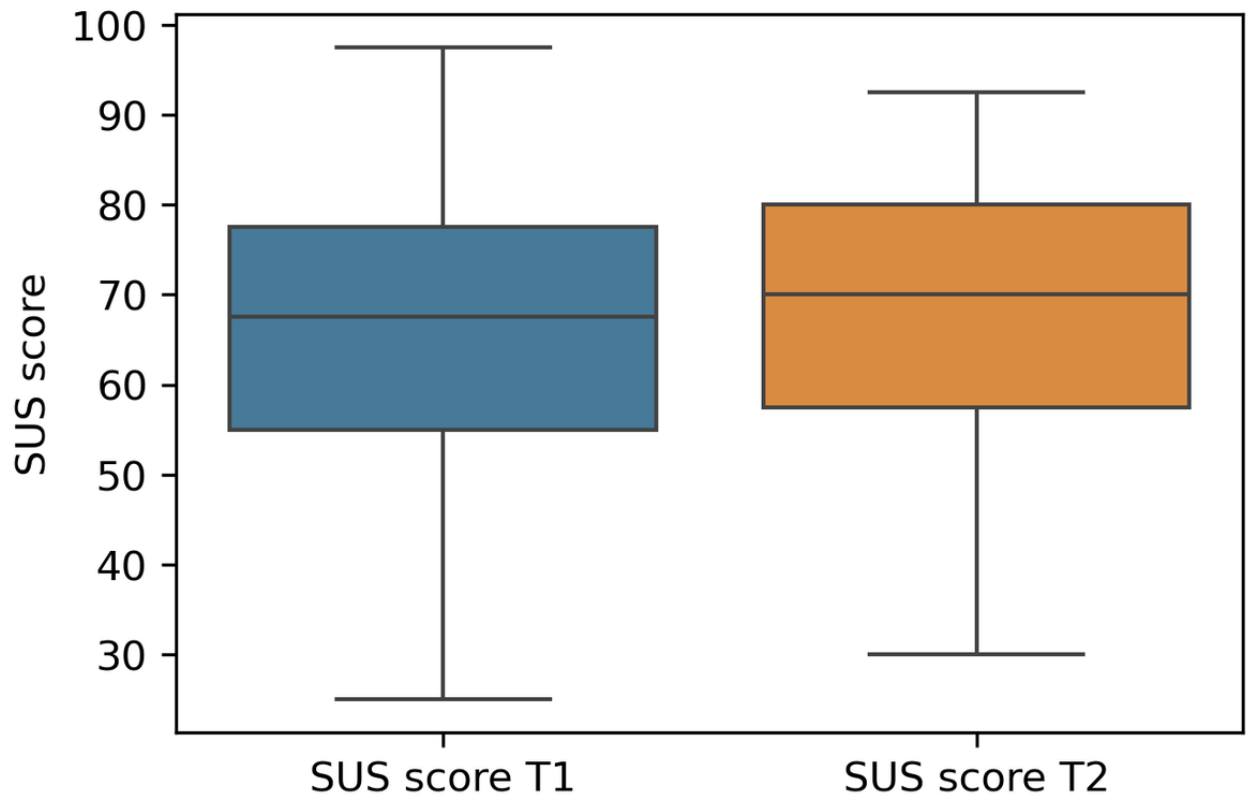
Primary Outcomes

Usability

The average SUS score among all older end users was 68, corresponding to the benchmark 50th percentile. More specifically, the mean SUS score of the primary users was 67.62. According to adjective ratings typically associated with SUS scores, this result would be classified as "OK," suggesting that although the system was generally usable, there remains room for improvement. The lowest SUS scores were observed in Austria (50.83 at T1 and 45.94 at T2), whereas the highest scores were observed in Romania (74.46 at T1 and 75.54 at T2). Among secondary users (caregivers), the average score was 66.3, which was also close to the "OK" range but still indicated room for improvement. Further details are provided in Table 6.

As shown in Figure 4, the SUS scores had median values of 67.50 (IQR 22.50) at T1 and 70.00 (IQR 22.50) at T2. The

XSL•FO
RenderX



Wilcoxon signed rank test indicated no significant difference between the 2 time points (P=.42).

Table 6. System Usability Scale and User Experience Questionnaire short version scores among older adults and caregivers.

Scales and their scores	Older adults (n=61), mean (SD)	Caregivers (n=17), mean (SD)
System Usability Scale score	67.62 (15.09)	66.2 (21.25)
Nation		
Austria (n=8)	45.94 (9.99)	N/A[a]
Italy (n=30)	67.33 (13.06)	N/A
Romania (n=23)	75.54 (11.28)	N/A
Gender		
Female	70.34 (14.51)	N/A
Male	63.44 (15.30)	N/A
Education level		
Primary or no education	57.08 (14.53)	N/A
Secondary education	66.96 (15.65)	N/A
Tertiary education	70.65 (13.95)	N/A
User Experience Questionnaire short version score		
Hedonic Quality	1.66 (0.90)	1.22 (1.39)
Pragmatic Quality	1.23 (1.02)	0.76 (1.31)
Overall	1.45 (0.83)	0.99 (1.27)

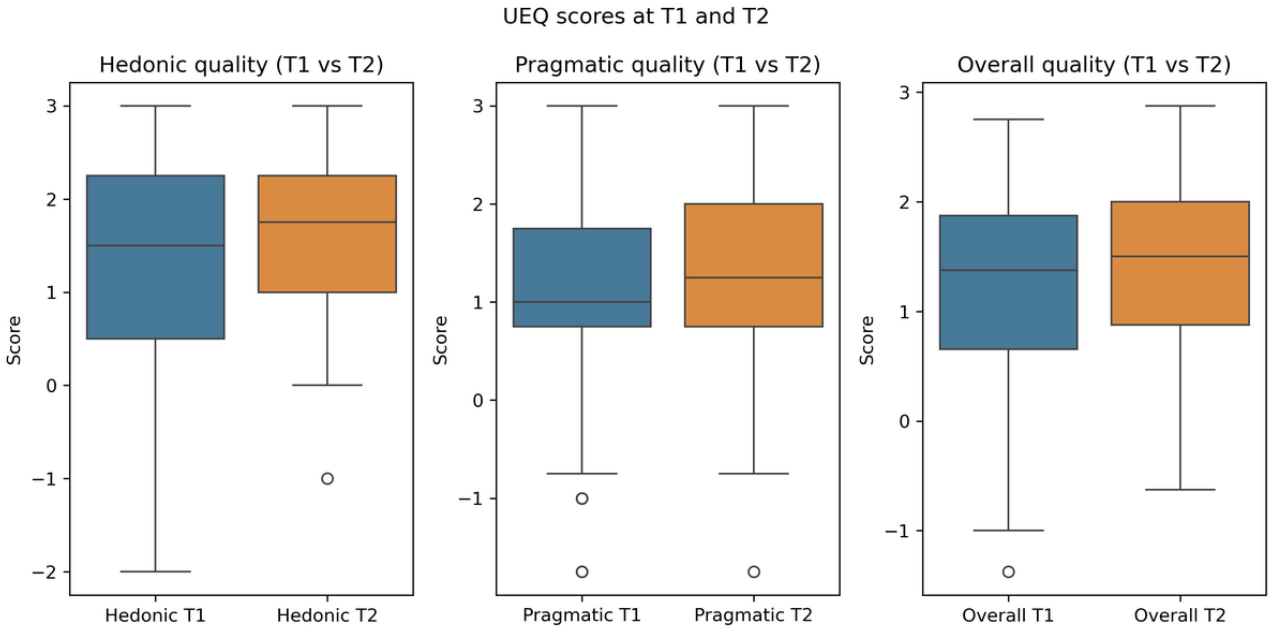
[a]N/A: not applicable.

Figure 4. Boxplot of System Usability Scale (SUS) score at T1 and T2.

XSL•FO
RenderX

User Experience

As reported in Table 6, the overall UEQ score among primary users was 1.45, suggesting a "good" overall user experience in which both functional and emotional needs were reasonably well met.



A high Hedonic Quality score of 1.66 indicated that the product was perceived as enjoyable, stimulating, and innovative. This emotional appeal enhanced user satisfaction and could promote greater engagement with the product.

A Pragmatic Quality score of 1.23 reflected above-average usability, indicating that the product was generally effective and supportive for task completion, although there was still room for improvement in areas such as clarity and efficiency.

As reported in Table 6, the overall UEQ score among secondary users was 0.99, suggesting a generally positive experience. A Hedonic Quality score of 1.22 indicated that users found the product somewhat engaging and emotionally appealing, although there was room for improvement to make it more exciting or innovative. Moreover, a Pragmatic Quality score of 0.76 suggested below-average usability, indicating that users experienced challenges related to efficiency, clarity, or task support.

As shown in Figure 5, the UEQ scores demonstrated statistically significant improvements from T1 to T2 across all evaluated dimensions. Hedonic Quality increased, with median values rising from 1.50 (IQR 1.75) at T1 to 1.75 (IQR 1.25) at T2 (*P*=.003). Pragmatic Quality improved from a median of 1.00 (IQR 1.00) to 1.25 (IQR 1.25) (*P*=.04). Overall experience also improved significantly, with median values increasing from 1.38 (IQR 1.25) to 1.50 (IQR 1.12; *P*=.001). These distributions are visually summarized by boxplots in Figure 5, illustrating both the positive trend and the distribution of scores at each time point.

Figure 5. Boxplots comparing the distribution of User Experience Questionnaire (UEQ) scores at 2 time points (T1 and T2). The subplots present hedonic quality, pragmatic quality, and overall experience scores, showing a general increase from T1 to T2. This trend is consistent with statistically significant improvements across all dimensions (hedonic quality: P=.003; pragmatic quality: P=.04; overall experience: P=.001).

Acceptance

Primary users reported a generally positive perception of the CAREUP platform, describing it as interesting, useful, and efficient (n=49). Frequently appreciated features included ease of use and innovative technology (n=25), health monitoring (n=20), games (n=5), the smartwatch for promoting physical activity (n=4), and the mattress sleep-tracking function (n=3).

Key issues raised included the excessive number of devices (n=7), unmet expectations over time (n=5), time-consuming technical and connectivity problems (n=20), game-related issues (n=5), repetitive questionnaires (n=5), overload caused by additional devices (n=3), and concerns regarding the reliability of the results (n=1).

Regarding recommendations, 48 participants stated that they would endorse the platform to a friend, 6 would recommend it only to individuals with strong technical skills, 3 would recommend it if improvements were made, 2 were undecided, and 2 would not recommend it. Regarding willingness to continue using CAREUP, 39 participants agreed, 8 stated they would use it occasionally, 2 would continue if fewer devices were required, 1 was undecided, and 11 declined.

Regarding the system's impact on daily routines, CAREUP improved daily routine management for 34 users, whereas 26 disagreed and 1 was undecided. CAREUP did not interfere with daily routines for 38 users; however, 21 reported interference, and 2 reported occasional interference.

Suggestions for new users included frequent use to become familiar with the system (n=17), active participation because the platform was perceived as simple and useful (n=16), maintaining confidence and patience (n=10), becoming familiar with the technology and reading the manual beforehand (n=7),

XSL•FO
RenderX

seeking help when needed (n=4), and following the provided instructions (n=3). Additional comments included requests for game enhancements (n=6), technical improvements (n=4), fewer devices (n=3), additional training or manuals to address system complexity (n=3), more exercises (n=3), clearer instructions or instructional videos (n=2), and dietary advice (n=1).

Secondary users identified the following as the best aspects of the platform: continuous health monitoring (n=8), data storage (n=10), games (n=4), integration of apps and devices (n=4), the smartwatch for promoting physical activity (n=2), and the sense of providing care and support (n=1).

Key criticisms included system complexity (n=5); difficulties in managing health results (n=2); unclear graphs (n=2); detection errors, technical issues, or a confusing interface (n=9); monitoring being perceived as a form of control (n=1); the short trial duration (n=2); and the need for prior familiarity with technology (n=1).

Regarding recommendations to other caregivers, 8 participants stated that they would endorse CAREUP, 1 would recommend it partially, 3 were undecided, and 4 would not recommend it.

Regarding willingness to continue using CAREUP, 6 participants agreed, 6 were undecided, and 5 declined.

Regarding interference with the care recipients' daily routines, CAREUP was reported not to interfere by 10 participants, to interfere by 3 participants, whereas 4 participants were undecided.

Suggestions for new users included being patient while learning to use the system (n=8), assessing older adults' interest in the platform (n=3), and maintaining real interpersonal relationships alongside technology use (n=1).

Experience-based comments highlighted the need to simplify the system and address technical issues (n=3).

All opinions regarding acceptance are summarized in Multimedia Appendix 3.

Secondary Outcomes

Data Overview

All data related to the secondary outcomes are reported in Table 7.

SF-12 v2

The results obtained from the primary users showed that the mean physical component summary scores remained overall stable over time, with values slightly below the standardized population mean of 50. The slight decrease observed at T2 did not appear to be clinically significant. In addition, women showed lower mean scores than men at all time points, indicating poorer physical health status. Men maintained stable scores over time, with values close to the standardized mean of 50, whereas women showed a slight decline at T2. Regarding the mental component summary score, the mean value improved slightly over time, from 49.74 at T0 to 51.37 at T2. The values remained close to the standardized population average of 50, indicating a mental health status consistent with the population average. Whereas the scores for men remained stable across the 3 assessments, women showed a slight improvement in mental well-being from T0 to T2.

IADL

The IADL (Instrumental Activities of Daily Living) scores of the primary users were very close to the maximum value of 8, indicating that participants were largely independent in their daily activities. Although both women and men demonstrated a high level of independence, women showed higher scores across all 3 assessments.

UCLA v3

Scores on the loneliness scale (UCLA Loneliness Scale) showed a slight decrease over time. Overall, the scores remained within the moderate-to-high loneliness range, with a trend toward slight improvement in the social and emotional well-being of the participants (primary users). However, the results showed no significant differences according to gender (*P*=.63) or country (Austria, *P*=.21; Italy, *P*=.23; and Romania, *P*=.81).

LSNS-R

Data analysis showed that the LSNS-R scores of the primary users fell within the 31-44 range on the LSNS scale, indicating moderate social support for the group as a whole. This finding suggested that most participants had a satisfactory social support network, although a slight decline was observed over time. No significant differences were observed between women and men (Austria, *P*=.23; Italy, *P*=.32; and Romania, *P*=.09).

GDS-15

All mean GDS-15 scores (T0 and T2) were below 5, indicating that most participants did not have significant depressive symptoms. No significant differences were observed between women and men (*P*=.79).

EQ-5D-5L

Analysis of the EQ-5D-5L results showed that more than half of the sample reported no problems with mobility, self-care, or performing usual activities. Approximately half of the sample reported slight physical pain, and nearly half reported slight anxiety. The Visual Analogue Scale component of the assessment, which evaluated perceived health status, indicated a generally positive perception of health.

MOCA

The mean MOCA scores of the primary users were 27.68 at T0 and 27.75 at T2, indicating good cognitive function among the participants.

Game Experience Questionnaire, Part 3 Postgame Module

The postgame module's positive experience score of 1.55 suggested that participants were able to play the games without difficulty. No negative experiences, tiredness, or issues related to returning to reality were reported. Further details are presented in Table 8.

XSL•FO
RenderX

Table 8. Postgame module scores.

Game Experience Questionnaire score	T1, mean (SD)	T2, mean (SD)	*P* value
Positive experience	1.55 (1.11)	1.56 (1.08)	.65
Negative experience	0.39 (0.74)	0.35 (0.67)	.55
Tiredness	0.18 (0.41)	0.15 (0.36)	.56
Returning to reality	0.44 (0.54)	0.40 (0.52)	.59

Cares Workload

Overview

The secondary users (caregivers) did not report any notable changes in caregiving workload.

Devices Used During the Pilot

Users utilized the system devices at varying frequencies across different device types and pilot countries. The least-used component was the PH app, which was accessed less than once per week in both Italy and Romania. This finding highlights the importance of tailoring the positive health questionnaires to better address key aspects of older adults' social and psychological well-being. On average, the devices were used 2 times per week. The most frequently used devices were those commonly adopted by older adults, such as the oximeter and blood pressure monitor, followed by the bathroom scale. Several users engaged with these devices very actively, with 1 participant from Romania recording more than 200 weight measurements during the course of the pilot. The glucose meter and hand-grip strength meter were used less frequently. Mattress sleep sensors were used only in Italy. Their average use was approximately 3 times per week, which may have reflected periods during which the devices were unplugged or used for only part of the pilot duration.

Component usage varied across countries. The PH app was used more frequently in Austria, whose population is generally more digitally literate than those of Italy and Romania. Device use was generally similar across countries; however, users in Austria used the devices less actively than users in Italy and Romania. The greatest difference in usage frequency was observed for the hand-grip dynamometer, which was rarely used in Romania. These differences indicate the importance of considering users' digital literacy and preferences when introducing novel technological solutions. Table 9 provides detailed information on weekly system device use across device types and pilot countries.

Discussion

Principal Findings

The CAREUP pilot feasibility study evaluated the usability, user experience, and acceptance of an integrated care platform for tracking the IC of older individuals using various monitoring devices. Secondary outcomes included assessments of physical and mental health, quality of life, social interaction, and caregiver workload.

The CAREUP platform demonstrated both successes and challenges during the study. Although participant numbers varied across countries, no direct correlation was found between country and SUS scores. Differences in SUS ratings appeared to be more closely related to factors such as device connectivity, interface clarity, and users' digital literacy levels than to cohort size [60]. These findings suggest that local contextual and technical conditions have a stronger impact on usability perceptions than the number of participants at each site. Digital skills vary among individuals according to their level of autonomy in using technology and are influenced by socioeconomic status [61]. Specifically, Austria's lower scores highlighted issues with device connectivity and interface clarity that remained largely unresolved by the end of the trial. By contrast, Romania's favorable scores suggested that the platform could be effective and well-received when it functions smoothly.

Despite these usability challenges, many older adults (the primary users) viewed CAREUP as engaging, innovative, and empowering. Adopting a technological health solution can initially pose varying degrees of difficulty, depending on an individual's prior experience and available resources [62]. Nonetheless, most people are willing to learn and adopt new digital tools if they perceive tangible benefits for their health and well-being [63]. User experience assessments reflected a predominantly positive outlook, especially regarding the platform's "hedonic qualities"—its emotional appeal. Participants valued access to cognitive games and health-monitoring features, which introduced stimulation and novelty into their daily routines. Nevertheless, some critical feedback was noted.

Acceptance among older adults and caregivers revealed a nuanced picture. Many users expressed enthusiasm for CAREUP, appreciating its capacity to track health parameters

XSL•FO
RenderX

and support proactive health management. However, persistent technical obstacles—such as connectivity issues between devices and software—tested participants' patience. Both groups also found the number of required devices cumbersome. Although health technologies are becoming increasingly accepted in older adults' lives, partly accelerated by the COVID-19 pandemic [64], a digital divide remains, contributing to divergent views on acceptance. Although older adults typically acknowledge the benefits of technology for improving care efficiency and quality, they often struggle with adaptation. Therefore, promoting digital literacy is crucial for fostering their engagement and inclusion in the digital health care landscape [65].

As secondary users, caregivers brought a nuanced perspective to CAREUP. They valued its ability to reduce worry through continuous health monitoring and to provide structured insights into their loved ones' health. However, many also found the system unnecessarily complex. This tension between appreciation and frustration highlighted the need for targeted refinements, particularly simplifying the platform and improving reliability. For digital solutions to succeed, it is vital to involve all key end users—patients, caregivers, and health care professionals—early in development [66]. Caregivers, in particular, play a pivotal role; thus, it is essential not only to engage them but also to provide sufficient digital training. Empowering caregivers in this way enables them to support older users more effectively and substantially increases the accessibility and success of digital solutions [67]. More broadly, the CAREUP pilot exemplified both the challenges and opportunities associated with introducing technology into complex, human-centered settings. Technical reliability emerged as a major challenge, repeatedly undermining the user experience. Frequent Bluetooth issues and software glitches frustrated users and, at times, alienated them from the platform. This underscores the cost of technological shortcomings: regardless of innovation, systems must function seamlessly to earn users' trust and loyalty. Poor reliability can foster frustration, leading to abandonment and an increased risk of digital exclusion [68]. Multiple factors influence the use of digital technology, and disengagement may stem from psychological reasons (such as low motivation, lack of confidence, or perceived lack of usefulness), physical barriers (such as limited access), or practical challenges (including insufficient digital skills) [69].

The issues described are also common in other platforms evaluated in usability studies reported in the literature. Issues such as connectivity problems leading to delayed data availability [22] and difficulties understanding how to use specific components [23,27,33] are particularly prevalent in novel solutions. Interface aesthetics are also a commonly raised concern, with users often requesting personalization options to better tailor the solution to their preferences [70].

Another key takeaway from the pilot was the importance of user education and support. Although digital technologies are a valuable resource in health care, older adults still lag significantly behind younger individuals in their use of these technologies [71]. Their limited digital health literacy is influenced by both subjective factors—such as anxiety, stress related to technology use, and lack of confidence—and objective factors [72]. These include sociodemographic factors (eg, age, education level, and economic status), digital device-related factors (eg, internet access and usability challenges), and social support factors (eg, support provided by family members) [73].

Even though each pilot site organized an instructional phase at the beginning of the pilot and provided a user manual, some participants, especially those less familiar with technology, struggled to fully understand the platform's capabilities. This was particularly evident during the early phase of the trial, when users were still acclimating to the system. User comments also highlighted the potential value of video tutorials or in-person training for enhancing familiarity and confidence with the system. This may serve as a recommendation for future implementation. Given the persistent gap between the availability of digital health solutions and older adults' ability to use them effectively, ensuring adequate digital health literacy is essential [74]. To provide tailored support, it is important to first assess users' level of digital literacy, specifically their ability to search for, navigate, understand, and evaluate digital health information and tools [75].

Limitations, Implications, and Future Directions

Pilot and Implementation Considerations

This study has several limitations inherent to pilot research and the implementation of digital health interventions:

Sample Size

The relatively small sample size (n=66 enrolled; n=61 completed) limits statistical power and the generalizability of the findings. As this was an exploratory pilot study, no formal sample size calculation was performed; therefore, the results should be interpreted as formative and hypothesis-generating rather than confirmatory. The small sample size, coupled with gender imbalance and the specific national contexts of Italy, Romania, and Austria, introduces potential bias and further constrains the generalizability of the findings. These demographic and cultural differences should be considered when interpreting the results.

Selection Bias

Recruitment was conducted at 3 sites using nonrandom convenience sampling. This may have resulted in a study population that was more motivated or technologically skilled than the general older adult population, thereby introducing potential bias.

Missingness

Participant dropout and incomplete app or device use contributed to missing data, particularly for secondary outcomes that relied on self-report and device connectivity.

Device and Data Constraints

Usability challenges, technical difficulties related to device connectivity, and variability in digital literacy affected the consistency and completeness of data collection. The short intervention duration and reliance on self-reported or device-captured metrics further limit the robustness of the clinical inferences.

XSL•FO
RenderX

Technology Readiness Level

Technology Readiness Level (TRL) may have influenced the results. Before the start of the pilots, the platform components (apart from the off-the-shelf sensors) had been tested only in a laboratory or simulated operational environment (TRL 5 and TRL 6). Despite the relatively low TRL, our approach is consistent with current research standards in the field [76], which identified numerous studies in this area that remain in the development and testing phase (TRL 5) or in the demonstration, pilot, and prototypical system validation phase (TRL 6).

Mitigation and Future Directions

To address these limitations, subsequent phases of the CAREUP project will target a larger and more diverse multicenter sample and implement randomized recruitment methods where feasible. Platform development will include expanded modularity and adaptive features to support broader usability and reduce technological barriers. Clinical end points (eg, hospitalization and independent living status) and longer follow-up periods will be incorporated to capture outcomes with greater relevance and reliability. Technical upgrades, enhanced user support, and expanded device interoperability are also planned.

A comprehensive impact evaluation is scheduled within the next 18-24 months, with interim analyses and publication of progress updates at 12 months to guide iterative refinement and reporting.

Sharing both the strengths and limitations of research is fundamental to enabling more effective advancement in the field. Although new technologies increasingly demonstrate substantial utility in supporting health maintenance, self-care, independence, and autonomy—all of which contribute to improvements in quality of life—current approaches remain limited in scope.

Looking ahead, the CAREUP project revealed several valuable lessons for future development. First, robust testing and debugging should be prioritized to ensure the reliability of devices and software. Second, the platform's interface should be simplified, with clearer pathways and visual guidance to make navigation intuitive for a broad demographic. Third, reducing the number of devices or integrating functionalities could address complaints about device overload and improve user-friendliness. Finally, cultural and contextual differences, as reflected in the varied reception across countries, should inform future adaptations to ensure that the platform resonates with diverse user groups. Relevant information was continuously shared with the technical partners to support integration and development of the advanced prototype and final product.

Conclusions

The CAREUP pilot study demonstrates the potential of integrated digital health platforms to support healthy aging through IC monitoring. Despite the challenges associated with introducing technology into human-centered health care, the platform's positive outcomes highlight the promise of digital health solutions for the future. The study also underscores the importance of cultural adaptation in digital health interventions, demonstrating that optimal adoption of multidimensional health-monitoring technologies among older adults requires attention to technical reliability, user interface design, and cultural context. Variations in usability scores across countries further emphasize this need.

Technical reliability is essential for user acceptance, as connectivity issues and software glitches can undermine the user experience and lead to platform abandonment.

However, system complexity and the need for digital literacy support underscore the importance of engaging all stakeholders—patients, caregivers, and health care professionals—early in the development process.

Future implementations of digital health platforms for aging populations must address technical infrastructure, user-friendly interfaces, comprehensive education, cultural adaptation, and multidimensional health monitoring. By meeting these requirements, platforms such as CAREUP can more effectively support healthy aging and enhance the quality of life of older adults and their caregivers.

The pilot also highlighted that technology-based interventions often focus on single domains (physical, cognitive, mental, emotional, etc) rather than adopting a multidimensional approach to health promotion. Expanding research in this direction could substantially strengthen the evidence base and further advance the field.

Funding

This research was cofunded by the Active Assisted Living Programme (reference number AAL-2021-8-95-CP). In Poland, the study was funded by the Polish National Centre for Research and Development (grant AAL/AALCall2021/52/CAREUP/2022). In Italy, the study was partially supported by Ricerca Corrente funding from the Italian Ministry of Health awarded to IRCCS INRCA. In Romania, the study was supported by grants from the Ministry of Research, Innovation, and Digitization (grant CNCS/CCCDI-UEFISCDI) and the AAL Programme, with cofunding from the European Union's Horizon 2020 research and innovation programme (project number AAL-CP-2021-8-95-CAREUP-1 within PNCDI III).

Abstract

Background: The population of adults aged 65 and older is rapidly increasing, while the availability of caregivers is declining. Smart homes that provide unobtrusive, continuous monitoring and alerting on clinically relevant changes in daily activity patterns offer a potentially innovative solution for aging in place.

Objective: This study aims to evaluate the barriers and facilitators to the adoption of a low-cost smart home embedded within a community-based approach to health monitoring for older adults with multiple chronic conditions and who are experiencing poverty.

Methods: Using a prospective, mixed methods design and iterative community co-design, 46 older adults from 7 different language groups were continuously monitored for 6 months with ambient sensors installed in their homes. Two older adults were monitored for 4 and 5 months, respectively, resulting in a total sample of 48. The system generated alerts based on movement pattern changes and escalated notifications to participants, support persons, community health workers, and nurses. Sensor data were analyzed descriptively to quantify alert patterns and response rates, while written text-based data from in-the-moment surveys, community health workers' and registered nurses' notes, and semistructured interviews underwent qualitative descriptive analysis and reflexive thematic coding.

Results: The system generated 37 million sensor readings condensed into 1.2 million high-level events and 4719 novel alerts. Qualitative data comprised 34,086 words of text. Participants responded to 1.57% (74) of the initial email alerts and 7.79% (368) of the follow-up SMS text message alerts sent when no email response was received. Community health workers and registered nurses responded to 78.36% (n=3698) of the escalated alerts, resulting in 1060 contacts with participants in response to alerts. Clinical contacts resulted in 72 interventions. Three major qualitative themes emerged: (1) Alone, (2) Trust, and (3) Human Connection. Subthemes included Safety, Personalization, and Digital Distress defined as stress associated with interacting with digital health-monitoring systems. Participants rated the system highly (mean likelihood-to-recommend rating 8.68/10, SD 1.68); however, they expressed a strong preference for phone calls over automated alerts. Cultural expectations influenced adoption, particularly in multigenerational households.

Conclusions: Communities can effectively engage in technology-delivered health care. Future research is needed to improve technical aspects of smart home monitoring systems, including accurate alerting using machine learning, data visualizations for older adults and health care workers, and culturally sensitive features. Additional work should address how and when to

XSL•FO
RenderX

communicate automated messaging, engage older adults with their own data, and integrate sensor-based monitoring into health care workflows. Research should also explore personalization through advanced computational approaches such as machine learning and strategies to reduce digital distress.

Introduction

Background

The global population is aging rapidly, with an estimated 1.6 billion adults aged 65 and over by 2050 [1]. This demographic shift is accompanied by a shrinking caregiver-to-older-adult ratio: in the United States, the ratio for adults aged 80 and older is projected to decline from 7:1 in 2010 to 3:1 by 2050, with fewer caregivers available for the growing aging population [2,3]. This imbalance presents the urgent challenge of how to support older adults in aging safely and independently at home.

Health monitoring smart homes (ie, sensor-based health monitoring at home) offer a promising solution [4,5]. These systems typically consist of ambient sensors (eg, motion, door, humidity, and more) connected to a central hub that transmits data to a secure platform. Algorithms analyze movement patterns to detect anomalies such as prolonged inactivity, disrupted sleep, or changes in kitchen or bathroom use, all potential indicators of emerging health concerns. Alerts can be communicated via email, SMS text message, or phone calls, and escalated to caregivers or clinical teams for follow-up.

However, most smart home health monitoring has been developed and tested in higher-income settings, leaving critical gaps in understanding their feasibility and acceptability among older adults experiencing poverty [6,7]. Older adults in subsidized housing or with limited income face distinctive barriers to technology adoption, including limited internet access, low digital literacy, mistrust of systems, and cultural expectations around caregiving [8-12]. Without deliberate attention to these barriers, smart home innovations may risk widening health disparities rather than closing them [13,14].

This study aims to identify and understand barriers to adopting smart home health monitoring occurring within a co-designed community support system among older adults experiencing poverty. To address these aims, a low-cost, community-in-the-loop “smart health system” prototype was developed, featuring continuous ambient health monitoring capabilities. Using mixed methods, we evaluated how older adults interacted with the system, the challenges they encountered, and the features that supported trust, engagement, and equitable access. Here, the term *smart home* refers broadly to ambient sensing in the home for the purpose of monitoring residents’ health. The prototype deployed for this study is referred to throughout as a *smart health system* because the smart home was embedded in a *community-in-the-loop* support system where older adults received a smart home along with systematic support from self-identified family and friends (ie, a support person) and from appointed community health workers (CHWs) and registered nurses (RNs).

This paper shares the findings from trialing the community-in-the-loop approach to health monitoring in resource-constrained settings that use smart homes and discusses the potential for smart home adoption by older adults living in poverty. The purpose of this paper is to provide insights into how, and if, continuous ambient health monitoring is possible in older adult populations experiencing poverty. The low-cost system is discussed in detail in Multimedia Appendix 1.

Smart Home Technologies for Health Monitoring

Smart home systems leverage ambient sensors, Internet of Things (IoT) devices, and data analytics to monitor daily activities and detect health-related changes [14-16]. Prior studies demonstrate their potential to support aging in place by identifying deviations in mobility, sleep, and self-care routines. Rantz et al [17,18] showed that sensor-based systems can detect early signs of health decline. Pioneering work by Cook and the team at the Center for Advanced Studies in Adaptive Systems (CASAS) developed lightweight, easy-to-install systems for activity recognition and health monitoring, including nurse-in-the-loop models and pain-related behavior detection [5,19-22]. More recent work has advanced IoT-based frameworks for secure remote monitoring [23] and patient-centric agents using blockchain on 5G networks [24]. Furthermore, work has been done that specifically identifies gaps in chronic disease applications [4].

Smart home systems show promise in detecting early signs of clinically relevant conditions such as cardiovascular disease, congestive heart failure, cancer, urinary tract infections, sleep disturbances, and cognitive decline [4,21,25]. These conditions disproportionately affect older adults experiencing poverty who often face delayed diagnoses and limited access to care [26-29]. Sensor-based alerts, such as changes in mobility, sleep patterns, or hygiene routines, can serve as proxies for emerging health issues and prompt timely interventions. These studies confirm the feasibility of unobtrusive monitoring but often remain focused on higher-income populations.

Barriers and Facilitators to Adoption in Low-Income Populations

While smart home technologies are well established, their adoption among diverse older adults remains understudied. Prior work has primarily focused on for-profit senior living settings, including Tiger Place [17,18], Touchmark [21,30,31], and early collaborative aging research using technology (CART)–related studies [32] where adoption has not faced many barriers. In

XSL•FO
RenderX

contrast, adoption barriers among low-income older adults persist, including privacy concerns, perceived intrusiveness, system complexity, digital literacy challenges, limited internet access, and inadequate technical support [4,7,33-35]. Similar inequities appear across digital health interventions, such as mobile health and telehealth [36], for chronic disease management [37-39].

Key facilitators for older adults and the health care team include ease of use, perceived usefulness, and a system's ability to enhance safety and independence [4,9,40-42]. Trust in the technology and the organizations deploying it strongly shapes adoption, particularly amid concerns about data security and reliability [4,9,43]. This study extends prior work by examining barriers and facilitators to adoption among older adults with multiple chronic conditions living in poverty, with particular attention to affordability, usability, cultural relevance, and community co-design as key determinants of trust and engagement.

Community Engagement and Co-Design

Co-design and community-based participatory research methodologies have proven effective in tailoring digital health interventions to the needs of diverse populations [44,45]. Involving end users in design and testing enhances trust, usability, and perceived ownership of technology [46,47]. However, few studies have applied these principles to smart home health monitoring systems serving low-income older adults with multiple chronic conditions.

This study embedded community engagement across all phases of system development and evaluation [48]. We brought together low-income older adult residents in subsidized housing and living in the community, subsidized housing managers, CHWs from diverse cultural and ethnic communities, and nursing and engineering researchers to co-design features including notification preferences, sensor placement, and privacy safeguards. Adapted from the "nurse-in-the-loop" model, this *community-in-the-loop approach* ensured alignment with participants' cultural, social, and socioeconomic contexts. Iterative feedback revealed preferences for low-burden devices, clear feedback loops, and direct human contact during alerts, showing how co-design can make smart home health systems more inclusive, acceptable, and scalable in resource-constrained settings.

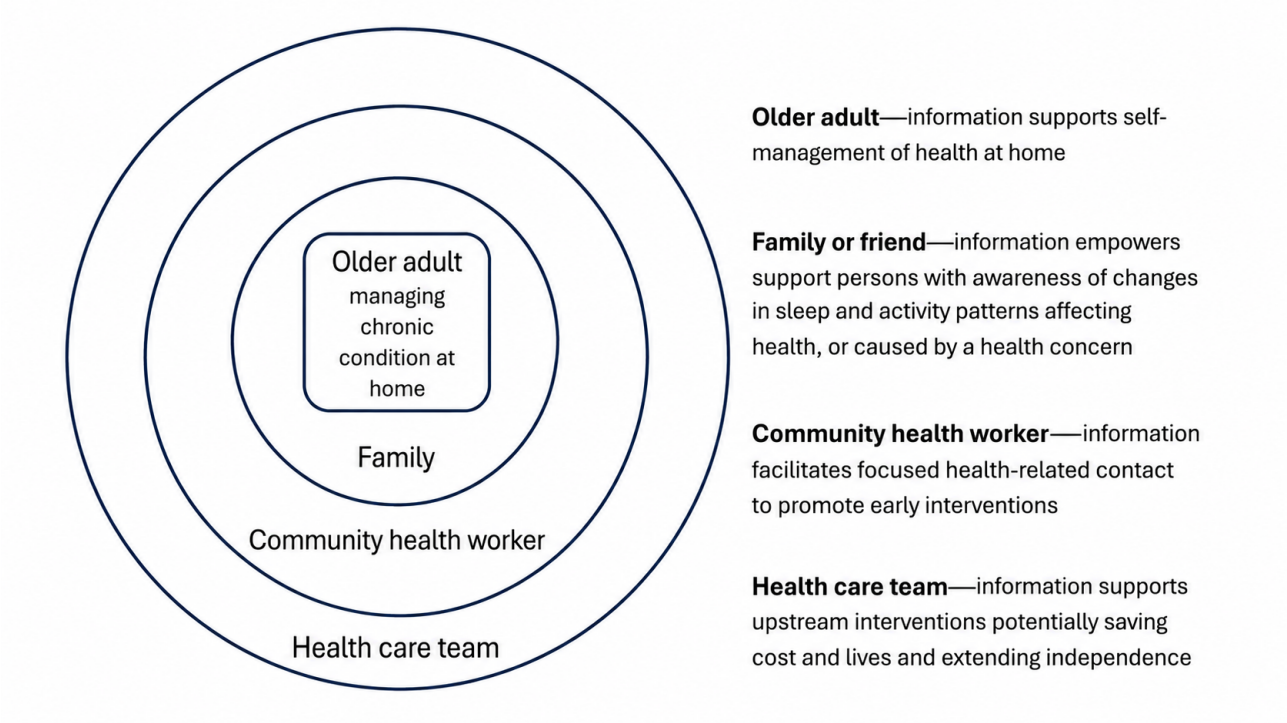
Methods

Ethical Considerations

This study was approved by the Washington State University Institutional Review Board (IRB) for human participants' research under IRB#19135. All participants provided informed consent in their preferred language. Seven languages were represented in the participant pool. Each participant received a US $50 gift card and a results summary after study completion.

Study Design and Setting

A community-engaged, prospective, mixed methods design was used to prototype and evaluate a low-cost smart health monitoring system for older adults managing multiple chronic conditions while experiencing poverty. The study was conducted in collaboration with local housing authorities, culturally based health organizations, and a free community health clinic in the US Pacific Northwest.



Smart Health System Prototype

The prototype system was designed as a closed-loop model to help families, communities, and health care teams support older adults aging in the place of their choosing (Figure 1). The system operated through three integrated components: (1) ambient sensing, (2) a rules-based algorithm developed for this study that continuously processed sensor data and automatically generated alerts for clinically relevant changes in daily behavior, and (3) community members who worked alongside the technology to respond promptly to alerts, including facilitating engagement with the health care team.

The prototype system included 6 alert types, with alert messaging designed not to imply judgment or provoke stress or fear. The system alerted for social isolation (Homebody), decreased activities (Daytime Resting), kitchen use (Eating Routines), decreased hygiene (Bathing), sleep disturbance (Restless Night), and sleep patterns (Changing Sleep Routine). The participant-facing alert terms associated with clinically relevant behavior changes are italicized. Multimedia Appendix 1 contains detailed descriptions of alerts, including defined thresholds.

XSL•FO
RenderX

Figure 1. The connected smart health system.

Study Sample and Recruiting

A convenience sample was recruited with the assistance of subsidized housing building managers. More than 80 residents across 7 subsidized housing properties attended information presentations about the smart health system, after which interested individuals met privately with a trained research assistant or the lead primary investigator (PI) to review consent forms in their preferred language. Residents were informed that the system was a research prototype, that it was not intended for emergency detection or intervention, and that the absence of alerts would not imply health or clinical stability. They were instructed to use usual health care and emergency services. Adults aged 50 years and above with 2 or more chronic conditions and income at or below the federal poverty level (US $14,580 annually for a single-person household) [49] were included. The lower age threshold was informed by community partner input, which emphasized that chronic conditions often develop earlier among racially and ethnically diverse populations. Older adults living alone were prioritized for recruitment, although homes with fewer than 2 residents met inclusion criteria. A target was set for recruiting >80% single-resident homes. Exclusion criteria included dementia, severe mental illness, or pets that could interfere with sensor readings.

Data Collection

Data collection combined continuous, ambient, home-based sensing with participant-facing and team-documented narratives, and in-the-moment surveys associated with health alerts. Table 1 contains the data elements of the study with descriptions. Alerts were triggered when anomalies exceeded preset thresholds (eg, no door use for 48 hours, reduced kitchen activity, sleep disruption). To minimize alert fatigue, some overlapping alerts were combined into a single alert, yielding 4719 novel alerts. For example, a Restless Night alert and a Changing Sleep Routine alert on the same night would be combined into one alert requiring one survey response. Because it was not possible to have continuous daily CHW coverage for the study duration, the full-time research RN or lead investigator (an RN) assisted in responding to alerts, and alert notifications were delivered only during business hours. Business hours were 9:00 AM to 6:00 PM Pacific Time, Monday to Friday. Nighttime sensing resulting in alerts saw the alerts delivered at 9:00 AM on weekdays, and weekend alerts were delivered at 9:00 AM on Mondays. No alerts were discarded.

XSL•FO
RenderX

Table . Data elements with descriptions.

Data element	Description
Sensor data from 6 multisensors per home	The sensor state (ON) when motion was sensed, or when temperature, humidity, and lights changed.
Alerts	Emails and SMS text messages generated by the system and sent to the participant, a support person, and a CHW[a] (sequentially escalating) when a change in daily routine met algorithm rules aligned with possible health changes.
Alert responses	Discrete and unstructured written text provided by participants, a support person, CHWs, or an RN[b].
Interview transcripts	End-of-study interviews about acceptance perceptions.
Likelihood-to-recommend rating	Participant rating on a 0 - 10 scale indicating how likely they would be to recommend the Smart Health System to family or friends when a system (like the prototype) would be available on the market. Ratings were subsequently categorized as promoters (9-10), passives (7-8), and detractors (0 - 6) to calculate the Net Promoter Score.

[a]CHW: community health worker.

[b]RN: registered nurse.

Each alert included a secure survey link for reporting current health status. Unacknowledged alerts prompted CHW follow-up and escalation to an RN as needed. Narrative data were drawn from three sources: free-text survey responses, CHW/RN field notes after alert-related contacts, and semistructured exit interviews. Although 6 additional languages (Cantonese, Mandarin, Korean, Vietnamese, Spanish, and Russian) were spoken beyond English, multilingual CHWs communicating in preferred languages documented all responses in English.

At a conceptual level, the smart health system generated alerts using 3 components: sensing, rule-based interpretation, and filtering. Ambient motion and door sensors continuously captured movement throughout the home, and these raw signals were aggregated into higher-level behavioral events representing where and when a participant was active (eg, time in the kitchen, nighttime location, frequency of door use). A set of rules, co-designed with community partners and the PIs who were RNs, compared each participant's recent behavior against their own established baseline routine to identify clinically meaningful deviations, such as prolonged inactivity, disrupted sleep, reduced kitchen use, or missed bathing patterns. When a deviation crossed a predefined threshold, an alert was generated. To prevent alert fatigue, repeat alerts of the same type within a 1-week window were suppressed.

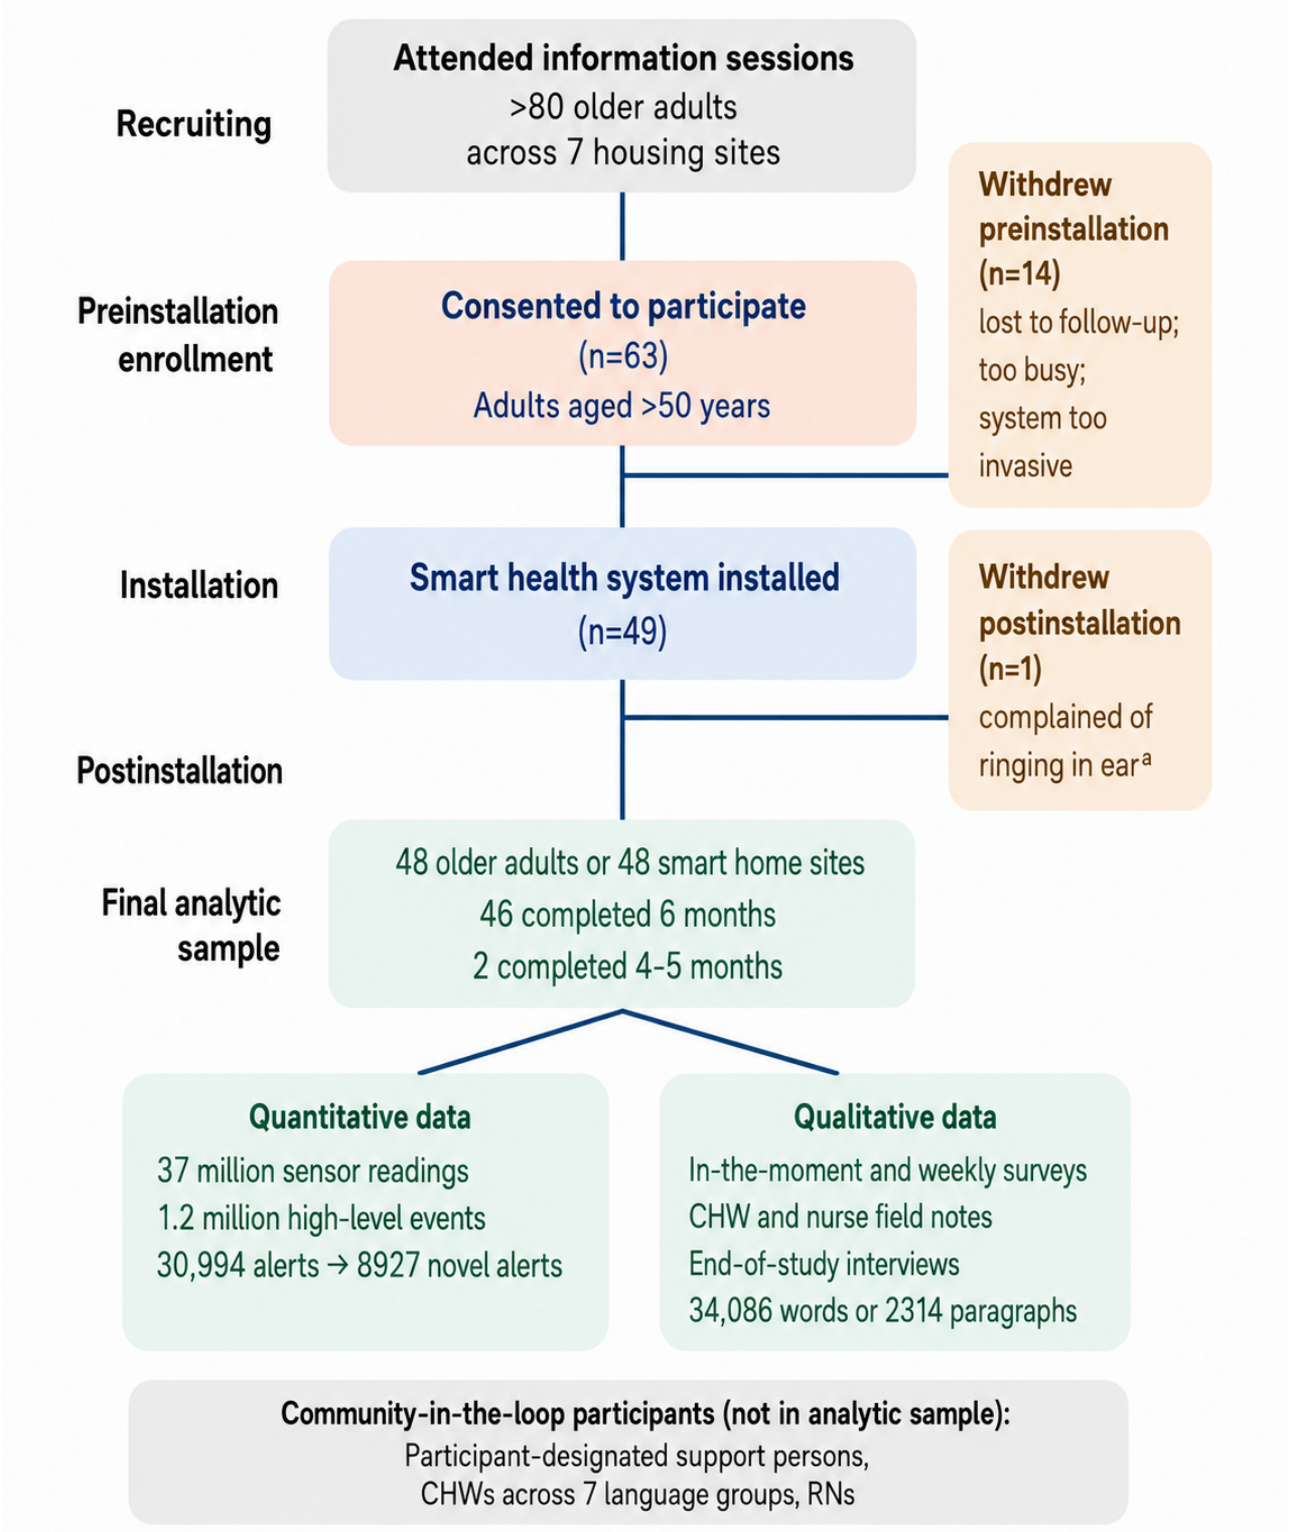
Multimedia Appendix 1 describes the full technical specifications of the sensors, processing pipeline, rule definitions, and figures exhibiting the health-monitoring dashboard (deidentified) and the clinical research dashboard, which shows an exemplary behavioral anomaly where a participant did not exit their home for nearly 3 days.

Data Analysis

Quantitative data, including participant characteristics, alert metrics, and response pathways, were summarized descriptively. Response trajectories were prospectively examined to identify alerts that elicited participant, support person, and CHW responses and those that resulted in subsequent RN action.

Qualitative data included free-text survey responses, follow-up narratives documenting health changes, and semistructured exit interviews. The data were analyzed using qualitative descriptive methods [50] and reflexive thematic analysis [51]. Coding was inductive [52] and iterative, with repeated review of written text-based data to refine codes, categories, and themes.

To strengthen rigor, the analytic team included RNs, a family nurse practitioner, bilingual CHWs, and engineering or computing expertise selected to reflect the linguistic, cultural, and clinical heterogeneity of the study population. The team met across 4 synchronous analytic circles and 8 asynchronous review sessions to discuss emerging patterns, compare coding perspectives, and refine thematic structure. After each session, written analytic summaries were synthesized into a shared memo for iterative team review. Related subthemes were consolidated into higher-order concepts through consensus discussion. An audit trail of analytic decisions, supporting written text-based excerpts, and reflexive memos was maintained throughout to enhance transparency and cultural sensitivity.



Results

Participant Characteristics

A total of 63 older adults consented to participate in the study, of whom 46 completed 6 months of monitoring and 2 completed 4 and 5 months of monitoring, respectively. These 2 individuals were included in the total sample because they completed two-thirds or more of the study. Fifteen participants withdrew, with reasons including privacy and system invasiveness, discomfort with the perceived invasiveness of questions asked by the Internet Service Provider if the internet was not already connected in the home (free internet was available in subsidized housing), and time constraints. The total sample included 48 older adults (ie, 48 smart home sites). Figure 2 summarizes participant flow from initial information sessions through to the final analytic sample.

XSL•FO
RenderX

Figure 2. Participant flow through the smart health system study. From >80 older adults who attended initial information sessions across 7 subsidized housing sites and individual low-income constituent homes of community partners, 63 consented to participate. Following 14 preinstallation withdrawals and 1 postinstallation withdrawal, the final analytic sample consisted of 48 older adults (48 smart home sites), of whom 46 completed the full 6-month monitoring period and 2 completed 4 to 5 months (≥2/3 of the study duration). [a]The ambient sensors did not have sound-producing capabilities. CHW: community health worker; RN: registered nurse.

Sample demographics are presented in Table 2. Participants ranged in age from 54 to 94 years, with 77.1% (n=37) identifying as female. Educational attainment varied, with 44% (n=18) holding a high school diploma and 17% a college degree. Seven languages were represented across 4 racial groups and 8 ethnicities. Most participants lived alone (n=44, 92%) and had access to the internet before consenting to participate (n=38, 79%). Ten (21%) participants received internet access via study-provided hotspots. The most prevalent conditions among participants were heart (n=23, 47.9%), musculoskeletal (n=12, 25%), and gastrointestinal (n=6, 12.5%) conditions.

Alert Response Rates and Follow-Up Actions

Participants received 4719 emails and SMS text message alert reminders when baseline movement patterns changed, breaching thresholds of the custom rules-based monitoring algorithm. If a participant did not respond to their email alert within an hour, they received an SMS text message reminder. If they still did not respond, their support person received an email followed by an SMS text message alert. If the support person did not respond, the alert was automatically escalated to a CHW who then contacted the participant as soon as possible by phone. After making contact, the CHW responded to the alert on behalf of the participant and either documented a nonissue or supported the health situation as needed, including escalating a health issue to the research team RN as needed per protocol. CHW and RN responses to alerts included phone outreach and asking targeted questions related to 1 of 6 alert types (Homebody, Daytime Resting, Eating Routines, Bathing, Restless Night, Changing Sleep Routines). For example, for a Homebody alert, the participant would be asked how they were feeling and how long it had been since they last left their house or had visitors over. For a Restless Night alert, the participant would be asked about changes in bedtime, morning wake time, and the number of sleep interruptions that included getting out of bed, as well as the participant's perspective on the cause of sleep interruptions (eg, needing to go to the bathroom to void, experiencing pain, or worrying). If appropriate, the participant was asked to take their vital signs on equipment provided by the study team. Across the 6-month monitoring period, CHWs and nurses completed 1060 participant contacts, resulting in 72 CHW or RN interventions combined (nonurgent and urgent). Commonly, CHW interventions included therapeutic listening and recommendations to avoid dehydration and get enough rest. Common RN interventions included advice to take medications as prescribed, check blood sugar, take vital signs (blood pressure, heart rate, oxygen saturation), or call their support person. For 93% (4389/4719) of the alerts, no action was required. In six instances, the RN suggested the participant call their provider the same day (n=6, <1%). In 5 instances (n=4, <1%), the RN recommended urgent care.

Participant digital response rates were 1.57% (n=74) for initial email alerts and 7.79% (n=368) for follow-up SMS text message alerts. Support persons responded to 2.37% (n=112) of the email alerts and 5.21% (n=246) of the SMS text message alerts. CHWs responded to 78.36% (n=3698) of the alerts, including 4.68% (n=221) within 1 hour, with the remaining responses occurring after 5 hours. In contrast to the very low response rates via email (n=186, 3.94%) and SMS text message (n=614, 13.01%) from participants and support persons, CHWs demonstrated substantially higher engagement, responding to 78.26% (n=3698) of the alerts.

Net Promoter Score

Participants in the study completed a likelihood-to-recommend rating during their end-of-study interview using a 0 - 10 scale (0=would never recommend the health monitoring system and 10=would highly recommend it to family or friends). Fifteen participants did not provide a rating. One response knowingly exceeded the scale maximum and was recoded to 10 prior to analysis in accordance with the instrument's scale limits.

Among respondents (n=33), the mean likelihood-to-recommend rating was 8.68 (SD 1.68), the median was 9.0 (IQR 8.0 - 10.0), and scores ranged from 3 to 10.

Following a standard Net Promoter Score methodology, respondents were then classified as promoters (9-10), passives (7-8), or detractors (0 - 6). Most respondents were promoters (22/33, 67%), while 21% (n=7) were passives and 12% (n=4) were detractors, resulting in a Net Promoter Score of +55.

Qualitative Insights From Participant Narratives

Overview

Three major themes emerged from qualitative analysis—Alone, Trust, and Human Connection—encompassing 11 subthemes and related supporting concepts (Table 3). Narrative data were drawn from in-the-moment surveys with free-text fields, CHW and RN field notes, and end-of-study interviews. The corpus included 34,086 words across 2314 paragraphs. Multimedia Appendix 1 contains an extended table of themes and supporting quotations from participants' own words.

Table . Major themes, subthemes, and supporting concepts emerging from text-based data written by participants, community health workers (CHWs), and registered nurses (RNs).

Theme	Subthemes	Supporting concepts
Alone	Safety, Timing, Reassurance	Watched Over, Comfort, Loneliness, Spoken Language, Promise
Trust	Safe or Secure, Harm, Burden	Fraud, Data Ownership, Reliance, Normalizing Symptoms
Human Connection	Features, Personalization, Digital Distress	Expectations, AI Not Good at Context, Who Assesses Symptoms

XSL•FO
RenderX

Theme 1: Alone

Participants frequently described concerns about being alone while managing multiple chronic conditions, particularly when feeling unwell or lacking nearby family support. Many described the system as increasing feelings of safety, support, and connection. Several participants stated that the system would be especially valuable for those living alone or without family support. One participant shared that at "[my] age and being alone it made [me] feel safe and supported" (participant 25), while another described seeing the sensor light activate at night and thinking, "I'm not alone" (participant 1).

Timing also emerged within this theme, with some participants describing the system as more relevant during periods of worsening illness or future decline. Participants additionally described the comfort associated with the system's presence in the home.

CHW and RN narratives documented many cases in which participants preferred direct phone communication rather than email or SMS text message alerts. Participants were much more responsive to calls than emails or SMS text messages. In addition, they were more responsive when the calls were conducted in their preferred language.

Theme 2: Trust

Trust-related narratives centered on technology, the clinical team introducing the system, data privacy, fraud, and system reliability. Some participants also described broader distrust of the health care system. One participant stated:

> *I've kind of given up on seeing doctors for it [neuropathy pain]; they don't seem to do much or offer any real help.* [Participant 50]

At the same time, participants described trust in nurses and reassurance associated with nurse availability. One participant noted it was comforting to have "a nurse more available than to wait on the line for a nurse" (participant 35). Others described reassurance for distant family members and reduced caregiving pressure, noting that the system allowed loved ones to know they were being "watched over" (participant 23) and the system could "take pressure off [my] daughter" (participant 20).

Three recurring subthemes were evident: Trust in Nurses, Data Security and Identity Protection, and Cultural Values surrounding intergenerational caregiving. Participants frequently reported answering calls only from known phone numbers, and several added the research number to their phone contacts to avoid thinking the number was a scam caller. Among culturally based communities, participants also questioned how the system aligned with traditional family caregiving expectations.

A cross-cutting concept involved participants' own perceptions of health in relation to the system's sensor-based feedback. One participant described ignoring alerts after perceiving that the system had misinterpreted movements (participant 56), whereas another interpreted the absence of an alert as an indication that she was well despite recent symptoms (participant 57).

Theme 3: Human Connection

Participants consistently described preferring direct contact with CHWs or nurses, by phone or in person, over automated alerts and response systems. Many requested CHW or RN phone numbers to save in their contacts and described these interactions as the most valued component of the system.

Access to a health care team member was also described in relation to contextual personalization when system alerts did not align with individual routines. One participant explained:

> *[M]y pattern is different from others, and the system was not getting it. I kept getting alerts that were not relevant to me … but if it worked, I would have a direct nurse to call versus an on-call nurse.* [Participant 47]

Participants also described uncertainty about whether they were using the system correctly, frequently asking questions such as "am I doing it right?" (participant 1). Others reported discomfort with sensor activity, including flashing lights that were "sometimes … bothersome" (participant 11).

Persons withdrawing from the study, both before and after the installation of the sensor, reported concerns about the lack of personalization, invasion of privacy, lack of preferred-language communication, and uncertainty regarding whether a human or the technology was responsible for monitoring health changes.

Discussion

Overview

Central Findings

This mixed methods study extends prior smart home and aging-in-place research by centering older adults managing multiple chronic conditions while experiencing poverty. Consistent with prior work, trust, avoiding aloneness, and human connection emerged as foundational to adoption [12,34,41,43,53-55]. Our findings deepen this literature by showing that adoption barriers in low-income settings extend beyond usability and technical performance to include identity theft concerns, digital distress, cultural caregiving expectations, and mistrust of institutional systems.

A central finding was that trust operated at multiple levels: trust in the technology itself, trust in the people introducing and supporting it, and trust in one's own bodily awareness relative to system feedback. Participants' willingness to engage was strongly shaped by the presence of trusted RNs and CHWs, who functioned as relational anchors and trusted messengers. This aligns with prior research showing that older adults prefer health technologies that augment, rather than replace, human care [56-58]. In this study, RN and CHW involvement increased confidence in the system, reduced uncertainty, and helped participants contextualize alerts within daily life.

The Human Connection theme further reinforces that relational support is not merely an implementation enhancement but may be a core design requirement for aging-in-place technologies. Participants consistently preferred speaking with CHWs or RNs over interacting with automated email or SMS text message

XSL•FO
RenderX

alerts, despite generally favorable overall system ratings. High CHW response rates, alongside low participant digital response rates, suggest that human-mediated communication may be more acceptable than direct self-management of digital alerts, particularly among older adults navigating multimorbidity and poverty. These findings support the integration of human-centered communication pathways into smart home ecosystems, ensuring that technology serves as an extension of trusted care relationships rather than a replacement. Collectively, these findings (the need for human connection alongside low digital response rates) argue against a binary choice between fully automated and fully human-mediated monitoring. Hybrid, tiered models may offer a more pragmatic path forward. Automated sensing can support continuous objective data capture, while human contact, particularly by phone, remains the primary mode of communicating clinically relevant changes. Such a model could reserve intensive CHW and RN involvement for higher-acuity alerts or higher-risk participants. Lower-acuity changes could be routed for brief check-ins by support persons or CHWs or asynchronous follow-up, allowing the relational core of the system to scale without requiring proportional growth in staffing.

Digital Distress

The findings also introduce digital distress as an important extension of the broader technostress literature. The first clues that the concept of digital distress would eventually emerge from the data were noted during the installation phase. Seven people changed their minds about participating after encountering too many stress-inducing personal and financial questions from internet service providers when enrolling in free internet so they could participate in the study. (Note: this led to a design change where we added hot spots to the system.) Additionally, 1 person said it would be too stressful to receive calls from unknown numbers (ie, for the nursing calls), and another said the system was too invasive and would stress them out. Overall, digital distress was noted when technologies felt intrusive, difficult to interpret, poorly personalized, or disconnected from participants' language and cultural context. Digital stress was especially pronounced when users were uncertain whether a human or the system was responsible for monitoring health changes. This role ambiguity, combined with concerns about fraud, flashing sensors, or burdensome connectivity processes, contributed to participant discomfort and study withdrawal. For older adults experiencing poverty, digital distress may be amplified by chronic illness burden, financial precarity, and prior experiences with scams or identity theft, making low-burden and transparent workflows essential. The antidote is the *human connection*, which can mitigate stress, reduce *aloneness*, and promote *trust*.

Safety

A related safety implication concerns the risk of false reassurance through error of omission. Though participants were told that the absence of alerts does not mean the health is stable, some participants still interpreted the absence of alerts as evidence that they were well, even when experiencing symptoms. This suggests that missed detections or insufficient personalization may unintentionally increase reliance on incomplete system feedback. Future smart home systems should therefore prioritize explainable alert logic, transparent thresholds, and explicit communication that the absence of an alert does not equate to clinical stability. These findings have direct implications for digital safety, implementation ethics, and the design of AI-supported aging-in-place tools.

Older Adults' Resources

Poverty-specific barriers were highly influential. The process of accessing free internet felt invasive or financially risky and resulted in several withdrawals from this study. Fear of hidden fees, identity theft, and lack of ongoing support after study completion undermined the willingness to continue with the internet sign-up process. These findings highlight how connectivity itself can become a structural barrier, even when technologies are designed to be low cost.

Though we met our target of less than US $400 per home for hardware, there were other development and implementation costs; primarily personnel time (engineering contractor, nursing, multilingual CHWs, research assistants), training staff, and hotspot connectivity subscriptions for participants without internet. Technical assistance throughout the study was included in the engineering contract, but that may not always be the case. Often, technical assistance is charged separately. Multilingual CHWs received differential pay for each additional language spoken (an additional US $3 per hour). Supply chain issues and inflation impacted hardware availability and costs over a 6-month purchase timeframe during the COVID-19 pandemic (November 2021-May 2022). These pragmatic discoveries suggest that equitable scaling requires budgeting not only for hardware but also for connectivity, technical maintenance, and language access.

Feasibility

Built Environment

The built environment also shaped feasibility. Older housing, limited outlets, and brick-and-steel walls interfered with connectivity and sensor placement. Participants also disliked visible flashing lights and preferred less obtrusive hardware. These findings reinforce that environmental adaptability and unobtrusive sensor design are central to adoption, especially in subsidized or aging housing where infrastructure limitations are common.

Individualization

Our results further suggest that rules-based algorithms are insufficient for diverse older adult populations. Participants frequently reported irrelevant alerts or missed meaningful changes because standardized thresholds failed to reflect individualized routines. One participant responded to an email alert saying they wanted alerts to their support person to stop because "I don't want to alarm her!" and the alerts, in the participant's opinion, were inaccurate. This mismatch undermined trust and increased burden. Context-aware machine learning models that adapt to personal schedules, cultural practices, and evolving health patterns may offer a more appropriate pathway for equitable smart home monitoring.

XSL•FO
RenderX

However, such systems must preserve transparency and human oversight to avoid exacerbating mistrust.

Cultural Sensitivity

Cultural expectations around caregiving were another key determinant of adoption. In some communities, participants expressed concern that technology might undermine family caregiving roles or conflict with intergenerational obligations. Systems that intentionally incorporate family, CHWs, and RN oversight may therefore better align with users' values and improve engagement. Rather than positioning monitoring technologies as substitutes for caregiving, framing them as tools that strengthen family and community support structures may enhance trust and long-term use.

These contextual findings suggest that successful smart home health systems for older adults experiencing poverty require more technical accuracy than was possible within the scope of this study. Such systems require relational trust, cultural responsiveness, personalization, environmental adaptability, and sustainable implementation infrastructure. Human support—particularly through CHWs and nurses—appears central to mitigating digital distress, strengthening trust, and promoting equitable aging in place.

Principal Results

This study identified several barriers to smart home adoption among older adults managing multiple chronic conditions while experiencing poverty. Beyond technical feasibility, adoption was shaped by digital access barriers, identity theft concerns, cultural caregiving expectations, environmental constraints, and structural inequities tied to poverty. Across qualitative themes, Aloneness, Trust, and Human Connection emerged as central determinants of engagement.

A key finding was that participants consistently preferred human-mediated communication, particularly with CHWs and RNs, over automated alerts. Although direct digital response rates were low, CHW engagement was high, suggesting that integrating trusted community and clinical personnel into the health care-technology-patient loop may be critical for sustained use in low-income settings. Future research should test how to reduce the staffing intensity of this model while preserving the human contact participants valued, including through acuity-based tiering, machine learning personalization, and language-concordant outreach.

This study also introduces digital distress, a novel concept describing stress that arises when technology feels intrusive, confusing, insufficiently personalized, or disconnected from linguistic and cultural context. Digital distress was most evident when participants were uncertain how the system worked, whether they were using it correctly, or who was responsible for monitoring health changes.

Collectively, these findings indicate that smart health systems designed around human relationships, cultural responsiveness, and contextual adaptation, and implemented with trusted CHW and nursing support, may better promote equitable aging in place among older adults managing multimorbidity while experiencing poverty.

Limitations and Future Research

This study has several limitations. The sample was relatively small and drawn from a specific population of older adults managing multimorbidity while experiencing poverty. Despite the extant literature defining older adulthood as age 65 years or above, the study sample included immigrant adults aged 50 years or above who were managing multimorbidity, which commonly affects these populations at younger ages due to the impacts of social determinants of health. This may limit transferability across populations, settings, and cultural contexts. In addition, the smart health system was a prototype that underwent iterative refinement during the study, and its rules-based alerting approach may have contributed to irrelevant or missed alerts. The intensive involvement of CHWs and RNs, while central to equitable implementation, may also limit scalability in other care settings. Because digital distress emerged inductively within this context, additional research is needed to examine its relevance across populations and technologies. Future work should evaluate scalable machine learning approaches, multilingual and culturally responsive interfaces, improved alert accuracy and data visualization, integration with clinical workflows, and strategies for communicating automated messages and engaging older adults and families with sensor-derived health data while preserving simplicity and trusted human support.

Conclusions

Smart home health monitoring systems hold promise for supporting aging in place and helping older adults maintain independence, but their success among those experiencing poverty depends on more than technological innovation. If systems are not designed with attention to the unique barriers faced by this population, they risk reinforcing existing health inequities. This study demonstrates that adoption is shaped by a complex interplay of digital literacy, cultural values, trust in institutions, and the physical realities of low-income housing. A community-in-the-loop approach that integrates ambient sensors, automated unobtrusive monitoring, and human-centered care networks may reduce isolation, foster trust, and maintain human connection while offering real-time health insights. To be effective and equitable, future smart health systems must be co-designed with communities and prioritize personalization, cultural sensitivity, and low-burden engagement. In addition, technology-enabled health monitoring for the home must include intentional, explicit strategies to mitigate digital distress. These findings offer a roadmap for researchers, designers, and policymakers seeking to close the digital divide and promote health equity through technology-enabled care.

Acknowledgments

We thank the publicly elected board of the Vancouver Housing Authority (2022 - 2025) for their support as well as the subsidized housing building managers in the Southwest Washington region. We also thank the leaders and community health workers at the Asian Health and Service Center (Oregon) and Battle Ground Healthcare (Washington) for their partnership and assistance in recruiting and data collection. These organizational partnerships and the individuals intimately involved in the study process were critical to the project's success.

Funding

This is funded by the Gordon and Betty Moore Foundation through Grant GBMF9048 to Washington State University Vancouver to support this work led by Roschelle Fritz, PhD, RN, FAAN, now Professor of Nursing at the University of California Davis Health Betty Irene Moore School of Nursing. Generative AI was not used in the preparation of this manuscript. All ideas, analyses, interpretations, and writing are the authors' own.

Data Availability

Deidentified data presented in this study are available for research purposes upon request, due to the small sample size and associated health information.

Authors' Contributions

RLF conceived the study, secured funding, designed the methodology, supervised the project, interpreted the findings, and wrote the manuscript and Multimedia Appendix 1. CKYN-T contributed to community partnerships, participant recruitment, data collection, interpretation of findings, preparation of Table 2, and critical revision of the manuscript. JP critically revised the manuscript and prepared Table A2 in Multimedia Appendix 1. THN contributed to data collection. GB contributed to the engineering, implementation, and technical data collection for the smart home system. HS contributed health economics expertise and critically reviewed the manuscript. EEH and AM contributed to data collection and interpretation of findings. YLBR contributed to interpretation of the findings. CZ contributed to the design and analysis of the Net Promoter Score, interpretation of Net Promoter Score findings, and wrote the associated content. MR provided senior scientific oversight, guided the study design and engineering collaborations, contributed to interpretation of the findings, and critically revised the manuscript. All authors reviewed and approved the final manuscript and agree to be accountable for all aspects of the work.

Abstract

Background: As people age over the coming decades, demand for in-home support and other interventions, such as home modifications, to help older adults age in place successfully, is also expected to rise. Smart home technologies have the potential to enhance aging in place by complementing traditional home modifications; however, adoption within federally funded home modification programs remains limited.

Objective: This study explored grantees' perspectives on the Older Adults Home Modification Program (OAHMP) to understand current practices, perceived benefits, barriers, and strategies for integrating smart home technologies into home modification services.

Methods: An exploratory qualitative study was conducted with staff, occupational therapists, and home builders from 3 OAHMP grantee organizations. A 1.5-hour virtual focus group was held and thematically analyzed using a deductive approach grounded in the discussion agenda.

Results: A total of 11 participants reported early adoption of select smart devices—most commonly smart speakers, doorbell cameras, motion-activated lights, and smart plugs—to enhance home safety, communication, and independence. Barriers to broader implementation emerged at three levels: (1) older adults' digital literacy, privacy concerns, and device maintenance burden; (2) contextual constraints, such as unreliable internet in rural areas; and (3) organizational limitations, including training needs, staffing capacity, and funding challenges. Participants emphasized the importance of progressive adoption, hands-on training, and low-maintenance technology. In addition, partnerships with university educational programs were well established among selected grantees to provide technology training resources for older adults. To inform a reasonable technology selection for home modifications, criteria were proposed across 5 domains: installation, usability, accessibility, sustainability, and security and privacy.

Conclusions: Integrating smart home technologies into home modification programs provides a scalable, cost-effective opportunity to improve aging in place outcomes. Policy support, workforce training, valid selection criteria, and sustainable funding models are needed to promote equitable adoption across OAHMP and similar federally supported programs.

Introduction

Background

The share of Americans aged 65 years and older is projected to increase from 17% to 22% by 2040, and the number of Americans aged 85 years and older is projected to double over that same period [1]. The prevalence of disability increases with age, as approximately 14% of adults aged 65 to 74 years and 29% of adults aged 75 years and older have an ambulatory difficulty, defined as a challenge walking or climbing stairs,

XSL•FO
RenderX

and approximately 11% of the population aged 75 years and older has a self-care difficulty, defined as a challenge with bathing or dressing [2]. As the population ages over the coming decades, demand for in-home support and other interventions, such as home modifications, to help older adults age in place successfully, is expected to rise.

"Aging in place" refers to maintaining functional independence and social connections while living in the home or community [3]. A national survey reported that 75% of adults aged 50 years and older wish to stay in their own homes as they age, and 73% hope to stay in their communities [4], underscoring the importance of residential environments in supporting daily living and well-being. While remaining at home is desired by the vast majority of older adults, many American homes lack key features that provide the best person-environment "fit" to support aging in place [5]. As of 2019, about 40% of homes were considered aging-ready, with a bedroom and full bathroom on the first floor and a step-free entryway [2]. Today, only 54% of older adults aged 80 years and older reside in single-floor homes with step-free entryways [6]. Correspondingly, demand for in-home support and residential adaptations is expected to continue, placing a greater emphasis on strategies that enable older adults to live safely and independently.

Home Modifications to Support Aging in Place

One of the most widely recognized approaches to supporting aging in place is home modification. Home modifications are a prominent and essential feature of evidence-based programs, such as Community Aging in Place–Advancing Better Living for Elders (CAPABLE), which seek to reduce falls and improve the safety and independence of older adults aging in place [7]. Home modifications—such as installing grab bars, building ramps, or improving lighting—have been shown to reduce environmental hazards, enhance accessibility, and lower the risk of falls or injury [8]. Evidence indicates that such a solution not only improves safety but also delays institutionalization and reduces health care costs [9]. Despite these benefits, current home modification programs face challenges, including limited funding, a lack of service providers, and difficulties tailoring interventions to the diverse needs of older adults and their caregivers, including considerations of cost and time required to implement home modifications [10-13].

The cost of home modifications varies significantly depending on the nature of the alteration: items such as grab bars typically cost a few hundred dollars to acquire and install, whereas wheelchair ramps or stairlifts can cost several thousand dollars. Nearly one-third of older adult households are cost-burdened, defined as spending at least 30% of their income on housing, utilities, taxes, and insurance [6,14]. To address gaps between the need for and access to home modifications, the Older Adults Home Modification Program (OAHMP), established by the US Department of Housing and Urban Development, focuses on high-impact, low-cost home modification solutions. The OAHMP grant, created in 2021, provides funding to organizations to support low-income older adults in aging in place through home modifications that enhance the safety and accessibility of their home environment [15].

Smart Home Technologies in Home Modification Programs

Over the past decade, smart home technologies have undergone rapid evolution and become increasingly prevalent in everyday life. Devices such as voice-activated intelligent assistants (eg, Google Assistant, Alexa, and Siri), remote monitoring systems, motion-sensor lighting, and video doorbells are now widely available at relatively low cost. These technologies offer new opportunities to extend the benefits of traditional home modifications by enhancing safety, improving communication and monitoring, and supporting independence [16]. Their potential application in home modification programs is particularly promising, given the growing emphasis on technology-enabled care and prevention [17].

Although some OAHMP grantee organizations have reported integrating products such as automatic door openers, security systems, and fall-detection devices into their home modification installations, most OAHMP and similar home modification programs do not include smart technologies in their menu of environmental modifications [15]. Incorporating additional smart home technologies into the OAHMP could support a range of aging in place goals. For example, smart, motion-sensitive lighting can improve visibility and reduce fall risk in areas such as stairwells and bathrooms. Smart speakers can enable automated control of door locks, lighting, window blinds, and other devices, helping individuals with reduced mobility maintain control over their environment. Smart plugs and appliances, such as coffee pots or stoves, can enable caregivers to remotely support and monitor daily routines. Despite the widespread availability of these technologies and the growing inclusion of home modification interventions, their adoption in home modification programs remains limited [18]. Barriers, including a lack of standardization, concerns about cost and maintenance, concerns about technology acceptance by older adults, and uncertainty regarding training and support, have prevented consistent integration into service delivery [16]. Additionally, incorporating smart technologies into traditional home modification approaches requires a readiness for change by both providers and consumers, which may inhibit the uptake and diffusion of this innovation for aging in place [19,20].

To better shape future program design and policy support, it is essential to understand how practitioners view the opportunities and challenges of integrating smart home technologies. This study aimed to explore OAHMP grantees' perspectives on current practices, perceived benefits, barriers, and strategies for integrating smart home technologies into home modification services, and to propose criteria to guide technology selection for program implementation.

Methods

This was an exploratory qualitative study with thematic analysis of focus group feedback.

Recruitment

On the basis of sample size recommendations for focus groups [21], the research team worked with leadership from 3 OAHMP grantee organizations representing rural, suburban, and national

XSL•FO
RenderX

programs to purposively select 9 to 12 (3 - 4 per organization) professionals, consisting of home modification contractors, remodeling contractors, Certified Aging-in-Place Specialists (CAPSs), occupational therapists, other assessment professionals, and home modification program administrators or staff. Recruitment information was emailed to the leaders and subsequently forwarded to English-speaking professionals working for the regional organizations. No professionals were excluded on the basis of gender, race, or ethnicity.

Procedure

A single focus group session was conducted via Zoom and lasted approximately 1.5 hours. An agenda was prepared in advance, with discussion questions organized into three sections: (1) background and ongoing home assessments and modifications; (2) attitudes, current adoption, and barriers related to introducing smart home technology into home modification programs; and (3) future expectations for integrating smart home technology and potential motivators to support adoption (Multimedia Appendix 1). The diffusion of innovations theory, readiness for change, and technology acceptance models were used to guide question content [19,20,22,23]. Two facilitators (HH and MC) from the research team guided the session, alternating leadership across the 3 sections. The primary facilitator in each section posed questions and encouraged participants to share their perspectives, ensuring that all 3 participating organizations responded with comments. While 1 facilitator engaged with participants, the other took detailed notes to capture key points and emerging themes. The entire session was audio-recorded via Zoom to ensure accurate capture of participants' responses.

Data Analysis

The audio recording was transcribed using Zoom's cloud-integrated transcription feature. Data were analyzed using a deductive thematic analysis approach, guided by the topics outlined in the focus group agenda. A 10-theme codebook was developed in advance based on the agenda questions (Table 1). Two independent reviewers (HH and MC) systematically coded the transcript and assigned responses to the predefined themes. Any discrepancies were reviewed by a third, experienced researcher (PT) until an agreement was reached. Beyond categorization, the analytical process involved interpretive synthesis across coded segments to identify patterns and their broader implications within and across themes. Following this process, the initial 10 themes were refined and synthesized by merging overlapping content and eliminating redundancies, yielding the final set of themes used to structure the results.

XSL•FO
RenderX

Table . Focus group agenda and the theme codebook.

Theme	Subthemes or a priori codes	Typical indicators
Clients and referrals	• Primary target population • Referral sources and pathways	• "Mostly low-income seniors" • "Hospital social workers send us referrals"
Assessment practices	• Standard checklist or protocol • Assessor roles (occupational therapist, contractor, and staff) • Data sources (self-report, observation, and performance demonstration) • Scope (entire home vs selected areas)	• "We observe meal prep tasks" • "We skip bedrooms unless requested"
Time and workflow	• Typical timeline (assessment to completion) • Factors that lengthen or shorten the process	• "Funding approval adds 3 weeks"
Common modifications	• Frequently delivered changes • Driven by funding rules or client priorities	• "Grab bars, handrails" • "Ramp only if grant covers it"
Current use of smart home technology and assistive technology	• Technologies already installed • Decision authority (client, assessor, or others) • Staff and contractor training • Client and caregiver receptiveness • Reasons for not using technology (cost, training, and funding compatibility)	• "We add voice-activated lights when caregivers ask"
Perceived benefits	• Promoting independence and safety • Injury prevention and fall reduction • Caregiver peace of mind • Staff workload reduction and service efficiency	• "Sensors alert us before incidents"
Barriers and concerns	• Homeowner resistance or stigma • Digital literacy and technology anxiety • Data privacy and security concerns • Installation complexity and maintenance burden • Cost and funding incompatibility	• "Clients fear being watched" • "Wi-Fi is unreliable"
Proposed solutions and facilitators	• Training and education strategies • Funding or cost-sharing ideas • Technical support models	• "Partner with a local tech club for setup help"
Implementation pathways	• When and where to integrate technology (assessment stage, standard package, or add-on) • Impact on daily practice, coordination, and documentation	• "Add a 'smart tech' checkbox to assessment form"
Organizational capacity and change	• Staff training needs • New roles or expertise required • Workflow restructuring • Leadership buy-in • External partnerships (technology vendors, universities, and aging services)	• "Need a dedicated tech coordinator"

Ethical Considerations

This study was reviewed and granted an exempt determination by the University of Pittsburgh Institutional Review Board (STUDY24120137). Verbal informed consent was obtained from all participants at the beginning of the focus group session, during which they were informed of the study's purpose, the voluntary nature of participation, and that the session would be audio recorded.

Results

Characteristics of Participants

A total of 11 participants from the 3 OAHMP grantee organizations attended the focus group interview. Organizational

XSL•FO
RenderX

roles of the participants are shown in Table 2. Organizational identifiers are not reported at the individual level to protect participant confidentiality, given the small size of the participating organizations and the risk of identification through role-organization combinations.

Table . Professional roles of the participants (N=11).

Roles	Participant, n (%)
President or chief executive officer	1 (9.1)
Program manager or director	3 (27.3)
Grant administrator	1 (9.1)
Occupational therapist	1 (9.1)
Certified Aging-in-Place Specialist	4 (36.4)
Home repair lead	1 (9.1)

Theme 1: Client Characteristics, Referral Pathways, and Technology Readiness for Home Modification

Participants from the 3 OAHMP grantees reported that they primarily served older adults aged 60 years and older, referred by local agencies or partner organizations, or self-referred. Assessments were typically led by occupational therapists, CAPS, or trained occupational therapy students. Notably, participants mentioned that home assessments sometimes involved the use of software, such as Home for Life and REDCap (Vanderbilt University), as well as informal observation or discussion [24,25].

Timelines from assessment to completed modifications varied among grantees, influenced by factors such as funding availability, staffing, contractor schedules, and program structure. Most participants indicated that their projects could be delayed beyond the initial estimates, even if assessments were completed promptly.

> *So you guys at any given time are probably working on 3 to 5 different projects at the same time. So again, sometimes it's just a capacity issue in terms of who is next in line, who has all their paperwork in here, and then which site team is available to go do that whole (renovation).* [Org2]

Regarding the major applications for home modifications, agreed upon by participants from various grantee programs, traditional home modifications—such as grab bars, bathroom safety features, and entry ramps—were still identified as the core service to enhance clients' safety, mobility, and accessibility. This continued reliance on traditional modifications, alongside the limited initial integration of smart technologies, reflects a broader pattern of cautious technology readiness among both clients and grantee organizations—shaped by clients' age profiles, varying levels of digital familiarity, and the constraints of existing program structures.

> *These are things that our staff member can accomplish. So they are comfortable. High toilets, grab bars, handrails, tub cuts, solar powered security lights, levered door handles, levered faucets.* [Org2]

Theme 2: Current Integration of Smart Home Technologies and Perceived Benefits

Several participants representing their OAHMP grantee programs reported that they had incorporated smart home devices into their modification projects, observed smart home technologies used by homeowners, and sometimes collaborated with contractors during installation. In addition, staff from one organization cited their indefinite delivery/indefinite quantity contract as a mechanism for formally recommending smart home devices.

> *The Amazon Echo, the Echo Show, the Echo dot, the Ring doorbell, and then the smart plugs and we also have on our IDIQ, which is what we use...for a lot of you know, items that we recommend a lot of the time. Some of the stuff on there does also have some smart home technology that can be recommended specifically by the occupational therapist, because they don't typically look at the volunteer services as often as the CAPS do so they do have that option to add it in there if they feel a contractor should put it in.* [Org1]

> *But we have had lots of requests for smart technology from homeowners. And so that's I'm glad I'm working with and listening to you all, because that's something that we're hearing more and more of; smart technology. And we need to figure out how to incorporate that better in our programs.* [Org3]

Most installations included Amazon Echo devices, Ring doorbells and cameras, smart plugs, and motion-activated lights. This pattern of selective adoption suggests that grantees prioritized devices that were low cost, easy to install, and directly addressed safety and emergency response needs, reflecting a pragmatic, needs-driven approach to technology integration within the constraints of existing program structures. These devices were valued for enhancing security, facilitating emergency response (eg, voice-activated 911 calls after a fall), and supporting independent living. Interestingly, 1 participant suggested additional applications of smart home technologies, such as detecting pets and wildlife and monitoring air quality for clients in rural or hazard-prone areas, which were not generally considered goals of incorporating those technologies into the programs.

XSL•FO
RenderX

> *One of our cases was really having 8 cats, and like raccoons like, you know, not even knowing that they're up in the top, because our older adults aren't traveling up to their second floor any longer. And so I don't know just thinking creatively to toss it out there...Is there any smart tech to help with that? Particularly when, you know, even if they are animals that are pets, there's that like environmental hazard for the home as well.* [Org2]

Theme 3: Barriers to Adoption and Use of Smart Home Technologies

As OAHMP grantees, participants identified multiple barriers that limited the uptake and sustained use of smart home technologies by older adults. These included older adults' digital literacy and confidence, proficiency in using smartphones and devices, concerns about privacy and data security, and the burden of device maintenance.

> *Do people have the wherewithal to even know what that is, and how it functions, and how to use it? Yes, some people do not have smartphones. They got the old flip phone, or they have their landlines. And okay, we would do this as a modification for them. But is it really gonna work for them?* [Org3]

> *I feel like we need to consider that you know all of us like, what's the maintenance plan and where's the education for when they need to replace that battery? So it doesn't just become something that you know is now a trip hazard, you know, and potentially isn't actually helping them, but could potentially hurt them, since it's not functioning as intended. So there is maintenance associated with this.* [Org2]

Additionally, contextual factors frequently hinder the adoption of smart home technologies. Older adults living in rural areas often face unreliable internet connectivity and limited geographical access to certain services, which restricts the use of specific devices.

> *From where I'm based. It's very rural, and our bandwidth is sometimes shoddy at best, so it's very, um, sometimes that can be kind of a huge obstacle to be able to incorporate the smart home technology.* [Org1]

Theme 4: Adoption and Implementation Strategies

For programs that have introduced smart home technologies, participants from those programs stated that current strategies to improve adoption include providing hands-on technical assistance—often through partnerships with university occupational therapy programs—and developing easy-to-use technology manuals for older adults. Interestingly, participants noted that their partnerships with local universities were viewed as mutually beneficial: older adults received guidance and support during the adoption process, while students gained hands-on learning experiences in aging in place and assistive technology.

> *They are a little bit reluctant because they are older adults and they don't typically like to learn about the technology. But that's kind of why we have the students go in because they go over it with them like very detailed, set up the accounts for them and everything, so that they don't feel overwhelmed. And they actually also leave them a number that they can call whenever they have questions regarding any of the apps that they use.* [Org1]

Participants also recommended choosing devices that require minimal maintenance and can operate with limited internet connectivity.

> *I feel like we need to consider that you know all of us like, what's the maintenance plan and where's the education for when they need to replace that battery? So it doesn't just become something that you know is now a trip hazard, potentially and isn't actually helping them, but could potentially hurt them, since it's not functioning as intended. So there is maintenance associated with this.* [Org2]

On the other hand, participants emphasized that the timing of adopting smart home technologies should be flexible—either during the initial assessment, as part of a standard package, or as optional add-ons later in the home modification process—to address older adults' specific needs. Some older adults initially declined certain devices but became more receptive as their needs evolved, suggesting the value of a progressive adoption approach.

> *We do find that many times any type of recommendation that is made, if declined, is then requested again once a fall or something terrible, unfortunately, happens. So I mean… we do currently implement our smart home technology at each different touch point.* [Org1]

Theme 5: Organizational Capacity and Change Readiness

All participants from various OAHMP grantee organizations agreed that integrating smart home technologies into home modification programs required organizational adaptation. Unlike client-facing adoption strategies, this organizational adaptation focused on building internal capacity—equipping staff, contractors, and volunteers with the knowledge and resources needed to deliver and sustain technology-enhanced services. This included training staff and contractors on device installation and troubleshooting, adding technical support roles, and fostering leadership buy-in. External partnerships with technology vendors, universities, and aging service providers were also seen as essential.

> *We are excited to increase the number of smart home tech devices that we're able to offer. But along with that you know, we would hope that we can coordinate more intensive trainings for both ourselves as staff and our CAPS, but also like to train the trainers, so that we can adequately train our volunteers. Specifically our student volunteers to be able to train the older adults and their caregivers to be able to use the devices appropriately and not cause them more*

XSL•FO
RenderX

> *stress and frustration in trying to use the devices that you know we're providing them.* [Org1]
>
> *Our volunteers perform these modifications. I think we may need some training for the volunteers, just what these smart technologies are, and how they can integrate those in the modifications, and how they can help a homeowner essentially set them up and make them work. So it would be some training that we would need for both ourselves and our and our volunteers who are doing this work.* [Org3]

Policy-wise, 1 participant emphasized that addressing funding limitations, staffing shortages, and technical expertise gaps was crucial for the sustainable implementation of the initiative at scale.

> *And then, you know, we're nonprofit, so more funding to not only support the devices, because, as (one participant) mentioned, they are costly, but also the operations and capacity to roll out and maintain the program, so that we're able to provide that staff support and training opportunities for the volunteers.* [Org1]

Discussion

Principal Results and Policy Implications

Findings from this focus group revealed that, while certain devices—particularly those supporting safety and emergency response—have begun to be integrated into home modification services for older adults, the broader implementation of smart home–equipped modifications remained limited. Barriers emerged across three levels: (1) older adults' perceptions and digital readiness, (2) physical and contextual environmental constraints, and (3) programmatic factors, including policies and budget limitations that shape service delivery.

With an aging population, a lack of accessible, age-friendly US housing stock, and a need for cost-effective solutions to support aging in place, demand for home modifications is likely to increase in the coming years. Incorporating smart home technology into evidence-based home modification programs, such as CAPABLE and OAHMP, can provide a relatively low-cost and high-impact pathway to enhance opportunities for aging in place. Pairing smart home technology with home modifications can provide a variety of benefits, including (1) enhancing mobility, communication, social engagement, safety, independence, and health, (2) compensating for functional limitations, (3) reducing caregiver burden, and (4) preventing injurious falls. Implementing smart-home-enhanced modifications within existing evidence-based home modification programs, such as OAHMP, that support low-income older adults and those in underserved communities can broaden access to impactful, cost-effective services that promote aging in place.

The 3-level barrier structure identified in this study—individual, contextual, and organizational—is consistent with findings from the smart home adoption literature. Digital literacy limitations, privacy concerns, and the burden of device maintenance among older adults have been consistently reported in prior studies [16]. However, our findings extend this literature in 2 important aspects. First, rural internet unreliability emerged as a particularly salient contextual barrier in home modification programs, where clients are often low-income and geographically isolated—a population underrepresented in existing smart home adoption research. Second, organizational-level barriers, including staff training gaps, funding constraints, and leadership buy-in, represent a distinct and underexplored dimension of implementation challenges that go beyond individual user acceptance [26]. These findings suggest that addressing smart home technology adoption in home modification programs requires a multilevel implementation strategy rather than interventions focused solely on end user behavior. Emerging pilot programs are demonstrating the feasibility of such integrated approaches for low-income aging populations [27].

The implementation strategies identified by participants—including university partnerships with reciprocal learning benefits, progressive technology introduction across care touchpoints, and hands-on training—align with emerging evidence on effective support for technology adoption among older adults. Programs pairing students with low-income older adults in community settings have demonstrated strong potential to reduce the digital divide through a reciprocal model in which older adults receive personalized guidance while students gain practical experience. Similarly, introducing technology progressively at multiple touchpoints across the care continuum [28]—rather than as a one-time intervention—aligns with best practices in technology acceptance frameworks that emphasize meeting users at their current readiness level [20-23,29]. These findings reinforce the value of embedding adoption support within existing program structures rather than treating technology training as a separate intervention.

Smart Home Technology Selection Criteria

To guide the selection of commercially available smart home devices for integration into existing home modification services, we derived practical criteria from participant responses during the focus group, organized thematically through the analytical process, and further developed these criteria based on established usability frameworks, including the System Usability Scale [30]. These criteria are organized across 5 perspectives: installation, usability, accessibility, sustainability, and security and privacy (Table 3).

Devices should be easy to install so they do not impose unnecessary burdens on contractors or disrupt home environments. Usability is essential; older adults require straightforward onboarding and intuitive operation without repeated training. Technologies should directly improve safety, mobility, or accessibility rather than complicate daily living. Notably, accessibility matters—interfaces must be clear, with indicators that accommodate sensory needs, and vendor technical support should be available to reduce reliance on program staff. Sustainability is critical for program feasibility, favoring devices that are durable, low maintenance, and free of ongoing costs. Finally, devices must safeguard both physical and digital safety by minimizing injury risks and ensuring strong data privacy protections.

XSL•FO
RenderX

Table . Criteria for selecting smart home devices.

Perspective	Criteria
Installation	• Easy to install with minimum home modifications
Usability	• Ease of onboarding • Ease of use • Easy adoption • No memory interaction • Improves safety, accessibility, or mobility
Accessibility	• Interface design • Clear indicators • Technical support or customer service
Sustainability	• Reasonable cost • Low maintenance requirements • No subscription fees
Security and privacy	• Avoid risks of injury (eg, strangulation and asphyxiation) • Avoid risks of injury (hazardous surfaces) • Protect private information

To our knowledge, standardized criteria for selecting commercially available smart home devices specifically for integration into home modification programs have not been previously proposed in the literature. Prior systematic reviews have called for clearer classification standards and technology selection guidance to align device functions with user needs in aging in place contexts [18,31]. The 5-domain framework proposed here represents an initial step toward filling this gap and warrants further validation through broader stakeholder input and empirical testing.

Limitations

This study has several limitations. First, only 3 OAHMP subawardee organizations participated, limiting the breadth of perspectives and potentially underrepresenting the diversity of all grantees across the program. Second, because participating organizations may differ in size, geographic location, or client characteristics from other OAHMP awardees, the views expressed may not be representative of the program as a whole. Furthermore, detailed organizational characteristics could not be reported at the organizational level to protect the confidentiality of participating organizations; however, purposive sampling ensured representation across rural, suburban, and national program contexts, as described in the Methods section.

From a design perspective, using a single 1.5-hour focus group session may have limited the depth of discussion and introduced dynamics such as unequal participation or social desirability bias. The analysis used a deductive coding approach based on the discussion agenda, which ensured alignment with study aims but may have limited the emergence of unanticipated or novel themes. Additionally, focus group participants represented a variety of roles within each home modification program. It is possible that the professional background of participants (eg, occupational therapist vs grant administrator) influenced perceptions of facilitators and barriers.

Conclusions

Overall, this study underscores the potential of smart home technologies to complement traditional home modifications and enhance aging in place outcomes. Clear technology selection criteria to inform the development of a standard smart home technology package were developed. Barriers to the sustainable implementation of this initiative include older adults' digital literacy, privacy concerns, and organizational capacity. Policy support and resource allocation will be crucial to increasing adoption rates, reducing inequities, and enhancing the impact of federally funded home modification programs. Future research should focus on validating the proposed selection criteria through broader stakeholder input, curating evidence-based device packages for integration into home modification programs, and evaluating the implementation and outcomes of smart home–enhanced modifications across diverse aging populations.

Acknowledgments

The authors thank the staff and program personnel of the participating Older Adults Home Modification Program grantee organizations for their time, expertise, and willingness to share their experiences. Their contributions were essential to this work.

Claude (Anthropic) Sonnet versions 4.5 and 4.6 were used during manuscript preparation for grammar checking and language editing only. The intellectual content, including all study design, data collection, analysis, interpretation, and original writing, was developed by the research team. Abstract

Background: The advent of the Smart Home 3.0 era imposes higher technical requirements for the construction of the home ecosystem. Music is an effective means for humans to regulate their emotions. The emergence of multimodal technology facilitates the use of music for emotional regulation by older adults in their home environment. Therefore, it is necessary to carry out further research on the emotional issues of the music interaction system in smart homes that are targeted at older adult users.

Objective: This study aimed to establish the mapping relationship between music parameters and emotional states based on the Valence-Arousal emotional model and through the analysis of electroencephalogram (EEG) signals. In addition, a novel Multimodal Fusion-Adaptive Wellness Interaction model was constructed to match the most suitable music and meet the emotional needs of older adult users.

Methods: A total of 68 older adult participants aged between 60 and 75 years were recruited. Four groups of music stimulus materials were formulated to conduct an experimental study on the relationship between the emotions of older adult participants and music parameters. Finally, the Multimodal Fusion-Adaptive Wellness Interaction model was constructed. With the recreational sofa as the main body, multimodal, emotional intelligent adaptive interaction was realized.

Results: During the experiment, approximately 68,970,528 EEG signal data were collected. After analyzing the EEG bands and extracting the event-related potential data, the following results were obtained: For P200, the music stimulus materials showed significant differences and activation in the left parietal and occipital lobe regions (P7, P3, O1, O2; $P<.001$). For N400, there were significant differences and activation in the prefrontal lobe region due to the music stimulus materials (O1, CZ, O2; $P<.001$). For P300, the music stimulus materials led to significant differences and activation in the occipital lobe region and the central line region of the temporal area (F7, FPZ, FZ, F8; $P<.001$).

Conclusions: Older adult users respond in a way that the A1 stimulus material, namely the music material with positive valence and high arousal (+V + A), can soothe the emotional state of older adult users. This provides a theoretical basis and evidence for the music interaction regulation module in smart home systems.

Introduction

The concept of the Smart Home has continually evolved over the past few decades. It was first introduced in the United States in 1984, when United Technologies Building presented the “Intelligent Building” with integrated and information-based building equipment [1]. With the advancement of Internet of Things technology, smart homes entered the 2.0 era, characterized by interconnectivity and remote control [2]. The advent of the Smart Home 3.0 era imposes higher technical requirements for the construction of home scenarios and user experience, characterized primarily by scenario-based synergy and context awareness [3]. During this evolution, human-computer interaction (HCI) modes have evolved from single-channel physical interfaces, such as buttons in traditional

XSL•FO
RenderX

smart home devices, to multimodal systems that integrate multiple input modalities, including voice, gesture, and eye movement [4]. This low-burden multimodal interaction not only reduces operational difficulty but also facilitates emotional companionship and psychological comfort. As a key potential user group for smart homes, older adults warrant particular attention regarding their growing needs for both physical and emotional support. Their acceptance and use of smart home devices exhibit significant heterogeneity, with increasing engagement particularly in voice-activated and entertainment devices [5]. Emotional interaction is becoming a mainstream adaptive strategy for smart homes in domestic environments, garnering increasing scholarly focus on the emotional integration and psychological adaptation of older adults within their home settings [6]. Consequently, this project aims to explore the integration of multimodal information to achieve adaptive interaction within a smart furniture system. By focusing on behavioral and emotional interaction, it seeks to provide older adult users with an optimized experience that promotes both leisure and emotional well-being.

Among various interaction modalities, music is widely recognized as an effective medium for emotional regulation and for supporting cognitive health for older adults [7]. As a complex auditory input, music plays a crucial role in influencing emotions within the home environment [8,9]. For the older adult population, music serves as a noninvasive means of emotional regulation, helping to alleviate negative emotions such as loneliness, anxiety, and depression, while also enhancing quality of life and overall home-based well-being by evoking positive emotional experiences [10]. Previous studies have demonstrated that music listening can effectively promote social engagement and emotional health among older adults and even improve cognitive function and memory to some extent [11]. Moreover, with the accelerating process of population aging, the dependence and engagement of older adults with music continue to increase. For example, in the United States, more than 50% of older adults report listening to music daily [12]. This indicates that music has gradually become an essential part of daily recreation for older adults and is regarded as an effective approach for emotional regulation and maintaining psychological well-being [13]. Therefore, the design and application of music-based interactions in smart home environments for older adult users hold substantial research significance.

In exploring music's role in emotional regulation mechanisms, studies have found that music intervention can promote hippocampal neurogenesis and improve emotional states [14]. At the same time, music primarily regulates users' emotions by influencing neuronal activity in the brain [15]. Therefore, using physiological measurement devices to examine human emotional changes offers multiple advantages [16], as these signals can continuously and objectively reflect users' behavioral and experiential information. By combining physiological measurements with subjective emotional assessments, researchers can more accurately reveal the mapping relationship between music and emotional states [17].

Compared with subjective evaluations, physiological measurements provide a more objective and comprehensive description of emotional changes [18]. Consequently, neuroscience research, particularly studies using electroencephalography, a noninvasive neurophysiological signal, has been widely applied to emotion recognition and regulation in recent years [19]. From a neural mechanism perspective, emotional processing in the human brain relies on complex neural networks. The amygdala is responsible for evaluating the emotional significance of stimuli, whereas the insular cortex modulates emotional responses [20]. Electroencephalogram (EEG) studies related to emotion have sought to clarify the roles of different frequency bands and brain regions in emotional processing [21,22]. Research has shown that emotional content can amplify certain event-related potentials (ERPs) in EEG signals [23], while hemispheric asymmetry in theta power reflects emotional valence [24]. Moreover, variations in EEG activity in the frontal and parietal lobes, including α, β, θ/β, and σ/β ratios, are associated with individual differences in emotional regulation [25]. The integration of musical stimuli and EEG signals has gradually evolved into the field of music neuroscience [26]. For instance, studies combine analyses of musical elements with EEG data to investigate music perception and training effects [27]. Recording motor-related EEG responses evoked by music has been regarded as a key approach to understanding emotional experiences [28]. By analyzing the neural activity patterns elicited by music through EEG, researchers can gain deeper insights into the mechanisms underlying older adults' emotional experiences induced by music.

The development of multimodal technologies has enabled smart home systems to capture the relationship between users' emotions and music within home environments with greater accuracy. On the one hand, multimodal perception methods such as speech recognition, facial expression analysis, and physiological signal monitoring allow for a more comprehensive understanding of the emotional states of older adults in home settings [29]. Moreover, studies have demonstrated that different musical melodies and rhythms can elicit distinct emotional responses in users [30-33]. Integrating music with smart home technologies can thus serve as an essential multimodal pathway for emotional regulation, providing older adult users with low-burden and continuous emotional regulation support through a closed loop of perception, feedback, and intervention.

With the support of multimodal technologies, smart homes can serve as an important platform for music-assisted emotional regulation. In fact, previous studies have already begun to explore the potential of integrating smart home technologies with music-based emotion regulation. Currently, emotional regulation in smart homes is mainly achieved through 2 approaches. The first involves contact-based acquisition of physiological signals to recognize and regulate emotions. For example, Wagner et al [34] extracted 3 types of features from heart rate, electrodermal activity, electromyography, and respiration signals and used multiple classifiers for emotion recognition with promising results. The second approach relies on computer vision analysis, using cameras to capture users' facial expressions for emotion recognition and feedback. For instance, Yu et al [35] designed a prototype of smart furniture called the "Magic Mirror Table," which can infer users'

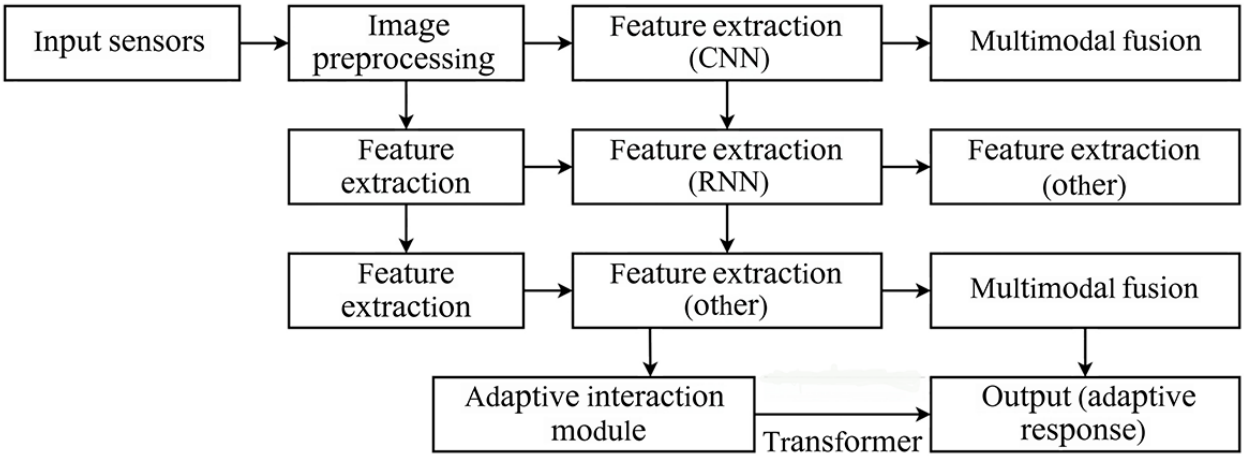
XSL•FO
RenderX

emotional states. It captures facial expressions through a camera, performs detailed analysis, and then plays appropriate sentences or music to influence users' emotions. Compared with other emotion recognition techniques, emotion regulation technologies applied in smart home environments have the advantage of passively and continuously collecting multimodal data in natural living contexts [36], thereby providing a more authentic reflection of individual emotional changes.

In the field of multimodal interaction, previous studies have explored various approaches to integrating visual, auditory, motion, and physiological signals to enhance emotion recognition and HCI performance. In the context of smart homes, multimodality enables systems to respond to user needs in a more natural and integrated manner [37]. Some studies have proposed multimodal interaction systems based on 3 different modalities, eye blinking, voice, and touch, to allow individuals with limited mobility to control smart home devices [38]. Other researchers have introduced multimodal interfaces designed to support independent living for older adults in smart home environments [39]. However, in domestic settings, key challenges for multimodal interaction include user diversity and the dynamic nature of interaction contexts [40,41]. Existing studies have primarily focused on improving home interaction by adapting to users and environmental conditions [42-44]. Current mainstream control modes in smart homes include voice and gesture interaction. Related research has also proposed a trajectory recognition interaction method based on vision, acceleration, and dynamic gestures, verifying its feasibility for integration into multimodal and adaptive smart home systems [45]. In terms of emotional regulation, multimodal interaction research has been applied to distraction detection, emotion recognition, and stress-level assessment [46]. Other scholars have investigated the relationship between multimodal fusion of emotional information and interactive behaviors. Their studies used emotional color as the theoretical basis for affective computing in HCI and applied neural network algorithms to datasets, ultimately developing an efficient multimodal affective interaction recognition method [47].

In this study, we expect to explore the relationship between different types of emotional music and the EEG changes of older adult users and derive the degree of stimulation of brain waves by other music genres, which will further perfect the emotion recognition linkage module of the smart home with the sofa as the carrier. The main contributions of this work include the following:

1. Innovative construction of the Multimodal Fusion-Adaptive Wellness Interaction (MF-AWI) model. The MF-AWI model theory can be disassembled into the Multimodal Fusion-Adaptive Wellness model. The main modules can be divided into a posture recognition module, an emotion recognition module, and a wellness HCI module. The theoretical approach guides the realization of the MF-AWI Multimodal Fusion Adaptive Wellness System. This article focuses on the emotion recognition module, relying on the theoretical basis, to achieve the real-time state of the recreation sofa on the older adult users' real-time state recognition, to make the real-time feedback of the recreation adjustment within the scope of the music adjustment, to meet the personalized needs of different older adult users in different scenarios.
2. In the module on emotional state recognition for older adult users, 4 music genres were classified based on the theory of the Valence-Arousal (VA) emotion model, and a control group was set up to explore the role of music genres in the emotional regulation of older adult users. Through the EEG physiological signals, the best music genres for older adult users in different scenarios were identified.



Methods

MF-AWI Model

The MF-AWI model theory can be decomposed into the MF-AWI model, which relies on the foundation of Multimodal Fusion theory to dynamically identify the target participant, locate the target participant, and use the MF-AWI model. The core of the MF-AWI model is based on the concept of multimodal fusion, that is, the integration of information from multiple sources or modalities to gain a more complete understanding of the target participant. In the context of the MF-AWI model, these modalities are poses and emotions that are used to identify the target participant and decompose the target state into its components, as shown in the recognition process in Figure 1.

XSL•FO
RenderX

Figure 1. The Multimodal Fusion-Adaptive Wellness Interaction model responds to process iterations. CNN: convolutional neural network; RNN: recurrent neural network.

The unified representations will be fed into the Wellness HCI module, which will use the pretrained Transformer model to generate adaptive feedback. The Wellness HCI module can recognize different gestalt states and emotional states of the older adult users, enabling the system to provide appropriate adaptive feedback to different older adult users' inputs. For example, if the user indicates that they want to go to a resting state based on their posture and emotional state, the Wellness HCI module can suggest that the wellness sofa adjust the backrest angle to give the older user a more comfortable position, or play soothing music to create a more relaxing environment. Similarly, if the older adult users appear to have negative emotions such as stress or anxiety, the Wellness HCI module can suggest relaxation exercises or provide calming music to help the user relax. The output of the wellness HCI module will be used to control the different module functions of the wellness sofa, including the adjustment of functional modules such as angles and music. This process can be repeated to provide a personalized and adaptive interactive experience for the older adult user on the wellness sofa. In this model, different input data from the wellness sofa is processed using a convolutional neural network (CNN) model, and a multimodal fusion technique is used to combine these output feature vectors. A unified representation of the older adult users' real-time posture and real-time emotion will be used by the wellness HCI module to generate control of the different adaptive modules to produce appropriate adaptive feedback interactions.

The camera captures video signals, which are then preprocessed by resizing and grayscale conversion to enable face detection of older adult users. Using the OpenCV library, once the user's face is detected by applying a pretrained machine learning model, the DeepFace model is used to extract facial features and identify the user's emotional state. Using a CNN, the extracted facial features are used to identify the user's emotion and determine sentiment tuning. Once the real-time emotional state of the older adult users is identified, the type of music required by the recreational sofa can be determined to suit the users' changing emotions. Adjusting the music of the wellness sofa can be done using the emotional state adjustment determined in the previous step to adjust the music of the wellness sofa to suit the emotional state of the user. Finally, the process can be repeated many times to ensure that the Convalescent Sofa adapts to the real-time emotions of the older adult users in real time, as shown in Textbox 1.

Materials

The generic continuous dimension model that has been widely adopted in music emotion recognition research is the Circomplex model, also known as the VA model [48]. Research shows that specific musical characteristics are significantly correlated with Valence and Arousal [49]. For example, +V +A refers to a fast tempo, major key, and bright timbre. –V+ A refers to dissonant chords and a fast, irregular rhythm. –V –A refers to a slow tempo, minor key, and dull timbre. +V A refers to slow yet harmonious harmonies. Existing studies have demonstrated that bodily sensations and emotions triggered by music and based on the VA model show consistency across different cultures [50]. In this experiment, 4 pure music genres conforming to the 4 quadrants of the VA model were selected, and the stimulus materials were named A1-A4, that is, A1: +V +A, A2: –V+A, A3: –V–A, A4: +V A, as shown in Figure 2. A control group was set up using white noise to simulate white noise to simulate the daily life environment, and the stimulus material was named A0. The use of white noise provided a constant and semantically neutral auditory background, helping to avoid interference from background sounds on participants' emotional responses [51].

XSL•FO
RenderX

Figure 2. VA emotion models as well as experimental stimulus material. VA: Valence-Arousal.

Participants

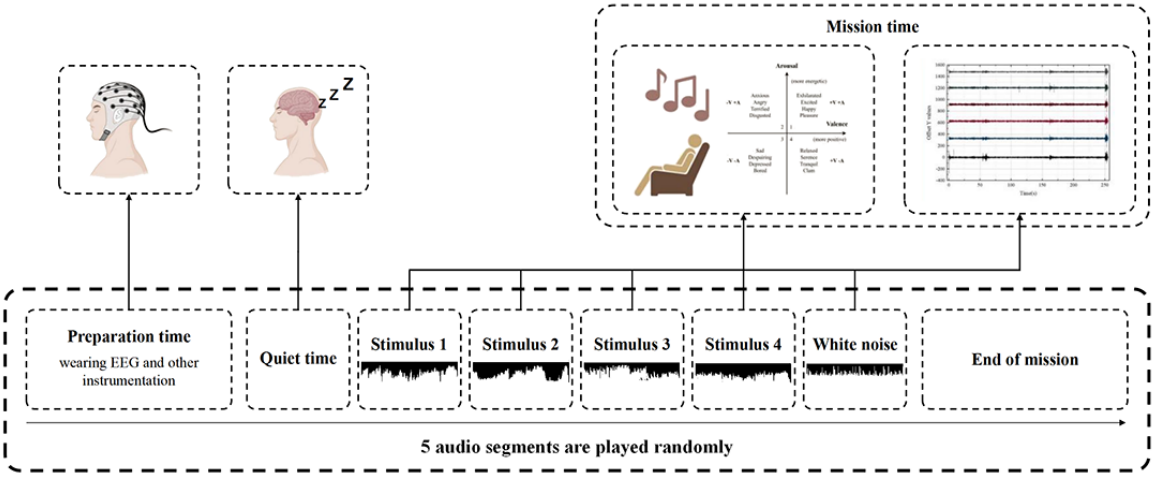
Sample size is critical to the reliability and representativeness of research findings. Following the standards proposed by Cohen [52], this study used G*Power software (Heinrich Heine University Düsseldorf, Germany) [53] to estimate the required sample size, selecting the within-factors repeated measures ANOVA design. The parameters included an alpha level of 0.05, a power level of 0.95, a medium effect size of 0.25, and a number of groups of 1. This setup yielded a total sample size requirement of 31 participants. In addition, to ensure greater statistical robustness and account for potential data loss among older adult participants during the experiment, the final sample size was further adjusted. This sample size is also consistent with previous EEG studies investigating music perception and stimulation in similar experimental contexts [54,55]. Therefore, a total of 68 older adult participants aged between 60 and 75 years were recruited for this experiment. All participants were recruited from various regions across China, with culturally diverse backgrounds and different living environments.

Among the participants, there were 34 female participants (n=34) with an average height of 160 cm and a mean BMI of 25.5, and 34 male participants (n=34) with an average height of 171 cm and a mean BMI of 24.86. All participants were required to be free of chronic diseases of the ear, back, and legs and in good physical condition.

Ethical Considerations

This experiment was conducted in strict accordance with ethical guidelines. Prior to the start of the experiment, the experimental procedures were fully explained to all participants, ensuring that the experiment would not pose any risks to them, and written informed consent was obtained from all participants. Also, explicit consent has been granted by a participant to use their images for publication. The experiment has been reviewed and approved by the Ethics Committee of Nanjing Forestry University (Science and Technology Department of Nanjing Forestry University) with the approval number: 2023-03-29. To protect the privacy of participants, all collected data were anonymized before analysis, with no personal identifying information retained. Upon completion of the experiment, each participant received a compensation of 100 RMB (1 RMB= US $0.14) for their time and participation.

Experimental Paradigm Design



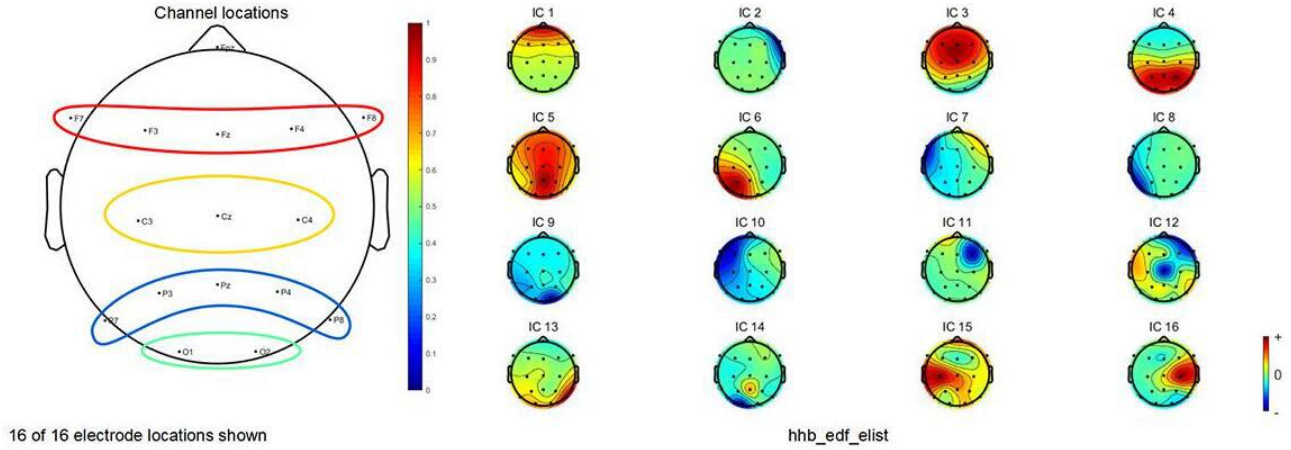
The older adult participants were seated calmly in a comfortable chair. The experimenter prepared 5 preanalyzed audio clips, including 4 audio segments based on the VA model, as the stimulus material. Meanwhile, a white-noise environment was established as the control condition to ensure a consistent auditory ambience. The decibel level of these audio clips was 45 dB. This level was determined with reference to previous studies, which indicate that 45 dB falls within the range of low-noise and quiet environments for older adults, which helps maximize auditory clarity while preventing auditory fatigue or discomfort [56,57]. Although background noise levels in real smart home environments may exceed 45 dB, this value was chosen to obtain stable and reproducible ERP data in a controlled and quiet experimental setting, thereby minimizing the impact of external interference on older adult participants.

Prior to the start of the experiment, the experimental content and precautions were carefully explained to the participants. However, no information regarding the specific types of audio stimuli or their emotional attributes was disclosed to minimize expectation effects. Participants were also instructed to avoid vigorous movements or vocalization. After obtaining the participants' consent, the informed consent form was signed, and preparations for the experiment, including scalp cleaning, began. The experimental equipment was worn by older adult

XSL•FO
RenderX

participants throughout the experiment. The first formal recording was started after the participant indicated full understanding and initial control of the EEG signal. During the experiment, the system continuously monitored electrode connectivity. When head movement or electrode displacement caused channel dropouts or abnormal impedance, the acquisition interface issued a real-time alert. The experimenter immediately paused the task, readjusted the electrodes, and resumed recording once stable contact was restored, ensuring the consistency and comparability of EEG data across all recording stages. The EEG signals were recorded continuously in each session and saved separately. All trial tasks were presented in a randomized order to effectively minimize order and learning effects. The duration of the entire experiment was 15 - 20 minutes, and the experimental paradigm is shown in Figure 3.

Figure 3. Experimental paradigm. The device worn by the participants was the Bitbrain hydroelectric electrode EEG, which had 16 channels, a rated voltage of 3.7 V, and a single-channel sampling rate of 256 Hz. The experiment started after the older adult participants entered the resting state. The experiment was divided into 5 recording stages, which were 5 sets of subexperiments, as a whole. In each stage, EEG signals were continuously recorded and saved separately, while each trial task was randomly ordered. EEG: electroencephalogram.



EEG Recording and Preprocessing

The EEG signal was acquired according to the international 10 - 20 system lead setup, with 16 electrodes selected, mainly placed in the frontal, parietal, and central regions, and covering the left and right hemispheres of the brain and the midline region, as shown in Figure 4. This study used a 16-channel EEG acquisition system, a configuration widely used in research on music-induced emotion and cognitive processing [58,59]. Although the number of electrodes was relatively limited, the layout covered key brain regions associated with emotional processing, auditory stimulation, and attentional allocation, effectively capturing the main activity characteristics of typical ERP components such as P200, P300, and N400 [60]. In addition, considering that the participants in this study were older adults, using fewer electrodes helped maintain signal quality while reducing physiological fatigue and discomfort caused by prolonged experiments, thereby improving experimental compliance and data stability. Based on the experimental acquisition parameters, it was estimated that approximately 65,313 data points could be collected per channel for each participant. After excluding 2 invalid samples, the total size of the raw EEG dataset in this study was 65,313×16×66, amounting to approximately 68,970,528 signal data points. This data volume resulted from the normal accumulation determined by the device sampling parameters and experimental design, without any redundant or oversampling processes; therefore, it did not introduce bias into the results.

XSL•FO
RenderX

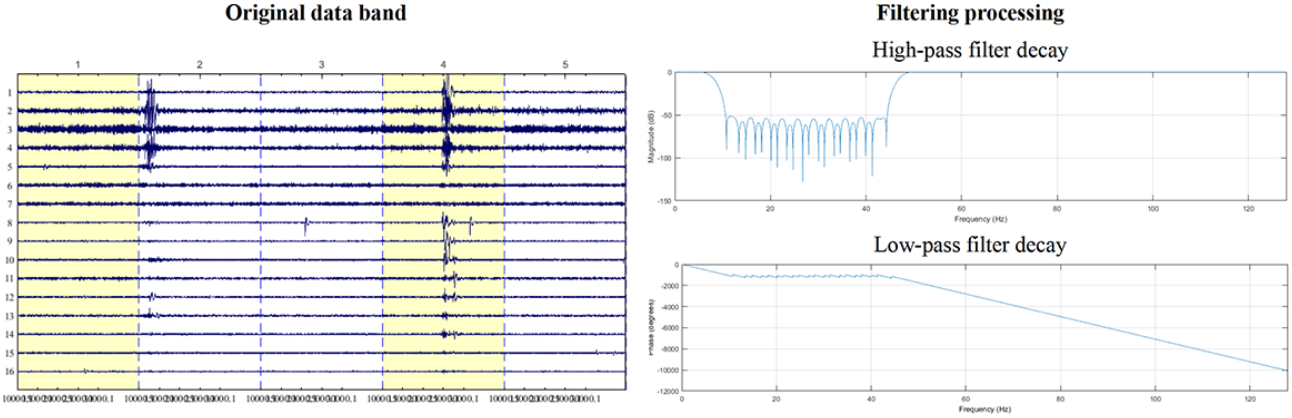


Figure 4. Diagram of the 16 electrode positions selected according to the international 10 - 20. EEG electrodes in the 10 - 20 system. The area within the red circle represents the frontal lobe (Fpz, **F7, F3, FZ, F4, and F8**), the yellow area represents the central region (**C3, CZ, and C4**), the blue area represents the parietal lobe (**P3, PZ, P4, P7, and P8**), and the green area represents the occipital lobe (**O1 and O2**). EEG: electroencephalogram.

During the acquisition process, the reference and ground electrodes were placed near the Cz electrode and the anterior part of the scalp, respectively. EEG signal preprocessing was conducted using MATLAB with the EEGLAB 2020 toolbox. The acquired .edf files were imported into EEGLAB 2020, and channel localization was performed based on the MNI Coordinate Systems standard brain imaging model. Sixteen channels were identified as Fpz, F7, F3, Fz, F4, F8, C3, Cz, C4, P7, P3, Pz, P4, P8, O1, and O2, as shown in Figure 4.

EEG data preprocessing was performed on the Jinfa EEG Signal Analysis Platform. First, all recordings were visually inspected by researchers to remove segments with obvious artifacts or discontinuities. A zero-phase finite impulse response filter was then applied for band-pass filtering (0.1 - 30 Hz), and a notch filter was used to eliminate 50 Hz power-line noise. The original and filtered signals are shown in Figure 5. The data were subsequently rereferenced to the average and interpolated for any bad channels. Artifact removal was based on the standardized pipeline of Infomax independent component analysis and canonical correlation analysis built into the ErgoLAB Man-Machine-Environment Testing Cloud Platform (ErgoLAB 3.0). Identification of artifact components referenced conventional criteria commonly adopted in EEG research. Independent component analysis–derived components were identified and rejected based on their temporal characteristics, scalp topographies, and spectral features corresponding to ocular or muscular artifacts. To further improve signal quality, canonical correlation analysis was applied to remove residual artifacts. For the ERP analysis, the event-related time window was set from −200 to 800 milliseconds, with a baseline period of −200 milliseconds and a measurement window of 200 to 400 milliseconds.

Figure 5. Comparison between the original band of the electroencephalogram and the data processed by filtering.

EEG Bands

The EEG bands in this experiment are divided into 5 bands. Gamma waves play an important role in the cognitive activity of the human brain and in higher-level activities such as the transmission of information in the brain, integrated processing, and feedback [61-63]. Beta waves, with amplitudes of 5-20 µV, are the fastest of the EEG waves and are more pronounced in the frontal and central regions [64]. Alpha waves, with amplitudes of 20-100 µV, are the fastest of the EEG waves and are more pronounced in the occipital and parietal regions [65]. Theta waves have an amplitude of 20 to 150 µV and are the slowest of the EEG waves, generally more pronounced in the parietal and temporal regions [66-69]. Delta waves, which typically exhibit amplitudes of up to approximately 200 µV, are the slowest type of EEG activity and are mainly observed in the frontal and occipital regions and generally occur during deep sleep, making them difficult to capture during the waking state [70-73]. The brain can be divided into parietal, temporal, frontal, and occipital lobes, of which the parietal lobe is mainly

XSL•FO
RenderX

responsible for processing internal feedback, such as skeletal muscles and limbs [74-77].

ERP Data

ERP is a high-level functional potential of the human brain [69]. ERPs are changes in brain potentials associated with cognitive processes such as judgment, attention, perception, decision-making, and working memory content [78]. Recent studies have shown that the amplitude and latency of ERPs are considered to be very important indicators of cognitive load in humans.

There are 3 key parameters of ERP, namely amplitude, latency, and distribution on the scalp [79]. By calculating the average amplitude of the ERP within the corresponding time window, the differences between different conditions can be analyzed. The latency represents the time interval from the onset of the stimulus to the occurrence of the ERP peak, usually expressed in milliseconds. The distribution of the ERP on the scalp can reveal which areas of the brain are functioning when the stimulus appears. The ERP with these 3 key parameters can reveal individuals' cognitive and emotional processing under specific conditions [80,81].

ERPs are typically defined as time-locked neural responses to brief stimuli. Nevertheless, previous studies have shown that ERP components with typical temporal characteristics can also be observed under continuous or natural musical stimulation, particularly when different audio segments exhibit distinct conditional variations [82-84]. In this experiment, each music clip was treated as an independent event type. The onset of each music clip was set as the event trigger point (time=0 milliseconds), and a time window of −200 to 2000 milliseconds was extracted with a 200 milliseconds baseline correction applied. For each participant, the trial waveforms of the same music type were extracted and averaged to obtain the ERP, which reflects the cognitive and emotional processing of different music types in older adults.

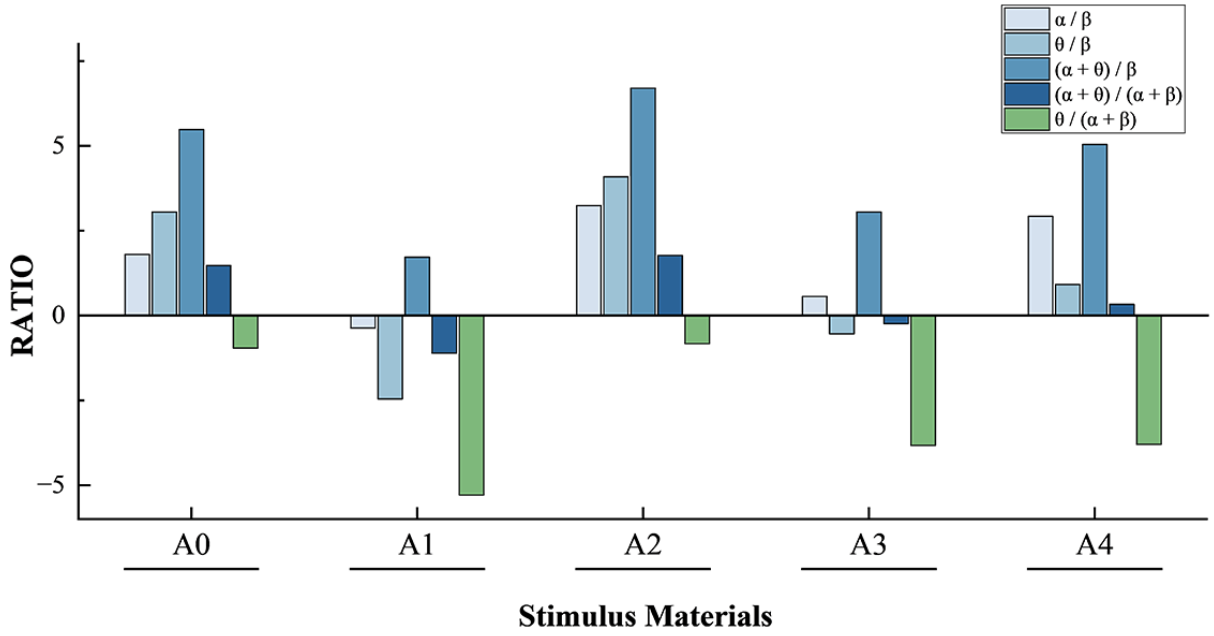
Results

EEG Band Analysis

This experiment mainly collected the EEG changes of the older adult participants in the leisure state, so the electrode position of the parietal lobe was mainly selected as the key observation object, and these 3 bands of θ, α, and β were selected as the main discriminating parameters of the brain fatigue in this experiment. The power of the EEG bands under the stimulation materials of A0-A4 is shown in Table 1.

XSL•FO
RenderX

Table . Electroencephalogram band power under A0-A4 stimulation material.



Stimulation materials and project	δ	θ	α	β	γ
A0

The total power value of the theta band was 20. Thirty-five at the highest in stimulus material A2 and occupied 43.56% of the power in this stimulus band, which can be monitored in the sleepy state, especially in the depressed or frustrated state. This indirectly verifies that the stimulus material A2, that is, –V+ A, can induce negative emotions such as sleepiness and frustration. The total power value of the alpha band accounted for the highest percentage of power, which was 44.20% when using stimulus material A4. Clinical research has shown that this is related to spatial attention. Therefore, the stimulus material A4 (ie,+ V A) may facilitate higher levels of creative thinking in older adult participants during cognitive tasks [85]. For stimulus material A1, the beta band's total power value accounted for the highest percentage, 33.89%. Clinically, this band is linked to emotional arousal, indicating that A1 (+ V +A) can easily trigger emotional fluctuations in older adult participants.

The ratio of theta to beta wave energy, F(θ/ β), and the ratio of the sum of theta and alpha wave energy to beta wave energy, F(α + θ) / β, are used as characteristic quantities for EEG fatigue assessment [47,48]. As F(θ / β) rises, the degree of fatigue further increases. The EEG band ratios for the A0 to A4 stimulus material states were derived by further processing of the ratios in Table 1, as shown in Figure 6.

XSL•FO
RenderX

Figure 6. Brain wave band ratio under A0-A4 stimulation material state.

This study found that different musical stimuli have an impact on the mental workload of older adult participants to some extent. The F(α + θ) / β value was much lower than the F(α + θ) / β values for the other 4 musical stimulus states when the stimulus material was A1. So the EEG fatigue level of the older adult participants was lowest when the stimulus material was A1, that is, +V+A, and highest when the stimulus material was A2, that is, –V+A. The F (α + θ) / β value of stimulus material A3 indicates that it can be selected as an auxiliary stimulus in moderate situations. The effect of music stimulation on the brain load of the older adult participants was therefore reflected in some way. It can be seen that music stimulates the brain waves of older adult participants and that different types of music can be used in daily life to induce emotions in older adult participants. +V+A music, such as exhilaration, excitement, and happiness, helps to reduce fatigue, while music of the −V+A type (eg, evoking anxiety, anger, or panic) induces negative emotions and increases brain load [86].

ERP Data Analysis

The frontal zone electrodes (F7, F8, FPZ, and FZ), central zone electrodes (CZ), parietal zone electrodes (P3, P4, P7, P8, and Pz), and occipital zone electrodes (O1 and O2) were selected for the analysis. EEG data from each condition were analyzed using Statistical Product Service Solutions (SPSS; IBM Corp) software. Given that the objective of this study was to explore differences in EEG activity among older adult participants under various music stimulation conditions, one-way ANOVA with least significant difference (LSD) post hoc comparisons was used to maintain sensitivity in detecting potential effects during this exploratory phase. The regions (left, middle, and right) were divided for the evoked P200, P300, and N400 EEG components, as shown in Table 2. The selection of P200, P300, and N400 components as analytical indicators was based on their respective neurophysiological significance in emotional and cognitive processing. The P200 component typically occurs approximately 200 milliseconds after stimulus onset and can be regarded as an initial perceptual response to auditory stimulation [87]. The P300 component usually emerges around 300 milliseconds after stimulus onset, reflecting neural activity associated with attention allocation, working memory, and cognitive evaluation processes [88]. The N400 component generally appears approximately 400 milliseconds after stimulus onset and represents a neural response to semantic incongruity or expectancy violation [89]. By analyzing these 3 components, individual emotional responses can be comprehensively evaluated across different stages of cognitive processing.

Table . Division of evoked potentials into brain regions.

EEG[a] component	Left area	Middle area	Right area
P200	P7, P3, O1	PZ	P4, P8, O2
P300	F7	FPZ, FZ	F8
N400	O1	CZ	O2

[a]EEG: electroencephalogram.

Statistical Analysis of P200 Components

For the P200 EEG component, the latency averages of each electrode (P7, P3, O1, PZ, P4, P8, and O2) were obtained by total superimposed averaging of the participants' waveforms in a total of 5 stimulus material states from A0 to A4, as shown in Table 3.

XSL•FO
RenderX

Table . A0-A4 mean latency for each electrode of the P200 component in the stimulated.

Stimulation materials	P7	P3	O1	PZ	P4	P8	O2
A0	0.094	0.086	0.095	0.088	0.093	0.091	0.088
A1	0.189	0.067	0.165	0.087	0.184	0.086	0.154
A2	0.034	−0.147	−0.099	−0.470	0.027	0.303	0.108
A3	0.072	0.003	0.050	0.080	0.181	0.079	0.110
A4	0.053	0.062	0.680	0.069	0.072	0.060	0.074

Analysis of the mean values of the latency of each electrode for the P200 component in the A0-A4 stimulation material condition shows that there were differences in the mean values of the latency of each electrode for the P200 component. In the A0 stimulation condition, the mean value of the O1 channel was the largest, and the mean value of the P3 channel was the smallest; in the A1 stimulation condition, the mean value of the P7 channel was the largest, and the mean value of the P3 channel was the smallest. In the A2 stimulation condition, the mean value of the P8 channel was the largest, and the mean value of the PZ channel was the smallest. In the A3 stimulation condition, the mean value of the P4 channel was the largest, and the mean value of the P3 channel was the smallest. In the A4 stimulation condition, the mean value of the O2 channel was the largest, and the mean value of the P7 channel was the smallest. The P200 component data obtained were imported into the SPSS mathematical analysis software. One-way ANOVA was used to test the influence of different stimulus materials on the P200 components of each electrode, and the means and SDs were calculated, as shown in Table 4. To further analyze the differences, we used the LSD method for post hoc multiple comparisons, as depicted in Figure 7.

Figure 7. Analysis of the P200 heat map under the states of stimulus materials A0-A4. Each cell in the heatmap represents the *P* value of the pairwise comparison between conditions, with deeper colors indicating more significant differences. The diagonal cells represent self-comparisons and are displayed as 1. The numerical values in the figure correspond to the *P* values from the least significant difference post hoc test, and significance levels are denoted as **P*<.05, ***P*<.01, and ****P*<.001.

Further analysis of the potential amplitudes of the P200 component revealed that there were significant differences in different types of musical stimulus materials on the electrodes P7, P3, O1, and O2. For the variable P7 ($F_{4, 268}$=12.342, *P*<.001,

XSL•FO
RenderX

η^2=0.168), the LSD test showed that the amplitude of the A1 stimulation (mean −0.276) was significantly lower than that of the A4 stimulation (mean 18.507, *P*<.001). For the variable P3 ($F_{4, 268}$=6.243, *P*<.001, η^2=0.092), the LSD test showed that the amplitude of the A2 stimulation (mean 0.914) was significantly lower than that of the A4 stimulation (mean 7.605, *P*=.010). For the variable O1 ($F_{4, 268}$=9.931, *P*<.001, η^2=0.140), the LSD test showed that the amplitude of the A1 stimulation (mean 0.450) was significantly lower than that of the A4 stimulation (mean 8.307, *P*=.001). For the variable O2 ($F_{4, 268}$=6.408, *P*<.001, η^2=0.095), the LSD test showed that the amplitude of the A0 stimulation (mean −0.126) was significantly lower than that of the A4 stimulation (mean 6.474, *P*=.014).

A detailed analysis of the heatmap shown in Figure 7 revealed that A4 stimulation, that is, +V A, had the strongest activation, with significantly higher average potential amplitudes across all channels compared with other stimuli and the A0 control. Musical stimuli also differentially activated the left parietal and occipital lobes.

Statistical Analysis of P300 Components

For the P300 EEG component, the voltage-phase EEG data of each electrode in the period of 150 - 250 milliseconds were extracted. The latency averages of each electrode of P300 (F7, FPZ, FZ, and F8) were obtained by averaging the superimpositions of the participants' waveforms in 5 stimulus material states of A0-A4, as shown in Table 5.

Table . A0-A4 mean latency for each electrode of the P300 component in the stimulated.

Stimulation materials	F7	FPZ	FZ	F8
A0	0.037	0.078	0.073	0.112
A1	−0.015	−0.407	0.071	−0.010
A2	−0.527	−0.470	0.274	0.303
A3	−0.340	−0.336	0.141	0.189
A4	0.046	0.167	0.126	0.109

Analysis of the latency averages for each electrode of the P300 component in the A0-A4 stimulus material condition shows that there were differences in the latency averages for each electrode of the P300 component. Under the A0 stimulation condition, the mean value of the F8 channel was the largest, and the mean value of the F7 channel was the smallest. Under the A1 stimulation condition, the mean value of the FZ channel was the largest, and the mean value of the FPZ channel was the smallest. Under the A2 stimulation condition, the mean value of the F8 channel was the largest, and the mean value of the F7 channel was the smallest. Under the A3 stimulation condition, the mean value of the F8 channel was the largest, and the mean value of the F7 channel was the smallest. Under the A4 stimulation conditions, the mean value of the FPZ channels was the largest, and the mean value of the F7 channels was the smallest. The obtained data of the P300 component were calculated for the means and SDs and subjected to one-way ANOVA, as shown in Table 6. The LSD method was used for post hoc multiple comparisons to further analyze the differences, as illustrated in Figure 8.

Figure 8. Analysis of the heat map of P300 at each electrode under the states of stimulus material A0-A1. Each cell in the heatmap represents the *P* value of the pairwise comparison between conditions, with deeper colors indicating more significant differences. The diagonal cells represent self-comparisons and are displayed as 1. The numerical values in the figure correspond to the *P* values from the least significant difference post hoc test, and significance levels are denoted as **P*<.05, ***P*<.01, and ****P*<.001.

A further analysis of the potential amplitudes of the P300 component revealed that there were significant differences and activation phenomena in the prefrontal lobe region for the musical stimulation materials. Specifically, for the variable F7 ($F_{4, 268}$=17.065, *P*<.001, η^2=0.218), the LSD test showed that the average potential amplitude under the A2 stimulation material (mean −0.101) was much lower than that under the A4 stimulation material (mean 13.404, *P*<.001). For the variable FPZ ($F_{4, 268}$=668.888, *P*<.001, η^2=0.916), the LSD test showed that the average potential amplitude under the A1 stimulation material (mean −1.146) was much lower than that under the A4 stimulation material (mean 57.083, *P*<.001). For the variable FZ ($F_{4, 268}$=30.449, *P*<.001, η^2=0.332), the LSD test showed that the average potential amplitude under the A3 stimulation material (mean −1.197) was much lower than that under the A4 stimulation material (mean 12.585, *P*<.001). For the variable F8 ($F_{4, 268}$=117.799, *P*<.001, η^2=0.658), the LSD test showed that the average potential amplitude under the A1 stimulation material (mean −0.152) was much lower than that under the A4 stimulation material (mean 44.444, *P*<.001).

A detailed analysis of the heatmap shown in Figure 8 reveals that there are significant differences among the different types of musical stimulation materials at the F7, FPZ, FZ, and F8 electrodes. The average potential amplitudes of the variables for each channel under the A4 stimulation material, that is, +V A, were much higher than those under the other 3 types of stimulation materials and the A0 stimulation material of the control group.

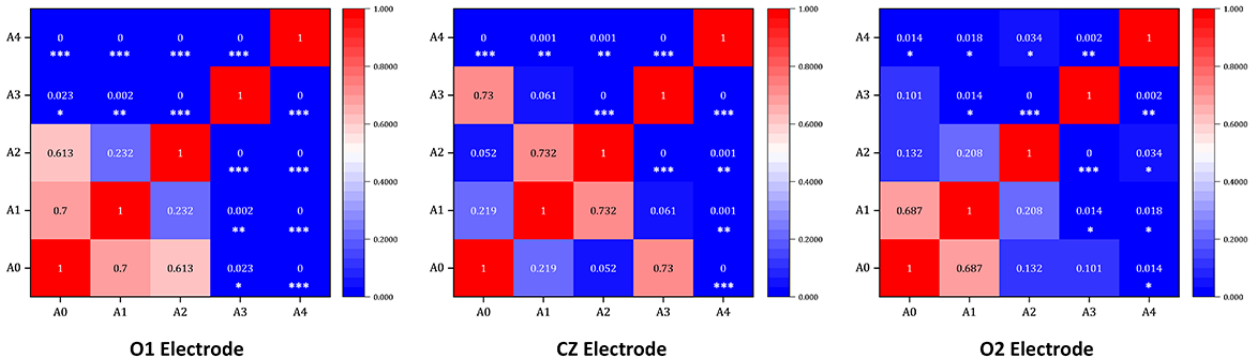
RenderX

Statistical Analysis of N400 Components

For the N400 EEG components, the voltage EEG data of each electrode in the period of 150 - 250 milliseconds were extracted. By averaging the total superposition of the participants' waveforms in the 5 stimulus material states from A0-A4, the latency averages of each electrode of the N400 (O1, CZ, and O2) were obtained, as shown in Table 7.

Table . A0-A4 mean latency for each electrode of the N400 component in the stimulated.

Stimulation materials	O1	CZ	O2
A0	0.095	0.088	0.072
A1	0.165	0.120	0.154
A2	−0.099	0.116	0.108
A3	0.050	0.136	0.110
A4	0.069	0.076	0.074



Analysis of the mean latency values of each electrode of the N400 component under the stimulation material conditions of A0-A4 shows that there are differences in the mean latency values of each electrode of the N400 component. Under the A0 stimulation condition, the mean value of the O1 channel was the largest, and the mean value of the O2 channel was the smallest. Under the A1 stimulation condition, the mean value of the O1 channel was the largest, and the mean value of the CZ channel was the smallest. Under the A2 stimulation condition, the mean value of the CZ channel was the largest, and the mean value of the O1 channel was the smallest. Under the A3 stimulation condition, the mean value of the CZ channel was the largest, and the mean value of the O1 channel was the smallest. Under the A4 stimulation condition, the mean value of the CZ channel was the largest, and the mean value of the O1 channel was the smallest. The obtained data of the P300 component were calculated for the means and SDs and subjected to one-way ANOVA, as shown in Table 8. The LSD method was used for post hoc multiple comparisons to further analyze the differences, as illustrated in Figure 9.

Table . N400 component ANOVA results.

Variable and value	Mean (SD)	F_1-score	*P* value
O1		63.016	<.001
A0	1.002 (7.944)		
A1	1.568 (6.642)		
A2	0.430 (0.808)		
A3	−1.806 (3.316		
A4	21.713 (15.859)		
Total	4.581 (12.160)		
CZ		12.095	<.001

A1	0.450 (5.555)		
A2	0.734 (1.840)		
A3	−1.279 (3.282)		
A4	8.307 (15.511)		
Total	1.452 (8.672)		
O2		6.408	<.001
A0	−0.126 (5.572)		
A1	0.280 (4.399)		
A2	1.092 (1.087)		
A3	−1.623 (3.135)		
A4	6.474 (17.694)		
Total	1.219 (9.023)		

XSL•FO
RenderX

Figure 9. Analysis of the heat map of N400 at each electrode under the states of stimulus material A0-A1. Each cell in the heatmap represents the *P* value of the pairwise comparison between conditions, with deeper colors indicating more significant differences. The diagonal cells represent self-comparisons and are displayed as 1. The numerical values in the figure correspond to the *P* values from the least significant difference post hoc test, and significance levels are denoted as **P*<.05, ***P*<.01, and ****P*<.001.

A further analysis of the potential amplitudes of the N400 component reveals that there are obvious differences and degrees of activation in the occipital lobe region and the central line region of the temporal area caused by the musical stimulation materials. The analysis shows that for the variable O1 ($F_{4, 268}$=63.016, *P*<.001, η^2=0.507), the LSD test reveals that the average potential amplitude under the A2 stimulation material (mean 0.430) is much lower than that under the A4 stimulation material (mean 21.713, *P*<.001). For the variable CZ ($F_{4, 268}$=12.095, *P*<.001, η^2=0.165), the LSD test indicates that the average potential amplitude under the A1 stimulation material (mean 0.450) is much lower than that under the A4 stimulation material (mean 8.307, *P*<.001). For the variable O2 ($F_{4, 268}$=6.408, *P*<.001, η^2=0.095), the LSD test shows that the average potential amplitude under the A0 stimulation material (mean −0.126) is much lower than that under the A4 stimulation material (mean 6.474, *P*<.001).

A detailed analysis of the heatmap shown in Figure 9 reveals that there are significant differences among different types of musical stimulation materials at the O1, CZ, and O2 electrodes. In the N400 component, the average potential amplitudes of the variables for each channel under the A4 stimulation material, that is, +V A, are much higher than those under the other 3 types of stimulation materials and the A0 stimulation material of the control group.

Discussion

Principal Results

This study aims to establish a mapping relationship between musical parameters and emotional states based on a music emotion model, and to provide empirical evidence for the design of a music-interaction module for intelligent leisure sofas in home environments. Based on the VA model, 4 sets of musical stimulus materials were formulated, and the state responses of older adult participants while listening to different musical stimulus materials were collected by the Bitbrain hydropolar EEG imaging system. The experimental results indicated that different types of musical stimuli exerted significant effects on the EEG activity of older adults.

First, compared with the white noise control condition, all 4 types of musical stimuli exhibited significant differences in EEG activation levels, indicating that music stimulation can effectively influence the neural workload of older adult participants. This finding is consistent with previous research on the regulatory effects of music on neural activity. For instance, Kučikienė et al [90] reported that preferred music enhanced EEG power across multiple frequency bands, particularly within the α/β bands. Similarly, Yang et al [91] found significant associations between brain activity in different frequency bands and musical rhythm. In the present study, we observed that +V+A pleasurable, excited, and happy types of music elicited higher levels of EEG activation, which may be associated with increased α and β power and decreased θ activity, changes that facilitate positive emotional experiences and reduce fatigue [92]. In contrast, –V+ A anxious, angry, and extremely panicky types of music were characterized by higher proportions of θ activity and peak (α+θ)/β ratios, which may correspond to EEG mechanisms commonly observed during negative emotional stimulation, such as enhanced θ and suppressed α power [93].

Analysis of the ERP data revealed significant differences among the 4 types of musical stimuli for the P200, P300, and N400 components, reflecting the modulatory effects of music on cognitive processing and emotional responses in older adult participants. Regarding the P200 component, our study showed significant differences across electrode sites P7, P3, O1, and O2, primarily localized in the left parietal and occipital regions. This suggests that music can activate the brain's perceptual and attentional networks at an early processing stage, facilitating the initial encoding of auditory information. Similarly, Patel et al [94] reported that musical stimuli could evoke early-stage neural responses for attention and perceptual processing, with the P200 component being closely linked to perceptual and selective attention processes. In addition, Portnova et al [95] found that the perception of emotional stimuli in comatose patients was associated with early P200 responses, whereas healthy individuals exhibited more complex ERP patterns.

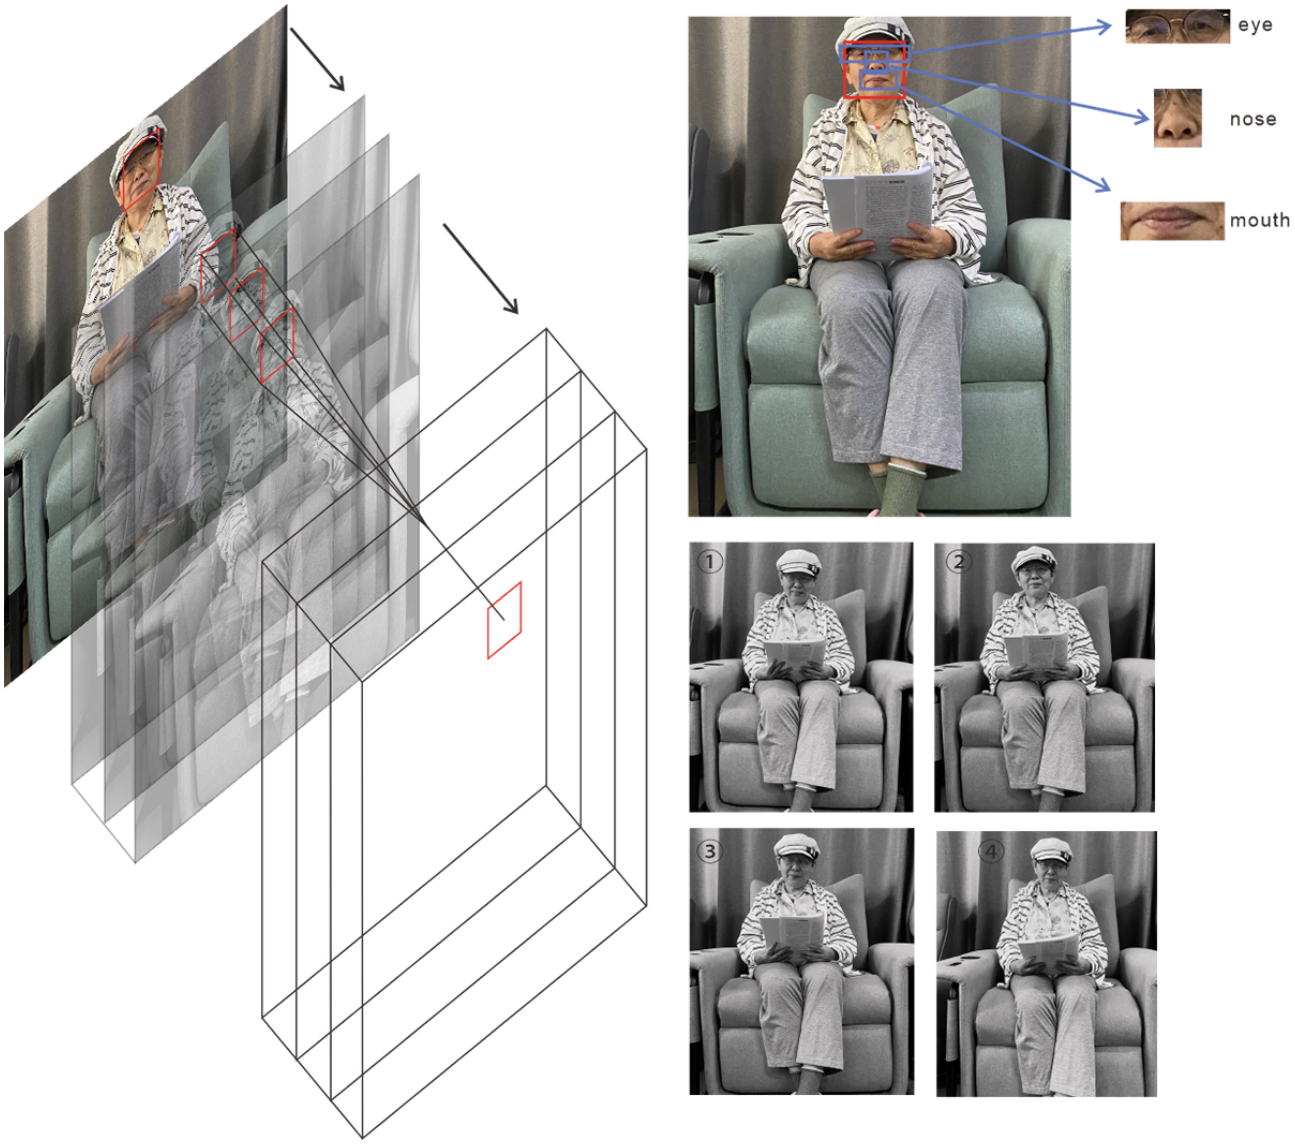
Regarding the P300 component, its amplitude is closely associated with attention, working memory, and emotional states

XSL•FO
RenderX

[96]. Evidence suggests that musical stimuli can modulate brain activity during later stages of cognitive processing, significantly influencing P300 amplitude. For instance, Pawlowski et al [97] noted that the P300 component is strongly related to cognitive evaluation and decision-making processes. In the present study, significant differences in P300 amplitudes were observed across electrode sites O1, Cz, and O2, with particularly prominent differences in activation in the occipital and temporal regions. These findings indicate that musical stimuli of different emotional types can significantly affect the allocation of attention and the level of cognitive evaluation in older adult participants, reflecting the specific modulatory role of music in brain cognitive processing.

Regarding the N400 component, although N400 was originally studied in the context of language processing, recent research has extended its application to the field of music to investigate the neural mechanisms underlying musical semantic processing. For example, Calma-Roddin et al [98] found that disharmonious or unexpected changes in familiar melodies elicited an N400-like effect similar to that observed in language, suggesting that music processing also involves semantic-related cognitive mechanisms. In our analysis of the N400 component, significant differences were observed across electrode sites F7, Fpz, Fz, and F8, particularly in the frontal region. This finding is consistent with previous research, indicating that musical stimuli can evoke brain neural responses associated with semantic processing and emotional evaluation. For instance, Portnova et al [95] reported that the N400 component is closely related to emotional perception and semantic processing, and that higher N400 amplitudes have been linked to the perception of emotional expression in sounds.

In summary, different types of musical stimuli exhibit significant differences in the brain activity of older adult participants. These results provide empirical evidence for the neural mechanisms underlying the regulatory effects of music on the emotions and cognition of older adults and offer a basis for the design of music-interaction regulation modules in smart home systems. From a theoretical perspective, the findings of this study further enrich the research framework regarding emotion-driven adaptability of home environments in smart home design [99] and support the necessity of introducing emotional response mechanisms in home environments [100]. Meanwhile, this study also provides empirical supplementation to the affective-rational theory [101,102]. The experimental results indicate an interaction between emotional experience and rational processing in the older adult users under musical stimulation. On this basis, the proposed music feedback mechanism can achieve adaptive regulation of users' emotions by identifying the corresponding relationship between emotions and music, which aligns with the laws of human cognitive processing and people-oriented HCI models [103]. Finally, through a comprehensive analysis of musical stimuli and EEG responses, this study reveals the emotional interaction relationships of the older adult users in the context of smart homes. As Desmet et al [104] noted, emotional artifacts promote well-being and psychological balance by evoking positive emotional experiences. This provides an actionable theoretical basis and experimental support for the future design of emotional products for older adult users and the development of health-promoting interaction systems.



Practice

The emotion recognition module plays a key role in the multimodal HCI system of the Recreation Sofa, which provides an immersive and personalized musical experience for the user. The module is designed to recognize the current behavioral and emotional state of the older adult user and adjust the music and interaction accordingly according to predefined criteria in the recreation module. This involves the integration of multiple sensors and algorithms to detect the emotional, behavioral, and activity levels of the older adult user and select music that matches their preferences and needs. For example, if an older user is feeling stressed or tired, the emotion recognition module can select calming or relaxing music to help them unwind. Or, if the older user is feeling energetic or happy, the music module can select more upbeat or lively music to enhance their emotions. If the older user is in a relaxed state, the emotion recognition module will select calm and soothing music to match the user's emotional and behavioral state. The emotion recognition module also adjusts the volume and tempo of the music to the user's preferences, ensuring a comfortable and enjoyable musical experience when using the lounge sofa. The emotion recognition module thus plays an important role in providing a personalized and adaptive user experience that is tailored to the user's emotional and behavioral state. The emotion recognition module uses the predefined music matching criteria set in the Recreation module to select the appropriate type of music.

The emotion recognition module carries out facial recognition of the older adult users through the Intel RealSense camera. The facial features are divided through the emotion recognition module, which mainly identifies the 3 main parts of the older adult users' face, the eyes, nose, and corners of the mouth, and the recognition process is shown in Figure 10. During the recognition process, the captured image will be grayed out to determine the gender of the target user, establish where the target facial range of the user lies, extract the 3 main facial feature parts of the target user in turn, and determine the actual emotional state of the user through a comprehensive evaluation of the algorithm. At this stage, the module has been developed as a prototype to test the feasibility of facial emotion recognition and its integration effect in the interactive music system. The study adopts the CNN-DeepFace framework to process the facial images of 68 older adult participants in the EEG-music experiment. These images serve as the initial dataset for verifying the effectiveness of the emotion mapping and adaptive playback process. The purpose of this stage is not to train a new deep learning model, but to evaluate the technical feasibility and response accuracy of the system in a controlled environment.

Figure 10. Model foundation framework.

The emotion recognition and music interaction module developed based on the conclusions of this experimental study aims not only to enhance user experience through its technical implementation, but also needs to be examined within the broader context of national, cultural, and ethical frameworks [105]. At the societal level, this study responds to the global trends of intelligent older adults' care and home-based health promotion [106]; it seeks to improve the psychological and emotional well-being of the older adults in home environments through noninvasive emotion perception and matched music interventions. At the cultural level, the randomized controlled experiment conducted using EEG in this study prioritizes cultural universality in music selection and intervention strategies. Music based on the VA model was selected to avoid emotional biases or culturally insensitive interventions caused by cultural differences, thereby ensuring the cross-cultural acceptability of the experiment [107].

At the level of technical ethics and safety practice, the design integrating the interaction module with the leisure sofa adheres to the design guidelines for HCI safety [108]. The main hardware involved includes a speech recognition microphone array, an emotion recognition camera, and an intelligent audio playback device. At the communication level, the system primarily relies on wireless communication protocols such as Wi-Fi, Bluetooth, and LoRa, while realizing multimodal data interaction and scenario linkage through a smart home gateway. However, subsequent research and practice need to consider data security, a critical consideration in the smart home ecosystem, which requires balancing the protection of user privacy with the migration and linkage between smart products [109]. From the perspective of ethics and social well-being, this system aims to provide older adults with an intelligent companionship solution that offers emotional comfort and is oriented toward social care. It enables music to serve not only as feedback for product functions but also as a carrier for emotional care, which aligns with the goal of technology facilitating a better quality of life [110]. Meanwhile, the system should also emphasize that technology should be people-oriented, explainable, and supportive of social dialogue. This requires prioritizing design values over technical implementation, rather than merely pursuing performance optimization [111].

Comparison With Prior Work

The analogies between the findings of this paper and the existing literature related to music emotion recognition or regulation are shown in Table 9.

Table . Correlation of the findings of this paper with the existing literature on musical emotion recognition and regulation.

Comparison	This work	Yang et al [112]	Takashima et al [113]	Wang et al [114]	Sutcliffe et al [115]	Vieillard and Gilet [116]
Research participants	Older adults	General	Datasets	Youth and older adults	Youth and older adults	Youth and older adults
Research methods	Model building, experiments, physiological data analysis	Model building, performance testing	Model building, dataset experiments	Experiments, physiological data analysis	Experiments, physiological data analysis	Experiments, physiological data analysis
Research tools	EEG[a] and ERP[b]	Multimodal research	EMER-CL[c]	Residual convolutional network	Research	Electromyogram (EMG)
Application scenarios	Age-friendly, smart sofa	Multimedia tools	Encoder training	Music generation	Deepen research	Emotion regulation

[a]EEG: electroencephalogram.

[b]ERP: event-related potential.

[c]EMER-CL: embedding-based music emotion recognition using composite loss.

These studies all aim to expand the possibilities of music emotion recognition from different perspectives, thus enabling mutual supplementation and validation. Through comparative and correlational analysis with other literature, this study demonstrates significant differentiation and innovation in several aspects. First, unlike previous studies that mainly targeted the mixed-age groups [112,113], this study specifically focuses on the older adult population, aiming to address the specific emotional regulation needs of the older adults in smart home environments. Methodologically, this study obtained the physiological responses of older adult participants through EEG and ERP analyses and established an emotional state mapping in combination with musical parameters. The MF-AWI model proposed in this study integrates multimodal data and health-promoting HCI, which differs from existing multimodal emotion recognition studies in terms of model framework. Examples include the rhythm prediction model by Wang et al [114], or the experiments on young and mixed-age groups by Sutcliffe et al [115] and Vieillard and Gilet [116]. The proposed model not only considers music and emotion recognition but also emphasizes individual adaptability in home interaction scenarios. Furthermore, numerous studies have demonstrated that multimodal fusion methods outperform single-modality approaches in emotion recognition tasks. For instance, when combining EEG with facial expressions for emotion classification, multimodal fusion consistently achieves higher accuracy than unimodal methods [117]. Therefore, the MF-AWI model incorporates emotional gradients and health-promoting thresholds in feature fusion, enabling personalized emotional feedback, and its preliminary validation in the intelligent home sofa scenario further highlights the potential of multimodal emotion recognition and regulation for practical adaptability and operability.

Limitations

This study has several limitations. First, regarding the participant population, the sample was restricted to older adults aged 60 - 75 years. Future research should further refine user needs and personal habits by examining behavioral habits and individual preferences, as well as potential gender differences in emotional responses and interaction behaviors. Second, all participants in this study were healthy older adults, as the primary aim was to establish a foundational model for music–emotion interaction within smart home systems. However, individuals with cognitive decline, dementia, or other impairments, who represent key potential beneficiaries of such systems, were not included [118]. Since cognitive processing and emotional responses may differ between healthy and cognitively impaired older adult populations, the generalizability of the findings remains to be verified in special older adult groups. Future studies should therefore expand the sample to include older adults with varying levels of cognitive function to comprehensively assess the applicability and effectiveness of the music interaction module across diverse user groups. Comparative studies between groups with different health statuses are also recommended to better understand how cognitive conditions influence emotional and behavioral responses to such interactive systems.

At the model and system level, this study primarily focused on using experimental data to validate the feasibility of the multimodal emotion recognition and adaptive music-matching mechanisms within the MF-AWI model. The study is positioned as a mechanism-level validation. In addition, the CNN–DeepFace emotion recognition component in this study mainly served to verify the feasibility of integrating visual emotion detection into the interactive music system, rather than to develop a fully trained and optimized recognition model. Consequently, systematic quantitative evaluations of the multimodal emotion recognition module and the adaptive feedback module, such as accuracy and F_1-score, have not yet been conducted, and their performance cannot be directly compared with existing EEG-based, multimodal, or single-modality emotion recognition models. Future work will involve large-scale experiments and cross-context validation, complemented by usability testing and subjective satisfaction

XSL•FO
RenderX

assessments, to comprehensively evaluate the model's effectiveness in real-world application scenarios. The model can also be further trained and optimized using larger and more diverse datasets of older adult users to enhance recognition accuracy and generalizability. In addition, standardized performance metrics will be applied to compare multimodal fusion methods with unimodal approaches in home-based environments, thereby further validating the practical benefits of the model in emotion recognition tasks. Finally, regarding statistical analysis, post hoc pairwise comparisons were performed using the LSD method following significant ANOVA results. As this study primarily focused on examining neural activity differences elicited by different musical stimuli, the LSD method provides high sensitivity for detecting effects. However, no further strict multiple comparison corrections were applied, which may increase the risk of type I errors. Future studies will consider using more rigorous correction methods, such as Bonferroni or false discovery rate adjustments, to verify the robustness of the results.

From an application and technical perspective, this study also has certain limitations. The experimental validation was carried out using a leisure sofa as the primary prototype. Future work could integrate multiple types of sensors to collect multichannel physiological signals, thereby improving emotion recognition accuracy and response speed. Moreover, EEG signal acquisition remains susceptible to environmental noise, poor electrode contact, and participant movement. Subsequent studies should focus on improving signal processing algorithms and denoising strategies, enhancing model generalization, and conducting long-term validation in real-world smart home environments to ensure system reliability and sustained usability and user experience.

Finally, from a social and cultural perspective, this study did not deeply address issues related to cross-cultural contexts or the socio-psychological effects of such systems among older adults. Although the system design and experiments were intended to promote user well-being, future interdisciplinary research should consider cultural diversity and social inclusiveness when evaluating and optimizing emotional smart products for the older adult population.

Conclusions

The research object of this paper is explicitly for the older adult users, and it aims to solve the problems related to the emotions of older adult users in their home environment. At the same time, the mapping relationship between music parameters and emotional state is constructed. In conjunction with experimental and physiological data analysis, several aspects are considered, and it is concluded that A1 stimulus materials can soothe the emotions of older adult users. In terms of research methodology, this paper uses EEG and ERP analysis, and the application scene is a smart sofa for older adults. It is compatible with the research object and has a certain degree of practicality. At the same time, based on this, the music emotion interaction module in the multimodal HCI system of the health care sofa is set up, and it provides health care thresholds and theoretical support for the health care sofa.

Abstract

Background: Home-based reablement programs have improved everyday functioning for people living with early-stage dementia or mild cognitive impairment (MCI), but the substantial time commitment required for delivery by health professionals has created a barrier to widespread implementation. Digital technology could facilitate delivery, but traditional devices such as smartphones and tablets present usability challenges for this population. We have co-designed a cognitive reablement program, VOICE-COG, that can deliver personalized interventions broadcast via voice-controlled digital voice assistants (DVAs).

Objective: This pilot nonblinded randomized controlled trial examined the feasibility and potential effectiveness of VOICE-COG for older adults living with dementia or MCI to guide the design of a full-scale trial.

Methods: Older adults (aged 60 - 85 years) with a self-reported diagnosis of dementia or MCI (N=30) were recruited via Facebook or the StepUp-for Dementia Research database and randomized to either a DVA intervention (n=15) or control (n=15) group for 12 weeks. Each participant randomized to the intervention group and their care partner met with a psychologist via Zoom to select 2 or 3 personalized goals from the VOICE-COG program. The personalized program was input into the software (BuddyLink) by researchers for broadcast via a DVA (Amazon Alexa Show 8). Participants in the control group received enhanced usual care, consisting of treatment as usual, plus weekly informational emails. Primary feasibility outcomes were recruitment, retention, device-recorded adherence, and the System Usability Scale (SUS). Secondary outcomes were self-reported by the participant and care partner via web-based Qualtrics forms and included the Goal Attainment Scale–Light (GAS), changes in participant mood, cognition, and everyday functioning, and carer burden.

Results: The recruitment rate was 86% (30/35) and the retention rate was 97% (29/30), with 1 participant in the intervention group lost to follow-up. Adherence to the VOICE-COG program ranged from 29% to 100% (mean 70%, SD 17%). The VOICE-COG program was rated as marginally acceptable (mean SUS score 56.3, SD 18.1). After 12 weeks, 60% (9/15) of the intervention group reported having met or exceeded their goals (GAS-Light t-score ≥50; mean 57.6, SD 15.4). The intervention group had a significantly higher increase in Multifactorial Memory Questionnaire–Strategy subscale score compared with control, mean difference 5.0 (95% CI 0.03-10.1, P=.049), representing a medium effect size (d=0.55). There were no other significant differences between groups.

Conclusions: This co-designed VOICE-COG program, delivered via DVAs, was feasible for older adults living with early-stage dementia or MCI, resulting in most participants meeting their reablement goals and increases in the use of memory strategies. System usability issues should be addressed in future adequately powered trials.

Introduction

Dementia is a growing public health concern worldwide due to its increasing prevalence and the associated burden of disability and dependency [1]. By 2030, the number of people living with dementia is predicted to reach 85 million, driven by the aging population and higher incidence rates in older adults [2]. As loss of cognitive functioning progresses, people living with dementia become increasingly dependent on informal and formal care, which was estimated to cost US $1.3 trillion globally in 2019 [3,4]. With limited pharmacological options to manage symptoms, studies have focused on nonpharmacological interventions to maintain independence at home and reduce the associated cost of care [5,6].

Previous research in reablement, also referred to as cognitive rehabilitation, has found that people living with dementia experience significant improvements in goal attainment related to daily functioning [7-9], while care partners reported enhanced well-being and coping outcomes [10,11]. Evidence from these studies suggests people living with mild or early-stage dementia experience greater benefits, with dementia severity a barrier to the collaborative goal-setting process [8,12]. However, the substantial time commitment for weekly home-based delivery from a qualified health professional (typically a nurse, occupational therapist, or psychologist), together with travel time and specialized training, has presented significant barriers to widespread implementation [13,14]. Technology could facilitate the remote delivery of reablement programs to overcome these barriers, increasing the availability of goal-oriented reablement programs for people living with dementia [15].

Recent studies have found telehealth delivery of reablement interventions just as effective as face-to-face home-based programs, eliminating the travel time requirement for health professionals [16,17]. This approach, however, still required a substantial time commitment from health professionals, as observed in the adapted Care of People with dementia in their Environments (COPE) [11] trial, which required 2 days training plus eight 1-hour sessions per person [17]. To date, no studies have determined if technology could improve support further by offering reablement self-management and remote monitoring from health professionals. A major issue in digital health research for this population concerns device usability, which is limited by the cognitive burden of remembering passwords and program navigation, in addition to age-related dexterity and vision impairments [18].

Digital voice assistants (DVAs) with embedded speakers and display screens that can broadcast personalized programs and interpret voice commands for navigation may offer a possible solution [19,20]. Existing evidence on DVA use for people living with dementia is confined to exploratory qualitative designs or technical usability evaluations [21-24]. These studies have suffered from methodological limitations such as case study designs, small sample sizes, and laboratory settings, limiting generalization to community-dwelling older adults living with dementia. Furthermore, while these studies provide evidence of daily activity reminders, cognitive stimulation, and social interaction, no studies have evaluated the use of DVAs to deliver a holistic, goal-based reablement program.

To address this need, we developed VOICE-COG, a cognitive reablement program delivered via DVA following a remote goal-setting meeting with a health professional. VOICE-COG is delivered to each participant's DVA in their homes using BuddyLink (Great Australian Pty Ltd) proprietary software [25] that broadcasts personalized health programs via audio, images, text, and video. Previous pilot studies using BuddyLink have demonstrated the feasibility of DVA to deliver personalized exercise and nutrition programs for cognitively healthy older adults [26-28]. The development and testing of VOICE-COG was expanded to include older adults living with mild cognitive impairment (MCI), given its characterization as a predementia stage with similar cognitive symptoms. Co-designed with older adults living with dementia/MCI, their care partners, and health professionals, VOICE-COG is intended to support reablement for regular leisure and ad hoc appointments, emotional regulation exercises, reminiscence activities, self-care adherence, and passive cognitive stimulation [29]. The primary aim of this pilot randomized controlled trial (RCT) was to determine the feasibility and usability of VOICE-COG for older adults living with dementia to inform a full-scale trial. Secondary aims were to assess potential efficacy on goal attainment, cognition, emotional well-being, daily activity functioning, and care partner burden.

Methods

Study Design and Randomization

This 12-week nonblinded pilot RCT examined the feasibility of VOICE-COG, a co-designed cognitive reablement program broadcast via DVA [29], with reporting guided by the Consolidated Standards of Reporting Trials of Electronic and Mobile Health Applications and Online Telehealth (CONSORT-EHEALTH) [30] (Checklist 1). Participants were recruited using convenience sampling, with eligible participants enrolled by the primary project lead. Following completion of baseline assessments, participants were block randomized (1:1), stratified by sex, to either the intervention (VOICE-COG program) or control group. The random allocation sequence was generated in advance using a computer-based randomization method in Microsoft Excel by a research assistant, who was independent of intervention delivery. The research assistant assigned participants according to the pregenerated sequence and notified the project lead of group allocation. Participants were not blinded to group allocation due to the provision of a DVA for the intervention group. Blinding was not possible for the lead researcher, who conducted a midtrial check-in with participants as required for this feasibility pilot study.

XSL•FO
RenderX

Participants and Research Setting

Eligibility criteria included older adults (aged 60 to 85 y) with a self-reported, recent (≤6 mo) clinical diagnosis of dementia and/or MCI, living anywhere in Australia with access to a residential Wi-Fi network. To guarantee an optimal internet connection for the Amazon Alexa DVA, the use of mobile data connections was not supported. Participants could be community-dwelling or in residential aged care, provided they had a care partner with at least 50% close contact during the 12-week trial and had access to a smartphone capable of making and receiving calls on an Australian network. Participants were required to be fluent in English. Digital literacy was not considered an inclusion criterion, as previous research has found prior experience does not influence adaptation for people living with dementia [31], and the voice navigation function of the DVA was expected to reduce this barrier. However, to reduce potential bias, all intervention participants were emailed personalized instructions on how to access their program via the DVA. Participants were excluded if they (1) were deemed to have difficulty communicating with a DVA due to speech or hearing problems, (2) were unwilling to be randomized, (3) planned to be away for ≥4 weeks during the 12-week intervention period, or (4) had any self-reported cognitive or physical impairment that, in the opinion of the research team, would result in the participant having difficulty interacting with the DVA or performing the VOICE-COG program safely. This included a self-reported clinical diagnosis of schizophrenia, bipolar disorder, or other psychotic disorders.

Participants were recruited via 2 methods. First, through paid targeted Facebook (Meta Platforms, Inc) advertisements, potential participants clicked an embedded hyperlink to read the plain language statement and completed an expression of interest form via Qualtrics. Second, eligible volunteers matching the study's inclusion criteria from the StepUp for Dementia Research database were contacted via phone call or email [32]. Individuals in this database have previously provided consent to be contacted for research. Interested participants were screened for eligibility via telephone and then emailed a link to the plain language and consent form on Qualtrics to provide written or electronic informed consent. Participants enrolled in the study provided details of the clinician responsible for their diagnosis, who was notified of the participant's eligibility and was given the opportunity to raise any concerns regarding participation. No further diagnostic criteria or cognitive assessment tools were used to determine eligibility.

Intervention

As detailed elsewhere [29], the development of VOICE-COG was guided by the IDEAS (Integrate, Design, Assess, and Share) framework [33], which combines co-design practice with identification of health behavior change strategies for digital interventions. The initial health professional facilitated goal-setting meeting used a modified, dementia-specific SMART (Specific, Measurable, Achievable, Relevant, and Time-bound) framework [34,35] that establishes current functioning and targeted goal attainment, aligned with previous hybrid digital health interventions [36,37]. The subsequent VOICE-COG program, broadcast via DVA, included several evidence-based behavior change techniques [36,38], such as motivational messages and preferences for social reward [39], individual tailoring with personalized audio and text prompts, and visual cues [40], in addition to instructional videos [41].

Intervention group participants selected goals from the VOICE-COG program that were personalized and broadcast via a DVA in their homes. Participants randomized to the intervention group were mailed a preregistered Amazon Echo Show 8 device ("Alexa") with instructions on how to connect the device to their home Wi-Fi. Each participant and their care partner were emailed a 1-page summary of the VOICE-COG program (Multimedia Appendix 1) in advance of meeting with a psychologist (qualified to a minimum Doctorate in Clinical Psychology with experience in motivational interviewing) via Zoom. Guided by the goal-setting reablement guide for people living with dementia [35], the psychologist assisted the participant in collaboratively setting 2 or 3 modified SMART-goals with their care partner that could be supported by the VOICE-COG program. Examples of participant goals can be found in Multimedia Appendix 2. These included (1) activities and appointments (attending regular weekly community activities and remembering appointments); (2) routine reminders (adherence to daily medication, hydration, and nutrition); (3) family and friends (writing their life story and maintaining relationships); (4) mood monitor (providing coping activities such as music and mindfulness); (5) active minds (providing cognitive stimulation through audiobooks, podcasts, news, and short videos); (6) household manager (remembering when and how to do home chores); and (7) kitchen helper (support for cooking favorite recipes). Further descriptions of how participants interact with the VOICE-COG modules can be found in Multimedia Appendix 3.

VOICE-COG used BuddyLink software to broadcast each participant's personalized program via an Alexa Skill on their Amazon Show 8 DVAs, similar to an app on a smartphone. Personalized goal-related information and preferred program broadcast timings were entered into an online Qualtrics form by the psychologist during the goal-setting meeting. Each participant's goal-related content was uploaded remotely to the BuddyLink software [32] by a research team member, who also configured program broadcast routines using deidentified individual Alexa accounts. A voice-initiated routine was added, "Alexa, Open Mind Buddy," for participants to access their program outside these times. Following the meeting, the intervention group was emailed a personalized 2-page instruction summary for the selected VOICE-COG goals. Participants who elected to write their life story (family and friends goal) received weekly emails with a link to an online Qualtrics form for data collection. Throughout the trial, all intervention participants received fortnightly emails requesting notification of any technical errors via completion of an online Qualtrics form. An optional midtrial check-in by a research team member was offered to participants to address any concerns regarding their program.

Control

Control group participants received usual care from their medical provider or aged care service, plus weekly emails with

XSL•FO
RenderX

Dementia Australia factsheets (available from their website) [42]. These were provided for ethical reasons, to ensure participants received some benefit while minimizing the potential impact on study outcomes.

Primary Outcome Measures

Feasibility

Participant recruitment, retention, and adherence rates were used to examine the feasibility of the VOICE-COG program to inform a future RCT. Recruitment rate (%) was defined as the total number of participants who provided consent at baseline divided by the total number eligible. Retention rate (%) was specified as the number of participants who completed the 12-week postintervention data collection divided by the number of participants randomized. The customized nature of the intervention allowed participants to have substantial variation in the type and number of weekly goal-related prompts. As such, adherence was defined as at least one weekly interaction with a personalized VOICE-COG goal via the DVA, as measured by a voice response to the initial dialog prompt recorded by the BuddyLink system (excluding "no" or "stop" responses). Adherence (%) was calculated as the proportion of weekly goal interactions recorded over the 12 weeks (24 or 36 possible goal interactions for participants selecting 2 or 3 goals, respectively). This measure, together with the predefined targets of ≥70% retention and ≥66% adherence to the VOICE-COG program, was based on previous evidence from DVA health intervention studies [26-28].

System Usability

Perceived usability of the VOICE-COG skill was assessed by DVA participants using the System Usability Scale (SUS) [43] form administered online via Qualtrics. The SUS uses 10 Likert-scale questions to determine subjective usability, providing a score from 0 to 100.

Secondary Outcome Measures

Goal Attainment

All data for baseline and 12-week outcomes were collected remotely via Qualtrics (unless stated otherwise). Demographic data were also collated at baseline. Participants and care partners were emailed a link to the survey including the questionnaires and informed they could complete the survey at any time throughout the week. They were advised that they could save their progress and return to it later if necessary.

DVA participants' goal attainment was measured using Goal Attainment Scale (GAS)–Light, a valid and reliable scoring system recommended for use with people living with dementia/MCI in reablement programs [35,44,45]. The intervention used a co-designed reablement program specifically developed for DVA delivery, thereby enabling administration by health professionals with minimal reablement training. Given the primary aim of this study was to establish feasibility, the control group did not receive a goal-setting-only intervention that would have required a reablement-trained health professional. The baseline goal attainment score was entered by the psychologist into the online Qualtrics goal-setting form during the goal-setting meeting (–2: no function or –1: some function). After 12 weeks, participants were emailed their personal goals and, together with their care partner, reported if they had achieved their goal and to what level: yes (+2 a lot more; +1 a little more; 0 as expected) or no (–0.5 partially achieved; –1 no change; –2 got worse). Results were entered into the GAS-Light spreadsheet [46] to calculate each participant's GAS-Light t-score, where t≥50 is interpreted as met or exceeded expectations.

Participant Questionnaires

Secondary outcome measures included differences in the following participant questionnaires (measuring mood, memory, and cognition) completed via online Qualtrics forms at baseline and at 12 weeks. The Geriatric Depression Scale (GDS) consists of 15 items rated "yes" or "no" to screen for depression in older adults and has been validated for use in older adults with mild to moderate dementia [47]. Scores of >5 suggest depression may be present; >10 is indicative of major depression. The Multifactorial Memory Questionnaire (MMQ) is a memory evaluation tool with 57 items covering 3 subscales—memory satisfaction, ability, and strategy use [48]. Participants' subjective memory experiences from the previous 2 weeks are rated using a 5-point Likert scale from 0 to 4. If there were <4 missing responses for any scale, scores were calculated using the prorated formula; for ≥4 missing items, participant scores were excluded from the analysis [48]. The Illness Cognition Questionnaire (ICQ) is an 18-item questionnaire using a 4-point Likert scale from 1 (disagree) to 4 (strongly agree) to measure the respondents' perception of their own illness with 3 subscales of acceptance, disease benefit, and helplessness [49]. For participants with 1 missing item in a subscale, the missing item was imputed using the mean of the other completed items within that subscale (provided at least 4 of 6 items were present).

Care Partner Questionnaires

At baseline and 12 weeks, care partners completed the following surveys: the Bayer Activities of Daily Living Scale (B-ADL) is a 25-item questionnaire assessing the difficulty that the person living with dementia/MCI has in performing daily activities, using a Likert scale of 0 (never) to 10 (always) [50]. The B-ADL score sums all items, excluding those rated "not applicable" or "unknown" divided by the number of items rated. The Everyday Cognition (ECog) Scale includes 39-items across 6 domains (everyday memory, language, visuospatial abilities, planning, organization, and divided attention) [51]. The Zarit Caregiver Burden 22-item questionnaire asked respondents to rate the level of burden caused using a Likert scale of 1 ("none") to 5 ("nearly always"), giving a score range of no burden (22 to 46), mild burden (47 to 55) or severe burden (56-110) [52].

Data Analysis

We recruited 30 participants (n=15 in each arm), consistent with sample size guidelines for pilot feasibility trials [53] and sufficient to provide preliminary estimates of medium effect sizes (d=0.5) to inform the design of a fully powered RCT [54].

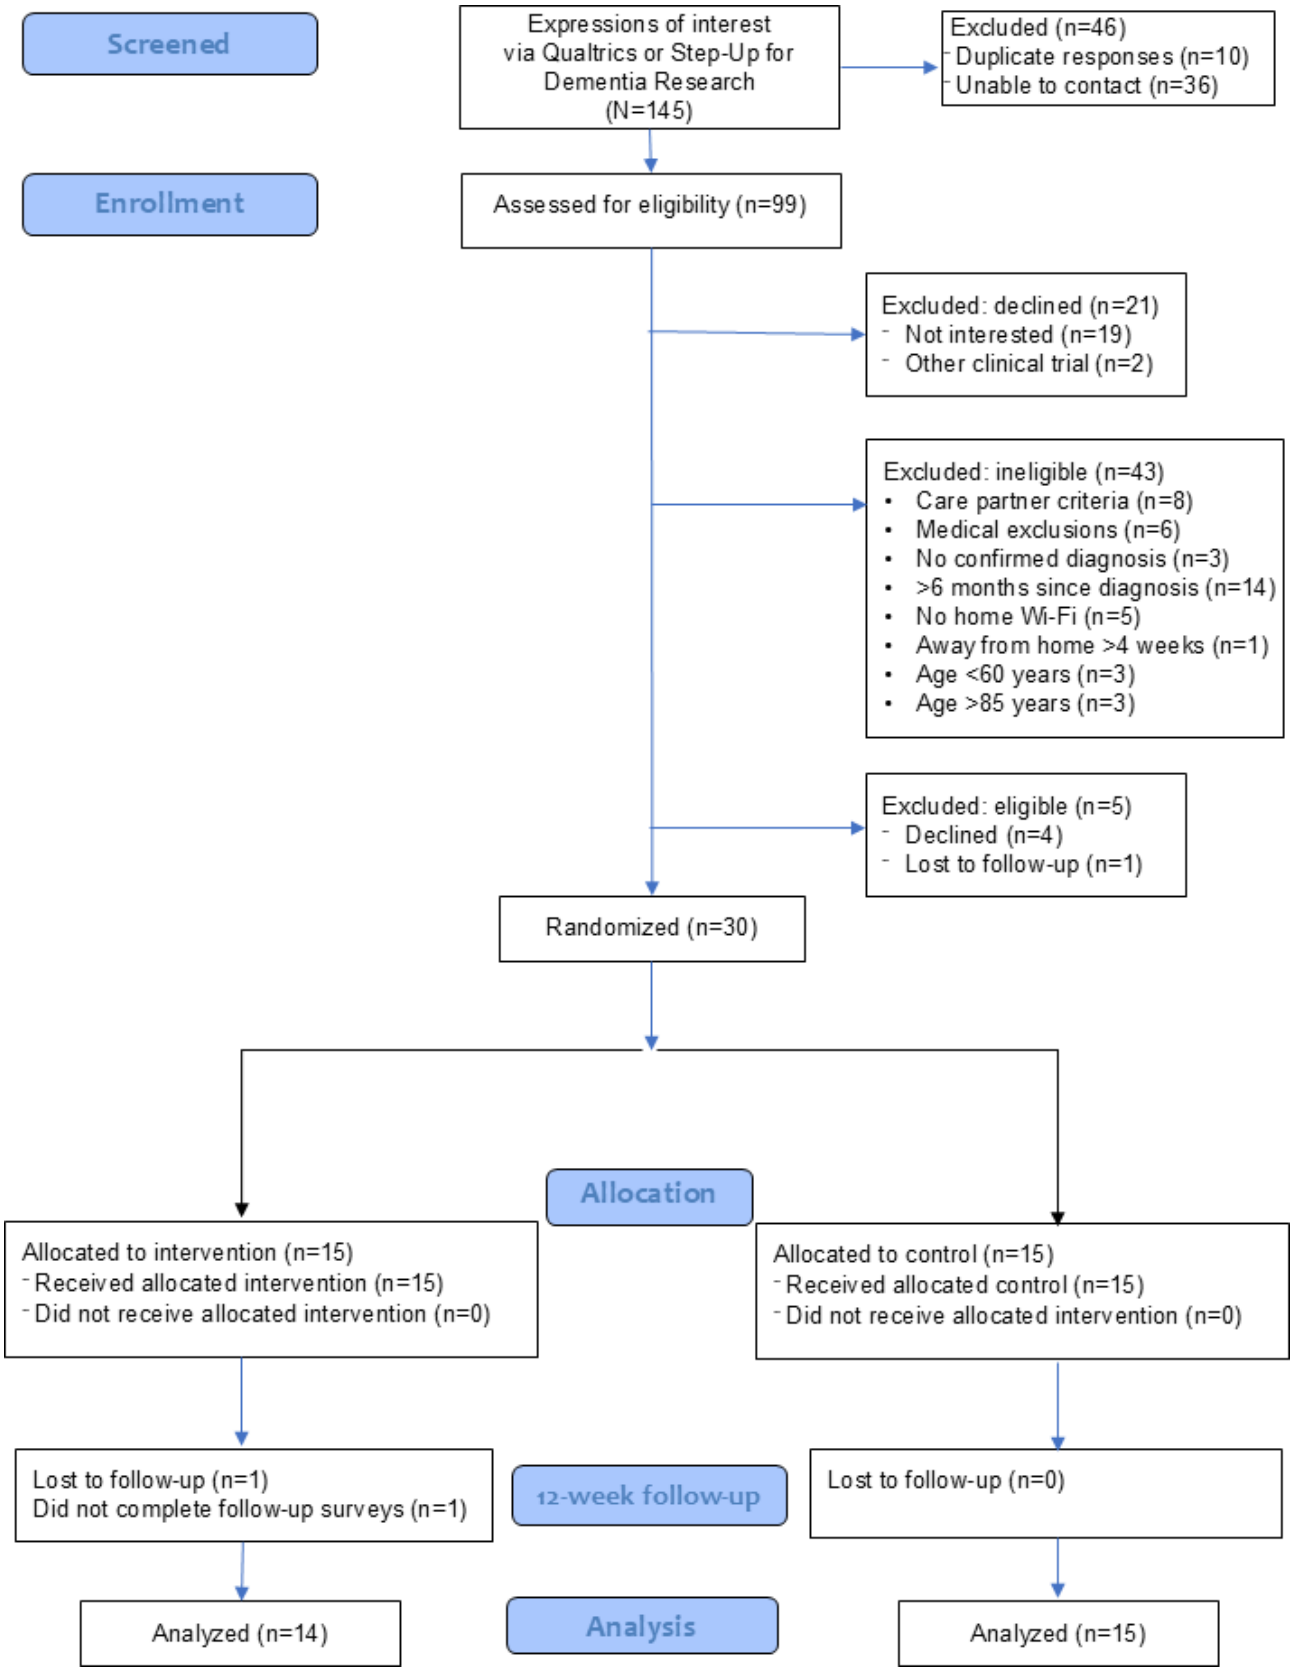
Descriptive data for feasibility and secondary outcomes are presented as either mean and SD or frequency (%). Differences in GAS-Light t-scores for the intervention group were compared using a 2-tailed paired-sample t test. SUS scores were entered

XSL•FO
RenderX

into the web-based analysis toolkit [55] to provide a box plot for visual comparison with the adjective quartile SUS score [56]. Differences in participant and care partner questionnaires were compared between groups using analysis of covariance adjusted for baseline values, and standardized effect sizes calculated using Cohen *d*. Missing data within scales was replaced by the mean value of item responses for that subscale. Effect estimates are reported with 95% CIs and *P* values set at $P < .05$, but as a pilot feasibility trial, this study was not powered to detect any significant changes. Shapiro-Wilk tests assessed assumptions of normality and homogeneity of variance, and natural logarithmic transformations were applied where required before conducting analysis of covariance analysis. All analyses were conducted using Stata Standard Edition (version 18.0; StataCorp).

Ethical Considerations

This study was approved by the Deakin University Human Research Ethics Committee (HREC 2022-043) and registered with the ANZCTR (Australian New Zealand Clinical Trials Registry: ACTRN12623000898651). Intervention participants received an Alexa Show 8 device, which they could retain after the trial to compensate them for their time. Control participants received an Alexa Show 8 device after the 12-week trial was completed.



Results

Overview

Participant flow is presented in Figure 1. In total, 145 expressions of interest were received, with 99 potential participants successfully contacted and screened between September 2023 and June 2024. A total of 30 participants completed baseline assessments and were randomly allocated to the DVA group (n=15) or the control group (n=15).

XSL•FO

Participant Demographics

Table 1 summarizes baseline demographics of the 30 participants. Participants' ages ranged from 60 to 85 years (mean 74.7, SD 5.2 y), and the majority (n=19, 63%) were women. Over half (n=18, 60%) were educated to university level, and while most (n=24, 80%) participants were retired and 13% (n=4) receiving a pension, 7% (n=2) were still employed. The vast majority (n=28, 93%) reported having at least one chronic health

XSL•FO
RenderX

condition in addition to dementia or MCI, with over half (n=17, 57%) having hypertension.

Table . Baseline participant characteristics of the DVA[a] intervention and enhanced usual care control groups (N=30).

Demographics	DVA group (n=15)	Control group (n=15)

[b]Cardiovascular disease included angina, stroke, peripheral vascular disease, and heart attack.

[c]Parkinson disease, multiple sclerosis, Crohn disease, kidney disease, liver disease, transplant, congenital deafness, vertigo, Sjögren syndrome, dumping syndrome, granulomatous disease, sleep apnea, hypoparathyroidism, hypothyroidism, hypoglycemia, melanoma, dystonic tremor, Marfan syndrome, depression, ankylosing spondylitis, and grand mal epilepsy.

Primary Outcomes

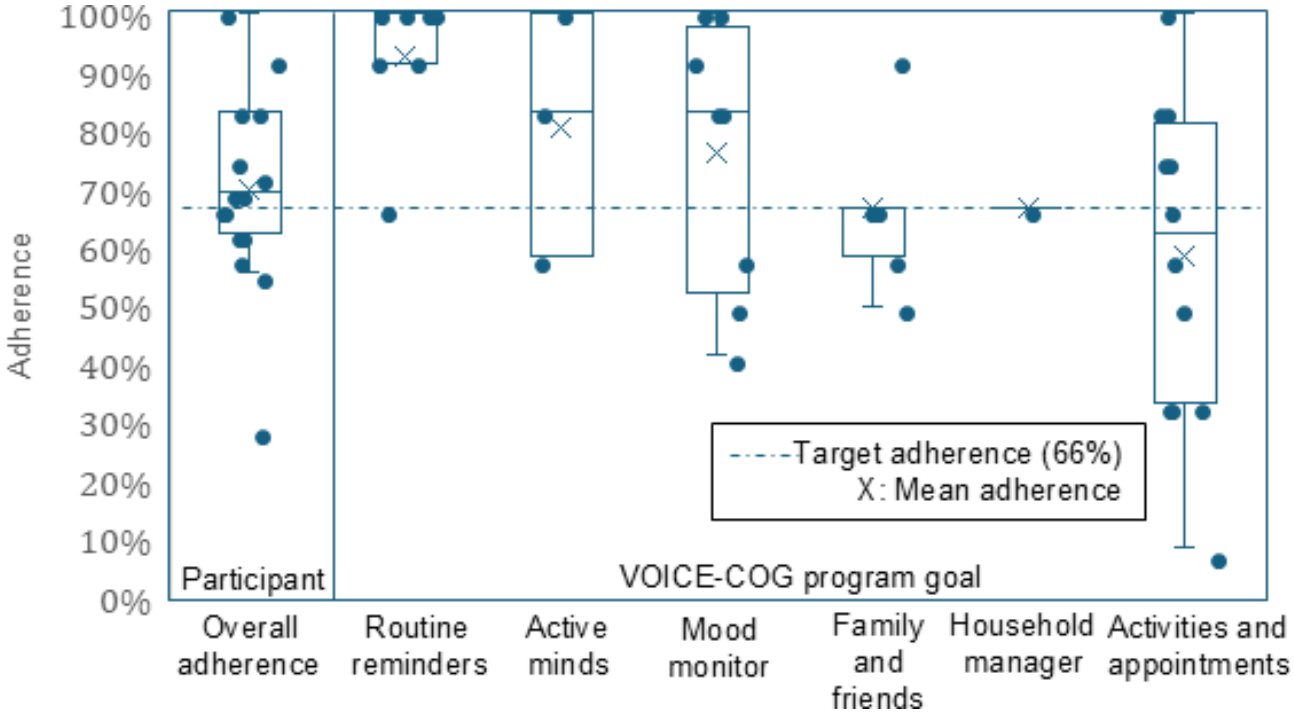
Feasibility

Primary outcome measures are summarized in Table 2. The recruitment rate was 86%; that is, of the 35 eligible participants, 30 people living with dementia/MCI and their care partners provided consent to participate. The overall retention rate was 97% (n=29). Retention was 100% (15/15) for the control group and 93% (14/15) for the intervention group, with 1 participant lost to follow-up (reason unknown). Adherence to the VOICE-COG program ranged from 29% to 100%, with a mean of 70% (SD 17%), exceeding the target adherence of 66%, with no adverse events. As shown in Figure 2, mean participant adherence met or exceeded the target for all VOICE-COG program goals except Activities and Appointments. Participants nominated between 7 and 52 VOICE-COG broadcasts per week, with a mean of 12 (SD 12) weekly voice interactions recorded by the DVA, as detailed in Multimedia Appendix 4.

XSL•FO
RenderX

Table . Primary outcomes of feasibility and usability.

Outcome	Time point	DVA group (n=15)	Control group (n=15)
Recruitment, n/N (%)	N/A[a]	30/35 (86)	30/35 (86)
Retention[b], n/N (%)	12 weeks	14/15 (93)	15/15 (100)
Adherence (%), mean (SD)[c]	Overall	70 (17)	N/A
System Usability Scale (SUS), mean (SD)[d]	12 weeks	56.3 (18.1)	N/A



[a]N/A: not applicable.

[b]Retention was defined as participants who completed all postintervention assessments at 12 weeks.

[c]Adherence was defined as ≥1 positive response to the program goal per week (out of the number of weekly goals broadcast over 12 weeks), reported as the percentage completed.

[d]Calculated as a score from 1 to 100.

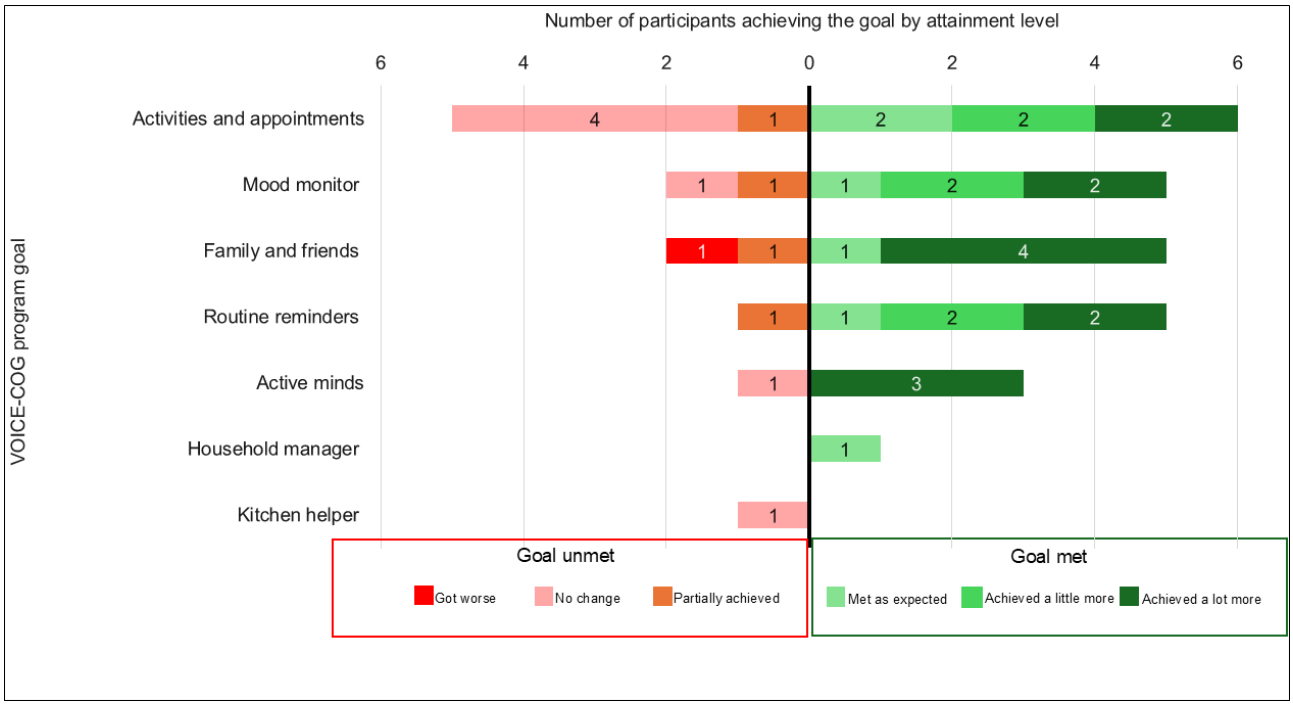
Figure 2. Box plots showing percentage adherence to the digital voice assistant–delivered VOICE-COG cognitive reablement program over 12 weeks, overall and by program goal.

System Usability

At 12 weeks, the SUS scores for DVA intervention participants indicated marginal acceptability of the VOICE-COG Program (mean 56.3, SD 18.1; range 28 - 79) [56]. The distribution of scores and responses to specific SUS questions can be found in Multimedia Appendix 5. Among the 15 participants, (n=11, 73%) agreed they would like to use the system frequently, and two-thirds (n=10, 67%) agreed the system was easy to use and that most people would learn to use the system very quickly. Just over half (n=8, 53%) believed the various functions in the system were well integrated and disagreed that the system was very cumbersome to use. However, just over half (n=8, 53%) felt they needed to learn a lot of things before they could get going with this system.

Secondary Outcomes

Goal Attainment



Among the 15 DVA participants, a mean of 2.6 (SD 0.5) goals was selected, with the majority (n=9, 60%) selecting 3 goals. DVA participants reported a significant increase in goal attainment, from a mean GAS-Light t-score of 36.8 (SD 0.7) at baseline to 57.6 (SD 15.4) at 12 weeks (P<.001). Most participants (n=9, 60%) met or exceeded their goals, as determined by a GAS-Light t-score of ≥50.

Thirty-nine VOICE-COG goals were set by participants overall, with 37 assessed at 12 weeks (1 participant who selected 2 goals was lost to follow-up). Further details, including example goals and attainment levels by VOICE-COG program goal, can be found in Multimedia Appendix 2. Of the 15 intervention group participants, 12 (80%) selected the activities and appointments assistant goal, 8 (53%) selected mood monitor, 7 (47%) selected

XSL•FO
RenderX

family and friends, 6 (40%) selected routine reminders, 4 (27%) selected active minds, and just 1 (6.6%) participant selected household manager as a reablement goal. The kitchen helper program goal had to be withdrawn after 2 weeks due to technical issues with device response timing and voice command difficulties with navigating recipes. Over two-thirds of VOICE-COG program goals (25/37, 68%) were attained at the expected level or above, with over a third (13/37, 35%) achieved "a lot more" than expected. Only 1 participant reported "getting worse" on a goal related to writing their life story (family and friends). Dichotomized goal attainment (scores of 0, +1, +2=goal met; scores of –0.5, –1, or –2=goal unmet) by VOICE-COG goal is shown in Figure 3.

Figure 3. Number of digital voice assistant intervention group participants achieving each goal attainment level after 12 weeks by VOICE-COG program goal.

Participant and Care Partner Questionnaires

Table 3 summarizes changes in participant and care partner questionnaire scores for both the intervention and control groups. After 12 weeks, the intervention group participants reported a significant increase in the MMQ-Strategy score (mean difference 5.0, 95% CI 0.03-10.1; *P*=.049) compared to control. This represented a medium size effect (*d*=+0.5). There were no other significant differences between groups after 12 weeks.

XSL•FO
RenderX

Discussion

Principal Findings

Findings from this pilot RCT demonstrate the feasibility of a co-designed cognitive reablement program broadcast via DVAs to support older adults living with dementia/MCI. The target sample was successfully recruited, and a high retention rate was achieved. Adherence, assessed as weekly interaction with program goals, exceeded target levels (66%), and the mean SUS score indicated marginal acceptability. Secondary outcomes showed the intervention group participants achieved a significant improvement in the attainment of personalized reablement goals. While most outcomes did not differ between groups, memory

XSL•FO
RenderX

strategy use was higher after 12 weeks in the intervention participants compared to the control group. Given that this feasibility study was not designed or powered to evaluate efficacy, a full-scale trial is required to evaluate the impact for people living with dementia/MCI.

Feasibility

Limited evidence on digital health applications to remotely deliver cognitive reablement programs for people living with dementia/MCI restricts comparisons of our study results [57-59]. Previous studies using smartphones or tablet-based apps for cognitive stimulation or training in people living with dementia have reported recruitment challenges related to device incompatibility [60,61]. The provision of the low-cost DVA, currently retailing at Aus $349 (Aus $1=US $0.70 as of Oct 8, 2026), as an additional device may, in part, explain our higher (30/35, 86%) recruitment rate. The intervention group retention rate of 93% (14/15) is higher than in previous telehealth reablement studies that observed retention rates of 60% [16] and 83% [17]. Careful interpretation is required given the significant difference in participant time burden for the virtual face-to-face studies. The 70% adherence rate was lower than 80% [28] and 85% [27] rates recorded in previous BuddyLink studies; however, this result should be interpreted with caution given personalization of VOICE-COG resulted in participants nominating between 7 to 52 weekly prompts compared to 1 or 2 in previous programs. A qualitative study with care partners of people living with dementia (n=5) explored the feasibility of DVA use for individual cognitive stimulation therapy (iCST), finding device accessibility, training provision, and visual stimulation could increase engagement [24]. The moderately high adherence rate in our study may have been due to the co-designed nature of the VOICE-COG program, which improved these functions and features through iterative feedback. Together, our feasibility findings provide support for a future large-scale trial.

System Usability

The VOICE-COG program's usability was rated as marginally acceptable (mean SUS 56.3, SD 18.1). It is possible this result was limited by the SUS outcome measure, which has not been fully validated for use in this population or with the DVA modality. The SUS is commonly used in technology evaluations by people living with dementia/MCI [62]; however, a modified version with simplified language has been proposed [63]. Furthermore, a recent review highlighted that usability assessments designed for graphical user interfaces need to be revised and validated for application with DVA systems [64]. The Voice Usability Scale could be considered as an outcome measure for future trials, having been tested as an alternative to the SUS on the Amazon Alexa [65]. Finally, in alignment with the IDEAS framework, a subsequent qualitative analysis of user experiences will be conducted to inform further development of VOICE-COG for evaluation in large-scale RCT. Future research should consider exploratory analyses examining associations between usability and other outcome measures to determine whether differences in usability for each VOICE-COG program goal influence effectiveness.

Goal Attainment

Goal attainment significantly increased among participants who received the VOICE-COG reablement program via their DVAs, with 60% (9/15) reporting having met or exceeded their goals. It is possible these results were influenced by the goal-setting behavior change process alone. While GAS-Light has recently been recommended for goal setting in reablement programs for people living with dementia [35], the heterogeneity of goal outcome measures used in previous studies limits comparability [66,67]. Furthermore, there is a lack of standardization in the application of the GAS with differences in scales and/or allocation of baseline scores [66]. A study using a touchscreen prompter to support household tasks (only) in people living with dementia (n=8) found 64% (14/22) of goals were met after 4 weeks [68], consistent with our finding of 68% (25/37) of goals achieved. More frequent use of the touchscreen prompter was associated with successful achievement of goals [69], highlighting future research should explore the relationship between adherence and goal attainment. The virtual telehealth study reported a higher percentage of goals were achieved (7/9, 78%) in the telehealth intervention group; however, the smaller sample size (n=3) limits comparison [16].

Cognitive Outcomes

Intervention participants in our study reported significantly higher use of memory strategies after 12 weeks compared with the control group. Despite this promising result, longer duration and adequately powered evaluation trials are required to determine if the increased use of DVA memory strategies could have a positive influence on memory performance and satisfaction over time [70]. It could be argued that this positive result was due to the integrated DVA reminder functions, which include alarms, timers, lists, calendars, and routines, which have been reported to support older adults with memory [71]. Future research should explore the effect of the VOICE-COG program that includes prompts and training support for the integrated functions compared to standalone DVA use. There is limited evidence on the effects of assistive technology for memory support in people living with dementia, with 0 studies included in a 2017 Cochrane review [72]. A recent smartphone study found people living with dementia (n=52) who used a voice recorder or reminder app reported improvements in prospective memory after 4 weeks, with higher levels of app engagement associated with a significant (P=.049) improvement in Instrument of Activities of Daily Living (IADL) [60]. Given the borderline statistical significance in both studies, additional research is needed to determine if there are meaningful effects on cognition and functioning for people living with dementia/MCI longer term.

Implications for Future Research

Feasibility results from this study support consideration of a full-scale trial to evaluate the impact of VOICE-COG, relative to usual care for people living with dementia/MCI. The effect sizes found in this study may be used to inform decision-making regarding adjustments, such as sample size for a future trial [73]. Recruitment via clinically facilitated partnerships, such as memory clinics, should be considered to reduce selection bias from web-based advertisements. VOICE-COG used

XSL•FO
RenderX

co-design to adapt a practical cognitive reablement framework for people living with dementia [74] and a theory-based goal-focused approach [75,76], drawing on various evidence of empirically supported strategies. Future research should examine reasons for lack of goal attainment unrelated to usability and ensure the latest reablement strategies for older adults with dementia are incorporated. This should include increasing accessibility of VOICE-COG to a more diverse population, including minority ethnic groups, or lower socioeconomic status, and those in rural areas. Digital competency measures should be collected at baseline in future trials to investigate potential bias and determine if this influences intervention engagement. Given the high prevalence of depression and anxiety in this population, consideration should be given to the use of positive psychology outcome measures currently in development [77,78]. An important issue for future research is consensus on an objective validated measure of adherence or engagement for digitally delivered reablement support programs and DVA interventions. Finally, the cost-effectiveness of VOICE-COG should be evaluated in comparison to a telehealth virtual reablement program before implementation at scale.

Limitations

Recruitment methods in this study used web-based applications that required a level of digital literacy, which could limit generalization of these findings to all people living with dementia/MCI. This may have led to an unintended bias of a highly educated sample, potentially limiting generalization to all people living with dementia/MCI. Since participants self-reported their diagnosis of dementia/MCI, cognitive impairment stage could not be determined. Therefore, the inclusion of an objective, validated cognitive assessment should be considered for future studies. Goal attainment measures were self-reported and could have been positively influenced by social desirability bias. Furthermore, control group participants did not set reablement goals, so we could not ascertain if goal attainment differences were associated with the intervention or the goal-setting process. Participants had not previously owned an Amazon Alexa Show 8 DVA, so SUS responses may have been influenced by the DVA's integrated features and functionality. Questionnaires were administered online, but several people living with dementia shared email addresses with their care partners, so responses could have been misrepresented due to proxy reporting bias. Secondary outcomes should be interpreted with caution as our sample size was not powered to detect effects. Consistent with the exploratory aims of feasibility studies, we did not correct for multiple comparisons in hypothesis testing, which may have led to false-positive findings. Finally, as a pilot feasibility trial of a minimum viable product, additional human support elements included researcher input during program configuration. Future trials should consider an integrated configuration interface, enabling direct transfer of data from web-based forms into the BuddyLink software for real-world implementation.

Conclusions

This co-designed VOICE-COG cognitive reablement program was feasible to deliver to older adults living with dementia/MCI via DVA, with high levels of retention and adherence. Larger trials with longer-term follow-up and cost-effectiveness evaluation are needed to determine how this remotely delivered and monitored program can support older adults living with early-stage dementia or MCI to meet their reablement goals.

Acknowledgments

StepUp for Dementia Research is funded by the Australian Government Department of Health and is implemented by a dedicated team at the University of Sydney.

TY acknowledges the use of Microsoft Copilot for occasional sentence refinement to improve the clarity and organization of the language while preparing the initial and revised drafts of the manuscript.

Funding

This research was funded by a Dementia Australia Research Foundation grant. TY was supported by an Australian Government Research Training Program (RTP) Scholarship (doi.org/10.82133/C42F-K220).

Data Availability

The datasets generated and analyzed during this study can be made available upon reasonable request and with approval from the Deakin University Human Research Ethics Committee.

Authors' Contributions

PJ, HM, DS, MC, and EG were responsible for the initial conceptualization, funding acquisition, and methodology design. PJ, HM, and DS were responsible for the supervision of the research team. TY was responsible for conducting the investigation, coordinating and planning research activities, creating co-designed modules, programming and testing of the software, data curation and analysis, writing the initial draft of the manuscript, and editing for submission. C Glavas, C Gourlay, and CC supported research activities and data curation. All coauthors, including RM, were responsible for reviewing and editing the manuscript.

Abstract

Background: Family or friend caregivers of older adults are critical in helping older adults navigate fragmented health and social systems, but they face significant challenges in doing so. Their needs for support, information, and resources are often unmet or remain largely invisible to health and social systems and public policy. In Ontario, Canada, Ontario Health Teams (OHTs) were established to integrate and streamline health care services. However, emerging evidence suggests that despite the requirement to integrate patient and caregiver advisors in these activities, caregivers still face substantial navigation barriers.

Objective: This study aimed to systematically evaluate the amount, nature, and accessibility of information provided on each of the 58 OHT websites. Specifically, we focused on information on services and supports for older adults and their caregivers.

Methods: Between November 2024 and May 2025, we conducted an environmental scan of all 58 OHT websites. Using a 5-point Likert scale, 2 team members independently rated how easy or difficult it was to identify services and supports for older adults and their caregivers. They also documented each service and support listed on each website and provided additional details on the experience of navigating the website in an open-text comment. The ratings were discussed in team meetings, and discrepancies were resolved through team consensus. Data analysis included thematic analysis of the services identified and of open-text responses (positive and negative experiences of navigating the websites, rationales for the ratings), as well as descriptive statistics of the ease of access ratings and of the types of services listed on OHT websites.

Results: Almost 60% of the websites were rated as difficult or very difficult to navigate, and 33% provided insufficient information on services and supports. However, information quality and accessibility varied significantly between websites. While some featured clear, well-organized resources, others were poorly designed, lacked a well-functioning search function, or provided vague or incomplete descriptions of services and supports. Design features that improved the accessibility and usefulness of websites included user-friendly, simple navigation and direct links to relevant services. In contrast, poorly designed websites often require multiple steps to access essential information, risking exacerbating caregiver burden.

Conclusions: Our findings highlight significant barriers for caregivers to access and navigate health and social service information, despite the intended goals of OHTs to improve system navigation. Health care system reforms focusing on integrated care need to include older adults and their caregivers as priority populations. Older adults and caregivers need to be engaged systematically and comprehensively, including in the development, design, and evaluation of health care system websites. Further, standards of public reporting need to be developed, and integrated care networks need to be required to follow these standards. This will help to improve transparency and accountability.

Ontario Health Teams; integrated care; caregivers; older adults; health care system navigation; health care system access; health care system websites

Introduction

Family or friend caregivers (subsequently referred to as caregivers in this paper) play a critical role in the care of older adults [1-4]. Caregivers are relatives, friends, partners, neighbors, or other informal supports who provide care (usually unpaid) to someone who needs help due to physical, intellectual, or developmental disabilities; medical conditions; mental illness; or aging-related needs [1,5]. In 2022, 24.1 million caregivers

XSL•FO
RenderX

in the United States cared for an older adult [6], and around 6.4 million Canadians (approximately 20% of the Canadian adult population) were caregivers to dependent adults [7]. The number of caregivers in Europe was 76.2 million (approximately 10% of the total population) in 2016 [8]. About 80% of ongoing care for older adults in Europe [9], and 90% in the United States [10], is provided by caregivers, and in Canada, 95% of those receiving formal home care also have an unpaid caregiver [11]. The economic value of caregiving (ie, the costs of labor to the health care system if caregivers were to be replaced by formal care) was US $600 billion in the United States in 2021 [12], $9 billion CAD (US $6.6 billion) in Canada in 2019 (estimated to increase to $27 billion CAD [US $36.6 billion] by 2050) [13], and €576.4 billion (US $675.1 billion, 3.6% of the gross domestic product) in Europe in 2016 [8].

Despite their critical role, and despite the fact that caregivers provide large amounts of care to older adults that otherwise would have to be provided by the health care system, caregivers remain largely invisible to public policy—receiving no (or barely any) financial compensation for the labor they provide, and facing a dearth of publicly funded supports to meet their own needs [1-4]. In fact, caregiver supports have been eroding, rather than expanding, in recent years [14-16]. Much has been written about the inherent propensity of capitalist societies to marginalize unpaid care [17-20]. Individuals are conceived as independent, self-interested agents, disregarding issues of dependency. Relationships are seen as reciprocal and contractual, ignoring care-related asymmetries. Care is relegated to the private, domestic sphere, largely considered the responsibility of women, and assigned an idealistic, rather than monetary value. The consequence is a devaluation of care, of those who provide it (primarily women), and of those who receive it (often older adults with frailty and physical and cognitive disabilities) [17-20].

Therefore, unsurprisingly, comprehensive evidence suggests that caregiving increases a person's risk for poor mental health (eg, stress, depression, and anxiety), physical health (eg, pain, hypertension, and diabetes), social relationships (eg, reduced social contacts and conflicts with care recipient), finances (eg, out-of-pocket expenses and loss of income), and quality of life [1,21-25]. These negative impacts of caregiving grow more severe with increasing duration of the caregiver role with higher client care needs, especially if these include responsive behaviors, mental health issues, or sleep disorders [1,21,25-27]. In turn, the health and well-being of caregivers is closely associated with that of the person they care for [1,28-33].

One of caregivers' key roles in the care of older adults is navigating fragmented health and social systems, and they face considerable challenges doing so [34-36]. For example, caregivers often lack information about available services and how to access them. Available services may not be publicly funded, the older adult may not be eligible for publicly funded services, or these services may not be a good fit for the older adult's and caregiver's needs. Caregivers face long waiting times, complicated access procedures, communication gaps between settings and providers that require them to repeat the same information over and over again, and health care providers are poorly informed about the older adult's history or do not have time to listen to or share information with the caregiver [34-36].

When trying to find and navigate services and supports for those they care for or for themselves, the primary source of information for many caregivers is the internet [37]. Therefore, the quality and accessibility of information about these services and supports on the websites of health authorities providing access to these services and supports are a critical issue. In the Canadian province of Ontario, 58 Ontario Health Teams (OHTs) are responsible for delivering and organizing care [38]. In 2019, Ontario introduced a health care system reform, aiming to build "a connected health care system to improve the patient, family, and caregiver experience" [39]. This provincial health care system transformation was informed by international evidence of integrated care models implemented in other countries, such as HealthOne Mount Druitt in Australia, the Massachusetts General Care Management Program in the United States, and the Norrtälje Model in Sweden [40,41]. These integrated care models are similar to the reforms implemented in Ontario in their focus on care coordination and management, multidisciplinary team involvement, and user experience improvement. However, there are variations among OHTs in their geographic scale, governance structures, condition focus, and the specific sectors involved [40,41].

OHTs were established to integrate and connect care among hospitals, primary care practices, and home and community care [38] to "make it easier for [patients and caregivers] to navigate the health care system and transition between health care providers and places where [they] receive care, making sure [they] don't feel lost or unsupported" [39]. Ontario's Ministry of Health decided to leave it to regional networks of health care providers and organizations to connect, decide whether to become an OHT, and undergo a stepwise process to become an approved OHT [42]. The steps to become an OHT were to be repeated until full provincial coverage was achieved and included [42]: (1) a readiness self-assessment; (2) review of this self-assessment by Ontario's Ministry of Health with the possible outcomes of "in discovery" (beginning stages of readiness) or "in development" (higher degree of readiness); (3) postreadiness review activities: for teams in the "discovery" stage, access to supports and continued work toward the "in development" stage and for teams in the "in development" stage, preparing and submitting a full application; (4) review of the full application by Ontario's Ministry of Health with the possible outcomes of "ready for an in-person visit or not yet ready for an in-person visit"; (5) post full application activities: for teams "not yet ready for an in-person visit," continued work on their readiness until they are "ready for an in-person visit" and in-person visit for teams deemed "ready" for that step with the possible outcomes of "full readiness for implementation or still in development"; (6) categorization as "OHT candidates" of teams deemed "fully ready for implementation," who went on to implement the OHT model; and (7) progression toward full designation as an OHT.

By December 2019, the first cohort of 24 OHTs was announced [43], and by November 2022, 54 OHTs had been approved [44]. Full provincial coverage was achieved in January 2024, when the last of the 58 OHTs was approved [45].

XSL•FO
RenderX

One important requirement for OHTs is to ensure meaningful patient and caregiver engagement [46-49]. The government-funded Ontario Caregiver Organization [50], whose mandate is to support caregivers in Ontario [51], actively collaborates with OHTs to support them in these endeavors [52]. While evidence suggests that caregivers have been meaningfully engaged in the development and ongoing activities of some OHTs [53-56], reports from nongovernmental caregiver advocacy organizations point to substantial challenges that caregivers face in navigating health and social supports in Ontario. According to the Ontario Caregiver Coalition, 39% of caregivers experience system navigation challenges [57]. Over half of caregivers with unmet mental health needs [58] and 20% of caregivers with unmet respite needs [59] were unaware of available supports or were never offered supports. According to the Canadian Centre of Caregiving Excellence, 59% of caregivers in Canada spend time each week researching supports and navigating systems, and 50% of caregivers (59% among caregivers aged older than 65 years) report difficulties in finding information about caregiver supports [60]. A snapshot of the Ontario-specific findings suggests that caregivers in that province face similar navigation barriers as those in other provinces [61].

When our team accessed websites of various OHTs for other research projects, we noticed that the information on services and supports for older adults or their caregivers varied substantially between websites. OHTs are required to ensure information about the OHT's "service offerings is readily available and accessible to the public (eg, through a website)" [42]. A document provides guidance to OHTs on public-facing communications [62]. For example, OHTs are required to make "best efforts to include patient and provider benefits in all communications," and to "directly connect people to the right care at the right time and provide 24/7 help in navigating the health care system." Our impression was that the degree to which OHT websites met these requirements—especially related to navigating services and supports for older adults or their caregivers—varied considerably, which is why we decided to conduct this research study. The objective was to systematically evaluate the amount, nature, and accessibility of information provided on each of the 58 OHT websites, related to services and supports available to older adults or their caregivers.

Methods

Research Design

We conducted an environmental scan of the websites of all 58 OHTs [38]. An environmental scan is a structured and adaptable method for identifying and synthesizing publicly available information on existing programs and practices across organizations [63]. In health services research, environmental scans map the current landscape, compare jurisdictions, and identify gaps by integrating diverse sources, ranging from passive reviews of public web content (eg, organizational websites and gray literature) to active approaches such as key informant input [63,64]. Given our aim to appraise public-facing information, we conducted a web-based environmental scan of all 58 OHT websites, an approach consistent with prior OHT scans, to compare structure, accessibility, informational content, currency, and usability at scale. The primary purpose of this study was to evaluate OHT websites from an older adult and caregiver perspective. Therefore, we did not include key informant interviews with OHT representatives. Older adults and caregivers were part of our research team (see below).

Setting and Sample

The Context of Older Adult Care in Ontario

Our setting was ongoing older adult care in the Canadian province of Ontario. Our sample was the websites of all 58 OHTs. With 16.2 million residents (39% of the Canadian population) as of March 2025, Ontario is Canada's most populous province [65]. Over 18% of people in Ontario (2.9 million) are 65 years or older [66], and the estimated number of caregivers to people of all ages is 4 million [51]. Older adult care in Canada is primarily the responsibility of each of the 10 provinces and 3 territories (refer to Deber [67], chapter 4, and Marchildon et al [68], section 5.8 for the following). On a federal level, the Canada Health Act regulates the terms and conditions that provinces and territories must adhere to access federal funding for essential medical services (eg, hospital care, treatment by physicians, and diagnostics). However, federal transfer payments cover only 20% of provincial and territorial health budgets. Provinces and territories individually regulate and organize coverage and delivery of these services. Ongoing care and supports for older adults and their caregivers (eg, home care, respite services such as adult day programs, or long-term care homes) are not insured under the Canada Health Act, meaning they are completely at the discretion of each province and territory. In Ontario, some publicly funded services require out-of-pocket contributions, and those who do not qualify for publicly funded services will have to pay for services themselves [69,70].

Residential Care

The Ontario Ministry of Long-Term Care licenses and oversees 626 long-term care homes with a total of almost 80,000 beds [71,72]. Access is limited to residents with complex care needs who need 24/7 nursing care, and eligibility is assessed by Ontario Health atHome [73]. Services in licensed long-term care homes are publicly funded (with some copayments for board and meals), regardless of whether the organization applies a for-profit or a not-for-profit model. In addition, about 780 licensed, privately owned retirement homes (around 85,000 spaces) rent space and offer services such as meals or assistance with dressing to older adults with less complex care needs, who have the financial means to afford paying for these costs out of pocket (since these services are not publicly funded) [69,74]. Finally, Ontario provides access to a confusing array of publicly subsidized supportive housing options. Each of the 3 ministries (Ministry of Municipal Affairs and Housing; Ministry of Health; and Ministry of Children, Community, and Social Services) provides their own programs (for a total of around 20 programs) with varying target populations, eligibility criteria, access processes, services provided, and copayments required [75]. Target populations often include people with physical or cognitive disabilities, mental health issues, HIV, AIDS, or other conditions, and older adults may be eligible if they meet the

XSL•FO
RenderX

eligibility requirements of the respective program. In contrast to retirement homes, supportive housing settings are owned by not-for-profit entities (eg, municipalities, faith groups, and housing cooperatives), and the rent charged is often either based on a person's ability to pay or publicly subsidized [76].

Home and Community Care

Ontario Health atHome provides various home- and community-based services to well over 650,000 clients, such as care coordination, nursing, physiotherapy, occupational therapy, nutritional counseling, speech therapy, social work, personal support, medical supplies and equipment, meal delivery and dining programs, assistance with daily activities, transportation services, caregiver support, friendly visits, and palliative care [77,78]. For clients who live at home or in a retirement home, and whose care needs are more complex than can be met by home care, assisted living services are available to avoid admissions to long-term care homes or hospitals [79]. Almost 440 publicly funded adult day programs [80] provide respite to caregivers and social and recreational care to clients [81]. On 1 or a few days per week, clients attend these programs for part of the day, returning to their home at night (with some programs providing overnight care and clients returning to their home in the morning) [81]. Publicly funded respite care at home may be available, but availability in general and the funded number of hours vary depending on the client's and caregiver's region and unique situation [82]. Clients' short stays in a long-term care home are funded for up to 60 days at 1 time and a maximum of 90 days per year if caregivers need to take a break, go on vacation, stay in a hospital, or experience health issues preventing them from providing care [82,83]. Short-stay long-term care is also available for up to 90 days per year to older adults who are recovering from a medical condition before returning to their home (convalescent care), or for those waiting for a long-term care admission, but whose care needs cannot be met at home (interim care) [83]. Finally, there are some limited provincial and federal tax credits, employment or leave benefits, and various information and advocacy resources for caregivers [84]. In addition to implementing OHTs, Ontario's home and community care system has also undergone substantial reforms since 2020 [85]. OHTs are not fully integrated in the delivery of home and community care services, and only starting in 2025, an initial group of 12 OHTs was chosen by Ontario's Ministry of Health to deliver home and community services [38].

Measures, Outcomes, and Data Collection

Using a brief electronic information extraction sheet (File S1 in Multimedia Appendix 1), each of 2 team members independently reviewed OHT websites between November 2024 and May 2025. An update to the ratings of all OHT websites was conducted in May 2025 to ensure our analyses reflected any website changes since the initial assessment. Using 5 categories (very difficult, difficult, neither difficult nor easy, easy, and very easy), team members rated, for each website, how easy or difficult they found it to identify services available to older adults or their caregivers. In addition, all services identified were documented, including the type of service, name of the service provider, the weblink, and comments. Additional comments about the website were captured in a final open-text response.

Raters used definitions of each category for their ratings (Table 1), which we developed based on the Web Content Accessibility Guidelines 2.2, developed and published by the World Wide Web Consortium as part of the Web Accessibility Initiative [86]. Team members involved in developing the definitions of each of the 5 rating options were experts in the areas of scale development and validation, and care and support of older adults and their caregivers. Three of our team members have lived experience as caregivers to an older adult, and 1 team member is an older adult with mild cognitive impairment. These team members were involved in the development of rating categories and definitions, website ratings, and reconciliations, and they are coauthors on this paper. We acknowledge the potential of such a setup to introduce bias to the evaluation. On the one hand, older adults and caregivers bring a very specific lived experience that will differ from that of other team members. On the other hand, senior team members who are experienced researchers are at risk of overruling the voices of team members with lived experience. To ensure a diversity of perspectives, we included team members of diverse backgrounds, including variations in ethnocultural background, gender, lived experience, expertise, and seniority. To ensure a safe space and well-rounded discussions, the team agreed on ground rules, such as not interrupting another team member, expressing disagreements in a respectful tone, and if in doubt, giving priority to the perspectives of persons with lived experience. Older adults and caregivers are primary audiences for OHT websites, and their feedback on navigation, accessibility, and usefulness is needed for assessing how public-facing platforms function in practice.

Table . Definitions of Likert scale categories to assess the level of ease or difficulty in identifying information on websites related to services and supports for older adults and caregivers.

Likert scale category	Definition
Very easy	The website is clearly and simply designed, with easily accessible links or dropdown menus directing users to resources relevant to older adults and caregivers. The process for locating nearby services involves straightforward and intuitive steps. The language used throughout the site is clear and easy to comprehend.
Easy	The website is clearly and simply designed, featuring accessible links and dropdown menus for resources relevant to older adults and caregivers. Navigation is generally intuitive, and the steps to locate services are easy to follow. However, users may need to make several clicks before accessing the desired resources. Additionally, the presence of unrelated services may cause some confusion for users specifically seeking support for older adults or caregivers.
Somewhat easy or difficult	While some services are accessible, they are often dispersed across unrelated sections, and the website lacks specific categories for dementia care or for family and friend caregivers. Despite a visually appealing layout, the depth of information provided is limited—often restricted to a phone number or a service provider's name—offering little practical guidance.
Difficult	The website is poorly organized or lacks a coherent structure. Specific categories or groupings such as "older adults" are absent. Although a general resources or support section may exist, it includes minimal content focused on older adults, making it challenging for users to locate relevant information or services.
Very difficult	The website does not offer a dedicated resources page and may simply redirect users to external services. In some cases, users are required to submit extensive personal information to access service details, only to discover that the results may still be irrelevant to their needs.

Team members' expertise and use of an established set of criteria (theory) were measures to ensure the content validity of these categories [87,88]. Using an open-text response option, raters explained their rating in more detail. These open-text responses were used to assess the response process validity [87,88]—that is, the raters' cognitive processes when making the ratings and whether their responses reflected the intended meaning (Table 1) of the respective category. After each dyad had assessed their first website, we met as a team, compared the 2 ratings, discussed and clarified our categories and definitions if needed, discussed discrepancies, and reviewed the website in question as a team until a consensus was reached. Team members then rated the next set of websites. The process continued until all websites were assessed. Because the intended use of the rating categories was purely descriptive and qualitative, and we did not include the ratings in any statistical models, establishing construct validity (ie, association of the category ratings with other outcomes as hypothesized) [87,88] was neither possible nor applicable in the context of this study. Similarly, an assessment of the internal structure of the categories was not conducted because the categories reflected a single item only (ease of navigating the website) [87,88]. Using the prereconciliation ratings (File S2 in Multimedia Appendix 2), we calculated the interrater reliability. The overall weighted kappa value [89] was 0.80 (95% CI 0.69-0.90), indicating strong agreement [90].

Analyses

We reported frequency distributions of difficulty ratings and types of services, as well as the mean (SD) and median (IQR) number of services listed across the websites examined. Two team members independently conducted thematic analysis [91,92] of open-text responses by identifying units of meaning (eg, a phrase, sentence, or paragraph) and assigning a short label to each common theme. The 2 team members compared coding trees and interpretations. Discrepancies were resolved by consensus.

Results

Three (5%) of the OHTs did not have a website. Accessing information was very difficult on 4 OHT websites (7%), difficult on 27 (46%), somewhat easy or difficult on 17 (29%), easy on 4 (7%), and very easy on 3 (5%). File S2 in Multimedia Appendix 2 lists the difficulty rating for each OHT.

Table 2 presents the different types of services listed on the various OHT websites and the number of websites explicitly listing the respective service. Three OHTs had no website, and no services were listed on the websites of 2 OHTs. The websites of each of the other 53 OHTs listed phone numbers or online forms for people to request more information on available services, or provided weblinks to external resources listing services. However, 3 of these 53 websites (6%) provided only this information and listed no other services, 5 (9%) listed only 1 other service, and 6 (11%) listed only 2 other services. Therefore, one-third of the websites (n=19, 33%) were deemed to provide no or insufficient information on services available to older adults or their caregivers, as additional steps were needed to access the required information.

XSL•FO
RenderX

Table . Types of services and supports for older adults and their caregivers listed on Ontario Health Team (OHT) websites and the number (percentage) of websites listing each service or support.

Service or support	Websites, n (%)
Phone numbers, web links, or online forms	53 (91)
Other services or supports	40 (69)
Mental health services	39 (67)
Medical treatments	31 (53)
Caregiver supports	29 (50)
Supports for persons with dementia	22 (38)
Home care	21 (36)
Housing	9 (16)
Meal services	9 (16)
Alzheimer Society supports	7 (12)
Transportation	7 (12)
Adult day programs	3 (5)
No website	3 (5)
No services listed on website	2 (3)

Characteristics of websites that were easy to navigate and that provided easy access to information were described by raters' comments as having "clear buttons or functions for the search." Searches identified a variety of "expected services" for older adults or their caregivers. Some websites even provided information beyond the raters' expectations, such as resources for "self-advocacy, community supports, or handbooks." Simplicity of the online contact form was highlighted as a positive website feature.

In contrast, characteristics that posed challenges in navigating websites and identifying information largely referred to search functions. Often, no search function was available at all. Search functions sometimes did not work properly (eg, dead links or dysfunctional buttons), or search buttons and functions were poorly worded, potentially causing confusion and frustration for users. Raters also commented on websites that required users to follow several steps to identify the expected information. Frequently, the overall website design was cluttered and confusing, making navigation challenging. Websites regularly provided very limited information on the services available to older adults and caregivers, either listing only very few services (if any), poorly describing the service (eg, how to access it, eligibility criteria, and what exactly is offered), or only providing links to external resources for additional information.

Discussion

Our study systematically evaluated the websites of all 58 OHTs, assessing the amount, nature, and accessibility of information on services and supports for older adults or their caregivers. While we found promising best practice examples, the majority of the websites were difficult to navigate, had design issues, or contents were either not available, not helpful, or difficult to access. Overall, website designs and contents varied widely between OHTs.

Numerous studies have identified similar challenges of public health website design and accessibility [93-96]. These problems are exacerbated for caregivers, who often lack the technical skills, time, or capacity to locate the required information [97]. Caregivers for whom English is not the first language, or who have lower levels of education or health literacy, may experience particularly high barriers [98]. Well-designed websites that provide multilingual and culturally safe content and are easily accessible are critical to mitigating these barriers [99]. Otherwise, these navigation challenges may further amplify caregiver burden and distress and negatively affect their mental health [100].

Given that OHTs are required to include caregivers as advisors [46-49], our findings raise the question of why, for many OHTs, caregiver involvement has not resulted in more caregiver-friendly website designs. It is possible that caregivers may not have been involved in the particular activity of website development and that caregiver input has not been obtained on the usefulness and accessibility of these websites. Researchers have pointed out that clear guidance on principles of caregiver involvement is lacking and that the best ways to evaluate the quality of caregiver involvement constitute a critical knowledge gap [101,102]. In fact, research has reported challenges among OHTs in meaningfully engaging caregivers [54]. It is possible that, despite the guidance documents on OHT's public-facing communication [42,62], OHTs may not have identified or prioritized providing information on services and supports on their websites, but rather focused on sharing information on the OHT's development. Also, despite the fact that all 58 OHTs were approved and declared fully functioning by Ontario's Ministry of Health, a fully functioning and searchable website may not have been a major criterion in the approval process, and some of the newer OHTs may not yet have developed such a website. Regardless, the consequences for an older adult or caregiver encountering such a situation are that they will be

XSL•FO
RenderX

unable to locate the required information and will need to identify alternative resources, adding to their burden.

Other reasons for less-than-ideal website design and accessibility may be systemic barriers. Health care systems may lack the technical skills and resources (ie, funding, expertise, and infrastructure) to properly design their websites, may have a poor understanding of their users' design and navigation needs, and the exact audience and goals targeted by the websites may be poorly defined [103,104]. However, best practice guidance for health care systems to support website design is lacking, and there is a critical knowledge gap related to health care system representatives' experiences and challenges in designing these websites [103,104].

In addition to these technological and resource-related challenges, there is reason to critically question whether older adults and their caregivers were given sufficient priority in the process of establishing the OHTs. For example, OHTs were required to select a small number of target populations on which they would initially focus [42]. However, older adults and their caregivers were not mentioned as examples of potential priority populations in the guidance for OHTs [42] or in the full application [105]. As a result, many OHTs may not have selected older adults and their caregivers as priority populations, and we found very limited publicly available documentation on OHTs' selected target populations. Fourteen OHTs explicitly mentioned that older adults were 1 of their priority populations, and 11 OHTs mentioned caregivers. More importantly, while home and community care were always listed, along with other care settings, as part of the care continuum to be integrated by OHTs [38,43], it was not until early 2025 that 12 of the 58 OHTs were selected to integrate the delivery of home and community care more systematically [38]. Not prioritizing the needs of older adults and their caregivers early on, but deferring them until 6 years into the reform process, represents a clear policy decision, suggesting that older adults and their caregivers may not have been at the top of the government's priority list. Systemic marginalization of older adults [106], especially those with dementia [107], and their caregivers [17-20] has been extensively documented in the international literature, including in Ontario [108-110].

We would like to highlight and acknowledge the tremendous work OHTs have done in working toward a more integrated health care system. OHTs are part of a system, and the system's context conditions substantially influence OHTs' possibilities and limits to act. Since the 1980s, every Canadian government has followed international trends of austerity measures [20,111,112], defunding and privatizing public services (including health care services), and dismantling social safety nets [113,114]. The Canadian government has constantly reduced transfer payments to provinces, and provinces, in turn, have implemented similar austerity measures [113,114]. Ontario is no exception [108]. OHTs have struggled with engaging care practitioners who already face heavy workloads [115] and with a lack of external supports and resources [116]. In line with concerns expressed by others [117-119], we strongly believe that without addressing the root causes of health care system issues (predominantly underfunding, privatization, workforce shortages, and burnout), this reform, like others before it, may fall short of its goals. Successful examples of integrated care reforms in Europe highlight the importance of legislation for supporting governance, financial support, and policy support at all levels, from the planning stages to final implementation [120,121].

Despite these struggles, we found various encouraging best practice examples of providing clear, comprehensive, and easily accessible information on services for older adults and their caregivers. Implementing systematic mechanisms for OHTs to connect with one another and to learn from each other's successes and challenges would be an important improvement.

These factors may all contribute to the fact that various OHT websites have seen little (if any) updates since the launch of these teams in 2019 [122], but studies examining the exact reasons for this are lacking. Concerns have been raised about the accountability and public transparency of OHTs [122]. While accountability has improved, a standard method for public reporting has yet to be implemented [122]. Greater accountability and transparency across OHTs could be achieved through a standardized approach to public reporting [122], for example, by leveraging data reporting and sharing by the Canadian Institute for Health Information [123] to provide OHT-level reports on hospital, long-term care, and home and community care performance.

Our study includes several key recommendations for governments or health authorities seeking to create accessible websites to help older adults and their caregivers navigate available services and supports. Providing integrated care networks with sufficient resources, supports, and expertise will be critical in light of population aging, increasingly complex care needs, a declining number of caregivers, and increasing caregiver burden. Clear policies are required that explicitly specify criteria for accessibility and ease of navigation that websites must meet, as well as required contents that websites need to list (eg, details on services and supports, including eligibility criteria, ways to access, funding mechanisms, and so on). Mechanisms of monitoring the availability and quality of websites need to be implemented, along with measures to hold integrated care networks accountable to these criteria. Finally, older adults and caregivers should systematically be integrated into defining criteria for website accessibility and ease of navigation and in assessing whether websites meet these criteria. More research is urgently needed to understand older adults' and caregivers' experiences with accessing and navigating services in more detail, including their interactions with digital platforms. Improving the accessibility and clarity of information should be seen as part of a larger effort to make the health and social care system more navigable, equitable, and responsive to the needs of caregivers and of those they care for.

Major strengths of our study include (1) its focus on an underresearched yet important topic—the usefulness and accessibility of health care system websites from the perspective of caregivers; (2) the comparison of a wide range of health care system websites (those of all 58 OHTs) in the largest Canadian province; (3) our rigorous approach to evaluating these websites (criteria based on best practice standards for website accessibility, independent rating by 2 raters, and reconciliation

XSL•FO
RenderX

of discrepancies); and (4) the inclusion of persons with lived experience (older adults with cognitive impairment and caregivers) in our research team. However, several limitations should be noted. Involving a larger group of older adults and caregivers would have provided more comprehensive and more generalizable insights into their experiences navigating the websites. Despite our approach of independent ratings and subsequent reconciliation, website characteristics remain subjective to some extent, further limiting the generalizability of our findings. While giving persons with lived experience a strong voice was important, we acknowledge that their ratings may differ from those of researchers without such experience. However, the purpose of our study was to evaluate OHT websites from the perspective of potential users. On the other hand, our team members with lived experience are probably not reflective of the typical older adult or caregiver using OHT websites. Our team members (including those with lived experience) were students and study staff with high health literacy. Therefore, the issues we identified with OHT websites are likely underestimated compared with those that a more typical user with lived experience would encounter. We intentionally focused on older adults' and caregivers' perceptions when navigating OHT websites and did not include key informant interviews with OHT representatives. These key informants might have provided important context on OHTs' priorities and processes for website design. However, identifying representatives from each of the 58 OHTs would have been immensely time-consuming, and many of them might not have agreed to participate. This is an important area for future research, but the required efforts would not have been justified given this study's different primary focus. While websites are a critical source of information for caregivers, they may not be the only source. Some caregivers may prefer to call centralized information lines, where the quality of support may vary widely depending on the individual assisting them. Future research should examine caregivers' experiences with such helplines. Finally, websites are dynamic and subject to frequent updates. Some of the websites evaluated in this study may since have improved their accessibility and navigability.

Acknowledgments

This study would not have been possible without the invaluable support of Andrea Ubell, Director of Programs and Client Services at the Alzheimer Society of York Region, whose guidance and introduction to the 58 OHT websites were instrumental to this study's success.

Funding

This study was funded by the Helen Carswell Research Chair in Dementia Care.

Data Availability

All data used to create the results of this study are either publicly available (eg, the OHT websites), presented in the main manuscript, or supplied in supporting files available for download along with the published manuscript (eg, the website ratings or rater comments).

Authors' Contributions

MH led the conceptualization of the study, with support from HN. KC led data curation, with support from HN. MH led the formal analysis, with HN and KC contributing equally. MH acquired the funding and led the methodology. An investigation was conducted equally by HN, KC, DV, NI, SS, SY, HLS, IS, BZB, and SM. Project administration was shared equally by KC and HN. KC led validation, with support from HN. Visualization was carried out equally by HN, KC, and MH. MH led the writing of the original draft and the review and editing process, with supporting contributions from HN, KC, DV, NI, SS, SY, HLS, IS, BZB, and SM.

Conflicts of Interest

DV is a board member of an organization that is a partner of an Ontario Health Team.

Abstract

Background: Dementia caregivers often want to support aging at home, but as neuropsychiatric symptoms (NPS) become more severe, caregiver challenges increase, often resulting in negative outcomes for both the caregiver and care recipient and institutionalization. Project CARE is a manualized in-person group intervention for dementia caregivers designed to reduce negative caregiver outcomes by teaching skills to manage NPS in care recipients in the home environment. Interventions that occur in person, however, can be difficult for caregivers to attend. Telehealth-based interventions are possible alternatives that reduce barriers to attendance.

Objective: The primary objective of this pilot study was to evaluate the feasibility and acceptability of offering CARE via telehealth (TeleCARE). The secondary objective was to explore quantitative outcome trends and effect sizes postintervention outcomes of TeleCARE for both caregivers and care recipients.

Methods: Rates of recruitment, attendance, and completion were used to assess the feasibility of TeleCARE. Data on technology use and telehealth-based adaptations were also collected. Acceptability was measured using participants' rated satisfaction with the intervention immediately postintervention. Questionnaires were administered at baseline and immediately and 3 months postintervention. Primary outcomes for exploratory analysis included NPS presence, severity, and caregiver NPS-related distress. Secondary outcomes included caregiver depression, anxiety, stress, self-efficacy, positive aspects of caregiving, and meaning and purpose in life.

Results: Of the 109 caregivers contacted for recruitment, 24 (22%) caregivers enrolled in TeleCARE, and 20 (83%) caregivers, predominantly female spouses, completed the study. Feedback from participants in the TeleCARE test group 1 (n=3) was used to modify the intervention to improve the telehealth experience, including adding procedures to improve safety, encourage rapport building, address etiquette, and ensure privacy. The final version of TeleCARE included 7 weekly synchronous video sessions. Ten out of 17 participants (59%) attended all 7 sessions, and all participants attended at least 5 sessions. Satisfaction ratings suggested adequate intervention acceptability. Most participants (11/17, 65%) required technological support, which was needed throughout the intervention. Quantitative trends were observed toward postintervention decreases in care-recipient NPS severity (Cohen *d*=0.16), caregiver depression (*d*=0.15), anxiety (*d*=0.23), and caregiver self-efficacy (*d*=0.21), as well as increases in positive aspects of caregiving (*d*=0.18) and meaning and purpose in life (*d*=0.09). Most improvements were not sustained at the 3-month follow-up.

Conclusions: In this pilot feasibility study, dementia caregivers were successfully recruited and engaged in TeleCARE. Overall, TeleCARE was deemed feasible and acceptable. The current findings suggest that offering interventions via telehealth requires modifications and technological support for older caregiver engagement but is a feasible and acceptable means of offering services.

Introduction

Most individuals with dementia experience neuropsychiatric symptoms (NPS), changes in emotional expression and behavior, during the disease course [1-3]. The presence of NPS is associated with increased caregiver depression and burden and decreased quality of life for both the caregivers and care recipients [4]. Although most dementia caregivers want to keep the care recipient aging at home [5], the presence of NPS often spurs institutionalization [6-9]. The association between NPS and institutionalization has been shown to be mediated by caregiver burden and distress [8]. Interventions that teach dementia caregivers skills to manage NPS have the potential to reduce negative caregiver and care recipient outcomes and institutionalization of the care recipient [6,9,10]. However, due to caregiving demands, attending in-person interventions can be prohibitive. Telehealth offers a solution.

The resources for enhancing Alzheimer's caregiver health (REACH) study [11] is one of the most well-studied, targeted, skills-based interventions aimed at improving caregiver well-being. Participation in REACH decreases dementia caregiver anxiety, depression, and burden [12-14]. The results of REACH suggest that targeted skills-based training may be more effective than broader psychoeducational interventions [11]. CARE was designed as a briefer intervention compared with REACH. CARE is a 5-session group intervention for dementia caregivers that teaches skills to manage NPS in the home environment through behavioral management training, pleasant events scheduling, and emotional regulation techniques [15]. CARE sessions run for 90 minutes weekly and are highly structured, consisting of primarily didactic learning and practice, with some space for content-related open discussion. CARE has been shown to reduce caregiver burden related to NPS. REACH, CARE, and other similar programs demonstrate that providing dementia caregivers with specific skills training to manage NPS can be an effective way to support caregivers and improve caregiver outcomes. Unfortunately, many dementia caregiver skills training programs have historically been offered in person only, limiting accessibility for people with barriers to accessing in-person services.

Many dementia caregivers have unique barriers to in-person care. For example, in 2025, 60% of dementia caregivers were working an average 35 hours per week while caregiving [5], limiting the time available to travel to and participate in interventions. Dementia caregivers also have disproportionate financial stressors, incurring approximately 4 times the average out-of-pocket costs compared with nondementia caregivers, creating a financial barrier to using in-person services (eg, they cannot pay for gas, respite care, or take time off from work) [5]. Other dementia caregiver–specific concerns that limit in-person accessibility of services include feeling uncomfortable leaving the diagnosed individual at home and having difficulty finding respite care [16,17]. For caregivers living in rural areas, there is less awareness of available services, greater difficulties accessing transportation, and barriers related to the sheer distance needed to travel for services compared to urban caregivers [18,19]. We can address these challenges by offering interventions via video telehealth [20].

The acceptance and use of telehealth in dementia care has expanded in recent years, demonstrating positive impacts on depression, anxiety, loneliness, NPS management, and satisfaction and quality of life for both caregivers and care recipients [21]. Rapid expansion of telehealth during the COVID-19 pandemic changed the landscape of the health care system [22]. Older adults and their caregivers expressed satisfaction with telehealth and a desire to keep using telehealth postpandemic [23]. Studies of dementia caregiver telehealth support groups have demonstrated effectiveness in improving caregiver burden, reducing depressive symptoms, and increasing coping skills [24-27]. A systematic review [28] suggested that telehealth supportive interventions were potentially as effective as in-person interventions for reducing dementia caregivers' depression, anxiety, stress, and improving self-efficacy. One recent meta-analysis and systematic review [29] specifically investigating the effectiveness of telehealth skills training for management of NPS in dementia found improvements in caregivers' ability to manage NPS, quality of life, and stress levels.

The primary goal of this study was to evaluate the feasibility and acceptability of offering CARE via a telehealth format (TeleCARE) to reduce many of the current barriers that dementia caregivers face in accessing skills training to manage NPS. Keeping the small sample size of this pilot study in mind, the second objective was to explore quantitative outcomes of TeleCARE with trends and effect sizes.

Methods

Participants

We recruited participants from the Bedford, Massachusetts, and Manchester, New Hampshire, Department of Veterans Affairs Medical Centers and surrounding communities using posted informational flyers. We also reviewed Veterans Affairs (VA) medical records to identify veterans with dementia and mailed recruitment letters to their homes and followed up with phone calls. Criteria for study inclusion were (1) providing informal care for someone with self-reported or physician-confirmed diagnosis of dementia, (2) at least 1 caregiver-reported NPS for the care recipient at the time of enrollment, (3) provision of a minimum of 5 hours per week of direct caregiving, and (4) access to a computer or tablet and internet or Wi-Fi. Participants could be caregivers of veterans with dementia or veterans caring for someone with dementia.

Pilot and feasibility work typically aims to explore recruitment, engagement, and practicality rather than statistical power [30,31]. Therefore, for this pilot study, the focus was on testing feasibility and acceptability rather than testing hypothesis-driven significance with associated power calculations for sample size. To accomplish these goals, we selected a target enrollment of 24 caregivers.

Ethical Considerations

This study was approved and monitored by the VA Bedford Health Care System Institutional Review Board (study no. 1598706). Written informed consent was obtained from all study participants. Privacy and confidentiality of all research

XSL•FO
RenderX

participants' data and identities were maintained using multiple methods, including using a Health Insurance Portability and Accountability Act–compliant web-based platform with end-to-end encryption, coding data so that only the research team had access to identifiable information, storing data securely behind the VA firewall and restricting access to the study team, analyzing coded data and reporting data in aggregate form, and establishing ground rules during group sessions to help participants protect their privacy. Participants received US $25 for completing each of the baseline and postintervention follow-up visits, and US $50 for completing the 3-month follow-up visit, receiving a possible total of US $100 to compensate for their time.

Methodological Adaptations, Procedures, and Intervention Description

Initially, we intended to conduct preintervention, in-person sessions to obtain written consent and complete baseline assessments, as well as to provide in-person instruction about technology use. However, prior to the start of the study, the COVID-19 pandemic forced us to convert all study visits to a virtual format. We added a preintervention live video session to provide technology instruction before the start of groups. Individual assistance to help participants access the initial tutorial was provided as needed by phone. Follow-up data collection visits were conducted by video immediately and 3 months post-treatment. Participants were compensated for their time.

A trained interviewer met with each eligible caregiver via video to explain the study, answer questions, review the Health Insurance Portability and Accountability Act authorization, and sign the informed consent forms. The interviewer also provided initial training on using the videoconferencing platform. During the same visit or a second visit, depending on participant preference, the interviewer administered the baseline questionnaires. Questions were presented visually via PowerPoint (Microsoft Corp) one at a time and read aloud. Participant responses were recorded in VA REDCap (Research Electronic Data Capture), a secure data management software, in real-time. After baseline assessment, a printed TeleCARE manual was mailed to the participant. All caregivers began the intervention within 6 weeks of baseline assessment. The collection of immediate and 3-month follow-up data followed the same procedures as baseline data collection. Additional supplemental visits took place by video or phone as needed to help participants troubleshoot technology issues. All video visits were conducted via Health Insurance Portability and Accountability Act–compliant, encrypted, VA-approved videoconferencing platforms.

TeleCARE was adapted from the original manualized CARE intervention [15]. As in CARE, TeleCARE groups met weekly for 90-minute sessions. At the beginning of each session, a doctoral-level occupational therapist leading the groups went through a series of prompts specific to telehealth to ensure safety and confidentiality during the session. Participants were given time during each session to discuss homework, troubleshoot any problems that may have arisen when attempting to use new skills, and offer each other support and advice.

The intervention was delivered to caregivers in 6 groups that ran sequentially from June 2021 to September 2022. We started with an initial TeleCARE test group (TeleCARE-test) to troubleshoot any issues before the formal pilot. TeleCARE-test participants reported that the 5 sessions did not provide adequate time to cover all the intervention material and allow for discussion. In response, we reviewed all intervention sessions to determine the number of additional sessions needed. The finalized program was extended to 7 sessions. Table 1 provides a summary of each session included in the final manualized intervention. Other intervention-specific modifications to adapt the program to the telehealth setting were made based on the experiences of the study team and feedback from the TeleCARE-test group. At the beginning of each session, we added unique steps to ensure participant safety in the telehealth setting. These steps included gathering information about where the participant was located in the event of a psychological (eg, expressed suicidal intent) or medical (eg, cardiac arrest) emergency. Unlike in-person interventions, telehealth interventions require the provider to know where the participant is located if the need arises to alert emergency services (eg, local police). The group leader also asked for updated contact information at the start of each session for participants joining from a new, unknown location. This information was provided to the group leader through secure chat to maintain privacy. The interventionist encouraged all participants to sign into the platform with their first name to facilitate group rapport. It became clear that video-specific etiquette guidelines should be added to the first session, including muting oneself when not speaking, using the raise hand feature, remaining primarily stationary during the group (eg, not walking around with the video device), and reducing background distractors (eg, television, pets, children). Participants were also asked to locate themselves in a suitable space to reduce privacy concerns (ie, a location where they could not be overheard discussing personal information). Finally, the need for broad technological support for older adults enrolled in TeleCARE. In response, we added a technology tutorial session before the intervention started, as noted above, and access to ongoing support as needed.

Table . Telehealth adaptation of CARE (TeleCARE) group sessions.

Session	Description
1 - 2	*Introduction*: Caregivers introduce themselves to begin building group cohesion. Facilitators review dementia and caregiver burden, with a focus on neuropsychiatric symptoms, the importance of increasing pleasant activities as one method for improving care recipients' behavior, and the caregiver–care recipient relationship. Facilitators present a Pleasant Activity Log.
3	*Increasing Pleasant Activities and Improving Communication*: Discuss the importance of engaging in pleasant activities, suggest common pleasant activities and strategies for generating personally meaningful pleasant activities, and provide education about how to increase pleasant activity engagement. Introduce strategies to improve communication. *Caregiver Homework*: Engage in one new pleasant activity daily and record it, generate additional ideas for pleasant activities, and compliment the care recipient at least once per day.
4 - 5	*Increasing Pleasant Activities and Understanding Behavior*: Review homework and problem-solve any difficulties with homework. Review strategies for increasing pleasant activities. Introduce behavioral management theory and teach participants to identify antecedents, behavior, and consequences (ABCs) to assist with behavior management. Discuss triggers for problem behaviors and how they can be avoided. *Caregiver Homework*: Engage in one pleasant activity daily. Identify and record 3 patient problem behaviors.
6	*Understanding and Changing Difficult Behaviors*: Review homework and problem-solve any difficulties with homework. Practice goal setting and methods for changing problem behaviors in the home. *Caregiver Homework*: Engage in 2 pleasant activities daily. Choose one difficult behavior and attempt to modify it.
7	*Final Review*: Review homework and problem-solve difficulties caregivers had while modifying behaviors at home. Provide guidance on how to continue using these new skills in the future. Caregivers discuss and explore plans for future use of strategies. Celebrate completion of the group, participant contributions, personal growth, challenges, and willingness to participate.

Measures

Following CONSORT (Consolidated Standards of Reporting Trials) guidelines [32] and the proposed guidelines for reporting feasibility study outcomes [33], we collected multiple measures of study feasibility, including recruitment rates, session attendance rates, study completion rates, and a formal rating of the acceptability of the intervention. Given our interest in the telehealth adaptation, we also collected data on technology use. Participants completed outcome measures at baseline, 1 to 2 weeks immediately after the intervention, and 3 months postintervention.

At baseline, caregivers completed a demographic and historical information survey, providing information about themselves and the care recipient. Caregivers also completed [1] the clinical dementia rating sum of boxes [34], a 5-point interview that characterizes 6 domains of the care recipient's cognitive and functional performance and disease severity.

At baseline, immediate follow-up, and 3-month follow-up, caregivers were asked to report on the presence of the care recipient's NPS and functional abilities. The Lawton Instrumental Activities of Daily Living (IADL) Scale [35] assesses the functional capacity of the care recipient in 8 domains of functioning. Scores total from 0 to 8, with higher scores indicating greater functional independence. The NPS inventory questionnaire [36] measures both the presence and severity of the care recipient's NPS and the caregiver's distress related to NPSs. Caregivers were also asked to complete measures related to their own well-being. These included the Beck Depression Inventory-II [37], a 21-item scale to assess the severity of depressive symptoms, and the Beck Anxiety Inventory [38], a 21-item scale to assess the severity of anxiety. The revised Caregiver Self-Efficacy Scale [39] is a 15-item scale exploring caregiver self-efficacy in obtaining respite, responding to patients' disruptive behaviors, and controlling upsetting thoughts. The positive aspects of caregiving (PAC) questionnaire [40] consists of nine items that load onto two factors, self-affirmation and outlook on life, and assesses positive reflections on caregiving. The Relative Stress Scale [41] consists of 15 items and can be divided into 3 subgroups of emotional distress, social distress, and negative feelings. The meaning in life questionnaire [42] is a 10-item self-report assessment designed to measure the presence of and search for meaning in life.

At immediate follow-up only (ie, immediately after completing the TeleCARE intervention), participants also completed the

XSL•FO
RenderX

client satisfaction questionnaire (CSQ-8) [43] to capture the acceptability of the intervention.

Data Analysis

The primary objective of this pilot study was to assess the acceptability and feasibility of TeleCARE. Descriptive statistics were used because the goal was to explore trends rather than test hypotheses, as appropriate for the pilot stage of the current project. As such, we explored numerical trends and effect sizes of outcome variables. Descriptive statistics are reported to characterize the sample and summary scores for each measurement time point (baseline, post-treatment, and a 3-mo follow-up). Cohen *d* effect sizes were calculated to compare changes from baseline to post-treatment and from baseline to 3-month follow-up. All statistical analyses were conducted using SAS software (version 9.4; SAS Institute Inc). Given the early stage of this investigation, data from the TeleCARE test group were excluded; analyses only included participants in groups 2 to 6 who completed the final format of the TeleCARE intervention (n=17). An intent-to-treat approach was not used for this preliminary feasibility investigation.

Results

Participant Characteristics

Participants included 17 White caregivers (100%), who were predominantly female (n=13, 76%) and spouses (n=14, 82%), with a mean age of 71.8 (SD 12.58) years. All caregivers lived with the care recipient (n=17, 100%), and nearly all caregivers (n=16, 94%) reported providing the majority of care. Care recipients had a mean age of 77.7 (SD 4.84) years, were White (n=17, 100%), male (n=15, 88%), and had a mean clinical dementia rating sum of boxes score of 10.8, indicative of moderate dementia severity [44]. See Table 2.

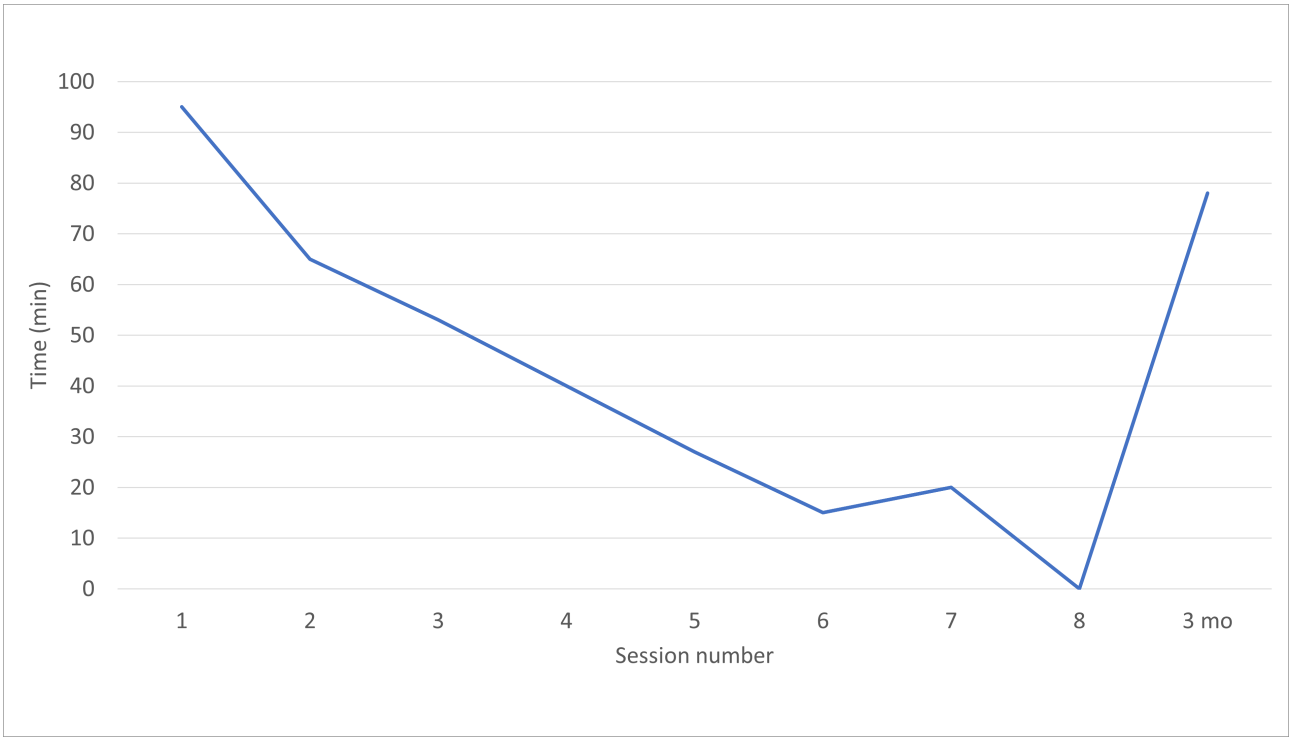
Feasibility Results: Recruitment, Enrollment, Attendance, and Retention

Of the 109 caregivers contacted for recruitment, 24 did not respond, 15 did not meet eligibility criteria, 38 declined participation, and 8 had other reasons (Figure 1). Among those who declined (38/109, 35%), the most common reason was that they felt that the intervention was not needed (20/38, 53%). The second most common reason was lack of time (11/38, 29%). The remaining provided no reason (3/38, 8%), said they were not interested (3/38, 8%), or reported a technological barrier (1/38, 3%). Of those that gave other responses (8/109, 7%), 5 said that their loved one was deceased when we contacted them, 2 had been admitted to long-term care, and 1 had recently been diagnosed with cancer. Overall, 24 caregivers (24/109, 22%) were enrolled in the study, with 4 in the TeleCARE-test group 1 and 20 in intervention groups 2 to 6. Across groups 1 to 6, 20 caregivers (20/24, 83%) completed the study. Of the 4 noncompleters, 1 was from the TeleCARE-test group 1, and 3 were from groups 2 to 6. Two of 4 noncompleters withdrew because they disliked the group setting. The remaining 2 noncompleters had medical issues arise that prevented continued participation (1 during the intervention and 1 prior to the start of the intervention but after study enrollment). Because the TeleCARE test group 1 was treated as a test group and subsequent changes were made to the intervention after their feedback, completers from TeleCARE test group 1 (3/4) were not included when reporting intervention attendance or exploratory quantitative analysis presented below. Of those within groups 2 to 6 (n=17), 10 attended all 7 sessions (10/17, 59%), 5 attended 6 of 7 sessions (5/17, 29%), and 2 attended 5 of 7 sessions (2/17, 12%). Occasionally, a participant arrived late, most commonly due to technological difficulties.

Figure 1. CONSORT (Consolidated Standards of Reporting Trials) flow diagram.



XSL•FO
RenderX

Feasibility Results: Technology Support

To assess the acceptability and feasibility of the telehealth adaptation, data were collected to better understand participant experiences related to the use of technology. Overall, 11 of 17 participants (65%) required some degree of technology support. As mentioned above, a study staff member was assigned to provide personalized technology assistance as needed. Examples of when assistance was needed included helping participants turn on the power if a tablet was provided, access their email and click the video-meeting link, retrieve and/or reset their password, turn on their camera, use the mute and unmute function, and use the raise hand feature. One study participant had no prior experience with technology and needed assistance at all levels, from setting up an email account to using the device. The largest amount of technological assistance was required at session 1, dropping considerably by session 2. Participants needed less support with each passing session, although some continued support remained necessary at almost all time points. Participants reported feeling a sense of accomplishment and increased comfort with technology at the conclusion of the study. At the 3-month follow-up visit, 3 of 17 participants (18%) required assistance with technology, which was an increase compared with session 7 of the intervention. This finding suggests that most study participants were able to retain the taught skills, even after 3 months, while a minority of participants experienced a decay in skills. Figure 2 provides a visual depiction of the amount of time spent providing technological assistance across all sessions for intervention groups 2 to 6.

Figure 2. Total duration of technology assistance given before each session for all participants in groups 2 to 6.

Intervention Acceptability

Smith et al [45] proposed the following guidelines for the interpretation of overall CSQ-8 scores into 4 levels of client satisfaction: “poor” (scores 8 - 13), “fair” (scores 14 - 19), “good” (scores 20 - 25) and “excellent” (scores 26 - 32). The mean CSQ-8 score was 22.3 (SD 1.08), suggesting good intervention acceptance.

Outcome Trends

As mentioned previously, this study was not adequately powered to detect statistical significance, as appropriate for the pilot stage, and the focus was on identifying numerical trends and examining effect sizes. Table 3 provides the mean scores of measures completed at every time point (n=17; also see Table S1 in Multimedia Appendix 1). Between baseline and immediate post-treatment time points, caregivers reported a decline in the care recipient’s ability to complete IADLs. There was no substantial change in the number of NPS reported by the caregiver, though there was a trend towards a decrease in the reported severity of NPS (Cohen d=0.16). Regarding caregiver psychological well-being, trends between baseline and post-treatment time points included a decrease in depression and anxiety symptoms and an increase in PAC and meaning and purpose. In fact, the largest effect between baseline and post-treatment was a decrease in anxiety. Participants reported little change in relative stress. Interestingly, despite improvements in psychological well-being, participants reported a decrease in caregiving self-efficacy between baseline and post-treatment, with the decrease in self-efficacy having the second largest effect size of the outcome measurements. Except for a statistically significant decrease in caregiver self-efficacy (t_{16}=2.17, P=.045, Cohen d=0.21), no outcomes were statistically significant.

RenderX

Table . Changes in clinical and psychological measures.

Measure	Baseline, mean (min-max)	Posttreatment, mean (min-max)	3-month follow-up, mean (min-max)
IADL[a]	1.9 (0 - 5)	1.6 (0 - 4)	1.5 (0 - 3)
NPI[b]			
Total	6.9 (4-10)	6.8 (2-11)	7.1 (3-10)
Severity	15.5 (6-28)	14.5 (5-28)	15.7 (5-28)
Distress	26.8 (10-46)	25.7 (9-53)	25.8 (9-45)
BDI[c]	8.8 (1-33)	7.6 (0 - 30)	8.5 (0 - 26)
BAI[d]	8.3 (0 - 25)	6.6 (0 - 29)	9.6 (0 - 40)
PAC[e]	34.6 (26-45)	35.8 (26-45)	34.4 (23-45)
RSS[f]	25.9 (9-47)	26.1 (11-42)	25.2 (9-45)
CSES[g]	1347.8 (880 - 1820)	1280 (730 - 1840)	1329.4 (900 - 1840)
MPL[h]	37.9 (17-57)	39.3 (23-62)	39.8 (27-55)

[a]IADL: Instrumental Activities of Daily Living.

[b]NPI: neuropsychiatric inventory.

[c]BDI: Beck Depression Inventory.

[d]BAI: Beck Anxiety Inventory.

[e]PAC: positive aspects of caregiving.

[f]RSS: Relatives' Stress Scale.

[g]CSES: Caregiver Self-Efficacy Scale.

[h]MPL: meaning and purpose in life.

Between baseline and 3-month follow-up, participants reported further decline in IADLs for the care recipient and an increase in NPS. In addition, most improvements reported between baseline and immediate post-treatment were lost by the 3-month follow-up. Participant meaning and purpose in life was the only improvement maintained from post-treatment to the 3-month follow-up. None of the changes between baseline and the 3-month follow-up visits were statistically significant.

Discussion

Feasibility and Acceptability

In this pilot study, we were able to recruit dementia caregivers and engage them in a telehealth adaptation of CARE (TeleCARE). Twenty caregivers completed TeleCARE, including 3 from an initial test group that informed intervention modifications, leaving 17 caregivers in the final intervention group. Caregivers were predominantly older female spouses of the care recipient. Most enrolled caregivers attended all sessions, suggesting that caregivers who engaged in the program stayed engaged throughout. Likewise, satisfaction with the intervention was good. Preliminary quantitative trends suggested immediate postintervention improvements in caregiver outcomes. Overall, TeleCARE was deemed feasible and acceptable, with preliminary quantitative results suggesting that TeleCARE has the potential for a larger-scale study. Future studies of TeleCARE could harness digital recruitment methods for scalability.

Importantly, intervention adaptations had to be made to successfully implement TeleCARE, including both intervention telehealth-specific modifications and the provision of broad technology support. Related to the modifications, previous research emphasizes the importance of safety and risk management, participant privacy, and platform etiquette in telehealth contexts. Telehealth inherently presents unique challenges compared to in-person care, including limited immediate clinical support and barriers to emergency response due to geographic variability and licensure restrictions [46-48]. Presession safety protocols, such as verifying participant location and emergency contacts, are increasingly recommended to mitigate risks during psychological or medical crises [47]. In addition to safety considerations, given evidence that clinical outcomes in telehealth are often comparable to in-person care, researchers emphasize the importance of replicating in-person standards through structured telehealth delivery [49], such as minimizing distractions, limiting movement, and encouraging stationary participation. Privacy concerns also remain central, with recommendations for participants to join from secure, confidential environments to protect sensitive information and foster psychological safety [48,50].

Compared with younger counterparts, older adults tend to have lower digital literacy, which presents a barrier to engaging in telehealth services [51]. Even after adding an initial (before the start of the intervention) technology tutorial session, the majority of study participants (11/17, 65%) required technological support, and though less support was needed after each passing session, some participants required ongoing support throughout.

XSL•FO
RenderX

Digital literacy training programs for older adults have emerged in response to the recognized need to improve access to technology-based services [52-54]. Many studies have found that older adults want to engage with technology and not feel left behind as digital opportunities increase [55]. At study completion, participants reported feeling a sense of accomplishment related to learning to use the necessary technology and increased comfort with technology, highlighting the ability of older adults to engage with technology with individualized and ongoing support.

It is worth noting that half of the caregivers who declined to join the group stated that they did so due to a lack of time, despite the program being less than a 2-month, 90-minute weekly commitment offered via telehealth, thereby minimizing the time needed to travel. Dementia caregivers consistently identify time constraints as a major barrier to participating in interventions [56-58]. Many caregivers report prioritizing the needs of the care recipient over their own and neglecting self-care, thereby reducing opportunities to participate in supportive services [59-61]. Recent research suggests that brief, flexible, telehealth-based interventions may help boost caregiver engagement [62]. The current findings suggest that offering interventions via telehealth may be only one small step toward improving intervention engagement and that brevity and flexibility may play a bigger role in helping to engage busy caregivers. In addition, finding innovative ways to increase respite time for caregivers so they can engage in supportive services offers promise. For example, Iacob and colleagues [63] demonstrated that an online scheduling and planning program with virtual coaching and education helped increase caregiver respite [63].

Outcome Trends

Although the study was not powered to statistically test changes between pre- and posttreatment, quantitative results suggested trends toward a decrease in NPS severity in care recipients, a decrease in caregiver depression and anxiety, and an increase in caregiver-expressed PAC and meaning and purpose in life after intervention completion. However, most improvements were not sustained by the 3-month follow-up. Also of note is the reduction in caregiving self-efficacy following intervention engagement, which may be unexpected. However, when learning new skills, individuals often experience initial failures early in the learning process. Although these failures are part of the growth necessary to learn new skills, failures can lead to temporary reductions in self-efficacy [64]. It is possible that caregivers in TeleCARE experienced reduced self-efficacy related to their initial unsuccessful efforts applying new skills. Caregivers may also have attributed their successes largely to the presence of the interventionist, causing self-efficacy to decline postintervention when transitioning to applying skills independently. In addition, skills may decay between the conclusion of an intervention and longer-term follow-up (in the current study, 3 mo), which can lead to further reductions in self-efficacy [65,66]. Future studies aimed at better understanding the conditions for gains in self-efficacy and sustainment of those gains are warranted. In addition, future trials of TeleCARE could incorporate theoretically driven self-efficacy enhancement techniques based on Bandura's four identified self-efficacy enhancing methods (mastery experience, modeling, social persuasion, altering emotional/somatic states) [67], while retaining the basic intervention elements.

Limitations and Future Directions

The major limitation of the current study is the homogeneous sample, which reduces generalizability. All of the participants in this study were white, mostly female, and primarily spouses of the individuals receiving care, with at least some college education. This fact limits the applicability of our findings to caregivers from diverse ethnic, cultural, and socioeconomic backgrounds.

Studies have found that the perception of caregiver differs for different cultures and, for those with more deprived socioeconomic disadvantage, knowledge about dementia may be low [68-70]. Intervention adaptations that take into account ethnic or cultural considerations and differences related to medical privacy, preferences for keeping the person with dementia at home, the role of religion, and the use of holistic or non-Western medicine approaches to care would be important to consider in future trials of TeleCARE [71-73]. TeleCARE may need to be adapted for caregivers with lower levels of education and lower income associated with limited or inadequate health literacy [74,75]. Of course, adapting the intervention for non-English speaking populations would improve reach. The original CARE intervention was successfully culturally and linguistically tailored for a Latino population and could serve as a basis for a TeleCARE adaptation in future trials [76]. Importantly, and aligned with the focus of telehealth adaptations, racial and ethnic minority caregivers and those with lower educational attainment are less likely to have access to technology (eg, stable internet connectivity, computer, smartphone) and the skills needed to engage with technology, and specific efforts to explore the use of telehealth for diverse cohorts of dementia caregivers is critical [77-80]. Building community partnerships for intervention adaptation, outreach, and recruitment can help strengthen future trials.

The predominantly female participants in the current intervention limit our ability to fully capture male caregivers' experiences. Male caregivers may differ in their use of coping strategies, emotional responses, and support-seeking behaviors, with literature suggesting a greater tendency to use problem-focused strategies, seek help earlier, and prioritize having time for themselves, engaging in personal activities that may buffer caregiving stress [81,82]. As caregiving intensity increases, male caregivers may experience higher burden than their female counterparts, who often develop caregiving-related stress earlier in the process [81-83]. Thus, interventions that have predominantly female participants may differ significantly from a predominantly male group. The current study also included predominantly spousal caregivers. Adult child caregivers face distinct challenges, including the need to balance caregiving responsibilities with employment and parenting obligations [84,85]. Future research should continue exploring these subgroup differences to tailor interventions accordingly.

In summary, we successfully adapted an existing evidence-based, in-person, manualized dementia caregiver intervention (CARE) for synchronous video telehealth

XSL•FO
RenderX

demonstrating good feasibility and acceptability. Successful adaptation required revising the manualized protocol to include procedures to ensure participant safety, etiquette instructions to improve group experience, and technological support to increase accessibility. These findings suggest that when attempting to transition an in-person program to video telehealth, these broad program-nonspecific adaptations should be considered. The important need for ongoing, available technological assistance was particularly salient.

Funding

This study was funded by the Alzheimer's Association Research Grant (AARG; number AARG-20 - 685186; SDS, principal investigator). The study was supported by resources and the use of facilities at the VA Bedford Health Care System and New England Geriatric Research, Education, and Clinical Center. The contents of this paper do not represent the views of the Department of Veterans Affairs or the United States government.

Abstract

Background: While telecare has considerable potential to improve home care services, benefit older adults, and support informal caregivers, its adoption remains limited. There is also a notable gap in empirical research on the factors that influence informal caregivers' behavioral intention to use telecare. In particular, existing theoretical acceptance models are insufficiently comprehensive, as they do not specifically address informal caregivers of older adults and have largely overlooked the psychosocial outcomes of engaging with telecare.

Objective: This study examined the behavioral intention of Slovenian informal caregivers of older adults to use telecare, focusing on the preuse stage of technology acceptance, by integrating the perceived psychosocial outcomes of telecare engagement (peace of mind, reduced anxiety, sense of safety, and perceived connectedness with the care recipient) into the Unified Theory of Acceptance and Use of Technology (UTAUT) model.

Methods: The study applied nested ordinary least squares regression analysis to survey data collected in 2021 in Slovenia from informal caregivers of older adults, all of whom were aged 40 years or older. Of 612 respondents in the dataset, 558 were retained after excluding current or former users of care-related assistive technologies; the regression analyses were based on the 526 participants with complete data on all model variables.

Results: The regression analysis used 3 nested models to examine predictors of the intention of informal caregivers of older adults to use telecare. The first model, which included only background variables (burden of care, financial coping, and caregiver sociodemographic characteristics), had limited explanatory power (R^2=0.03), with financial coping as the only significant predictor (β=−0.14, P=.005). Adding UTAUT predictors significantly improved the model's fit (R^2=0.49). Performance expectancy (β=0.52, P<.001), facilitating conditions (β=0.11, P=.005), and social influence (β=0.21, P<.001) emerged as additional significant predictors. Incorporating perceived psychosocial outcomes further improved the model's fit and increased the explained variance (R^2=0.54); this additional factor also showed the strongest association (β=0.41, P<.001). Patterns for the other predictors remained consistent across models, but including perceived psychosocial outcomes substantially reduced the coefficient for performance expectancy.

Conclusions: In this cross-sectional sample, perceived psychosocial outcomes were the predictors most strongly associated with behavioral intention in the extended UTAUT model, indicating that they may be important factors in understanding telecare acceptability among informal caregivers. The findings suggest that developers, policymakers, and health and social care providers should consider not only functional aspects of telecare but also the psychosocial needs of informal caregivers. As the study measured self-reported intention at the preuse stage rather than actual use, longitudinal and behavioral research is needed to establish whether these associations translate into telecare adoption.

Introduction

Background

Population aging and the increasing prevalence of multiple chronic conditions among older adults are amplifying demand for caregiving services [1,2]. In this context, informal caregivers, who provide unpaid care to someone with a long-term illness, disability, or other long-lasting health or care need outside professional or formal frameworks, are essential [3]. Globally, the number of individuals providing such care is increasing [4,5], with informal caregivers representing a substantial share of the population in many countries, such as 9% in the United Kingdom and 11.5% in the United States [6-8]. In Europe, they provide 80% of all care [3,9,10], making them the largest providers of social care. In Slovenia, informal caregivers form the backbone of the long-term care system [11], with 23.6% of the adult population providing informal care to older adults [12]. This reflects a familialist care model in which the caring responsibilities for older people primarily fall on the family [13,14]. Despite this reliance, strong policies to support and facilitate these responsibilities are lacking [3,11,14].

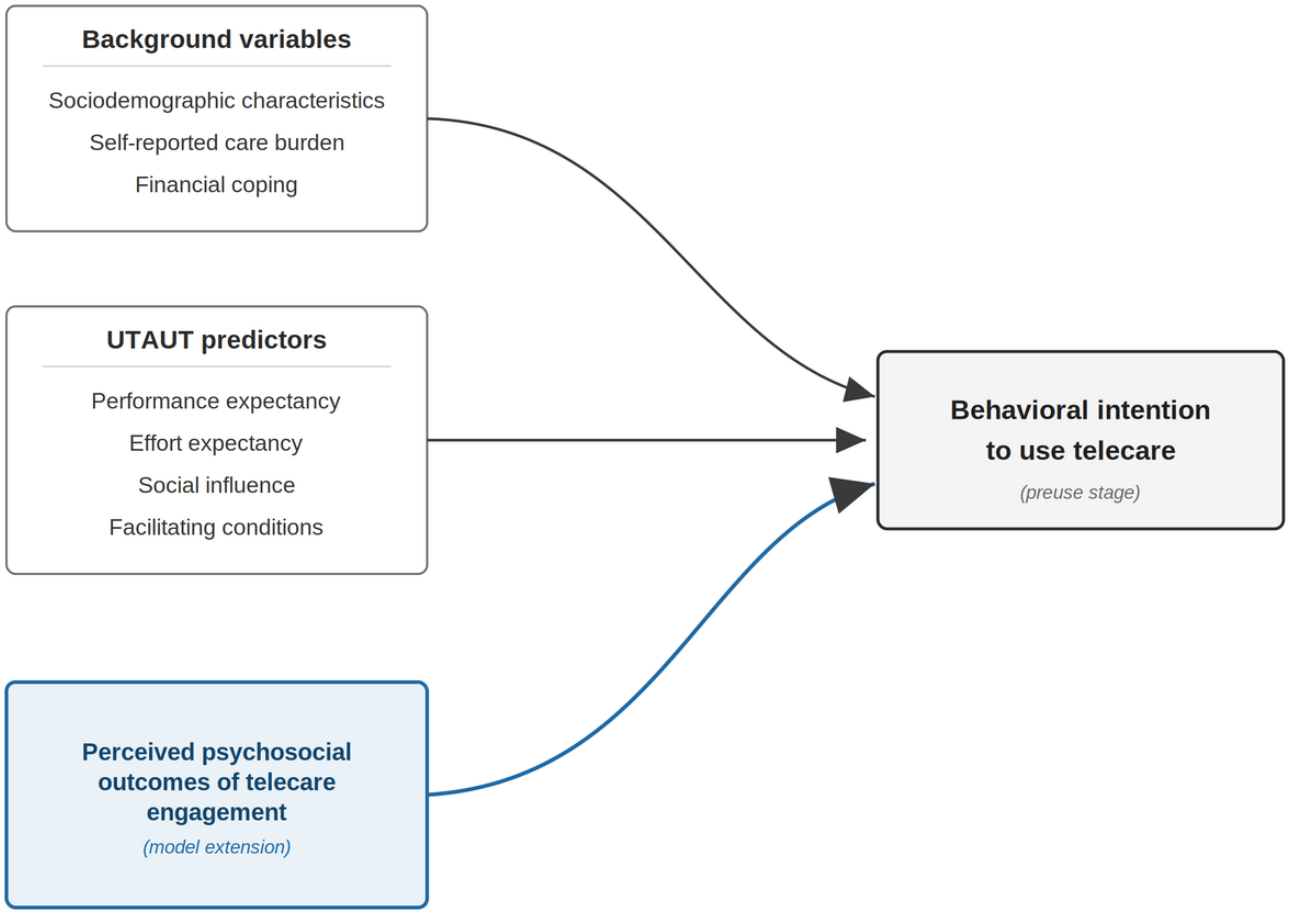
Caregiving responsibilities can be extensive and demanding. They often place a significant burden on informal caregivers and affect their physical and emotional well-being [11,15-18]. They are likely to experience significant stress when they lack the internal and external resources needed to manage their caregiving responsibilities [19].

In this context, there is growing evidence supporting the potential benefits of telecare solutions in empowering and supporting informal caregivers [9,10,20-24]. In informal care for older adults, the term telecare refers to services that use digital technologies to enable older people to live more independently and safely in their homes for longer [25,26]. Telecare encompasses many services and devices that use digital technology to provide remote health care and social support, including personal alarm systems, trackers, environmental sensors, and reminders. Such services can also help informal caregivers manage their caregiving responsibilities more efficiently while offering peace of mind by providing reassurance about the well-being of the person they care for [25,26]. These technologies can thus represent supportive external resources that can relieve some of the pressure on informal caregivers.

While telecare has considerable promise for improving home care services, benefiting older people, and helping informal caregivers, its adoption remains limited [20,23,26]. Nevertheless, according to a report by Berg Insight [27], the number of telecare users in Europe was 9.0 million at the end of 2023 and is expected to exceed 13.1 million by 2028. This growth, fueled by an aging population and the increasing prevalence of chronic diseases [1,2], indicates the scale of potential telecare use. Notwithstanding the growing need and potential demand, several challenges hinder the wider implementation of telecare solutions [9,28,29]. In particular, their acceptability to informal caregivers is a key barrier [16,25,26,30].

Theoretical Framework and Goal of the Study

Although telecare offers significant potential in informal caregiving, there is a lack of research into the factors that influence informal caregivers' behavioral intention to use it [23,26]. Existing research in this area typically focuses on the classic variables of technology acceptance models: usefulness and ease of use. Several theoretical models have been applied to explore the factors influencing the intention to use telecare [31-34], including the health belief model [35], theory of reasoned action [36], theory of planned behavior [36], diffusion of innovations theory [37], domestication theory [38], technology acceptance model [39], and Unified Theory of Acceptance and Use of Technology (UTAUT) [40]. Among these, UTAUT was selected as the theoretical framework for this study because it integrates key determinants from earlier technology acceptance models and has been widely applied in studies examining the acceptance of digital health and assistive technologies, including research involving informal caregivers [32,41].



While UTAUT provides a solid foundation for examining factors influencing the intention to use telecare, it was not specifically developed to explain telecare use among informal caregivers of older adults and therefore does not adequately capture factors particularly relevant in health care settings [42] and informal caregiving contexts [43]. Furthermore, it and other telecare acceptance models have largely overlooked the psychosocial outcomes [23,43] associated with telecare engagement, such as peace of mind, reduced anxiety, and a sense of safety. These outcomes are particularly relevant in informal caregiving contexts because telecare technologies are often valued not only for functional support but also for the emotional reassurance they provide to caregivers [23,44-47]. Psychosocial outcomes of telecare engagement refer to the mediating effects of both internal factors (such as psychological and emotional responses) and external sociotechnical environments on an individual's social and psychological well-being [48-50]. In this context, telecare is part of the sociotechnical environment that shapes informal caregivers' responses while delivering unpaid care to older adults within a particular social and structural framework. The psychosocial outcomes of telecare engagement can then affect psychological and social functioning, feelings, behaviors, relationships, interactions, and cognitive processes [51]. A recent scoping study [23] identified peace of mind, reduced anxiety, a sense of safety, and perceived connectedness with the care recipient as the most common psychosocial outcomes of telecare engagement among informal caregivers.

To address the limitations of UTAUT and other acceptance models in this field and to enhance understanding of telecare acceptability among informal caregivers of older people, this study aims to integrate the perceived psychosocial outcomes of telecare engagement into the UTAUT model. The dependent variable in the UTAUT model is the behavioral intention to use telecare, defined as a measure of the strength of one's intention to perform a specified behavior [40,52-54]. Behavioral intention refers to a person's motivation to engage in a specific behavior [52]; the more a person is willing to perform a particular behavior, the more likely it is that the behavior will be performed [53,54].

XSL•FO
RenderX

The aim of this study is, therefore, to examine the behavioral intention of Slovenian informal caregivers of older adults to use telecare by integrating perceived psychosocial outcomes into the UTAUT model. According to the UTAUT model, behavioral intention is influenced by performance expectancy (the degree to which using the system is perceived to improve performance), effort expectancy (the degree of ease associated with system use), social influence (the degree to which important others are perceived to influence its use), and facilitating conditions (the degree to which resources and support are perceived to be available) [40]. We extend this model by including perceived psychosocial outcomes of telecare engagement as an additional predictor (Figure 1). Based on prior research [23,25,55-57], we hypothesize that perceived psychosocial outcomes will positively predict the behavioral intention to use telecare.

Figure 1. Conceptual model of telecare acceptability among informal caregivers, extending the Unified Theory of Acceptance and Use of Technology (UTAUT) framework with perceived psychosocial outcomes. The blue box represents the model extension. Perceived psychosocial outcomes comprise 4 indicators: peace of mind, reduced anxiety, sense of safety, and perceived connectedness with the care recipient.

This study thus addresses the following research question: how are background characteristics (sociodemographics, self-reported care burden, and financial coping), UTAUT constructs (performance expectancy, effort expectancy, social influence, and facilitating conditions), and the perceived psychosocial outcomes of telecare engagement associated with the behavioral intention of Slovenian informal caregivers of older people to use telecare? The study makes a theoretical, methodological, and practical contribution by extending the UTAUT model with psychosocial outcomes, providing empirical evidence on telecare acceptability among informal caregivers of older people in Slovenia, and offering insights relevant to the design and implementation of telecare solutions.

Following the technology acceptance lifecycle [43], which conceptualizes technology acceptance as a staged process, this study focuses on the initial preadoption stage (termed “preuse acceptability” [43]), which occurs prior to the actual first use of the technology, rather than on actual use or postadoption experiences. The research concentrates on 4 distinct telecare functionalities, grouped into 2 main categories: personal alarm systems, comprising the emergency call button and automatic fall detection, and mobility-related devices, comprising home activity sensors and location-tracking devices. Telecare acceptability is thus captured through behavioral intention to use, reflecting caregivers’ motivational readiness to use the technology in the preuse stage.

Methods

Study Design

The study population was Slovenian residents aged 40 years or older who had provided at least 4 hours of unpaid care per week to a family member or relative aged 65 years or over during the previous 6 months. The lower age threshold of 40 years was applied because international evidence indicates a higher prevalence of informal caregiving in this age group [58,59],

XSL•FO
RenderX

while comparable population-level data on informal caregivers were not available for Slovenia. Unpaid care was defined as the provision of activities of daily living, instrumental activities of daily living, or emotional support.

In the absence of appropriate sampling frames for informal caregivers, a survey with a probability sample of the general population was not feasible. Estimates of the prevalence of informal caregivers vary substantially across studies, depending on the definitions and characteristics of care recipients, which further complicates the construction of a reliable sampling frame [59]. Considering estimates of the proportion of informal caregivers in Slovenia in the target age group [60,61], such an approach would require large-scale screening to identify eligible individuals, which would result in prohibitive costs and practical challenges. We therefore used a nonprobability online panel with web survey data collection as a feasible approach to accessing this hard-to-reach population. This approach is increasingly used in social research to survey relatively small and difficult-to-identify population segments. Because nonprobability online panels may vary considerably in quality [62], we paid particular attention to the choice of panel provider, including an assessment against established ESOMAR guidelines for online panels [63]. The study requirements were clearly laid out, and the contract with the selected provider included a minimum sample size, within-panel selection and recruitment guidelines, control over questionnaire content and format, and clear reporting of the sample recruitment and data collection procedures.

Participants and Recruitment

Data were collected between April and May 2021. The panel provider sent invitations to individuals selected from the panel members by quota sampling. Quotas were defined by 10-year age groups, sex, and region to approximate the structure of the general population rather than that of the informal caregiver population due to the lack of reliable population-level data about informal caregivers. In addition, to improve the comparability of the sample with the population of informal caregivers, we incorporated screening questions into the representative Slovenian Public Opinion Survey [64] to identify family caregivers and obtain their sociodemographic characteristics. These data were used to calculate poststratification weights.

Eligible respondents were identified with a screening web questionnaire consisting of questions about the respondent's age, types of care provided to a family member, and the average number of hours spent weekly on care provision. Respondents with answers matching the definition of the target population were immediately routed to the main web questionnaire. Respondents who completed the questionnaire were assigned value points according to the standard incentivization practice of the panel provider. Information about voluntary participation, survey length, and data protection measures was provided, and no personally identifiable information about the participants was obtained. The respondents were allowed to skip individual questions and change their answers until the questionnaire was completed. To reduce nonresponse bias, the panel provider sent at least one email reminder to nonrespondents before attempting to contact additional panelists to meet the preset quotas. Access to the survey was limited to the invited panelists via unique access codes, and a respondent was able to participate in the survey only once.

Of 3284 panelists invited, 1834 completed the screening questionnaire and 781 were eligible. After excluding invalid, duplicate, and low-quality entries and respondents with insufficient completion or ineligible answers, 612 (18.6%) respondents remained in the final dataset. As the study focused on preuse behavioral intentions rather than user experience, 54 respondents were excluded because they were current or former users of care-related assistive technologies, such as emergency call services, fall detectors, sensors, or mobility trackers, or had failed to answer questions on prior use. This distinction is important, as factors influencing preuse behavioral intentions may differ from those shaping actual usage experience. This group was relatively small, reflecting the limited use of telecare services in Slovenia at the time of the study. A total of 558 participants were therefore included in the analysis. In summary, 1834 of the 3284 invited panelists completed the screening questionnaire, 612 were retained after exclusions, and 558 remained after removing current or former users of care-related assistive technologies. This sample of 558 was used for the reliability and factor analyses, while the regression analyses were based on the 526 participants with complete data on all model variables (see *Data Quality and Missing Data* section).

Instruments and Measures

Questionnaire

The main questionnaire had 64 questions, with several of these comprising multiple items (see Multimedia Appendix 1 for key items; full materials are available online [65]). The number of questions presented varied across respondents because inapplicable questions were automatically skipped based on relevant previous answers. The mean questionnaire completion time after screening was 17 minutes.

The questionnaire included items on participants' care provision and personal characteristics, as well as the study constructs. Self-reported care burden was measured using the Self-Rated Burden Scale [66], a single-item self-assessment scale ranging from 0 ("not burdensome at all") to 10 ("extremely burdensome"), with higher scores indicating greater burden. UTAUT constructs and behavioral intention were measured using items adapted from prior studies, while perceived psychosocial outcomes were assessed separately through items capturing peace of mind, reduced anxiety, sense of safety, and perceived connectedness with the care recipient. The questionnaire was developed by the research team and evaluated in a multistage process, including initial pilot testing with informal caregivers (n=93), cognitive interviews (n=9), expert review (n=4), and a final pilot test (n=49), to identify and address potential issues.

Measures of Behavioral Intention

In this study, behavioral intention represents a person's motivational readiness to engage with telecare [40,52,53], that is, how firmly they plan or are willing to use it. We operationalized the construct as the willingness to invest personal resources, specifically, time and money, to reflect the

XSL•FO
RenderX

commitment they are prepared to make to potentially use the technology. This operationalization reflects the typical cost of comparable telecare services in Slovenia and was adopted because pretesting indicated that respondents had difficulty assessing their intention to use such services without information on potential costs, particularly given the low levels of awareness and use of telecare at the time of data collection. Behavioral intention to use telecare was assessed as the average score of 2 items, adapted from the UTAUT behavioral intention items [40], and measured on 5-point agreement scales ranging from 1 (strongly disagree) to 5 (strongly agree): "I would be willing to devote some time to learn how to properly use the services" and "I would be willing to pay 25 EUR (€1=US $1.14 as of September 21, 2026) per month for the services."

UTAUT Measures and Perceived Psychosocial Outcomes

Four types of perceived psychosocial outcomes of telecare engagement identified in a prior scoping study [23] were measured: peace of mind, reduced anxiety, sense of safety, and perceived connectedness with the care recipient. For the exact wording of the questionnaire items, and their assignment to individual constructs, see Multimedia Appendix 1. All items were rated on a 5-point Likert-type scale from 1 (strongly disagree) to 5 (strongly agree). Four UTAUT constructs (performance expectancy, facilitating conditions, effort expectancy, and social influence) were measured with items adapted from prior studies [39,40,67], using the same response scale. Scores were calculated as means of the responses to their respective items.

Measurement Characteristics

The Cronbach α values for the scales with 3 or more items indicated good-to-acceptable reliability, with α=0.87 for perceived psychosocial outcomes, α=0.88 for performance expectancy, and α=0.62 for facilitating conditions. The somewhat lower α for facilitating conditions can be partially attributed to the scale's small item count (3 items). The mean interitem correlation (r=0.35) falls within the recommended range of 0.2 to 0.4 [68]; however, α is mathematically constrained by the number of items for a given level of interitem correlation [69]. Given this, the obtained alpha is generally considered acceptable in exploratory research [70].

A confirmatory factor analysis supported the expected one-factor structure of the measures for the 3 scales comprising 3 or more items. Standardized loadings were all significant (P<.001), ranging between 0.73 and 0.91 for perceived psychosocial outcomes, between 0.62 and 0.86 for performance expectancy, and between 0.52 and 0.70 for facilitating conditions. Model fit was evaluated using the root mean square error of approximation (RMSEA), comparative fit index (CFI), Tucker-Lewis index (TLI), and standardized root mean square residual (SRMR). Model fit was good for perceived psychosocial outcomes (χ^2_1=0.92, P=.34, RMSEA<0.001, CFI>0.99, TLI>0.99, SRMR=0.004) and for performance expectancy (χ^2_3=3.26, P=.35, RMSEA=0.013, CFI >0.99, TLI>0.99, SRMR=0.004). Because the factor model for facilitating conditions was just identified, fit indices could not be computed.

Common Method Bias

Given that the data were collected using a single self-report survey, we assessed the potential for common method bias using the Harman single-factor test. The first factor accounted for 41% of the variance, which is below the commonly accepted threshold of 50% [71]. These results indicate that a single factor did not account for the majority of the variance, suggesting that common method bias is unlikely to substantially affect the findings. However, the Harman single-factor test has recognized limitations and cannot conclusively rule out the presence of common method variance. To further mitigate this risk, several procedural remedies were applied, including the use of validated measurement scales, careful questionnaire design, comprehensive pretesting, and assurances of respondent confidentiality, thereby reducing the likelihood of systematic response bias and common method bias.

Data Analysis

Methods of Analysis

Univariate distributions of all the included variables were inspected before commencing the data analysis. The measurement properties of the latent constructs were evaluated using correlational analyses, reliability (internal consistency) analyses, and exploratory and confirmatory factor analyses.

We used nested ordinary least squares regression to determine the degree to which adding perceived psychosocial outcomes to the UTAUT model increases its explanatory power. Behavioral intention to use telecare was specified as the dependent variable, while background characteristics, UTAUT constructs, and perceived psychosocial outcomes were treated as independent variables. Since the dependent variable was constructed as the average of two 5-point agreement scale items, the resulting composite measure was treated as approximately continuous, following common practice in the literature. Accordingly, ordinary least squares regression was considered appropriate for the analysis, and the results were robust to alternative specifications using ordered logit models.

First, we fit a model containing only background variables (burden of care and the sociodemographic characteristics of caregivers) as predictors. Second, we added the scores for the 4 UTAUT predictors (performance expectancy, facilitating conditions, effort expectancy, and social influence). Finally, we added the score for perceived psychosocial outcomes.

Multicollinearity was assessed using variance inflation factors (VIFs). The maximum VIF among the independent variables was 3.97, with only 2 variables exceeding a value of 3. These values remain below commonly accepted thresholds, indicating that multicollinearity is not a concern.

Possibilities for creating weights to improve the match with the studied population were explored using estimates from another population survey based on a probability sample. However, the sufficient accuracy of the source estimates could not be reliably confirmed. In addition, evaluation of substantive differences between weighted and unweighted regression models, as well as a nonsignificant F test result [72], revealed no substantive effects of weighting on the regression estimates in any of the 3

XSL•FO
RenderX

models. We therefore used unweighted data for the analyses, while weighted regression results are reported in Multimedia Appendix 2 for comparison.

Data Quality and Missing Data

As noted above, respondents who did not complete at least 50% of the questionnaire were excluded from the analysis. A combination of response quality indicators was analyzed to identify potential low-quality responses, including straightlining indicators (frequency of selecting the same scale value to all items in grid questions), speeding (exceedingly short times on individual survey pages), and other response patterns (consistent tendencies to choose initial answers, midpoints, etc). No such patterns were observed among eligible respondents that would warrant further exclusions.

For the majority of statistical analyses, we used listwise deletion to maintain a consistent sample across the analyses. Of the 558 participants eligible for this study, 526 answered all items and were thus included in the regression analyses. For the reliability and factor analyses assessing measurement characteristics, we used all available data (n=558). Given the relatively low proportion of missing data, the resulting reduction in sample size is unlikely to have biased the results or meaningfully reduced statistical power.

Ethical Considerations

The study was conducted in accordance with Slovenian and international codes of medical ethics, declarations, and conventions and with the General Data Protection Regulation [73], and it was approved by the Committee for Ethics in Research at the Faculty of Social Sciences of the University of Ljubljana on March 12, 2021 (801-2021-020/JG). This study was designed and is reported in accordance with the CHERRIES (Checklist for Reporting Results of Internet E-Surveys). The completed checklist is provided in Checklist 1.

Results

Characteristics of the Respondents

Table 1 presents the structure of survey respondents by key socioeconomic characteristics. They were, on average, 55.5 years old; the majority were female and in active employment. The relatively high average age and the proportion of individuals aged 70 years or older are in line with expectations, given the definition of the target population: a lower age bound of 40 years and the requirement of providing at least 4 hours of unpaid care, which becomes more likely with age.

[a]ISCED: International Standard Classification of Education.

The survey reached a low proportion of individuals with primary school education or less (International Standard Classification of Education [ISCED] 1 - 2), which is likely related to the structure of the panel from which the sample was obtained.

Slightly below half of the respondents reported being able to just cope financially, while a minority (n=80, 15.2%) found their financial situation difficult or very difficult. The self-reported care burden for the majority of respondents was low, with a higher burden identified among nearly a fifth of respondents.

Correlations Between Constructs

Behavioral intention, perceived psychosocial outcomes, performance expectancy, effort expectancy, and social influence were all positively correlated as expected (Table 2). Behavioral intention was particularly strongly correlated with perceived psychosocial outcomes and performance expectancy, whereas its correlation with facilitating conditions was relatively weak and the weakest among all correlations between behavioral intention and its predictors.

[a]Not applicable.

The correlations between the predictors varied considerably, with a strong correlation between performance expectancy and perceived psychosocial outcomes (r=0.83). This strong association is conceptually expected, as both constructs tap closely related evaluations of telecare's value; performance expectancy reflects the functional usefulness of telecare, whereas perceived psychosocial outcomes capture its anticipated emotional benefits (see *Discussion*). Despite the strength of this correlation, it did not produce multicollinearity problems in the regression models: the maximum VIF among the independent variables was 3.97, which is below commonly accepted thresholds (see *Data Analysis*).

Regression Analysis

Table 3 presents the results of 3 nested regression models. The first model contains only background variables (sociodemographics and self-reported care burden), the second model adds UTAUT predictors, and the third model adds perceived psychosocial outcomes.

[e]Standardized regression coefficient.

[f]Not applicable.

The model containing only background variables explains behavioral intention relatively poorly, with financial coping being the only significant predictor. The proportion of explained variance is low (3%), although the overall model fit is significant. The inclusion of UTAUT predictors significantly improves the model fit and its explanatory power, increasing the proportion of explained variance by 46 percentage points. The associations of performance expectancy, social influence, and facilitating conditions with behavioral intention are significant and positive. Consistent with the initial model, those struggling to cope financially are less willing to invest time and money.

The addition of perceived psychosocial outcomes again significantly improves model fit and also increases the explained variance. While this increase may seem modest, the added variable has the strongest effect size among all predictors, with a positive effect as expected. The pattern of observed relationships between the other predictors and the dependent variable is consistent with the previous model, except for performance expectancy, which has a markedly smaller effect size. The 2 constructs share a high proportion of the explained variance. Perceived psychosocial outcomes are associated with a reduction in the effect size of performance expectancy.

Discussion

Principal Findings and Comparison With Prior Work

In this study, perceived psychosocial outcomes emerged as the strongest predictor of informal caregivers' behavioral intention to use telecare, and adding these outcomes significantly improved the explanatory power of the UTAUT model. Performance expectancy, social influence, and facilitating conditions were also significant predictors, whereas effort expectancy and self-reported care burden were not.

This study extended the UTAUT model by incorporating perceived psychosocial outcomes to explain the behavioral intention of Slovenian informal caregivers of older adults to use telecare. While existing acceptance models provide a useful foundation, they do not consider psychosocial factors that are central to caregiving contexts [23,44-46]. To address this gap, we investigated whether including perceived psychosocial outcomes (such as reduced anxiety and increased peace of mind) improves the UTAUT model's explanatory power beyond conventional sociodemographic variables and standard UTAUT predictors (performance expectancy, effort expectancy, social influence, and facilitating conditions).

The model including only background variables showed limited explanatory power, which is consistent with previous research showing mixed or weak effects of sociodemographic factors on behavioral intention [74-76]. Financial coping (ie, having sufficient income) was the only statistically significant sociodemographic variable associated with behavioral intention. This finding aligns with previous studies in which coping financially was found to be an important factor in informal caregivers' acceptability of telecare [9,75-77]. Self-reported caregiving burden was not a significant predictor, although prior research has indicated that higher burden may increase the need for support [25,47,78]. One possible explanation is that, before caregivers have actually used telecare, their intention to do so may depend more on what they expect it to offer (its practical and psychosocial benefits) than on how much strain they are currently under. Such strain might instead translate into actual uptake only once the technology is available and its relevance to a specific caregiving situation becomes apparent. The single-item measurement of subjective burden may also have limited its predictive value, a point to which we return in the *Strengths and Limitations* section.

Adding the UTAUT factors significantly improved the model's explanatory power. Performance expectancy, social influence, and facilitating conditions were significant positive predictors, in line with previous research [23,25,56,79]. However, the relatively weak effect of facilitating conditions suggests that in the preadoption stage, structural and resource-related aspects may play a less prominent role compared with performance expectancy and social influence. Effort expectancy was not a significant predictor, which is likely due to the respondents' lack of direct experience with telecare [80]. Without hands-on experience, users may find it difficult to assess ease of use [23,80,81], whereas evidence identifying effort expectancy as a significant predictor largely comes from postimplementation research involving participants with direct experience of the technology [82-84]. This suggests that cross-sectional studies (especially those involving nonusers) may need to consider alternative or additional constructs. For instance, assessing caregivers' perceptions of the importance of ease of use may be more germane than asking them to estimate the ease of use of hypothetical or unfamiliar technologies.

Although UTAUT is a robust model for predicting behavioral intention to use telecare, our results show that extending it with perceived psychosocial outcomes is well justified. Their inclusion in the UTAUT model improved its explanatory power. Psychosocial outcomes showed the strongest association among all variables, indicating their key role in explaining informal caregivers' preuse behavioral intention to use telecare. This inclusion substantially reduced the traditional dominance of performance expectancy in explaining telecare acceptability. This may suggest that psychosocial outcomes partially mediate the relationship between performance expectancy and behavioral intention. However, given the study design, mediation cannot be formally established. An alternative interpretation is that psychosocial outcomes represent a distinct but closely related dimension of perceived usefulness that is not fully captured by standard measures of performance expectancy. In line with the original formulation of the technology acceptance model and its extensions, perceived usefulness (and performance expectancy) is typically defined in terms of functional and performance-related benefits, such as efficiency and effectiveness [40]. At the same time, research in telecare and caregiving contexts shows that emotional benefits, such as reassurance, peace of mind, and reduced anxiety, are central to how technologies are evaluated and are often treated as either implicit components of usefulness or as distinct experiential drivers of acceptability [56,85,86]. Notably, while quantitative models tend to emphasize functional utility as the primary predictor of acceptance, qualitative research consistently identifies emotional benefits as key motivations underlying caregivers' decisions [24,25,47,55], suggesting that these dimensions may be insufficiently captured in standard model operationalizations. The strong association between performance expectancy and psychosocial outcomes observed in this study is consistent with this partial conceptual overlap, with performance expectancy reflecting functional usefulness and psychosocial outcomes capturing anticipated emotional benefits, while their independent effects indicate that psychosocial outcomes contribute additional explanatory value. These findings indicate that psychosocial outcomes represent a central, yet still underrepresented, dimension of telecare acceptability in existing technology acceptance models.

Implications for Practice, Policy, and Future Research

These findings have practical implications for how telecare solutions are designed, implemented, and supported in policy. In addition to functional features, telecare services should address the psychosocial needs of informal caregivers by providing reassurance, reducing anxiety, and enhancing a sense of safety. These aspects are often overlooked in favor of technical features or the needs of care recipients, despite informal caregivers often codeciding on the use of telecare [22]. Developers, service providers, and policymakers should

XSL•FO
RenderX

therefore consider these dimensions when designing, communicating, implementing, and evaluating telecare solutions.

Based on our findings, future research should look at how the influence of psychosocial outcomes varies at different stages of the acceptance process. While our study focused on the initial stage of the user journey (ie, preuse acceptability), actual use of the technology and user engagement are likely to shape acceptance during both the initial and sustained use stages [43]. Consequently, the predictive strengths of specific acceptance factors, including psychosocial outcomes, may vary at these stages. Future studies could also further examine the interaction between functional and psychosocial determinants of telecare acceptance, including by testing whether psychosocial outcomes mediate the relationship between performance expectancy and behavioral intention and how these relationships evolve over time. In addition, there is a need to better integrate insights from qualitative research into quantitative models, particularly through the development of more refined measures of psychosocial outcomes.

Strengths and Limitations

A strength of this study is its focus on the theoretical framework for the acceptability of telecare by informal caregivers of older adults, which is often overlooked. The study also introduces a new dimension, namely the psychosocial impact of telecare use, which existing empirical models of telecare acceptability have largely neglected [23,43].

However, it has several limitations. As a cross-sectional survey of self-reported intention, the study describes associations rather than causal relationships, and behavioral intention at the preuse stage is not equivalent to actual telecare use.

First, the sampling relied on a nonprobability online panel due to the absence of a dedicated sampling frame for informal caregivers in Slovenia. This may introduce self-selection bias and limit the representativeness of the results, as individuals who participate in online panels may differ systematically from the broader population of informal caregivers. The lack of a reliable source of population-level data on caregivers in Slovenia limits our ability to assess how representative the sample is of the broader caregiver population. A comparison with a similar target group in an independent, probability-based population survey suggests that the panel sample somewhat overrepresents female (by 3.3 percentage points), highly educated (by 8.3 percentage points), and younger respondents (2.2 y younger on average), with urban and employed respondents also likely overrepresented. Because the 2 surveys differed in question design and coverage, a formal statistical comparison of sample structures was not possible, and these findings should be interpreted as indicative. In addition, respondents with greater familiarity with digital environments may be overrepresented, making the results less representative for less digitally engaged caregiver populations. At the same time, as telecare services typically require access to and basic proficiency with digital technologies, such as a smartphone and an internet connection, individuals without such access would be unlikely to use these services even if they were available. To mitigate this problem, we applied poststratification weights based on data from the representative Slovenian Public Opinion Survey [64], which improved the accuracy of population estimates. However, regression analyses were conducted on unweighted data, as weighting did not substantively affect the results. The findings should therefore be interpreted with caution when generalizing to caregiver populations that are less digitally engaged or to contexts outside Slovenia.

Second, as with all survey-based research, the survey instrument and context may have influenced the results. In particular, social desirability bias may affect responses, especially when reporting perceived psychosocial outcomes, which may result in more favorable assessments. Although self-administration and the assurance of confidentiality generally reduce such effects, their influence cannot be entirely excluded. Furthermore, because all variables were collected using the same survey instrument, the observed relationships may be partially influenced by common method variance, which could inflate correlations between constructs. However, the Harman single-factor test did not indicate that this is a major concern. In addition, caregiving burden was measured using a single-item indicator, which, although commonly applied, may not adequately reflect the multidimensional nature of caregiving experiences [66]. The facilitating conditions scale also showed limited, albeit acceptable, reliability, which indicates the need to improve the measurement characteristics of the scale.

Third, the study surveyed family caregivers aged 40 years and older because international research suggests caregiving prevalence peaks in middle adulthood and remains high into older age [87,88]. This decision is further supported by data from the Slovenian Public Opinion Survey [64], indicating that 77% of informal caregivers of older adults fall within this age range.

Fourth, contrary to expectations, care burden was not a significant factor in our model, which may be due to the use of a single-item subjective burden measure that may not adequately account for the complexity of caregiving experiences. Additionally, self-reported measures are prone to biases, such as social desirability, caregiver guilt, and individual coping mechanisms. Perceptions of burden may also fluctuate over time, further affecting the accuracy of the assessment. Future studies should therefore incorporate both subjective and objective measures of care burden to ensure a more complete assessment.

Fifth, the operationalization of behavioral intention also as willingness to pay for telecare services may introduce bias related to respondents' financial situation, as individuals with fewer financial resources may express lower intention independent of their attitudes toward the technology. To partially account for this, financial coping was included as a control variable in the regression models, although it may not capture all income-related influences on the measure. Relatedly, the 2 items used to operationalize behavioral intention capture conceptually distinct facets of motivational readiness: willingness to invest time reflects an attitudinal commitment to engaging with the technology, whereas willingness to pay reflects an economic commitment that is more strongly conditioned by personal financial circumstances. Treating them as a single measure is therefore a simplification, since it may

XSL•FO
RenderX

blur the line between the attitudinal and economic sides of intention. Future research should measure attitudinal intention and economic willingness separately to better untangle the role each one plays in the acceptability of telecare.

Finally, this study was conducted in a single country, and the relatively low representation of participants with lower educational levels may further limit the generalizability of the findings, as this group may have different levels of digital literacy and attitudes toward telecare. Differences in informal care systems, elder care practices, and the availability of telecare solutions may also limit the transferability of our findings to other contexts.

Despite these limitations, our findings offer a better understanding of informal caregivers' acceptability of telecare. They may help research and policy across different countries and for different technologies.

Conclusions

This study aimed to assess telecare acceptability among informal caregivers of older people and to identify relevant acceptance factors. Our findings show that adding perceived psychosocial outcomes of telecare engagement significantly improved the explanatory power of the UTAUT model and that these outcomes were the predictor most strongly associated with self-reported behavioral intention. This suggests that psychosocial factors are key to telecare acceptability within informal caregiving contexts. Their inclusion goes beyond improving the model empirically by also advancing it theoretically, as it incorporates the emotional aspects of caregiving (peace of mind, reduced anxiety, sense of safety, and perceived connectedness with the care recipient) that traditional technology acceptance models do not capture. Developers, policymakers, and health care providers should consider psychosocial outcomes when designing, testing, and deploying telecare solutions, as addressing informal caregivers' needs for reassurance, safety, and reduced anxiety may be important for their adoption. This can be translated into practice by incorporating caregiver perspectives into user-centered design, addressing psychosocial outcomes in implementation, and reflecting them in evaluation processes. Future research should examine how psychosocial outcomes influence technology acceptance at different stages, such as preadoption, initial adoption, and sustained use, to better understand how this influence changes over time.

Acknowledgments

The authors thank the informal caregivers who took part in pilot testing and cognitive interviews during questionnaire development, as well as the experts who reviewed the questionnaire. We also thank all the informal caregivers who participated in the survey.

The authors declare the use of generative AI (GenAI) in the preparation of this manuscript. According to the GAIDeT (Generative AI Delegation Taxonomy) taxonomy [89], the following tasks were delegated to a GenAI tool under full human supervision: proofreading and editing; and visualization, namely generating Figure 1 and the table of contents image. The tool used was GPT-5.6, including its built-in image-generation capability. No GenAI tool was used to generate original text, ideas, arguments, analyses, or interpretations. The AI-generated images are illustrative; they do not display study data and do not depict identifiable real individuals. GenAI tools are not listed as authors and do not bear responsibility for the final outcomes; responsibility for the final manuscript lies entirely with the authors.

Abstract

Background: Caregivers of persons living with dementia are at increased risk of reporting high stress. Mindfulness-based interventions (MBIs) teach caregivers mindfulness skills and are effective at reducing stress. Digital MBIs are a feasible way to improve access to MBIs for caregivers of persons living with dementia. Yet, caregiver improvement with digital MBI utilization is less defined in the literature.

Objective: The goal of this secondary data analysis was to characterize weekly mindfulness and stress ratings among caregivers of persons living with dementia and to examine how digital MBI utilization impacted these ratings throughout 12 weeks of a feasibility trial.

Methods: Participants were eligible for this secondary analysis if they were randomized to the digital MBI condition (Healthy Minds Program for Caregivers [HMP-C], n=46) and completed weekly ratings over the 12-week trial. At baseline and at the end of each week of the trial, participants rated their mindfulness and stress in the past week from 0 to 10. Weekly HMP-C utilization was defined as the time spent using HMP-C in the week prior to the weekly ratings. Descriptive statistics and visualizations were used to characterize mindfulness and stress ratings. Generalized linear mixed models were used to estimate the effect of mindfulness on stress and the effect of HMP-C utilization on stress and mindfulness throughout the trial (α=.05).

Results: Baseline mindfulness and stress ratings were 4 (IQR 3-6, range 0 - 8) and 7 (IQR 6.5-8, range 4 - 10), respectively. Stress had the greatest decrease between baseline and week 3 (−2 points on average), whereas mindfulness had the greatest increase between baseline and week 4 (+2.5 points on average). There was a significant fixed effect of baseline mindfulness on baseline stress (β=.5, *P*<.001), with a significant interaction between mindfulness and study week (β=.05, *P*=.001), suggesting that this relationship was attenuated over time. There was variability in baseline stress (τ_{00}=2.04) and the relationship between mindfulness and stress ($\tau_{1\ 1}$ =0.08), with a high correlation (ρ_{01}=0.86), suggesting that those with high baseline stress benefited most from increases in mindfulness. For every 10 minutes of HMP-C utilization between baseline and week 1, mindfulness and stress ratings were 0.14 points higher (*P*<.001) and 0.14 points lower (*P*<.001), respectively. Despite a significant interaction between HMP-C utilization and study week in both models, the effect size was small (mindfulness: β=.02, *P*<.001; stress: β=.01, *P*=.013), suggesting that this relationship was sustained over time.

Conclusions: Mindfulness and stress changed mostly during the first 3 to 4 weeks of the trial. During this time of mindfulness skill acquisition, mindfulness and stress were most significantly negatively associated, especially among those with high baseline stress. The consistent relationship between HMP-C utilization and mindfulness and stress suggests that continued use of HMP-C may be helpful for skill maintenance.

Introduction

There are approximately 53 million informal caregivers of persons living with dementia in the United States [1]. Caregivers of persons living with dementia are at higher risk for poor mental and physical health outcomes compared with age-matched noncaregiver peers [2]. Notably, caregivers of persons living with dementia experience high levels of stress [3], defined as a state of worry or mental tension caused by difficult situations [4]. Reducing stress provides an opportunity to improve caregiver well-being, and approximately half of caregivers report a desire for stress management interventions [5]. Together, there is a need and demand for stress reduction interventions among caregivers of persons living with dementia.

Mindfulness-based interventions (MBIs) are an effective nonpharmacological treatment for caregiver stress [6]. Mindfulness can be conceptualized as both a *trait*, or one's predisposition to be mindful in daily life, and a *state* that is achieved while practicing mindful meditation [7]. A framework proposed by Dahl et al [8] posits that state mindfulness meditation practices consist of skills that can be trained and developed (awareness, connection, insight, and purpose). MBIs primarily teach participants mindfulness skills as a coping strategy to manage everyday stressors. Mindfulness skills center on nonjudgmentally observing thoughts, feelings, and behaviors in the present moment [9]. The continual practice of state mindfulness through these skills increases trait mindfulness over time [7]. Both state and trait mindfulness are associated with lower perceived stress across multiple populations [10-12], including caregivers of persons living with dementia [13-15].

Although MBIs can reduce caregiver stress, caregivers often experience barriers to accessing these interventions in outpatient settings. For example, caregivers may experience limited access to respite care [16], limited free time [17], and resistance to leaving their care recipient due to guilt or fear [18], all of which interfere with help-seeking. Even when interventions are offered remotely, they are often synchronous and do not allow for additional flexibility when acute caregiving responsibilities arise. Digital MBIs provide an opportunity to overcome these barriers and increase access to MBIs for caregivers [19-22]. Digital MBIs are often delivered via mobile phone apps, are free or inexpensive, and can be accessed at any time, promoting flexibility in use, which may be particularly beneficial for those in the caregiving role. Digital MBIs are feasible and acceptable among caregivers of persons living with dementia in pilot trials [23-25] and align with a growing trend of technology acceptance among caregivers [26,27].

Although digital MBIs show promise for reducing stress among caregivers, the trajectory of skill acquisition and perceived stress reduction during participation in digital MBIs is rarely studied. According to Dahl and colleagues' [8] conceptualization of mindfulness as a series of skills to be learned, mindfulness is not expected to increase indefinitely, but rather to be learned (ie, skill acquisition), applied (ie, used as a state in stressful situations), and maintained (ie, developed as a trait across situations). A more granular understanding of the trajectory of skill acquisition and perceived stress reduction could help the scalability of interventions in a real-world context (eg, recommended usage, benchmarks for progress). This information may be particularly beneficial for self-directed interventions, such as digital MBIs, which lack regular monitoring of progress by a trained clinician.

This study aimed to elucidate the relationships among caregiver mindfulness, stress, and utilization of a digital MBI. This study is an exploratory secondary analysis of a feasibility pilot randomized controlled trial (RCT) of Healthy Minds Program for Caregivers (HMP-C), a digital MBI tailored to caregivers of persons living with dementia [25]. The primary pilot RCT reported findings primarily in the domains of feasibility, acceptability, treatment satisfaction, and adherence. The distinct aims of this study were 3-fold: (1) to characterize the trends of caregiver mindfulness and stress across the 12-week duration of the primary study, (2) to characterize the relationships between participants' weekly mindfulness and stress ratings, and (3) to explore how participants' utilization of the digital MBI is associated with their weekly mindfulness and stress ratings across the study duration.

Methods

Study Design

This study is an exploratory secondary data analysis of a single-blind pilot RCT (National Institutes of Health Stage Model, Stage 1b) of HMP-C, a digital MBI tailored for caregivers of persons living with dementia.

Ethical Considerations

This trial is registered with ClinicalTrials.gov (NCT05732038), and all study procedures were approved by the affiliated institutional review board (2022P001601) [25,28]. Informed consent was collected electronically. A member of the study staff was present to answer any questions. Participants received a total of US $50 for completing the postassessment and follow-up assessments. The privacy and confidentiality of all participant data were maintained.

Participants

The primary single-blind feasibility pilot RCT recruited informal adult caregivers of a known person living with Alzheimer disease or a related dementia reporting elevated levels of perceived stress. Recruitment was carried out through flyers and online advertisements. Interested caregivers referred themselves via an online link included in the recruitment materials. Here, they completed a brief eligibility questionnaire (verified by a phone call with study staff) based on the following inclusion criteria: (1) >18 years old, (2) English literacy, (3) self-identify as an informal caregiver, (4) Perceived Stress Scale-10 score of ≥6 [29,30], (5) willing to be randomized, and (6) care recipient rated >1 on the Functional Assessment Staging Tool [31]. Exclusion criteria included (1) any planned change in psychotropic pharmacological treatment for the duration of the study, (2) use of any consumer-based mindfulness meditation app for more than 60 minutes per month in the past 6 months, (3) current participation in a meditation program, (4) major illness anticipated to worsen dramatically or require surgery in the next 20 weeks, (5) active treatment for cancer (eg,

XSL•FO
RenderX

chemotherapy, radiation), (6) placement of the care recipient in a nursing home, (7) involvement in another clinical trial for caregivers, and (8) 4+ errors on the Short Portable Mental Status Questionnaire (ie, for caregivers older than 65 years of age) [32]. The primary feasibility RCT analyzed 90 participants across the HMP-C intervention (n=46) and a control (n=44) condition [25]. The present secondary analysis utilized participants in the intervention condition only, as the control condition did not teach mindfulness skills.

Intervention

HMP-C is a digital MBI tailored for caregivers of persons living with dementia, based on content from HMP, a publicly available mobile app [25,33]. HMP consists of written and guided listening content that aims to help users develop the following mindfulness skills: (1) awareness (eg, mindfulness, attention, self-awareness), (2) connection (eg, appreciation, kindness, compassion), (3) insight (eg, self-inquiry, self-knowledge, transcending the self), and (4) purpose (eg, purpose clarity, embodying values, finding meaning) [8,33]. Based on the Dahl et al [8] framework, these skills are taught to listeners through educational content based on the science of well-being and procedural guided mindfulness practices [25].

Primary Pilot RCT Procedures

Participants were directed to use the app for at least 10 minutes per day, or 70 minutes per week, for 12 weeks. Participants were reminded each week by text message to use their respective phone app for the prescribed amount of time. App utilization data were reviewed weekly by study staff, and participants who did not use at least 75% of their recommended amount in the past week were sent an additional standardized reminder message. Participants who did not complete their recommended utilization for 2 consecutive weeks were called by a study staff member to problem-solve potential barriers to adherence. Throughout the 12-week trial period, participants were emailed a REDCap (Research Electronic Data Capture) link to weekly single-item stress and mindfulness assessments. Participants who completed all assessments were offered a monetary incentive of up to US $50.

Measures

Weekly Mindfulness and Stress Assessments

At the end of each trial week, participants were asked to self-report perceived levels of mindfulness and stress from the prior week on single-item assessments, with scores ranging from 0 to 10. These assessments were also administered at baseline for a total of 13 weekly assessments (ie, baseline and 12 trial weeks). The stress assessment asked, “During the past week, how would you rate your stress on a scale from 0 to 10? (0=not at all; 10=extremely stressed).” The mindfulness assessment asked, “During the past week, how would you rate your mindfulness on a scale from 0 to 10? (0=not at all; 10=extremely mindful).” Mindfulness and stress among caregivers are multifaceted constructs, and several sources may contribute to stress among caregivers of persons living with dementia. The single-item measures utilized in this study represent broad, subjective ratings of mindfulness and stress regardless of perceived source.

Weekly HMP-C Utilization

Weekly HMP-C app utilization was defined as a continuous measure representing the sum of minutes of HMP-C utilization in the 7 days prior to each participant’s completion of their weekly mindfulness and stress assessments. These data were automatically captured through the HMP-C app.

Statistical Analysis

Overview

All statistical analyses were conducted using R (R Foundation for Statistical Computing) [34]. Four participants were removed from the data prior to analysis due to missing data. Specifically, 2 participants completed no weekly stress or mindfulness assessments, and 2 participants completed several weekly assessments in batches (eg, completing 2 or more weekly assessments at the same time). The final analytic dataset used in this study comprised the remaining 42 participants who received HMP-C. Descriptive statistics were used to describe participant characteristics for the 42 eligible participants included in this analysis. Statistical approaches relevant to each aim are detailed below. Consistent with study aims outlined below, we analyzed completers only. An α of .05 was used for all statistical tests.

Aim 1: Characterize Stress and Mindfulness Throughout the Study

Weekly stress and mindfulness assessments were characterized using descriptive statistics, including the median, minimum, maximum, and IQR. Further, we described change scores for the study variables throughout the trial.

Aim 2: Characterize the Relationship Between Weekly Mindfulness and Stress Ratings Throughout the Study Duration

Generalized linear mixed models (GLMMs) were used to assess the relationship between mindfulness and stress throughout the course of the 12-week trial period. Mindfulness was mean-centered to improve interpretation. This model also included an interaction term for mindfulness and time (study week) to assess how the effect of mindfulness on stress changed throughout the study duration. This model included a random intercept and a random slope for mindfulness to account for individual differences in baseline stress and the effect of mindfulness on stress. Random and fixed effects are reported for the effect of weekly mindfulness ratings on weekly stress ratings. Additionally, we visualized the Pearson correlation coefficient between weekly mindfulness and stress ratings. The final reported model was assessed for the following model assumptions: (1) linearity of fixed effects, (2) residual distribution, (3) outliers, (4) autocorrelation, (5) dispersion, (6) link function specification, and (7) zero inflation. No major deviations were detected for any of the aforementioned criteria. A power analysis was conducted using a simulation-based approach (1000 replications) and the observed effect size for the interaction term.

XSL•FO
RenderX

Aim 3: Explore How HMP-C Utilization Is Associated With Weekly Mindfulness and Stress Ratings Throughout the Study Duration

GLMMs were used to test the association between HMP-C utilization and weekly mindfulness and stress ratings. Both models included an interaction term between HMP-C utilization and time (study week) to assess how these effects changed throughout the study duration. Initially, models were specified to include a random slope and random intercept, as in Aim 2. However, both models in Aim 3 exhibited a singular fit, indicating that the variance of the random slope was approximately zero. This is common in datasets with small-to-medium sample sizes [35]. Due to the inability to estimate a random slope, we reported models that only included a random intercept, which aligns with guidelines for building GLMMs [35]. HMP-C utilization was mean-centered for improved interpretation, and study week was centered at week 1 (as opposed to baseline), as no participants utilized HMP-C prior to the baseline assessment. Since we are interested in how past-week HMP-C utilization is associated with stress and mindfulness, centering study week at week 1 allows for a week's worth of HMP-C utilization to transpire before estimating that association. Random and fixed effects are reported for the effect of HMP-C utilization on weekly mindfulness and stress ratings. The final reported model was assessed for the following model assumptions: (1) linearity of fixed effects, (2) residual distribution, (3) outliers, (4) autocorrelation, (5) dispersion, (6) link function specification, and (7) zero inflation. No major deviations were detected for any of the aforementioned criteria. Power analyses were conducted for both models using a simulation-based approach (1000 replications) and the observed effect size for the interaction term.

Results

Participants

Table 1 outlines participant characteristics at baseline for the 42 eligible caregivers included in this study. The average age was 55 (SD 14) years. Most participants were female by sex (n=39, 93%) and gender identity (n=38, 90%). Most participants were White (n=34, 81%). Most participants were married and living with their partner (n=28, 67%). Participants in this study used HMP-C for a median of 70 (IQR 41.7-102.2) minutes per week.

Aim 1

Median mindfulness and stress ratings at baseline were 4 (IQR 3-6, range 0 - 8) and 7 (IQR 6.5-8, range 4 - 10), respectively (Figure 1). By week 6 (ie, midway through the study), median mindfulness ratings increased to 7 (range 2 - 10) and stress ratings decreased to 5 (range 0 - 8). This represents a net increase in median mindfulness of 3 points and a net decrease in median stress of 2 points between baseline and week 6. Mindfulness and stress ratings remained similar throughout the remainder of the trial, with a net increase in median mindfulness and stress of 1 point between week 6 and 12 of the trial. Overall, there was an increase in median mindfulness of 3 points and a decrease in median stress of 1.5 points across the full trial (ie, baseline to week 12).

According to Figure 1, stress ratings appear to have the greatest decrease between baseline and week 3. By week 3, the median stress rating was 5 (IQR 4, range 0 - 10), which corresponds to a 2-point decrease from baseline. Mindfulness appears to experience the greatest increase between baseline and week 4. By week 4, the median mindfulness rating was 6.5 (IQR 3, range 2 - 10), which corresponds to a 2.5-point increase from baseline.

Figure 1. Weekly stress and mindfulness ratings among caregivers of persons living with dementia using the Healthy Minds Program for caregivers.

Aim 2

Figure 2 demonstrates the variability in the correlation between weekly mindfulness and stress ratings. Table 2 reports the results of the GLMM characterizing the relationship between mindfulness and stress. There was a significant fixed effect of mindfulness on stress, such that every additional point of mindfulness above the mean at baseline was correlated with a decrease in participant stress by an average of 0.5 points (P<.001). Similarly, participant stress was reduced by 0.06 (P=.007), on average, for each week throughout the duration of the study. However, the significant interaction between mindfulness and study week (β=.05, P=.001) showed that this association attenuated over time (ie, the stress-reducing effect of mindfulness was most potent during the early weeks of the trial and less potent during the later weeks in the trial). Random effects showed variability in baseline stress (τ_{00}=2.04) and the association between mindfulness and stress ($\tau_{1\ 1}$ =0.08) among participants. Notably, there was a high correlation (ρ_{01}=0.86) between intercepts and slopes, meaning that participants with higher baseline stress had a higher association between mindfulness and stress reduction over the course of the trial. Simulation results for the interaction term in this model show approximately 88.80% (95% CI 86.70-90.70) power to detect effects.

Figure 2. Pearson correlation between mindfulness and stress ratings over time among caregivers of persons living with dementia using Healthy Minds Program for Caregivers.

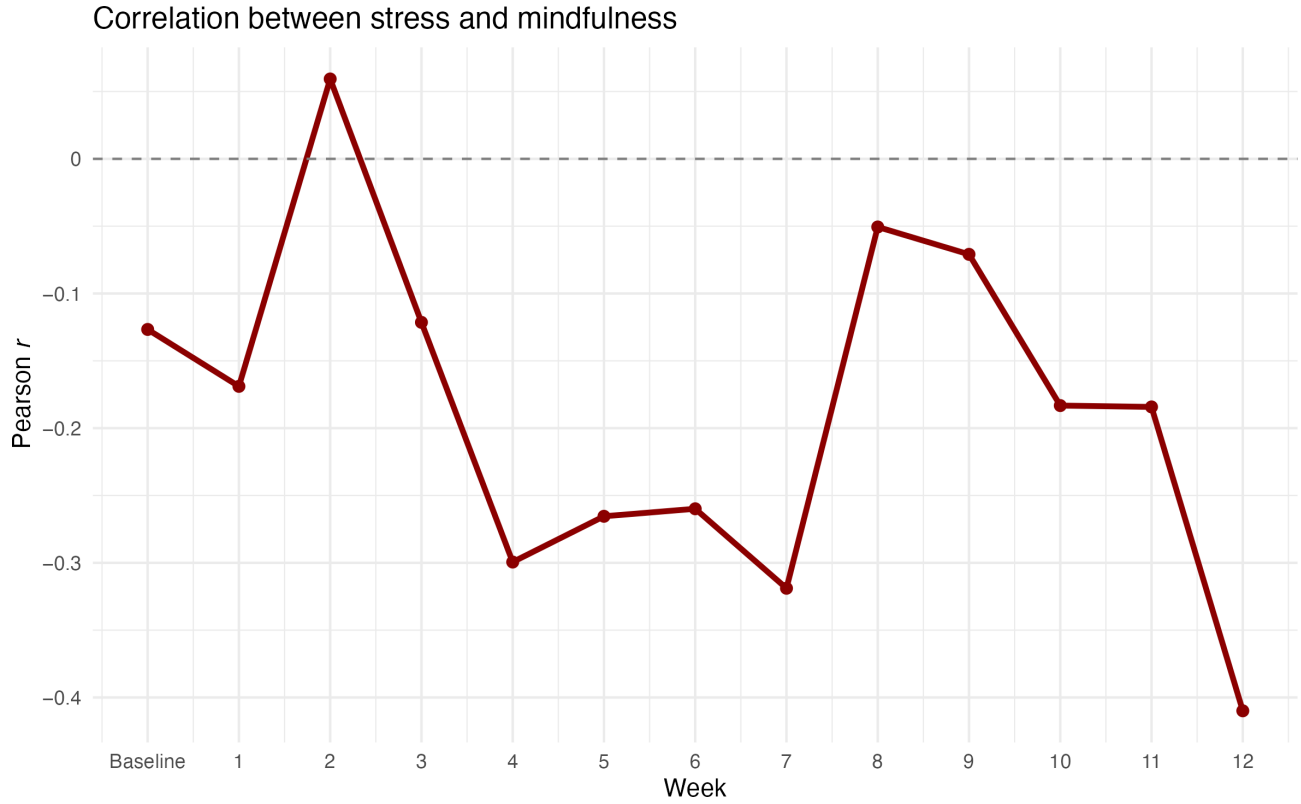

Table . Longitudinal effect of mindfulness ratings on stress ratings among caregivers of persons living with dementia using Healthy Minds Program for Caregivers (N=42).[a]

Predictors	Estimate (95% CI)	*P* value
(Intercept)	5.56 (5.03 to 6.09)	<.001
Mindfulness rating	−0.52 (−0.72 to −0.32)	<.001
Study week	−0.06 (−0.11 to −0.02)	.007
Mindfulness rating × study week	0.05 (0.02 to 0.08)	.001

[a]Random effects: σ^2=2.77; τ =2.04; $\tau_{1\ 1}$ =0.08; ρ_{1} =0.86; intraclass correlation coefficient=0.44.

Aim 3

Figure 3 details the variability in the correlation between HMP-C utilization and stress and mindfulness ratings each week through the 12-week trial. Correlations largely reflect an inverse relationship, where utilization generally correlates with higher mindfulness and lower stress. This is reflected in Table 3, where the fixed effects of utilization on mindfulness and stress were both significant. For every additional 10 minutes of HMP-C utilization between baseline and week 1, participants rated their mindfulness as 0.14 points higher on average (*P*<.001). Similarly, for every additional 10 minutes of HMP-C utilization, participants rated their stress as 0.14 points lower on average (*P*<.001). Both models demonstrated an effect of time, where for every week of utilization, participants' mindfulness increased by 0.10 (*P*<.001) and stress decreased by 0.07 (*P*<.001) on average. Both models had statistically significant interaction terms with study week. However, the effect sizes of these interaction terms were very small for both mindfulness (β=.02, *P*<.001) and stress (β=.01, *P*=.01). This suggests that while there is a statistically significant attenuation of the impact of HMP-C utilization on stress and mindfulness ratings, the size of that impact was very small, meaning that this correlation was mostly stable throughout the trial. Simulation results for the interaction term show approximately 99.50% (95% CI 98.84-99.84) power and 68.90% (95% CI 65.93-71.76) power in the mindfulness and stress models, respectively.

Figure 3. Pearson correlation between Healthy Minds Program for Caregivers (HMP-C) utilization and mindfulness or stress ratings over time among caregivers of persons living with dementia using HMP-C.

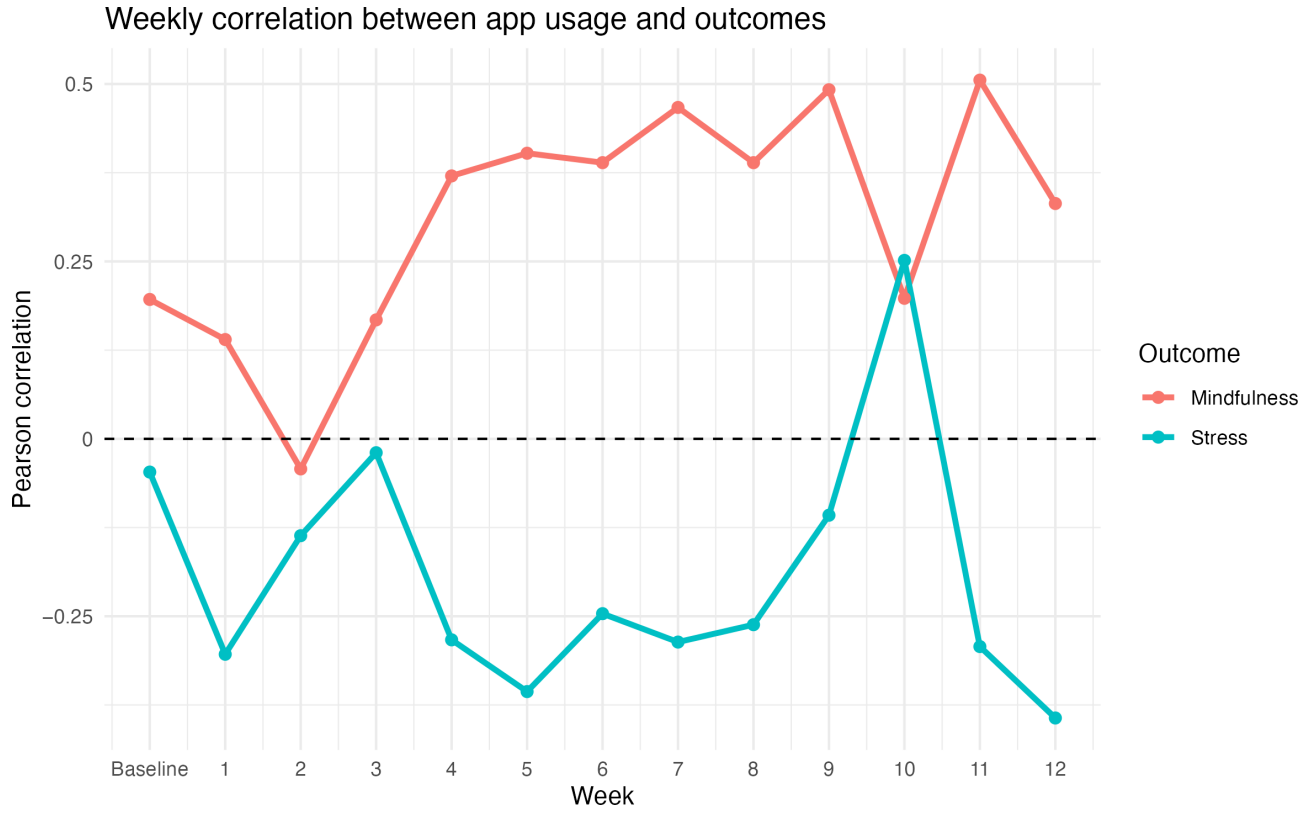

Table . Longitudinal effect of Healthy Minds Program for Caregivers (HMP-C) utilization on weekly mindfulness and stress ratings among caregivers of persons living with dementia using HMP-C (N=42).

Predictors	Mindfulness ratings[a]		Stress ratings[b]	
	Estimates (95% CI)	*P* value	Estimates (95% CI)	*P* value
(Intercept)	5.73 (5.22 to 6.23)	<.001	5.62 (5.11 to 6.13)	<.001
HMP-C utilization[c]	0.14 (0.10 to 0.18)	<.001	−0.14 (−0.20 to −0.08)	<.001
Study week[d]	0.10 (0.07 to 0.13)	<.001	−0.07 (−0.12 to −0.03)	.001
HMP-C utilization × study week	−0.02 (−0.02 to −0.01)	<.001	0.01 (0.00 to 0.02)	.01

[a]For the mindfulness ratings model, random effects were σ^2=1.51, τ =2.39, intraclass correlation coefficient=0.61, and N=42.

[b]For the stress ratings model, random effects were σ^2=3.00, τ =2.03, intraclass correlation coefficient=0.40, and N=42.

[c]HMP-C utilization was mean-centered and scaled to show the effect per 10 additional minutes.

[d]Study week was centered at the first week after baseline because HMP-C utilization captures past week utilization.

Discussion

Principal Results

This secondary data analysis aimed to characterize weekly mindfulness and stress ratings among caregivers of persons living with dementia and explore how digital MBI utilization was associated with those ratings throughout 12 weeks of a feasibility trial. We found that, on average, participants' mindfulness and stress ratings improved throughout the initial weeks of the study and then sustained that improvement throughout the remainder of the study duration. Further, we found that there was a significant association between mindfulness and stress ratings throughout the study duration among our sample of caregivers of persons living with dementia, such that in weeks when mindfulness was high, stress was low. However, this association became weaker as the study progressed, suggesting that perceived stress and mindfulness are less intertwined over time. Finally, HMP-C utilization was associated with changes in mindfulness and stress ratings, suggesting that continued utilization may be helpful for maintaining these improvements over time.

The sample of participants from this study in some ways reflects the broader population of caregivers of persons living with dementia and in other ways potentially deviates from the average caregiver of persons living with dementia. On the one hand, participants overwhelmingly identified as women. Women have historically undertaken the role of caregiving for persons living

XSL•FO
RenderX

with dementia, and this finding is consistent across geographic regions. Further, women often spend more time caregiving than their male caregiver counterparts and often experience a higher level of caregiver burden [36]. Conversely, the present sample of participants is largely White, has attained a graduate degree, and is earning more than US $100,000 per year. Past work has shown that approximately two-thirds of caregivers of persons living with dementia are White (compared to roughly 4 in 5 caregivers in the present sample). Further, past work has shown that the average caregiver of persons living with dementia earns US $50,000 or less per year. Additionally, the present sample represents a cohort of individuals positioned to have greater access to and literacy with technology due to their demographic characteristics (eg, race, income, education, and age) [37]. The complex intersectionality of underresourced identities and technological access and literacy can impact digital intervention engagement. Indeed, past reviews have shown that technological literacy is a significant barrier to implementing digital interventions for caregivers of persons living with dementia, despite their high health literacy [38-44].

Both mindfulness and stress ratings improved throughout the first 6 weeks of the study, with most of the improvement occurring between the first 3 to 4 weeks. From there, mindfulness and stress ratings leveled off throughout the remainder of the study. These findings suggest that participants may have developed some level of mastery in mindfulness skills within the first 4 weeks of HMP-C utilization, with more minor improvements occurring after week 4. Since Dahl et al [8] conceptualize mindfulness practice through a series of developable skills, it would be expected that once those skills are mastered, continued practice would lead to maintenance (ie, not a linear increase). This study reflects this trajectory, where caregivers improved mindfulness and stress early (weeks 1 - 4) and then stabilized by week 6. This may reflect acquisition of new skills followed by subsequent consolidation of those skills. It remains plausible that continued practice would yield additional benefit at longer follow-up. Future work should evaluate this by extending assessments over a longer period of time.

Improvements in weekly mindfulness ratings correlated with stress reductions throughout the study duration. However, there is context to this finding. First, there was variability in baseline stress and the association between mindfulness and stress across participants. Notably, there was a positive correlation between baseline stress and the effect of mindfulness on stress reductions, meaning those who were the most stressed at baseline benefited the most from increases in mindfulness. This suggests that mindfulness skills may have offered these participants a strategy to immediately manage stressful situations in their lives. However, the association between mindfulness and stress decreased over time, regardless of baseline stress levels. This trajectory in mindfulness and stress ratings reflects several previous findings, where an initial effect of mindfulness skills on the primary outcome is observed, followed by a period of attenuation [45-48]. These findings underscore the importance of considering both individual differences at baseline and the temporal dynamics of mindfulness practice. The early pronounced association for those with higher stress highlights mindfulness as a potentially powerful mechanism for alleviating acute distress (ie, state mindfulness for coping). At the same time, the subsequent attenuation of effects suggests that the role of mindfulness may shift from producing large, immediate reductions in stress to supporting the maintenance of stress reduction over time (ie, trait mindfulness). This pattern is consistent with theoretical models, such as Dahl et al [8], that view mindfulness as a set of skills that, once acquired, foster a sense of resiliency and stability, rather than indefinite linear improvement. Taken together, these results suggest that digital MBIs should emphasize intensive early engagement while also providing education and strategies to sustain and deepen benefits during later phases of practice. Future research should aim to assess the mediating role of mindfulness in stress reduction for caregivers of persons living with dementia as compared to an attention-placebo control condition in a fully powered efficacy trial.

HMP-C utilization was broadly associated with increases in mindfulness and reductions in stress ratings throughout the duration of the study. Despite a statistically significant interaction of HMP-C utilization and time in study weeks in both utilization models, the effect sizes of these interactions were very small. While there may be some minor attenuation of the association between HMP-C utilization on mindfulness and stress over time, the association was largely maintained throughout the study duration. This suggests that continued utilization of HMP-C may serve as an important tool for mindfulness skill maintenance, such that utilization may be protective against returning to baseline levels of mindfulness and stress. Therefore, continued use of the digital MBI would be recommended for achieving and sustaining improvements in mindfulness and stress among caregivers of persons living with dementia. These findings suggest several directions for future work. First, to examine if and to what extent a dose-response relationship exists between HMP-C utilization and mindfulness or stress, a future study could randomize participants to incrementally different “dosages” of HMP-C utilization (eg, 45, 60, 75, and 90 min/wk). Further, future research is needed to address whether mindfulness skills and their effect on stress can be maintained without continued practice or the same amount of continued practice. For example, future studies may choose to randomize participants to continued, reduced, or no HMP-C utilization after an initial period of 4 weeks. These would provide the rigorous groundwork needed to tune digital MBI utilization recommendations.

Limitations

There are several limitations to consider when interpreting the findings from this study. First, the participants in this study were a small sample from a stage 1b feasibility RCT. In many ways, the sample was not representative of caregivers of persons living with dementia broadly with respect to race, income, education, and potentially digital literacy. Due to this, the generalizability of these findings to the broader population of caregivers may be limited. Further, analytically, we were not powered to control for possible sources of confounding, such as digital and health-related literacy, which may have led participants to be more adept at improving from mindfulness

XSL•FO
RenderX

skill practice. Second, this study does not include a control or comparator arm in the analysis. This precludes making causal statements about the efficacy of HMP-C or digital MBIs with respect to changes in mindfulness and stress. Possible sources of confounding due to lack of randomization include seasonal changes, regression toward the mean, or simply random fluctuations. Third, single-item weekly ratings are less explanatory than more comprehensive measures. For example, from this study, we cannot ascertain exactly what stressors participants were experiencing or were being mitigated. However, single-item measures have been shown to be comparable to full-scale measures as broad measures of stress or mindfulness, suggesting that the overall trends observed are likely valid [49-51]. Fourth, week-over-week changes in mindfulness and stress may be reflective of the Hawthorne effect or assessment reactivity, as opposed to true changes in the measured constructs.

Conclusions

This study is an exploratory secondary analysis of a feasibility pilot RCT of HMP-C, a digital MBI tailored for caregivers of persons living with dementia. We found that mindfulness and stress ratings improved throughout the first 3 to 4 weeks of the trial before leveling off throughout the remainder of the trial. Particularly, in these first 4 to 6 weeks of skill acquisition, mindfulness and stress were significantly negatively related to one another. This association was higher for those with high baseline stress. Together, these findings highlight the potential benefit of digital MBIs for stress reduction among caregivers of persons living with dementia and suggest that mindfulness skills may be acquired within the first 4 to 6 weeks of the intervention and then maintained over a longer period of time. Future research is needed to move closer to precise dosing recommendations for mobile apps with this population.

Abstract

Background: Dementia caregiving entails chronic, fluctuating stress with downstream risks to caregivers' mental health and quality of care. Mindfulness-based interventions can reduce caregiver stress; however, moment-to-moment fluctuations in stress may limit receptivity to practice at any given time. We developed a brief mindfulness just-in-time adaptive intervention (JITAI) that aims to deliver support at the right moment by using machine learning algorithms to optimize notification timing based on receptivity to engage in brief mindfulness practices.

Objective: This study aims to evaluate the feasibility, acceptability, and effectiveness of a brief mindfulness JITAI for caregivers of people with dementia on stress, depressive symptoms, caregiver burden, sleep, quality of life, and trait mindfulness.

Methods: A single-arm, pretest or posttest design was adopted. A total of 120 community-dwelling caregivers were recruited to participate in the 18-day intervention, which included 4 days of psychoeducation delivered via videos and phone coaching, alongside an in-app brief, low-dose mindfulness-based stress reduction component. From days 5 to 11, prompts were delivered either by a static machine learning model trained on prior pilot data or at random times, with equal probability. From days 12 to 18, three delivery models were used with equal probability, namely static, random, and adaptive models, which updated per participant using accumulating receptivity data. Feasibility and acceptability were assessed post intervention. Standardized measures of stress, depressive symptoms, caregiver burden, positive aspects of caregiving, sleep, quality of life, and trait mindfulness were collected via phone interviews at baseline and post intervention.

Results: Retention was 100%. Most participants (111/120, 92.5%) found the app easy to use, 81.7% (98/120) perceived it as helpful for stress management, and 80% (96/120) would recommend it to other caregivers. Pre-post analyses indicated significant reductions in perceived stress (P<.001), depressive symptoms (P<.001), and caregiver burden (P=.003), as well as a significant increase in positive aspects of caregiving (P<.001) and subjective sleep quality (P=.02). Health-related quality of life and trait mindfulness did not change significantly.

Conclusions: A brief, smartphone-delivered mindfulness JITAI for caregivers of people with dementia was feasible and acceptable, with high retention and positive user evaluations. Pre-post findings suggest reductions in perceived stress, depressive symptoms, and caregiving burden, alongside increased positive aspects of caregiving and improved sleep, supporting the potential of adaptive, technology-enabled interventions to provide timely support to caregivers.

Introduction

Dementia is a neurodegenerative condition characterized by progressive declines in functional abilities and substantial care needs, with caregiving often provided by family members. With an aging global population, the prevalence of dementia is projected to rise from 55 million in 2019 to 139 million by 2050 [1]. Consequently, the number of family caregivers assuming these demanding roles will increase. The stress associated with dementia caregiving is substantial and can lead to adverse health outcomes for both caregivers and care recipients. For caregivers, prolonged exposure to stress is linked to insomnia, compromised immune function, and psychological distress, including depression and anxiety [2-4]. For care recipients, high levels of caregiver stress can increase the likelihood of premature institutionalization and, in some cases, elder abuse [5,6]. Therefore, developing effective strategies to mitigate caregiver stress is a pressing public health priority.

Since stressors are a normative and unavoidable part of the long-term dementia caregiving trajectory, emotion-focused coping approaches that emphasize the positive reappraisal of caregiving-related emotions, in contrast to problem-focused approaches that target modification of the stressor itself (eg, caregiving skills training), are particularly important for stress management [7]. Mindfulness is one such approach and has been shown to reduce stress among caregivers of people with dementia [8,9]. The mindful coping model emphasizes decentering, defined as the capacity to observe one's thoughts and feelings from a detached perspective [10]. This shift in attentional focus enables caregivers to reframe stressors, engage in positive reappraisal, and ultimately reduce stress. A systematic review has confirmed that mindfulness-based interventions (MBIs) have a moderate effect size in reducing caregiver stress in this population [8].

Despite their effectiveness, MBIs for caregivers of people with dementia are hindered by practical challenges. A primary barrier is the significant time commitment required by traditional program structures. For example, a trial of mindfulness-based cognitive therapy found that about 20% of 113 participants discontinued regular mindfulness practice during follow-up, with lack of time being the most common reason for discontinuing their practice [9]. Caregivers often juggle numerous caregiving tasks and other life commitments, which can disrupt the self-directed practice central to these interventions. The fluctuating nature of caregiving demands and stress can also create episodes of cognitive interference, making it difficult to focus attention during periods of high strain [11]. If an intervention is perceived as too intensive or inflexible, caregivers may be less motivated to engage in self-practice. Therefore, tailoring the delivery of mindfulness practices is crucial to support sustained engagement. To address this challenge, interventions should be delivered at moments of optimal receptivity, defined as states in which a caregiver is able, available, and willing to receive, process, and use support [12].

A just-in-time adaptive intervention (JITAI) can optimize receptivity by delivering support at opportune moments while adapting to a user's changing internal and external contexts [12]. This approach has been applied to a wide range of public health issues, including physical inactivity [13], smoking cessation [14], and obesity [15]. More recently, JITAIs have been integrated with MBIs for individuals with chronic pain, demonstrating reductions in cravings, pain, and stress, along with increases in positive affect [16]. Receptivity in JITAI delivery can be optimized using several models: (1) static, (2) random, and (3) adaptive [17]. A static model delivers prompts at predetermined times, often derived from machine learning analyses of prior user data; however, receptivity patterns from one group may not generalize to others [18]. A random model delivers prompts at random times and often underperforms machine learning–based models [17]. An adaptive model uses machine learning to learn each participant's receptivity patterns as the study progresses. Prior research suggests that although an adaptive model may underperform initially, its performance improves as user-specific data accumulate over time [17].

Taken together, a brief mindfulness-based JITAI may offer a promising approach to the unique challenges of delivering support to this population. By tailoring delivery to moments of high receptivity, a JITAI can facilitate the self-directed practice essential for maximizing the stress-reduction benefits of MBIs [19]. However, there is limited research applying mindfulness-based JITAIs to caregivers of people with dementia. Consequently, their effectiveness for stress reduction, as well as their feasibility and acceptability within this population, remains unclear.

This study aims to address this gap by introducing and evaluating a novel, brief mindfulness JITAI for caregivers of people with dementia using Android phones. The study objectives are (1) to evaluate the feasibility and acceptability of the intervention (eg, retention, adherence or engagement with prompted practice, and user feedback) and (2) to estimate preliminary pre-post changes in caregiver psychosocial outcomes (eg, perceived stress and related outcomes). To operationalize these objectives and manage the initial learning phase of the adaptive model, the program was implemented in the following steps: step 1 (1‐4 d) provided brief psychoeducation and coaching with access to app-based mindfulness content; step 2 (5‐11 d) delivered prompts using either a static model informed by pilot usage data (n=75) or a random model (equal probability) to accumulate initial data;

XSL•FO
RenderX

and step 3 (12‐18 d) introduced an adaptive model (alongside static and random, equal probability) that personalized prompt timing based on continuously collected, participant-specific data.

Methods

Study Design

This is a single-arm, quasi-experimental study. The study is reported in accordance with the CONSORT (Consolidated Standards of Reporting Trials) guidelines (Checklist 1). It was conducted in compliance with the Declaration of Helsinki (and its subsequent amendments) and Good Clinical Practice guidelines.

Ethical Considerations

Ethical approval was obtained from the corresponding author's institution (reference: A2021-2022-0276-01). All participants provided written informed consent prior to participation. Participants were informed of the study's purpose, procedures, the voluntary nature of participation, and their right to withdraw at any time without penalty. Privacy and confidentiality were protected by deidentifying participant data and restricting access to research data to authorized members of the research team only. Participants who completed all assessments and attended at least 80% of the intervention sessions received HK $500 (US $64.10) in supermarket coupons as compensation for their time and participation. The trial was registered at the Chinese Clinical Trial Registry (ChiCTR2300071361).

Participants

Participants were family caregivers of people with dementia, recruited through a network of nongovernmental organizations providing community services for older people, caregiver support groups, and the Alzheimer's Association in Hong Kong.

Eligibility criteria included being aged 18 years or older, serving as a family caregiver for a community-dwelling individual with a confirmed medical diagnosis of any type of dementia, providing at least 20 hours per week of assistance with activities of daily living and instrumental activities of daily living for a minimum of 1 year prior to recruitment, having an Android smartphone, and reporting moderate to high stress as measured by the 14-item Perceived Stress Scale (PSS-14) [20]. A cutoff score of 18 was used to identify caregivers with elevated stress (PSS-14>18), consistent with thresholds applied in previous studies [21].

Exclusion criteria included participation in any structured mind-body intervention, cognitive behavioral therapy, or structured psychosocial intervention within the previous 6 months, as well as acute psychiatric or medical comorbidities that were potentially life-threatening (eg, suicidal ideation) or could limit participation or adherence (eg, acute psychosis).

Procedures

Recruitment and Assessment

Interested individuals were approached by a research assistant, who administered a brief screening questionnaire via phone interviews to confirm eligibility. Those who met the inclusion criteria received a standardized study briefing and then provided electronic informed consent via the Qualtrics platform (Qualtrics International Inc). The research team carefully explained the required commitments to ensure that participants were aware of expectations and to minimize attrition during the study period.

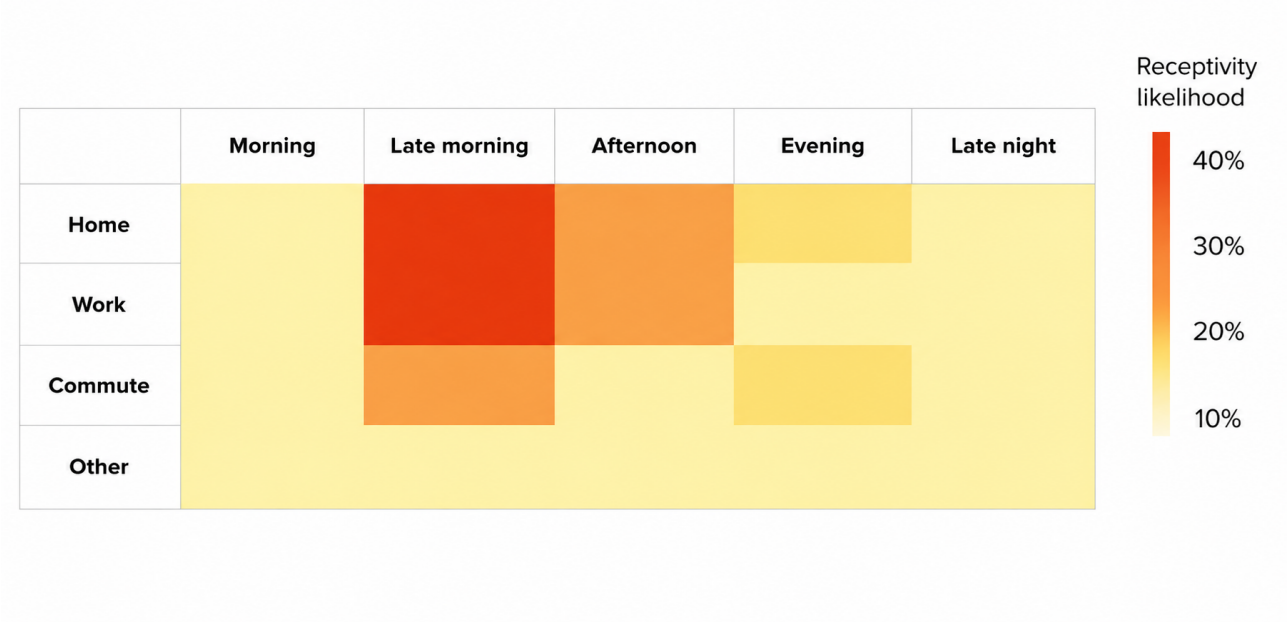
Data were collected through structured telephone interviews conducted by a trained research assistant at baseline (T1; the first day of the study period) and post intervention (T2; the last day of the study period).

The Brief Mindfulness JITAI

The brief mindfulness JITAI lasted 18 days. During days 1 to 4, participants received daily 30-minute psychosocial education sessions comprising short videos and phone-based coaching, alongside access to a brief, app-embedded mindfulness program (Figure 1). The study app was distributed to participants as an Android Package Kit for installation and was not publicly available via commercial app stores at the time of the study. Intervention content was developed by a certified mindfulness instructor and drew on "low-dose" mindfulness-based stress reduction (MBSR) elements [22]. MBSR was selected given its demonstrated feasibility, acceptability, and benefits for stress reduction among family caregivers of people with dementia [8,23,24]. Beginning on day 5, participants received push notifications prompting mindfulness practice.

XSL•FO
RenderX

Figure 1. Screenshots of the mobile app. The top-left panel shows the home screen, which greets the user (“您好”) and prompts them to start practice (“開始練習”) for week 0 (“第0週”). The top-right panel displays guided practice for a mindful walking exercise (“靜觀步行練習”), with a progress bar and playback controls. Participants can skip the exercise by pressing “略過.” The bottom-left panel features a check-in function (“每日練習”) that asks users to rate their stress level for the day (“今天你經常感受到的壓力有多大？”). The bottom-right panel showcases the video library (“影片”), which contains modules such as “Communication Skills with Dementia Patients” (“與認知障礙症患者溝通技巧和應對方法”) and “Stress Faced by Caregivers” (“照顧者面對的壓力”).



From days 5 to 11, the timing of intervention prompts was determined either by (1) a static machine learning model trained in a pilot study with 75 participants using 4 weeks of passive smartphone sensing data (day of week, time of day, type of day [weekday vs weekend], battery level, and location) and observed receptivity, operationalized as the just-in-time response rate (ie, whether a delivered notification prompted engagement with the mindfulness practice within 10 min of delivery), consistent with definitions used in prior JITAI studies [17] (Figure 2), or (2)

XSL•FO
RenderX

random scheduling with equal probability. The static model remained fixed across all participants and days.

Figure 2. Receptivity likelihood heatmap for training the static model.

From days 12 to 18 (post–warm-up period), an adaptive model was added in addition to the static and random models. The adaptive model updated its predictions as the study progressed using each participant's accumulating observed receptivity data (just-in-time response rate) and the same contextual feature set used in the static model. We introduced the adaptive model after 1 week to ensure that sufficient participant-specific data had been accumulated to inform model predictions.

Decision logic for notification timing was as follows: the static and adaptive models each used a classifier to infer whether the current moment was "receptive" for delivering a prompt; the random scheduler did not screen for receptivity and always approved delivery. If a model judged the current moment as not receptive, the app queried the same model again every 5 minutes. If no receptive moment was inferred within 30 minutes, a notification was sent, and this delivery was recorded under the random model.

Measures

Feasibility Outcomes

Intervention feasibility was assessed using recruitment, attendance, completion, and retention metrics. The recruitment rate was defined as the proportion of eligible individuals who enrolled. The attendance rate reflected the proportion of the 4 psychoeducation sessions attended. The completion rate referred to the proportion of participants who finished all study assessments. The retention rate represented the proportion of enrolled participants who remained throughout the study period.

Acceptability Outcomes

Intervention acceptability was assessed at T2 using a questionnaire with three sections: (1) acceptability of the mobile app, (2) acceptability of notifications, and (3) acceptability of mindfulness activities.

In the app section, participants indicated whether the app was easy to install and use (yes or no), whether they ignored the app's notifications (yes or no), whether the app helped them manage stress (able or helpful or not able or not helpful), and whether they would recommend the app to other caregivers (would or would not).

In the notifications section, participants rated the number of messages (too many, appropriate, or too few) and the helpfulness or appropriateness of their delivery timing (helpful, appropriate, or not helpful). They also reported whether they liked the wording of the reminders (yes or no).

In the mindfulness activities section, participants indicated whether the activities helped them manage stress (able or helpful and not able or not helpful), whether they liked the graphics and characters used (like or do not like), and whether learning mindfulness through these activities was helpful (helpful or not helpful).

Effectiveness Outcomes

The primary outcome was perceived stress, measured using the PSS-14 [20]. Items are rated on a 5-point Likert scale (0="never" to 4="very often"), with higher scores indicating greater perceived stress. Cronbach α for the Chinese PSS-14 was 0.72 at T1 and 0.82 at T2.

Depressive symptoms were assessed using the 9-item Patient Health Questionnaire, which measures the frequency of depressive symptoms over the past week [25]. Items are rated on a 4-point scale (0="not at all" to 3="nearly every day"), with higher scores reflecting greater depression severity. Cronbach α for the Chinese Patient Health Questionnaire-9 was 0.91 at T1 and 0.89 at T2.

Caregiving burden was measured using the 12-item Zarit Burden Interview [26]. Items assess the perceived impacts of caregiving on emotional strain, physical fatigue, role restriction, and social

XSL•FO
RenderX

well-being. Each item is rated on a 5-point scale (0="never" to 4="nearly always"), with higher scores denoting greater burden. Cronbach α for the Chinese 12-item Zarit Burden Interview was 0.86 at T1 and 0.87 at T2.

Positive caregiving appraisal was measured using the Positive Aspects of Caregiving Scale (PAC) [27]. The PAC assesses perceived gains from caregiving, including self-affirmation (a confident, capable self-image derived from the role) and outlook on life (interpersonal relationships and positive life orientation). Items are rated on a 5-point Likert scale (1="strongly disagree" to 5="strongly agree"), with higher scores indicating a more positive appraisal. Cronbach α for the Chinese PAC was 0.91 at both T1 and T2.

Subjective sleep quality and disturbances were assessed using the Pittsburgh Sleep Quality Index [28]. The Pittsburgh Sleep Quality Index aggregates component scores—subjective sleep quality, latency, duration, efficiency, disturbances, and daytime dysfunction—into a global score; higher scores indicate poorer sleep quality. Cronbach α was 0.69 at T1 and 0.67 at T2.

Health-related quality of life was measured using the EQ-5D-5L [29]. The EQ-5D-5L indexes problems across 5 domains (mobility, self-care, usual activities, pain or discomfort, and anxiety or depression), each rated on 5 levels (no, slight, moderate, severe, and extreme problems). A 0 to 100 visual analog scale records self-rated health. Higher scores reflect better health-related quality of life. Cronbach α for the Chinese EQ-5D-5L was 0.71 at T1 and 0.69 at T2.

Trait mindfulness was assessed using the 15-item Mindful Attention Awareness Scale, which measures the frequency of attention lapses and mindlessness in daily life [30]. Items are rated on a 6-point scale (1="almost always" to 6="almost never"), with higher scores indicating greater dispositional mindfulness. Cronbach α for the Chinese Mindful Attention Awareness Scale was 0.91 at T1 and 0.90 at T2.

Sociodemographic and Caregiving Characteristics

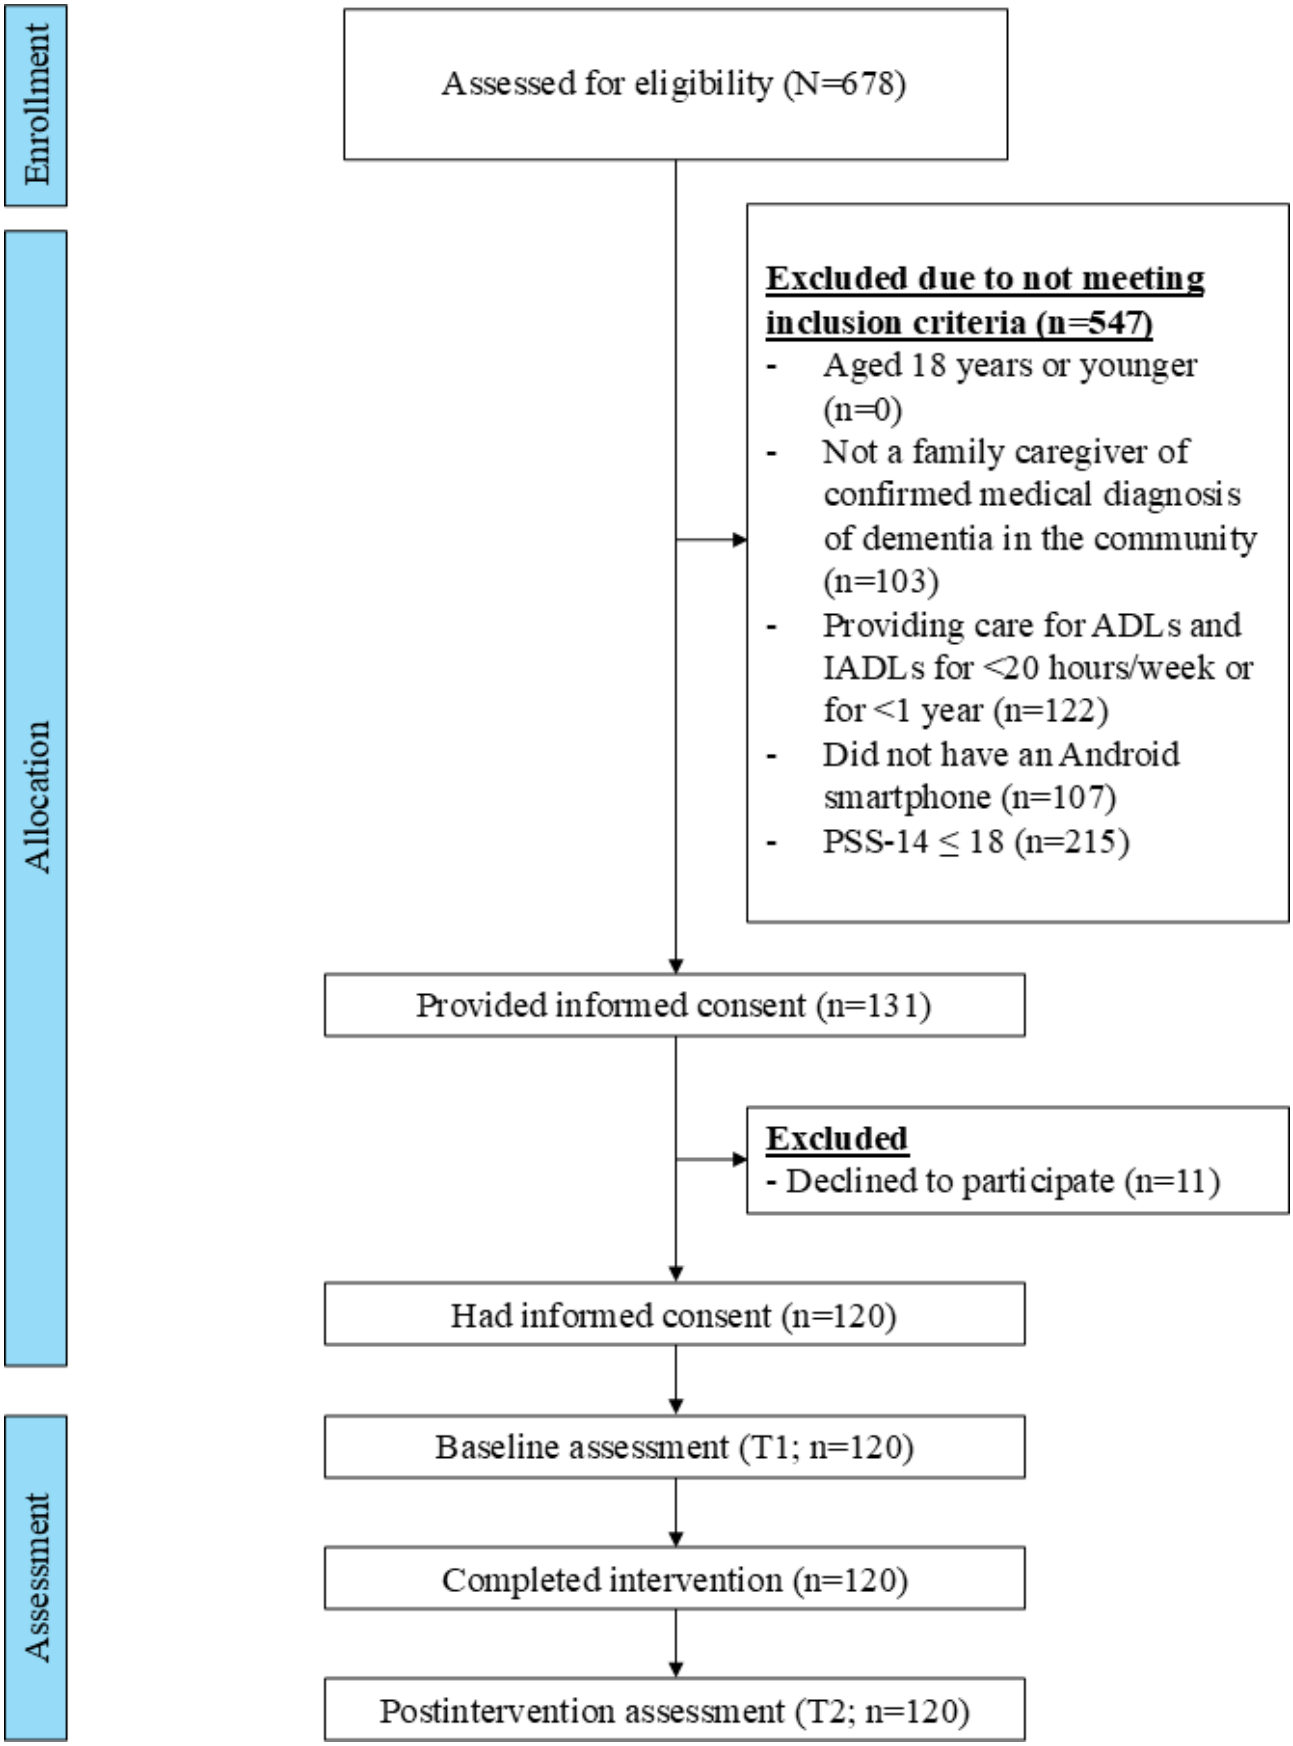
Caregivers' sociodemographic characteristics included age, gender (male and female), educational level (primary or below, secondary, and tertiary), economic status (economically inactive and economically active), household size, household income, the use of government or organizational financial assistance (yes or no), and the presence of chronic illness (yes or no) and disability (yes or no). Care recipients' sociodemographic characteristics included age, gender, chronic illness, and disability.

Caregiving characteristics included living arrangement (co-residing with the care recipient: yes or no), sole-caregiver status (yes or no), duration of caregiving (years), and weekly caregiving hours. The quality of the relationship between the caregiver and the care recipient was rated on a 5-point scale from "very good" to "very poor."

Statistical Analysis

Data were analyzed using IBM SPSS version 29. We first examined participants' sociodemographic characteristics, followed by a descriptive assessment of feasibility and acceptability outcomes. Paired-samples *t* tests were then used to compare effectiveness outcomes from T1 to T2. Unless otherwise specified, all tests were 2-tailed with an α level of 5%.

We calculated the sample size using G*Power 3.1 (Heinrich Heine University Düsseldorf). The primary effectiveness outcome was perceived stress, with an effect size of d=0.33 drawn from a prior meta-analysis of MBIs for caregivers of people with dementia [31]. A 2-tailed pre-post analysis with an α level of .05 and 80% power indicated a required sample size of 75 to detect this effect. Allowing for 20% attrition, the target was increased by 15 participants, yielding a total of 90. Recruitment continued as time and resources permitted to further increase statistical power.



Results

Sociodemographic and Caregiving Characteristics

A total of 120 caregivers participated in the study. A CONSORT flow diagram illustrating the participants' progression is shown in Figure 3. Table 1 presents the participants' sociodemographic and caregiving characteristics.

[a]Tertiary education was defined as the completion of any postsecondary program, including subdegree (associate degree or higher diploma), bachelor's degree, or postgraduate qualification.

Caregivers ranged in age from 18 to over 80 years, with a mean age of 45.4 (SD 11.8) years. Most were female (80/120, 66.7%), had completed tertiary education (66/120, 55%), and were economically active (94/120, 78.3%). The mean household size was 2.9 (SD 0.9) persons. The average monthly household income was HK $31,541.70 (SD HK $20,079.10), approximately US $4052.48. A minority of households (11/120, 9.2%) received financial assistance from the government or other organizations. Most caregivers reported having no chronic illness (108/120, 90%) and no disability (120/120, 100%).

Care recipients were older, with a mean age of 76.3 (SD 7.4) years, and the majority were female (66/120, 55%). Most had chronic health conditions (97/120, 80.8%), while a smaller proportion reported disabilities (20/120, 16.7%). The caregiving relationship was predominantly intergenerational. Most caregivers were caring for a parent, most commonly their mother (55/120, 45.8%) or father (44/120, 36.7%). Smaller proportions cared for a spouse (9/120, 7.5%) or other relatives, including grandparents and in-laws (12/120, 10% combined).

Regarding the caregiving characteristics, 70% (84/120) of caregivers lived with their care recipients. Approximately one-third (43/120, 35.8%) were identified as the sole caregiver. The duration of caregiving averaged 5.5 (SD 3.5) years. On average, caregivers devoted 45.9 (SD 20.1) hours per week to caregiving. The caregiver-care recipient relationship was generally positive: 48.3% (58/120) rated it "good" and 17.5% (21/120) "very good."

Feasibility Outcomes

Of the 131 eligible caregivers, 120 (91.6%) enrolled. Attendance, assessment completion, and retention were 120/120 (100%): all participants attended the 4-day psychoeducation sessions and completed both the T1 and T2 assessments, and no dropouts occurred during the study period.

Acceptability Outcomes

Table 2 presents the acceptability outcomes of the brief mindfulness JITAI. Most participants (111/120, 92.5%) found the app easy to install and use. Although a notable proportion of participants reported ignoring notifications at times (68/120, 56.7%), the majority felt the app helped them manage stress (98/120, 81.7%) and would recommend it to other caregivers (96/120, 80%). Regarding notifications, most participants considered the number of messages appropriate (87/120, 72.5%), and a substantial proportion found the timing of the messages appropriate (52/120, 43.3%). The majority of the participants liked the wording of the reminders (107/120, 89.2%).

Yes	107 (89.2)
No	13 (10.8)
Acceptability of mindfulness activities	
Mindfulness helped me manage stress	
Able or helpful	102 (85)
Not able or not helpful	18 (15)
Liked the graphics and characters used	
Like	99 (82.5)
Do not like	21 (17.5)
Learning mindfulness through these activities was helpful	
Helpful	102 (85)
Not helpful	18 (15)

[a]JITAI: just-in-time adaptive intervention.

Participants also indicated that the mindfulness activities generally helped them manage stress (102/120, 85%), that they liked the app's graphics and characters (99/120, 82.5%), and that the app was helpful for learning mindfulness (102/120, 85%).

Effectiveness Outcomes

Table 3 presents the effectiveness outcomes of the brief mindfulness JITAI. Figure 4 provides a visual summary of the standardized pre-post changes (effect sizes) across outcomes. The analysis of preintervention and postintervention effectiveness outcomes revealed statistically significant improvements across several psychosocial domains. Participants

XSL•FO
RenderX

showed a significant reduction in perceived stress (P<.001), depressive symptoms (P<.001), and caregiving burden (P=.003). Conversely, there was a significant increase in the positive aspects of caregiving (P<.001). A significant improvement in subjective sleep quality (ie, scores decreased) was also observed (P=.02). However, no statistically significant changes were found for health-related quality of life (P=.08) or for trait mindfulness (P=.14).

Figure 4. Forest plot of standardized outcome changes from T1 to T2. Positive values indicate improvement. For outcomes in which lower scores reflect better status (perceived stress, depressive symptoms, caregiving burden, and subjective sleep quality), effect sizes were sign-reversed so that positive values consistently represent improvement across measures. Error bars indicate 95% CIs.

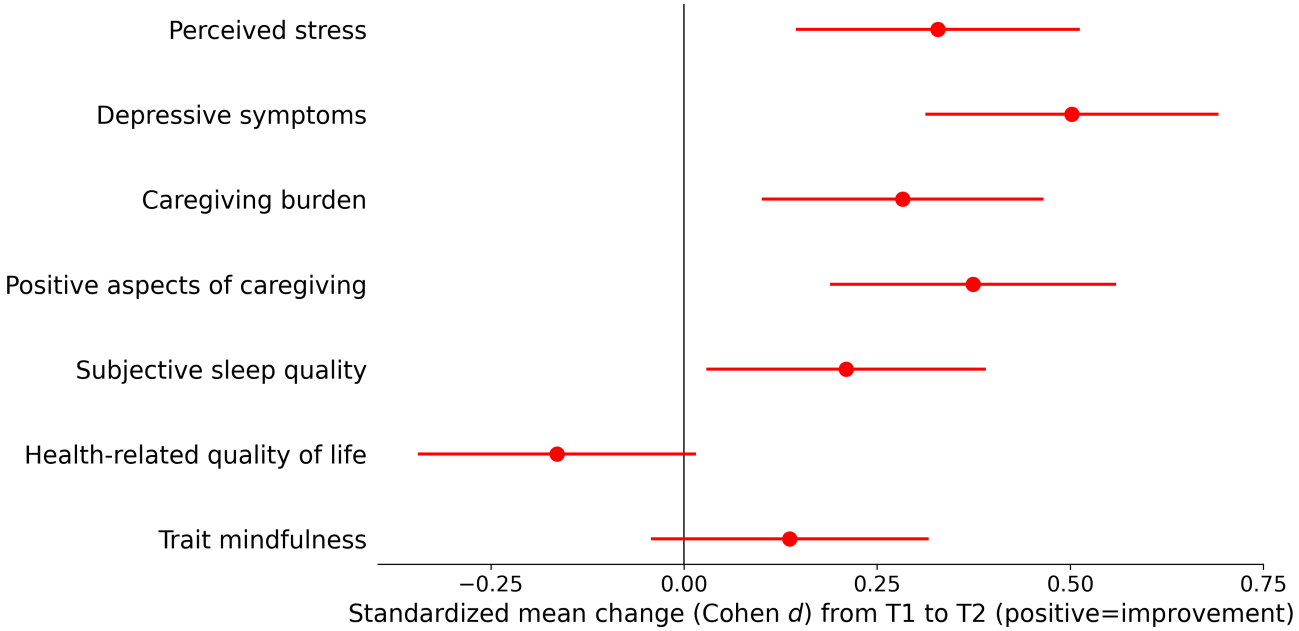

Table . Effectiveness outcomes of the brief mindfulness JITAI[a].

Outcomes	Baseline (T1), mean (SD)	Postintervention (T2), mean (SD)	*t* (*df*)	*P* value	*d*
Perceived stress	30.1 (3.8)	28.6 (4.8)	–3.6 (119)	<.001	–0.33

[a]JITAI: just-in-time adaptive intervention.

Discussion

Principal Results

This study evaluated a brief mindfulness JITAI for family caregivers of people with dementia and found it to be a feasible, acceptable, and potentially effective approach for improving the mental well-being of caregivers. The intervention demonstrated high feasibility, with a recruitment rate of 91.6% and 100% attendance, completion, and retention. These metrics suggest that the 18-day program was appealing to caregivers and did not place an undue burden on participants.

Acceptability was also high. Most caregivers reported that the application was easy to install and use (111/120, 92.5%), helpful for managing stress (98/120, 81.7%), and something they would recommend to other caregivers (96/120, 80%). Although some participants (68/120, 56.7%) acknowledged ignoring notifications at times, most found the number of messages (87/120, 72.5%) and their delivery timing (99/120, 82.5%) to be helpful or appropriate. The mindfulness activities were positively received, with 85% (102/120) of users reporting that they were helpful for both stress management and learning mindfulness.

Regarding effectiveness, pre-post analyses revealed significant reductions in perceived stress, depressive symptoms, and

XSL•FO
RenderX

caregiving burden, along with a significant increase in positive aspects of caregiving. Sleep quality also improved significantly. However, the intervention did not produce statistically significant changes in health-related quality of life or trait mindfulness.

Comparison With Prior Work

Our findings align with prior JITAI research conducted primarily among noncaregiver populations, including smoking cessation and obesity or dietary adherence interventions, as well as mindfulness-triggering approaches in chronic pain [14,16,32]. However, to our knowledge, this is the first study to apply a mindfulness-based JITAI to family caregivers of people with dementia, a group with distinct constraints and stress dynamics that can undermine adherence to traditional MBIs. Most participants reported that the app was easy to use and helpful for learning and applying mindfulness to reduce stress, consistent with proposed mindfulness-based JITAI mechanisms that target negative affect and automatic responding by increasing present-moment attention in real time [14]. Notably, our results suggest that just-in-time delivery is especially well suited for caregivers of people with dementia, who face substantial time constraints due to heavy caregiving duties and other life commitments. By emphasizing brief windows of receptivity, the intervention may facilitate engagement, as reflected in the high attendance and retention rates. Although mindfulness can help caregivers manage stress, dementia care is a long-term trajectory, and traditional MBIs often struggle to achieve sustained impact because of the required time commitment [9]. By targeting receptive moments for self-practice, the JITAI approach shows promise for supporting longer-term practice across the caregiving trajectory.

Prior mindfulness-based JITAIs, such as those targeting substance use, often trigger intervention prompts at moments of vulnerability (eg, cravings) [14]. For caregivers of people with dementia, however, high-vulnerability states (eg, acute stress) can impede practice because stress taxes attentional control, creating cognitive interference that hinders engagement [11]. As such, our brief mindfulness JITAI focused on prompting during receptive moments. To optimize receptivity, we used three complementary approaches: (1) a machine learning–informed static model derived from pilot data, (2) a random-timing model, and (3) a machine learning–based adaptive model that updated using each participant's receptivity data over time. Overall, most participants rated message frequency and timing favorably, though some notifications were ignored, indicating room for improvement. Because multiple models were deployed concurrently, we cannot isolate the most optimal approach. Future work should directly compare static, random, and adaptive models to maximize receptivity and, in turn, enhance the benefits of mindfulness for this population.

Regarding self-reported outcomes, we observed small to medium reductions in stress and depressive symptoms, consistent with prior MBIs for caregivers of people with dementia [9,24,33]. The mindful coping model posits that decentering disrupts negative thought cycles and supports more positive stress appraisals [10]. Through this mechanism, mindfulness may reduce depressive symptoms by decreasing rumination, which is a repetitive, problem-unresolved focus on negative thoughts [34]. These findings suggest that a mindfulness-based JITAI can yield benefits that align with traditional MBIs while requiring a less intensive and more flexible structure than standard 8-week programs. Such a less intensive approach may reduce burden and improve accessibility by delivering support via a mobile app, thereby enhancing reach for more caregivers. However, because we did not include a traditional MBI control, we cannot directly compare effect sizes on psychosocial outcomes. Future research should compare JITAI-based mindfulness interventions with standard, group-based mindfulness interventions to clarify their relative efficacy in reducing stress and depressive symptoms among caregivers of people with dementia.

We also observed a small reduction in caregiving burden, diverging from findings in previous trials of MBIs for caregivers of people with dementia that often show no effect on caregiving burden [24,33]. One explanation is that self-directed practices and face-to-face attendance in traditional MBIs add to already busy schedules and are frequently affected by low adherence to self-directed practice. If caregivers perceive the intervention as too intensive, they may lack the motivation to engage in self-practice; yet informal mindfulness practice has been linked to improvements in psychological well-being [35]. By delivering prompts when caregivers are most receptive, a just-in-time approach may better motivate self-directed practices. Heightened moment-to-moment attention in real time via a JITAI may also foster more positive appraisals of caregiving experiences, aligning with our observed gains in positive aspects of caregiving, an outcome rarely examined in prior MBI trials in this population. Cross-sectional evidence similarly links mindfulness with more positive caregiving experiences [36]. Consistent with reduced burden, we also found improvements in subjective sleep quality, which contrasts with some prior findings from MBIs in this population [37,38]. A recent scoping review supports an association between caregiving burden and subjective sleep quality [39]. Because behavioral and psychological symptoms of dementia are often a major source of burden [40], delivering mindfulness via a JITAI with increased self-practice may facilitate caregivers' translation of mindfulness into more positive responses to behavioral and psychological symptoms of dementia, potentially reducing burden [9]. Given the absence of a control group, these findings should be interpreted cautiously and not as evidence of causality. Randomized controlled trials (RCTs) with process evaluations are needed to elucidate mechanisms underlying reductions in caregiver burden in mindfulness-based JITAIs for this population.

In contrast, neither trait mindfulness nor health-related quality of life improved after the brief mindfulness–based JITAI. This suggests that the 18-day dosage, including 4 days of psychoeducation, may be insufficient to shift dispositional mindfulness, which typically requires sustained practice over a longer period [41]. For example, longer programs (eg, 16-wk formats) have shown gains in trait mindfulness in caregivers of people with dementia [23]. This may also explain the absence of improvement in health-related quality of life, given that trait mindfulness can mediate the relationship between stress and

XSL•FO
RenderX

health-related quality of life [42]. Future JITAI-based mindfulness interventions should systematically examine dose-response relationships to clarify their effects on trait mindfulness in this population.

Implications

This study demonstrates the feasibility and preliminary effectiveness of a mindfulness-based JITAI to support family caregivers of people with dementia. By prompting brief mindfulness micropractices at moments of higher receptivity, the intervention directly addresses practical barriers that commonly limit caregivers' engagement with traditional MBIs (eg, time constraints, competing care demands, and difficulty sustaining self-directed practice). If these findings are confirmed in controlled trials, this delivery approach could be implemented as a low-intensity, scalable adjunct to the existing community and nongovernmental organization caregiver services by providing between-session support, extending reach to caregivers who are homebound or unable to attend groups regularly, and improving service efficiency through engagement data that can help identify caregivers who may benefit from additional dose, booster support, or stepped-care escalation. In this way, a mindfulness JITAI may strengthen routine caregiver services by enhancing access, personalization, and continuity of support with minimal additional manpower burden to the health and community care system.

Limitations

This study has several limitations. First, the pre-post, quasi-experimental design lacks a control group, precluding causal inference. Although we observed pre-post reductions in perceived stress and other psychosocial outcomes, these changes cannot be attributed solely to the brief mindfulness JITAI. We encourage future studies to evaluate the program using more rigorous research designs, such as RCTs. Second, we did not include process indicators to examine mechanisms of action; thus, we cannot confirm that improvements resulted from enhanced self-directed mindfulness practices. Future studies should incorporate process measures and mediation analyses to elucidate the mechanisms of change in JITAIs and clarify their unique benefits relative to traditional delivery. Third, although our goal was to examine the general effects of a JITAI, the optimal delivery algorithm remains unclear. Future trials may consider using a microrandomized trial design to test whether a static, random, or adaptive model most effectively predicts and acts upon moments of receptivity. Fourth, this study examines only the effects of the brief JITAI on caregivers. However, a recent meta-analysis highlights dyadic psychosocial effects, whereby depressive symptoms in people with dementia can negatively affect caregivers' quality of life [43]. Given the close linkage between caregivers' and care recipients' psychosocial health, future research should evaluate the effects of the brief mindfulness JITAI at the dyadic level. Fifth, the study's generalizability may be affected by the sample characteristics and the technology eligibility criteria. In our sample, participants were relatively young (mean age of 45.4, SD 11.8 y), predominantly female (80/120, 66.7%), and highly educated (66/120, 55% tertiary education), whereas territory-level data on carers of older people overall suggest an older caregiver profile (74.5% female among 966 respondents; mean age of 54.5, SD 18.1 y) [44]. Due to the development and resource constraints in implementing the intervention on both operating systems in parallel, the study was delivered on Android only, and caregivers who primarily used iOS devices were excluded. This platform restriction may have introduced selection bias toward more digitally ready participants and may partly explain the relatively younger and more educated sample. In addition, higher educational attainment may reflect self-selection (eg, greater health literacy or confidence with app-based, self-guided interventions), potentially inflating feasibility, acceptability, and engagement estimates. Future trials should broaden recruitment channels and support multiplatform delivery, alongside enhanced onboarding and technical support, to better capture older, male, and lower-literacy caregiver subgroups. Sixth, the intervention was brief, and there was no long-term follow-up; thus, the sustainability of effects remains unclear. The program lasted 18 days, and outcomes were assessed only immediately post intervention, limiting conclusions about whether observed improvements would be maintained after prompts ended. Given that dementia caregiving is a long-term role, future studies should include longer follow-up (eg, 1-3 - 6 mo) to evaluate durability and to determine whether maintenance supports (eg, tapered prompting, booster sessions, or continued low-intensity prompting) are required to sustain practice and benefits under real-world caregiving conditions.

Conclusions

A brief, mindfulness-based JITAI appears feasible and highly acceptable for supporting caregivers of people with dementia. We observed statistically significant reductions in perceived stress, depressive symptoms, and caregiving burden, alongside increased positive aspects of caregiving and subjective sleep quality, supporting the potential of adaptive, technology-enabled interventions to provide timely, personalized support tailored to caregivers' complex needs. Future work should involve a rigorously designed, adequately powered RCT to confirm efficacy, clarify mechanisms, and inform broader implementation.

Acknowledgments

The authors extend their sincere gratitude to all participants who contributed to this study. No generative artificial intelligence tools were used.

Abstract

Background: The growing aging population has increased the need for technologies that support informal caregivers in home-based older adult care. Digital twin (DT) systems offer promising capabilities; yet, their effectiveness depends on usability, an aspect still insufficiently evaluated among caregivers.

Objective: This study aimed to assess the usability of an older adult care DT system using a dual-method evaluation that integrates subjective and objective behavioral performance.

Methods: Fifty caregivers participated in a usability assessment combining the System Usability Scale (SUS) and detailed system activity log analytics. Log-based measures included task completion, time on task, errors, and abandonment rate. A composite user engagement score was computed and analyzed for correlation and predictive association with SUS ratings. Engagement clusters were also explored.

Results: Caregivers reported an excellent mean SUS score of 80.45. System logs showed a 94.08% task completion rate, 2.66% abandonment, and an average task duration of 89.16 seconds. User engagement score demonstrated significant correlations with SUS (r=0.626, ρ=0.552; P<.001) and significantly predicted usability in regression analysis (β=52.94, R^2=0.392; P<.001). Engagement-based clustering identified high-, medium-, and low-tier user groups, each exhibiting distinct usability patterns.

Conclusions: Integrating subjective usability ratings with objective behavioral metrics provides a rigorous and comprehensive approach to evaluating DT systems for older adult care. The findings highlight strong usability of the system and offer actionable insights for refining caregiver support technologies.

elderly digital twin; usability study; System Usability Scale; user engagement score; caregiver support

Introduction

Background

The global demographic shift toward an aging population presents unprecedented challenges for health care systems worldwide. The world's population older than 60 years is projected to double from 1.06 billion (13.5%) in 2020 to 2.13 billion in 2050 (22.0%), raising significant concerns about the impact of aging [1]. This rapid aging process is characterized by an increased prevalence of chronic diseases, complex health care needs, and a growing demand for personalized and proactive health care models [2,3]. In the current technology-driven age, digital twin (DT) has emerged as a transformative approach in health care, offering the potential to revolutionize older adult care through predictive analytics and personalized interventions. DTs are virtual representations of physical entities that enable the dynamic simulation of potential treatment strategies, monitoring and prediction of health trajectories, and early intervention and prevention [4]. In the context of older adult health monitoring, DTs create comprehensive virtual models that integrate multimodal data, including clinical records, genetic information, wearable sensor data, and environmental factors, to provide a holistic view of an individual's health status [5,6].

The application of DT technology in older adult care is particularly compelling because of its ability to monitor vital signs, physiological parameters, and other health-related data in real time, enabling health care providers to detect early signs of deterioration or anomalies and proactively intervene in such scenarios [6]. Recent implementations have demonstrated the potential of this technology in aging-in-place scenarios, where DTs facilitate continuous health monitoring while preserving

XSL•FO
RenderX

the independence and quality of life of seniors [7]. For example, DT systems have been successfully deployed to monitor older adult patients for fall detection, abnormal posture recognition, and health risk assessment, with validation trials showing promising results in real-world nursing home environments [8].

The complexity of older adult care often necessitates significant involvement from both formal and informal caregivers, who play crucial roles in health monitoring, decision-making, and care coordination. Informal caregivers, predominantly family members, face substantial challenges in navigating complex health care systems and making informed decisions [9,10]. Family caregivers' decision support interventions have shown promise in improving care outcomes, with studies demonstrating that well-designed decision support tools can reduce family caregivers' decision uncertainty and improve satisfaction with the quality of care [9]. Such tools leverage trust, cultural humility, strength-based approaches, and effective information sharing to facilitate meaningful conversations between caregivers and health care providers. In the context of DT systems for older adult care, caregiver-facing interfaces have become essential components that must translate complex health data into actionable insights that support informed care–related decisions [10].

The success of DT systems in older adult health care depends critically on their usability, particularly in home care settings, where family members are involved in a variety of experiences [11]. In health care contexts, poor usability can have serious consequences, including medical errors, reduced adoption rates, and compromised patient safety [12]. For DT systems targeting older adult populations and their caregivers, usability considerations have become even more critical because of the potential age-related changes in vision, dexterity, and cognitive processing. Older adults often require caregiver mediation when interacting with digital health technologies, and systems must be designed to accommodate both direct older adult users and caregiver interactions [13].

In health care usability research, evaluation has largely relied on subjective self-report instruments, most prominently the System Usability Scale (SUS), which has been applied across diverse digital health systems such as caregiver monitoring tools HELMA [14], self-management apps for heart failure (Engage) [13], exergame training systems [15], and interdisciplinary hospital information platforms such as therapy and monitoring systems [16]. While SUS provides standardized benchmarking, its reliance on user perception limits insights into actual system interaction. Studies have attempted to complement the SUS with performance or log data: the HELMA project tracked caregiver login frequency and session duration, the Engage system analyzed task completion and observed errors, and exergame interventions logged exercise scores and reaction accuracy. However, these measures often remain surface-level, focusing on frequency, duration, or clinical outcomes rather than granular task behavior analytics such as navigation sequences, error recovery, feature usage, task completion, time on task, click on task ratio, retry rate, session duration, or task abandonment ratio. Moreover, limitations such as older adults' reliance on caregiver mediation [14,17] and testing in controlled settings [13,15] constrain the validity of existing evaluations. Collectively, these findings underscore a critical gap: while subjective usability assessments dominate and objective measures have been trailed, few health care studies [13,14] have integrated log-based behavioral data with standardized questionnaires. To address this gap, our study proposes a dual-method evaluation framework that unites SUS scores with detailed behavioral engagement metrics, providing both perceived and observed dimensions of usability in caregiver-facing DT systems.

To address this gap, this study conducted a usability evaluation of an elderly digital twin (EDT) system designed to support informal caregivers in home care settings. In our previous work [18], we proposed a comprehensive EDT framework to assist caregivers in making informed decisions. To evaluate the feasibility and applicability of the framework, we developed a working EDT system prototype. Unlike prior studies that emphasized technical modeling or data integration, this study explicitly targets the informal caregiver perspective, in which usability is critical for adoption in daily home care. Our evaluation follows a dual-method approach with the following two objectives: (1) subjective evaluation of the usability of our proposed EDT system by assessing caregivers' perceptions using the hugely popular SUS; (2) objective evaluation of usability by proposing a novel behavioral engagement metric that can be used in conjunction with the SUS.

We present a dual-method usability evaluation framework that combines log-based behavioral analytics (objective measurement) with a standardized SUS questionnaire (subjective measurement) [19]. This approach leverages the complementary strengths of objective behavioral data and subjective user feedback to provide a comprehensive view of the system's usability. The log-based component captures detailed user behavior, including interaction patterns, feature usage, task completion pathways, error rates, and temporal usage characteristics. These metrics offer insights into real-world usage that may not be revealed through self-reported measures alone. In parallel, the SUS component provides standardized usability scores that enable benchmarking against established norms in health care applications and allow comparisons with other digital health interventions.

This dual-method approach directly addresses a noticeable gap in existing evaluation practices: the dominance of subjective methods with limited or superficial use of objective interaction data. Previous health care systems' usability studies often relied on the SUS or combined it with a basic usage log [13,14,17], which failed to capture how systems are actually navigated and used in real practice. By integrating behavioral engagement metrics with subjective user perceptions, our study provides an evidence-based, user-centered, and replicable framework for evaluating digital health applications. Applied specifically to caregiver-facing interfaces for DTs of the older adults, this methodology not only fills the gap but also offers actionable insights to guide iterative design and ensure more effective, caregiver-friendly digital health systems. The remainder of this manuscript is organized as follows: Section 2 reviews related work, Section 3 outlines the methods, Section 4 presents the results, Section 5 offers a discussion, and Section 6 concludes the study.

Related Work

The growing complexity of older adult care has driven the development of digital health technologies, including DT systems, to support clinical decision-making and informal caregivers. As these systems advance, ensuring their usability, particularly for nonprofessional caregivers, is critical for adoption and effectiveness. Previous studies have evaluated digital health technologies using subjective measures, such as the SUS or qualitative interviews. This section reviews usability studies and highlights the methodological gap addressed by our dual-method approach.

Usability Evaluation Methods: Subjective Versus Objective

Usability evaluation methods fall into 2 primary categories: subjective and objective. Each category offers unique advantages and faces distinct limitations, making the choice between them or their combination critical for comprehensive usability assessment. SUS remains the most widely adopted usability instrument, valued for its brevity, reliability, and extensive benchmarking data [20,21]. Recent validation studies have reinforced SUS's psychometric properties of the SUS. A validation study of voice user interfaces confirmed SUS's usefulness across different interaction modalities. Additionally, researchers have developed item-level benchmarks for the SUS, allowing practitioners to interpret individual items when specific usability attributes require targeted assessment. These benchmarks enable a more granular evaluation while maintaining the scale's standardized scoring advantage [20,22].

In addition to the SUS, several other standardized questionnaires serve specific evaluation contexts. The usability metric for user experience (UMUX) and its shortened variant, UMUX-LITE, offer alternatives that are more closely aligned with the ISO (International Organization for Standardization) 9241 definitions of usability. Recent psychometric evaluations suggest that the UMUX-LITER provides the closest correspondence to SUS scores when converted to comparable scales [23]. The NASA-TLX (National Aeronautics and Space Administration–Task Load Index) addresses perceived workload in complex, high-consequence environments, making it particularly valuable for health care, aerospace, and military applications. However, its complexity and administration time limit its usefulness for consumer product evaluations [24]. AttrakDiff occupies a unique position by measuring both the pragmatic and hedonic quality dimensions of the user experience. This dual focus allows for the evaluation of traditional usability metrics alongside emotional and aesthetic responses, although recent studies have raised concerns about translation reliability and cultural adaptation [25].

Subjective methods are easy to administer, resource-efficient, and standardized, enabling benchmark comparisons and effective communication among practitioners [26,27]. However, subjective measures have significant limitations. Social desirability bias is a primary concern, with users potentially providing responses they believe evaluators want to hear rather than their genuine perceptions. Cultural factors also influence responses, with different populations rather than actual performance potentially missing critical usability issues that users may not consciously recognize [25,26,28].

Objective evaluation centers on measurable performance indicators, such as task completion, time on task, and error analysis, which together provide insights into system effectiveness and efficiency [29-31]. Error analysis offers detailed insights into the usability problems. Error rates can be calculated globally (total errors divided by total attempts) and task-specific (errors per task opportunity), providing different perspectives on system performance. Modern approaches distinguish between error types and severity levels, enabling targeted improvements [29,31].

Clickstream analysis is a core component of behavioral log methods and has emerged as a powerful objective approach for tracking user navigation patterns, feature usage, and drop-off points. By capturing the sequence of interactions, it highlights problems that are invisible to traditional subjective metrics [32-34]. Advanced behavioral analytics extend this further by combining multiple interaction types, such as clicks, mouse movements, and page transitions, to generate comprehensive user journey maps. These methods are particularly valuable for detecting navigation bottlenecks and optimizing conversion paths in digital systems.

Objective methods generally provide concrete evidence for design decisions by revealing fine-grained interaction patterns that users may not consciously recognize or accurately report [35,36]. However, they also face implementation challenges: data collection and analysis can be complex and resource-intensive, and these methods may not directly capture user satisfaction or emotional responses, requiring supplementary subjective measures. Moreover, standardized interpretation frameworks for many objective metrics remain underdeveloped, complicating cross-study comparisons [26]. Recent health care usability studies have demonstrated effective hybrid implementation [37] and described a hybrid approach that satisfies both pragmatic development needs and academic research requirements. Their framework captures detailed behavioral data for intermediate iterations while enabling deeper qualitative analysis for academic dissemination. Contemporary usability evaluation is shifting toward integrated approaches that combine machine learning with behavioral subjective data analysis. Advanced statistical methods improve the correlation between objective performance and user satisfaction [38]. Recognizing that no single method offers a complete picture, the field increasingly adopts multimethod strategies that balance methodological strengths and limitations while maintaining practical feasibility [37].

Clinical Relevance of Fitbit Sense 2 Data

Consumer wearables are increasingly used in digital health because they enable continuous, low-burden physiological monitoring outside clinical settings. Their clinical relevance, however, is parameter-specific rather than uniform. A systematic review of Fitbit devices found the strongest evidence for step counting under selected conditions, whereas energy expenditure, sleep, and some other measures showed less consistent accuracy and should be interpreted cautiously in health-related decision contexts [39]. A later meta-analysis of wrist-worn Fitbit sleep

XSL•FO
RenderX

models reported that newer sleep-staging devices performed better than earlier motion-only models but still were not substitutes for polysomnography [40]. Because this study used Fitbit Sense 2, newer-generation evidence is also relevant: a prospective multicenter validation study of 11 consumer sleep trackers found that Fitbit Sense 2 showed moderate agreement with polysomnography for sleep-stage classification and competitive performance among wearables, including relatively strong performance in deep-stage detection [41].

Taken together, these findings support a measured role for Fitbit Sense 2 in caregiver-facing systems. Recent free-living validation of a newer Fitbit device against medical-grade references showed moderate to good agreement for daily steps, resting heart rate, respiratory rate, and some heart rate variability (HRV) measures but weaker agreement for oxygen saturation, indicating that some physiological channels are more dependable than others [39,41,42]. Accordingly, Fitbit Sense 2 data in the EDT are best viewed as supporting longitudinal trend monitoring, anomaly awareness, and caregiver-oriented decision support rather than diagnostic inference.

Current Usability Evaluation Methods for Health Care Systems

As shown in Table 1, prior usability studies of digital health systems have relied on subjective methods, particularly the SUS, interviews, and qualitative feedback [13-15,17,43-48]. Only a few studies incorporated partial task-based or observational measures, and these were typically limited and not derived from detailed real-time interaction logs [13,14,45]. Moreover, studies focused on patients, older adults, or clinical professionals in institutional settings rather than informal caregivers in home-based care [16,17,44-48]. Synthesizing these studies reveals three major gaps: (1) heavy reliance on subjective measures without integrating detailed objective interaction logs, (2) limited focus on formal caregivers in home settings, and (3) superficial assessment of task behavior, where satisfaction or completion was reported but navigation patterns, retries, and feature usage were not captured. To address these gaps, this study integrates subjective usability perceptions (SUS) with objective system usage data (user activity logs), providing a more ecologically valid and holistic framework for evaluating caregiver-facing DT systems for older adults.

Table . Comparison of usability methods, target groups, and system features across related studies.

Target users	Method	SUS[a]	Log	Setting	Focus	Behavioral metrics	References
Informal caregivers	SUS, interview	No	No	Home	Stroke support	No	[43]
Older adults + Caregivers	SUS, interview	72.2	Partial	Home	Cognitive monitoring	Partial	[14]
Older adults + Caregivers	SUS, NASA-TLX	82.6	No	Home + Clinical	Heart Failure	Partial (observed)	[13]

Methods

Study Design

This study evaluated the usability of the EDT system for supporting informal caregivers in home-based care. To provide a comprehensive assessment of user interaction, both subjective and objective measures were integrated. The following sections describe the study design, system features, participant recruitment, testing procedures, and analytical methods used to assess usability.

Overall System Flow

We used a cross-sectional observational design to evaluate the usability of the caregiver-facing EDT prototype. Figure 1 illustrates the system architecture and data flow during the usability sessions. Older adult participants wore a Fitbit smartwatch to collect physiological data, including heart rate, sleep, and activity measures. These data were transmitted to the cloud for secure transfer and preprocessing and then processed and stored by the back end for analysis and insight generation. Caregivers accessed the EDT system through computers, tablets, iPads, or smartphones, where they viewed real-time and historical health information, including digital biomarkers and artificial intelligence (AI)–generated recommendations. During the sessions, informal caregivers completed representative tasks such as exploring dashboards, reviewing AI-based recommendations, and navigating system features. User interactions were recorded through back-end logs, and caregiver feedback was collected using a questionnaire. Sample user interfaces of the system are presented in Figure 2 for cardiac DT and Figure 3 for sleep stage monitoring, while detailed system feature interfaces are provided in the Multimedia Appendix 1.

Figure 1. Illustration of the system usability session setup, showing data flow from a home-based older adult to a digital twin platform accessed by an informal caregiver.

RenderX

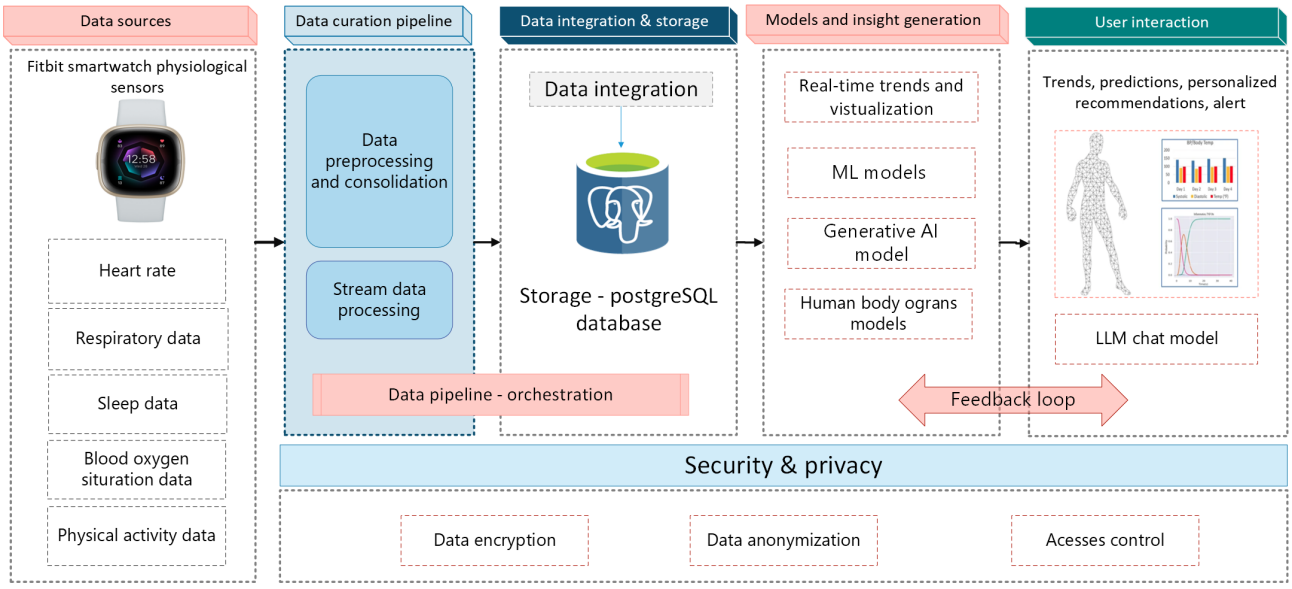

Figure 3. Sleep stages analysis user interface.

System Features

The EDT system evaluated in this study was designed to provide informal caregivers with real-time, personalized insights into the health status of older adults in their homes. The system follows a modular architecture with 5 core components: data sources, data curation pipeline, data integration and storage, models and insight generation, and user interaction, with a dedicated security and privacy layer and a dynamic feedback loop between the user and intelligent models, as shown in Figure 4.

Figure 4. High-level architecture of elderly digital twin system. AI: artificial intelligence; LLM: large language model; ML: machine learning.

Data Sources

The system captures multimodal physiological data using a Fitbit smartwatch worn by older adults. These signals included heart rate, respiratory data, sleep log data, blood oxygen saturation (SpO_2), and physical activity.

Data Curation Pipeline

Incoming sensor data are streamed into an automated preprocessing module that handles data cleaning, synchronization, and consolidation across modalities. A dedicated stream processing engine prepares the data for integration and downstream analysis in real time. This stage ensures quality and consistency before the data are forwarded through an orchestrated pipeline.

Data Integration and Storage

The processed data were stored centrally in a PostgreSQL database. This layer supports structured data storage and efficient querying for both real-time and retrospective analyses. Integration mechanisms ensure temporal alignment of physiological signals for model consumption.

XSL•FO
RenderX

Models and Insights Generation

The EDT system comprises 2 main components: a Cardiac Digital Twin and a Sleep Monitoring Digital Twin, which monitor physiological signals and generate insights for caregivers. The EDT prototype was evaluated as a caregiver-oriented decision support research system rather than as a diagnostic tool, and the sensing device used in this study, Fitbit Sense 2, is not a Food and Drug Administration–approved device for clinical use. Cardiac Digital Twin tracks heart health in older adults through real-time heart rate monitoring, trend visualization, and HRV analysis. A 3D cardiac model simulates a beating heart with animation driven by current beats per minute. For continuous monitoring during data loss, a bidirectional long short-term memory (Bi-LSTM) model predicts beats per minute at 5-minute intervals. Bi-LSTM was selected because of its ability to capture temporal dependencies and improve physiological prediction accuracy. When activated, the system notifies the caregivers that synthetic predictions are being used. The Bi-LSTM model was trained in 579,486 heart rate records, achieving a mean squared error of 0.2944 and a mean absolute error of 0.3410. The reported model performance metrics are presented to characterize the technical behavior of the prototype components and should not be interpreted as evidence of clinical-grade validity.

The Sleep Monitoring Digital Twin processes multisensory physiological data to monitor sleep behavior. It analyzes patterns across sleep stages, including light, deep, rapid eye movement, and awake, and visualizes trends to support long-term observation. The system computes sleep quality metrics, such as efficiency, latency, and awakenings, using probabilistic models to map the stage transitions. These outputs enable the detection of sleep disruptions and behavioral anomalies linked to health decline in the older adult population. A long short-term memory model was developed to infer sleep stages from SpO_2 and heart rate data, chosen for its memory structure suitable for temporal dependencies in physiological time series. The model achieved 92% validation accuracy for 9125 sequences, maintaining sleep-tracking continuity. In this study, however, the sleep-monitoring model was included to enable the functional operation of the caregiver-facing EDT interface and was evaluated as part of the overall usability workflow rather than as a stand-alone clinically validated diagnostic model. A submodule monitored SpO_2 levels to detect hypoxemia, triggering alerts and large language model (LLM) feedback when oxygen saturation fell below the critical threshold. The LLM outputs are intended to support caregiver awareness and follow-up, rather than provide medical diagnosis or treatment advice.

To enhance real-time interpretability and caregiver empowerment, both DT models were supported by a fine-tuned GPT-4o LLM through instruction-based fine-tuning in caregiving. This LLM module delivers context-aware personalized feedback by interpreting physiological indicators, including abnormal heart rate patterns, HRV, disrupted sleep trends, sleep efficiency, latency, awakening, and hypoxemia through SpO_2 monitoring. When the system detects anomalies such as elevated heart rate, low HRV indicating stress, oxygen saturation below thresholds, or deviations from sleep benchmarks, it triggers the LLM to generate clear, caregiver-facing recommendations. These responses are personalized based on recent health trends and are presented in an understandable language. LLM summarizes patterns and provides decision support recommendations for caregiver actions such as monitoring hydration or seeking clinical evaluation. This fine-tuned GPT-4o model translates complex sensor data into actionable guidance, strengthens decision support capabilities, and fosters informed caregiving responses.

In our previous study, the caregiver-facing recommendations were subjected to structured medical experts' evaluation across the dimensions of clinical appropriateness, usefulness, safety, and alignment with clinical guidelines, with overall positive ratings and substantial interrating agreement, supporting their use as decision support guidance in the present system [18]. To reduce the hallucinations, the GPT-4o model was developed using instruction-based fine-tuning in caregiving and grounded in structured physiological indicators from the EDT. The model was activated only when anomalies or threshold deviations were detected. The decision support recommendation generation was constrained through restricted prompting and limited output scope. Its outputs were designed as caregiver-friendly guidance and human-readable summaries of observed sensor patterns and not diagnosis or treatment advice. The system also used escalation language, such as advising clinical evaluation for concerning cases.

User Interaction

The system provides a web-based interface for informal caregivers that is accessible through desktops, smartphones, and tablets. The dashboard enables navigation across modules such as heart rate trends, sleep analysis, SpO_2 monitoring, and alerts. This alert section presents LLM-generated alert messages and recommendations when abnormal physiological patterns or threshold violations are detected. Visualizations use color-coded indicators and summaries to reduce cognitive load. The GPT-4o chatbot further generates natural language feedback and recommendations based on health data and caregiver queries. Caregivers can review alerts, add notes, and interact with the system across devices, thus ensuring flexible and informed older adult care support.

Feedback Loop for Adaptive Learning

The architecture incorporates a dynamic feedback loop based on caregiver responses and system logs. These feedback signals are used to retrain the detection thresholds, improve alert relevance, and fine-tune the language model for more accurate and useful recommendations.

Security and Privacy

A dedicated privacy layer ensures compliance with data protection standards. It includes data encryption, access control mechanisms, and data anonymization to protect sensitive health data and support the deployment of ethical systems.

Participants Recruitment

This study included 2 groups of participants: older adults and their informal caregivers. Six older adult participants were recruited to generate real-world physiological data for the

XSL•FO
RenderX

validation of the monitoring function of the system. These individuals, aged 60 - 85 years, were Thai nationals residing in home care environments and were cognitively and physically capable of using a Fitbit Sense 2 device. Patients with stable chronic health conditions were included in the study, while those with known skin sensitivities, cognitive impairments, or conditions interfering with the use of wearable devices were excluded.

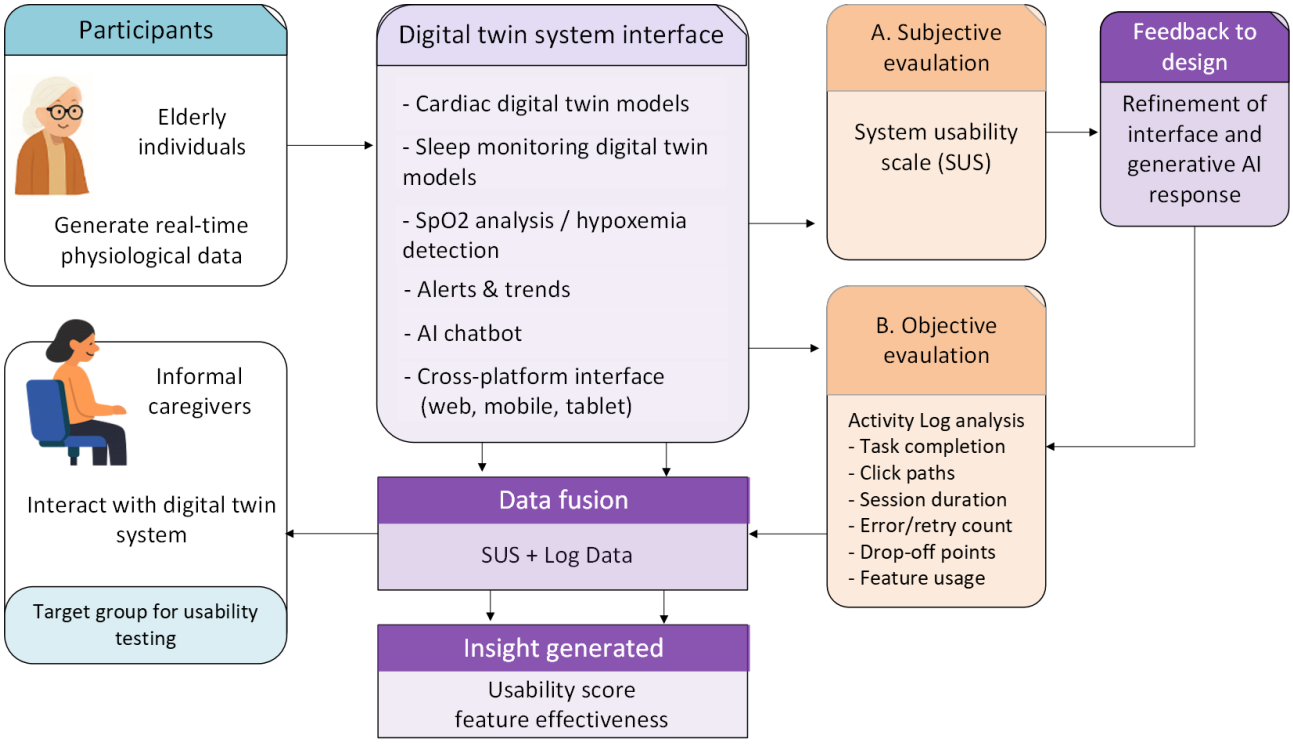
Fifty informal caregivers were recruited for the usability evaluation using a purposive sampling strategy to ensure the representation of individuals actively engaged in home-based older adult care. Table 2 summarizes the demographic characteristics of the informal caregiver participants. Eligible caregivers were adults aged 18 - 55 years with at least 3 months' caregiving experience. To support meaningful interaction with the system, participants were required to demonstrate basic digital literacy (eg, prior use of smartphones or web apps) and the ability to navigate English-language interfaces. Screening interviews confirmed these criteria prior to enrollment. For better recruitment and participant comfort, all initial communications and consent discussions were conducted in the local Thai language with caregivers and older adult individuals. A local Thai assistant was engaged to explain the study procedure and provide step-by-step system guidance in Thai, ensuring clarity and inclusivity during the sessions. Caregivers received a stipend of 100 Thai Baht (average THB to US dollar exchange rate in July 2025: THB 1=US $0.03082; THB 100=US $3.082) to acknowledge their time and contribution. The Fitbit Sense 2 smartwatch used in this study was separately provided by the research team to all older adult participants.

Table . Demographic characteristics of informal caregiver participants.

Characteristic	Caregivers (n=50)
Age (years), mean (SD)	35.6 (7.6)
Age (years), range	18 - 55
Age (years), group distribution, n (%)	
18 - 25	3 (6)
26 - 35	25 (50)
36 - 45	15 (30)
46 - 50	6 (12)
51 - 55	1 (2)
Sex, n (%)	
Male	21 (42)
Female	29 (58)
Caregiving experience (years), n (%)	
<1	11 (22)
1 - 3	21 (42)
4 - 6	12 (24)
>6	6 (12)

Ethical Considerations

The study protocol was reviewed and approved by the institutional review board of King Mongkut's University of Technology Thonburi under reference number KMUTT-IRB-COA-2025 - 048 on July 7, 2025. Written informed consent was obtained from all participants prior to data collection. Specifically, informed consent was secured from both the older adult participants and their informal caregivers before their involvement in the study. Caregiver participants received a small stipend of THB 100, equivalent to approximately US $3.08, as compensation for their time. This compensation was not linked to task performance, usability ratings, or study outcomes and was not considered coercive. All collected data were deidentified prior to analysis, and participant confidentiality was maintained throughout the study.



Usability Evaluation Framework

This study used a dual-method usability evaluation framework designed to capture subjective perceptions and objective behavioral interactions with the EDT system. The framework, illustrated in Figure 5, consists of 3 key components: participant roles, system interaction, and evaluation methods, integrated through a feedback-driven design loop. Two participant groups were involved: older adults who contributed real-time physiological data using a Fitbit Sense 2 smartwatch, and informal caregivers who interacted with the system to evaluate its usability. Usability was assessed using both subjective and objective methods. Subjectively, SUS was used to collect caregiver-reported feedback on ease of use, satisfaction, and overall system experience. Objectively, the activity log data captured granular interaction behaviors, including task completion rates, click paths, session duration, error rates, drop-off points, and module usage frequency. These 2 data streams were then fused to generate comprehensive usability

XSL•FO
RenderX

insights. This fusion enabled us to assess both how users perceived the system and how they interacted with it.

Figure 5. Usability evaluation framework for the elderly digital twin system. The framework integrates subjective (System Usability Scale) and objective (log-based) evaluation methods to assess system usability and inform design improvements. AI: artificial intelligence.

Data Collection

Data Collection was conducted over an 8-week period (July 7 to August 31, 2025) and involved 2 participant groups: older adults and informal caregivers. The older adult participants wore the Fitbit Sense 2 smartwatch in their home environments to generate real-time physiological data, including heart rate, respiratory rate, SpO_2, sleep logs, and physical activity. Before commencing data collection, all older adult participants completed a brief health and comfort assessment to confirm their suitability for using a smartwatch. The survey gathered basic demographic information and screened for potential risks, such as allergies, history of skin irritation, relevant medical conditions, or wrist swelling, which could affect comfort or safety. Participants with contraindications were excluded. The results of the health and comfort screening are summarized in Table 3. This prescreening step ensured that the smartwatch could be used safely and comfortably during subsequent data collection.

Table . Health and comfort screening outcomes for older adult participants.

Screening item	Yes/No, n (%)
Allergy to smartwatch materials (silicone, metal, and adhesives)	0 (0)/6 (100)
History of skin irritation from wristband/watches/jewelry	0 (0)/6 (100)
Skin/medical conditions affecting smartwatch use	0 (0)/6 (100)
Swelling in wrist/hands	0 (0)/6 (100)
Physical activity	Daily: 3 (50), occasionally: 1 (16.7), and rarely: 2 (33.3)

The data were streamed to the system back end to validate the predictive analytics and monitoring capabilities of the EDT models under real-life conditions. Informal caregivers evaluated the system usability through guided interaction sessions using their smartphones, tablets, or computers. Each caregiver used the EDT system for 4 consecutive days, engaging with it for 20 - 30 minutes daily. The SUS questionnaire was administered after the fourth day to capture the caregivers' consolidated perception of usability after repeated interactions. This approach balanced ecological validity with participant burden: 4 days ensured sufficient system interaction while remaining feasible for busy caregivers. We also captured users' behavioral data through system-generated activity logs, which were passively recorded through automatic instrumentation. The system obtained informed consent prior to log data collection, disclosing that no personally identifiable information was recorded. All logged data were anonymized and stored per institutional guidelines.

A total of 24 system tasks were predefined for the log data collection phase. These tasks were systematically constructed from the core functional modules of the EDT prototype,

XSL•FO
RenderX

including heart monitoring, sleep tracking, SpO_2 assessment, AI-driven health advice, and the AI chatbot assistant. The task set was designed to ensure structured coverage of the system's principal functions during usability testing, so that all key user interactions could be consistently captured in the log analysis. Thus, the tasks were intended primarily to exercise the major features of the prototype rather than to directly reproduce naturally occurring caregiving workflows derived from interviews, observational studies, or clinical workflow analysis. Each task represented a meaningful user interaction within the prototype (eg, viewing 24-hour heart rate trends or checking sleep stage analysis), and each was assigned a unique code for consistent identification in the analysis, as detailed in Table 4.

[a]AI: artificial intelligence.

[b]TC: task completion.

[c]ToT: time on task.

[d]FU: feature usage.

XSL•FO
RenderX

[e]HR: heart rate.

[f]RR: retry rate.

[g]NF: navigation frequency.

[h]TAR: task abandonment rate.

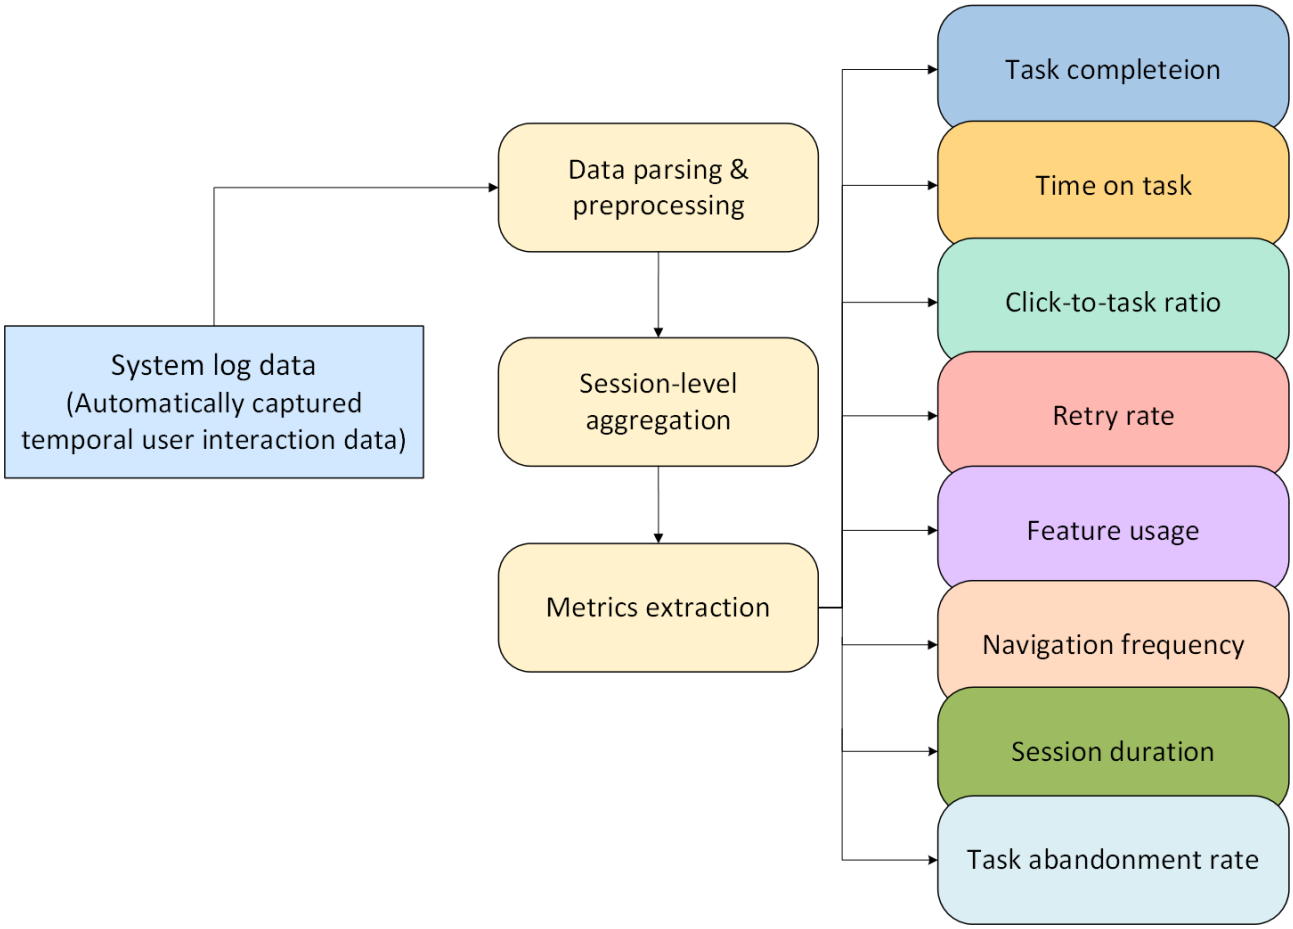
[i]HRV: heart rate variability.

[j]CTR: click-to-task ratio.

[k]REM: rapid eye movement

The mapping tasks for objective metrics were derived from the functional characteristics of each task. Metrics such as task completion and time on task were applied universally as core usability indicators. The retry rate was assigned to tasks with likely repeated attempts in monitoring and chatbot interactions. Feature usage was linked to AI-driven features, demonstrating user engagement beyond basic monitoring. Navigation frequency was applied to tasks involving timelines and log exploration. Session duration was associated with tasks requiring extended engagement, such as report generation. The click-to-task ratio was included for tasks with multiple interaction steps. The task abandonment rate was assigned where drop-offs were likely, such as when viewing summaries and reports. This mapping ensures the replicability of linking system interactions to the 8 objective usability metrics.

To ensure that the objective usability measures reflected actual user behavior, each logged task was operationalized as a concrete interface-level action. Tasks such as view and observe were defined as opening and accessing a specific dashboard, chart, or panel until the user exited or switched pages. AI-related tasks were defined as explicit user-triggered actions, such as clicking an AI insight or advice function or submitting a chatbot query, with completion recorded when the system response was displayed. In Table 4, open indicates that the user accessed a dashboard, chart, panel, or report. Click AI indicates an explicit user request for AI-generated insights or advice. Exit/switch page indicates that the user left the target screen or moved to another module. AI output shown indicates successful system generation and display of the requested response.



Data Analysis

User Activity Log Analysis

User activity logs were extracted from the system back end for all caregiver interaction sessions that were conducted during the study period. Each log entry included a time stamp, session identifier, user identifier, task name, action type (eg, started, completed, error, retry, and abandoned), task duration (in seconds), navigation events, and click events. As shown in Figure 6, these raw entries were processed at the session-level metrics, aggregated across sessions for each user, and normalized by relevant totals (eg, total tasks started) to enable cross-user comparisons.

XSL•FO
RenderX

Figure 6. Sequential steps for transforming raw log data into quantified usability measures.

Metrics Computation

The raw interaction logs were parsed and preprocessed, aggregated at the session level, and used for metric extraction. From this pipeline, key objective behavioral indicators were computed, including task completion (TC), time on task (ToT), click-to-task ratio (CTR), retry rate (RR), feature usage (FU), navigation frequency (NF), session duration, and task abandonment rate (TAR). TC is the percentage of started tasks that were completed. This metric was calculated using equation 1.

(1)TC(%)=CiSi×100

where C_i is the number of tasks of user i with completed status and S_i indicates the number of tasks with started status of user i. ToT measures how long it takes a user to begin or complete a task once they start interacting with the system. It is defined as:

(2)ToT=∑i=1ndin

where d_i is the duration of the $i - th$ completed task and n is the number of completed tasks. The RR measures how often users had to repeat a task before succeeding. For each task, if a user has multiple STARTED events before success, everything after the first event is a retry, defined as follows:

(3)RRi=riai

where r_i is the number of retries for user i repeated a task after a failed attempt (errors, abandoned, and reclicks) and a_i the total number of tasks the user initiated. FU counts the interaction of users per system feature and was calculated as, $FU_x = N_x$, where, N_x is the count of feature x in the navigation logs. Session duration was calculated as follows:

(4)SD=tend−tstart

where t_{start} and t_{end} are the first and last actions in a session, respectively. The TAR is the percentage of tasks started but never completed and is defined as follows:

(5)TAR(%)=(AS)×100

where A is abandoned tasks. CTR is the number of clicks per completed task, defined as CTR = K/C, where K is the click event. NF is the number of times each navigation step/module is used, defined as $NF_x = N_x$. All metrics were calculated per session and aggregated for user and cross-user analysis. Table 5 presents the descriptive statistics of the 8 objective usability metrics collected from caregivers' interactions with the EDT system.

XSL•FO
RenderX

Table . Descriptive statistics of objective usability metrics.

Metric	Minimum	Maximum	Mean (SD)
TC[a] (%)	82.93	98.02	94.08 (4.10)
RR[b]	0.00	1.00	0.25 (0.28)
ToT[c] (seconds)	39.20	175.67	89.16 (21.97)
TAR[d] (%)	0.00	14.13	2.66 (2.87)
CTR[e]	0.12	1.32	0.48 (0.22)
NF[f]	5.00	12.00	11.02 (1.39)
Session duration (minutes)	36.97	171.90	101.59 (30.17)
FU[g] (event count)	52	98	54 (13.4)

[a]TC: task completion.

[b]RR: retry rate.

[c]ToT: time on task.

[d]TAR: task abandonment rate.

[e]CTR: click-to-task ratio.

[f]NF: navigation frequency.

[g]FU: feature usage.

To establish the relationship between objective usability metrics derived from user activity logs and the dimensions of SUS, we mapped each metric to the SUS factors originally proposed by [49,50]. Their analysis suggested that the SUS can be interpreted as comprising 2 correlated but distinct dimensions: usable (covering items related to effectiveness, efficiency, and overall ease of use) and learnable (covering items reflecting the ease of learning and initial onboarding, specifically items 4 and 10).
