The mapping of objective usability metrics to the SUS dimensions is presented in Table 6. In this study, we adopted the 2-factor structure of SUS (usability and learnability) as proposed by Borsci et al [49] and Lewis and Sauro [50], which is the most widely validated and parsimonious model compared with alternative factor structures. In this mapping, performance-related measures such as task completion, efficiency, engagement, and error-related indicators are aligned with the usability factor, as they reflect effectiveness and overall ease of use. In contrast, retry-related measures are aligned with the learnability factor, as they directly capture the effort required for users to acquire proficiency during initial interactions. This mapping provides a conceptual bridge between objective behavioral-based metrics and subjective usability perceptions, ensuring that activity log analysis contributes to the broader usability assessment framework represented by Borsci et al [49] and Lewis and Sauro [50].

Table . The definitions of the usability metrics derived from system activity logs.

Objective metric	Relevant usability aspect (from literature)	Mapped SUS factor (Lewis and Sauro [50])	References
TC[a]	Effectiveness (core usability outcome)	Usable (items 1, 3, 5, 7, 8, and 9)	[49-52]
ToT[b]	Efficiency	Usable (efficiency items contribute to overall ease-of use perceptions)	[49,50,53]
RR[c]	Learnability (ease of initial learning, errors before success)	Learnable (items 4 and 10: technical support and things to learn)	[49,50,52]
FU[d]	Discoverability (linked to usability breadth)	Usable (items 5 and 9: confidence and integration)	[49,50,54]
Session duration	Engagement	Usable (general usability experience, confidence, ease, and satisfaction)	[49,50,52]
TAR[e]	Usability issues/unclear flow	Usable (same rationale as drop-off points)	[49,50,55]
CTR[f]	Efficiency	Usable (efficiency dimension of usability)	[49,50,52]
NF[g]	User flow analysis	Usable (task integration, item 5 “functions well integrated”)	[49,50,56]

[a]TC: task completion.

[b]ToT: time on task.

[c]RR: retry rate.

[d]FU: feature usage.

[e]TAR: task abandonment rate.

[f]CTR: click-to-task ratio.

[g]NF: navigation frequency.

User Engagement Based on Composite Behavioral Metrics

To capture a more holistic measure of user interaction with the EDT system, we computed a user engagement score (UES) by incorporating multiple behavioral indicators that were derived from the system logs. Specifically, 6 objective metrics were included: feature usage, average session duration, session frequency, task completion rate, error rate, and navigation diversity. Each captures a distinct aspect of usability: task efficiency, effectiveness, temporal aspects, and behavioral diversity [51-54,56]. This composite scoring approach is essential for usability studies because it provides a multidimensional perspective on user interaction. These holistic measures are recognized as valid indicators of sustained adoption and user satisfaction [57,58]. To derive the composite engagement score, we initially extracted 8 metrics from the system log. Because not all metrics uniquely represented user engagement, we retained 6 core metrics that directly reflected the breadth, depth, and effectiveness of user interactions. These metrics included FU, ToT (seconds), total session duration (seconds), TC, error count, and NF. Each metric was then normalized to a (0, 1) scale using the maximum value observed in the dataset. The normalized values were subsequently combined using equal weights to produce a composite engagement score, as presented in equation 5.

(6)Engi=αFi+βSi+γRi+δCi+ Ei+ζDiα+β+γ+δ+ +ζ

where F_i is the normalized feature usage for user i, S_i indicates normalized session duration, R_i is the normalized ToT, C_i shows the normalized values of TC, E_i is normalized error rate, D_i is the normalized navigation diversity, and α, β, γ, δ, ε, and ζ symbols show the weights. All weights were set to be equal (α = β = γ = δ = ε = ζ = 1) so that each engagement dimension contributed uniformly to the composite score. An equal-weight additive formulation was selected as a pragmatic postnormalization approach to combine the engagement metrics while avoiding bias or subjective prioritization in the absence of empirical evidence regarding their relative importance. Prior literature on composite scoring has similarly used unit weights as a baseline when neither theoretical nor empirical justification exists for different weighting [59-61]. Because formal testing of interdependence or dimensional structure among the component metrics was not performed in this study, the resulting engagement score should be interpreted as an operational composite summary rather than a formally validated latent construct. For interpretability, k-means clustering with k=3 was then applied to classify users into low-, medium-, and high-engagement groups.

The SUS

The usability of the EDT system was evaluated using the SUS, a standardized 10-item questionnaire widely used to assess the perceived usability of interactive systems. Each item was rated on a 5-point Likert scale ranging from 1 (strongly disagree) to 5 (strongly agree). SUS data were collected from 50 informal

XSL•FO
RenderX

caregivers. To compute individual SUS scores, responses to odd-numbered items were scored as the participant's rating minus 1, whereas responses to even-numbered items were scored as 5 minus the rating. The adjusted item scores were summed and multiplied by 2.5, yielding total SUS scores ranging from 0 to 100. In addition, item-level descriptive statistics were computed for all 10 items. Internal consistency was evaluated using Cronbach α [62] after reverse-scoring the negatively worded items so that higher scores consistently indicated greater perceived usability, as defined in equation 6.

(7)α=kk−11−∑i=1kσi2σT2

where *k* is the number of items, σi2 is the variance of each individual item, and σT2is the variance of total score (sum across all items).

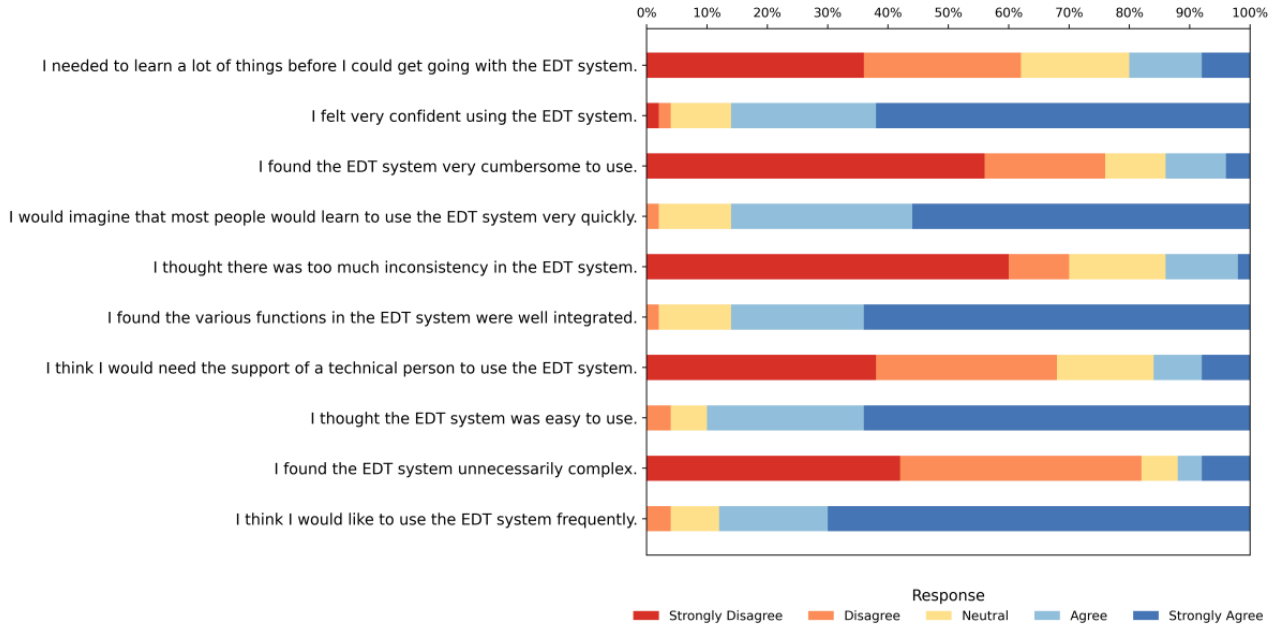
Correlation and Regression Analysis of Engagement and Perceived Usability

To investigate the relationship between the composite behavioral metric and perceived usability, we first examined the correlation between the UES and the SUS. The normality of both variables (UES and SUS) was tested using the Shapiro-Wilk test. As SUS scores deviated from normality, Spearman rank correlation (ρ) was selected as the primary measure of association, and Pearson correlation (*r*) was also reported for completeness. Bootstrapped 95% CIs were computed to quantify the precision of the correlation estimates. Following the correlation analysis, we conducted a simple linear regression to test whether the UES predicts the SUS. The regression was specified as follows:

(8)SUSi=β0+β1·UESi+ i

where SUS_i is the usability score for user *i*, UES_i is the engagement score, β_0 is the intercept, β_1 is the regression coefficient, and ε_i is the error term. Model fit was evaluated with R^2, F-statistics, and coefficient significance. This 2-step approach enabled us to first establish the strength and direction of the association between user engagement and usability and then the predictive power of the UES for the SUS, thereby linking objective behavioral data with subjective ratings.

Results



Overview

This study assessed the EDT system usability among informal caregivers by analyzing objective user interactions and subjective perceptions of usability (SUS). Three aspects were analyzed: (1) SUS survey results reflecting perceived usability, (2) patterns of composite UESs from system logs, and (3) the relationship between user engagement and usability using correlation and regression analyses. These findings address the study aim of assessing EDT system usability using objective behavioral metrics and subjective measurements and examining whether behavioral engagement indicates perceived system usability.

SUS Results

Item-level response patterns for the 10 SUS items are presented in Figure 7, with descriptive statistics shown in Table 7. Overall, caregivers responded positively to the positively worded items and showed low agreement with the negatively worded items, indicating favorable usability perceptions of the EDT system. Higher mean scores were observed for confidence in using the system, integration of system functions, and intention to use it frequently, whereas lower engagement on negatively phrased items suggested limited perceived complexity, inconsistency, and need for technical support. The SUS also demonstrated strong internal consistency, with a Cronbach α of 0.87, indicating reliable measurement of perceived usability.

Figure 7. Distribution of responses to the 10 System Usability Scale items among caregivers (n=50). Percentages are shown on the top axis (0% - 100%). EDT: elderly digital twin.

XSL•FO
RenderX

Table . Item-level descriptive statistics for the 10 System Usability Scale questions.

Item	Mean (SD)	Minimum	Maximum
Q1	4.54 (0.8)	2.0	5.0
Q2	1.96 (1.18)	1.0	5.0
Q3	4.50 (0.79)	2.0	5.0
Q4	2.18 (1.26)	1.0	5.0
Q5	4.48 (0.79)	2.0	5.0
Q6	1.86 (1.20)	1.0	5.0
Q7	4.40 (0.78)	2.0	5.0
Q8	1.86 (1.20)	1.0	5.0
Q9	4.42 (0.91)	1.0	5.0
Q10	2.30 (1.30)	1.0	5.0

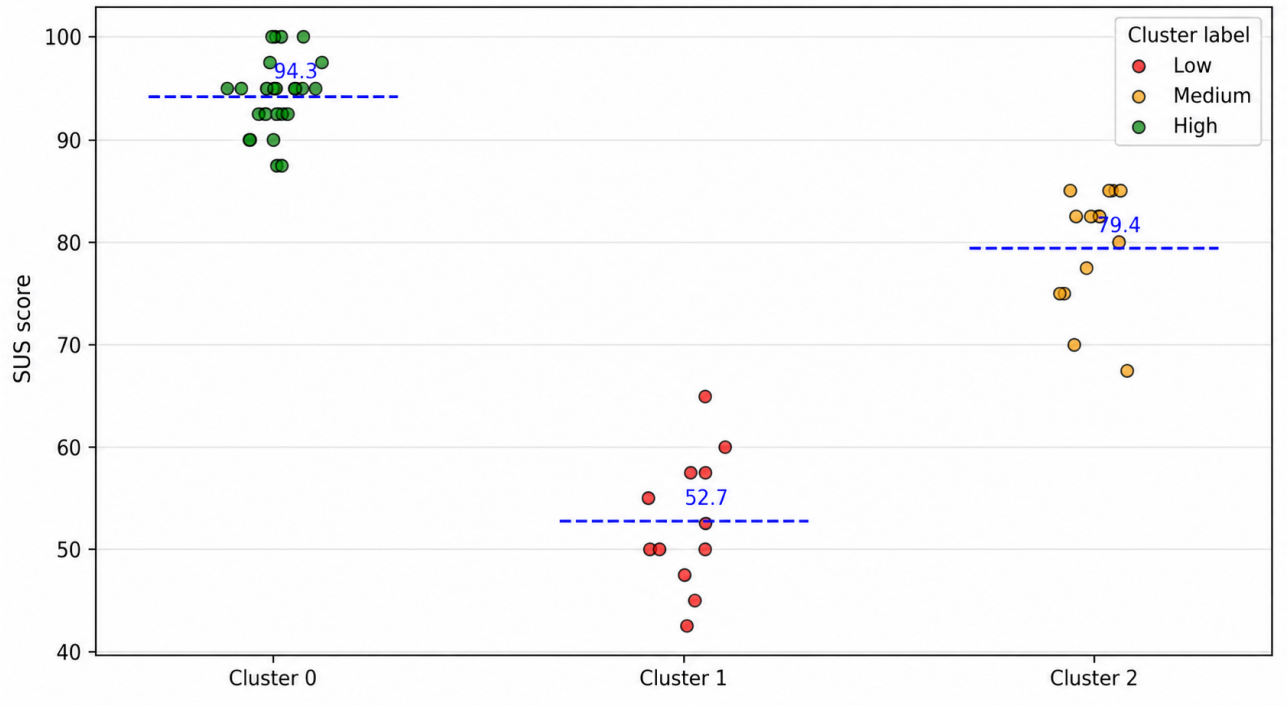
The overall SUS scores (N=50) ranged from 42.5 to 100, with a mean of 80.45 (SD 17.6), indicating a generally favorable perception of usability by caregivers. As shown in Table 8, the SUS scores varied descriptively across the caregiving experience levels. Caregivers with more than 6 years of experience reported the highest mean score (mean 86.7, SD 21.8), followed by those with 1 - 3 (mean 83.5, SD 14.5) years and 4 - 6 (mean 81.0, SD 16.8) years of experience. Caregivers with less than 1 year of experience reported the lowest mean score (mean 70.9). A 1-way ANOVA was used to test whether these differences were statistically significant. Although the descriptive pattern suggested higher usability perception among more experienced caregivers, the ANOVA results were not statistically significant ($F_{3,46}$=1.58; P=.208, η^2=0.093). The effect size indicates that approximately 9.3% of the variance in the SUS scores was explained by caregiving experience, reflecting a small to moderate effect.

Table . Mean System Usability Scale scores by caregiving experience and age group.

Category (group)	Mean (SD) SUS[a] score[b]
Caregiving experience (years)	
<1	70.9 (20.3)
1 - 3	83.5 (14.5)
4 - 6	81.0 (16.8)
>6	86.7 (21.8)
Age group (years)	
18 - 25	80.8 (17.0)
26 - 35	80.8 (16.1)
36 - 45	77.0 (21.6)
46 - 50	83.3 (18.4)
51 - 55	92.5 (0.0)

[a]SUS: System Usability Scale.

[b]Overall mean score 80.45 (SD 17.65).



SUS scores also showed descriptive variation across age groups, as presented in Table 8. Caregivers aged 51 - 55 years reported the highest mean score (mean 92.5, SD 0.0), while those aged 36 - 45 years reported the lowest (mean 77.0, SD 21.6). Younger caregivers (aged 18 - 25 and 26 - 35 years) reported similar mean scores (mean 80.8), and caregivers aged 46 - 50 years also rated usability favorably (mean 83.3, SD 18.4). However, 1-way ANOVA found no statistically significant differences across age groups ($F_{4,45}$=0.399; P=.808, η^2=0.034). This small effect size indicates that age accounted for only approximately 3.4% of the variance in the SUS scores. Thus, age did not meaningfully influence caregivers' evaluations of the system. Overall, the mean SUS score of 80.45 exceeded the commonly cited 68-point benchmark and fell within the "excellent" range (≥80), showing that caregivers evaluated the EDT system very favorably.

Beyond demographic differences, we performed k-means clustering to classify caregivers' SUS scores into 3 groups: low (mean 52.7), medium (mean 79.4), and high (mean 94.30). As shown in Figure 8, the clusters clearly distinguished participants with below-average usability perceptions from those who reported excellent usability. Most caregivers fell into the medium to high clusters, reinforcing the overall favorable

XSL•FO
RenderX

evaluation of the system, while a smaller subgroup reflected lower usability perceptions, indicating areas for targeted improvements.

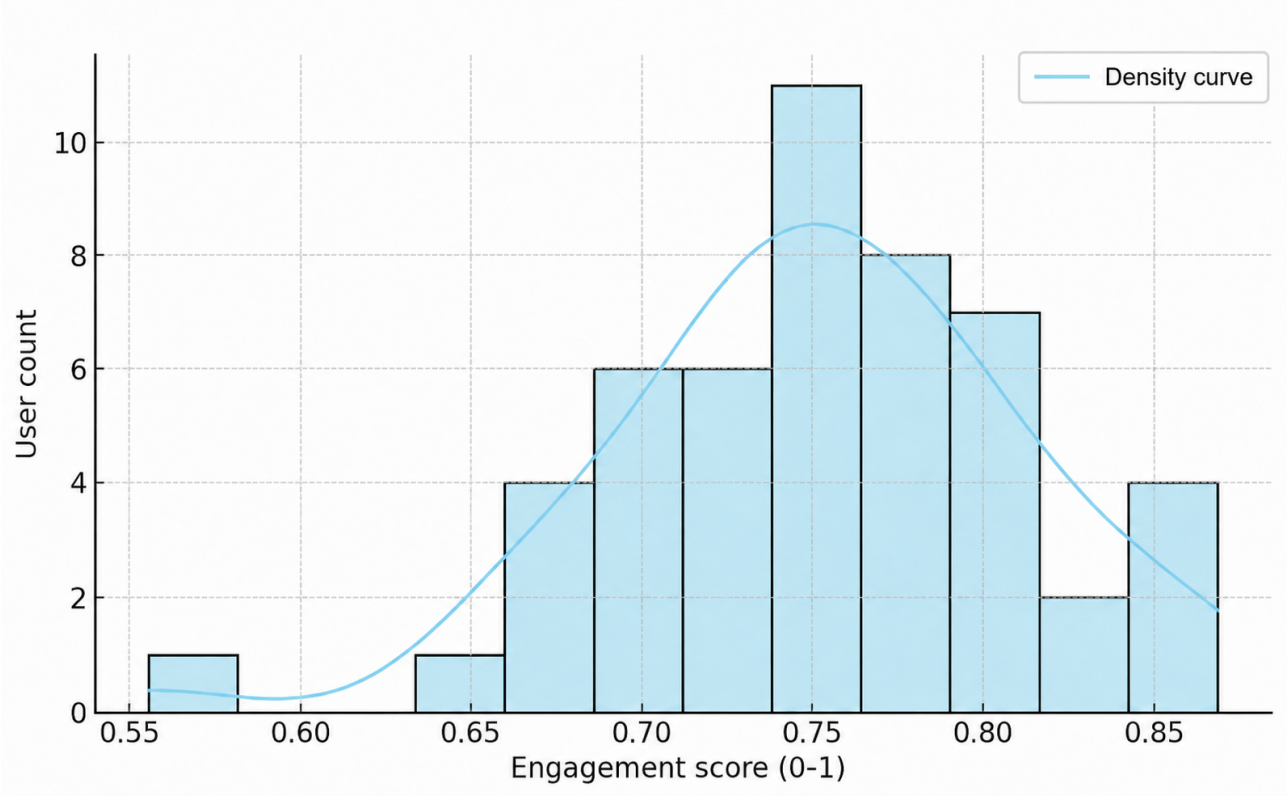


Figure 8. K-means clustering of SUS (N=50) into low, medium, and high groups. Dashed lines indicate cluster centroids. SUS: System Usability Scale.

User Engagement Based on Composite Behavioral Metrics Results

The composite UES was computed for all participants based on normalized behavioral metrics. The scores ranged from 0.55 to 0.86, with the majority of users clustering between 0.70 and 0.80, as shown in Figure 9. The distribution was slightly skewed toward higher engagement, indicating that most participants interacted consistently with the EDT system features, whereas only a few exhibited lower engagement levels.

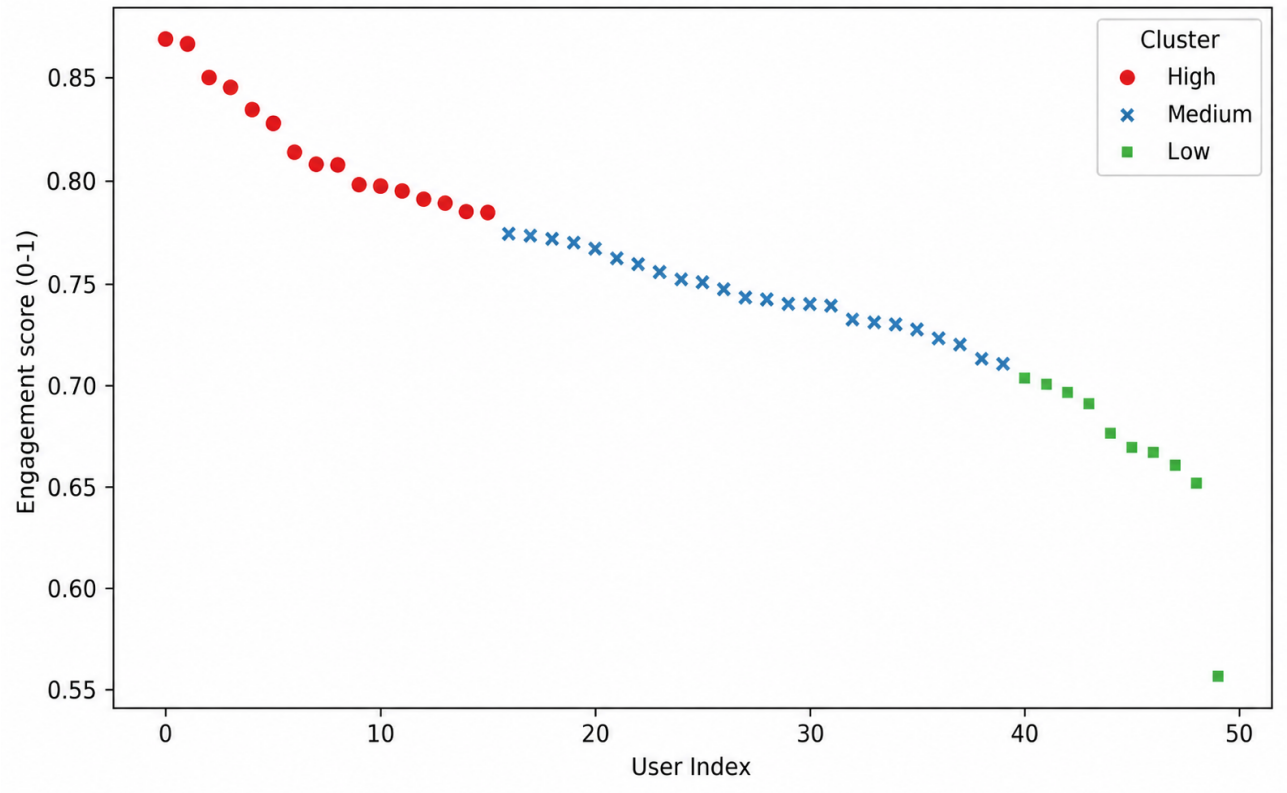

Figure 9. Distribution of composite engagement scores across users.

XSL•FO
RenderX

For interpretability, users were classified into 3 engagement tiers (low, medium, and high) using k-means clustering (k=3). The results showed that most users belonged to the medium engagement group, with smaller proportions in the high- and low-engagement tiers, as shown in Figure 10. This distribution indicates distinct user subgroups, with strong engagement among highly engaged users and lower, yet observable, interaction among the least engaged. Overall, the pattern suggests that the EDT system supported sustained interaction for most users.

Figure 10. Composite user engagement tiers using k-means clustering (k=3).

Correlation and Regression Results for Engagement and Perceived Usability

Building on the relationship between the UES and SUS, we examined how user behavioral measures can predict the SUS of the EDT system. As shown in Table 9, the regression analysis further demonstrated that UES significantly predicted usability scores ($F_{1, 48}$=31.00, P<.001), explaining 39.2% of the variance (R^2=0.392). Engagement was a positive predictor (β=52.94, t_{48}=5.57; P<.001), indicating that higher engagement was associated with higher SUS ratings. Figure 11 illustrates the correlation between SUS and UES.

Regression						
Intercept	55.73	<.001	45.97-65.49	—	4.86	11.48
UES (β)	52.94	<.001	33.82-72.05	0.392	9.51	5.57

[a]*r* indicates the Pearson correlation coefficient; ρ indicates the Spearman rank correlation coefficient; β indicates the regression coefficient.
[b]Not available.

Discussion

Principal Findings

This study found that the EDT system achieved generally positive usability outcomes among informal caregivers based on both subjective perceptions and objective behavioral metrics. SUS results suggested favorable perceived usability, and user activity logs reflected meaningful engagement with system features. The observed association between SUS and UES further indicates that behavioral metrics may complement self-reported usability measures in evaluating caregiver-facing digital health systems.

Usability Evaluation Outcomes

The EDT system attained a mean SUS score of 80.45, exceeding the widely accepted threshold of 68 for above-average usability [19]. A score above 80 is typically interpreted as excellent usability [63]. In this sample, these results suggest that the participating informal caregivers perceived the EDT interface as relatively easy to learn and efficient to use. The composite UES derived from detailed activity logs was positively correlated with the SUS (Pearson *r*=0.626, Spearman ρ=0.552). The significant correlation between UES and SUS highlights the complementary nature of behavioral and perceptual usability measures. While the SUS captures caregivers' subjective impressions of the system's ease of use and satisfaction, the UES quantifies the depth and quality of their actual interactions.

XSL•FO
RenderX

The strength of the observed correlation between the UES and the SUS can be interpreted as moderate to strong, where the correlation between performance and satisfaction metrics generally ranges from 0.38 to 0.70 and often does not exceed 0.7 [23,64].

Beyond this association, regression analysis demonstrated that UES was a meaningful predictor of the SUS, explaining 39.2% of its variance. In the regression model, the *F*-test result ($F_{1, 48}$=31.00, *P*<.001) indicated that the model with UES as a predictor of SUS was statistically significant overall. The intercept (constant = 55.73) represents the predicted SUS value when UES equals zero; because zero engagement was not observed in the study data, this value should be interpreted as a model constant rather than a substantively meaningful estimate. Engagement score (β=52.94, *P*<.001) indicates that for every 1-point increase in UES (on its 0 - 1 scale), SUS is predicted to increase by about 53 points. The coefficient of determination (R^2=0.392) indicated that 39.2% of the variance in SUS was explained by UES. Because the model included only 1 predictor, this value is also consistent with the squared Pearson correlation between UES and SUS. The adjusted R^2 value of approximately 0.38 suggests a comparable level of explained variance after accounting for sample size. Although much of the remaining variance is likely attributable to other factors influencing perceived usability, these results support a meaningful association between behavioral engagement and perceived usability within this sample.

In human-computer interaction research, behavioral predictors typically explain only a partial variance in subjective satisfaction metrics. Studies have shown that behavioral log data account for 30% - 40% of the variance in perceived usability, with the remainder due to unobserved factors [65,66]. This aligns with strong task performance metrics: task completion 94.08%, time on task 89.16 seconds, abandonment rate 2.66%, and retry rate 0.25%, as shown in Table 5, demonstrating that objective engagement correlates with perceived usability.

The clustering of engagement scores into high-, medium-, and low-tier groups (Figure 10) reveals how caregivers interact with the EDT system. Users in the high-engagement cluster achieved strong task performance and high SUS scores, reflecting meaningful interactions. The medium engagement group showed satisfactory engagement with lower SUS scores, whereas the low-engagement group displayed limited interaction and lower usability perception. This analysis shows that users experience the system differently, highlighting the need to tailor system design and support for different engagement profiles. Demographic checks showed no significant difference in SUS scores by age (ANOVA $F_{4, 45}$=0.399; *P*=.81, η^2=0.034) or caregiving experience (ANOVA $F_{(3, 46}$=1.58; *P*=.21, η^2=0.093), indicating consistent perceived usability across the groups. The convergence of high perceived usability with high task performance provides evidence that the EDT system is usable and effective for caregivers. Higher SUS ratings correlated with more intensive interactions, demonstrating the system's support for meaningful use in caregiving contexts. These behavioral indicators in the composite UES strengthen the predictive relationship between the UES and the SUS, showing that engaged caregivers achieve higher task success and perceive better usability.

Theoretical Implications

The results demonstrate the complementarity between subjective and objective measures. While the SUS provides standardized user perception data with benchmarking values [19,22], it cannot reveal how users succeed or struggle during interactions [64]. By combining the SUS with UES behavioral analytics, our study showed that objective measures strengthen construct validity and highlight engagement heterogeneity that postuse scores may miss. In developing the UES, we refined the engagement score using foundational indicators of breadth, depth, and effectiveness of use, avoiding redundant measures, and ensuring interpretability. Equal weights were applied to the metrics, a defensible choice without prior evidence of differential importance. Future research could explore data-driven weighting strategies, such as principal component analysis, regression models, or SHAP analyses, using larger datasets [67].

Another important implication concerns the demographic sensitivity of the SUS. The ANOVA analysis showed no significant differences in usability scores by age or caregiving experience, suggesting that the SUS may be relatively stable across these demographic groups within this sample. The positive association between SUS and UES indicates that perceived usability and behavioral engagement are related. However, the present findings primarily demonstrate convergence between these measures rather than fully establishing their empirical complementarity. Future work should also examine more directly how both measures may capture distinct usability patterns and subgroup needs.

Practical Implication for Health Care Systems

The findings of this study have important implications for the use of DT systems in health care settings. First, the alignment between high SUS scores and favorable task performance metrics suggests that designers should prioritize core workflows that caregivers value most: real-time vital sign monitoring, health trend visualization, abnormal event alerts, and AI-based recommendations. Maintaining simplicity in these functions is essential for building caregiver trust and encouraging adoption. Second, the clustering analysis of the composite UES showed varied system engagement levels, with a small subgroup in the low engagement cluster. This finding indicates the need for an adaptive user interface. Designers should provide configurable interaction modes, progressive onboarding, and contextual help features to address the diverse needs and digital literacy levels of caregivers. Such adaptations can reduce the engagement barriers among different user groups. Third, given the central role of predictive modeling in EDT systems, such as Bi-LSTM for heart rate prediction and long short-term memory for sleep stage interface, AI-generated insights must be transparent and actionable. Caregivers must distinguish between real-time data and predictions, with alerts that are accompanied by clear rationales. This enhances interpretability and reduces inappropriate decision-making in care settings.

Finally, this study emphasizes the need to support informal caregivers who frequently multitask and experience cognitive

XSL•FO
RenderX

and emotional strain. EDT systems should adopt design strategies for rapid comprehension, including glanceable dashboards, consistent information hierarchies, and conservative notification policies to avoid alarm fatigue in users. This study demonstrates the value of behavioral analytics in pilot deployments, with system-generated logs supporting usability evaluation and providing feedback for refinement. Health care DT developers should integrate privacy-preserving analytics to monitor navigation issues and feature abandonment during real-world applications to guide design improvements and caregiver training. The results show that caregiver-facing DT systems must optimize core workflows while offering adaptability and transparency. These principles enable health care DT systems to support informal caregivers, enhance decision-making, and integrate digital health technologies into caregiving practices.

Comparative Positioning and Methodological Contribution

To situate the usability of the EDT system within the broader digital health literature, we compared its SUS scores with those reported in prior studies on related technologies, as shown in Table 10. The EDT system achieved 80.45, which falls within the "excellent" range and exceeds the values reported for many comparable systems, such as VITAAL (58.3), Pocket Gait (59.7), and ED Health Information System (53.1). Some systems, such as the CHES eDiary (87.5), achieved similarly high SUS scores, although often in more narrowly defined use cases than the others. This benchmark highlights 2 important contributions to literature. First, the EDT system ranks among the higher-performing digital health technologies in terms of perceived usability, reinforcing its readiness for use in caregiver-facing applications. Second, unlike most prior studies that relied exclusively on the SUS or paired it with limited subjective feedback (eg, interviews and acceptability scales), our study integrated objective behavioral metrics derived from detailed user activity logs. This dual-method approach strengthens the robustness of valuation and provides a replicable methodological pathway for future assessments of DT technologies in health care.

Table . Comparative System Usability Scale scores of related studies and the elderly digital twin system.

Study/System	SUS[a] score (reported)	Measures/Metrics used
HELMA [14]	72.2 (caregivers)	SUS + Partial usage logs
Engage [13]	66.3 → 82.6	SUS + NASA-TLX
VITAAL [15]	58.3	SUS + Feedback sessions
Pocket Gait [17]	59.7	SUS + Acceptability scale
CHES eDiary [45]	87.5	SUS + Walkthrough
TMS [16]	69.2	SUS
HeartAround [46]	62.2 → 78.8	SUS + Interview
ED Health Info System [47]	53.1	SUS + Interview
Our Study (EDT System)	80.45	SUS + Activity log metrics (UES[b], tasks)

[a]SUS: System Usability Scale.

[b]UES: user engagement score.

Limitations

Despite these strengths, several limitations must be acknowledged in this study. First, the sample size (n=50) limits the generalizability of the findings, and future research should validate the results with larger and more diverse caregiver populations. Second, the evaluation was conducted in a single-system context (the EDT prototype), which constrains external validity; usability outcomes may differ when deployed in varied care environments or integrated with other health systems. Third, although the SUS is a widely validated tool [63], it remains a subjective self-reported measure that can be influenced by user expectations, prior experience, or social desirability bias [68]. Although we mitigated this limitation by complementing SUS with objective behavioral logs, reliance on a single subjective scale may not fully capture all dimensions of usability. Finally, the cross-sectional study design limits our ability to assess the evaluation of engagement and usability perceptions evolved over time. Longitudinal studies are needed to capture the changes in caregiver interactions and satisfaction with sustained system use.

This study does not establish clinical validity or support the use of EDT as a diagnostic or treatment tool. The prototype was evaluated as a caregiver-oriented decision support and usability research system rather than as a regulated medical device, and the Fitbit Sense 2 used for sensing should be regarded as a consumer-grade wearable rather than a clinical reference device. In addition, the predictive components were evaluated only on the available study dataset, and no independent external sample validation was performed. Accordingly, the reported model performance metrics should be interpreted as preliminary indicators of technical feasibility rather than evidence of clinical-grade validity, external validity, or broader generalizability. Similarly, the LLM-generated outputs were intended to provide caregiver-friendly support, monitoring guidance, and follow-up suggestions rather than medical diagnosis or treatment advice. Furthermore, the composite engagement score was constructed using a pragmatic

XSL•FO
RenderX

equal-weight additive approach, and formal testing of interdependence among its component metrics was not conducted.

System Improvements and Future Work

This usability evaluation provided valuable lessons for refining the EDT. The system demonstrated excellent usability and high effectiveness, with a 94.08% task completion rate and low error rates. However, the findings reveal areas for enhancing system inclusivity and adoption. The small proportion of abandoned tasks (2.66%) and minimal retries (0.25 per task) indicated that certain interactions may challenge some users, particularly those in the low-engagement cluster identified in UES tiering. The average task time indicates overall efficiency but varies across engagement tiers. Medium- and low-engagement users required more time and retries, suggesting opportunities to streamline workflows. Simplifying navigation and reducing cognitive load can improve efficiency across different user profiles. Clustering analysis showed varied usability outcomes across users. Future development should address caregiver experience heterogeneity by tailoring features to different profiles, such as contextual prompts for low and advanced features for high-engagement users. Future work should expand the evaluation to more diverse caregiver populations, examine patterns of engagement and usability, incorporate contextual factors such as digital literacy and caregiving intensity, and evaluate the EDT in more naturalistic home care settings using scenarios grounded in real caregiver workflows to strengthen ecological validity. Future research should also examine intermetric correlations, dimensional structure, and alternative weighting strategies to further validate the composite engagement score. In addition, independent external datasets, prospective evaluation, and real-world deployment testing are needed to establish the robustness and generalizability of the predictive components more rigorously. Together, these efforts will help validate our findings and guide further improvements to ensure that the EDT system remains usable and responsive to caregiving practices.

Conclusions

This study evaluated the usability of the EDT system by combining subjective perceptions with objective behavioral data. The findings demonstrated excellent usability and strong task performance, with high completion, low error, and abandonment rates. Correlation and regression analyses showed that the composite UES was not only positively associated with but also a significant predictor of usability, explaining 39.2% of the variance in SUS. Clustering further revealed differences in engagement tiers, underscoring that usability outcomes are not uniform across users. Taken together, these results highlight the value of integrating subjective and objective measures to capture a comprehensive picture of product usability. This study contributes methodologically by linking behavioral engagement metrics with perceived usability, particularly by identifying the strengths and areas for improvement in EDT systems. Future studies should validate these findings in larger and more diverse caregiver populations, explore longitudinal engagement patterns, and incorporate adaptive features to support users with varying engagement profiles.

Acknowledgments

The authors would like to thank all study participants for their valuable time and insights during the usability testing sessions. The authors also extend special thanks to Miss Sutthikarn Chanthakup for her assistance as a local Thai research assistant, particularly in facilitating communication with Thai participants during data collection. This research was supported by the Petchra Pra Jom Klao Research Scholarship from King Mongkut’s University of Technology Thonburi (KMUTT). The authors confirm that no generative artificial intelligence tools were used for writing, editing, data analysis, figure generation, or other content generation during the preparation of this manuscript. The authors take full responsibility for the accuracy, originality, and integrity of all content in the manuscript.

Funding

No financial support or grants were received from any public, commercial, or not-for-profit entities for the research, authorship, or publication of this article.

Data Availability

The dataset generated and analyzed in this study are available in Zenodo [69] and include anonymized data and supporting materials required to reproduce the study findings. Access to the elderly digital twin system link is available from the authors upon reasonable request.

Authors' Contributions

ZM contributed to conceptualization, methodology, data collection, formal analysis, and writing – original draft. PM participated in supervision, validation, and writing – review & editing. Multidimensional Digital Literacy and Quality of Life Among Informal Care Dyads in Malaysia: Cross-Sectional Survey

Abstract

Background: Digital literacy (DL) is a key determinant of health and social participation in later life. In Malaysia, where population aging and family caregiving are rising, limited digital engagement among older adults may widen the gray digital divide. As caregivers and care recipients are interdependent, their digital capacities may jointly shape each other's quality of life (QoL).

Objective: This study examined the multidimensional associations between DL and QoL among informal caregivers and care recipients in Malaysia and explored dyadic actor-partner effects.

Methods: A cross-sectional dyadic survey was conducted with 72 caregiver-care recipient dyads (N=144) recruited from 4 sites across Klang Valley, Malaysia, through purposive sampling. Dyads were the unit of analysis. DL was measured using the 22-item Everyday Digital Literacy Questionnaire across 3 dimensions (information and communication, content creation and management [CCM], and safety and security [SS]), while QoL was assessed with the World Health Organization Quality of Life-BREF. Partial least squares structural equation modeling tested dimension-specific links, and the actor-partner interdependence model examined bidirectional effects.

Results: Caregivers reported higher DL and QoL than care recipients. Among caregivers, only "SS" significantly predicted QoL (β=.44, *P*<.001); among care recipients, all 3 dimensions were significant, with "CCM" showing the strongest effect (β=.53, *P*<.001). The actor-partner interdependence model indicated significant actor and partner effects (caregiver actor β=.53, partner β=.34; care recipient actor β=.60, partner β=.45; all *P*<.001), explaining 62% and 60% of variance in QoL.

Conclusions: DL shows a clear actor-partner pattern. For actor effects, caregivers' QoL was linked to their own SS skills, while care recipients' QoL was linked to their own CCM skills. Partner effects showed that care recipients' CCM skills also predicted caregivers' QoL. Both effects were significant, indicating interdependence within the caregiving dyad. These findings can inform dyad-focused and dimension-specific DL interventions to enhance mutual well-being.

Introduction

Population aging is a global phenomenon. It is transforming social, economic, and health systems worldwide [1]. Increasing longevity and declining fertility rates have led to a larger proportion of older adults in the population. This has caused reliance on informal caregivers, such as spouses or relatives, who provide unpaid care at home [2]. Meanwhile, caregivers have a pivotal role in maintaining the health and well-being of older adults. However, they often experience heavy burdens, such as physical strain, emotional stress, and financial burden, which reduce their quality of life (QoL) [3]. Research has shown that the health and well-being of caregivers and care recipients are interdependent. Emotional distress in one often mirrors the experience of the other [4,5]. This interdependence highlights that we should seek digitally inclusive solutions to improve the well-being of both caregivers and care recipients. In Asia, this need is even more crucial with the rapid growth of the aging population and the spread of digital technologies.

Population aging is progressing rapidly in Asia [6], and the need for long-term and family-based care systems is increasing [7]. Malaysia is an example of this demographic shift, with an estimated 15% of the population projected to be over 60 years of age by 2030 [8]. However, the digital engagement and

XSL•FO
RenderX

participation of older adults are still limited. A recent study in Malaysia highlighted that while device ownership is increasing, actual utilization, specifically for health information, remains low (27%). Furthermore, a majority of older adults (68%) perceive online information as unreliable or lack the necessary confidence and skills to navigate digital platforms effectively [9]. These figures indicate a persistent "digital gray divide." This means that inequalities in access, trust, and digital skills among older adults persist [10]. As family-based caregiving is still the main form of supporting older adults in Malaysia [11], strengthening digital skills within these caregiving relationships is essential.

Digital literacy (DL) is the ability to find, evaluate, and use digital information effectively [12]. It has been identified as a major determinant of health and care outcomes [13]. DL goes beyond technical skills. It helps people access online health care services, communicate with health care professionals, and use digital resources for their daily living. Higher DL is associated with lower caregiver stress and better QoL for both caregivers and care recipients [14,15]. A recent scoping review shows that informal caregivers with stronger digital skills experience greater empowerment. As a result, they feel confident in their caregiving role [16]. Yet, a lack of DL is associated with limited access to reliable information. It is linked to increased vulnerability to misleading information and may exacerbate inequalities in health participation [17,18]. This gap not only affects how caregivers search for information but also how they support care recipients.

Malaysia's aging policies have identified technology as a tool to enhance independence and achieve "supported aging" [19]. However, the National Policy for Older Persons [19], which was developed in the early 2000s, was formulated at a time when concepts such as "digital literacy" and "digital inclusion" were not yet embedded in social policy-making. For this reason, this document does not explicitly address digital participation or the role of informal caregivers in technology use and adoption [20]. Similarly, the Malaysia Digital Economy Blueprint [21] focuses more on innovation, economic growth, and industrial transformation. Although the document emphasizes the need for DL, it does not pay much attention to the specific needs of care recipients and caregivers. Overall, despite the growing attention to technology in existing policies, a comprehensive framework for integrating care recipients and caregivers into the country's digital ecosystem has not yet been formed [16].

Recent studies suggest that digital skills can be associated with increased autonomy, social participation, and health-promoting behaviors among care recipients and caregivers [7,22]. Targeted training programs have also been shown to improve digital skills and self-efficacy in these groups [23,24]. In dyadic caregiving relationships, the caregiver's use of technology is associated with the care recipient's level of digital participation [25], such that higher DL in one person is associated with higher DL in the other. Although several recent studies have applied dyadic approaches to examine health literacy or eHealth literacy in patient-caregiver dyads [26,27], these investigations have generally focused on health behaviors or technology use intentions rather than on everyday DL or QoL. Consequently, little is known about how multidimensional DL shapes actor-partner patterns of QoL within informal caregiving relationships.

Given the distinct roles and digital engagement patterns of caregivers and care recipients, we expected that different DL dimensions might show differential importance for each group. For caregivers, who frequently seek health information online on behalf of care recipients, safety and security (SS) skills may be particularly salient in reducing exposure to misinformation and digital risks [16,28]. For care recipients, communication and content creation skills may be more strongly linked to QoL, as these dimensions enable active social participation and self-expression, key components of autonomy and social connectedness in later life [29,30].

Building on this evidence and the concept of interdependence in caregiving relationships [4,31], this study examines how multidimensional DL, including the dimensions of "information and communication (IC)," "content creation and management (CCM)," and "SS," is related to the QoL of informal caregivers and care recipients in Malaysia. Using the actor-partner interdependence model (APIM), this study seeks to test the hypothesis that the DL of each member of a caregiving dyad is related not only to their own QoL (actor effect) but also to the QoL of their partner (partner effect). It is expected that examining this model will lead to a more comprehensive understanding of the multidimensional role of DL in promoting the mutual well-being of caregivers and care recipients and provide a basis for future research and intervention programs in the field of digital aging.

Methods

Study Design, Setting, and Participants

This study was a cross-sectional, dyadic design conducted in the Klang Valley region of Malaysia (Selangor and the Federal Territory of Kuala Lumpur) between May and October 2025. Eligible participants were informal caregivers aged 18 years and older and community-dwelling older adults aged 60 years and older (hereinafter referred to as "care recipients") residing in the urban Klang Valley region. The caregiver had to be the primary support person nominated by the care recipient, and both were required to complete the questionnaire independently. Informal caregiver-care recipient dyads were the unit of analysis.

A pilot study with 20 dyads was conducted to estimate the population parameters for sample size determination. To address the dyadic nature of the data, a Monte Carlo power analysis was performed using Mplus Version 8.3 [32], following guidelines for sample size estimation in structural equation modeling (SEM) [33]. Based on pilot results and dyadic research recommendations, we hypothesized standardized actor effects of 0.50 and partner effects of 0.37. The simulation parameters were set at α=.05 with 1000 replications using the maximum likelihood robust (MLR) estimator. Results indicated that a sample size of 69 dyads would achieve a statistical power of greater than 0.80 to detect both actor and partner effects. Participants were recruited from 4 sites, including community centers, care service organizations, and public events across Klang Valley, through purposive sampling. A total of 100 dyads

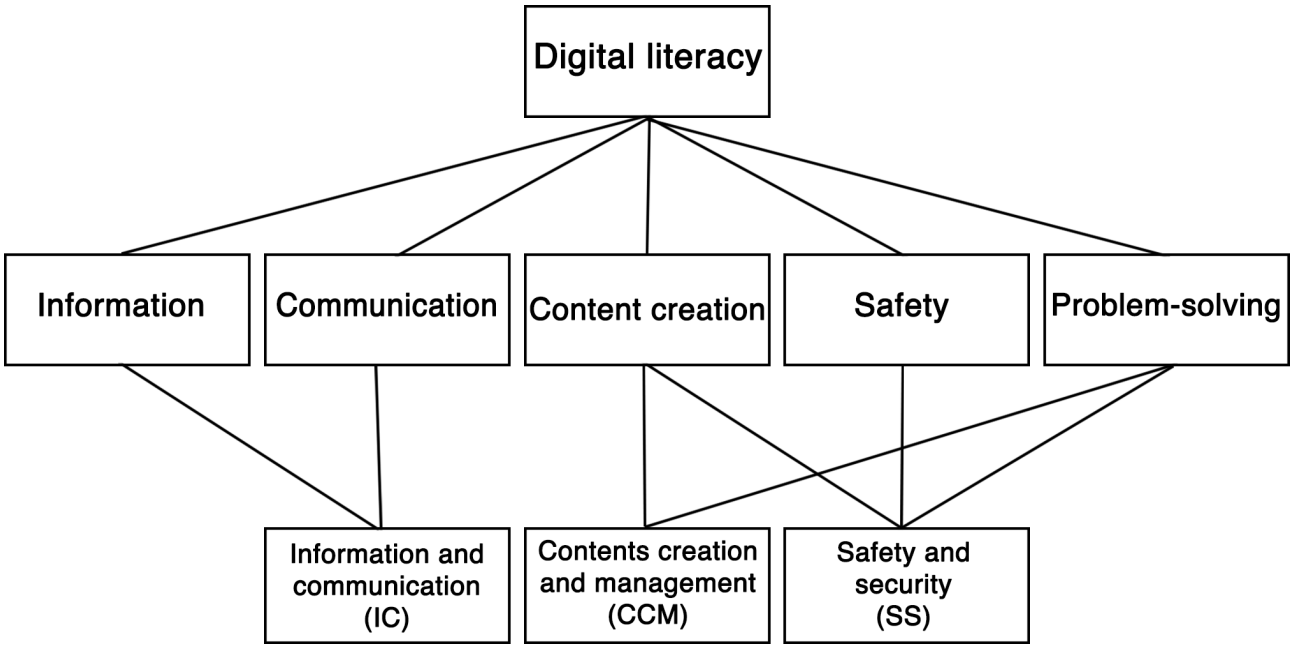
XSL•FO
RenderX

were approached and consented. As expected in dyadic field research, some dyads were incomplete because one member did not return the questionnaire, in which case the entire dyad was excluded. Ultimately, 72 complete dyads were obtained (72% dyad-level participation), exceeding the a priori target and falling within the sample size range often recommended for stable estimation in APIM studies [34].

To ensure reliable self-reports, participants were screened for subjective memory complaints using a single-item cognitive self-assessment. This brief approach is supported by previous research showing that the absence of memory complaints is a useful indicator of adequate cognitive ability for independent questionnaire completion [35]. No dyads were excluded based on this screening item.

Measures

Demographic Characteristics



Demographic characteristics were collected for both caregivers and care recipients, including age, gender, marital status, ethnicity, education level, employment status, and monthly household income. Information on internet access (frequency, connection quality, and device use) and self-rated health status was also obtained.

Digital Literacy

DL was assessed using the 22-item Everyday Digital Literacy Questionnaire (EDLQ) [36]. The instrument is conceptually grounded in the European Commission's DigComp framework and broader multidimensional conceptualizations of DL. It was validated with a 3-factor structure. Each item is rated on a 5-point Likert scale ranging from 1 ("Never True") to 5 ("Always True"), with higher scores indicating greater DL.

Following the authors' scoring guidelines, 3 domain scores were calculated: IC (mean of DL01-DL09), CCM (mean of DL10-DL13), and SS (mean of DL14-DL22). In addition, a total score (sum of all 22 items, range 22 - 110) was computed to capture overall DL. Scores were calculated separately for caregivers and care recipients. The EDLQ was originally developed and validated in Korean. English versions of all 22 items were available in the original validation study [36]. The English items were translated into Malay and reviewed by a bilingual academic with expertise in gerontology for linguistic clarity and cultural appropriateness. Due to sample size constraints, measurement invariance testing across languages was not conducted and is acknowledged as a limitation. The 3 domains of the EDLQ are illustrated in Figure 1.

Figure 1. The Everyday Digital Literacy Questionnaire structure, adapted from Choi et al [36].

Quality of Life

QoL was assessed using the World Health Organization Quality of Life-BREF (WHOQOL-BREF), a 26-item instrument developed by the World Health Organization to measure individuals' perceived QoL across 4 domains: physical health, psychological health, social relationships, and environment [37,38]. Each item is rated on a 5-point Likert scale with varying anchors (eg, 1="very poor" to 5="very good," or 1="not at all" to 5="completely"), reflecting the intensity, capacity, frequency, or evaluation of life experiences during the past 2 weeks. Higher scores indicate better QoL. Domain scores were computed following WHO scoring guidelines and transformed to a standardized 0 to 100 scale using the recommended formula: (transformed score=[raw score–minimum possible score]×100/[maximum possible score–minimum possible score]) [37].

An overall QoL index was calculated by averaging the 4 domain scores. In this study, the 4 WHOQOL-BREF domains showed very high intercorrelations (caregivers: r=0.851-0.928; care recipients: r=0.863-0.938; all P<.001), indicating substantial shared variance and supporting the use of a composite measure of overall well-being [38]. Moreover, examining all 4 domains separately would require multiple independent models (raising concerns about statistical power and Type I error inflation with

XSL•FO
RenderX

N=72 dyads). Therefore, this composite score was used for subsequent SEM and APIM analyses. Scores were analyzed separately for caregivers and care recipients.

Ethical Considerations

Data were collected through structured, self-administered questionnaires. The questionnaires were available in both English and Malay, and participants completed the version in their preferred language. Each dyad received 1 set of questionnaires, and an online completion option was also provided. Responses were checked to ensure caregiver-care recipient matching.

Institutional Review Board approval was granted by the Ethics Committee for Research Involving Human Subjects (JKEUPM) of Universiti Putra Malaysia (approval number: JKEUPM-2025-037). Participation was voluntary, and written informed consent was obtained from all respondents. Confidentiality was ensured through anonymized data, and participants could withdraw at any stage without consequence. Participants were not compensated for their participation in this study.

Statistical Analysis

Statistical analyses for this cross-sectional dyadic data were conducted to describe participant characteristics, validate the measurement model, and examine dyadic actor-partner effects of DL on QoL.

Descriptive statistics (means, SDs, frequencies, and percentages) were computed in IBM SPSS Statistics Version 26. Construct validity and reliability of the measurement model were evaluated in SmartPLS Version 4.0.9.6 for both the EDLQ and WHOQOL-BREF. Reliability and convergent validity were confirmed based on item loadings ≥0.70, Cronbach α and composite reliability >0.70, and average variance extracted >0.50. Discriminant validity was established via the heterotrait-monotrait ratio <0.85. Collinearity was assessed using the variance inflation factor (VIF<3.6). Model fit was assessed using standardized root mean square residual (SRMR=0.069 for caregivers; 0.075 for care recipients). Path significance was tested using bootstrapping with 5000 resamples, and predictive relevance (Q^2=0.429 for caregivers; 0.499 for care recipients) was examined via blindfolding.

To test dyadic relationships, the APIM was estimated in Mplus Version 8.3 using MLR, consistent with established applications of dyadic data analysis [32,39,40]. Dyads were treated as distinguishable (caregiver vs care recipient). Because these roles are theoretically and structurally nonexchangeable, an empirical distinguishability test was not required [41]. Missing data were handled using full-information maximum likelihood (FIML), which used all available data under the missing-at-random assumption. In the APIM variables, there were no missing data for the DL predictors, whereas QoL outcomes had 25% (18/72) missing values for caregivers and 18% (13/72) for care recipients.

To assess the robustness of FIML estimates, 3 sensitivity analyses were conducted: Little MCAR test to verify the missing-at-random assumption, expectation-maximization (EM) imputation to assess potential bias from missingness, and APIM re-estimation using listwise deletion (n=47 complete dyads) to compare with FIML results. These analyses were performed in IBM SPSS Statistics 26 (Little MCAR, EM imputation) and Mplus 8.3 (listwise deletion APIM).

It is important to note that while APIM permits the examination of actor and partner effects, the cross-sectional design limits the ability to infer causality or temporal precedence. The APIM framework is used here to model patterns of association and interdependence within dyads at a single time point, consistent with standard applications in cross-sectional dyadic research [34].

The APIM accounts for actor effects (an individual's DL → their own QoL) and partner effects (one member's DL → the other's QoL). Residuals of the 2 QoL outcomes were allowed to covary. Standardized coefficients (β), standard errors, 95% CIs, and explained variance (R^2=0.619 for caregivers; 0.595 for care recipients in the basic model) were reported. Because both APIM specifications (basic and multivariate) were saturated (df=0), global fit indices (Comparative Fit Index, Tucker-Lewis Index, root mean square error of approximation, SRMR) were not interpreted, and modification indices were not applicable. Model evaluation focused on path coefficients and explained variance.

Two APIM specifications were estimated. The basic model used each member's composite DL score to predict their own QoL (actor effect) and their partner's QoL (partner effect). Composite scores were used in the model because latent APIM requires substantially larger samples for stable estimation, and APIM is commonly estimated using observed scores in small to moderate samples [39,41]. Additionally, the high reliability of the measures (care recipient >0.90), as shown in Table 4, supports the use of composite scores as valid proxies for the latent constructs. The multivariate model simultaneously included the 3 EDLQ dimensions (IC, CCM, and SS) as predictors of QoL, allowing estimation of domain-specific actor and partner effects while retaining dyad distinguishability and correlated residuals. All analyses were 2-tailed, and statistical significance was set at P≤.05.

Results

Participant Characteristics

Figure 2 presents the participant recruitment and selection flow. Of the 100 dyads approached, 72 caregiver-care recipient dyads were included in the analysis. The mean age of caregivers was 51 (SD 7.4) years and that of care recipients was 75.3 (SD 4.5) years. Most caregivers were female (43/72, 60%). Among care recipients, 57% (41/72) were female. The sample was predominantly Malay, followed by Chinese and Indian participants. Educational levels were generally higher among caregivers than care recipients. About one-third of caregivers had a bachelor's degree or higher, compared to 11% (8/72) of care recipients. Caregivers reported better internet access than care recipients, more than half of whom had weak access. Most caregivers rated their health as good, whereas only one-third of

XSL•FO
RenderX

care recipients reported good health. Table 1 presents the characteristics of caregivers and care recipients.

Figure 2. Flowchart of participant recruitment and selection process.

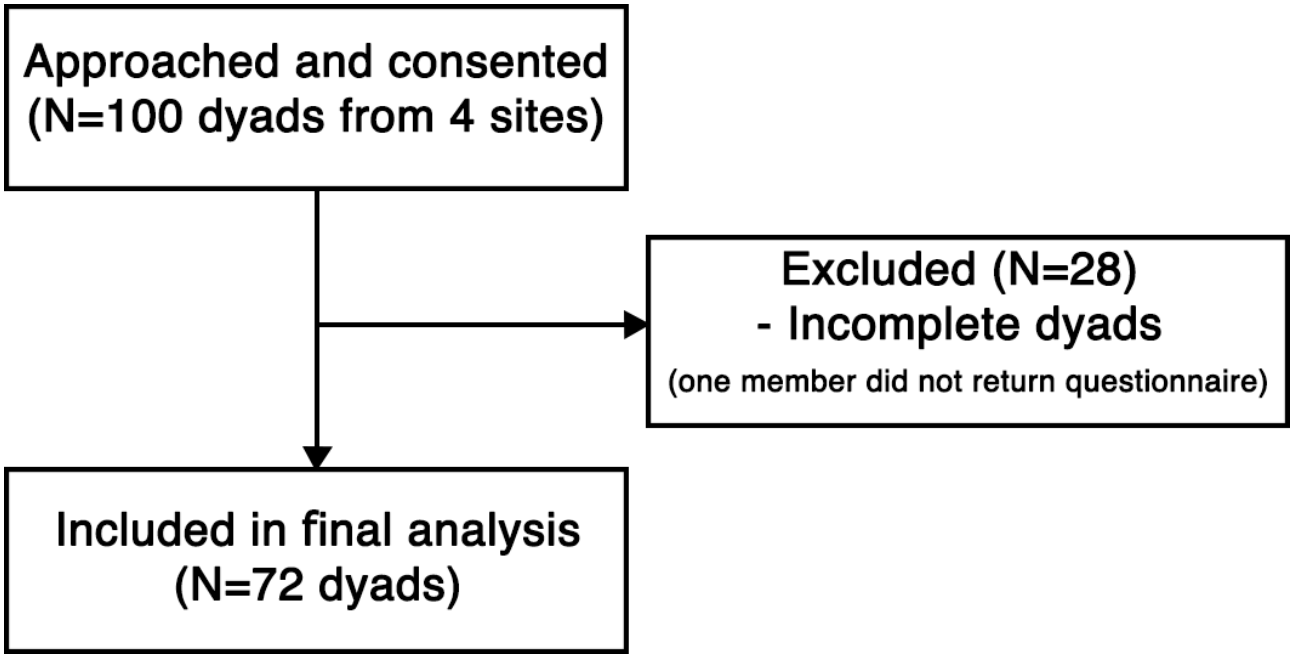


Table . Participant characteristics of caregivers and care recipients (N=72 dyads).

Characteristics	Caregivers	Care recipients
Age (y), mean (SD; range)	51 (7.4; 37 - 65)	75.3 (4.5; 61 - 85)

[a]Percentages may not sum to 100% due to rounding and missing data.

Descriptive Statistics and Correlations

Table 2 presents the descriptive statistics for the main study variables. Caregivers reported moderate levels of DL across the 3 dimensions (mean range 3.4 - 3.6; Table 2). Care recipients showed slightly lower scores, particularly for CCM. Caregivers had higher overall QoL scores than care recipients, and because care recipient QoL was nonnormally distributed, median (IQR) is also reported.

XSL•FO
RenderX

Table . Descriptive statistics of caregivers and care recipients (N=72 dyads).

Variables	Mean (SD)	Minimum-maximum	Median (IQR)
Caregivers			
Information and Communication	3.47 (0.74)	1.63-5.00	—[a]
Content Creation and Management	3.44 (0.76)	1.25-5.00	—

[a]Not applicable.

[b]QoL: quality of life.

[c]Median and IQR are reported for QoL variables.

The 3 DL dimensions were positively intercorrelated within each group. All DL dimensions were significantly and positively correlated with QoL within each group (all $P<.001$). Cross-dyad correlations also emerged: caregivers' DL dimensions were positively associated with care recipients' QoL, and vice versa. These preliminary results suggest potential interdependence between caregiver and care recipient DL and QoL, supporting the rationale for subsequent APIM analyses. Pearson correlations among study variables (computed using pairwise deletion) are shown in Table 3.

Table . Pearson correlation coefficients among digital literacy dimensions and QoL[a] (N=72 dyads).

[c]Not applicable.

[d]CR: care recipient.

[e]The correlation between CR content creation and management and CG QoL (0.96) reflects the subsample with complete data (n=54). Note that the primary actor-partner interdependence model analysis uses FIML (full-information maximum likelihood; n=72) to handle missingness, yielding a robust but lower standardized estimate (β=.83) as reported in Table 7. A scatter plot confirming variable distinctness is provided in Multimedia Appendix 1.

XSL•FO
RenderX

Measurement and Partial Least Squares SEM

The measurement model demonstrated satisfactory reliability and validity. All constructs demonstrated adequate reliability and convergent validity (Table 4). Discriminant validity was established using heterotrait-monotrait ratio criteria (all values <0.85). VIF values indicated no multicollinearity among constructs (all VIF <3.6). Model fit was acceptable for both caregiver and care recipient models (SRMR=0.069 for caregivers; 0.075 for recipients).

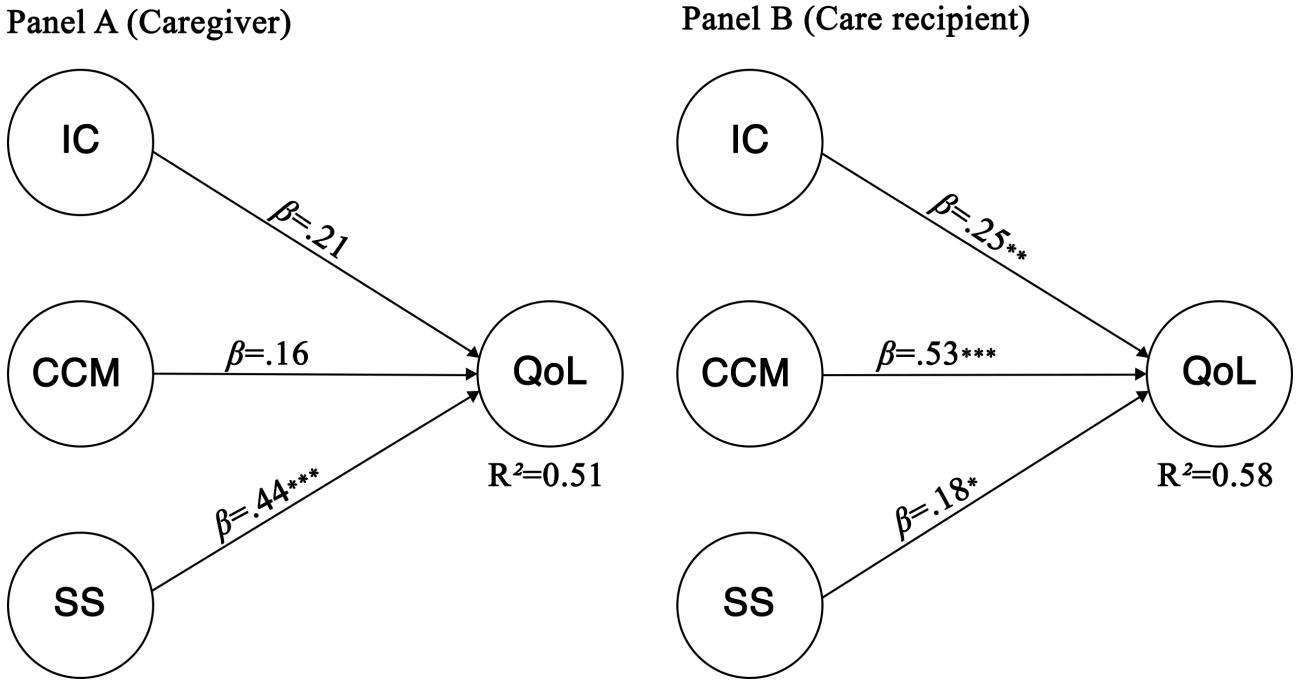
[b]CCM: content creation and management.

[c]IC: information and communication.



[d]SS: safety and security.

[e]QoL: quality of life.

The structural model explained 51% (37/72) of the variance in caregivers' QoL and 58% (42/72) of the variance in care recipients' QoL. Predictive relevance was supported for both models. Among caregivers, only the SS dimension significantly predicted QoL (β=.44, *P*<.001), whereas other dimensions were not significant. For care recipients, all 3 dimensions significantly predicted QoL, with CCM showing the strongest effect (β=.53, *P*<.001). Effect size analyses supported these patterns, indicating large effects for CCM among care recipients and for SS among caregivers. Figure 3 shows the structural partial least square-SEM models with standardized path coefficients and explained variance (R^2) for caregivers (panel A) and care recipients (panel B). Full results are displayed in Table 5.

The partial least squares-structural equation modeling analyses established the validity of the measurement model and identified dimension-specific associations between DL and QoL within each role. These analyses treated caregivers and care recipients as independent groups. To examine bidirectional interdependence between dyad members as a central feature of caregiving relationships, we next employed the APIM, which explicitly accounts for the nonindependence of paired observations and tests whether each member's DL predicts both their own (actor effect) and their partner's (partner effect) QoL.

Dyadic Analysis (APIM)

The basic APIM was estimated for 72 dyads using MLR estimation with full-information handling of missing data. Observed composite scores were used for caregiver and care recipient DL and QoL. The model included actor and partner paths for both caregivers and care recipients, allowing for correlated predictors and residuals between dyad members. All 4 APIM paths were statistically significant. Actor effects were positive for both caregivers (β=.53, P<.001) and care recipients (β=.60, P<.001). Partner effects were also significant, from caregiver to care recipient (β=.34, P<.001) and from care recipient to caregiver (β=.45, P<.001). Predictors were moderately correlated (r=0.31, P=.004). The residual correlation between caregiver and care recipient outcomes was small but significant (r=0.29, P=.045). Variance explained was substantial,

XSL•FO
RenderX

with R^2=0.619 for caregivers' QoL and R^2=0.595 for care recipients' QoL. These R^2 values represent the combined variance explained in each outcome by both actor and partner effects. Figure 4 shows the basic APIM with standardized path coefficients and explained variance. Full statistical results are presented in Table 6.

Figure 4. Basic actor-partner interdependence model of digital literacy predicting quality of life, showing standardized path coefficients (β), correlations (r), and explained variance (R^2). N=72 dyads; QoL: quality of life. *P<.05, **P<.01, ***P<.001.

In the multivariate APIM, caregiver and care recipient QoL were simultaneously regressed on 3 dimensions of DL (IC, CCM, and SS) for both members of the dyad. For caregiver QoL, a significant actor effect was observed for caregiver SS (β=.11, P=.022, 95% CI 0.02 - 0.20). Other caregiver DL dimensions were not significant predictors. Among partner effects, care recipient CCM strongly predicted caregiver QoL (β=.83, P<.001, 95% CI 0.75 - 0.91), whereas the other recipient dimensions were nonsignificant. The predictors explained 92% of the variance in caregiver QoL (R^2=0.92). Model diagnostics indicated high intercorrelations among predictors, suggesting that the large R^2 primarily reflects shared variance rather than independent predictive effects. For care recipient QoL, significant actor effects were found for IC (β=.33, P<.001, 95% CI 0.15 - 0.51) and CCM (β=.40, P<.001, 95% CI 0.21 - 0.59). The effect of SS was positive but did not reach significance (β=.16, P=.072). Among partner effects, caregiver CCM significantly predicted care recipient QoL (β=.20, P=.047, 95% CI 0 - 0.40), while other caregiver dimensions were nonsignificant. The predictors explained 67% of the variance in care recipient QoL (R^2=0.67). Figure 5 shows the multivariate APIM with standardized path coefficients and explained variance. Full statistical results are presented in Table 7.

Table 8 shows correlations among predictors in the multivariate APIM. Several strong associations were found, particularly between caregiver IC and caregiver CCM (r=0.57, P<.001), between caregiver IC and SS (r=0.64, P<.001), and between care recipient IC and SS (r=0.62, P<.001). These findings indicate moderate-to-strong associations among DL dimensions.

[a]Estimator: maximum likelihood robust.

[b]Reported values are standardized (STDYX) correlations among predictor variables in the multivariate APIM.

[c]CG: caregiver.

[d]IC: information and communication.

[e]CCM: content creation and management.

[f]SS: safety and security.

[g]CR: care recipient.

Sensitivity Analyses

Three sensitivity analyses confirmed the robustness of FIML-based findings. Among 72 dyads, 47 (65%) dyads had complete data, 12 (17%) dyads had missing care recipient QoL only, 7 (10%) dyads had missing caregiver QoL only, and 6 (8%) dyads had both QoL variables missing. Little MCAR test (χ^2_8=7.82, *P*=.45) indicated that data were missing completely at random, supporting the MAR assumption underlying FIML.

EM imputation showed minimal deviation from observed values. For caregiver QoL, EM-estimated mean was 64.38 (SD 13.96) versus the observed mean of 64.46 (SD 14.68), a difference of 0.08 points. For care recipient QoL, EM mean was 54.69 (SD 16.12) versus the observed mean of 55.27 (SD 16.34), a difference of 0.58 points.

Re-estimating the basic APIM using listwise deletion (n=47 dyads) produced results highly consistent with FIML (N=72 dyads), as shown in Table 9. All 4 APIM paths remained significant (all *P*<.001), effect directions were unchanged, and standardized coefficients differed by an average of only 0.04 units. The consistency across missing data approaches confirms that FIML estimates are robust and that substantive conclusions are unchanged.

Table . Comparison of actor-partner interdependence model parameter estimates using full-information maximum likelihood and listwise deletion (N=72 dyads)[a].

Parameter	FIML[b]	Listwise[c]	Difference[d]
Actor effects			
Caregiver DL[e] → Caregiver QoL[f]	0.53	0.52	0.01
Care recipient DL → Care recipient QoL	0.60	0.54	0.06
Partner effects			
Care recipient DL → Caregiver QoL	0.45	0.41	0.04
Caregiver DL → Care recipient QoL	0.34	0.39	0.05
Explained variance (R^2)			
Caregiver QoL	0.62	0.65	0.03
Care recipient QoL	0.60	0.65	0.05

[a]All path coefficients are standardized (β). All $P<.001$ for both full-information maximum likelihood and listwise deletion models. The average absolute difference across all 6 parameters was 0.04 units, indicating high consistency between methods.

[b]FIML: full-information maximum likelihood using all 72 dyads (18 caregivers and 13 care recipients with missing QoL data).

[c]Listwise deletion: complete-case analysis using 47 dyads with no missing QoL data.

[d]Absolute difference between FIML and listwise deletion estimates.

[e]DL: digital literacy.

[f]QoL: quality of life.

Discussion

DL and QoL: Role-Specific Patterns

The results of this study showed that DL has a multidimensional and role-specific relationship with QoL. The pattern of this association differed between caregivers and care recipients. Among caregivers, only the dimension of "SS" was a significant predictor of QoL. This finding suggests that the ability to navigate online spaces safely and maintain privacy was associated with a greater sense of control [16,28] and higher reported QoL.

Among care recipients, all 3 dimensions were associated with higher QoL. The largest effect was for "CCM," followed by "IC." This pattern suggests that care recipients who actively produce and organize digital content or engage in online communication are not just passive consumers of information but are also more likely to report greater autonomy, social connectedness, and overall satisfaction [29,30]. The findings are consistent with the study by Kyaw et al [7] among Korean older adults, which found that higher DL was associated with better perceived health and more technological self-care behaviors.

The APIM showed that the effects between caregivers and care recipients were reciprocal but asymmetric. Care recipients' CCM skills showed a strong partner effect on caregivers' QoL, while similar skills in caregivers showed a smaller but significant partner effect on care recipients' QoL. These results emphasize that DL is not a uniform skill but rather a multidimensional construct that operates through different yet interdependent pathways between members of the caregiving dyad. The models explained more than 50% of the variance in QoL, indicating strong and stable associations.

In psychological and behavioral terms, safety-related DL can be associated with better perceived outcomes for caregivers. This skill is linked to higher trust in online resources and lower exposure to digital risks. For care recipients, communication and content creation skills were associated with greater self-expression and social engagement, 2 key components of psychological and social well-being. Recent research has also shown that improving digital health literacy increases self-efficacy and health-promoting behaviors in both groups. Taken together, these findings suggest that DL should be viewed as a multidimensional and relational factor within caregiving contexts [12,42].

Dyadic Interdependence Between Caregivers and Care Recipients

The present study showed a clear pattern of bidirectional interdependence between caregivers and care recipients in DL and QoL. In the APIM, both the actor and partner effects were significant; that is, each individual's DL predicted not only their own QoL but also their partner's QoL.

In the basic model, interaction effects were observed in both directions. In the multivariate model, the paths were asymmetrical: CCM skills of care recipients showed a stronger association with caregivers' QoL, while similar skills in caregivers showed a smaller but significant association with care recipients' QoL. In contrast, safety-related DL in caregivers was associated only with their own QoL and was not significantly associated with the other party's QoL. This finding suggests that digital safety may contribute more to caregivers'

XSL•FO
RenderX

sense of competence and personal stability than to care recipients' direct outcomes.

This interdependence can be seen as part of the social and behavioral bonds in caregiving relationships [43]. When care recipients have higher DL, especially in communication and content creation, they become more active in self-care and digital interaction. This was associated with higher caregiver QoL and strengthens mutual reciprocity. On the other hand, caregivers' DL was associated with the perception of a safer and more supportive environment within online environments, which was linked to greater trust and confidence among care recipients.

Therefore, educational interventions should be 2-way and interactive, moving beyond solely individual-focused approaches; they should involve training that focuses on shared learning and collaborative use of technology [44,45]. In Asian societies, where the family is still the center of care, strengthening DL within caregiving dyads may improve mutual well-being and may help reduce the digital divide in older adults. Future programs should consider DL not simply as an individual skill but as a relationship-centered asset that enhances the QoL of both.

Digital Divide and Socio-Contextual Factors

In this study, care recipients had lower levels of DL than caregivers. Although this difference was not statistically tested, it is likely to reflect the "gray digital divide" that has also been reported in both global and regional studies. Recent meta-analyses suggest that eHealth literacy in older adults is still below optimal levels. This issue is particularly evident among women, the very old, single individuals, and those living in lower-income countries [46]. Similarly, in a national study conducted in China, differences in education, economic status, and media attitudes led to significant variations in technology use [47]. These underlying inequalities could explain the DL gap observed in Malaysian caregiving dyads.

As shown in Table 1, a significant portion of care recipients 54% (39/72) reported weak internet access, which may contribute to the digital divide and impact their QoL. At the national level, studies from Malaysia have shown that cognitive impairment and low socioeconomic status reduce the likelihood of using digital tools. Gender, age, and education also play a role in this pattern [48]. Broader research in Southeast Asia has also highlighted specific cultural barriers, such as fear of making mistakes, reliance on family, and limited rural infrastructure, that limit older adults' independence in technology use [49]. Therefore, improving internet access and digital infrastructure for older adults may help alleviate these challenges and reduce the burden on caregivers. Overall, the digital divide in the care context is rooted in cultural and social factors rather than simply individual ones. These inequalities may undermine older adults' digital self-efficacy and reduce their online participation. They may also place a greater educational burden on caregivers. Therefore, to achieve equitable well-being, digital inclusion programs should be designed at the family and community levels.

Cultural-Contextual and Policy Dimensions of DL in Malaysia

Digital inclusion among Malaysian older adults is not limited to individual skills alone. It is also shaped by cultural norms and national policies that determine how technology is used. In our data, care recipients had lower DL than caregivers, consistent with a common pattern in collectivist Asian cultures, where older adults rely on family for digital access and decision-making. Digital learning in this context is often achieved through intergenerational interaction rather than through self-learning [50-52]. This may explain why, in our model, care recipients' digital competence was associated with higher caregivers' QoL.

In policy terms, Malaysia's National Aging Policy recognizes the role of technology in enhancing independence but has yet to consider DL and participation as part of active aging. Similarly, Malaysia's Digital Economy Roadmap [21] focuses on innovation and competitiveness but does not address the specific needs of care recipients and informal caregivers. As a result, despite our findings showing that DL is associated with better outcomes for both groups, existing policies still view technology as an economic and individual phenomenon rather than a social and relational one. The results showed that caregivers' SS skills strongly predicted their QoL. Therefore, national aging programs should incorporate targeted cyber-safety modules for caregivers. Results also showed a strong effect of content-creation and communication skills on care recipient QoL. Hence, community DL initiatives should include training for care recipients to create, manage, and communicate digital content. These targeted areas align more closely with the dyadic and multidimensional patterns observed in this study. Together, these dyad-level recommendations operationalize a "2-way digital inclusion" approach, in which digital skills are developed reciprocally across care partners to enhance shared well-being and participation.

Policy and Practice

The findings of this study emphasize that DL is a multidimensional and bidirectional concept that is related to the QoL of both members of the caregiving couple. The observed effects highlight 2 priority areas for intervention: caregivers' SS skills and care recipients' information, communication, and content-creation abilities. These results indicate that DL interventions should be dimension-specific and relationship-oriented.

Research by Dong et al [24] suggests that theory-based training programs, delivered in brief face-to-face or blended formats, can improve self-efficacy and digital health literacy.

In Malaysia, this approach could be incorporated into the "MyAgeing Digital Literacy Modules" [53], which align with the EDLQ domains. Integrating such modules into Pusat Aktiviti Warga Emas (PAWE) centers [54] and the Digital Rakyat platform [21] may strengthen caregivers' cyber-safety practices and enhance care recipients' content-creation competencies. This integration is likely to be more effective when supported by intergenerational guidance and real-time assistance. These efforts can complement broader national initiatives, including

XSL•FO
RenderX

MyDIGITAL [21] and the Healthy Ageing 2030 plan [8], by promoting equitable and relationship-centered digital participation.

Limitations and Future Directions

The cross-sectional design of this study limits the ability to infer causality and examine behavioral changes over time. Longitudinal dyadic studies are needed to establish how changes in one member's DL may causally influence changes in the other's QoL over time.

Moreover, our use of a composite QoL score, while methodologically necessary for the APIM framework and empirically supported by very high intercorrelations among WHOQOL-BREF domains (r>0.85), precluded examination of domain-specific effects. Future research with larger samples could employ separate APIM models for each QoL domain to explore whether DL dimensions differentially predict physical, psychological, social, or environmental QoL.

In terms of participant screening, our reliance on a single-item subjective memory complaint screen to ensure reliable self-report may not have adequately excluded participants with mild cognitive impairment, particularly among care recipients aged 75 years and older. While this pragmatic approach was necessary for feasibility in a community-based survey, the absence of objective cognitive screening means that some participants with undetected cognitive impairment may have been included, which could affect the reliability of self-reported DL and QoL assessments.

Although the multivariate model explained a high percentage of the variation in caregivers' QoL (R^2=0.92), this should be interpreted with caution. The high correlations between the different dimensions of DL (Table 8) suggest that part of this value may be attributed to the overlap of the constructs rather than the independent effect of each dimension.

As this study used purposive sampling and was conducted only in urban areas of Klang Valley, the generalizability of the findings to care recipients and informal caregiver populations in semiurban or rural areas of Malaysia is limited. Klang Valley differs from many other states in terms of DL, internet access, and socioeconomic conditions; therefore, the patterns obtained are not necessarily representative of the entire country.

Furthermore, the Malay translation of the EDLQ was reviewed by a bilingual academic with expertise in gerontology for linguistic appropriateness, but formal forward-backward translation protocols and comprehensibility pretesting were not conducted. Although both English and Malay versions were offered based on respondents' language preference, the sample size did not permit measurement invariance testing to confirm equivalence across language versions. Future work with larger samples is needed to confirm measurement consistency across languages and respondent groups.

Future research should be conducted with more diverse samples from different regions to increase generalizability. Longitudinal or intervention studies could also shed more light on the causal pathways and lasting effects of digital education. Additionally, designing bidirectional and dimension-based programs with a focus on SS for caregivers and communication and content creation for care recipients can better demonstrate the mechanisms of digital empowerment. Finally, attention to digital equity and cultural adaptation is essential to improve access for less advantaged groups.

Conclusions

In summary, this study demonstrated that DL is a multidimensional and bidirectional factor that is associated with QoL in informal caregiving relationships. Considering both actor and partner effects, the results revealed that caregivers' safety skills and care recipients' communication and management abilities were jointly associated with the well-being of both parties. Integrating bidirectional and dimension-based interventions into Malaysia's national digital health and aging strategies can expand digital inclusion, reduce technological inequality, and may improve the experience of care. Future studies with longitudinal and educational designs can demonstrate how digital empowerment may enhance sustainable well-being in increasingly digital societies.

Acknowledgments

We sincerely thank the older adults and their family caregivers who participated wholeheartedly in this study. We are also grateful to the community centers and service organizations in the Klang Valley for their support in participant recruitment and data collection.

Funding

This study was part of the Transforming Cognitive Frailty to Later-Life Self-sufficiency (AGELESS) study funded by the Ministry of Higher Education Malaysia Long-Term Research Grant Scheme (LRGS/1/2019/UM/01/1/2). The study was also supported by the Research Management Centre (RMC), Universiti Putra Malaysia (UPM).

Abstract

Background: Exergames, which combine physical exercise with interactive gameplay, are increasingly being incorporated into fall prevention programs for older adults. Gamified elements, such as real-time feedback and progress tracking, may enhance motivation, engagement, and adherence. Although several systematic reviews have examined the effects of exergaming on balance and physical function, fewer have focused specifically on clinically meaningful outcomes, such as falls and injurious falls, or on indicators that may influence real-world adoption of exergames.

Objective: This study aimed to evaluate the effectiveness of exergaming interventions for preventing falls and injurious falls in people aged ≥60 years and to synthesize evidence on implementation-related outcomes, including adherence, acceptability, concerns about falling, quality of life, adverse events, and cost-effectiveness.

Methods: MEDLINE, Embase, CINAHL Plus, PsycINFO, and the Cochrane Central Register of Controlled Trials (CENTRAL) were searched from inception to February 2025 for randomized controlled trials evaluating exergaming interventions in older adult populations across all settings. Outcomes included fall rate, number of fallers and injurious falls, and implementation-related secondary outcomes. Risk of bias was assessed using RoB 2.0, and certainty of evidence was assessed using Grading of Recommendations Assessment, Development, and Evaluation (GRADE). Data were synthesized narratively and, where appropriate, pooled using meta-analysis.

Results: Nine studies (N=1385) met the inclusion criteria. Comparator-specific analyses suggested that exergaming may reduce fall rates compared with active intervention comparators, although the magnitude and certainty of effect varied, and substantial heterogeneity was present across analyses. Moderate-certainty evidence also suggested that exergames reduced the number of older adults experiencing one or more falls at 12-month follow-up compared with usual care (risk ratio 0.75, 95% CI 0.61 - 0.92). Evidence for injurious falls, quality of life, concerns about falling, adherence, acceptability, and cost-effectiveness was limited or inconsistent. When pooled across all control groups, exergaming interventions were associated with a lower overall fall rate than comparator interventions (incidence rate ratio 0.53, 95% CI 0.41 - 0.68), although substantial heterogeneity was present (I^2=76%).

XSL•FO
RenderX

Conclusions: Low- to moderate-certainty evidence suggests that exergames may reduce fall rates, particularly in comparisons with active intervention control groups, and may reduce the number of fallers compared with usual care. These findings indicate that exergaming may offer a useful adjunct to established fall prevention strategies for older adults, particularly where sustained engagement with conventional exercise is challenging. However, substantial heterogeneity, modest sample sizes, and limited long-term follow-up reduce confidence in these estimates, and more rigorous, large-scale trials are needed before routine implementation can be recommended. This review extends previous exergaming syntheses by focusing on clinically meaningful outcomes, including falls and injurious falls, while also considering implementation-related factors relevant to real-world uptake.

Introduction

Rationale

Each year, approximately one-quarter to one-third of adults aged >65 years living in the community experience a fall, a finding consistently reported across international populations [1-3]. A fall is defined as “an unexpected event in which the participant comes to rest on the ground, floor, or lower level” [4]. The consequences of falls range in severity from minor bruising to debilitating fractures or even death [5]. Beyond physical injuries, falls can also have considerable psychosocial effects, as concerns about falling and loss of independence can lead to reduced social engagement and diminished quality of life (QoL) [6].

Falls also place a substantial financial burden on health care systems worldwide due to hospitalizations and the need for long-term care following injurious falls [7]. Many risk factors for falls, including balance and strength deficits, cognitive decline, and reduced muscle mass, are associated with aging and low levels of physical activity [8]. Regular physical activity can mitigate these issues by improving muscle strength, balance, and overall physical function, as well as enhancing cognitive performance, mood, and QoL [9-11]. Strong evidence suggests that physical activity programs, particularly those incorporating balance and functional exercises, can reduce both the rate of falls and the number of older people who experience falls in the community [12]. Nevertheless, adherence to these programs is often modest and tends to decline over time, with systematic reviews reporting full adherence rates as low as 21% for home-based programs [13] and only approximately half of participants remaining adherent at 12 months [14,15].

Exergaming offers a promising alternative by providing an immersive and engaging experience, incorporating gamified elements such as feedback, achievements, and progress tracking to enhance motivation and adherence [16]. Exergames, broadly defined as active video games that integrate gameplay with physical exercise, use real-time motion detection to track players’ movements [17]. These games may be delivered via animated gaming platforms or within 2D or 3D virtual reality (VR) environments and are increasingly being explored as a tool for fall prevention [18,19].

As exergaming can be tailored to an individual’s functional ability, it may make physical activity more accessible, enjoyable, and acceptable for older adults, addressing barriers such as low motivation and physical limitations [16,20]. As a fall prevention tool, exergaming interventions often gamify physical activities targeting balance, strength, 3D movement (eg, dance), endurance [20-22], and cognitive function [23,24]. These interventions can be provided to individuals or groups in a wide range of settings, including home-based settings, community settings, and hospitals, with or without facilitation by a health professional.

Several systematic reviews and meta-analyses have examined exergaming in older adults, reporting improvements in intermediate outcomes, such as balance, physical function, cognitive outcomes, and concerns about falling [25-32]. These findings suggest that exergaming may improve important fall-related risk factors and may enhance exercise engagement through interactive feedback and gamification. However, comparatively less attention has been given to whether these interventions translate into reductions in clinically measured falls and injurious falls, which remain the most meaningful outcomes for patients, clinicians, and health services. In addition, previous reviews have given limited consideration to implementation-relevant factors, such as adherence, acceptability, adverse events, and cost-effectiveness, all of which are important when evaluating the real-world feasibility of integrating exergaming into fall prevention pathways. Furthermore, prior syntheses have rarely distinguished between usual care, evidence-based active exercise controls, and non–evidence-based active comparator interventions, limiting the interpretation of whether exergaming offers benefit beyond established fall prevention practice. A more clinically focused synthesis of the available evidence is therefore needed.

Objectives

To address these gaps, the aim of this systematic review and meta-analysis was to evaluate the effectiveness of exergaming interventions for preventing falls and injurious falls in adults aged ≥60 years. The secondary objectives were to synthesize evidence relating to QoL, concerns about falling, balance confidence, adherence, acceptability, adverse events, and cost-effectiveness and to examine findings according to comparator type.

Methods

Overview

We followed Cochrane systematic review methods [33]. The review was conducted and reported in accordance with the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) 2020 statement, using the PRISMA 2020 expanded checklist [34], the PRISMA 2020 for Abstracts checklist [35], and the PRISMA-S extension for reporting literature searches [36]. The study protocol was prospectively registered with PROSPERO (CRD42020214721).

Information Sources and Search Strategy

Searches were completed first in March 2023 and updated using the same search strategy in February 2025. The following databases were searched from inception to this date: MEDLINE (Ovid), Embase (Ovid), CINAHL Plus (EBSCO), PsycINFO (Ovid), and Cochrane Central Register of Controlled Trials (CENTRAL) (Ovid). The PICOS framework was used to develop eligibility criteria around the themes of exergames, falls, and older people (Table 1). The search strategy combined database-specific controlled vocabulary terms (eg, MeSH, Emtree, CINAHL Headings, and APA Thesaurus) with free-text terms. Full search strategies for all databases, including database-specific adaptations, are provided in Supplementary Material S1 in Multimedia Appendix 1. No date restrictions were applied, but searches were limited to studies published in English in accordance with the eligibility criteria. Where published reports lacked sufficient methodological or outcome detail, study authors were contacted for clarification or to request additional data. In addition to database searches, reference lists of included studies and relevant systematic reviews were screened, and forward citation searching was conducted manually by 2 independent reviewers (CE-T and YY) using Google Scholar to identify any additional eligible studies.

Table . Inclusion and exclusion criteria.

Eligibility criterion	Inclusion	Exclusion
Population	• Sample was predominantly aged ≥60 y (operationalized as mean age minus one SD >60 where necessary) • All health conditions	• Sample was predominantly aged <60 y
Interventions	• All types of exergaming interventions • All delivery methods	• Nonexergaming intervention
Control	• No intervention or usual care • Active intervention not believed to reduce falls • Active intervention considered likely to reduce falls	• None
Outcomes	• Primary: falls or injurious falls • Secondary: health-related quality of life, concern about falling or fear of falling, balance confidence, adherence and/or acceptability, adverse events, cost-effectiveness	• Studies where the only outcomes relate to balance, functional mobility, and/or strength
Setting	• All settings	• None
Types of studies	• Randomized controlled trials • Cluster randomized controlled trials	• Nonrandomized studies • Observational, quasi-experimental, qualitative
Aim	• Main purpose is to investigate the effectiveness of exergaming on falls or injurious falls in older people	• Main purpose is not to investigate the effectiveness of exergaming on falls or injurious falls in older people
Type of publication	• Peer-reviewed journal publication	• Not a peer-reviewed journal publication • Conference abstract, theses, letter to editor, reviews, descriptive (editorials, books, and reports), and protocol only
Language	• English language	• Other languages
Dates	• All dates	• None

XSL•FO
RenderX

Eligibility Criteria

We included randomized controlled trials from any setting that evaluated the effects of exergaming interventions on falls or injurious falls in older adults aged ≥60 years (Table 1). This threshold aligns with international definitions of older populations (eg, World Health Organization [2]) and allows inclusion of a broad range of relevant studies. We included trials with generally healthy participants and participants with conditions that may increase the risk of falls (eg, dementia, stroke, Parkinson disease, and frailty).

We included trials in which the main purpose of the study was to investigate the effectiveness of exergaming. We excluded studies that focused solely on the design of exergaming interventions.

Interventions and Comparators

The review considered all types of exergaming interventions and all delivery methods. This included all interactive active games and immersive or nonimmersive VR platforms, and interventions of any length and duration were eligible. Control interventions included usual care, standard exercise programs with an evidence base in fall prevention (eg, strength and balance training), as well as those with no evidence base in fall prevention (eg, an educational leaflet on exercise and low-intensity or low-frequency exercise) [12].

The types of exercise primarily targeted by the intervention were categorized according to the Prevention of Falls Network Europe (ProFaNE) taxonomy [37], as follows: (1) gait, balance, coordination, and functional training; (2) strength or resistance training; (3) flexibility; (4) 3D exercise (eg, Tai Chi or dance); (5) general physical activity; (6) endurance (eg, treadmill walking); and (7) other kinds of exercise.

Outcomes

The primary outcomes of interest were (1) rate of falls (number of falls over a period and falls per person-year), (2) number of fallers (number of people experiencing one or more falls), and (3) number of people who experienced one or more injurious falls [38].

The secondary outcomes were (1) health-related QoL (measured using a validated scale such as the EQ-5D [39]); (2) concern about falling (measured using a validated scale such as the Falls Efficacy Scale-International [40]); (3) balance confidence (measured using a validated scale such as the Activities-Specific Balance Confidence Scale [41]); (4) adherence to the intervention (defined as the extent to which participants completed the prescribed exergaming program, including attendance, exercise frequency, duration, or retention); (5) acceptability of the intervention (defined as participants' perceptions of usability, satisfaction, enjoyment, and willingness to engage with or continue the program, as reported by study authors); (6) adverse events (defined as any negative outcome resulting either directly or indirectly from the assigned treatment [42], measured as the number of people who experienced one or more adverse events); and (7) cost-effectiveness of the intervention. These outcome definitions were based on measures reported in the included studies.

Protocol Registration and Amendments

This review was prospectively registered in PROSPERO (CRD42020214721) and conducted in accordance with the registered protocol. One methodological amendment was made during the review process. We initially planned to combine all active intervention comparators into a single analysis; however, important conceptual and clinical differences were identified between evidence-based fall prevention interventions and non–evidence-based active controls. These comparator groups were therefore analyzed separately to improve the interpretability and clinical relevance of the findings. This decision was made prior to final data synthesis. No other substantive deviations from the registered protocol were made.

Study Selection

Titles and abstracts from the database searches were imported into the Rayyan web app for systematic reviews [43], and duplicate records were removed. Records were then screened for relevance by 2 independent reviewers (selected from a pool of CE-T, LM, EDB, ES, KD, YY, AM, KG, RC, and AA), and full texts of studies considered potentially relevant were assessed for eligibility. The reasons for exclusion at the full-text stage were recorded and are reported in Supplementary Material S2 in Multimedia Appendix 1. The same prespecified eligibility criteria (Table 1) were applied at title or abstract and full-text screening, and the table served as the screening framework for reviewers. No automated decision-making tools were used, and all decisions were made by reviewers. Any disagreements were resolved through discussion with a third independent reviewer from the pool.

Data Extraction

Data were extracted from included studies by 2 independent reviewers (KG and YY) using a standardized data extraction form in an Excel (Microsoft) spreadsheet, and an independent reviewer (CE-T or AA) checked for accuracy. Extracted data included author details, country, year of publication, participant characteristics (eg, age, gender, and health status), study characteristics (eg, design, location, setting, sample size, and length of follow-up), intervention details (eg, exergaming device and dose), outcomes measured, and key results.

We used PROGRESS-Plus criteria (place of residence, race/ethnicity/culture/language, occupation, gender/sex, religion, education, socioeconomic status, and social capital) [44] when extracting participant characteristics.

The TIDieR (Template for Intervention Description and Replication) checklist was used to describe the included interventions and controls [45].

Risk of Bias Assessment

The Excel version of the Cochrane risk of bias (RoB 2.0) tool was used to assess the risk of bias [46,47]. Two independent reviewers assessed the risk of bias for each study, and any disagreements were resolved through discussion with an additional reviewer. Risk of bias was classified as high, low, or some concerns, across the following domains: randomization process, deviations from intended interventions, missing

XSL•FO
RenderX

outcome data, measurement of the outcome, and selection of the reported result.

Reporting Bias Assessment

Reporting bias, including publication bias and selective reporting, was considered during synthesis. Formal statistical assessment (eg, funnel plots or Egger test) was not undertaken because of the small number of studies included in each meta-analysis, making such methods unreliable. Potential reporting bias was therefore considered qualitatively when interpreting the findings.

Assessment of the Certainty of Evidence

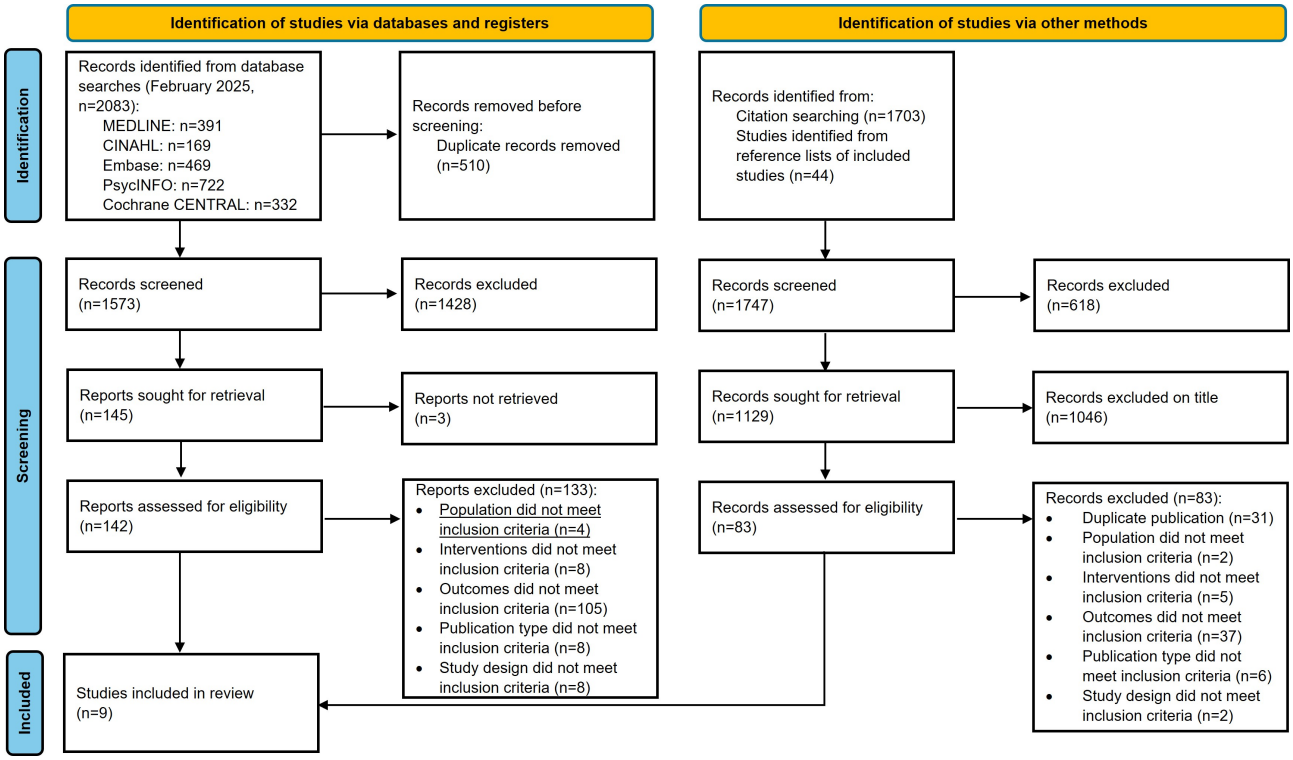
We conducted GRADE assessments on the overall evidence for each primary outcome, split by comparator group [48]. Two independent reviewers assessed each outcome (CE-T and AM or LM and SA), and any disagreements were resolved through discussion. Overall bias per outcome was based on the majority rating across domains.

Effect Measures and Data Synthesis

Findings were synthesized narratively and summarized in overview tables to facilitate comparison across interventions. Where 2 or more studies contributed sufficiently clinically comparable data, pooled overall or comparator-specific meta-analyses were conducted in Review Manager (RevMan; version 5.4) [49]. Outcomes informed by single studies are presented for consistency of effect estimation but interpreted narratively. Incidence rate ratios (IRRs) with 95% CIs were calculated for fall rate outcomes, risk ratios (RRs) with 95% CIs for binary outcomes (number of fallers and number of participants experiencing one or more injurious falls), mean differences (MDs) for continuous outcomes reported on the same scale, and standardized MDs (SMDs) where different measurement scales were used. Fixed effects or random effects models were selected according to the clinical comparability between studies. Where pooling was not appropriate because of limited study numbers, heterogeneous outcome measures, or inconsistent reporting, results were synthesized narratively in accordance with Synthesis Without Meta-analysis guidance [50].

Subgroup Analysis

Planned subgroup analysis for the primary outcomes included participant age (older vs younger populations), health condition (eg, healthy, stroke, Parkinson disease, and frailty), and intervention setting (community, residential care home, hospital, assisted care facility, sheltered housing, and retirement community). However, these analyses were not feasible because too few studies contributed data within each subgroup. Comparator-specific analyses were undertaken instead, as these provided the most clinically interpretable basis for exploring variation in effect estimates.



Results

Study Selection

We identified 3830 records, and after removal of duplicates, 3320 (86.7%) were screened on title and abstract, and 225 (5.9%) full-text reports were assessed for eligibility. Of these, 216 (96%) full-text reports were excluded, most commonly because of ineligible study design, inappropriate intervention, ineligible population, or absence of relevant fall outcomes. A full list of studies excluded at the full-text screening, together with reasons for exclusion, is provided in Supplementary Material S2 in Multimedia Appendix 1. Nine randomized controlled trials involving 1385 participants met the inclusion criteria, with 51% (701/1385) in intervention groups and 49% (684/1385) in control groups. Studies varied considerably in participant populations, intervention formats, comparator types, and follow-up duration (Figure 1).

XSL•FO
RenderX

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flowchart of the systematic review process.

Participant Characteristics

Participant characteristics and PROGRESS-Plus aspects of equity are presented in Table 2. In total, 59% (817/1385) were women (intervention groups: 416/817, 51% and control groups: 401/817, 49%). The mean age of participants was 72.8 (SD 7.9; intervention groups: 72.9, SD 7.8, and control groups: 72.6, SD 8.0) years. The mean age of participants in the no contact or usual care control studies was 72.8 (SD 6.9) years; in the active control studies (evidence based), the mean age was 73.1 (SD 9.0) years; and in the active control studies (non–evidence based), the mean age was 72.6 (SD 7.9) years. Four studies recruited participants based on a diagnosis of Parkinson using clinical criteria [51-54]. Participants were recruited in 3 studies on the basis that they had a history of falls [51,53,55], and 1 study specifically recruited participants with mild cognitive impairment [53].

[a]PROGRESS-Plus: place of residence, race/ethnicity/culture/language, occupation, gender/sex, religion, education, socioeconomic status, and social capital.

[b]I: intervention.

[c]C: control.

[d]P: place of residence.

[e]R: race, ethnicity, or culture.

[f]O: occupation.

[g]SES: socioeconomic status.

[h]SC: social capital.

[i]E: education.

[j]MCI: mild cognitive impairment

No study included data on the research locale (eg, urban or rural), 2 studies noted race, ethnicity, or culture [56,58], and 1 study each presented data on the participants' language [58], occupation [56], number of years in education [53], and

XSL•FO
RenderX

socioeconomic status [56]. Three studies included some information on aspects, which could contribute to social capital (ie, living arrangements) [56-58].

Study and Intervention Characteristics

Overview

A summary of study and intervention characteristics is presented in Table 3. Studies were conducted across 11 countries, including 1 study each from India [51], Switzerland [59], China [55], Italy [52], Singapore [58], the United Kingdom [56], Australia or New Zealand [54], and Australia [57], and 1 study from a multicountry study (Belgium, Israel, Italy, the Netherlands, and the United Kingdom) [53]. Study settings included 2 clinics: a clinical center [53] and a geriatric clinic [59]. The remaining studies were conducted across hospital and community settings [51], in both community and university laboratory settings [54], in a satellite center, and at home [58], and 4 in community settings, such as the home [52], an assisted living facility [56], a nursing home [55], and 1 unspecified community location [57].

[j]ACC: acceptability.

[k]C/CE: costs/cost-effectiveness.

[l]BC: balance confidence.

[m]AC: active control.

[n]vii: other kinds of exercise, which improve the correct use of ankle and hip strategy during static conditions.

[o]ii: strength or resistance training (alternating biceps curl).

[p]iii: flexibility.

[q]VR: virtual reality.

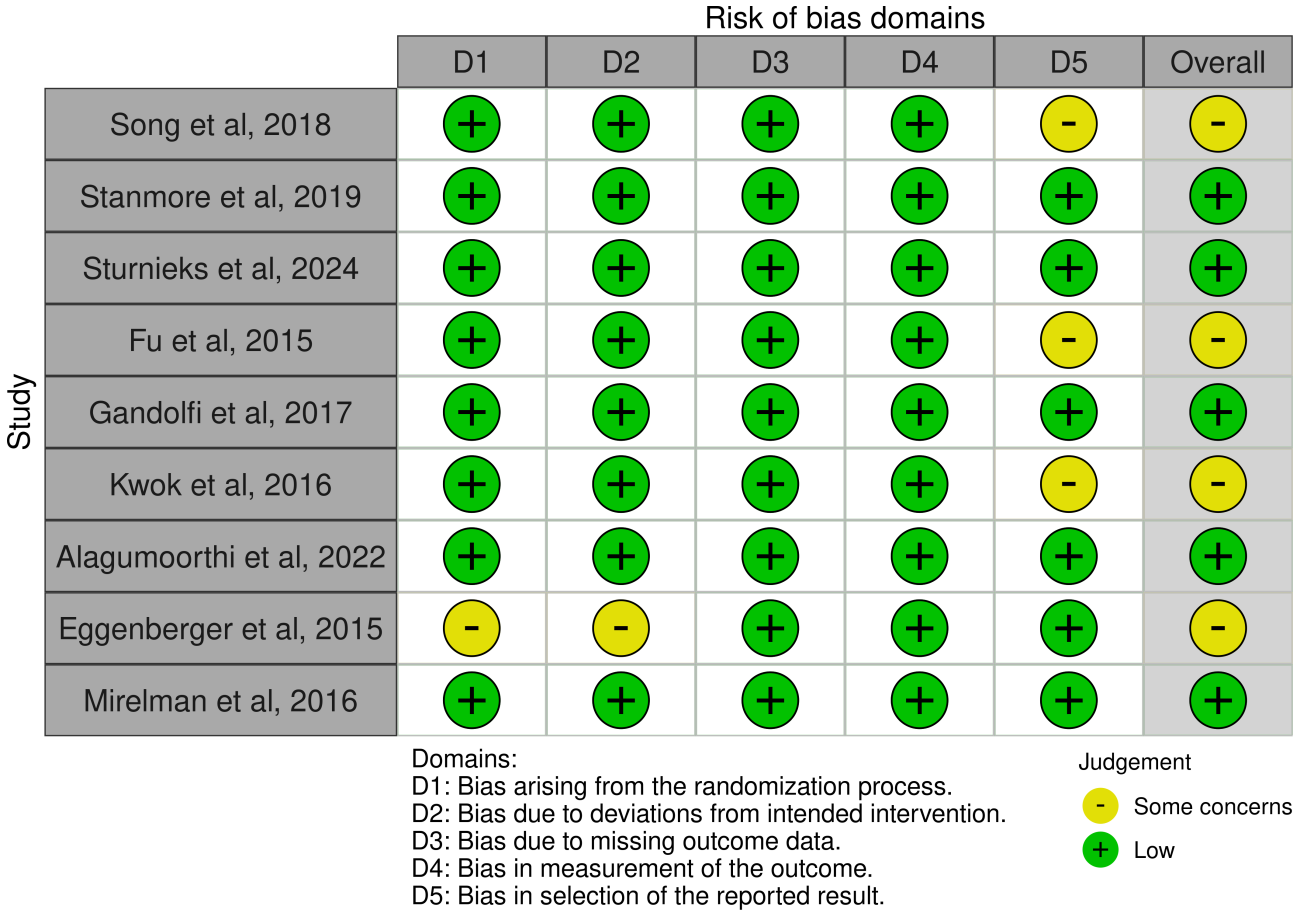
The interventions in the included studies were described using the TIDieR checklist (see Supplementary Material S3 in Multimedia Appendix 1 for details). A range of exergaming and VR systems were used across studies: 4 used the Nintendo Wii platform, 1 used Microsoft Kinect with tailored software, 1 used a modified Microsoft Kinect combined with nonimmersive VR and treadmill training, 2 used dance-based systems (Konami Dance Dance Revolution or Positive Gaming Impact Dance Platform) paired with a Stepmania mat, and 1 used bespoke stepping software with a pressure-sensitive mat [57].

In terms of the control group, 3 studies included usual care or no intervention [54,56,57], 3 included an evidence-based exercise fall prevention program [52,55,58], and 3 used a non–evidence-based program [51,53,59]. Active controls included balance training (with or without physiotherapy)

XSL•FO
RenderX

[51,52,55], treadmill training [53,59], or gym-based exercises [58].

Intervention Dosage and Delivery Characteristics



The active exergame dose ranged from 6 to 52 weeks, with a frequency of 2 to 3 sessions per week, where specified. Session duration ranged from 15 minutes to 1 hour. One study gave an overall number of minutes per week to be completed but did not specify how many sessions should be undertaken or how long each should last [57].

All studies involved support for the exergame sessions provided by physiotherapists, health care professionals, or trained postgraduate students. Seven interventions included supervised sessions throughout the study [51-53,55,56,58,59], while the remaining 2 provided supervision during the initial setup and training session, with ongoing technical support and advice available as needed for the remainder of the study [54,57]. Studies did not report on the type and frequency of help needed by participants to undertake the exergame exercises.

Risk of Bias and Certainty of the Evidence

Risk-of-bias (RoB 2) summary assessments are shown in Figure 2.

Figure 2. Risk of bias summary assessments [51-59].

Due to the nature of the intervention, no studies were able to blind participants to their group assignment. Nevertheless, 8 studies were single blinded with assessors blinded to the participant group [51-55,57-59], and the final study was nonblinded because the cluster design revealed participants' allocation due to their assisted living facility [56]. Four studies had some additional concerns over the risk of bias: 3 over the selection of the reported result because there was a lack of information about whether the data that were used to produce the results had been analyzed following a prespecified analysis plan, which had been finalized before the unblinded outcome data were available for analysis [54,55,58]. The fourth study had some concerns over a lack of information on the randomization process and deviations from the intended intervention [59].

Certainty of evidence (GRADE) for each primary outcome is presented in Table 4, with full assessment details provided in Supplementary Material S4 in Multimedia Appendix 1. Key drivers for downgrading of outcome certainty were imprecision and inconsistency across studies.

Effectiveness of Interventions

The effectiveness of exergaming interventions is presented according to comparator type: usual care, evidence-based active controls, and non–evidence-based active controls. This approach was used to distinguish the effects of exergaming against usual care or no intervention, against established exercise programs with evidence for fall prevention, and against active control activities not specifically designed to reduce falls.

Comparison 1: Exergames Versus Usual Care or No Intervention Control Group

Three studies, including 652 participants, compared the use of exergames against usual care or no intervention [54,56,57]. Forest plots for this comparison are presented in Figure 3.

XSL•FO
RenderX

Figure 3. Forest plots of exergames versus usual care [54,56,57]. HR: health related; IRR: incidence rate ratio; QoL: quality-adjusted life year.

XSL•FO
RenderX

Primary Outcomes

Rate of Falls: IRR

All 3 studies reported fall rates, which were converted to IRR for comparison (n=652) [54,56,57]. Using a random-effects model, the pooled estimate suggested a possible reduction in fall rate (low certainty evidence). However, the CI crossed the line of no effect, indicating uncertainty in the effect estimate. Substantial heterogeneity was present, and this finding should therefore be interpreted with caution (IRR 0.60, 95% CI 0.35 - 1.01; I^2=86%). Heterogeneity was evident in participants, settings, and intervention components, and one small study, which included participants with Parkinson disease, showed no significant result with wide CIs [54].

Number of Fallers (Number of People Experiencing One or More Falls)

Three studies (n=652), 2 at low risk of bias and 1 with some concerns, presented data on the number of fallers (low certainty evidence): one each at 3-month follow-up [56], 6-month follow-up [54], and a 12-month follow-up [57]. No significant differences were found at 3-month or 6-month follow-up (RR 0.80, 95% CI 0.40 - 1.63 and RR 0.84, 95% CI 0.55 - 1.28, respectively). At 12-month follow-up, exergames may result in a reduction in the number of fallers (RR 0.75, 95% CI 0.61 - 0.92).

Number of People Who Experienced One or More Injurious Falls

One study (n=507) [57] showed exergaming may reduce the relative risk of people experiencing one or more injurious falls by an average of 19% (low certainty evidence). This estimate was imprecise, ranging from a 39% reduction to an increase of 8% (RR 0.81, 95% CI 0.61 - 1.08).

Secondary Outcomes

Quality of Life

One study (n=92) reported on QoL using the EQ-5D-5L VAS scale [56]. The evidence suggests that exergames do not improve QoL at 3-month follow-up (MD −3.40, 95% CI −12.40 to 5.60).

Effects on Concerns About Falling

Three studies (n=652) reported on the effect of exergaming interventions on concerns about falling [54,56,57]. Two studies reported this outcome at 12-week follow-up [54,56] and the third study at 6- and 12-month follow-up [57]. For this study, we focused on the 12-month data, as it represented the longest follow-up period. The evidence from a meta-analysis of the 12-week follow-up data suggests that exergames result in no difference in concerns about falling (SMD −0.28, 95% CI −1.18 to 0.61), and there was high heterogeneity between the studies (I^2=85%). Evidence from the study with the 12-month follow-up period [57] also suggested that exergames did not reduce concerns about falling (SMD −0.10, 95% CI −0.23 to 0.02).

Balance Confidence

No study reported on balance confidence in this comparison.

Acceptability

Two studies (n=599) included acceptability measures [56,57]. The System Usability Scale [60] mean score in the first study was 82.4 (SD 15.5) at 12-week follow-up [56]. The second study measured the System Usability Scale at 6 and 12 months and found a mean score of 80.4 (SD 15.8) at 6-month and 83.3 (SD 13.9) at 12-month follow-up [57]. At all measurement points in both studies, scores were above 80, which is considered excellent and indicates good usability. The Technology Acceptance Model [61] was included in one paper [56] at 12-week follow-up, and overall, all domains were considered high or very high, but with some variation in behavioral intention and perceived usefulness: easy to use, 6.3 (SD 1.4); useful, 5.9 (SD 1.9); favorable attitude, 6.6 (SD 1.2); and intention to use, 5.7 (SD 2.2).

Adherence

All 3 studies reported on retention rates, with a median of 87% and a range from 81% to 91.7% [54,56,57]. The median adherence rate to the minimum prescribed dose of exercise was 69%, ranging from 50.8% to 85%. However, 1 study also noted that only 0.6% of participants achieved the target of 120 minutes of exercise per week over the 12-month intervention period [57].

Adverse Events

No studies reported serious adverse events as a result of the intervention: 2 reported no adverse events from the intervention [56,57] and the third study reported 1 noninjurious fall while completing the exergame step training under the guidance of an experienced physiotherapist [54].

Cost-Effectiveness

One study (n=92) included the cost-effectiveness of the exergame intervention [56]. The authors reported a point estimate incremental cost-effectiveness ratio of £15,209.80 (US $20,239.71) per quality-adjusted life year (QALY). Using 1000 bootstrap replications, they found there was a 61% probability that exergames were cost-effective at the lower National Institute for Health and Care Excellence threshold of £20,000 (US $26,624.08) per QALY, rising to 73% at the upper threshold of £30,000 (US $39,970) per QALY.

Comparison 2: Exergames Versus Evidence-Based Active Control

Three studies (n=210) reported on the use of exergame interventions and an evidence-based active control [52,55,58]. Forest plots for this comparison are presented in Figure 4.

XSL•FO
RenderX

Figure 4. Forest plots of exergames versus evidence-based active controls [52,55,58]. HR: health related; IRR: incidence rate ratio; QoL: quality-adjusted life year.

XSL•FO
RenderX

Primary Outcomes

Rate of Falls: IRR

The IRRs were calculated for all studies, and the evidence from a meta-analysis suggests that exergames result in a reduction in fall rate (IRR 0.41, 95% CI 0.27 - 0.62; $I^{2=}$39%; low certainty evidence).

Number of Fallers (Number of People Experiencing One or More Falls)

A single study (n=80) reported intervention effects on the number of fallers at 12-month follow-up [58]. The evidence, which was of low certainty, showed that exergames result in little to no difference in the number of fallers (RR 1.38, 95% CI 0.62 - 3.06).

Number of People Who Experienced One or More Injurious Falls

No studies reported on this outcome.

Secondary Outcomes

Quality of Life

One study (n=70) examined the effects of an exergame intervention on QoL using the EQ5D scale [52]. Findings indicated that exergames do not increase QoL compared to evidence-based active controls (MD −1.91, 95% CI −8.49 to 4.67).

Concerns About Falling

Concerns about falling were reported in one study (n=80), using the Modified Falls Efficacy Scale [58]. The evidence suggests exergames result in a reduction in concerns about falling at 12-week follow-up (MD 0.80, 95% CI 0.61 - 0.99).

Balance Confidence

Balance confidence was reported in 1 study (n=70), using the Activities-Specific Balance Confidence scale [52]. Exergames may result in little to no difference in balance confidence at 1-month follow-up (MD −4.61, 95% CI −13.10 to 3.88).

Acceptability

Two studies included measures of acceptability (n=150) [52,58]. Evidence from a meta-analysis of these studies suggests that exergames result in little or no difference in acceptability (SMD −0.19, 95% CI −0.53 to 0.16 I^2=0%).

Adherence

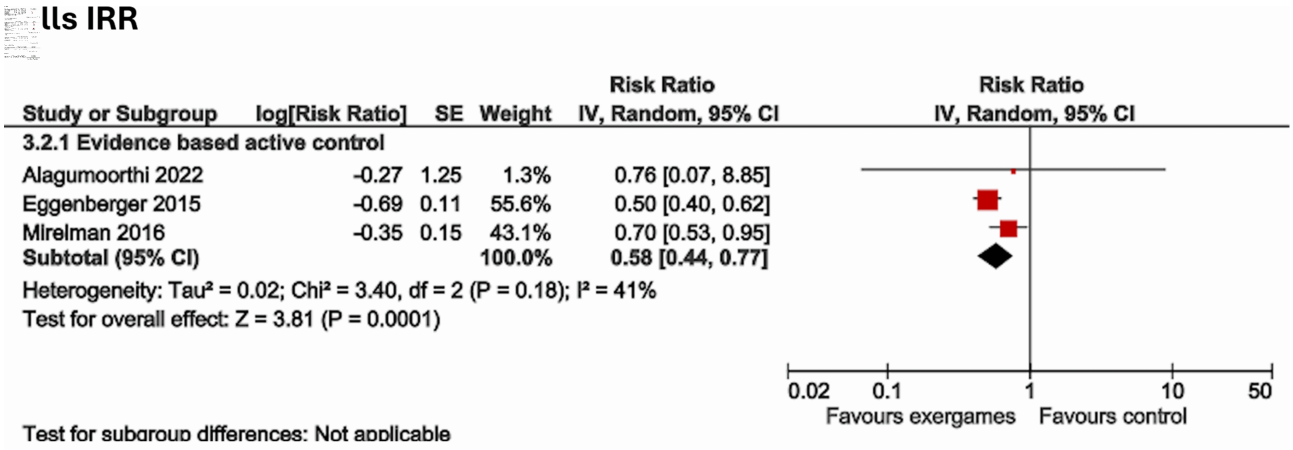
One study (n=80) reported on adherence rates [58], assessed through attendance at intervention sessions and the frequency of home exercises performed. Attendance data suggest little to no difference in adherence (MD 0.10, 95% CI −1.02 to 1.22). The home exercise compliance (number of days per week completed over the 1-y follow-up) also suggested no difference in adherence (MD 0.30, 95% CI −0.34 to 0.90).

Adverse Events

Two studies included adverse events [52,58], but both reported no adverse events during the studies or follow-up periods.

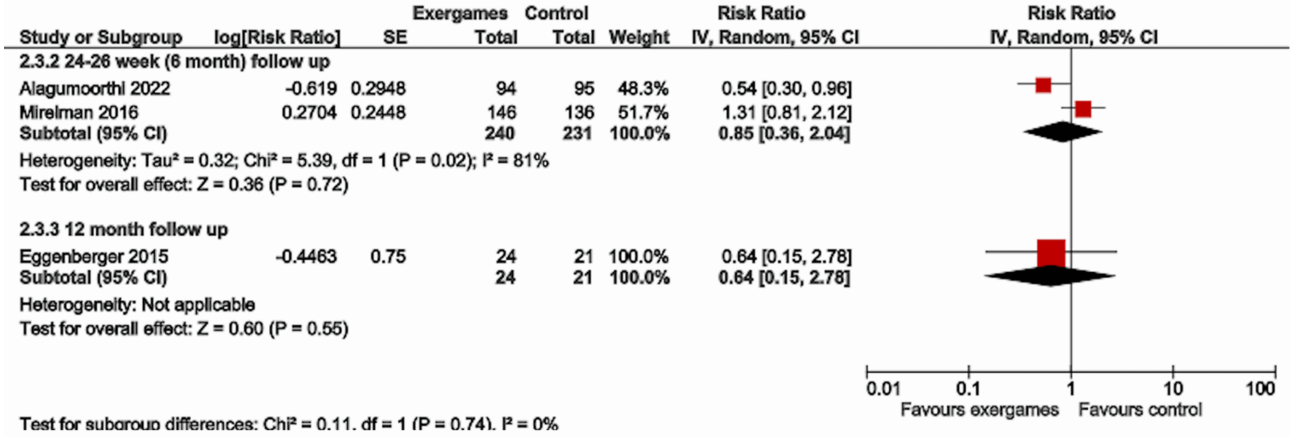
Cost Data

Cost-effectiveness was not included in any study; however, one study did consider cost (n=70) [52]. The cost of rehabilitation was calculated as €383.55 (US $439.20) per intervention group participant (€23,299.00 [US $26,679.22] for the whole intervention group) and €602.10 (US $689.45) per control group participant (€28,899.80 [US $33,092.58] for the whole control group).



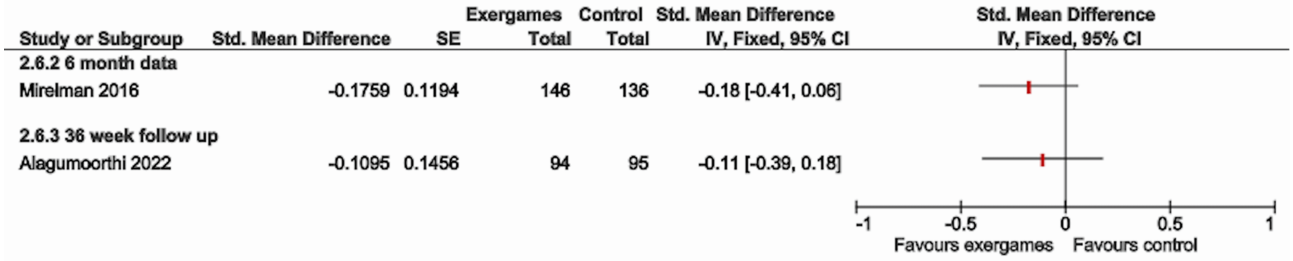
Comparison 3: Exergames Versus Active Intervention (Non–Evidence Based)

Three studies (n=523) reported on the use of exergame interventions and a non–evidence-based active control [51,53,59]. Forest plots for this comparison are presented in Figure 5.



XSL•FO
RenderX

Figure 5. Forest plots of exergames versus non–evidence-based active controls [51,53,59]. HR: health related; IRR: incidence rate ratio; QoL: quality-adjusted life year.



XSL•FO

Concerns about falling

Adherence

XSL•FO
RenderX

Primary Outcomes

Rate of Falls: IRR

All 3 studies reported the effects of exergame interventions on the fall rate in this comparison [51,53,59]. Two reported follow-ups at 6 months (n=474) [51,53] and one at 12 months (n=49) [59]. These data were converted to IRR for comparison, and the moderate-certainty evidence from a meta-analysis indicates that exergames likely result in a reduction in fall rate (IRR 0.58, 95% CI 0.44 - 0.77; I^2=41%).

Number of Fallers (Number of People Experiencing One or More Falls)

Three studies (n=523) reported the number of people experiencing one or more falls [51,53,59]. At 6-month follow-up, evidence from a meta-analysis of 2 studies (n=474) suggests no difference in the number of fallers (RR 0.85, 95% CI 0.36 - 2.04) [51,53]. At 12-month follow-up, low-certainty evidence indicated that exergames did not reduce the number of fallers (RR 0.64, 95% CI 0.15 - 2.68) [59].

Number of People Who Experienced 1 or More Injurious Falls

No studies reported on this outcome

Secondary Outcomes

Quality of Life

QoL was measured in 2 studies (n=474) using either the 36-Item Short Form Health Survey (SF-36) [62] at 6-month follow-up [53] or the Parkinson's Disease Questionnaire (PDQ-39) summary index [63] at 36-week follow-up [51]. Evidence from the studies suggests that exergames result in little or no difference in QoL.

Concerns About Falling

One study (n=49) reported on concerns about falling using the FES-I scale [59]. The evidence is very uncertain about the effect of exergames on concerns about falling (MD 1.60, 95% CI −0.63 to 3.83).

Balance Confidence

No studies in this comparison group reported on this outcome.

Acceptability

No studies in this comparison reported on this outcome.

Adherence

Evidence from a single study (n=282) [53] was very uncertain about the effect of exergames on adherence (MD −0.20, 95% CI −0.62 to 0.22).

Adverse Events

Two studies reported on adverse events [51,53]. Although overall 24 events were reported, none occurred because of the study.

Cost-Effectiveness

No studies in this comparison reported on this outcome measure.

Overall Falls Pooled Effect Across Comparator Groups

An exploratory pooled analysis across all comparator groups, with low- to medium-certainty evidence, suggested that exergaming interventions were associated with a lower fall rate than comparator interventions (IRR 0.53, 95% CI 0.41 - 0.68). However, substantial heterogeneity was present (I^2=76%), indicating considerable variation in effect estimates across studies, and therefore, this pooled effect should be interpreted cautiously. Comparator-specific analyses are likely to provide more clinically meaningful insights, as the magnitude and certainty of effect differed across control categories. Differences in participant populations, intervention characteristics, comparator content, and follow-up duration are likely to have contributed to the observed heterogeneity.

Discussion

Summary of Findings

This review synthesized evidence on the effectiveness of exergaming interventions for fall prevention in older adults by examining falls and injurious falls as primary outcomes alongside implementation-relevant secondary outcomes. Comparator-specific analyses suggest that exergaming interventions may reduce fall rates when compared with usual care and some active comparators, although the magnitude and certainty of effect varied across comparisons. When data were pooled across all comparator groups, exergaming was also associated with an overall reduction in fall rate; however, this broad summary estimate should be interpreted cautiously because substantial heterogeneity indicates important variation between intervention contexts, participant groups, and comparator conditions. Moderate-certainty evidence also indicated that exergames may reduce the number of older adults experiencing one or more falls at 12-month follow-up compared with usual care. However, evidence for injurious falls was limited to a single study, and confidence in several pooled estimates was reduced by substantial heterogeneity, small numbers of contributing studies, and imprecision.

These findings suggest that exergaming may have value as an adjunct to established exercise-based fall prevention approaches, particularly where motivation, adherence, and sustained participation in conventional exercise programs are challenging. At the same time, the review highlights that exergaming interventions are not homogeneous, and effectiveness is probably influenced by intervention design, level of supervision, participant health status, comparator type, and follow-up duration.

Evidence for secondary outcomes, including QoL, concerns about falling, balance confidence, adherence, acceptability, and cost-effectiveness, was limited, of low certainty, or inconsistently reported. Adverse events were uncommon and were not clearly attributed to the interventions, but the small number of studies reporting implementation outcomes limits broader conclusions regarding long-term feasibility, sustainability, and economic value. Overall, these findings suggest that exergaming may offer a promising additional approach within fall prevention; however, the current evidence

XSL•FO
RenderX

base is not yet robust enough to support widespread routine adoption.

Comparison With Prior Work

Previous systematic reviews have generally reported beneficial but mixed effects of exergaming on intermediate outcomes, such as balance, mobility, physical function, concerns about falling, and cognitive performance, but have offered limited synthesis of clinically meaningful fall outcomes [64-74]. This review extends this literature by focusing specifically on falls and injurious falls, by examining implementation-related outcomes relevant to real-world delivery, and by considering effects according to comparator type. This provides a more clinically relevant understanding of where exergaming may offer a benefit within fall prevention pathways.

Our findings are broadly consistent with previous reviews in suggesting that exergames can be effective, but they also confirm that these effects are not uniform and may depend on intervention design, comparator type, and duration of follow-up. Previous reviews, including Chen et al [75], have reported short-term improvements were more commonly seen than long-term effects, and this was evident in our included studies. This highlights the importance of longer follow-up periods, in line with ProFaNE recommendations, to establish whether short-term gains translate into sustained reductions in falls over time.

Variation in game design, exercise challenge, alignment with the Systems Framework for Postural Control [76], progression, feedback, and professional supervision may also explain differences in effectiveness across studies. Standardizing key intervention components and clearer reporting of intervention dose and support needs would improve comparability across future studies and improve confidence in findings [45]. This is particularly relevant given that adherence was stronger in studies with structured supervision, consistent with previous work emphasizing declining motivation in unsupported programs [77].

Economic and implementation evidence is also limited. Only 2 included studies reported intervention costs and only one considered cost-effectiveness [56], reflecting the limited economic evaluation seen across the wider exergaming literature [78,79]. Similarly, acceptability and usability were also underreported, despite their importance for long-term use of digital interventions among older adults [16,77,80,81]. Together, these gaps indicate that future exergaming studies should move beyond efficacy measures alone and address whether exergames represent a viable and scalable fall prevention approach for real-world adoption [82,83].

Strengths and Limitations

This review has several strengths, including a comprehensive multi-database search, prospective protocol registration, comparator-stratified analyses, and use of established tools including RoB 2.0 and GRADE. However, several limitations should be considered.

Our search was limited to studies published in English, which may have introduced language bias. There was also considerable clinical and methodological heterogeneity across studies in participant populations, intervention design, comparators, outcome reporting, and follow-up duration, which limited the precision and generalizability of pooled estimates. Exergame interventions varied widely in the types of equipment used, the extent to which games were purpose designed and the degree to which they were based on known effective strength and balance exercises (eg, Otago [84]), the amount of supervision by physiotherapists or health care professionals, and the duration and frequency of delivery. Furthermore, in several studies, exergames were delivered as part of a wider package of support, making it difficult to isolate the individual contribution of the exergame.

Notably, the studies involving support did not report on the amount or types of support needed by participants. Future research should therefore collect and report this information to better understand its impact on outcomes and to help assess the cost of delivery of the intervention in the real world.

Participant health status also varied considerably: 4 studies included people living with Parkinson disease or mild cognitive impairment, and 3 studies specifically recruited people with a history of falls. Such comorbidities, known to affect strength, balance, and falls, may have impacted the study outcomes [85-88]. Although we planned to conduct subgroup analyses, including those based on health status and PROGRESS-Plus, as outlined in the PROSPERO protocol, the relatively small number of studies included in meta-analyses limited the feasibility of more extensive subgroup analyses and formal assessment of publication bias. Many of the studies also had small sample sizes, limiting their ability to detect intervention effects and increasing the risk of type II error. While pooled “overall” estimates are presented, these should be interpreted with caution, and subgroup analyses by comparator type are likely to provide more clinically meaningful insights.

In addition, pooled estimates were calculated using the standard DerSimonian-Laird random effects approach in RevMan, which, although widely used, may provide less conservative interval estimates than alternative methods such as Hartung-Knapp-Sidik-Jonkman when only a small number of studies are available. Follow-up periods ranged from 1 to 12 months but were often relatively short, with 22% of studies including a follow-up of less than 6 months, and 33% at 6 months. Given that the ProFaNE recommends a minimum follow-up of 12 months in fall prevention trials, because these interventions may produce delayed effects, requiring sustained adherence over time to demonstrate efficacy [12], the longer-term sustainability of exergaming effects remains uncertain.

Implications for Policy and Practice

The findings of this review suggest that exergames may play a role as a complementary component of fall prevention programs for older adults, particularly given the evidence that they may reduce fall rates and the number of people experiencing a fall when compared with usual care. However, the current evidence does not support exergames as a stand-alone replacement for established exercise-based fall prevention interventions.

XSL•FO
RenderX

While the included studies varied considerably in intervention design and dosage, several interventions associated with favorable outcomes incorporated structured, progressive exercise delivered multiple times per week over several weeks or months. This is broadly consistent with established fall prevention exercise principles, which emphasize sufficient frequency, intensity, and progression [12,89]. Given the heterogeneity of interventions and limited evidence on optimal dosage, specific recommendations for exergaming interventions cannot yet be made, and further research is needed to determine the most effective training parameters. However, given the variability in intervention design and delivery, standardized guidelines for exergame design and delivery could be developed to ensure greater consistency across interventions. Purpose-designed serious exergames with appropriate theoretical underpinnings should be developed to unlock the full potential of exergame-enhanced fall prevention interventions [90]. This would facilitate the integration of exergaming with established exercise-based fall prevention programs such as Otago [91] or FaME [92], potentially optimizing effectiveness.

Adherence remains a recognized challenge. Most studies reported good adherence rates when structured support, such as supervision by physiotherapists, was provided, suggesting policies promoting supported or remotely monitored delivery may improve engagement and effectiveness [77]. Ensuring equitable access will therefore require investment in user-friendly technology, digital literacy programs, and technical support to reduce barriers to sustained participation among older adults [93-95].

Finally, our review highlights the need for longer follow-up periods and more robust economic evaluations before exergames can be confidently integrated into routine service delivery. Given the preliminary evidence suggesting cost-effectiveness within National Institute for Health and Care Excellence thresholds, further evaluations are needed to confirm these findings. Policymakers should consider further evaluations to guide future resource allocation and determine whether exergames represent a financially sustainable addition to health care and social care fall prevention pathways.

Conclusions

This review suggests that exergaming interventions may help reduce falls among older adults, particularly in comparisons against active intervention control groups, while pooled analyses also indicate potential overall benefit across diverse intervention settings. However, these findings should be interpreted cautiously because effect estimates varied considerably between studies and were limited by substantial heterogeneity, modest sample sizes, and relatively few long-term follow-up assessments.

Evidence for injurious falls and implementation-relevant outcomes, such as adherence, acceptability, QoL, and cost-effectiveness, remains limited or inconsistently reported. As such, although exergaming appears to offer a potentially engaging and clinically relevant adjunct to existing fall prevention programs, the evidence base is not yet sufficiently robust to support widespread routine implementation. Larger, methodologically rigorous trials with standardized fall reporting and longer follow-up are needed to determine which exergaming formats, doses, and delivery models are most effective for sustained fall prevention in older adults.

Acknowledgments

Generative artificial intelligence (ChatGPT-5.3, OpenAI) was used under full human supervision for language editing, proofreading, and formatting support during manuscript revision. No artificial intelligence tools were used for study selection, data extraction, data analysis, or interpretation of findings. Abstract

Background: Falls and fractures are a major clinical concern for older adults. International clinical guidelines recommend annual fall risk screening for all adults aged 60 years and older. However, existing falls risk–screening algorithms have shown limited sensitivity and specificity in detecting future falls. Emerging health technologies, including wearable sensors, in-silico finite element models (FEMs), and virtual reality (VR) technology, show promise in enhancing fall and fracture risk assessments by providing more personalized objective data to support targeted primary prevention. However, large-scale longitudinal studies are required to evaluate their predictive accuracy and cost-effectiveness for systematic community–based screening.

Objective: The TARGET (Targeted Assessment and Recruitment of Geriatrics for Effective Fall Prevention Treatments) study is an ongoing national prospective cohort study in Singapore designed to develop cost-effective and scalable frameworks for the early detection and prevention of falls and fractures using novel health technologies. This paper describes the rationale, design, and baseline characteristics of TARGET, and provides preliminary insights into how these novel technologies perform in discriminating between older adults with and with no history of falls at study baseline.

Methods: A total of 2291 community-dwelling Singapore residents aged ≥60 years were enrolled between 2022 and 2024. Participants underwent a comprehensive baseline fall risk assessment comprising (1) home-based interview to assess sociodemographic, anthropometric, cognitive, physical, functional, and psychosocial status; (2) gait assessment using wearable inertial measurement units (IMUs) motion sensors; (3) dual-energy X-ray absorptiometry and whole-body 3D scans to construct subject-specific FEMs; and (4) VR-based cognitive assessment to probe spatial navigation deficits. Prospective follow-up for 2 years is ongoing, with linkage to national electronic medical records (EMRs) to obtain detailed clinical, medication, and pathological data.

Results: Of the total cohort, 58% (1327/2291) were female, with a mean age of 74.6 years at baseline. TARGET represents a relatively healthy older adult population, with 83% (1898/2291) remaining fully independent, 44% (1016/2290) with mild cognitive impairment, 50% (440/879) with osteopenia, and 15% (358/2291) reporting falls in the past year. Significant baseline functional, psychosocial, cognitive, and biomechanical differences were identified between fallers and nonfallers. Fallers had poorer physical and psychosocial health, greater gait variability, and a higher risk of osteoporotic fractures. Novel risk prediction models integrating epidemiological, IMUs, FEM, VR, and EMR data are in development and being validated against gold standard clinical assessments, with cost-effectiveness evaluations of the economic feasibility of adopting these screening measures at scale.

Conclusions: Leveraging comprehensive epidemiological, EMR, and health technology data, TARGET is well positioned to identify novel biomarkers and systemic interactions that may predict falls and fracture risk, with potential application to other age-related diseases with shared pathophysiology. In particular, TARGET's focus on community-based screening using technologies

XSL•FO
RenderX

that can be administered by nonclinical personnel has the potential to reduce substantial burden and costs within the health care sector.

aging; falls; fractures; health technology; predictive algorithms; population health

Introduction

Falls and fall-related injuries are a major public health and clinical challenge worldwide, especially given the ubiquity of population aging [1]. Approximately 30% of community-dwelling adults aged 65 years or older sustain at least 1 fall each year, increasing to 50% in persons aged older than 80 years [2,3]. Falls are a prominent clinical feature in later-life diseases affecting older adults, defined as persons aged 60 years or older. Notably, falls occur frequently in neurological disorders, affecting up to 70% of individuals with Parkinson disease [4], at least 50% of stroke survivors [5], and 20% - 30% of older adults with peripheral neuropathy [6]. The incidence of falls has been estimated to be 50% among older adults with diabetes, particularly when peripheral neuropathy or hypoglycemia is present [7]. Moreover, falls occur in 30% - 50% of older adults with cardiovascular diseases [8] or cancer, especially among those receiving chemotherapy [9]. Together, these data highlight the considerable significance of falls in the context of aging and disease.

Critically, falls are often a sentinel event for older adults and mark a turning point in the trajectory toward the end of life [10]. A single fall can result in hospital admission, major surgical intervention, and a prolonged convalescence [11]. Recurrent falls are a widely accepted clinical indicator of advanced underlying pathology [12]. Notably, severe acute fall-related injuries such as hip fractures often trigger cascading complications, including prolonged hospitalization and secondary infections [13-15]. The 12-month mortality rate following a hip fracture is between 22% and 29% with excess mortality observed up to 10 years postinjury compared with age-matched controls [16]. In the United States and Europe alone, US $50 billion is spent annually on medical costs related to nonfatal fall injuries, while US $754 million is spent related to fatal falls [17].

Age-related physiological decline significantly increases fall susceptibility [18]. Senescent cells accumulate with age, displaying shortened telomeres and altered signaling that impair tissue repair [19], while sarcopenia progressively weakens skeletal muscles, slowing reflexes and postural control [20]. Changes in visual, vestibular, and proprioceptive pathways compromise precise feedback on body positioning and motion [21]. In parallel, age-related neurodegeneration, including brain atrophy and reduced synaptic connectivity, disrupts the central coordination of motor signals [22]. Endothelial dysfunction and reduced mitochondrial capacity also impair cardiovascular reserves, manifesting as orthostatic hypotension or arrhythmias that lead to sudden drops in cerebral perfusion [23]. Collectively, these age-related physiological and cellular changes not only elevate the risk of falls but also contribute to broader age-related diseases through shared pathophysiological pathways [18].

Given the multisystem involvement of falls, the challenge remains how to optimally screen for fall risk in older adults at the population level. Current best practice is focused on secondary and tertiary fall risk prevention and management following a fall event. The seminal American Geriatrics Society and British Geriatrics Society Clinical Practice Guidelines [24] and recent World Falls Guidelines [15] both recommend annual screening of adults aged 65 years or older for fall risk during routine health care encounters. Currently, there is no universally validated biomarker for predicting falls. While inflammatory mediators (eg, interleukin-6 and tumor necrosis factor-α), hormonal factors (eg, insulin-like growth factor-1 and vitamin D metabolites), and markers of neuromuscular integrity (eg, creatine kinase and neurofilament light chain) have been investigated, there remains no definitive gold standard biomarker for fall risk prediction [25,26]. In the absence of validated biomarkers, fall history in the past 12 months is commonly used as a first-line screener for future fall risk, as research shows that a previous fall is the single best predictor for future falls [27]. The relative risk of falling is 3 times greater for older adults who have previously fallen than for those who have not [28,29], and those who present to health care services with a fall or fall-related injury have a 70% risk of falling again in the next year without intervention [15]. Multifactorial investigations are then recommended for older adults with a positive 12-month fall history to identify specific risk factors, including medication review and assessments for gait, balance, strength, neurological function, cardiovascular status, and visual acuity [24,30].

However, this approach is limited as it does not allow for the identification of at-risk individuals prior to their first fall for targeted primary prevention. Indeed, the sensitivity of common falls-screening algorithms based on the American Geriatrics Society and British Geriatrics Society and World Falls Guidelines, such as the STEADI (Stopping Elderly Accidents, Deaths, and Injuries) algorithm [31], has been shown to be around 60% - 70% with a high false-negative rate in the low-risk categorization group [32,33]. Moreover, current screening approaches rely on patient recall of fall history, which may be impaired by age-related cognitive decline [34], as well as clinician judgment of gait patterns, which can vary depending upon experience, training, and underlying knowledge of gait [35]. Among older adults with a negative 12-month fall history, gait and balance deficits have been identified as the most consistent predictors of future falls [29]. Thus, recognition of gait and balance problems is crucial for identifying persons at risk of first-time falls. However, gait patterns ascertained from clinic and laboratory-based settings often differ from the real-world movement patterns that cause falls, posing an added

XSL•FO
RenderX

challenge for clinicians to assess [36]. Furthermore, implementation of physician-led screening in clinical practice has been challenging, with studies finding that over 60% of primary care providers did not routinely ask older adults about fall history or initiate multifactorial falls assessments due to time and resource constraints [31].

In view of these limitations, there has been considerable interest in novel and scalable approaches that can objectively screen and identify individuals at risk of falls, including first-time falls, in real-world settings [36,37]. The ability to predict and prevent falls holds considerable significance in the context of global aging and disease. It is especially critical in Asia, where many regions are experiencing unprecedented population aging. Singapore, in particular, is among the top 5 nations most affected by population aging, with the proportion of older adults in the population expected to reach 40% by 2050 [38]. The standardized incidence rate of fractures among adults aged older than 50 years in Singapore is 314.2 per 100,000, ranking third highest globally and the highest in Asia [39]. By 2050, more than 50% of hip fractures are predicted to occur in Asia [40]. The estimated total economic burden for osteoporotic fractures alone is expected to cost at least SG $289.9 million (SGD $1=US $0.79 as of September 11, 2026) by 2035 [41]. Thus, there is an urgent need for solutions to reduce the health and associated socioeconomic burden of falls and fractures in Singapore and other Asian populations.

While a number of cohort studies have investigated fall or fracture risk factors in Singapore and Asia, the focus of these studies was on general aging [42-44], broad population health [45,46], cancer [46], and eye disease [47], with falls or fractures as a secondary outcome. To bridge this knowledge gap, we implemented a national prospective cohort study of older adults in Singapore to study fall and fracture risk, titled the “Targeted Assessment and Recruitment of Geriatrics for Effective fall prevention Treatments (TARGET)” study. The specific focus of the TARGET study is risk prediction and stratification to support effective therapeutic measures. Its objectives are to (1) develop and validate personalized screening algorithms for assessing the risk of falls (including first-time falls) and fractures among community-dwelling older adults, (2) create risk stratification methods to segment the older adult population into different fall and fracture risk levels with individualized intervention recommendations, (3) conduct cost-effectiveness analyses to support clinical decision-making by identifying the optimal therapeutic window of falls and fractures risk where older adults derive the greatest benefit from interventions, and (4) determine the psychosocial, cognitive, and sociodemographic correlates of the risk of falls and fractures. In this paper, we provide a detailed description of the rationale, design, methodology, and baseline characteristics of the TARGET cohort.

Methods

Study Design

TARGET is an ongoing national prospective cohort study of community-dwelling older adults in Singapore, evaluating 3 novel health technology approaches to identify objective functional, cognitive, and imaging-based biomarkers of fall and fracture risk for population-based screening. Between October 2022 and October 2024, a total of 2291 older adults aged 60 years and older were recruited. After study enrollment, participants underwent a comprehensive baseline fall risk assessment (T_0), followed by 8 follow-up assessments (T_1-T_8) via telephone every 3 months for 2 years to prospectively monitor their fall, fracture, and cognitive status. A 2-year follow-up period was selected to inform the development of clinically meaningful predictive models, which can identify individuals at short- (<1 year) and medium-term (1 - 2 years) risk for falls for targeted preventive intervention. This duration also provides a balance between collecting sufficient fall events for statistical validity and minimizing participant attrition and recall bias. Ongoing follow-up of the TARGET cohort beyond the initial 2 years is planned to ascertain longer-term fall and fracture risk and outcomes.

Ethical Considerations

Ethics approval for the study was granted by the National University of Singapore Institutional Review Board (NUS-IRB-2021 - 168) and ETH Zurich Ethics Commission (EK 2021-N-145). Written informed consent was obtained from all participants at study enrollment. Participant information sheets and informed consent forms were translated into Chinese, Malay, and Tamil languages by a certified translation company. All participants received an SG $50 (SGD $1=US $0.79 as of September 11, 2026) grocery voucher as a token of appreciation upon successful completion of the baseline home-based assessment. In addition, participants received an SG $140 (SGD $1=US $0.79 as of September 11, 2026) grocery voucher, including the reimbursement for transportation costs, for completion of the baseline clinic assessment.

Sampling and Recruitment

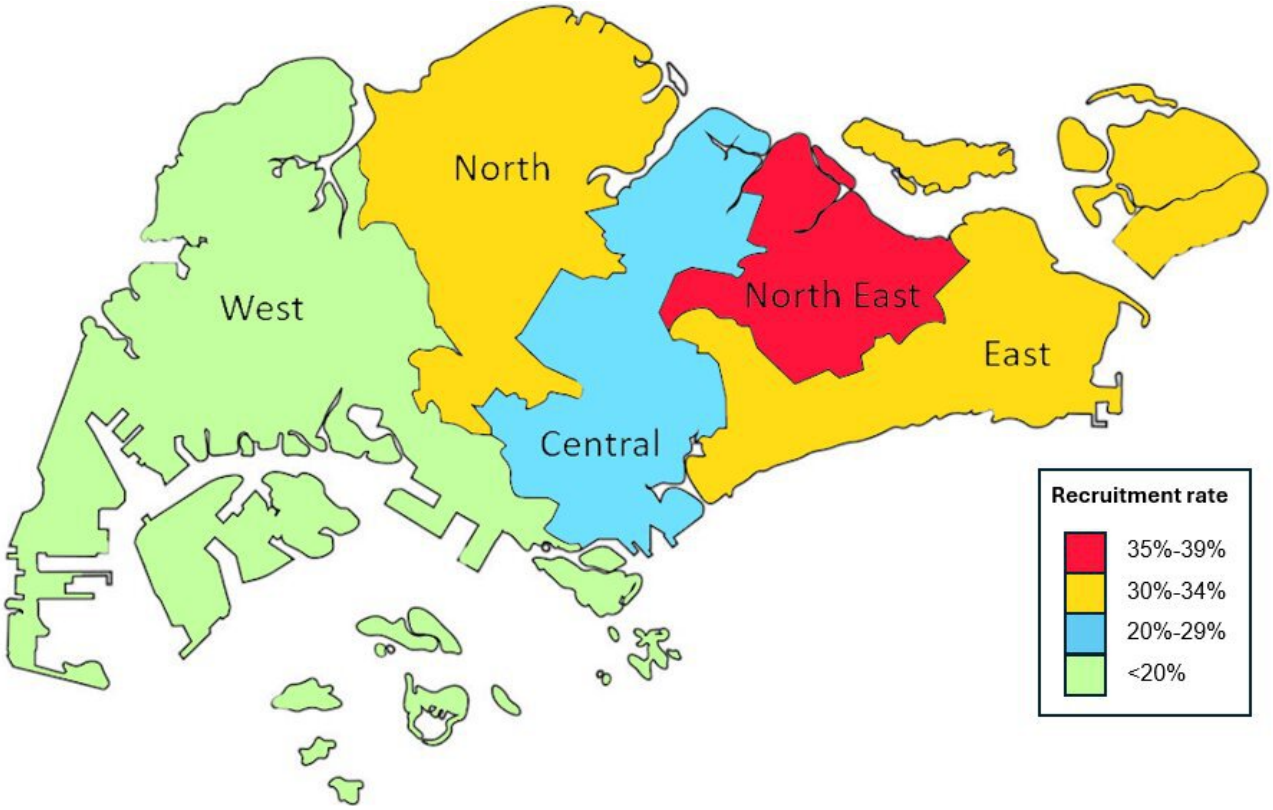
Overview

A multistage random sample of 7501 households with at least 1 older adult resident (Singapore citizen or permanent resident) was purchased from the Department of Statistics of Singapore representing approximately 2.2% of all households with an older adult resident in Singapore in 2022. Household addresses were sampled across all 5 geographic regions of Singapore (Central, East, North, Northeast, and West). To increase the participant count and precision of statistical estimates within minority subgroups, we oversampled addresses with predominant (1) Malay and (2) Indian residents, and with (3) at least 1 resident aged 75 years or older by a factor of 2.

Eligibility Criteria

Individuals residing in the random sample of households were eligible for inclusion in the TARGET cohort if they were (1) a Singapore citizen or permanent resident, (2) aged 60 - 105 years, (3) spoke at least 1 of the 4 official languages in Singapore (English, Mandarin [or a Chinese dialect], Malay, and Tamil), (4) ambulatory with or without mobility aids, (5) able to see with or without glasses, and (6) able to hear with or without hearing aids. Individuals with at least one of the following criteria at the time of recruitment were excluded: (1) possible delirium or dementia defined as an Abbreviated Mental

XSL•FO
RenderX



Test score <6 [48]; (2) blood pressure outside the normal range (defined as ≥200/110 mm Hg or ≥180/100 mm Hg and heart rate >120 per minute or ≤90/60 mm Hg); (3) any symptoms of chest discomfort, breathlessness, dizziness, or profuse sweating; or (4) any acute cardiac event in the past 30 days.

Recruitment

An invitation letter was mailed to each household in the random sample stating that participation in the study was completely voluntary, and the study team could be contacted to opt out of the study. Trained field interviewers then conducted home visits 2 - 4 weeks later to households that did not opt out. All willing potential participants within each household were first screened to determine their eligibility against the inclusion and exclusion criteria. Multiple residents from the same household were able to participate if they independently met the eligibility criteria. Once participants consented to the study, they were able to complete the baseline assessment on the same day, if convenient, or reschedule the assessment for a later date. Interviewers made up to 5 visits at differing times of day to each residence to recruit participants. Households, which remained uncontactable after 5 visits, were excluded due to nonresponse.

At least 1 participant was recruited from 1674 households, giving a household recruitment rate of 22.3% (1674/7501). The household participant yield was 1.3 participants per household (range: 1-4). Anecdotally, the field interviewers reported that the households approached were generally reluctant to interact with strangers, coinciding with active national scam prevention campaigns targeting older adults in Singapore during the recruitment period. Demographic characteristics were compared between household responders and nonresponders. There was no significant difference in the age group of the household reference person (primary resident) between household responders and nonresponders. However, differences in housing type and region were identified. The proportion of private households (ie, residential properties that are not subsidized, built, and managed by the Singapore government) was significantly higher among nonresponders. Response rates also significantly differed by geographic region (Figure 1). The highest response was within the Northeast Region (577/1516, 38.1%) while the West Region (215/1549, 13.9%) yielded the lowest response rate.

Figure 1. TARGET (Targeted Assessment and Recruitment of Geriatrics for Effective Fall Prevention Treatments) study household recruitment rate by geographic region in Singapore.

Data Collection

Data Collection Overview

Table 1 summarizes key measures, variables, and outcomes. Both primary and secondary data sources were used. Primary data collected included epidemiological survey data (eg, sociodemographic, anthropometric, cognitive, psychosocial, physical, and environmental data), biomechanical data, clinical imaging, and spatial performance data to provide a holistic understanding of fall and fracture risk factors. Additionally, secondary data in the form of electronic medical records (EMRs) containing data on health status, health care use, prescriptions, procedures, and mortality status are being linked from the Singapore Ministry of Health's TRUST (Trusted Research and Real-World Data Utilisation and Sharing Tech) platform [49] for participants who have consented to this linkage.

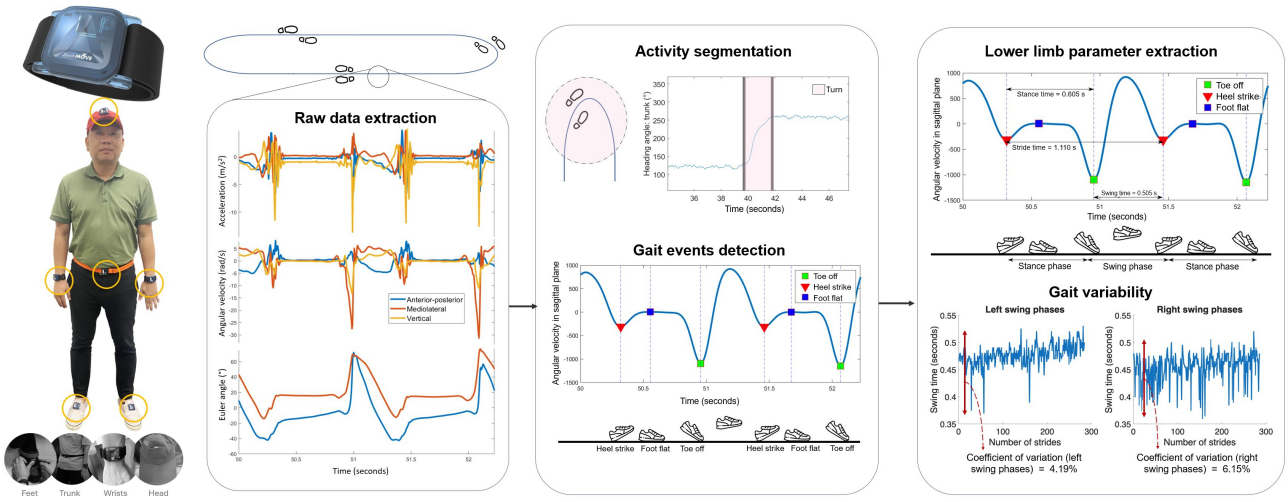
[a]TARGET: Targeted Assessment and Recruitment of Geriatrics for Effective Fall Prevention Treatments.

[b]Not available.

[c]DXA: dual-energy X-ray absorptiometry.

[d]GP: general practitioner.



Baseline Interview

A face-to-face computer-assisted personal interview was conducted with each participant at their residence or other preferred place of convenience using a structured questionnaire to capture sociodemographic, environmental, physical, sensory, medical, cognitive, and psychosocial characteristics related to fall and fracture risk at baseline. Anthropometric measurements (height, weight, and bilateral hand grip strength) were also taken. Responses were collected using the survey software Qualtrics (Qualtrics). The survey was designed by TARGET study investigators and administered by trained field interviewers in the participant's preferred language (English, Mandarin or Chinese dialect, Malay, or Tamil). The baseline interview took approximately 2 hours to complete, including the screener, consent-taking, and gait assessment detailed in the following text.

Gait Assessment

As a component of the home-based interview, all participants performed a 5-minute walk inside or outside their home, in an open physical space, with the freedom to walk at their preferred pace and navigate turns, while wearing 6 ZurichMOVE inertial measurement units (IMUs) motion sensors [65] affixed to designated anatomical locations (feet, wrists, trunk, and head; Figure 2).

Figure 2. Participants were requested to wear 6 inertial measurement unit sensors (2 each on the feet and wrists, as well as 1 on the trunk and head) while performing a 5-minute walk test under natural settings. The data from the sensors are processed to provide information on turning, gait events, and variability and asymmetry of foot placement while walking.

There has been growing research and clinical interest in the use of wearable sensors for identifying fall risk through biomechanical data, specifically, dynamic gait signatures [37,66,67]. Gait and balance assessments are a core component of fall risk assessments in clinical practice. However, existing gold standard assessments such as the Timed Up and Go test and Berg Balance Scale have shown poor predictive accuracy (pooled sensitivity ranging from 0.25 to 0.32) in predicting prospective falls [68,69]. As the majority of falls occur while walking, dynamic gait characteristics such as step length, step time, variability, and asymmetry need to be factored into fall risk assessments for accurate risk prediction [66,70]. Wearable sensor systems can objectively measure a wide range of dynamic gait characteristics, which can then be used to train predictive models for fall risk assessment [71]. IMU sensors, which acquire data using accelerometers and gyroscopes, have gained research and clinical interest as a possible alternative to the current gold standard optical motion capture systems for gait analysis [72]. Compared with optical motion capture, IMU sensors are compact, inexpensive, easier to operate, and can be combined with functional walking tests for gait assessment in the home environment [73].

The IMUs embedded within ZurichMOVE are time-synchronized and have a dynamic range of ±16 g for the accelerometer and 2000° per second for the gyroscope at a sampling frequency of 200 Hz and have been shown to reliably assess gait and identify gait differences in healthy and neurological populations across laboratory settings and real-world environments [74,75]. Triaxial acceleration and angular velocity signals recorded during the walk test are first filtered and analyzed with the validated gait event detection

XSL•FO
RenderX

algorithm [70,71], identifying key phases in the gait cycles over the 5 minutes. From these phases, key spatiotemporal parameters such as stride time, length, cadence, and double-limb support time were computed for every participant. Furthermore, intercycle variations are evaluated during the entire walking trial to capture fluctuations and variability in movement patterns, indices associated with deficits in gait, balance, and risk of falling [37,76,77].

Fracture Risk Assessment

After the home-based interview, participants who reported that they did not have bilateral hip replacement were invited to a clinic visit at the Singapore Eye Research Institute for a dual-energy X-ray absorptiometry (DXA) scan. Each participant underwent 3 DXA scans (hip, lumbar spine, and whole-body) within a 20 - to 30-minute session using the Hologic Horizon W scanner (Hologic, Inc). The hip and lumbar spine scans were used to assess areal bone mineral density (aBMD), which was then used to calculate the T-score to evaluate osteoporotic status. Participants with a T-score of ≤−2.5 were classified as osteoporotic, those with a T-score between −2.5 and −1 were classified as osteopenic, and those with a T-score of >−1 were classified as normal, while the whole-body DXA scan captured clinical anthropometric data and body composition, including measurements of fat mass, lean mass, and total mass across the trunk, limbs, and head. These data were used to categorize participants into the low muscle mass group, defined as appendicular lean mass/height^2 of <7 kg/m^2 for males and <5.4 kg/m^2 for females [78]. Additionally, a subset of participants completed 3D-optical body shape scans using the TC2-19M scanner (TC2 Labs LLC), wearing tight-fitting clothing (Spandex top and pants). Participants held an A-line stance for approximately 9 seconds during scanning, which generated a triangular mesh representing their body shape. Data from both the whole-body DXA and 3D optical scans were used to estimate trochanteric soft tissue thickness (TSTT) [79]. TSTT refers to the thickness of the soft tissues, including skin, fat, and muscle, over the greater trochanter of the femur. Clinical risk factors were also gathered, and the risk for major osteoporotic fractures (MOFs) and hip fractures was assessed using the Fracture Risk Assessment Tool (FRAX) without aBMD for the entire cohort. For those who had a DXA scan, FRAX was calculated with the aBMD from the femoral neck. A high risk for MOF was assigned if FRAX-MOF ≥9%, and a high risk for hip fractures was assigned if the FRAX–Hip Fracture (FRAX-HF) score is ≥2% [80]. Age- and sex-adjusted analyses were conducted for all variables, except FRAX-related variables, as age and sex are already incorporated into the FRAX calculation algorithm.

Despite widespread use, studies have shown that aBMD measurements from DXA scans and the 10-year fracture probabilities of hip or MOFs computed using FRAX [61] often fail to detect individuals at risk, as only between 28% and 61% of hip fractures occur in individuals with osteoporosis [62,81,82]. Although FRAX incorporates 12 risk factors and provides country- and ethnicity-specific scores, research suggests that FRAX may be less accurate in Asian populations, compared with Caucasians [63,64]. Finite element models (FEMs) have demonstrated strong potential for improving fracture risk prediction, especially given the limited sensitivity of current standard-of-care methods. Subject-specific FEMs based on computed tomographic scans provide direct estimates of femoral strength and have outperformed aBMD in predicting future fractures, with 1 recent study demonstrating this superiority over a follow-up period of up to 16 years [83-85]. Emerging research from Caucasian cohorts also suggests that FEM-based strength estimates derived from DXA outperform aBMD alone in identifying individuals with hip fractures [86,87]. This body of evidence paves the way for FEM-based fracture risk assessment, particularly when adapted for use with clinical DXA scans for primary screening and with tomographic scans for opportunistic screening, as a more accurate alternative to current methods.

Virtual Reality Spatial Navigation Assessment

Participants who completed the DXA scan were also invited to play a virtual reality (VR) spatial navigation game during the clinic visit to assess their cognitive ability. The SPACE (Spatial Performance Assessment for Cognitive Evaluation) is a novel iPad serious game designed to identify deficits in spatial navigation indicative of cognitive impairment and potential fall risk [88]. SPACE has been validated with participants across community and clinical cohorts in Singapore. Studies revealed that SPACE is well suited for older adults [88], and its performance metrics correlate with scores from the Montreal Cognitive Assessment (MoCA); predict hippocampal atrophy beyond age, education, and standard neuropsychological tests [89]; and distinguish between dementia severity levels with high accuracy [90].

Studies have highlighted the potential application of VR technology for identifying markers of cognitive impairment and fall risk [88]. While analysis of cerebrospinal fluid and positron emission tomography can reliably detect dementia-related pathophysiological changes, these methods are invasive and costly, which limits their use for population-based screening [91]. Blood biomarkers are a promising alternative, but these are still undergoing clinical validation and are not yet widely available for routine diagnostic use [92]. In contrast, neuropsychological tests, such as the Mini Mental State Examination and MoCA, are relatively easier to deploy but have shown limited sensitivity to detect early cognitive impairment [93,94]. Critically, most cognitive assessments do not include tests that assess deficits in spatial navigation ability. This lacuna is surprising since spatial disorientation is one of the earliest signs of declining cognitive ability. Indeed, the hippocampus and the entorhinal cortex, which play an instrumental role in navigation, are also among the earliest brain regions to be affected by Alzheimer disease pathophysiology [95-98]. VR technology now offers an accurate, cost-effective, and safe method to assess navigation deficits indicative of cognitive impairment and fall risk in a quick and portable manner [88,99].

In SPACE, participants assume the role of an astronaut tasked with exploring an unfamiliar planet by completing a series of spatial navigation tasks with the help of a companion robot. Each task is specifically designed to probe different aspects of their spatial navigation abilities. SPACE includes a detailed training phase in which players can familiarize themselves with

XSL•FO
RenderX

the controls while being assessed on basic visuospatial and motor skills. After the initial training phase, participants perform 5 spatial tasks (ie, path integration, egocentric pointing, mapping, associative memory, and perspective taking) designed to recruit critical brain regions involved in spatial navigation. During gameplay, both performance data and metadata (eg, position and orientation, time, coordinates, and screen interaction) are stored and used to produce individual scores for the various tasks [88].

Prospective Follow-Up

Prospective follow-up of the TARGET cohort is currently ongoing. The cohort is being followed up via telephone every 3 months from the baseline interview for 2 years to determine (1) whether they have experienced a fall or fall-related injury over the past quarter, and (2) their cognitive status every 6 months measured using an abbreviated version of the MoCA designed for telephone administration (T-MoCA [51]). Interviewers may also visit participants to conduct the follow-up assessments in person if the participant has difficulties communicating clearly over the phone. As of May 24, 2026, T_6 (18-month follow-up) is complete for all participants, with 80.5% (1844/2291) successfully followed up (48/2291, 2.1% deaths, and 399/2291, 17.4% lost to follow-up), and 55.3% (1267/2291) of participants have completed T_8 (24-month follow-up). The study protocol allows for participants with missing follow-up data to be recontacted at subsequent follow-ups to maximize data completeness and cohort retention. Prospective outcomes will be validated against national EMR data. These data will provide granular diagnostic, procedural, and laboratory data on falls, fractures, and broader age-related diseases for the cohort.

EMR Linkage

Finally, EMRs for each TARGET cohort member who provided consent for record linkage at baseline (1243/2291, 54.3%) are being obtained through Singapore Ministry of Health's TRUST platform [49]. TRUST is a secure data exchange platform that enables the fusion and sharing of anonymized health-related research and real-world data for research purposes between public institutions and the public and private sectors. Linked datasets to be requested for the TARGET cohort will include health records (from acute hospitals, polyclinics, general practice clinics, and medical centers), health (emergency department presentations), and birth and death registry (mortality). EMR data will be used to analyze longitudinal pathology, morbidity, and mortality patterns associated with falls and broader age-related diseases in older adults. Analysis will be performed on the deidentified fused datasets in the secure TRUST Workspace.

Table S1 in Multimedia Appendix 1 compares key characteristics between participants who completed and did not complete the clinic visit components (DXA and 3D body scans and SPACE game), and participants who consented and did not consent to the EMR linkage to evaluate potential selection bias. Overall, participants who did not complete the clinic visit components were more likely to be older and have greater ADL/IADL difficulty.

Quality Assurance and Control

All researchers were required to complete the Collaborative Institutional Training Initiative online program for research ethics and compliance education. Fieldwork interviewers, including university interviewers and interviewers from a survey research company, were required to undergo training and fieldwork shadowing and to demonstrate competency in the relevant procedures and questionnaire administration prior to being approved to perform household recruitment with participants. Study documents, including participant information sheets, informed consent forms, and questionnaires, were translated into Chinese, Malay, and Tamil languages by a certified translation company. The study team validated the translated documents to ensure that the meaning is consistent with the original version. A computer-assisted personal interview questionnaire was designed in Qualtrics using logic and rules to assist fieldwork interviewers to conduct proper inclusion and exclusion criteria eligibility checks. A pilot study (n=18) was undertaken to test recruitment processes and ensure that interviewers were familiar with the recruitment and interviewing procedures. Data collected by all fieldwork interviewers were checked periodically by key study team personnel. Blood pressure machines and weighing scales were checked and certified by the supplier before being issued to the interviewers. All faulty study instruments are either serviced or replaced depending on the availability of spare parts to ensure measurement accuracy.

Study Outcomes and Planned Analysis

Primary Outcomes

The primary outcomes of interest are the incidence of falls and fractures over the 2-year prospective follow-up period. Falls are defined following the World Health Organization's definition as "an event which results in a person coming to rest inadvertently on the ground, floor, or lower level" [100]. Fracture events will include both self-reported and electronically validated incident fractures identified during follow-up and through linkage with EMR data. MOF will include fractures of the hip, clinical spine, wrist, and humerus, consistent with the FRAX definition. Hip fractures will be analyzed separately due to their substantial morbidity, mortality, and health care burden among older adults.

Prospective outcomes collected through quarterly follow-up interviews will be validated against linked EMR using relevant diagnostic and procedural coding systems, including ICD (International Classification of Diseases) codes, available within the TRUST-linked datasets. Time-to-event analyses will be conducted to evaluate predictors of incident falls and fractures over the follow-up period.

Risk Prediction and Stratification

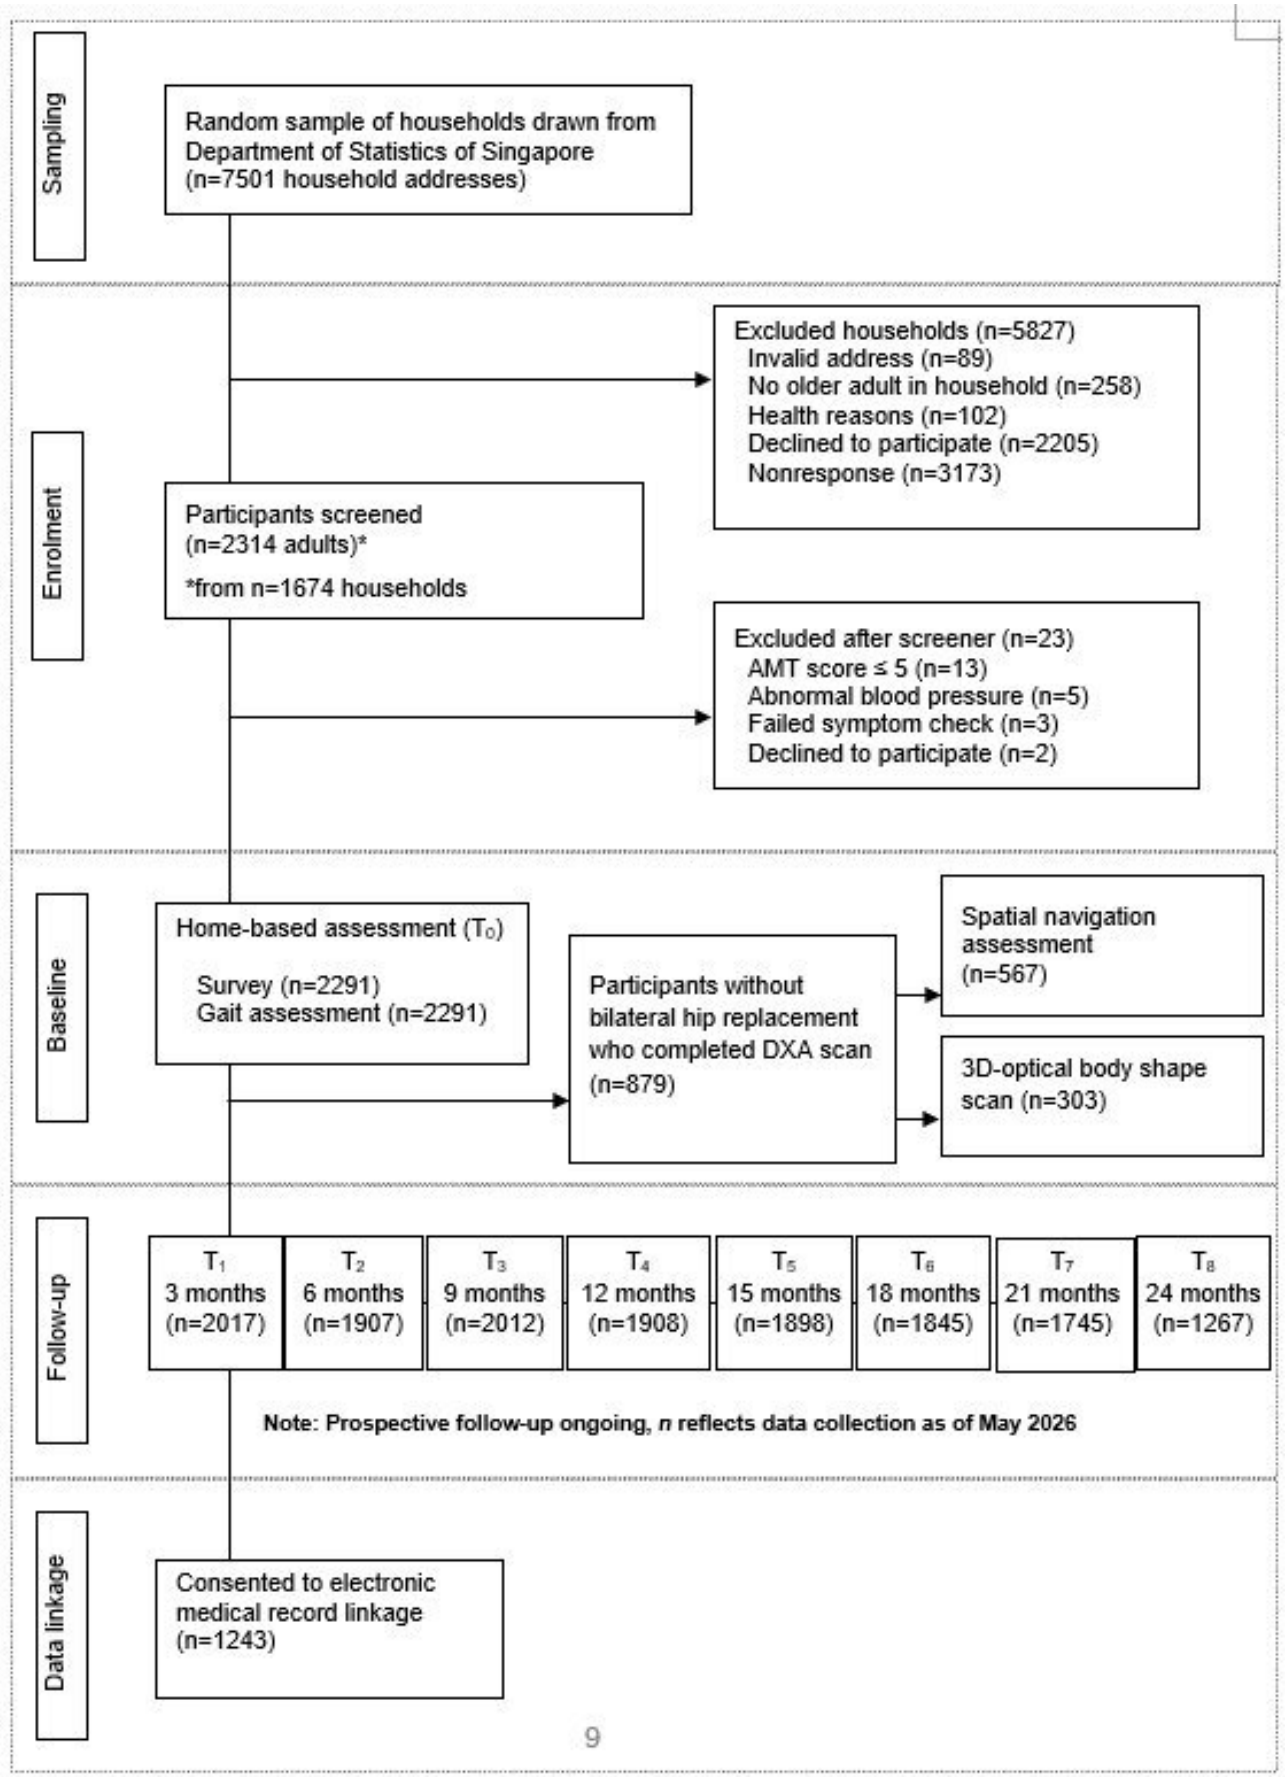
Primary analyses will focus on the development and validation of novel personalized risk prediction models integrating variables from the epidemiological survey, gait assessment, clinical imaging, SPACE, and EMR data to segment the older adult population into different fall and fracture risk levels. Risk prediction models will be built using state-of-the-art machine learning, deep learning, and statistical techniques. The

XSL•FO
RenderX

performance of the novel risk prediction models will be evaluated against existing gold standard assessments (eg, STEADI algorithm, Three Key Questions, and FRAX) and validated against the prospective data. Secondary analyses will focus on (1) developing predictive models of fracture risks among older adults based on holistic body composition parameters obtained from DXA and whole-body 3D shape scans, (2) assessing the performance of SPACE to detect cognitive impairment and its predictive usefulness in detecting falls, and (3) assessing the psychological and sociodemographic correlates of fall risk.

Economic Analysis

Cost-effectiveness analyses of screening strategies will be evaluated using decision tree models. The analyses will use Markov models to simulate the long-term costs and quality-adjusted life years over the lifespan. Prospective epidemiological data collected from TARGET will be used as input parameters for event rates and diagnostic accuracy. Performance of novel risk prediction tools (ie, sensitivity, specificity, and accuracy) will be evaluated against current methods of evaluating falls and fracture risk to determine the incremental cost-effectiveness ratios of different screening strategies. A budget impact analysis will determine the short- and medium-term fiscal implications of a national implementation of these strategies.



Results

Cohort Characteristics

Baseline data collection was completed in October 2024. Baseline cohort characteristics and key preliminary findings to date are summarized in this section. Figure 3 summarizes the TARGET study design and participant flow. Of the 2291 older adults in the TARGET cohort, the majority were female (327/2291, 57.9%) with a mean age of 74.6 (SD 7.9) years at study enrollment (Table 2). Most participants were Chinese (1521/2291, 66.4%), followed by Malay (433/2291, 18.9%), Indian (290/2291, 12.7%), and Other ethnicity (47/2291, 2.1%). Compared with national population reference data from 2023, representing the midpoint of the baseline data collection, the TARGET cohort had a higher proportion of older adults aged ≥75 years, females, and ethnic minorities, and participants from the Northeast region.

[a]Targeted Assessment and Recruitment of Geriatrics for Effective Fall Prevention Treatments.

[b]From Department of Statistics Singapore 2023 (representing the midpoint of baseline data collection).

[c]N/A: not applicable.

Over 80% (1898/2291) of the cohort were fully independent at baseline (Table 3). Most participants had mild cognitive impairment (1016/2290, 44.4%; based on MoCA score 18‐25, which represents a level of cognitive impairment greater than expected for age without significant functional impairment) [101], or no cognitive impairment (926/2290, 40.4%; MoCA score ≥26), and 70% (1610/2291) had 2 or more chronic health conditions.

Falls Epidemiology and Risk Profile at Baseline

Among the total cohort, 15.6% (358/2291) reported at least 1 fall within the prior 12-month period and 4.5% (104/2291) reported recurrent falls. This is comparable with previously reported fall incidence rates in community-dwelling older adult populations in Singapore [102] but lower than reported rates in the international literature (33%) [15]. Regional differences in falls incidence have previously been identified between Asian and Western countries owing to differences in sociodemographic, geographic, environmental, and cultural factors [103].

Psychosocial and Sociodemographic Correlates of 12-Month Fall History

Table 4 compares baseline characteristics for TARGET participants by 12-month fall history. Older adults who had fallen in the past 12 months demonstrated significantly poorer physical and psychosocial health across multiple measures at baseline than nonfallers, reinforcing the need for fall risk screening and early intervention in this population. Notably, fallers demonstrated significantly poorer functional independence and quality of life, greater depressive symptoms, higher number of chronic health conditions, and greater fear of falling than nonfallers. However, it is unclear whether preexisting poorer physical and psychosocial health contributed to falls or was a consequence of the fall sequelae. Structural equation modeling analyses are in progress to better understand the causal pathways between falls, functional independence and quality of life, and the potential mediating and moderating mechanisms that can be targeted through interventions. Predictive analyses using the follow-up data are also underway to determine risk factors of prospective falls and fractures in the cohort.

Gait Assessment

During the home-based interview, 86.4% (1980/2291) of TARGET participants independently completed the full 5-minute walking test, while the remaining 13.6% (311/2291) were able to walk between 3 and 5 minutes. Table 5 compares selected extracted baseline gait metrics between participants with a 12-month history of falls and those without. All participants were analyzed together without adjusting for walking duration as our prior research has shown that 3 minutes of walking covers more than 50 gait cycles (strides) and is sufficient for reliably measuring gait variability [104]. There were no significant differences in the mean and variability of temporal parameters (cadence, stride time, stance time, and double-limb support time) or the spatial measures (step length and gait speed) except for average step length. Among the signal-derived metrics, fallers showed significantly greater variability in the magnitude of foot acceleration (P=.02) and significantly lower angular velocity root-mean-square on the trunk sensor (P=.02). These preliminary findings suggest that higher gait variability and reduced movement intensity are likely to be associated with a history of falls. These gait parameters are being used for fall risk prediction modeling using machine learning and deep learning models, validated by prospective follow-up of fall status.

Table . Age- and sex-adjusted comparisons of gait parameters extracted from inertial measurement units sensors by fall status in past 12 months (N=2149).

Gait parameters, mean (SD), range	Faller (n=339)	Nonfaller (n=1810)	*P* value

BMD, Body Composition, Morphometry, and FRAX Assessment

Among the 38.4% (879/2291) participants (n=6 were removed for scan artifacts) who underwent DXA scans, 54.9% (483/879) were female. Data from 4 participants were excluded due to lumbar spine scans with motion artifacts. Table 6 summarizes the baseline prevalence of osteoporosis, osteopenia, low muscle mass, and high fracture risk by DXA and FRAX, stratified by gender and ethnicity. A higher percentage of females had osteoporosis than males. However, fewer females were classified as osteopenic than males, and fewer females had low muscle mass than males. Chinese participants had lowest TSTT across both genders compared with Indians and Malays [79]. A higher

XSL•FO
RenderX

percentage of females exceeded the FRAX-MOF threshold with aBMD and FRAX-HF threshold with aBMD than males. Similarly, a greater proportion of females surpassed the threshold for FRAX-MOF without aBMD and FRAX-HF without aBMD than males. When comparing ethnicities, the prevalence of osteoporosis, osteopenia, and low muscle mass was the highest in Chinese participants, regardless of gender, compared with their Indian and Malay counterparts [79].

Table . Prevalence of osteoporosis, osteopenia, low muscle mass, and high FRAX[a] with aBMD[b] score (n=879) and FRAX without aBMD score (n=2285), stratified by gender and ethnicity.

[h]Computed without areal bone mineral density.

Table 7 compares baseline aBMD, body composition, morphometry, and FRAX scores by fall status in the past 12 months. TSTT was calculated for the subcohort of 260 participants who had 3D-optical scans (39 fallers and 221 nonfallers, excluding 43 scans with motion artifacts); no significant difference in TSTT was found between fallers and nonfallers. Following age and sex adjustment, the relationships between fallers and nonfallers remained nonsignificant. The mean FRAX scores for both fallers and nonfallers were significantly above the respective clinical thresholds of 9% for FRAX-MOF and 2% for FRAX-HF. Specifically, fallers had significantly higher FRAX-MOF with aBMD scores (mean 13.16, SD 8.34%) than nonfallers (mean 9.97, SD 6.57%), and higher FRAX-HF with aBMD scores (mean 6.11, SD 5.21% vs mean 4.44, SD 4.43%; $P<.001$ for both). Similar patterns were observed without aBMD, with fallers showing higher FRAX-MOF without aBMD scores (mean 14.27, SD 8.58%) and FRAX-HF without aBMD scores (mean 7.17, SD 6.12%) than nonfallers (mean 10.81, SD 6.72% and mean 5.12, SD 4.61%, respectively; $P<.001$).

With the body shapes from the 3D-optical scans used to develop a soft tissue database for Asian adults across genders and ethnicities, DXA-derived FEMs will be enhanced by incorporating this soft tissue information to more accurately predict fracture risk in a patient-specific manner. These models will be prospectively validated against fracture outcomes obtained from electronic health records. Through this validation, we aim to determine optimal thresholds for identifying high-risk individuals. Establishing these thresholds will, in turn, inform screening protocols, ensuring that they are cost-effective and scalable for implementation within Singapore's health care system.

SPACE

Of 2291 participants, the subset of 567 (24.7%) participants who completed SPACE had a higher average MoCA score (mean 25.9, SD 3.6), scoring 2.8 points above the remainder of the cohort. All tasks in SPACE significantly correlated with MoCA scores. Robust comparisons using the M-estimator median method revealed no significant differences between fallers and nonfallers for all tasks in SPACE; however, a large group imbalance was noted (Table 8). Planned analyses using the TARGET cohort will focus on evaluating the combined predictive usefulness of SPACE and gait metrics in detecting falls and fractures. SPACE has been shown to predict hippocampal atrophy beyond age, education, and neuropsychological assessment [89], and can accurately distinguish between dementia severity levels (area under the curve=0.94 - 0.95) [90].

Table . Age- and sex-adjusted comparisons of SPACE[a] performance by fall status in the past 12 months (N=567).

Discussion

Principal Findings

To the best of our knowledge, TARGET is the largest prospective cohort study in Asia to jointly investigate fall and fracture risk factors among a national population of community-dwelling older adults. Overall, the TARGET cohort represents a relatively healthy community-dwelling older adult population, with over 80% retaining full functional independence at baseline. However, there is some evidence of early or moderate age-related decline: 70% (1610/2291) of the cohort reported at least 2 chronic conditions, 59% (1356/2290) exhibited mild-moderate cognitive impairment, and among those who underwent DXA scans, 50% (440/879) had osteopenia. Falls were reported by 15% (358/2291) of participants in the past year, whereas 85% (1933/2291) remained fall-free. Thus, TARGET is an ideal cohort for investigating the risk factors that predispose relatively healthy older adults to transition to first-time falls and fractures. Through EMR linkage, this can be extended to study the onset of broader age-related diseases.

By leveraging novel health technology data, TARGET aims to identify novel patterns in gait, cognition, and skeletal fragility as key markers of fall and fracture risk, and potentially other age-related diseases with shared pathophysiology. Data from the wearable IMU sensors capture subtle deficits in balance, stride variability, and reaction times, which cannot be detected through clinical observation alone, providing ecologically valid measurements of real-world performance where traditional clinical thresholds of 0.8 meters per second [15] or 1.0 meter per second [78] may no longer be applicable. These data can be particularly informative for age-related diseases where gait and balance impairments play an early or significant role such as Parkinson disease, stroke, multiple sclerosis, and peripheral neuropathy [105]. SPACE tasks probe spatial orientation that is often overlooked by traditional cognitive tests, with important implications for the early detection of falls as well as dementia [88,89]. The DXA-derived FEM-based models may also identify

XSL•FO
RenderX

more subtle skeletal vulnerabilities that might be missed by standard T-score classifications [83,86,87], offering potential insights into other skeletal conditions such as degenerative joint disease or metabolic bone disorders.

These novel health technology data are strengthened by clinical and laboratory data from EMR linkage, which add essential pathological and biochemical context, allowing for correlations between physiological changes and real-world health outcomes. Finally, robust epidemiological survey data capturing sociodemographic, environmental, psychosocial, and functional parameters enable the identification of synergistic risk factors such as social isolation and psychological resilience that may affect fall and fracture risk and accelerate age-related decline. Collectively, these rich and novel cohort data place TARGET in a strong position to identify emerging biomarkers and systemic interactions that may predict falls and fracture risk and potential other broader age-related pathophysiology.

Critically, insights generated by the TARGET study are likely to make a significant contribution to the development of personalized community-based screening and intervention frameworks for Asian populations, where differences in genetics, lifestyle, health care systems, and environmental factors have been shown to influence both fall and fracture risk profiles and outcomes; yet, where there remains a critical gap in region-specific evidence and scalable screening solutions. While the fracture risk component of TARGET relies on specialized equipment such as DXA scans and 3D body scanning, the fall risk component uses portable, low-cost technologies (eg, IMU sensors) that allow trained nonclinical personnel to conduct on-site assessments. This expanded approach has the potential to reduce substantial burden and costs within the health care sector, with whom the responsibility of health screening traditionally lies, by broadening access in community settings.

Limitations

The TARGET cohort is not a fully representative national sample of community-dwelling older adults in Singapore. Specifically, TARGET contains a higher proportion of individuals aged 75‐84 years and of Malay and Indian backgrounds, reflecting the intentional oversampling of these minority groups to ensure statistical power for subgroup analyses. Furthermore, it excludes certain older adult subgroups, such as those not ambulatory or with possible delirium or dementia. While this approach allows for more nuanced investigation of fall and fracture risk factors within these subpopulations, it may limit the generalizability of the findings to the broader older adult population in Singapore. Additionally, not all participants contributed data for every health technology assessed in the study, particularly for the DXA scan and VR assessment. As a result, some analyses will be based on subcohorts, which could affect the statistical power and introduce potential bias in technology-specific findings. Finally, it is acknowledged that our household response rate of 22.3% (1674/7501) is lower than expected compared with previous national surveys of older adults we have conducted in Singapore (35% response rate) [106]. This lower response rate may introduce selection bias, as individuals who chose to participate could differ systematically from those who declined, potentially in terms of health status, sociodemographic characteristics, or other relevant factors.

Abstract

Background: Falls are one of the leading causes of injury or death among older adults. Falls occurring in individuals during hospitalization, as an adverse event, are a key concern for health care institutions. Identifying older adults at high risk of falls in clinical settings enables early interventions, thereby reducing the incidence of falls.

Objective: This study aims to develop and validate machine learning models to predict the risk of falls among hospitalized older adults.

Methods: This study retrospectively analyzed data from a tertiary general hospital in China, including 342 older adults who experienced falls and 684 randomly matched nonfallers, between January 2018 and December 2024, encompassing demographic information, comorbidities, laboratory parameters, and medication use, among other variables. The dataset was randomly split into training and testing sets in a 7:3 ratio. Predictors were selected from the training set using stepwise regression, least absolute shrinkage and selection operator, and random forest-recursive feature elimination. Seven machine learning algorithms were employed to develop predictive models in the training set, and their performance was compared in the testing set. The optimal model was interpreted using Shapley Additive Explanations (SHAP).

Results: The gradient boosting machine model demonstrated the best predictive performance (C-index 0.744, 95% CI 0.688 - 0.799). The 8 most important variables associated with fall risk were dizziness, epilepsy, fall history within the past 3 months, use of walking assistance, emergency admission, Morse Fall Scale scores, modified Barthel Index scores, and the number of indwelling catheters. The model was interpreted using SHAP to enhance the clinical utility of the predictive model.

Conclusions: The gradient boosting machine model was identified as the optimal predictive model. The SHAP method enhanced its integration into clinical workflows.

Introduction

Falls, the second leading cause of global unintentional injury deaths, are a significant public health concern. They are defined as “an event that leads to a person inadvertently coming to rest on the ground, floor, or other lower surface than their original position [1].” Age is one of the main risk factors for falls [2], and statistics indicate that the incidence of falls among older adults is approximately 26.5% [3]. Among individuals aged >60 years globally, falls are one of the most common causes of injury or death, with one out of every 5 falls resulting in a fracture or head injury [2,4]. In addition, falls generate

XSL•FO
RenderX

substantial medical costs, imposing a heavy economic burden worldwide [5].

Notably, falls are adverse events in hospitals, and the prevention of falls is also a priority for improving the quality of nursing care [6]. The incidence of falls in hospitals is typically in the range of 2 to 16 per 1000 bed days [7,8]. Despite a declining incidence of falls among hospitalized older adults, the increasing number of older adults admitted to hospitals, driven by an expanding aging population, suggests that falls prevention will remain a critical concern in hospitals [8,9]. Falls are preventable adverse events in hospitals, and implementing fall prevention programs can avoid costs of US $14,600 per 1000 patient-days [6]. Therefore, identifying individuals at high risk of falls in hospitals to take preventive measures is particularly important, especially among older adults.

The MFS (Morse Fall Scale) and STRATIFY (St. Thomas's Risk Assessment Tool in Falling Elderly Inpatients), widely used in hospitals to identify individuals at high risk of falls, have drawbacks such as low specificity [10,11]. Several studies have developed predictive models for fall risk in older inpatients [12-17]. While some employed traditional regression methods [12-15,17], these conventional approaches often struggle with complex, multidimensional data [18]. Other models exhibit limited applicability, being restricted to specific clinical settings or units [12,13,17]. Additionally, certain models rely solely on clinical texts for prediction, a methodology constrained by single-variable limitations that compromise performance [14].

In recent years, machine learning (ML) algorithms have attracted considerable interest in health care predictive modeling due to their capacity to develop highly accurate prediction models at low cost [19]. The capacity of ML algorithms to process high-dimensional data not only enhances the accuracy and efficiency of predictive models but also enables personalized risk prediction [4,20]. Although existing studies have employed ML algorithms to develop fall prediction models for hospitalized older adults, these models exhibit limitations, including suboptimal performance, applicability restricted to specific geriatric subpopulations, and reliance on environmental detection systems that hinder their widespread clinical adoption [16,21-23]. Critically, limited studies have offered comprehensive explanations or analyses of model predictions, restricting clinical applicability and diminishing the practical value of these models.

Therefore, the objective of our study is to develop and validate multiple ML models utilizing clinically accessible data to predict fall risk of hospitalized older adults. We seek to identify the optimal model while interpreting its predictions through the Shapley Additive Explanations (SHAP) method.

Methods

Data Source and Participants

Using an adverse event reporting system integrated into electronic nursing workstations of a tertiary general hospital, researchers retrieved fall incident records for hospitalized older adults (aged ≥60 y) occurring between January 2018 and December 2024, extracting hospitalization identifiers and fall timestamps. An electronic health record (EHR) system was used to record admission and discharge dates along with hospitalization identifiers for older adults without a history of falls hospitalized between January 2018 and December 2024. The fall timestamp of each case patient was used to anchor the index time for the matched controls. For each case, 2 controls were matched. Specifically, we first preprocessed the data by removing duplicate records from individuals with multiple hospitalizations (retaining only the first admission). From this refined pool of potential controls, we then used a Visual Basic algorithm in Microsoft Excel (version 16.0) to identify patients whose entire hospitalization period (from admission to discharge) encompassed the fall timestamp. This approach ensures that both cases and controls were exposed to similar time-dependent clinical factors at the same specific time point, thereby minimizing potential time-dependent bias. The case and control groups were not matched on demographics such as age or gender in order to maintain the natural distribution found in real-world clinical settings. With the aim of capturing all relevant information, variables with clinical or predictive relevance were included as model features for the ML algorithm to parse their associations with the outcome.

Matched controls identified as day cases were excluded and replaced until a 1:2 case-control ratio was maintained. This ratio was selected based on considerations of statistical power, cost-effectiveness, and practical constraints, as increasing the control-to-case ratio beyond 2:1 yields diminishing returns in power while substantially increasing costs and workload [24,25]. Cases were initially identified from the adverse event reporting system as any patient with a documented fall event occurring within the hospital premises and were excluded if they were aged <60 years old at admission, experienced subsequent falls occurring during the same hospitalization, or were nonhospitalized patients or day cases. Controls were selected from the EHR system as hospitalized patients aged ≥60 years with no record of an in-hospital fall and were excluded for having duplicate admission records (only the first was retained), day-case status, or if they could not be matched to a case. We excluded day case patients because more than 20% of the data were missing in EHR. The sample size was estimated using the "pmsampsize" package in R software (version 4.5.0). According to other researchers, the c-statistic is 0.73, the number of predictor parameters chosen for our study is 17, and the prevalence is 0.33 (1/3), with a required sample size of 992 for the calculation.

Ethical Considerations

The study was approved by the Ethics Committee Board of the Second Affiliated Hospital of Anhui Medical University (approval number: YX2025-162). This study adheres strictly to privacy protection principles. Nonessential identifying information is omitted during data processing, and informed consent is obtained when necessary. Informed consent was waived for patients who died or were disconnected. No financial compensation is provided to participants. This study conforms to the principles outlined in the TRIPOD (Transparent Reporting of a multivariable prediction model for Individual Prognosis or Diagnosis) statement.

XSL•FO
RenderX

Data Collection and Processing

All records containing timestamps and hospitalization identifiers were randomly split into 2 datasets. Two uniformly trained data collectors independently extracted variables through the EHR system using these identifiers, followed by cross-verification upon completion. Five categories of variables were collected: demographic characteristics, comorbidities, medications, laboratory indicators, and other variables. Table S1 in Multimedia Appendix 1 provides the list of 64 extracted variables. Demographic characteristics and sleep duration data were extracted from hospital admission records. The absence of BMI values was directly attributable to practical barriers in anthropometric data collection for patients with mobility limitations (bedridden or wheelchair-dependent status). Comorbidities were identified by integrating inpatient diagnoses from admission summaries with discharge diagnoses in corresponding discharge records. Medication administration records were retrieved from both permanent and temporary medical orders to capture all medications administered within the 24-hour period preceding the timestamp. Polypharmacy was defined as taking 5 or more medications daily. Laboratory indicators were collected from laboratory test reports. For indicators with repeated measurements, data within the 7 days before and after the timestamp were selected for analysis. The remaining variables were extracted from nursing records within 1 week before and after the timestamp. Given that at least 2 nursing records are documented weekly, there is no missing data for these variables. A total of 64 variables were initially extracted. With 27.49% missing values, BMI was removed from analysis. For the remaining variables, only albumin and hemoglobin contained missing values (0.03% and 0.04%, respectively). The missing values for albumin and hemoglobin were imputed using the random forest (RF) imputation method, implemented via the "missForest" package in R software (version 4.5.0). This approach offers the advantage of handling mixed data types (continuous and categorical) and effectively capturing nonlinear relationships among variables [26].

Feature Selection

The dataset was randomly split into a training set (70%) and a testing set (30%). A three-step selection strategy was implemented in the training set to identify optimal predictors. First, univariate (LR) was applied for preliminary screening (P<.05) to retain statistically significant variables. Second, 5 feature selection methods were integrated: stepwise regression (SR) comprises 3 variants—forward selection, backward selection, and bidirectional elimination; least absolute shrinkage and selection operator (LASSO); and random forest-recursive feature elimination (RF-RFE). Predictors were determined by the overlap among the results of these methods. This approach aimed to mitigate high correlation among predictors while capturing their complex relationships with the outcome variable [27]. SR iteratively adjusts variables based on statistical significance, LASSO addresses high dimensionality and multicollinearity while preventing overfitting, and RF-RFE captures nonlinear patterns and variable interactions. Both LASSO and RF-RFE incorporated 10-fold cross-validation. Finally, clinical experts validated the selected predictors to ensure clinical applicability.

Models Development and Validation

To comprehensively evaluate predictive performance and ensure robust results, we employed multiple algorithms to construct predictive models in the training set, including seven ML models: LR, support vector machines, RF, gradient boosting machine (GBM), extreme gradient boosting (XGBoost), k-nearest neighbor (KNN), and neural network (NN). Grounded in distinct modeling philosophies, each algorithm offers unique advantages. LR establishes an optimal linear decision boundary, valued for its conceptual simplicity and high interpretability, serving as a reliable performance benchmark [20]. Support vector machines aim to determine a separating hyperplane that maximizes the geometric margin for robust classification. They address nonlinear problems by employing kernel functions to project data into a higher-dimensional feature space where the maximum-margin principle is applied [20]. As a representative bagging ensemble, RF enhances predictive stability and captures complex feature interactions by aggregating numerous decorrelated decision trees, also providing inherent resistance to overfitting and enabling feature importance evaluation [20,28]. GBM employs a sequential modeling strategy that iteratively corrects errors from preceding models, often achieving high predictive accuracy [20]. XGBoost, an optimized implementation of gradient boosting, incorporates regularization and advanced algorithmic techniques to further improve computational efficiency and performance [20]. KNN is an instance-based learning method operating on the principle of local similarity. Predictions are derived from the majority label or average value of a sample's KNNs in the feature space, offering an intuitive perspective on the local data structure [29]. NN, or deep learning models, function as universal approximators by leveraging multiple layers of tunable nonlinear transformations. This architecture enables them to automatically learn hierarchical data representations and extract complex, high-level features through training [30]. This systematic selection of algorithms, encompassing linear models, kernel methods, bagging and boosting ensembles, instance-based learning, and NNs, ensures our evaluation is comprehensive and avoids bias toward any single modeling strategy.

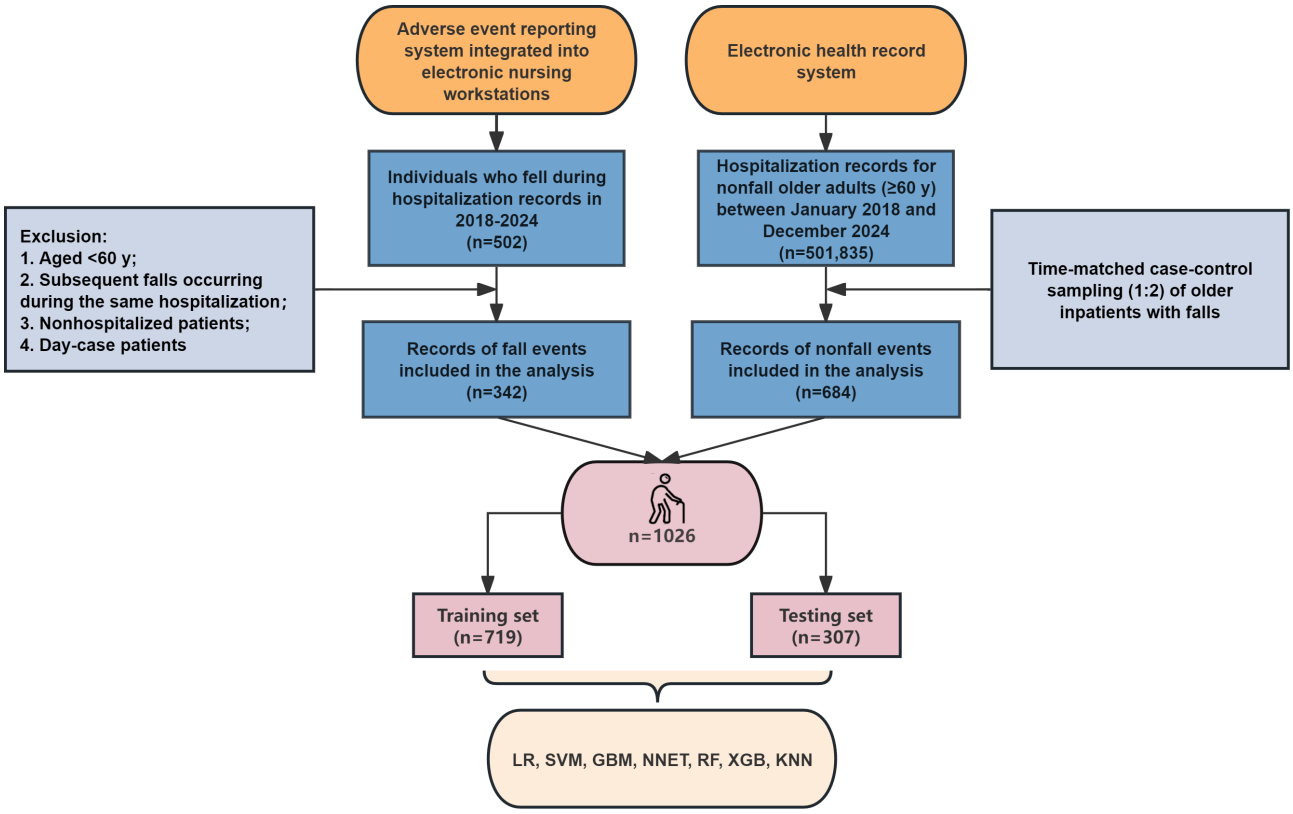
To mitigate class imbalance, we applied random upsampling to the training dataset, which involves duplicating instances from the minority class at random to balance the class distribution. Subsequently, to rigorously tune hyperparameters and guard against overfitting, we performed a grid search with 10-fold cross-validation on this processed training set to identify the optimal parameters. The test set was used to evaluate model performance. The area under the receiver operating characteristic curve (AUROC) in the testing set served as the primary metric for assessing discriminative ability. Model discrimination was primarily assessed using the AUROC. This metric is considered a standard method for evaluating ranking ability, as it provides a threshold-independent assessment of a model's inherent discriminative power [31]. Additionally, model performance was comprehensively evaluated using the area under the precision-recall curve (AUPRC), which is particularly informative for imbalanced datasets, along with sensitivity, specificity, accuracy, recall, F_1-score, positive predictive value, and negative predictive value. Calibration curves were plotted

XSL•FO
RenderX

to assess prediction accuracy. Decision curve analysis (DCA) was performed to quantify clinical utility. SHAP is a model interpretation tool that calculates feature contribution values to provide both global (model-level) and local (individual prediction) explanations, making models more interpretable and applicable [20,32].

Therefore, we employed the SHAP method to elucidate how individual features influence fall risk predictions in hospitalized older adults within the optimal model.

Statistical Analysis



All statistical analyses were performed using R software (version 4.5.0), with categories merged when necessary to address sparse data. Use of walking assistance (UWA) was classified into 4 groups: no assistance, wheelchair or bedridden, support by others or furniture, and walker/crutches/cane. Continuous variables were categorized as follows: age into 60 to 69, 70 to 79, and ≥80 years; serum albumin into ≥34 and <34 g/L [33]; MFS scores into <45 points and ≥45 points [34]; modified Barthel Index (mBI) [35] scores into 0 to 20 points, 21 to 60 points, 61 to 90 points, 91 to 99 points, and 100 points; Nutritional Risk Screening 2002 (NRS 2002) scores into <3 points (no nutritional risk) and ≥3 points (at risk) [36]; and Numeric Pain Rating Scale scores into 0 points (no pain) and ≥1 point (pain) [37]. Continuous variables, none of which followed a normal distribution, were expressed as medians and IQR (M, Q1-Q3). Categorical variables were reported as numbers and percentages (n, %). Differences between groups were analyzed using the Mann-Whitney *U* test for nonnormally distributed continuous variables and the Chi-square test (or Fisher exact test for sparse data) for categorical variables. A 2-sided $P<.05$ was considered statistically significant.

Results

Baseline Characteristics

Ultimately, 1026 older adults were included in the study. Figure 1 illustrates the process of patient screening. The comparison between fallers and nonfallers in the overall dataset is presented in Table S2 in Multimedia Appendix 1. Among the 1026 patients, 40.84% (419/1026) were aged 60 to 69 years and 55.65% (571/1026) were male. Among the 342 fallers, 40.06% (137/342) were aged 70 to 79 years and 52.05% (178/342) were male. Significant differences were observed between fallers and nonfallers in the following variables: age, blood pressure, diabetes, chronic kidney disease, heart failure, hypothyroidism, cancer, Parkinson's disease, dizziness, stroke, gait abnormality, epilepsy, visual impairment, hearing impairment, polypharmacy, antiplatelet drugs, statins, α-blockers, vasodilators, antidiabetic drugs, anti-Parkinson's disease drugs, antiepileptic drugs, benzodiazepines, Z-drugs, albumin levels, fall history in the past 3 months, UWA, emergency admission (EA), MFS scores, NRS 2002 scores, mBI scores, number of indwelling catheters (Indw Cath), and departments.

Figure 1. Flowchart of the patient screening. GBM: gradient boosting machine; KNN: k-nearest neighbor; LR: logistic regression; NNET: neural network; RF: random forest; SVM: support vector machine; XGB: extreme gradient boosting.

Selection of Predictor Variables

Univariate LR identified 26 potential predictors ($P<.05$) in the training set. The mBI did not reach statistical significance in the univariate analysis, but its *P* value was .054, which is very close to the threshold. Given that the mBI is an important clinical indicator associated with fall risk and to avoid omitting

XSL•FO
RenderX

potentially influential factors due to a rigid threshold, we decided after expert discussion to include it as the 27th variable in the subsequent feature selection, as detailed in Table S3 of Multimedia Appendix 1. Table 1 displays the predictors identified by the 5 methods (SR-forward selection, SR-backward selection, SR-bidirectional elimination, LASSO, and RF-RFE). Table S4, Figure S1, and Figure S2 in Multimedia Appendix 1 provide detailed information. Figure 2 visualizes the overlap of predictors selected across 5 methods. The intersecting predictors from these methods formed the final predictor set, comprising dizziness, epilepsy, fall history in the past 3 months, UWA, EA, MFS scores, mBI scores, and Indw Cath. After expert consultation, no predictors were added or removed. The final development model included these 8 predictor variables.

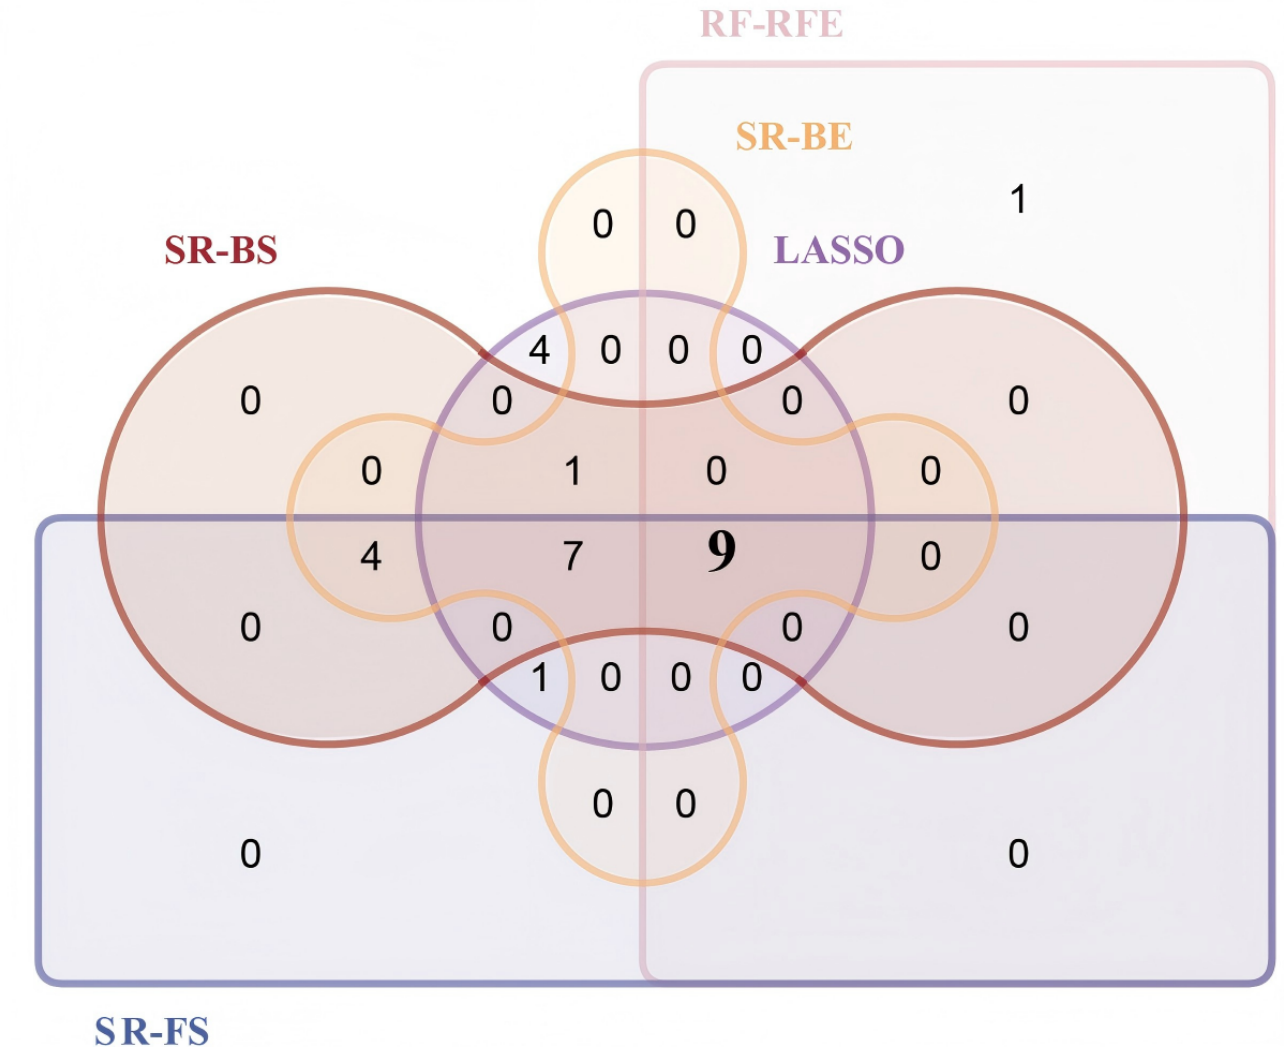


Table . The predictors obtained through 5 selection methods.

Models Development and Validation

Table S5 in Multimedia Appendix 1 compares the characteristics of the training and testing sets. The training set comprised 719 (70%) older adults, while the testing set included 307 (30%). All final model predictors and fall status (yes/no) were balanced between the training and testing sets, as shown in Table 2. The AUROC for the 7 models in the testing set is shown in Figure 3B. Among these, the GBM model demonstrated the highest discrimination with an AUROC of 0.744 (95% CI 0.688 - 0.799) compared to the other 6 models. The LR model followed closely with an AUC of 0.742 (95% CI 0.685 - 0.798). The NN and RF models had the lowest AUROCs, at 0.705 (95% CI 0.646 - 0.765) and 0.715 (95% CI 0.657 - 0.772), respectively. Table 3 displays the detailed predictive performance of the 7 ML models. In the testing set, the LR model achieved the highest AUPRC of 0.570 (0.475 - 0.663), while the RF model showed the lowest AUPRC of 0.477 (0.386 - 0.580). Regarding other performance metrics, the NN models had the best sensitivity (0.931), the XGBoost model had the best specificity (0.644), and the LR model showed the highest accuracy (0.687). The calibration curves for the predictive models in the testing set are shown in Figure 3D. The LR model demonstrated the best calibration ability in the testing set. The DCA curves for the predictive models in the testing set are shown in Figure 3F. The DCA curves suggest that the 7 models have certain clinical utility, generating net benefits within the threshold range of 0 to 0.5. Considering AUROC, sensitivity, and specificity, the GBM was determined to be the best-performing model.

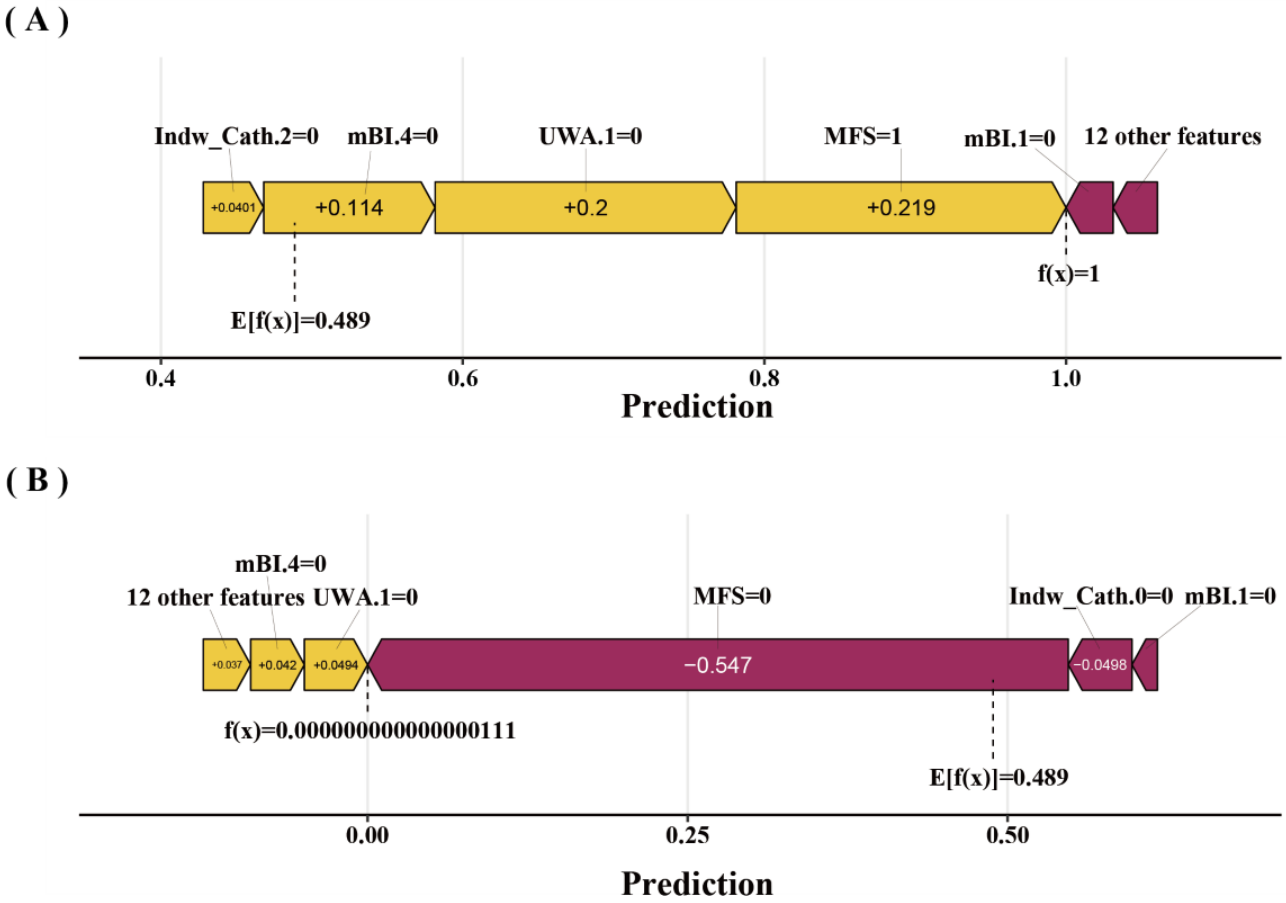
Interpretability Analysis



SHAP was utilized to illustrate how the features predict the occurrence of falls in old adults during hospitalization within the GBM model. Figure 4A displays the 17 features sorted by their average absolute SHAP values, and higher absolute SHAP indicates greater contribution to fall risk. Figure 4B shows the impact values and explanations of these features, and yellow dots represent high risk, while purple dots indicate low risk. An MFS score of ≥45, an mBI score that is not 100 points, an mBI score not between 0 and 20 points, having fewer than 2 indwelling tubes, a history of falls in the past 3 months, EA, epilepsy, dizziness, use of a walker/cane/crutch, requiring assistance from others/furniture for walking, and not using a wheelchair or not being bedridden are associated with a higher risk of falls in old adults during hospitalization. Beyond global SHAP interpretations, local interpretability was demonstrated. Figure 5A and B visualizes how the GBA model makes predictions about falls in older adults during hospitalization; yellow arrows indicate risk-increasing features and purple arrows risk-decreasing features. The *f(x)* values inside arrows quantify each feature's contribution. Summing these yields the model's final prediction, which is represented by the *f(x)* value outside arrows.

Figure 4. Interpretation of the gradient boosting machine model by the Shapley Additive Explanations (SHAP) method. (A) A bar summary of the most important features according to the SHAP values. (B) Summary and explanation of the most influential features. Yellow dots indicate high-risk values, and purple dots indicate low-risk values. EA: emergency admission; FH-3M: fall history in the past 3 months; Indw Cath.0: number of indwelling catheters 0 (0); Indw Cath.1: number of indwelling catheters 1 (1); Indw Cath.2: number of indwelling catheters 2 (≥2); mBI.0: modified Barthel Index scores category 0 (0-20 points); mBI.1: modified Barthel Index scores category 1 (21-60 points); mBI.2: modified Barthel Index scores category 2 (61 - 90 points); mBI.3: modified Barthel Index scores category 3 (91 - 99 points); mBI.4: modified Barthel Index scores category 4 (100 points); MFS: Morse Fall Scale; UWA.0: use of walking assistance category 0 (no assistance); UWA.1: use of walking assistance category 1 (wheelchair or bedridden); UWA.2: use of walking assistance category 2 (support by others or furniture); UWA.3: use of walking assistance category 3 (walker/crutches/cane).

Figure 5. Compositional risk of feature contributions for predicting the occurrence of falls in 2 older adults during hospitalization. Purple arrows denote factors that decrease the risk of falls for old adults during hospitalization, while yellow arrows indicate features that increase the risk. (A) An older adult with fewer than 2 indwelling catheters, a modified Barthel Index (mBI) score not equal to 100 and not within the range of 21 - 60 points, not using a wheelchair or bedridden, and a Morse Fall Scale (MFS) score ≥45 points experienced a fall during hospitalization. (B) An older adult with an mBI score not equal to 100 or within the range of 21 - 60 points, not using a wheelchair or bedridden, with the presence of indwelling catheters, and an MFS score <45 points did not experience a fall during hospitalization. Indw Cath.0: number of indwelling catheters 0 (0); Indw cath.2: number of indwelling catheters 2 (≥2); mBI.1: modified Barthel Index scores category 1 (21 - 60 points); mBI.4: modified Barthel Index scores category 4 (100 points); UWA.1: use of walking assistance category 1 (wheelchair or bedridden).

Discussion

Principal Results

In this study, we used 7 ML algorithms to predict in-hospital falls among hospitalized older adults based on clinically accessible data, including demographic characteristics, comorbidities, laboratory parameters, and medications. The GBM algorithm demonstrated the optimal predictive performance. Model interpretability was achieved at both global and individualized patient levels using SHAP [38]. The SHAP approach bridges the gap between ML models and realistic clinical decision-making, enabling health care providers to understand the model's predictive process and trust its predictive power [39].

In our study, multiple ML algorithms based on distinct principles were employed to develop predictive models. However, the predictive performance across these methods showed limited variation, consistent with prior research [20], which suggests that advanced ML algorithms generally perform well on relatively small and low-dimensional datasets. Through a comprehensive evaluation of the AUROC, AUPRC, sensitivity, and specificity, the GBM model was ultimately selected as the optimal model. Notably, LR also demonstrated competitive performance, and DCA curves indicated that the LR model could provide favorable clinical net benefit. Nevertheless, compared to LR, GBM offers distinct advantages in handling nonlinear relationships and complex data patterns [27].

Fall risk factors among hospitalized older adults encompass multiple domains, including demographic characteristics, comorbidities, laboratory parameters, and medications [40-42]. Previous studies have relied on subjective nursing documentation texts, comprehensive geriatric assessments, or environmental detection systems to develop fall prediction models for hospitalized individuals [16,21], which limits their clinical utility. Identifying predictors is a critical step in building predictive models. It is notable that the predictors identified in our study are aligned with routinely collected clinical data, ensuring practical accessibility in health care settings. Conventional approaches often select predictors using a single method, such as regression models, whereas combining multiple feature selection techniques may yield simplified models with higher generalizability [43]. Different from previous studies, we used multiple methods such as SR, RF-RFE, and LASSO to identify predictors, which is one of the advantages of our study.

XSL•FO
RenderX

Eight variables were ultimately identified: dizziness, epilepsy, fall history within the past 3 months, UWA, EA, MFS scores, mBI scores, and the number of Indw Cath. They are also key predictors in other predictive models [11,15,16,44]. Our study identified MFS scores ≥45, nonbedridden and not using a wheelchair, and scores of mBI not 100 as the 3 strongest predictors of falls in hospitalized older adults. These findings align with previous studies [11,15,16]. MFS is widely used for fall risk assessment in hospitals. Previous research has shown that MFS exhibits lower sensitivity than ML models [11,44]. Nevertheless, including it as a predictor in ML models permits the evaluation of its predictive contribution relative to other variables. MFS remains a valid predictor of falls among hospitalized patients [11]. Similarly, in our study, MFS emerged as a strong feature in the ML model.

Moreover, since patients' clinical data often include MFS scores, an integrated model that incorporates MFS can better simulate real-world decision-making, providing a more practical foundation for clinical decision. One of the key strengths of our study lies in integrating a simple, widely used assessment tool with a high-performance ML method, leveraging the advantages of both methodologies to develop and validate a simple, easily generalizable predictive model. This study found that older adults who are not bedridden or not using a wheelchair had a higher fall risk during hospitalization. This may occur as over half of falls happen during daily activities [45], whereas bedridden or wheelchair-bound patients have very low activities of daily living (ADL) ability, limiting activity engagement and thereby reducing fall risk. Similarly, patients with mBI scores >0 had higher fall risk, where higher scores indicate better ADL ability [35]. Notably, those with mBI scores <100 or 21 to 60 also showed increased risk, implying a nonlinear relationship between mBI scores and fall risk. This contradicts findings by Dormosh et al [15] and Chu et al [16] that low ADL ability predicts falls but aligns with Nagarkar et al's [45] longitudinal study linking difficulty with >4 ADL to higher fall odds. Functional decline impairs musculoskeletal integrity and body composition, reducing mobility and increasing fall risk [45-47]. However, the relationship between functional ability and fall risk in elderly patients requires further investigation. Identifying functional states associated with the highest fall risk and implementing dynamic interventions are crucial for preventing falls in this population.

Despite the growing number of ML-based clinical prediction models being developed, most studies lack interpretability of these models, limiting their clinical understanding and practical adoption. The interpretability of ML predictions requires attention from researchers so that physicians can understand, trust, and ultimately apply these predictive models to guide their clinical practice [28,38,39]. SHAP is a model-agnostic interpretation framework grounded in cooperative game theory. Its core lies in computing Shapley values to quantify the marginal contribution of each input feature to individual predictions. This approach provides consistent and locally accurate explanations for every prediction made by the model [38]. In this study, we addressed the "black-box" nature of ML models by implementing SHAP to interpret the GBM model at both global and individualized levels. This means that in a clinical setting, the model can calculate a patient's fall risk in real time and simultaneously provide the primary clinically interpretable factors contributing to that risk, thereby enabling rapid screening and informed decision-making. SHAP improves the clinical utility of prediction models, providing fall risk prediction and interpretable descriptions for older adults during hospitalization, thereby demonstrating its potential to address the "black-box" problem [28,39].

Limitations

This study has several limitations. First, the predictive model was developed using single-center retrospective data, which may introduce potential biases and limit its generalizability to other health care settings. External validation in multicenter cohorts is required to confirm broader applicability. Second, incorporating environmental variables (eg, ward layout, lighting conditions) was challenging due to constraints in single center data collection. Lastly, the exclusion of additional laboratory parameters may have overlooked potential predictors. Future research should prioritize integrating environmental variables, expanding laboratory indicators, and leveraging multicenter datasets for model development and validation.

Conclusions

In this study, multiple ML models were developed and validated using multifaceted clinical data to identify the risk of falls among hospitalized older adults. The GBM model demonstrated the optimal predictive performance. By SHAP, the clinical utility of the predictive model was significantly enhanced. In the future, this GBM fall prediction model could be integrated into the hospital EHR system as an embedded decision support module to dynamically assess fall risk among inpatients and generate real-time alerts. Simultaneously, based on the SHAP values provided by the model, the system could offer evidence to support health care providers in developing personalized intervention measures, thereby translating risk prediction into clinical actions aimed at reducing the incidence of falls in hospitalized older adults.

Funding

This study was supported by Nursing Project of Anhui Institite of Translational Medicine (No. 2024zhyx-hl-A04).

Authors' Contributions

XY, JR, and DS cooperatively designed the study, analyzed the data, and drafted the manuscript. NM conceived and designed the study. MB and MZ contributed to the revision of the manuscript. XC, YL, ZW, XD, ZW, SZ, YZ, JL, XL, and JX contributed to the acquisition of data.

Abstract

Background: Falls are a leading cause of injury, disability, and death among older adults, posing significant public health challenges. However, comprehensive global analyses of fall-related burdens in older populations remain scarce.

Objective: This study aimed to explore the patterns and distribution of the global, regional, and national burden of falls among adults aged 65 years and older.

Methods: Data from the Global Burden of Disease study 2021 were used to assess the overall, disability, and mortality burden of falls among adults aged 65 years and older. Age-standardized rates of disability-adjusted life years (DALYs), years lived with disability (YLDs), and years of life lost were calculated to compare burdens across countries. Health inequalities were evaluated via the slope index of inequality and the concentration index. Frontier analysis identified optimal burden levels by sociodemographic index (SDI). Bayesian age-period-cohort models projected trends up to 2050.

Results: DALY age-standardized rates showed a U-shaped distribution across SDI regions: lower-SDI countries faced higher mortality burdens, while higher-SDI countries had elevated disability burdens. Despite an increase in absolute overall burden inequality from 1990 to 2021, absolute inequalities in YLDs and years of life lost declined, with DALYs and YLDs exhibiting relatively more balanced distributions. Frontier analysis pinpointed countries with the greatest burden reduction potential. Projections suggest decreasing overall and mortality burdens by 2050 but rising disability burdens.

Conclusions: Higher- and lower-SDI countries face distinct fall-related challenges. Reducing cross-national health inequalities and closing gaps between the observed burden and the optimal burden level achievable at a similar SDI level are critical. Despite projected declines in the overall burden (DALYs), the rising disability burden (YLDs) could present evolving challenges, potentially underscoring the importance of proactive preparedness.

Introduction

Falls are one of the leading causes of injury, disability, and death among older adults, posing significant challenges to both public health and health care systems worldwide. As global populations age, the burden of falls is expected to increase, particularly among individuals aged 65 years and older. According to the Global Burden of Disease (GBD) study 2021, the age-standardized rate (ASR) of fall incidence was 6198.42 per 100,000 population in 2021, while the ASR of fall-related mortality was 78.36 per 100,000 population among older adults [1,2]. Furthermore, the World Health Organization reports that approximately 28% to 35% of older adults experience falls each year, resulting in outcomes ranging from minor injuries to severe fractures and mortality [3,4]. Beyond the immediate physical consequences, falls are linked to long-term disability, loss of independence, psychological trauma, and increased health care costs, making them a critical concern for both individuals and society at large [5,6].

XSL•FO
RenderX

In light of this growing issue, understanding the global, regional, and national burden of falls has become increasingly important. The GBD study 2021 offers a robust framework for quantifying the impact of diseases and injuries worldwide, including falls. While falls among older adults have been widely studied, many of the existing studies are limited in scope—either focusing on specific regions or countries or addressing only certain aspects of mental and physical effects [7-10]. A study based on the GBD study discussed the mortality rate of falls across 59 high-income and upper-middle–income countries [11]. However, significant gaps persist in comprehensively understanding the global-scale mortality and disability burdens across diverse populations and regions, as well as the underlying socioeconomic, environmental, and health care–related factors driving these disparities.

This study aimed to examine the global, regional, and national burden of falls among individuals aged 65 years and older using the latest data from the GBD study 2021. By analyzing variations in fall burdens across countries or regions, the research sought to identify current and future challenges across different development levels and geographic locations.

Methods

Study Data

This study was a secondary data analysis primarily using the GBD study 2021 database [1,2]. The GBD study 2021, led by the Institute for Health Metrics and Evaluation at the University of Washington, provides comprehensive global health data, covering 369 diseases, injuries, and risk factors. Data on the burden of falls from 1990 to 2021 were retrieved using the GBD Results Tool across 7 age groups: 65 to 69 years, 70 to 74 years, 75 to 79 years, 80 to 84 years, 85 to 89 years, 90 to 94 years, and 95 years and above [12]. Demographic data from 1990 to 2050 were acquired from the GBD study database and a projection of the population [13,14]. Additionally, the sociodemographic index (SDI) was accessed from the GBD study database to evaluate the development status of the included countries and territories [15].

Definition

The disability-adjusted life years (DALYs) represent the total number of years lost due to ill-health, disability, or early death. This study selected DALYs as the measure of overall burden of falls, with years lived with disability (YLDs) measuring burden of disability and years of life lost (YLLs) measuring burden due to premature mortality. ASR is a statistical measure used to compare rates of health metrics (per 100,000 people) across different populations, adjusting for variations in age distribution. By standardizing the measures using the GBD study world population age standard, the rates of DALYs, YLDs, and YLLs become comparable across countries or regions. The SDI is a composite measure used to summarize a country or region's sociodemographic development; it ranges from 0 to 1, where higher values indicate greater sociodemographic development [16,17].

Statistical Analysis

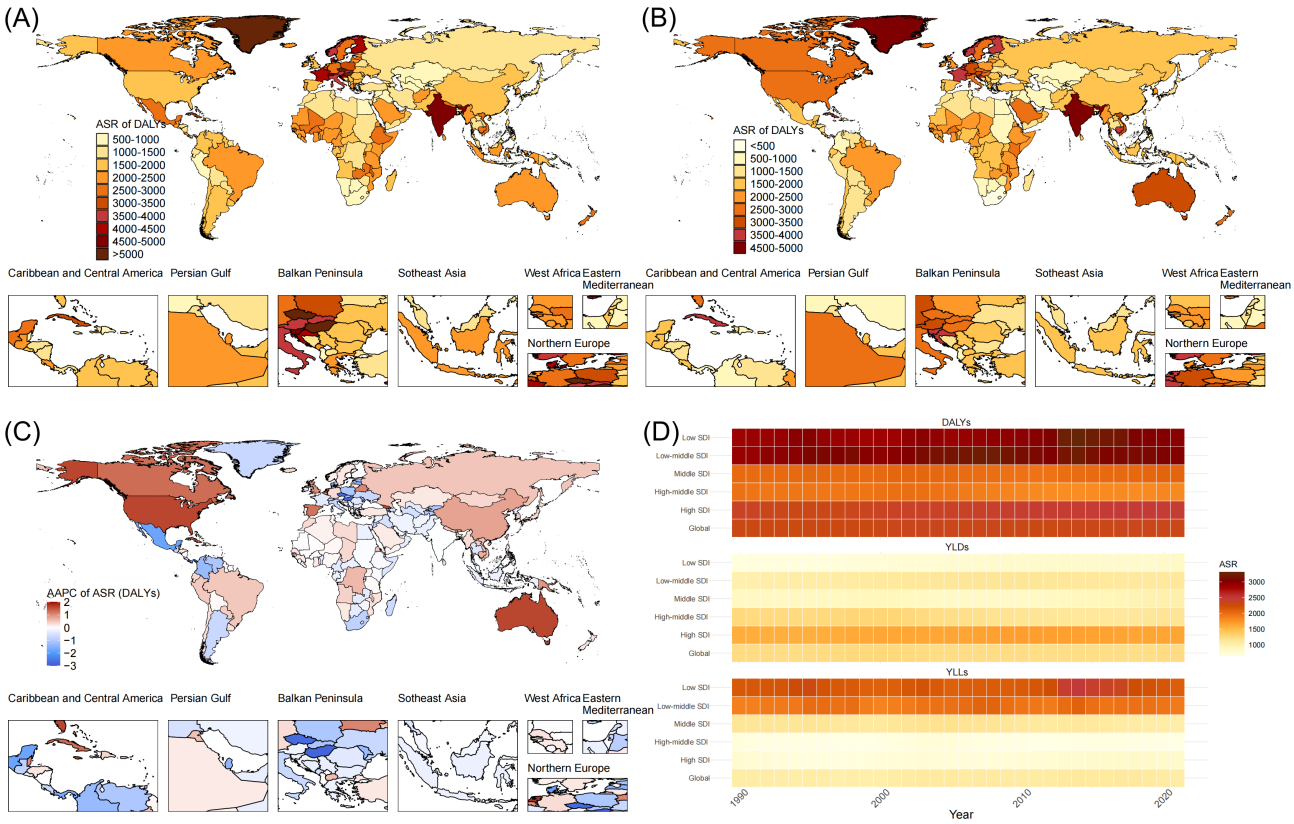
Joinpoint regression analysis was performed using the Windows command-line (batch/callable) version of Joinpoint Regression Software (Surveillance Research Program, National Cancer Institute) to acquire the annual percentage change (APC) and average APC of ASRs [18-20]. This study calculated 2 key indexes of health inequality: the slope index of inequality (SII) and the concentration index, which reflect absolute and relative health inequities, respectively. The SII measures absolute inequality by quantifying the difference in indicator values between the most disadvantaged and most advantaged subgroups considering the overall population distribution. It is derived from a regression model that accounts for the cumulative distribution of the population. Larger SII values indicate greater disparities between these groups. The concentration index is a relative measure that assesses the concentration of a health indicator across subgroups. It ranges from −1 to 1, with 0 indicating no inequality. Positive values suggest concentration in advantaged groups, while negative values indicate concentration among disadvantaged groups. The further the concentration index is from 0, the greater the level of inequality [21]. Frontier analysis was conducted to identify the optimal burden levels that countries could achieve based on their corresponding development statuses [22]. A Spearman rank correlation analysis was conducted to evaluate the relationship between the burden of falls and aging-related indicators among older adults. Bayesian age-period-cohort models and integrated nested Laplace approximations using the R packages *BAPC* (version 0.0.36) and *INLA* (version 24.06.27; R Foundation for Statistical Computing) were used to project the future trends in the burden of falls among older adults [23,24].

Ethical Considerations

This study was a secondary analysis of publicly available, deidentified, aggregated data from the GBD study 2021, used in accordance with the relevant data use terms. No additional ethics approval was sought for this study because it was based exclusively on publicly available, anonymized data and involved no direct contact with human participants. This study involved no collection of, or access to, identifiable personal information; therefore, additional informed consent was not required. All analyses were conducted using anonymized, publicly available data, ensuring privacy and confidentiality. No participants were recruited, and no compensation was provided.

Results

Spatiotemporal Patterns of Falls Among Older Adults



In the initial analysis, it was found that ASRs of mortality and incidence due to falls varied among countries with different SDIs (Figures S1-S3 in Multimedia Appendix 1 and Tables S1-S4 in Multimedia Appendix 2). Higher-SDI countries exhibited lower ASRs for mortality and higher ASRs for fall incidence, whereas lower-SDI countries exhibited more falls and higher mortality rates among older adults. To gain a comprehensive understanding, we used DALYs, YLDs, and YLLs as indicators to assess the overall burden, disability burden, and mortality burden of falls among individuals aged

XSL•FO
RenderX

65 years and above (Tables S5-S10 in Multimedia Appendix 2).

From 1990 to 2021, the overall burden of falls among older adults remained consistently high in India, Australia, Europe, North America, and Africa (Figures 1A and 1B). Specifically, North America and Australia exhibited an increasing trend in their overall burden, while other regions maintained stable levels or experienced only minor increases (Figure 1C). Regarding disability and mortality burdens, regions with low and low-middle SDI exhibited higher mortality burdens, whereas high-SDI regions exhibited greater disability burdens. The overall burden of falls among older adults followed a U-shaped distribution, with middle- and high-middle–SDI regions experiencing the lowest burden and low-, low-middle–, and high-SDI regions facing heavier overall burdens (Figure 1D).

Figure 1. Spatiotemporal patterns of burden of falls among older adults: (A) age-standardized rate (ASR) of disability-adjusted life years (DALYs) in 1990; (B) ASR of DALYs in 2021; (C) average annual percentage change (AAPC) in the ASR of DALYs from 1990 to 2021; and (D) heat map of the ASR of DALYs, years lived with disability (YLDs), and years of life lost (YLLs) at the global and sociodemographic index (SDI) region levels in 2021.

Health Inequality Analysis

The SII was used to quantify absolute differences in ASRs (rates) of burden indicators between the most disadvantaged and most advantaged countries. From 1990 to 2021, the SII for DALYs increased from 337.11 to 425.22, indicating a widening of absolute overall health inequality (Figure 2A). In contrast, the SII for YLDs decreased from 1274.84 to 1086.98, and the SII for YLLs decreased from −912.00 to −660.57, suggesting a reduction in the absolute inequality of both disability and mortality burdens (Figures 2B and 2C). Consistent with the patterns presented in Figure 1D, these metrics reveal distinct underlying drivers for disability and mortality: the positive SII for YLDs confirms that the disability burden was disproportionately concentrated in higher-SDI countries, while the negative SII for YLLs aligns with our finding that the mortality burden remained more pronounced in lower-SDI regions.

XSL•FO
RenderX

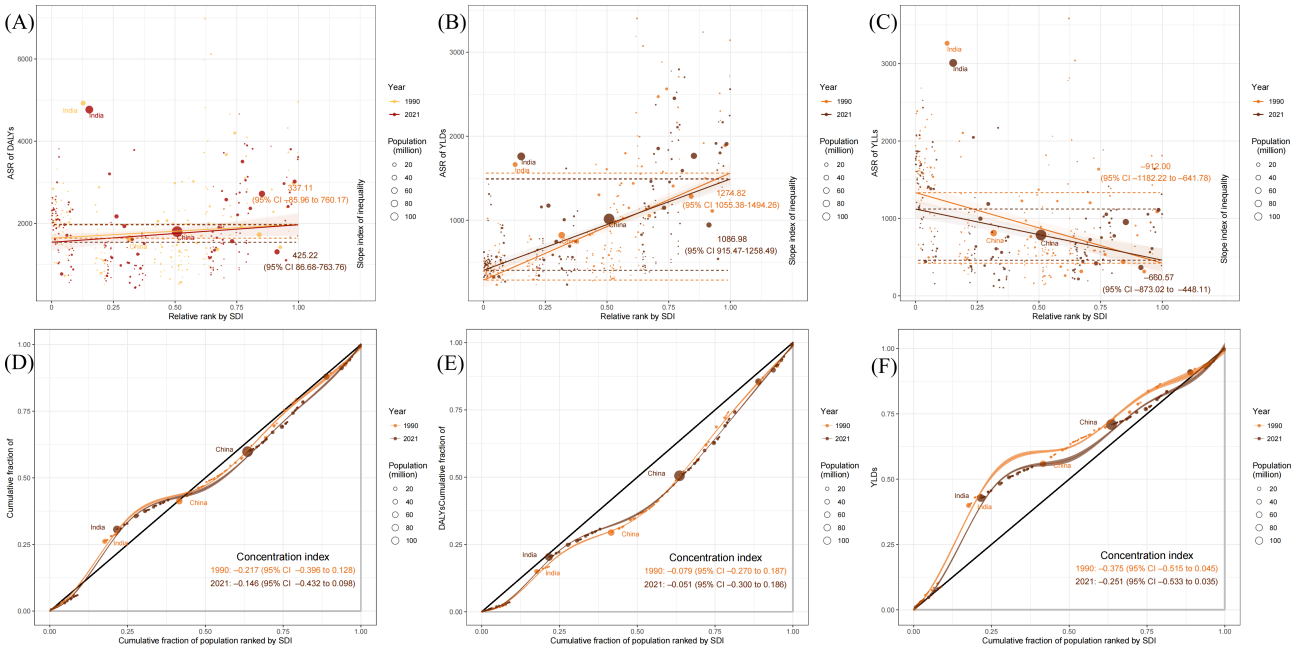


Figure 2. Health inequality analysis: (A-C) slope indexes of inequality for the age-standardized rates (ASRs) of disability-adjusted life years (DALYs), years lived with disability (YLDs), and years of life lost (YLLs) and (D-F) concentration indexes for DALYs, YLDs, and YLLs. CI: confidence interval. SDI: sociodemographic index.

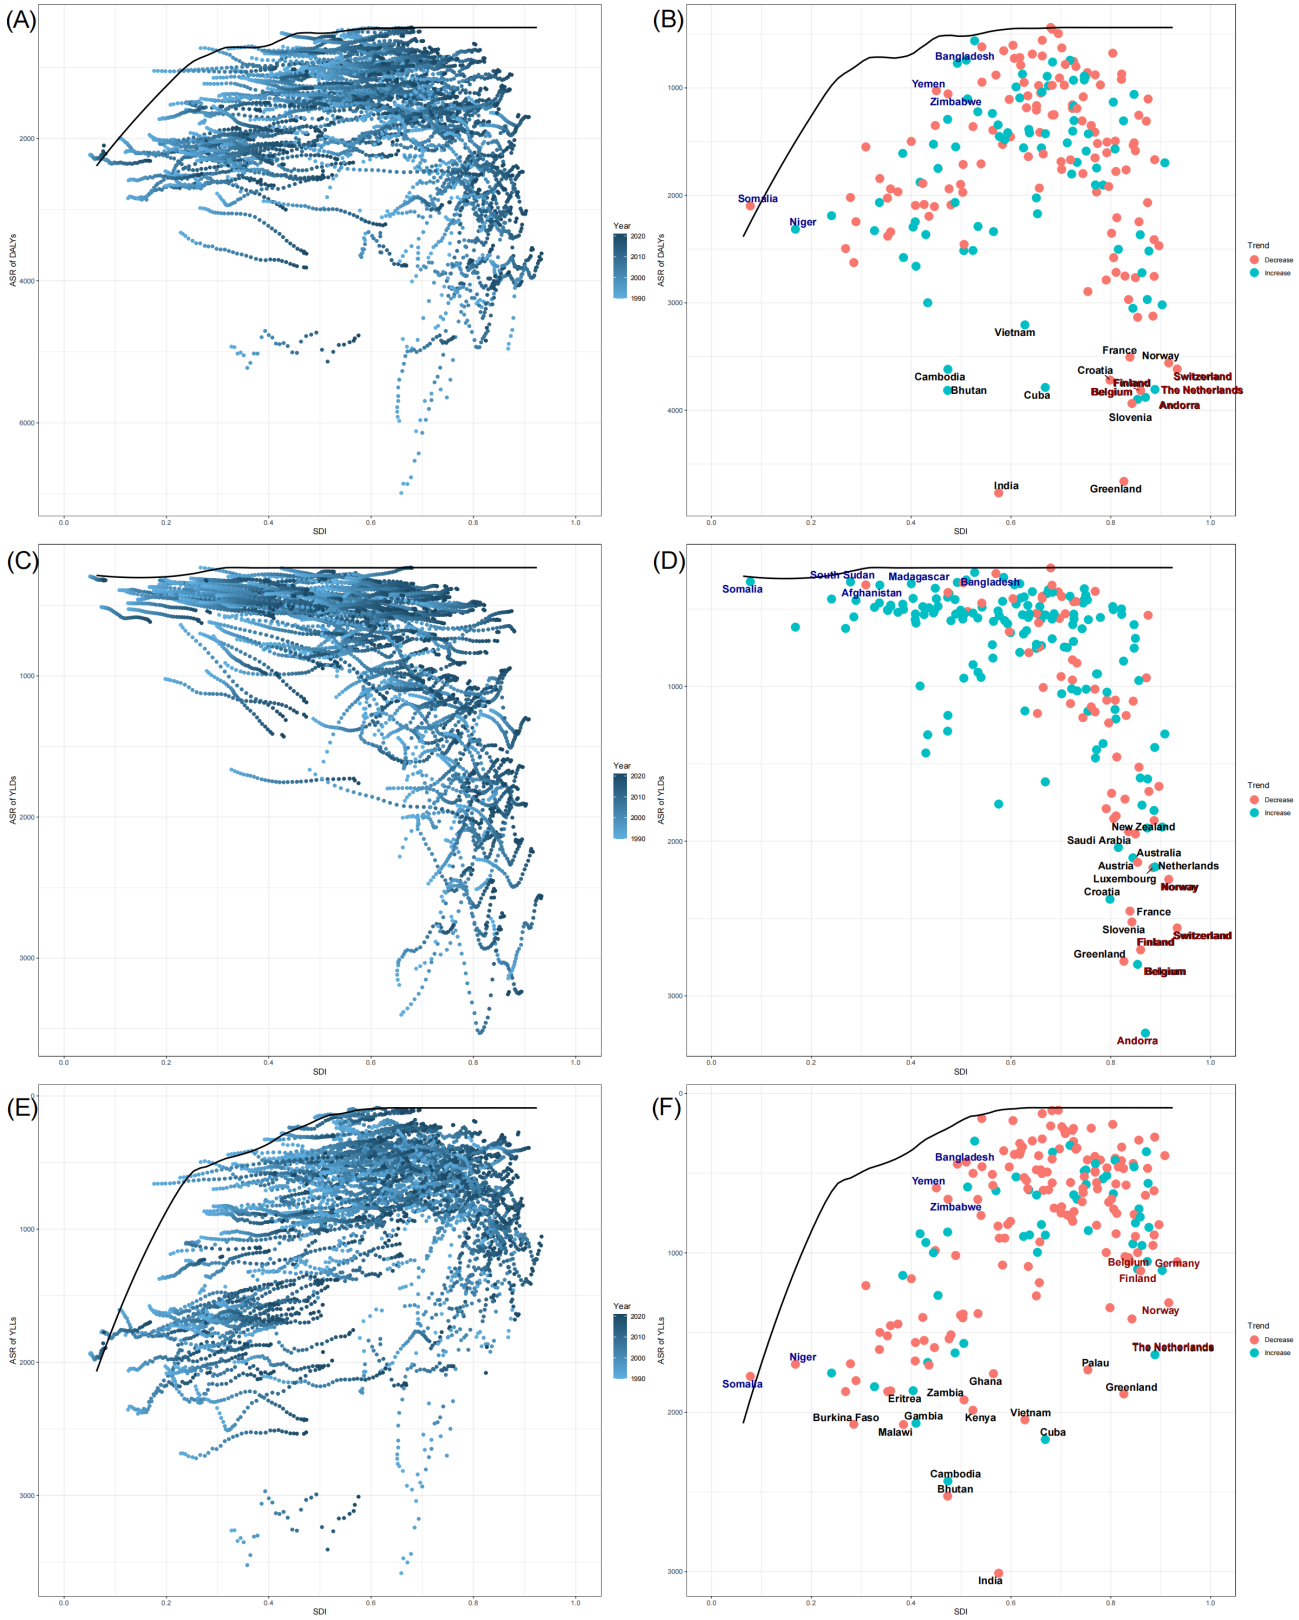


Distinct from the SII, which compares absolute inequality at the country level, the concentration index evaluates relative health inequality by analyzing the distribution of burden indicators (total numbers) across the global population ranked by SDI. Between 1990 and 2021, the concentration index for DALYs shifted from −0.217 to −0.146, indicating a reduction in relative inequality. For YLDs, the concentration index values remained close to 0 (−0.079; *P*=.50; and −0.051; *P*=.68, respectively), suggesting that the disability burden was distributed relatively evenly across the global population [25]. Meanwhile, the concentration index for YLLs increased from −0.375 to −0.251, reflecting a narrowing of relative inequality in mortality. Notably, the negative concentration indexes for both DALYs and YLLs indicate that, despite improvements over time, the overall and mortality burdens remained disproportionately concentrated in lower-SDI populations.

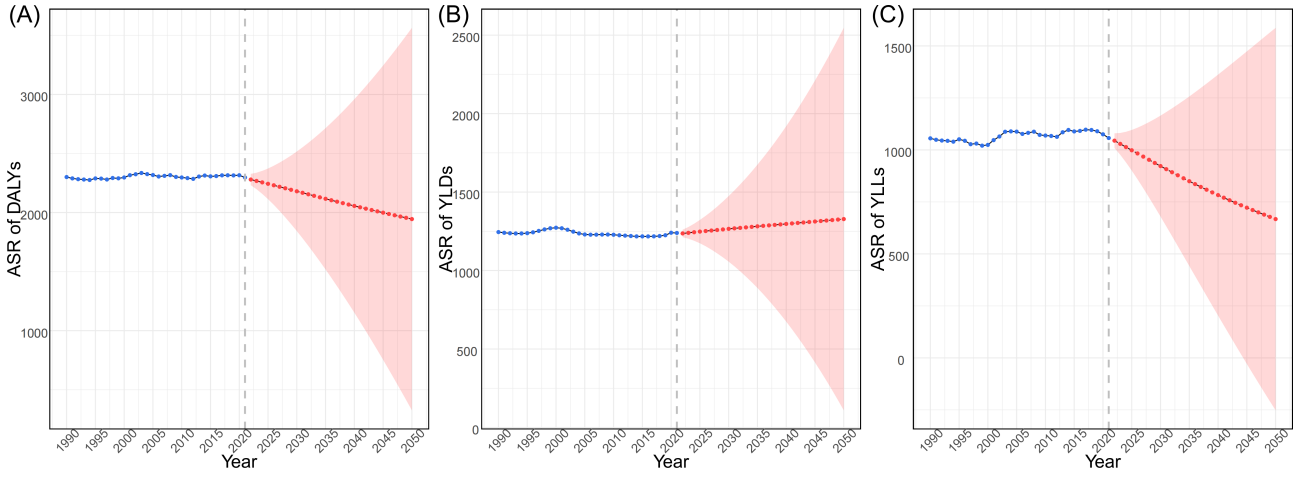
Frontier Analysis

Frontier analysis was conducted to determine the lowest burden that could be potentially achieved based on development status. In Figures 3A, 3C, and 3E, the scatterplot illustrates the relationship between SDI and the ASRs of DALYs, YLDs, YLLs (the color change from light blue [1990] to dark blue [2021]), indicating a shift in their distribution over time. The black frontier line represents the efficiency frontier, which delineates the lowest possible burden of DALYs, YLDs, and YLLs for a given SDI level. The distance from the frontier represents the gap between the observed burden and the potentially achievable burden of falls in a given country or territory considering its SDI. For ASRs of DALYs, countries with both low and high SDIs experienced a higher burden, while those with middle SDI levels had the lowest DALYs. In addition, for ASRs of YLDs, countries with higher SDIs generally exhibited higher disability burdens. High-SDI countries showed a declining or stable trend, while low-SDI countries exhibited an increasing trend in YLDs. In contrast, for ASRs of YLLs, most curves showed a stable or slight decline, and countries with higher SDIs generally exhibited lower mortality burdens.

XSL•FO
RenderX

Figure 3. Frontier analysis based on sociodemographic index (SDI) and age-standardized rates (ASRs) of disability-adjusted life years (DALYs), years lived with disability (YLDs), and years of life lost (YLLs) in 204 countries and territories: (A-B) ideal ASRs of DALYs corresponding to the SDI, (C-D) ideal ASRs of YLDs corresponding to the SDI, and (E-F) ideal ASRs of YLLs corresponding to the SDI.

In Figures 3B, 3D, and 3F, the scatterplots show the relationship between SDI and the ASRs of DALYs, YLDs, and YLLs across different countries in 2021. The colors indicate the trend of ASRs between 1990 and 2021, where red dots represent countries with a decrease in ASRs, while blue dots indicate an increase. High-SDI countries (SDI>0.85) with the top 5 largest distances are marked in red. In contrast, among countries with an SDI below 0.50, those performing best are marked in blue. Additionally, the top 15 countries and territories that are furthest from the frontier are colored in black.



XSL•FO
RenderX

Among the ASRs of DALYs, the countries furthest from the frontier line include India, Greenland, Slovenia, Belgium, and Andorra. For ASRs of YLDs, the countries furthest from the frontier line include Andorra, Belgium, Greenland, Finland, and Switzerland. Regarding ASRs of YLLs, the countries furthest from the frontier line include India, Bhutan, Cambodia, Cuba, and Vietnam. The frontier fit line for ASRs of YLDs is flatter than those of other burden indicators, denoting that the ideal ASRs of YLDs vary little across SDI levels.

Projections of Burden of Falls Among Older Adults

This study projected the global ASRs of DALYs, YLDs, and YLLs over the next 3 decades by integrating demographic forecasts from 2020 to 2050 using the Bayesian age-period-cohort model (Figure 4). The blue dots in the figure illustrate actual data from 1990 to 2021, and the red dots represent forecasts for the period spanning 2022 to 2050. Overall, the global burden exhibits a declining trend. However, the ASR of YLDs shows an upward trend, indicating that the disability burden may become the future challenge in terms of improving falls among older adults.

Figure 4. Projection of age-standardized rates (ASRs) of disability-adjusted life years (DALYs), years lived with disability (YLDs), and years of life lost (YLLs) up to 2050.

Discussion

Principal Findings

In this study, we used DALYs, YLDs, and YLLs to evaluate the overall, disability, and mortality burden of falls among individuals aged 65 years and above. APCs and average APCs of ASRs were calculated to provide insights into trends in burden from 1990 to 2021. Our findings demonstrate that the burden of falls exhibited distinct patterns according to development status. Specifically, YLDs (disability burden) were more prevalent in high-SDI regions, whereas YLLs (mortality burden) were more concentrated in low- and low-middle–SDI regions, reflecting a heavier mortality burden. Consequently, the overall burden (DALYs) followed a U-shaped distribution, with burdens being comparatively more severe at both development extremes.

The observed variations in fall-related burden across geographical regions appear to mirror the broader patterns observed across different levels of socioeconomic development. In high-SDI regions such as Australia, Europe, and North America, the high burdens are primarily driven by older population structures [26,27]. However, beyond demographics, environmental and lifestyle factors play a significant role. Higher rates of urbanization and sedentary lifestyles in these regions may contribute to age-related sarcopenia and impaired balance [28-30]. While infrastructure in high-income settings is generally superior, the urban built environment introduces unique hazards; complex public transportation systems, high-speed escalators, and dense pedestrian traffic can pose challenges for older adults with diminished reaction times [31-33]. Additionally, seasonal climatic factors significantly modulate this burden in high-latitude regions, where winter ice and snow create hazardous conditions that drive seasonal surges in fall-related fractures [34-36]. Furthermore, while health systems in these regions often demonstrate high proficiency in acute trauma surgery, potentially reducing short-term mortality, the elevated YLDs potentially point toward a relative gap in specialized geriatric rehabilitation [37-40]. This indicates that, although life-saving interventions are effective, the current infrastructure for long-term fall prevention and functional recovery might not yet fully keep pace with the needs of an increasing aging population [41-43].

In contrast, the burden observed in countries such as India and parts of the African region appears to reflect a dual pattern of persistent mortality alongside rising disability, potentially shaped by an interplay of systemic, environmental, and cultural factors [44-47]. Structurally, health system capacity may represent a significant challenge; limited emergency medical services and a scarcity of geriatric specialists are potentially associated with suboptimal clinical outcomes and higher case fatality rates following fall injuries [48]. Environmentally, natural topography and infrastructure limitations appear to play a notable role, particularly in rural settings. Older adults often navigate uneven, unpaved terrain and steep slopes, frequently without the aid of stabilized walkways or safety railings [49,50]. These risks may be further compounded by insufficient lighting in both communal and domestic spaces, which can hinder navigation for individuals with age-related visual impairments [51,52]. Additionally, domestic environments in these regions may not

XSL•FO
RenderX

always feature age-friendly modifications such as grab bars or standardized step heights [53]. Culturally, while the traditional reliance on informal family caregiving is significant, access to the specialized medical and physiotherapeutic knowledge required for effective postfall rehabilitation may be limited [54-56]. Without professional guidance on secondary prevention, these informal care structures, despite their supportive intent, might correlate with challenges in preventing recurrent falls and managing long-term disability [57,58].

The observed epidemiological transition in fall-related burdens is further elucidated by the health inequality analysis, which reveals distinct patterns between absolute gaps (country-level rates) and relative distributions (population-level volume). Regarding absolute inequality, the positive SII for DALYs and YLDs indicates that higher-SDI countries bear a greater absolute burden per 100,000 population, particularly in terms of disability. This is likely attributable to the fact that higher-income countries possess more advanced medical and nursing resources, ensuring timely intervention and survival after a fall. While these resources successfully reduce the mortality burden (YLLs), the combination of survival following injury and a higher proportion of older individuals leads to a more pronounced disability burden. Conversely, the negative SII for YLLs confirms that mortality rates remain higher in lower-income regions, where limited medical infrastructure often results in higher fatality rates following falls. From a temporal perspective, the period from 1990 to 2021 witnessed a narrowing of the absolute gaps in both disability (YLDs) and mortality (YLLs) between the most advantaged and least advantaged countries. It was observed that the absolute gap in the overall burden (DALYs) expanded during this time frame; however, this divergence should be interpreted with caution. It appears to be linked to the reduction in age-standardized DALY rates in lower-SDI countries, suggesting that the gap may be widening due to unequal rates of improvement rather than worsening outcomes [59,60].

While absolute gaps indicate disparities in rates between the highest- and lowest-income countries, the analysis of relative inequality (concentration index) provides a complementary perspective by examining how the total burden (absolute number) is distributed across the global population ranked by SDI. Notably, a near-zero concentration index for YLDs suggests a relatively even distribution of disability, and the negative concentration indexes for DALYs and YLLs underscore a persistent health inequity. This implies that, despite higher disability rates in the highest-income countries, the global volume of mortality and overall burden remains predominantly concentrated among populations in lower-income regions. This concentration of burden appears to be driven by 2 primary factors: first, lower-SDI countries often have significantly larger population sizes, meaning that even a moderate incidence rate translates into a much larger absolute number of affected individuals, and second, the dominant contribution of mortality (YLLs) in disadvantaged regions is often exacerbated by inadequate emergency response and a lack of specialized geriatric rehabilitation. Therefore, while high-SDI countries are increasingly challenged by the long-term care of survivors, the most disadvantaged populations continue to carry the heaviest cumulative weight of the burden due to high fatality rates and large population volumes.

However, this global landscape has evolved favorably over the past 3 decades, as indicated by the narrowing concentration indexes for DALYs and YLLs between 1990 and 2021, suggesting a more balanced global distribution of the fall burden. This shift may be partly attributable to the socioeconomic advancements in populous emerging economies, most notably China and India. As these countries experienced steady increases in their SDI, their massive populations gradually shifted toward higher-SDI quintiles. This demographic-economic transition has played a pivotal role in reducing relative inequality. In summary, while absolute metrics (SII) highlight an increasing disability rate in high-SDI countries as a byproduct of aging and survival, relative indexes (concentration index) emphasize that global health efforts must remain focused on the persistent inequities in lower-income areas. Thus, addressing the fall-related burden requires a dual strategy: managing the rising disability in aging, high-income societies while simultaneously tackling the high mortality burden in disadvantaged populations.

The frontier analysis identified the ideal levels of burden that countries could achieve given their stage of development. Thus, countries positioned farther from the frontier have greater potential to enhance fall prevention among older adults. The analysis also highlights which countries excel in controlling the burden of falls and which fail to meet these ideal levels. Although one might expect higher-SDI countries to more effectively manage the burden of falls in older populations, the relatively flat frontier curve for YLDs against SDI suggests little difference in ideal burden of disability between lower- and higher-SDI countries.

Projections of the fall-related burden among older adults highlight potential public health challenges in the coming decades. Although the age-standardized overall burden (DALYs) is expected to decline, the ASR of YLDs is projected to increase, suggesting that the disability burden may pose an increasingly significant future challenge. To mitigate this anticipated shift toward a disability-predominant burden, forward-looking strategies must simultaneously address 3 critical dimensions: preserving intrinsic capacity, minimizing extrinsic hazards, and generalizing system capacity.

Specifically, prevention efforts may benefit from prioritizing the preservation and enhancement of intrinsic capacity, defined as the composite of an individual's physical and mental reserves [61]. The integration of systematic screening approaches such as the World Health Organization's integrated care for older people framework into primary health care systems could facilitate the early identification of deficits in functional ability [62,63]. Crucially, screening must be coupled with targeted interventions; identifying risk is only the first step. Comprehensive management should extend to personalized lifestyle guidance, encompassing nutritional optimization to combat sarcopenia, sleep hygiene to maintain cognitive alertness, and psychological support to alleviate the fear of falling [64-66]. Subsequent individualized exercise prescriptions, such as the Otago Exercise Program or tai chi, should be implemented to improve muscle strength and balance [67,68].

XSL•FO
RenderX

This proactive continuum aims to reverse physical frailty, thereby fortifying the individual's intrinsic resilience against falls.

Complementing these active measures, policy efforts may benefit from prioritizing the reduction in extrinsic hazards through environmental modifications. Implementing universal design principles in urban planning, including barrier-free walkways and adequate street lighting, alongside subsidizing home modifications such as grab bars and nonslip flooring, is critical for supporting "aging-in-place" [69-71]. By systematically mitigating external environmental stressors, such measures can provide a passive safety buffer that operates independently of an individual's fluctuating physical condition, thereby lowering the probability of injury in daily life.

Finally, the adoption of emerging technologies offers a potential solution to generalize and extend system capacity, bridging the workforce gap in geriatric care [72,73]. Wearable fall detection sensors and tele-rehabilitation platforms could provide continuous, unobtrusive monitoring and accessible home-based training [74-77]. These technologies hold the potential to democratize access to specialized resources, supporting the delivery of fall prevention and rehabilitation services and ensuring they are available even in resource-constrained or remote settings.

Limitations

While this study provides a comprehensive global overview of fall-related burdens among older adults, several limitations warrant consideration. First, this research used a macrolevel analysis examining national data from 1990 to 2021; consequently, it did not involve in-depth clinical investigations or granular subnational analyses of individual countries. Localized heterogeneity, such as specific rural-urban disparities within a single country, unique cultural safety practices, or variations in regional infrastructure, may not be fully captured by national-level SDI metrics. Second, the findings are subject to the inherent limitations of the GBD study's primary data sources. In many low-SDI regions, vital registration systems may be fragmented or inconsistent. This can lead to potential underreporting or the misclassification of fall-related injuries. However, to mitigate these disparities, the GBD study framework uses rigorous statistical modeling methods to calibrate data inconsistencies and fill gaps. While these advanced techniques significantly reduce bias and ensure global comparability, the estimates in data-sparse regions should still be interpreted with a degree of caution. Finally, while the frontier and inequality analyses provide robust insights into global patterns, they are based on aggregated statistical models. These models describe observed trends and performance gaps but do not account for sudden shifts in health policy or major global disruptions. Future research using more granular, local-level data would be beneficial to validate these national trends and further explore the specific sociocultural drivers of the fall-related burden.

Conclusions

This study elucidates divergent patterns in the global burden of falls among older adults, consistent with an epidemiological transition: lower-SDI regions bear a predominant mortality burden (YLLs), while higher-SDI regions face an elevated disability burden (YLDs). Regarding health inequality, although the relative distribution of the overall burden (concentration index) showed signs of convergence during the study period, the absolute gap (SII) in ASRs between the most and least advantaged populations appears to persist. Furthermore, the frontier analysis indicated that potential exists for countries across the sociodemographic spectrum to further reduce their burden relative to achievable benchmarks.

Projections of the fall-related burden suggest that, while overall rates may decline, the disability burden (YLDs) is likely to pose an increasingly significant challenge in the coming decades. Collectively, these findings suggest that enhanced proactive preparedness could play a pivotal role in mitigating this anticipated future strain.

Abstract

Background: Older adults who have fallen are at an increased risk of future falls. Training cognitive and physical functions simultaneously, known as dual-task (DT) training, has been shown to improve mobility and reduce fall risks. With appropriate digital tools, such as smartphones and mobile apps, it is possible to deliver DT training in unsupervised, home-based settings, thereby increasing accessibility beyond the clinical environment.

Objective: This study aimed to evaluate the feasibility and acceptability of a technology-based DT training program delivered through a blended model of supervised and self-directed sessions for older adults with a history of falls. Perspectives of health care professionals working in fall-prevention services were also explored.

Methods: A single-arm, nonrandomized feasibility study was conducted with 45 community-dwelling adults aged 65 years or older with a history of falls. Participants were recruited through primary care practices, secondary care fall-prevention services, and community outreach. The 24-week DT program, which integrated balance and strength exercises with cognitive training using a mobile app, was delivered in two phases: (1) for12 weeks, weekly 50-minute physiotherapist-led group classes in the community, and 2 additional 50-minute self-directed sessions at home, and (2) for 12 weeks, 3 weekly 50-minute self-directed sessions at home. Feasibility and acceptability were assessed through recruitment and retention rates, adherence, app usage, and self-reported satisfaction. Qualitative data were obtained from focus groups with 28 participants who completed the program and 16 health care professionals. Quantitative data were analyzed descriptively, and qualitative data were analyzed thematically.

Results: We recruited 45 of the target 50 participants, with most participants (n=41) recruited through community pathways; 4 were recruited via National Health Service (NHS) pathways. Adherence was 64%, with higher adherence during phase 1 (81%) than phase 2 (50%). App usage was high (95%), and self-reported program satisfaction was moderate to high. Retention at 24 weeks was 76%, and no adverse events occurred. The qualitative findings supported the program's feasibility and acceptability, emphasizing social connection and tailored exercises as key to adherence—especially in home-based sessions. Health care professionals identified community organizations and referral pathways as the most practical routes for implementation.

Conclusions: A blended, technology-based DT training program is both feasible and acceptable for older adults at risk of falling and can be effectively delivered beyond clinical settings. Community-based recruitment outperformed NHS pathways, highlighting

XSL•FO
RenderX

the value of community engagement. These findings support the feasibility and acceptability of a full-scale trial, with targeted refinements to recruitment, support structures, and delivery to maximize scalability and impact.

KEYWORDS

dual-task; aging; falls prevention; exercise; cognition; older adults; technology

Introduction

Falls and fall-related injuries are a major public health concern. One in three adults over 65 years experiences at least 1 fall each year, and individuals who have already fallen are at an increased risk of falling again [1,2]. Globally, falls are the second leading cause of unintentional injury–related deaths [3], and in the United Kingdom, falls and fall-related injuries cost an estimated £4.4 billion annually [1]. It is estimated that by 2050, 1 in 6 people worldwide will be aged 65 years or older. This demographic shift highlights the urgent need for effective prevention strategies [4,5].

Evidence suggests that falls can be prevented using appropriately prescribed exercise programs. Aging affects not only balance but also cognition, and domains such as attention, memory, and executive function are linked to mobility [6]. Dual-task (DT) training, which combines physical and cognitive exercises simultaneously, has been shown to improve walking speed, executive function, and balance and reduce fall risk in older adults [7,8]. Several lines of evidence suggest that training motor and cognitive function simultaneously, that is, DT training, is superior to single-task (balance or resistance) training or no training for improving mobility, global cognition, and reducing fall rates [9-11], leading to a better quality of life [12]. Training cognition and physical function simultaneously rather than sequentially is more beneficial [13,14]. Simultaneous cognitive and physical training can be delivered via technology (eg, mobile apps), enabling professionals to select cognitive exercises that are suitable to be combined with balance exercises, allowing DT training to be delivered unsupervised at home. Mobile apps are interactive, provide instant feedback, and can send reminders to users. These features promote engagement and adherence to exercise [15-17]. Emerging evidence supports the remote delivery of balance and strength exercise training using technology for falls prevention in older adults [18-20]. For example, a smartphone app delivering an unsupervised, home-based DT program to community-dwelling older adults without a history of falls showed feasibility, high adherence, and improved balance [20]. However, it remains unclear whether older adults with a history of falls, who are at greater risk of recurrence, would be willing or able to engage in an unsupervised, technology-supported DT exercise program. Additionally, the potential role of such programs within existing health care services is uncertain. Current services often cater to frailer individuals with multiple comorbidities who typically require close supervision [21], raising questions about the feasibility of recruitment solely through fall-prevention services as well as whether technology-supported DT training is better delivered in clinical or community settings.

The objectives of this study were to evaluate (1) the feasibility of recruiting and retaining community-dwelling older adults with a history of falls in a blended DT program combining supervised and self-directed sessions supported by technology; (2) the acceptability of the program to participants; (3) its potential effects on mobility, cognition, fall risks (eg, number of falls, fear of falling), quality of life, and use of health care resources; and (4) health care professionals' perspectives on integrating a blended DT program into existing care pathways for older adults.

Methods

Study Design

This was a prospective, single-arm, nonrandomized feasibility study. The study protocol has previously been published [22]. The study is reported according to the CONSORT (Consolidated Standards of Reporting Trials) pilot and feasibility trials checklist (Checklist 1).

Ethical Considerations

The study received ethical approval from the Health Research Authority East of England – Cambridge East Research Ethics Committee (Reference: 24/EE/0059) and was registered with ISRCTN (ISRCTN15123197; April 16, 2024). All participants provided written informed consent and were assigned a unique study ID to ensure anonymity. Personal data were stored securely on password-protected University of Birmingham servers, with identifiable information accessible only to authorized members of the research team and managed in accordance with the Data Protection Act 2018, UK General Data Protection Regulation, and relevant research governance frameworks. Participants were reimbursed for travel expenses associated with study participation.

Recruitment

Recruitment took place in 3 periods—May to August 2024, October to November 2024, and March to May 2025—to align with program delivery schedules and public holidays. Participants were recruited through text messages or invitation letters from general practitioners and hospital fall-prevention clinics, and community outreach (eg, retirement villages, charities, interest groups) using open events and study flyers. All participants received the intervention in the gym of the partnering retirement villages and community well-being and leisure centers.

XSL•FO
RenderX

Participants

The sample size (n=50) was chosen based on the recommendations of published literature for feasibility studies [23-25]. If we approach 100 eligible participants, we will be able to estimate a participation rate of 50% (green stop-go criteria; see Table 1) within a 95% CI of ±9.8%. With a sample size of 50 participants, we will be able to estimate an attrition rate of 20% (green stop-go) within a 95% CI of ±11%. Inclusion criteria included community-dwelling adults aged 65 years or older who had experienced at least 2 falls in the past year (including near misses); had access to a smartphone or tablet; could stand with 1-hand support on their usual walking aid for at least 60 seconds; could stand up from a chair and walk 6 m independently with their current walking aid; were self-toileting; and demonstrated sufficient cognition, hearing, and vision to follow the instructions for the assessment and exercise program. Exclusion criteria included medical conditions precluding safe exercise participation and current participation in another research study involving a fall-prevention intervention. Health care professionals involved in services for older adults within the study regions were recruited to participate in qualitative focus groups or one-to-one interviews.

Table . Stop-go criteria.

	Criteria
Green	Recruitment ≥50%; adherence ≥80% (ie, completion of at least 58 out of 72 prescribed sessions over 24 weeks); and retention ≥80%. Qualitative data confirm the intervention being feasible and acceptable, with no safety concerns identified.
Amber	Recruitment: 30%-49%; adherence: 50%-79%; and retention: 50% - 79%. Qualitative data indicate that modifications to program design or delivery are needed, but no safety concerns identified.
Red	Recruitment: <30%; adherence: <50%; and retention: <50%. Qualitative data do not support progression to a larger-scale randomized controlled trial and/or indicate unresolved safety concerns.

Dual Task Exercise Program

All participants underwent the 24-week DT exercise program, consisting of 2 phases:

- Phase 1 (weeks 1 - 12): weekly 50-minute physiotherapist-led group sessions (4 - 8 participants per group) and two 50-minute home-based sessions, which replicated the class exercises but were completed independently and unsupervised.
- Phase 2 (weeks 13 - 24): three weekly 50-minute home-based sessions, guided by a structured exercise plan provided by the research team.

Each session included a 5-minute warm-up, 20-minute DT exercises (static balance or strength exercises while engaging with cognitive games using the commercial *Peak Brain Training* app [26]; Supplementary Material 1 in Multimedia Appendix 1), 20-minute dynamic balance and strength training, and a 5-minute cool-down. The app was used on participants' smartphones or tablets, positioned on adjustable stands for ease of use.

All participants received a handbook with detailed exercise instructions and had access to online videos demonstrating the balance and strength exercises. Participants recorded weekly adherence in an exercise diary. At the end of phase 1, an in-person education session was provided to reinforce fall awareness and explain the program content in phase 2. Participants could contact the research team for technical support with the app as needed. A TIDieR (Template for Intervention Description and Replication) checklist is presented in Checklist 2. The intervention was co-designed with members of the patient and public involvement and engagement (PPIE) group, particularly regarding the selection of cognitive games to ensure they were appropriate and engaging for older adults. The PPIE group also helped refine program components intended to promote social interaction and engagement, including strategies for maintaining contact during the home-based phase.

Outcome Measures

Overview

The primary outcome measures were the feasibility and acceptability of the program, assessed through:

1. Recruitment rate: calculated as (number recruited via National Health Service [NHS] pathways/number of patients approached by primary and secondary care teams)×100. Recruitment via community pathways was excluded due to unquantifiable outreach.
2. Adherence: calculated as (class attendance +self-reported home-based sessions)/(total prescribed sessions)×100. It was reported separately for phase 1, phase 2, and overall.
3. Retention rate: calculated as (number of participants completing the study/number consented) × 100. Completion was defined as attendance at the postintervention assessment.
4. Acceptability: assessed via a mixed methods exit survey administered at the end of phase 1 (wk 12) and phase 2 (wk 24). The survey comprised structured closed-ended items to capture quantitative data on usability, satisfaction, and perceived effectiveness, alongside open-ended free-text fields designed to elicit qualitative insights into participants' experiences and perspectives.

Stop-Go Criteria

Predefined stop-go criteria [22] were used to provide guidance on whether the project should progress to a full trial with an

XSL•FO
RenderX

internal pilot (green), progress to a full trial with an internal pilot with adaptation (amber), or no progression (red; Table 1).

Data were also collected on the following outcomes before and after the intervention. These were possible primary and secondary outcome measures for the main trial, so this enabled the assessment of data collection methods and data completeness of these measures, and exploratory data analysis:

1. Mobility and balance were assessed using the Timed Up and Go (TUG) test and TUG with a DT version of concurrent cognitive task (TUG-Cog), where participants counted backward by 7 from a randomly selected number between 100 and 200. The time taken to complete the test was recorded. All participants first completed 1 familiarization trial, followed by 1 recorded trial for the TUG and 1 recorded trial for the TUG-Cog.
2. Cognitive function was assessed by the total score of the 12-item Everyday Cognition (ECog-12) scales short version [27,28].
3. Fear of falls was assessed by the total score of the Falls Efficacy Scale-International (FES-I) questionnaire [29].
4. Health-related quality of life was assessed using the EQ-5D-5L [30].
5. Usage of health care resources was self-reported using ModRUM [31].
6. Self-reported number of falls in the last 6 months.

TUG and TUG-Cog were assessed in person by an experienced physiotherapist; all other outcomes were collected using a REDCap (Research Electronic Data Capture; v15.4.3) online survey. Survey links were sent to participants 1 week before the intervention and again in week 24, with up to 3 reminders to facilitate response rates. Paper copies were provided to participants upon request.

At baseline, demographic information was collected, including age, sex, ethnicity, level of education, area deprivation (Index of Multiple Deprivation), and type of residence. Frailty was assessed retrospectively using the Clinical Frailty Scale [32] to characterize the participant cohort in this feasibility study and to provide insight into the types of individuals for whom the intervention may be feasible and appropriate. An experienced geriatrician (DW) determined a frailty score following a detailed review of the demographic and functional data alongside a discussion with the team using the Clinical Frailty Scale [33].

Qualitative Methods

Focus Groups

Ten focus group semistructured interviews with 28 participants who completed the DT program (2 - 5 participants per group) were conducted. The focus groups were constructed to provide explanatory data on the study objectives (Supplementary Material 2 in Multimedia Appendix 1). Additionally, 4 online focus groups (n=12) and 4 online one-to-one interviews (n=4) were conducted with health care professionals (12 were physiotherapists, 1 occupational therapist, 1 general practitioner, 1 consultant geriatrician, and 1 research nurse) using a semistructured interview guide (Supplementary Material 2 in Multimedia Appendix 1). Focus groups were led by a member of the research team (PM), took place at the same venues as the exercise classes, were audio-recorded, and later transcribed verbatim. Online interviews were conducted using Microsoft Teams and were transcribed using the Microsoft Teams function. The interviews with the participants and health care professionals lasted between 45 and 80 minutes and 25 and 70 minutes, respectively.

Exit Surveys

Data were also collected from participants at the end of each program phase using an exit survey, which included both quantitative satisfaction ratings (Likert-scale items) and qualitative feedback from 8 open-ended questions. The questions were related to perceived benefits from the program, the experience of using the PEAK app while dual tasking, and recommendations for improving program delivery (Supplementary Material 3 in Multimedia Appendix 1).

Qualitative Data Analysis

Data from the focus groups and exit surveys were organized using NVivo 14 (Lumivero). Framework analysis was applied to the dataset to guide the examination of the study objectives, while also allowing for the identification of unanticipated themes and insights that emerged during the analytical process [34]. The data were initially coded deductively by members of the research team (PM, AS, and SYC) using a set of predefined categories that had been agreed upon in advance. These categories were directly aligned with the study objectives and included engagement and adherence, app usability, and retention. Once the data were organized according to these categories, an inductive approach was used to explore and identify additional factors contributing to each of the main categories. The coding process was led by PM and SYC, and a deliberative strategy [35] was used to enhance rigor. This involved multiple researchers (PM, SYC, AS, VAG) collaboratively reviewing and discussing the codes to refine interpretations and develop overarching themes. PPIE members also contributed to the interpretation of the focus group findings, providing perspectives that helped contextualize participants' experiences and identify practical implications for program delivery.

The explanatory themes were organized within the main categories identified through the framework analysis, which aligned with the study's objectives. These qualitative findings were then integrated with the descriptive quantitative analysis during the reporting phase. To ensure analytical rigor, a relativist approach to quality was applied, guided by key criteria including breadth, credibility, and coherence in the study design [36].

Quantitative Data Analysis

The analysis undertaken within this feasibility study was mainly descriptive. The progression criteria in the stop-go were summarized as proportions or means along with 95% CIs. The number of days of exercise and the number of physical exercises and cognitive games completed and recorded in the exercise diaries during the program were summarized to describe the adherence and usage of the app. To understand any change in the usage of the app between phase 1 and phase 2, we assessed the number of cognitive games completed in phase 1 and phase 2 separately.

XSL•FO
RenderX

The data collected on proposed outcome measures (eg, TUG) were summarized at baseline and follow-up using appropriate summary statistics. Exploratory analysis using a paired *t* test or Wilcoxon signed-rank test (depending on the distribution of the data) was undertaken to provide an exploratory assessment (using CIs; no *P* values are reported) of the effect of the blended intervention. All analyses were conducted in IBM SPSS Statistics (version 29; IBM Corp., 2022).

Results

Participant Recruitment

Forty-five older adults were recruited: 41 (91%) from community sources and 4 (9%) through NHS pathways (Figure 1). Community recruitment involved 10 retirement villages, 19 local activity groups, 8 instructors, and the Birmingham 1000 Elders mailing list, using open events and flyer distribution. As these approaches were open-access and did not involve direct invitations or approaches, it was not possible to determine the number of individuals exposed to the study information or formally approached. Therefore, a conventional recruitment rate (approached vs consented) could not be calculated for the community pathway. In the NHS recruitment pathways, 155 potential participants were identified through general practitioner surgeries (n=105) and secondary care falls clinics (n=50), but only 4 were enrolled (2.6%; 95% CI 0.7% - 6.5%), meeting the red stop-go criteria (Table 2-4). Nonparticipation was mainly due to health concerns, travel distance, or lack of a suitable device (eg, smartphone).

Figure 1. Flowchart. GP: general practitioner; NHS: National Health Service.

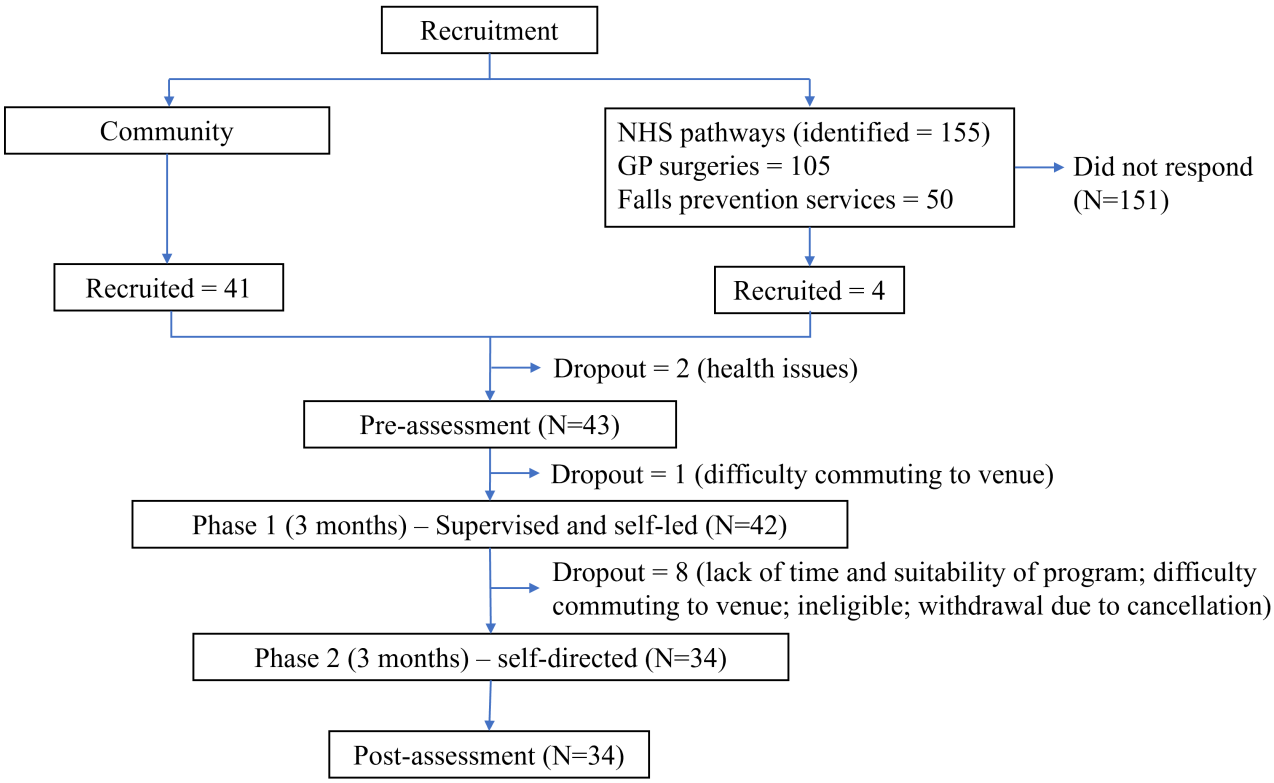

Table . Feasibility study outcomes and the stop-go criteria.

Outcome	Values; stop-go criteria	Full stop-go criteria
Recruitment rate from the NHS[a] pathways	Proportion 3% (95% CI 1% - 7%); red (red to red)	Green: ≥50%; amber: 30% - 49%; red: <30%
Adherence	Median 64% (IQR 46% - 82%; 95% CI 53% - 72%); amber (amber to amber)	Green: ≥80%; amber: 50% - 79%; red: <50%
Retention rate	Proportion 76% (95% CI 60% - 87%); amber (amber to green)	Green: ≥80%; amber: 50% - 79%; red: <50%

[a]NHS: National Health Service.

XSL•FO

Table . Median adherence in each phase and overall.

Phase	Number of actual exercise days, median (IQR; 95% CI)	Adherence (%), median (IQR; 95% CI)
Phase 1	27 (24 - 31; 22 - 29)	81 (67 - 87; 64 - 82)
Phase 2	18 (14 - 21; 14 - 23)	50 (17 - 83; 39 - 65)
Phase 1+2	46 (33 - 57; 37 - 51)	64 (46 - 82; 53 - 72)

Table . Number of physical exercises and cognitive games completed (in each phase and overall).

Phase	Number of physical exercises completed, median (IQR; 95% CI)	Number of cognitive games completed, median (IQR; 95% CI)
Phase 1	156 (122 - 148; 123 - 167)	78 (69 - 92; 63 - 85)
Phase 2	137 (73 - 190; 94 - 162)	67 (36 - 96; 44 - 80)
Phase 1+2	275 (194 - 338; 224 - 322)	133 (98 - 174; 111 - 161)

The program consists of 3 exercise days per week in each phase (12 weeks); the total number of prescribed exercise days is 36 in each phase (Table 3). Participants are prescribed 6 physical exercises and 3 cognitive games in a week in each phase; the total number of prescribed physical exercises and cognitive games in each phase is 216 and 108, respectively (Table 4).

Sample Characteristics

The mean age of the participants was 78.3 (SD 7.6) years, and the majority were female participants (n=31, 68.9%). The number of participants recruited from sheltered and private accommodation was 13 (28.9%) and 32 (71.1%), respectively. The median Index of Multiple Deprivation score was 4 (IQR 1-10). The majority of the participants were White British (n=42, 93.3%). All participant characteristics as well as the characteristics of participants contributing to the qualitative study are presented in Table 5.

XSL•FO
RenderX

Table . Participant characteristics for all participants (N=45) at baseline and for participants (n=28) who took part in the focus groups.

Characteristics	All participants	Participants in focus groups

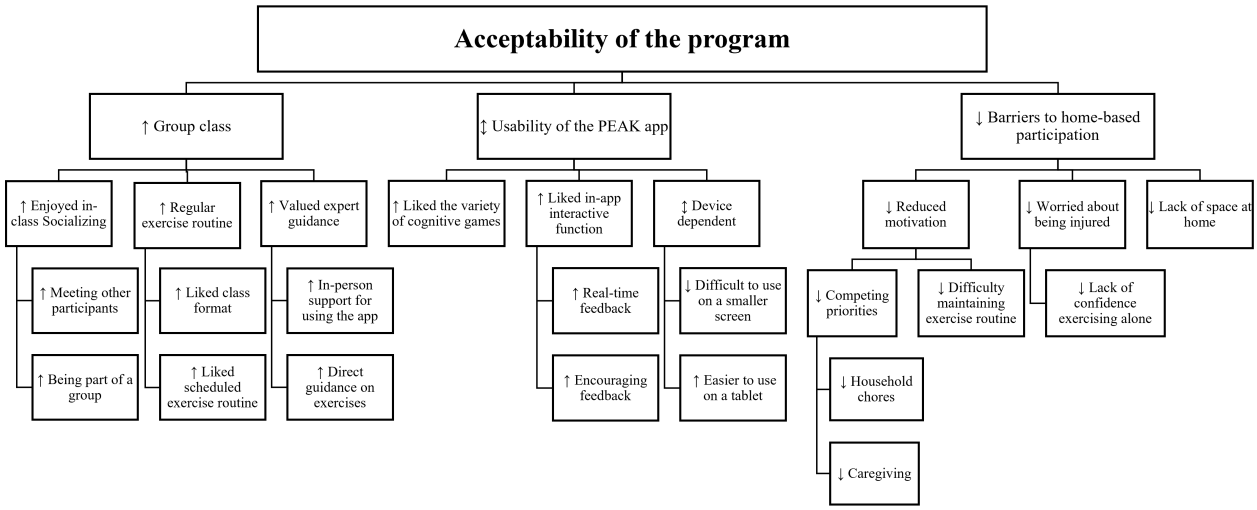
[g]This variable corresponds to the first item of the Modular Resource-Use Measure; the full results are reported in Supplementary Material 5-6 in Multimedia Appendix 1.

Study Retention

Thirty-four of the 45 participants completed the study, giving a retention rate of 76% (95% CI 60% - 87%), which met the amber stop-go criteria (Tables 2-4). A total of 11 participants did not complete the trial. Three withdrew after providing consent but before commencing the intervention due to health issues (n=2) and difficulty commuting to the venue where exercise classes were scheduled to take place (n=1). A further 8 participants withdrew during the intervention phase. Five withdrew due to time constraints or because they felt the program was not suitable for them. One participant was later deemed ineligible due to severe balance issues. Two additional participants were recruited during a third recruitment round; however, one of them withdrew after the first session because the venue was too far from their home. As this left only 1 participant in that group, the planned group sessions could not

XSL•FO
RenderX

proceed, and the final participant was therefore withdrawn from the study (Figure 1).



Adherence and Acceptability of the Intervention

Overall adherence to the program was 64% (95% CI 53% - 72%), meeting the amber stop-go criteria (Tables 2-4). On average, participants completed 46 days (95% CI 37 - 51) of combined cognitive and physical exercises out of the 72 days prescribed. Of the 432 prescribed physical exercises and 216 prescribed cognitive games, participants completed 275 physical exercises (64%, 95% CI 224 - 322) and 133 cognitive games (62%, 95% CI 111 - 161), respectively. These results indicate that participants engaged with and completed the intervention largely as intended. Adherence was higher in phase 1 (27 out of 26 days, 81%), which combined supervised and self-directed sessions, compared with phase 2 (18 out of 36 days, 50%), which was entirely self-directed. Within phase 1, supervised class attendance was 81% (9 out of 12 classes), and adherence to home-based sessions was 79% (18/24 home sessions). Difficulty finding time for weekly exercises was noted by 17% (n=5) of the participants in phase 1 and 41% (n=12) in phase 2. Adherence to the PEAK app was 95% (n=32). Participants valued its flexibility (n=23, 69%), although the proportion reporting ease of use declined from 59% (n=17) at the end of phase 1 to 34% (n=10) at the end of phase 2. No adverse events were reported.

The results of the exit survey highlighted that the median perceived program benefit was 7 out of 10 (1=not beneficial; 10=very beneficial). To explore whether perceived benefit influenced adherence, participants were divided into 2 groups based on this median score. Those who rated the program as highly beneficial (score ≥7) demonstrated higher adherence (n=15, 83%; median 33.3, IQR 63.9-97.2) compared to those with lower perceived benefit (score <7; n=13, 36%; median 27.8, IQR 16.7-44.4). Just over half (52%) of the participants agreed that integrating the app into the blended digital therapy program was a good way to improve balance. The majority (n=25, 86%) expressed satisfaction with the support received from both the research team and the physiotherapist. On average, participants reported a 6 out of 10 likelihood of continuing the program after the study concluded. The full results from the exit survey are available in Supplementary Material 3 in Multimedia Appendix 1.

Qualitative findings reinforced the quantitative results, highlighting social interaction as key to participant engagement (Figure 2—thematic tree). Group classes were valued for structure, motivation, enjoyment, and social connection, while the unsupervised phase saw reduced motivation and adherence due to competing priorities. Participants appreciated app features such as age-based rankings and the variety of cognitive games, though some struggled with small smartphone screens. Barriers to home exercise included limited space, low confidence, inappropriate difficulty levels, and concerns about joint pain. Illustrative quotes are provided in Supplementary Material 4 in Multimedia Appendix 1.

Figure 2. Thematic tree from the focus group with participants. Symbols indicate positive (↑), negative (↓), and neutral (↕) feedback.

Participants appreciated the feedback features (eg, ranking within age group, positive reinforcement) of the app and the variety of cognitive games, many of which were perceived as appropriately challenging. Challenges included difficulty using the app on smaller screens of smartphones.

Exploratory Analysis of Proposed Outcome Measures

The TUG is the planned primary outcome for the proposed future trial. Both TUG and TUG-Cog scores decreased after the program (Table 6). The FES-I scores decreased following the program, suggesting a reduction in fear of falling; changes in the category of the FES-I [29] at postassessment are presented in Table 7. There was no change in ECog-12 scores, but there were decreases in EQ-5D-5L tariff and VAS scores (Table 6). The completion rates for TUG and TUG-Cog were 93.94%, and for ECog-12, FES-I, Modular Resource-Use Measure, and EQ-5D-5L, the rates were 98.5%.

Table . Exploratory data analysis of proposed outcomes for the full trial.

Outcomes	Preassessment	Postassessment	95% CI of the difference
TUG[a] (s; n=31), mean (SD)	10.32 (4.17)	8.80 (5.74)	−0.94 to 0.99
TUG-Cog[b] (s; n=31), mean (SD)	12.13 (7.66)	11.51 (8.52)	−1.90 to 0.94
ECog-12[c] (points, n=33), mean (SD)	1.57 (0.36)	1.52 (0.39)	−0.21 to 0.48
FES-I[d] (points, n=33), mean (SD)	29.50 (11.25)	25.00 (9.75)	−5.50 to −1.50
High concern, n (%)	20 (60.61)	14 (42.42)	—[e]
Moderate concern, n (%)	12 (36.36)	13 (39.39)	—
Low concern, n (%)	1 (3.03)	6 (18.18)	—
Number of falls in last 6 months (n=33), median (IQR)	2 (0 - 8)	0 (0 - 10)	—
EQ-5D-5L[f] tariff (n=33), mean (SD)	0.675 (0.191)	0.652 (0.212)	−0.316 to 0.367
EQ-5D-5L VAS (n=33), mean (SD)	73.79 (16.91)	71.30 (17.54)	−0.13 to 0.56
Number of A&E[g] visits (sum, n=33)[h]	16	10	−0.5 to 0.00

[a]TUG: Timed Up and Go test (seconds; lower scores indicate better mobility).

[b]TUG-Cog: Timed Up and Go test with a concurrent cognitive task (seconds; lower scores indicate better dual-task performance).

[c]ECog-12: The Everyday Cognition scales short version (higher scores indicate greater perceived cognitive difficulty).

[d]FES-I: Falls Efficacy Scale International (higher scores indicate greater fear of falling).

[e]Not applicable.

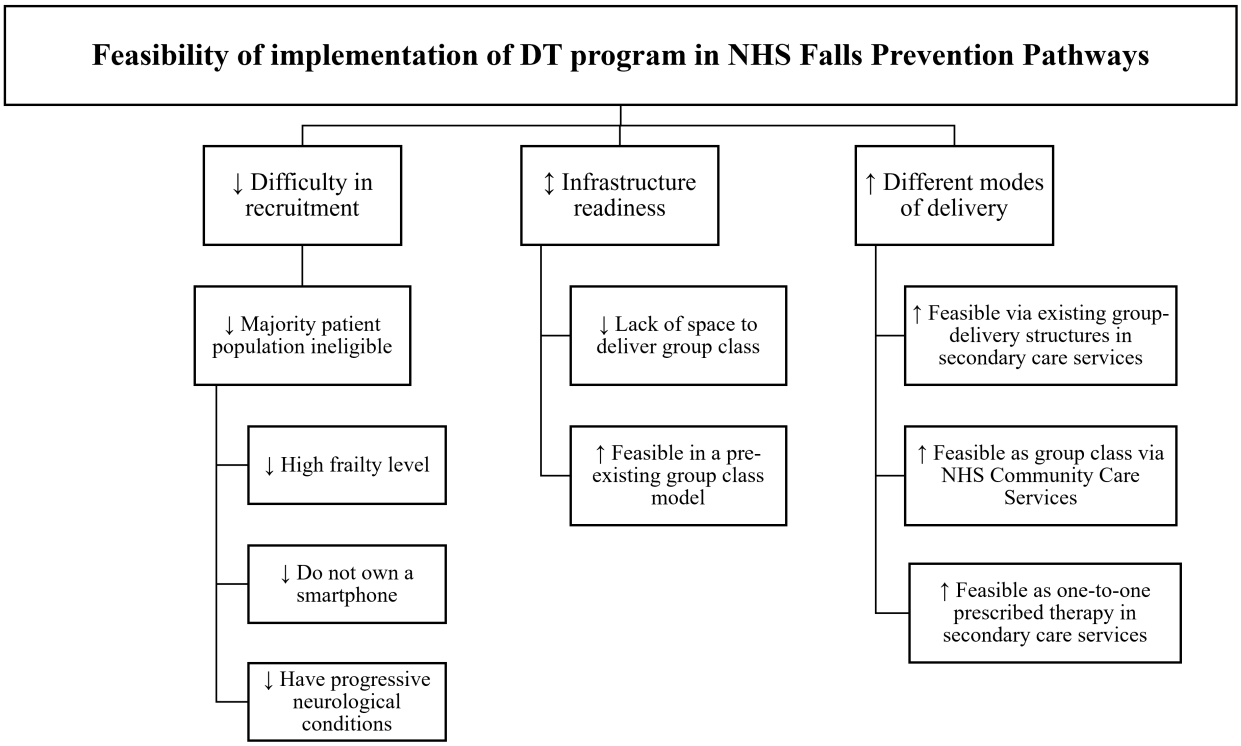
[f]Higher scores indicate better health-related quality of life.

[g]A&E: accident and emergency.

[h]This variable corresponds to the first item of the Modular Resource-Use Measure; the full results are reported in Supplementary Material 5-6 in Multimedia Appendix 1.

Table . Changes in the category of Fall Efficacy Scale–International (FES-I)[a].

FES-I cutoff scores	Postassessment		
	High	Moderate	Low
Preassessment			
High[a]	11	2	7
Moderate	0	1	0
Low	3	3	6



[a]High concern: 28 - 64; moderate concern: 20 - 27; low concern: 16 - 19 [29].

Implementation of the Intervention in Health Care and Community Pathways

A thematic tree illustrating the qualitative results is presented in Figure 3. Health care professionals viewed recruitment from the NHS as challenging, as many patients attending fall-prevention clinics were too frail, had comorbidities (eg, syncope), lacked the capacity for unsupervised balance exercises, or did not have access to suitable devices for cognitive training. Several suggested widening recruitment beyond falls services to include people under 65 years or those beginning to notice balance difficulties, allowing issues to be managed earlier.

XSL•FO
RenderX

Figure 3. Thematic tree from the focus group with health care professionals. Symbols indicate positive (↑), negative (↓), and neutral (↕) feedback. DT: dual-task; NHS: National Health Service.

Implementation was seen as dependent on hospitals. Hospitals already offering group classes were viewed as best suited for integration, while those without such provisions were less likely to consider adopting the program. One-to-one delivery was seen as a possible option if supported by evidence and a wider range of exercise levels to enable personalization. Many professionals also emphasized that delivery through community organizations, accessed via health referral pathways, would reduce travel demands for older adults. Qualitative quotes are in Supplementary Material 4 in Multimedia Appendix 1.

Discussion

Principal Findings

This study demonstrates that a blended, technology-supported DT training program can be both feasible and acceptable for older adults who have experienced at least 2 falls in the past 12 months (including near misses). The combination of supervised group sessions and self-directed home training was well received, with digital engagement enhanced by appropriate support. With design modifications to improve adherence and retention, DT training can be effectively delivered in community settings, representing a shift from clinic-based rehabilitation models that typically rely on one-to-one supervised, therapist-led exercise interventions [37].

The study's key contribution lies in demonstrating that complex interventions, such as DT training, can be adapted for scalable, community-based formats that integrate digital health technologies. This approach has the potential to extend the reach of evidence-based fall-prevention strategies and support their integration into routine community health care pathways.

Participant Recruitment

Recruitment via NHS fall-prevention and primary care pathways—using emails, letters, or texts—was difficult and met the red stop-go criteria. This aligns with prior trials on the physical health of older adults reporting low general practitioner recruitment rates (~6%) [38-40]. Recruiting older adults into exercise studies is widely recognized as challenging. Many older adults experience complex health needs, chronic pain, and multiple comorbidities, all of which may limit their capacity or willingness to participate in research [41]. In our study, health care professionals within NHS Falls Prevention Services also reported a limited pool of eligible participants. Many of their patients were frail, dependent on caregivers, or living with progressive neurological conditions, such as dementia, which restricted their ability to safely participate in group-based or self-directed, unsupervised exercise programs. The literature further highlights several barriers to recruiting older adults into exercise studies. These include social stigma associated with programs targeted at "older people" or " fallers", logistical barriers such as transportation, concerns about the demands or expectations of participation [42-44], and protective attitudes from family members [41].

To address these challenges, we suggest several strategies for future trials. These include working with patient groups to develop more acceptable and inclusive language when describing the study, forming partnerships with community organizations to help address logistical barriers, and framing study aims in ways that appeal to older adults with diverse motivations for participation.

Limited contact (a single invitation) and ethical restrictions on reminders likely contributed to our low response rate. Evidence

XSL•FO
RenderX

supports the use of multiple prompts [41], and Cochrane reviews recommend telephone follow-up reminders in low-response trials [42].

Despite limited success with NHS-based recruitment, the study did enroll 45 of the planned 50 participants (90% of the target), the majority (41/45) through community-based strategies. Face-to-face events and flyers distributed via local organizations were more effective, with in-person engagement supporting informed decision-making—especially important for digital interventions unfamiliar to some older adults [45].

Although NHS-based recruitment met the red stop-go criteria, the study still achieved 90% of its recruitment target, primarily through community routes—demonstrating feasibility for a larger trial. Expanding recruitment to include services such as frailty front door services and fracture liaison services could enhance reach and inclusivity.

Study Retention

Retention met the amber stop-go criteria, indicating a need for trial design modifications. The main reasons for withdrawal were the distance of class venues from participants' homes and perceptions that the program was not sufficiently tailored to individual needs. Classes were scheduled at different times of the day but were restricted to a single day each week due to limitations in staff availability and venue costs. Increasing delivery resources and expanding venue options could improve accessibility and retention [46]. Additionally, incorporating greater flexibility and personalization may boost relevance and continued engagement [47].

Adherence and Acceptability of the Intervention

Adherence met the amber stop-go criteria, indicating the need for trial design modifications—particularly for the unsupervised home-based phase. Consistent with previous evidence, adherence to home-based exercise was lower compared with the group-based programs, particularly when structured supervision and support were reduced [38,48-50]. For comparison, a meta-analysis of community-based group exercise reported an average adherence of 69% (SD 14.6) [51]. Participants valued the motivation, enjoyment, and accountability of supervised group classes but reported reduced motivation, competing priorities, and difficulties sustaining routines once the program became self-directed. Other programs with ongoing support (eg, coaching [52], follow-up calls [19]) have achieved higher adherence rates (75% and 85%, respectively).

Social interaction emerged as a key driver of engagement with participants, suggesting that peer-support groups; virtual group sessions; and reminders via text, phone calls, or app notifications could help support longer-term engagement. Additionally, in-app feedback and a sense of progress also supported adherence [53].

These findings highlight that continuous support, rather than delivery format alone, is key to sustaining engagement among older adults. While supervised sessions help build initial confidence, long-term adherence depends on ongoing social interaction, feedback, and motivational support. Incorporating continuous support mechanisms—delivered in person, virtually, or through structured follow-ups—can help maintain participation and maximize program effectiveness over time.

Implementation of the Intervention in Health Care and Community Pathways

Health care professionals' views on implementing the DT program within NHS services were shaped by patient profiles and infrastructure. According to National Institute for Health and Care Excellence guidelines on falls assessment and prevention, patients referred to fall-prevention clinics are typically frail, present with multiple comorbidities, or have impaired mobility [21]. These individuals often require close supervision (eg, one-to-one delivery) and are therefore not well suited to a program that includes group-based and unsupervised components. The findings from the qualitative data suggest that clinicians in fall-prevention services tended to view this supervised and self-directed technology-based DT program as more appropriate for preventive care in at-risk populations, rather than as a treatment option for those already attending specialist services.

While established programs (eg, Otago and Falls Management Exercise) primarily target physical components of falls risk (eg, strength and balance), the DT program additionally trains executive functions such as attention allocation and task switching during movement—skills that are important for navigating real-world environments where falls often occur during multitasking. This approach may complement existing programs by addressing cognitive-motor demands that are not explicitly targeted in the existing interventions.

In contrast, clinicians working in preventive pathways reported that many of their patients could benefit from the program and were more receptive to its integration into the NHS. Infrastructure was also identified as a key factor influencing implementation. The findings from the qualitative interviews indicated that a lack of space for group classes was commonly cited by health care professionals as a barrier to implementation, whereas services with existing exercise programs expressed greater readiness to adopt the intervention (Figure 3). While the intervention in this feasibility study was delivered by physiotherapists from NHS Falls Prevention Services, health care professionals indicated that, in routine practice, the program could be delivered by appropriately trained exercise professionals, such as therapy assistants or support workers, personal trainers, and qualified community-based exercise instructors. Embedding the program within primary care and community-based infrastructures—such as Primary Care Network referral pathways, social prescribers, local support groups, and leisure providers—offers a scalable, sustainable model aligned with evidence supporting high-dose, balance-challenging exercise [54] and may enhance accessibility and adherence through community engagement and health care referral pathways. These settings often already use qualified instructors and provide accessible venues, which may facilitate wider reach and long-term delivery.

Strengths and Limitations

A key strength of this feasibility study was its mixed methods approach, which added valuable context to the quantitative

XSL•FO
RenderX

outcomes. High completion rates of the exploratory outcome measures among participants who completed the study (>90%) support the suitability of the data collection methods used in this study for older adults. However, the participants recruited lacked ethnic diversity and were skewed toward participants with higher education. While exercise frequency was captured via participant diaries, we did not collect data on exercise intensity (eg, heart rate, perceived exertion) or exercise quality during independent home sessions. This limits our ability to fully assess intervention fidelity and determine whether differences between phases may have been influenced by variations in exercise dose or execution. Future trials should incorporate objective or structured monitoring of home-based exercise intensity and quality to strengthen fidelity assessment. Furthermore, conducting the study exclusively in English—due to funding constraints—also limited inclusivity. Future trials should consider translation services to improve representativeness and reach.

Conclusions

This feasibility study shows that a blended DT training program is acceptable to older adults and can be delivered outside clinical settings. Adherence declined when participants were without direct supervision, highlighting the importance of ongoing support and social connectedness for sustained engagement. Community-based recruitment outperformed NHS pathways, and health care professionals identified community organizations and referral schemes as the most viable implementation channels. Overall, these results support progression to a full trial with adaptations to recruitment strategies, support mechanisms, and delivery pathways to enhance feasibility and scalability.

Acknowledgments

The authors are grateful to all the study participants for their time and generosity. They also thank the Hawkesley Community Centre and Longbridge Retirement Village for kindly providing venues free of charge. Special thanks go to Liz Hensel and Tom Tierney for their valuable contributions on the intervention design and results interpretation as members of the patient and public involvement and engagement group.

Funding

This project is funded by the National Institute for Health and Care Research under its Research for Patient Benefit Programme (grant NIHR205389). The views expressed are those of the author(s) and not necessarily those of the National Institute for Health and Care Research or the Department of Health and Social Care.

Abstract

Background: Higher step width variability while walking is associated with poor physical function and falls. Sleep is an established modifiable risk factor for both gait and physical function impairments, but it remains to be examined whether sleep is also related to step width variability.

Objective: This study aimed to evaluate the cross-sectional associations between objectively measured sleep quality, using cardiopulmonary coupling spectrograms, and step width variability during a preferred walking condition among middle-aged and older adults.

Methods: This study included 72 adults (mean age 71, SD 8.3 y; n=37, 51% female; n=65, 90% non-Hispanic White) who had ≥2 nights of objectively measured sleep (cardiopulmonary coupling via SleepImage ring) and completed a 10-m walk at preferred speed while wearing inertial sensors (APDM Mobility Lab). Sleep measures included sleep duration, efficiency, fragmentation, stability, apnea-hypopnea index, percentage of time oxygen saturation level <90%, oxygen desaturation index, and respiratory disturbance index. Additional derived sleep variables were explored using least absolute shrinkage and selection operator models. Step width variability was defined by the asymmetry of lateral step variability and categorized as medial (≤−7.5 cm), minimal (within ±7.5 cm; reference), or lateral displacement (≥7.5 cm). Multinomial logistic regression models adjusted for age, sex, race, education, BMI, and usual gait speed evaluated cross-sectional associations between sleep and step width variability categories.

Results: We found that a 1% higher sleep fragmentation was associated with a 6% higher probability of step width variability ≥7.5 cm (95% CI 1.01 - 1.11), while a 1% higher sleep stability was associated with a 5% lower probability of variability ≥7.5 cm (95% CI 0.91 - 0.99), compared to minimal variability. From the least absolute shrinkage and selection operator models, we found that a 1% higher sleep quality index, a 1% higher rapid eye movement sleep, a 1-second shorter apnea duration, and a 1-beat per minute slower mean heart rate were also associated with a lower probability of lateral compared to minimal displacement.

Conclusions: Poor sleep quality was associated with higher step width variability among middle-aged and older adults. This suggests that sleep may be a modifiable risk factor for maintaining postural stability while walking among middle-aged and older adults. Future studies are needed to examine whether intervening in these sleep measures also lowers the risk of falls.

Introduction

Ambulating within one's environment is a complex task that requires cognitive coordination of the motor, vestibular, proprioceptive, and sensory systems [1]. This is typically an automatic task that has low variability [1,2]. Variability in gait reflects stride-to-stride fluctuations in parameters such as gait speed, stride length, step time, and other spatiotemporal characteristics [2]. Gait variability tends to increase with age as ambulation becomes less automatic [3,4]. A key variability measure is step width variability, which reflects dynamic postural control and balance [5-7]. Alterations in gait spatiotemporal characteristics, such as step width variability, impact gait biomechanics. Indeed, variations in step width are associated with alterations in stride time, step length, lower extremity muscle activity, as well as rearfoot, ankle, joint (eg, knee, hip), or trunk kinematics, all of which are related to stability and posture during walking [8]. Step width variability is a marker of poor physical function, as higher variability is associated with slower usual gait speed [9], longer time to complete chair stands [9], and a higher risk of falls [6,10]. Given the high prevalence of falls and physical function impairment among older adults [11,12], studies are needed to identify modifiable risk factors to help maintain step width variability in later life.

Sleep is an established risk factor for both gait and physical function impairments. A recent systematic review found that sleep efficiency, sleep duration, and wake after sleep onset were related to motor outcomes, such as gait speed, time to complete chair stands, and postural control [13]. Among older adults, lower self-reported sleep quality is associated with falls and slower gait speed [14], longer sleep latency is associated with an increased risk of mobility difficulty [15], and shorter sleep duration is associated with declines in gait speed [15]. Self-reported insomnia is also linked with differences in gait speed, stride or step length, and variability in single support, double support, stance, stride or step length, and stride or step time [16]. A study of 49 participants also reported associations between apnea-hypopnea index severity and stride time variability [17]. Most prior studies have focused on gait speed, stride or step length or time variability, or falls, and less is known about the relationships between sleep and step width variability. Many epidemiologic studies also rely on self-reported sleep measures, which may misclassify sleep quality [18,19]. As such, there is a need to evaluate associations between objectively measured sleep quality and step width variability.

Methods to assess sleep have evolved from electroencephalographic (EEG) measurements to actigraphy and autonomic or respiratory signals. One such method is cardiopulmonary coupling (CPC), which integrates electrocortical activity, autonomic activity, and respiration to provide profiles of sleep stability [20,21]. With the increasing availability of wearable devices, the easy assessment of free-living sleep quality is possible. By reducing the need for more traditional in-clinic procedures, such as EEG measurements, wearable devices may also lessen participant burden and improve accessibility [22].

This study aimed to establish associations between sleep and step width variability by leveraging digital data from a clinical sample of middle-aged and older adults. We hypothesized that lower objectively measured sleep quality would be cross-sectionally associated with higher step width variability during a preferred walking speed condition. Given that associations between sleep and gait have been found to differ by sex or cognitive function [14,23,24], we also expected that associations between sleep quality and step width variability would be stronger among men or individuals living with cognitive impairment compared to their respective counterparts.

Methods

Participants

This study included participants enrolled in the Boston University (BU) Alzheimer's Disease Research Center (ADRC) Clinical Core who opted into a digital brain health platform study (Digital Study). In brief, the BU ADRC is one of over 30 ADRCs nationwide that aim to promote collaborative research on Alzheimer's disease and related dementias. The BU ADRC enrolled adults aged ≥50 years with and without memory complaints who were English-speaking, community-dwelling, and local to the greater Boston area. The BU ADRC sample is representative of a clinic-based sample, including people with concerns about their cognition either because they have cognitive complaints or because they have certain risk factors such as head trauma or a family history. Full inclusion and exclusion criteria are published elsewhere, but participants were generally eligible unless they had a history of major psychiatric or neurologic illness (eg, schizophrenia, bipolar disorder, epilepsy) or head injury with significant loss of consciousness [25].

Starting in 2021, BU ADRC participants have had the option to use various technologies both at home and in the clinic as part of the Digital Study. Participants are given the choice of which technologies they would like to use [22]. This study included Digital Study participants who chose to use both sleep and gait digital technologies. All participants were eligible to complete the sleep and gait assessments. Participants were excluded from the analysis if sleep and gait data were measured >90 days apart (n=2) or if covariate data were missing (n=3). The flowchart for inclusion in the study sample is shown in the *Results* section.

Ethical Considerations

All study procedures were approved by the Boston University Medical Campus Institutional Review Board (approval number: H-40542). All participants provided written informed consent. The original informed consent and institutional review board approval allowed secondary analysis of the data without requiring additional participant consent. All data analyzed in this study were deidentified. No financial compensation was provided to participants.

Sleep Measures

Recording Process and Automated Analysis

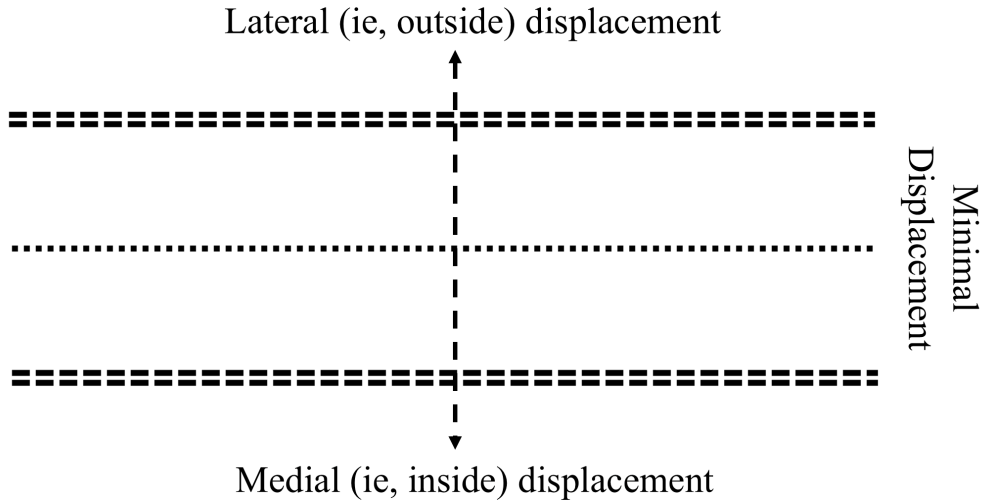
Participants were asked to wear the SleepImage ring (MyCardio LLC) in the free-living environment for at least 3 nights. The ring contains a photoplethysmography sensor that collects heart rate, oxygen saturation (SpO_2), and actigraphy data. Data were automatically uploaded and processed by SleepImage using the CPC algorithm.

Cardiopulmonary Coupling

The CPC method analyzes changes in signals modulated by the autonomic nervous system (eg, heart or pulse rate variability and breathing) to derive sleep stages, states, and a Sleep Quality Index (SQI). The method is based on calculating coupling and coherence between heart or pulse rate variability (eg, time between peaks of consecutive R-waves [RR interval time series]) and fluctuations in R-wave or pulse-wave amplitude induced by respiration to detect changes in breathing (eg, tidal volume variability [TVV]) [20]. These outputs are strongly modulated by sleep-wake state and stage. The cross-spectral power and coherence of the RR time series and corresponding TVV time series are calculated for consecutive windows, and a product of coherence and cross-spectral power is used to obtain the ratio of coherent cross power in the low frequency (0.01 - 0.1 Hz) to that in the high-frequency band (0.1 - 0.4 Hz). The logarithm of the high-to-low-frequency CPC ratio is then computed to yield a continuous and moving average of overlapping CPC windows and output of stable and unstable nonrapid eye movement (NREM) sleep, REM sleep, and wake. Graphing CPC at relevant frequencies versus time provides the SleepImage spectrogram [20,26]. Stable NREM sleep is characterized by stable breathing and stable oxygenation, high vagal tone, non–cyclic alternating pattern on the EEG, continuous occurrence of slow oscillations, high delta power, blood pressure dipping, and stable arousal threshold. Unstable NREM sleep is a marker of sleep instability and has exactly the opposite features of stable NREM sleep, with variability in TVV, cyclic variation in heart rate, cyclic alternating pattern on EEG, low relative delta power, nondipping of blood pressure, and unstable arousal thresholds. The SQI is a proprietary summary index of the CPC biomarkers of sleep quality, sleep stability, fragmentation, and periodicity, which provides a meaningful unit of measure for sleep health. The SQI is displayed on a scale of 0 to 100 with expected values for both children and adults [27-30]. Sleep spectrograms for participants with higher versus lower SQI values are shown in Figure S1 in Multimedia Appendix 1.

Sleep Measures

The following SleepImage measures were identified a priori: (1) sleep duration (hours), defined as the total hours of sleep per night; (2) sleep efficiency (%), defined as the proportion of time asleep out of the total time in bed; (3) sleep fragmentation (%), defined as the probability of transitioning from sleep to wakefulness; (4) stable sleep (%), defined as the proportion of sleep classified as stable (eg, regular breathing, heart rate, etc); (5) apnea-hypopnea index (events/hour), defined as the number of apnea or hypopnea events with ≥4% desaturation per hour; (6) duration (minutes) or percentage (%) of time SpO_2 levels were <90%; (7) oxygen desaturation index (events/hour), defined as the number of events lasting ≥10 seconds with ≥4% desaturation per hour; and (8) respiratory disturbance index (events/hour), defined as the number of times per hour that breathing was disrupted during sleep. The full methods for calculating these sleep measures are described elsewhere [31]. The remaining variables from the SleepImage report were examined using least absolute shrinkage and selection operator (LASSO) models, as described in the *Statistical Analysis* section.



Step Width Variability

As part of the in-clinic visits for the Digital Study, participants completed several walking trials while wearing inertial sensors (Opal; APDM) over the L4-5 vertebra, on each wrist, and on each foot. After the sensors were attached, participants walked back and forth down a 10-m hallway at their preferred comfortable (eg, usual) speed for 1 minute. The number of straight walking bouts varied depending on the participant's usual walking speed. Participants completed this 1-minute walking trial at their usual pace, as well as additional trials at a fast pace, slow pace, and fast-paced dual-task (eg, serial subtractions). Only the usual pace walking trial was included in this analysis. Then, the data were uploaded and processed using Mobility Lab version 2 [32]. Derived variables from these sensors have been validated among healthy adults (mean age 24, SD 6.2 y) [33] and populations with Parkinson disease [34]. These sensors have been used to monitor gait and balance [35-40], and several studies have also evaluated step width variability [36-40].

The outcome of interest was step width variability, as measured by asymmetry in lateral step variability during the preferred comfortable speed walking trial. This was defined as the variability of perpendicular deviations of the middle foot placement from the line connecting the first and third placements, when considering 3 consecutive foot placements made by the same foot [32]. Negative values indicated movement to the inside (eg, medial displacement), whereas positive values indicated movement to the outside (eg, lateral displacement; Figure 1) [32]. Mobility Lab 2 generated 1 summary value of asymmetry in lateral step variability. Mobility Lab 2 generated separate derived variables for information related to turning during the walking trials, which were not used in this analysis. For this study, variability was categorized as displacement within ±7.5 cm (eg, minimal displacement), ≤−7.5 cm (eg, medial displacement), or ≥7.5 cm (eg, lateral displacement). To determine whether greater displacement to either the inside or outside was associated with poor sleep quality, we also calculated the absolute value of asymmetry lateral step variability and analyzed this continuously (eg, higher values reflecting greater displacement in either direction).

XSL•FO
RenderX

Figure 1. Measurement of asymmetry in lateral step variability by Mobility Lab. For an individual walking along the center dashed line, displacement of the foot to the outside is defined as lateral displacement, displacement of the foot to the inside is defined as minimal displacement, and displacement of the foot within the outside and inside limits is defined as minimal displacement.

Covariates

Covariates were measured at each ADRC visit as part of the National Alzheimer's Coordinating Center Uniform Data Set [41]. Age was measured in years. Sex was categorized as male or female. Race was categorized as White, Black, American Indian or Alaska Native, Native Hawaiian or Other Pacific Islander, Asian, other, or unknown. Participants in the current sample identified as White, Black, or Asian. Due to small sample sizes, participants were classified as White or either Black or Asian. Educational attainment (years) was self-reported. BMI was measured as body mass (kg) divided by squared height (m^2). Usual gait speed (m/s) was measured by the APDM sensors [32]. Cognitive status was measured by the Clinical Dementia Rating (CDR) [42]. Participants were classified as having scores of 0 (n=56) or ≥0.5 (n=16; range 0.5 - 2.5).

Statistical Analysis

Sample characteristics were compared overall and by categories of step width variability. Means and SDs or counts and percentages were calculated for continuous or categorical variables, respectively.

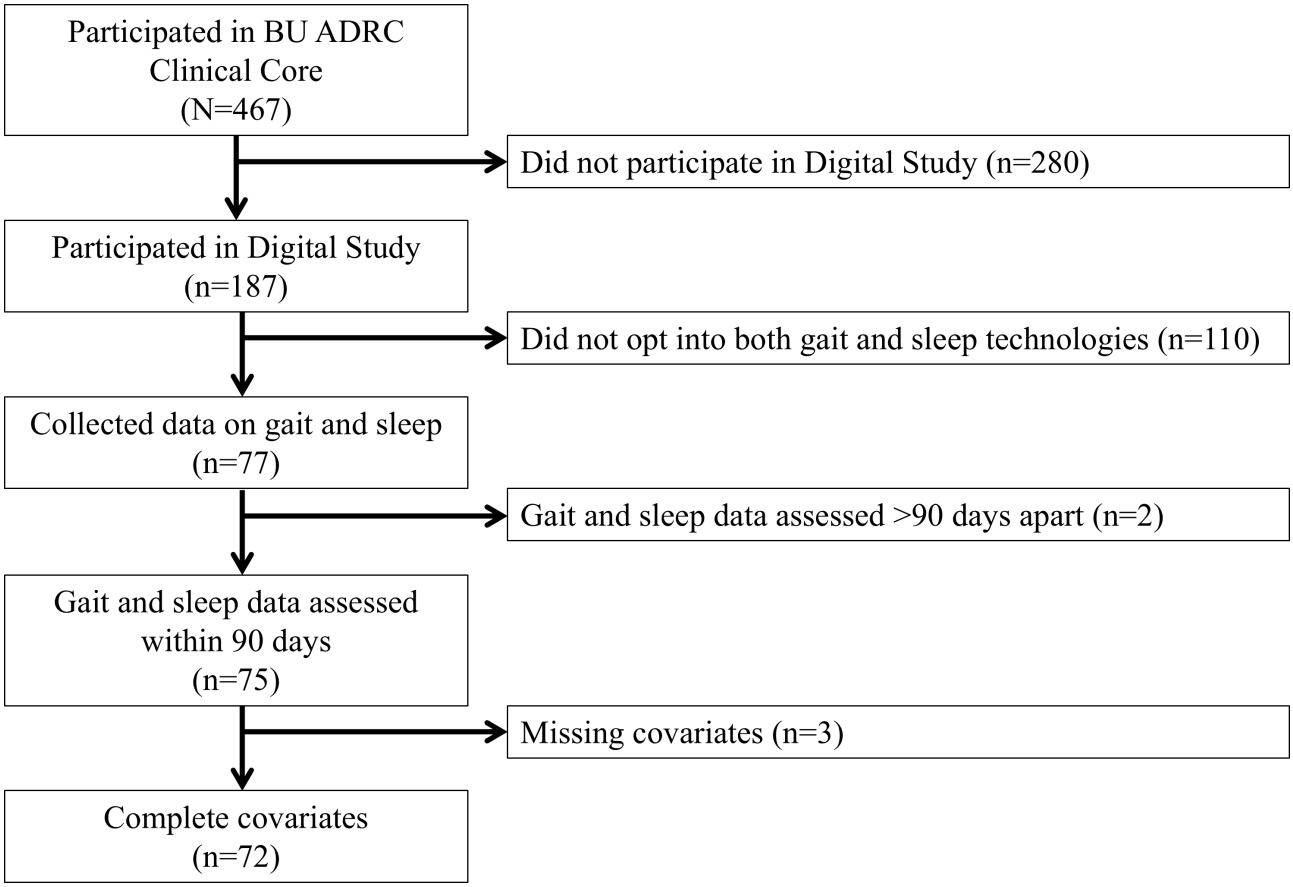
Cross-sectional associations between each a priori sleep measure and categories of step width variability were estimated using separate multinomial logistic regression models. These models estimated the relative risk ratio (RRR) and 95% CIs for medial or lateral displacement compared to minimal displacement (eg, reference group). RRR is a measure of association that estimates the probability of being in a particular outcome category (eg, medial or lateral displacement) relative to the reference category (eg, minimal displacement), per 1-unit increase in the exposure variable (eg, sleep measure). All models were adjusted for age, sex, race, education, BMI, and usual gait speed.

LASSO models evaluated the remaining SleepImage features to identify additional sleep variables for differentiating step width variability categories. In brief, this method is a machine learning approach that selects a subset of independent variables (eg, sleep) that best describe a dependent variable (eg, step width variability). A regularization process is applied to shrink the coefficients of variables that are less related to the outcome to zero. Then, variables with a nonzero coefficient are selected. This method is particularly useful for providing higher prediction accuracy and reducing the risk of overfitting in datasets with smaller sample sizes and a larger number of possible variables [43]. The features identified from the LASSO model were examined in separate multinomial regression models adjusted for the same covariates.

We also conducted several sensitivity analyses. First, to determine whether associations differed by certain individual-level characteristics, we stratified each model by sex (men vs women) or cognitive status (CDR of 0 versus ≥0.5). Second, to examine whether poor sleep was associated with higher step width variability irrespective of direction (eg, medial or lateral), we estimated the cross-sectional associations between sleep measures and the absolute value of step width variability using linear regression models. Finally, to evaluate whether associations were driven by extreme values, we repeated the primary analyses after excluding 1 participant with step width variability >57 cm.

The significance level for the multinomial logistic regression models was set to $P<.05$. Due to the number of comparisons, we applied a Benjamini-Hochberg false discovery rate correction (false discovery rate–corrected *P* value [pFDR]) for models estimating associations between either the a priori (9 comparisons) or LASSO-identified (5 comparisons) sleep features with step width variability categories [44]. All analyses were performed using Stata (version 18.0; StataCorp). Figures were generated using R (version 4.2.2).

Results



Sample Characteristics

Of the 72 participants in this sample (Figure 2), the mean age was 71 (SD 8.3; range 52 - 88) years, 51% (n=37) were female, 90% (n=65) were non-Hispanic White, and 22% (n=16) had CDR scores ≥0.5. On average, asymmetry in lateral step variability was 1.92 (SD 20.54) cm, with a range of −38.85 to 57.91 cm. For step width variability categories, 31% (n=22)

XSL•FO
RenderX

had minimal, 29% (n=21) had medial, and 40% (n=29) had lateral displacement. Participants with minimal displacement (eg, step width variability within ±7.5 cm) were older; more likely to be White; had higher educational attainment; slower usual gait speed; and lower prevalence of hypertension, diabetes, or cognitive impairment compared to those with medial (eg, ≤−7.5 cm) or lateral (eg, ≥7.5 cm) displacement. However, none of the differences in sample characteristics across step width variability groups were statistically significant (Table 1).

Cross-Sectional Associations Between Sleep and Step Width Variability Categories

Of the sleep features identified a priori, sleep fragmentation and stable sleep percentage were associated with the probability of having high step width variability. After adjustment for age, sex, race, education, BMI, and usual gait speed, a 1% higher sleep fragmentation was associated with a 6% higher probability of lateral displacement, and a 1% higher stable sleep percentage was associated with a 5% lower probability of lateral displacement compared to minimal displacement (fragmentation: RRR 1.06, 95% CI 1.01 - 1.11; stable sleep: RRR 0.95, 95% CI 0.91 - 0.99; Table 2). However, these findings were not statistically significant after FDR correction (Table S1 in Multimedia Appendix 1). There were no associations between sleep duration, sleep efficiency, apnea-hypopnea index, SpO_2 <90%, oxygen desaturation index, or respiratory disturbance index with step width variability categories or between any sleep measure and probability of medial displacement (Table 2). The results were unchanged after excluding 1 participant with step width variability >57 cm (data not shown).

Sleep Measures Identified by LASSO Models

The LASSO model identified SQI, REM sleep percentage, mean SpO_2, minimum apnea duration, and mean heart rate as being related to lateral compared to minimal displacement. After full covariate adjustment, 1% higher SQI and 1% higher REM sleep were associated with lower probability of lateral displacement, whereas a 1-second longer minimum apnea duration and a 1 beat per minute faster mean heart rate were associated with higher probability of lateral displacement compared to minimal displacement (SQI: RRR 0.92, 95% CI 0.87 - 0.98; REM sleep: RRR 0.87, 95% CI 0.77 - 0.99; apnea duration: RRR 2.34, 95% CI 1.06 - 5.16; heart rate: RRR 1.14, 95% CI 1.03 - 1.26; Table 3). The findings related to SQI were robust at the trend-level after FDR correction (*P*=.09; Table S2 in Multimedia Appendix 1). The LASSO model did not identify any sleep measures associated with medial displacement. However, 1 beat per minute faster mean heart rate was associated with 13% higher probability of medial compared to minimal displacement (95% CI 1.01 - 1.25; Table 3). The results were unchanged after excluding 1 participant with step width variability >57 cm (data not shown).

Table . Cross-sectional associations between the additional sleep measures identified from least absolute shrinkage and selection operator (LASSO) and step width variability categories (N=72).

Sleep variable	Medial[a,b] (RRR[c], 95% CI)	Lateral[a,b] (RRR, 95% CI)
SQI[d] (%)	1.00 (0.95-1.05)	0.92 (0.87-0.98)
REM[e] sleep (%)	0.91 (0.81-1.03)	0.87 (0.77-0.99)
Mean SpO_2[f] (%)	1.01 (0.69-1.48)	1.31 (0.90-1.92)
Minimum apnea duration (s)	1.35 (0.59-3.05)	2.34 (1.06-5.16)
Mean heart rate (BPM[g])	1.13 (1.01-1.25)	1.14 (1.03-1.26)

[a]Minimal displacement within ±7.5 cm (reference); medial displacement ≤−7.5 cm; and lateral displacement ≥7.5 cm during the preferred walking speed condition.

Effect Measure Modification by Sex

Among men (n=35), the findings were robust for stable sleep percentage, SQI, and REM sleep percentage. All other primary findings were attenuated, but the magnitude of the effect sizes was consistent with the primary analyses. Among women (n=37), the findings were robust for mean heart rate. All other primary findings were attenuated, but the magnitude of the effect sizes was consistent with the primary analyses (Table S3 in Multimedia Appendix 1).

Effect Measure Modification by Cognitive Status

The models among participants with CDR ≥0.5 did not converge due to small sample sizes with the addition of usual gait speed as a covariate. Therefore, these models were adjusted for age, sex, race, education, and BMI. Among participants with normal cognition (CDR=0; n=56), the findings were robust for SQI. All other findings were attenuated, although the magnitude of the effect sizes was consistent with the primary analyses. Among participants with cognitive impairment (CDR ≥0.5; n=16), all findings were attenuated. The magnitude of the effect size was similar for sleep fragmentation and mean heart rate (Table S4 in Multimedia Appendix 1).

Cross-Sectional Associations Between Sleep and the Absolute Value of Step Width Variability

After taking the absolute value of step width variability, the mean was 16.63 (SD 12.05) cm, with a range of 0.19 to 57.91 cm. After covariate adjustment, 1% longer REM sleep was associated with 0.81 cm lower step width variability (95% CI −1.32 to −0.30). There were no associations with any other sleep measures (Table S5 in Multimedia Appendix 1).

Discussion

Principal Results

In this clinical sample of middle-aged and older adults, lower objectively measured sleep quality was cross-sectionally associated with higher step width variability during the preferred speed walking condition. Specifically, lower SQI, shorter stable or REM sleep, higher sleep fragmentation, longer apnea duration, and faster mean heart rate were each associated with a higher probability of having lateral (eg, ≥7.5 cm) versus minimal displacement (eg, within ±7.5 cm). The associations between sleep and step width variability were also independent of usual walking pace. Overall, these findings suggest that sleep may be a modifiable risk factor for minimizing step width variability. This has potentially important implications for preventing falls and physical function decline in later life.

This study found that several objectively measured sleep variables related to lower sleep quality were associated with higher step width variability. Most prior studies have focused on associations between sleep and gait speed [14,15,23,24], despite evidence that measures of gait variability may be stronger risk markers for falls [45]. Postural control, which is related to step width variability [2], is impaired among individuals who experience sleep deprivation [46] or sleep-disordered breathing [47]. Additionally, studies have evaluated other measures of gait variability, such as variability in stride length, step length, stride time, or step time. Indeed, lower sleep efficiency, the presence of insomnia, or sleep-related breathing disorders are associated with higher variability in these measures [13,16,17]. This study builds on existing evidence to suggest that sleep quality, even without a sleep disorder, may be an important modifiable risk factor for gait dysfunction, including higher step width variability.

There are several possible mechanisms through which sleep may impact gait and step width variability. Gait is a complex task that requires coordination of several systems [48,49]. Brain regions, including the prefrontal cortex, basal ganglia, brainstem, and cerebellum, are responsible for receiving information about body positioning from the visual, vestibular, and proprioceptive systems. These brain regions must interpret afferent signals and coordinate a motor response through the pyramidal tract, peripheral nerves, and neuromuscular system [48,49]. Further, step width variability is a measure of postural control during locomotion [2], and dynamic postural control is likely mediated through spinal pathways, the cerebellum, the sensorimotor thalamus, the supplementary motor area, and the premotor cortex [50]. Evidence links intermittent hypoxia, which occurs during sleep apnea, with damage to the prefrontal cortex and cerebellum [51], as well as sleep apnea with incident cognitive impairment [52]. Poor sleep quality is also associated with the dysregulation of synaptic homeostasis and the glymphatic system, a higher burden of cerebrovascular disease (eg, white matter hyperintensities) and amyloid-β, and worse cognitive performance [53]. While the role of the basal ganglia in normal sleep mechanisms is less well defined than cortical and brainstem neural circuits, the profound changes associated with disorders of the basal ganglia suggest key roles [54]. These findings may reflect alterations of neural networks from cortical to spinal cord levels, while cortex-to-brainstem areas are more involved in sleep regulation, including the interactions mapped by CPC outputs.

These mechanisms align with prior studies linking poor sleep with gait dysfunction. First, sleep deprivation is associated with poorer postural control among older adults [55]. Sleep deprivation among college students is also related to lower metabolic activity in the prefrontal cortex, basal ganglia, cerebellum, and thalamus, as well as greater difficulty synchronizing gait to an auditory signal [56]. Second, sleep disruption is associated with reduced gait complexity (eg, less adaptability to the environment) [57], indicating greater regularity of stride-to-stride fluctuations [58]. Finally, sleepiness due to poor sleep quality may be related to gait dysfunction. This is supported by several studies linking cumulative exposure to drugs with sedative properties to decreased gait regularity, pace, and complexity [45,59], as well as self-reported sleepiness with a higher risk of falls [51]. Additional research is needed to identify the specific mechanisms through which sleep may impact step width variability.

In this study, associations between sleep quality and step width variability were stronger among men than women. Indeed, several findings were robust for male participants, while only associations with mean heart rate persisted among female participants. However, the magnitude of the effect sizes was similar for both men and women. This aligns with a prior study

XSL•FO
RenderX

that found that slower gait speed was cross-sectionally associated with poor sleep quality and longer sleep duration (eg, >8 h) among men but not women [23]. One potential mechanism explaining the links between sleep and gait among men is that poor sleep quality leads to reductions in muscle mass and strength. This mechanism is supported by a study finding that grip strength mediates associations between self-reported sleep quality and both gait speed and falls among men but not women [14]. Though replication is needed, these preliminary findings suggest that men may be particularly susceptible to higher step width variability related to poor sleep.

Contrary to our hypothesis, the findings for SQI were robust among participants with normal cognition, while no findings were statistically significant among those with cognitive impairment. Given that cognitive decline and dementia are associated with slower gait speed and abnormal gait patterns [4,60], we hypothesized that individuals with cognitive impairment would be more susceptible to gait dysfunction related to poor sleep quality. Populations living with cognitive impairment, such as Alzheimer or Parkinson disease, have higher gait variability [61], lower postural control [61], and a higher risk of falls [62] than cognitively intact controls. As such, we would expect that lower step width variability may be of particular importance for postural control and balance during walking among those with cognitive impairment. Additionally, slower gait speed is linked with lower global cognition among individuals with sleep apnea [24] and lower executive function or attention [49]. The combination of slow gait and poor sleep duration is also associated with higher odds of cognitive impairment [63]. There are a few possible explanations for why we did not observe associations between sleep and step width variability among participants with cognitive impairment in our study. First, we used a global measure of cognitive impairment, but specific cognitive domains, particularly attention and executive function, are linked to both gait and sleep [49,64,65]. Sleep may be more strongly related to step width variability among those with impairment in these domains. Second, the system coordinating gait may have already been disrupted among those with cognitive impairment, potentially attenuating the added harm from poor sleep quality. Finally, we may have been underpowered to detect associations with global cognitive impairment or within specific cognitive domains due to the modest sample size. The replication of the findings is needed in larger, more diverse cohorts.

This study supports the feasibility of remotely monitoring risk factors using digital technologies in the free-living environment. Integrating digital technologies into research has several advantages, including improved feasibility and accessibility, as well as reduced participant burden [22]. Data from these technologies provide additional information about an individual's free-living behaviors and function. Indeed, studies have criticized self-reported questionnaires for misclassifying sleep quality [18,19]. The digital acquisition of gait characteristics in this study also allowed for more nuanced measures of gait characteristics, including step width variability. While this study is limited by a modest sample size and cross-sectional design, these findings support continued research to identify digital sleep biomarkers that relate to functional outcomes. Future studies are also needed to evaluate whether these digital sleep measures also relate to the risk of falls or physical function decline (eg, grip strength, lower extremity strength, balance) and to test whether intervening in these sleep characteristics improves gait and physical function.

Limitations and Strengths

This study has several important limitations. First, there is a lack of consensus on cut points to define minimal, medial, and lateral displacement. Future studies are needed to validate these cut points for asymmetry in lateral step variability. Second, there was a gap in time between measurement of sleep and step width variability. We attempted to address this by excluding participants with measurements >90 days apart. Third, the BU ADRC is a clinical cohort that may be less representative compared to population- or community-based samples. This sample also had limited racial and ethnic diversity, including variations in skin pigmentation, which can bias optoelectronic sensing (eg, plethysmography sensors). Future studies with larger, more diverse samples are needed to evaluate generalizability and sensor performance. Fourth, the sample size was modest, and some analyses may be underpowered. This study is a first step toward establishing associations between sleep and step width variability. Finally, there is a possibility of residual or unmeasured confounding. A major strength of this study is the use of objectively measured sleep quality and step width variability. The use of digital tools provided nuanced measures of both our exposure and outcome. Machine learning methods were also leveraged for sleep feature selection, reducing the risk of overfitting given the modest sample size [43]. Additionally, data were available on cognitive function and important covariates.

Conclusions

This study found that poor objectively measured sleep quality was associated with higher step width variability during preferred speed walking. Future studies are needed to evaluate whether monitoring, or possibly intervening in, these sleep measures could help to minimize the risk of falls or physical function decline in later life.

Abstract

Background: Age-related cognitive and sensorimotor declines co-occur and reinforce one another, increasing vulnerability to functional dependence and falls. Exergaming offers integrated cognitive-motor training, but most systems lack features that support personalized care for socially vulnerable, community-dwelling older adults. Low-income older adults receiving Public Community Care services bear a disproportionate burden of cognitive and sensorimotor decline, yet remain underrepresented in digital health research. As part of a broader program to develop a digital health monitoring-to-intervention framework, we evaluated a pressure sensor–based exergame designed to deliver targeted cognitive-motor training within the existing Public Community Care infrastructure.

Objective: This study evaluates the feasibility and preliminary effects of the Brain Step exergaming intervention on cognitive and sensorimotor frailty in low-income older adults living alone who were receiving Public Community Care services through a pilot study (study 1) and a randomized controlled trial (RCT; study 2).

Methods: Study 1 (n=15) was a 12-week single-arm pilot study. Study 2 was a parallel-group pilot RCT conducted in Seoul, South Korea. Thirty-one low-income older adults living alone who were receiving Public Community Care services (mean age 81.5 years; 26/31, 84%, female) were randomized to the intervention (n=16) or control (n=15) group. The 16-week intervention used custom hardware with integrated safety bars and arcade-style games that progressed from single- to dual-task challenges.

XSL•FO
RenderX

Primary outcomes were cognitive function (Korean Mini-Mental State Examination [K-MMSE]), physical function (Berg Balance Scale [BBS] and Timed Up and Go [TUG]), and sarcopenia indicators (appendicular skeletal muscle mass [ASM], Appendicular Skeletal Muscle Mass Index, and grip strength). Secondary outcomes were the Korean Montreal Cognitive Assessment, physical fitness (Figure-8 Walk, 30-second Sit-to-Stand, and 2-Minute Step Test), and fall incidence. Generalized estimating equations with Benjamini-Hochberg false discovery rate (FDR) correction for multiple testing were applied.

Results: In the single-arm pilot study (study 1), a pre-post increase in BBS scores and a reduction in TUG time survived FDR correction among the primary outcomes (both FDR-adjusted *P*=.002), as did all 3 secondary physical fitness outcomes (Figure-8 Walk, FDR-adjusted *P*=.006; 30-second Sit-to-Stand, FDR-adjusted *P*=.01; and 2-Minute Step Test, FDR-adjusted *P*=.02). The K-MMSE Visuospatial subscale showed an uncorrected pre-post improvement (*P*=.02), with differential risk-stratified patterns for Recall (*P*=.04) and Attention (*P*=.006). In the pilot RCT (study 2), a nominally significant group × time interaction was observed for ASM (*P*=.04, FDR-adjusted *P*=.11), with the intervention group maintaining muscle mass while the control group declined. The risk-stratified analyses showed an uncorrected significant 3-way interaction for K-MMSE Recall (*P*=.01). No findings from study 2 survived FDR correction.

Conclusions: These sequential studies demonstrate the feasibility of delivering a culturally adapted exergaming intervention through the existing Public Community Care infrastructure. The pilot study (study 1) showed FDR-corrected pre-post improvements in balance and mobility within an uncontrolled single-arm design. In the pilot RCT (study 2), no primary outcomes survived FDR correction. The observed preliminary signals for muscle mass preservation and, in exploratory risk-stratified analyses, cognitive improvement in the high-risk subgroups should be regarded as hypothesis-generating only. Adequately powered trials with risk-enriched samples and active comparators are needed to evaluate efficacy.

Introduction

Aging brings concurrent declines across cognitive, sensory, postural, and muscular systems that together threaten independent living in older adults [1,2]. Frailty is increasingly understood not as disability or comorbidity but as a biologic syndrome of decreased physiologic reserve and reduced resistance to stressors, arising from cumulative declines across multiple systems and conferring vulnerability to falls, disability, and loss of independence [3]. This study addresses 2 interrelated aspects of this syndrome. Cognitive frailty denotes the co-occurrence of physical frailty and cognitive impairment in the absence of Alzheimer disease or other dementia—a potentially reversible, pre-neurodegenerative state distinct from physiologic brain aging and, thus, a target for early intervention [4]. Its sensorimotor counterpart, here termed sensorimotor frailty, comprises age-related deficits in proprioception, balance, postural control, and skeletal muscle function that increase the risk of falls and functional dependence [3,5]. It is closely linked to cognitive decline, sarcopenia, and increased fall risk [2,6]. Critically, these 2 aspects are interrelated rather than independent. This interdependence provides the rationale for integrated interventions that simultaneously engage cognitive, sensory, and motor systems rather than targeting each domain in isolation.

The relationship between sensorimotor decline and cognitive aging is bidirectional. Executive subdomains such as attention, sensory integration, and motor planning are strongly associated with postural instability and gait dysfunction [7], while age-related loss of proprioception and sarcopenia independently compromise both mobility and cognitive function [8,9]. Sarcopenia—the progressive loss of skeletal muscle mass and strength with aging—further compounds these vulnerabilities, as lower limb muscle mass is a critical determinant of balance confidence and functional independence in older adults, and sarcopenia is associated with increased risks of falls, fractures, cognitive impairment, and mortality [9-11]. Integrated dual-task approaches that simultaneously engage cognitive and sensorimotor systems may therefore be more effective than targeting either domain alone [12,13]. Such approaches may be particularly relevant for older adults experiencing preclinical functional decline—those who remain independently ambulatory but show individualized deterioration below their own functional baseline. Network meta-analyses have confirmed that exercise interventions significantly reduce both the number of fallers (risk ratio 0.83, 95% CI 0.77-0.89) and the rate of falls (risk ratio 0.79, 95% CI 0.73-0.86), with emerging evidence favoring combined physical-cognitive training [13]. In South Korea, where adults aged 65 years and older constitute 19.2% of the population [14], preserving functional independence through early detection and recovery from these preclinical declines represents a pressing public health priority. While the number of Koreans with dementia is projected to exceed 1 million by 2026 [14,15], up to 45% of dementia cases may be attributable to modifiable risk factors, including sensory loss, physical inactivity, sarcopenia, and depression [16], underscoring the value of interventions that target the functional precursors of cognitive and sensorimotor decline before irreversible impairment occurs.

Exergaming—physically active video gaming that requires whole-body movements—has emerged as a promising approach for delivering integrated cognitive-motor training. Recent

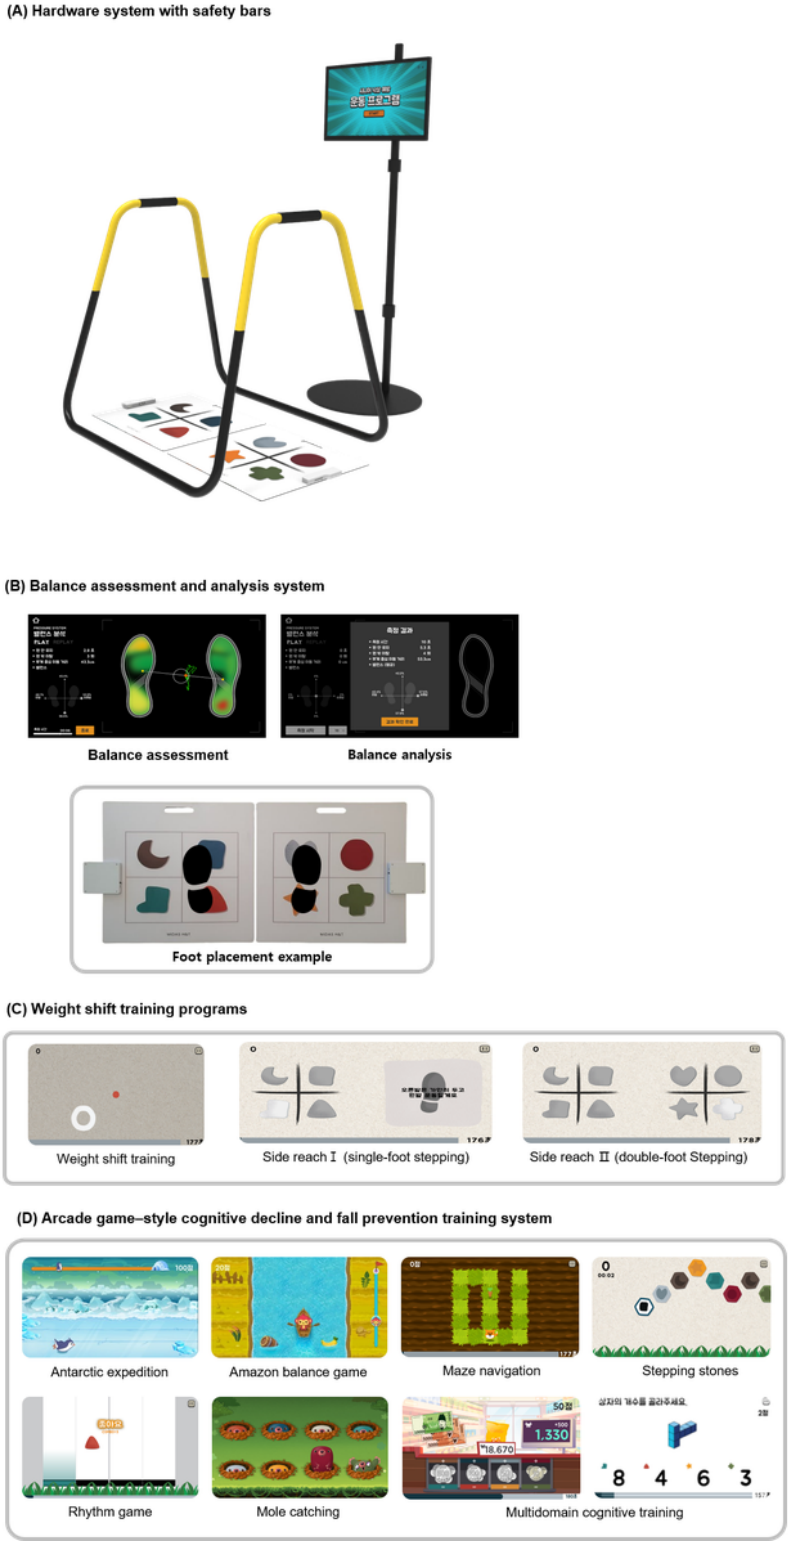
randomized controlled trials (RCTs) have demonstrated that exergaming can improve executive function [17,18], dual-task performance [19], and global cognition [18,20] in older adults, with a landmark trial by Sturnieks et al [21] showing that home-based step exergaming and cognitive training reduced fall rates by 26% over 12 months. However, most exergaming research has used commercially available gaming systems—primarily Nintendo Wii, Microsoft Xbox Kinect, or stationary cycling platforms [12,18,19]—which may present significant barriers for older adults with limited technology experience, cognitive impairment, or balance deficits that require postural support during exercise [18].

Despite the growing evidence base for exergaming interventions, critical gaps remain. First, socially vulnerable populations, who bear disproportionate burdens of both falls and cognitive decline, are typically underrepresented in clinical trials, limiting the generalizability of existing evidence [22]. Low-income older adults living alone face multiple barriers to accessing conventional rehabilitation services, including transportation difficulties, financial constraints, and social isolation [23]. Second, most prior RCTs have been conducted in individual home-based settings [12] or laboratory settings [18,19]. While home-based approaches can reduce falls, the social isolation inherent in such formats may limit engagement for some populations. Third, the generational appropriateness of gaming content—identified by Begde et al [12] as a critical determinant of usability and adherence—has not been systematically explored. Most commercially available gaming systems were designed for younger, technology-literate users, and their game interfaces and interaction paradigms may not align with the cultural preferences and prior experiences of today's older adults.



To address these gaps, we developed the Brain Step program, a pressure sensor–based exergaming intervention specifically designed for older adults with elevated cognitive and fall risk (Figure 1). The program features custom hardware with integrated safety bars for postural support, culturally adapted arcade-style games familiar to the target generation, and a progressive structure that advances from single-task to cognitive-motor dual-task challenges [12,18]. The intervention was embedded within the existing service infrastructure of a community welfare center, with on-site staff trained as facilitators to ensure sustainability beyond the research period.

This research is part of a 3-phase program to develop and evaluate a digital health monitoring-to-intervention framework for low-income older adults receiving government-supported Community Care services. Phase 1 established a digital health monitoring platform integrating smartphone chatbots, smartwatch sensors, and motion-sensing technology [24], and phase 2 demonstrated that this platform, combined with caregiver-mediated intervention within the public Community Care infrastructure, could maintain functional status in low-income older adults living alone [25]. This study (phase 3) evaluates Brain Step, a pressure sensor–based exergaming intervention designed to deliver targeted cognitive-motor training when signs of functional decline are detected through the monitoring platform.

By embedding the intervention within the existing Public Community Care service infrastructure, this study aims to address a critical translational gap between digital health monitoring and actionable interventions for populations that face structural barriers to conventional rehabilitation services. This research consisted of 2 sequential studies that used a user-centered, community-participatory approach to develop and evaluate the intervention. Study 1 was a single-arm pilot study designed to evaluate the feasibility, safety, and preliminary efficacy of the Brain Step program and to refine the intervention protocol based on participant and staff feedback. Study 2 was a pilot RCT designed to estimate the preliminary effects of the refined 16-week Brain Step intervention on cognitive and sensorimotor frailty in socially vulnerable older adults receiving Public Community Care services. Secondary objectives were to explore the preliminary effects on self-reported health outcomes (depressive symptoms, sleep quality, and pain-related functional limitations) and to examine whether baseline functional risk status moderated intervention effects. Given the exploratory nature of this pilot RCT, we examined whether the intervention group would show preliminary signals of change in cognitive and sensorimotor frailty compared with the control group and whether individuals with higher baseline risk would show differential intervention responses.

Methods

Overview

This research consisted of 3 phases conducted at the Seongbuk Municipal Senior Welfare Center (hereafter, the Welfare Center) in Seoul, South Korea. Study 2 participants were recipients of the Korean government's Public Community Care Service—a nationally standardized, publicly funded program that provides independently ambulatory, low-income older adults living alone with regular caregiver support, including twice-weekly phone calls, weekly home visits, and additional follow-up during episodes of acute illness [26]. Although this study was conducted at a single site, the standardized service protocol—with regulated caregiver work hours (25 hours/week) and caseloads (up to 12 older adults per caregiver)—offers a replicable infrastructure for embedding intervention programs nationwide. A brief prepilot phase tested the initial safety and feasibility of the Brain Step system. Study 1 was a single-arm pilot study designed to evaluate the feasibility and safety of the Brain Step program. Based on the findings of study 1, the intervention protocol was refined and tested in study 2, an RCT. In both studies, participants were predominantly female (38/46, 83%, with 12/15 in the pilot and 26/31 in the RCT), had a mean age of approximately 80 years, and presented with fall risk factors such as a history of falls or gait difficulties. Study 1 recruited community-dwelling older adults from the Welfare Center without income restrictions, whereas study 2 specifically enrolled low-income older adults living alone who were receiving the Public Community Care Service.

Ethics Approval

This study was conducted in accordance with the Declaration of Helsinki and was approved by the Institutional Review Board of Korea University (approval number KUIRB-2023-0360). The study was registered at ClinicalTrials.gov (NCT06664229). Written informed consent was obtained from all participants before enrollment.

Pre-Pilot Testing

Before the pilot study, a brief prepilot phase was conducted with 4 older adults to assess the initial safety and feasibility of the Brain Step system. Participants attended sessions 3 times per week for 1 week. This preliminary testing confirmed that the system was safe for use by older adults and that the basic exercises could be completed without adverse events, informing the design of the subsequent pilot study. The overall development approach—progressing from needs assessment through pilot testing to RCT evaluation—was guided by a participatory, user-centered process that engaged older adult participants, community caregivers, and welfare center administrators through qualitative interviews and open-ended feedback collected at posttest. Their input informed device and program design decisions, including the adoption of safety features (integrated support bars), difficulty-level adjustments, and gradual progression from sensorimotor to more complex dual-task training, ensuring that the intervention was contextually appropriate for this population.

Study 1: Pilot Study

Design and Participants

Study 1 was a single-arm pre-post study conducted from March to May 2024. Community-dwelling older adults aged 65 years or older were recruited through bulletin board postings at the community senior welfare center. Inclusion criteria were (1) the ability to communicate and follow instructions and (2) fear of falling. Exclusion criteria were (1) severe sensory impairments (hearing or vision), (2) cognitive or psychiatric impairments (eg, hallucinations), and (3) inability to ambulate independently.

Of 20 older adults screened, 18 met the eligibility criteria and agreed to participate. Three participants withdrew (2 before baseline because of sequelae of back surgery and 1 during the intervention because of scheduling conflicts), resulting in 15 participants (mean age 80.20 years, SD 6.88 years; 12/15, 80%, were women) who completed the study. The characteristics of the pilot study participants are reported in Table S1 in Multimedia Appendix 1.

To examine differential effects according to baseline cognitive function and sensorimotor risk levels, staff at the community senior welfare center assisted with recruitment to ensure balanced enrollment of participants across high- and low-risk categories.

Intervention

Participants received the Brain Step program for 12 weeks, attending 50-minute sessions twice weekly. The program consisted of pressure sensor–based exercises, including center of gravity training, single- and double-foot stepping, and exergames (maze navigation, stepping stones, and mole catching). Sessions were conducted in small groups (≤8 participants per session because of space constraints at the Welfare Center) with trained facilitators, including 2 nonclinical welfare center staff members who served as session facilitators from this pilot phase onward, providing guidance and safety monitoring.

Outcomes and Analysis

Primary outcomes included cognitive function (Korean Mini-Mental State Examination [K-MMSE]), physical function (Berg Balance Scale [BBS] and Timed Up and Go [TUG]), and sarcopenia-related measures (appendicular skeletal muscle mass [ASM], Appendicular Skeletal Muscle Mass Index [ASMI], and handgrip strength).

Secondary outcomes included physical fitness measures (30-second Sit-to-Stand, 2-Minute Step Test, and Figure-8 Walk) and device and program usability. Participants also completed qualitative interviews and satisfaction surveys. Pre-post changes were analyzed using generalized estimating equations (GEEs). Participant feedback was collected through focus group interviews with participants and senior welfare center staff.

RenderX

Study 2: RCT

Design

Study 2 was a parallel-group RCT. Recruitment began in August 2024, the intervention was delivered from November 2024 to March 2025, and the final assessment was completed in April 2025. Participants were assessed at 3 time points: baseline (preintervention), 8 weeks (mid-intervention), and 16 weeks (postintervention).

Participants

Study 2 targeted low-income older adults living alone who were receiving the Customized Community Care Service described above. Participants were identified through the Community Care service database at the Welfare Center. Community Care providers facilitated recruitment by identifying eligible older adults from their caseloads, arranging initial contact with the research team, and coordinating transportation to the Welfare Center for intervention sessions. Through this involvement, Community Care providers also learned the intervention procedures and progressively assumed facilitator roles, further supporting the program's sustainability within routine welfare center operations. The inclusion and exclusion criteria were identical to those of study 1.

Sample Size

Sample size was calculated using G*Power version 3.1.9.7. Based on a repeated-measures analysis of variance with a within-between interaction, a medium effect size (Cohen *f*=0.25) [27] was assumed. This assumption was based on meta-analytic evidence from exergaming interventions reporting pooled effect sizes of standardized mean difference of 0.35 for executive function [28] and standardized mean difference of 0.36-0.78 for balance outcomes in older adults [29], consistent with prior meta-analytic evidence [17]. Assuming an α level of .05, statistical power of 0.80, 2 groups, and 3 measurement time points, a minimum of 28 participants was required. Accounting for a 15% (5/33) dropout rate, the target sample size was 33 participants. To ensure balance between groups, 34 participants were planned for recruitment.

Randomization and Blinding

The random allocation sequence was generated using block randomization with a fixed block size of 4 by an independent researcher who was not involved in participant recruitment, intervention delivery, or outcome assessment. The allocation sequence was concealed from the other investigators until the time of assignment. Owing to the nature of the intervention, participants were not blinded and were aware of their group assignment, whereas outcome assessors were blinded to group allocation to minimize detection bias.

Intervention

As shown in Figure 1, the Brain Step program consists of a large pressure sensor mat (1100 mm × 1100 mm) with 4 quadrants and 8 response zones, a display screen, and integrated safety bars.

Participants attended 50-minute sessions twice weekly for 16 weeks (32 sessions total). Sessions were conducted in small groups of up to 8 participants (limited by the available space and time at the Welfare Center), with morning and afternoon sessions available. Each session was led by 1 trained facilitator, with 1-2 research assistants providing individual guidance and safety monitoring. Instructional videos were provided to explain the program objectives and demonstrate each game task. Facilitators received training in device operation, safety monitoring, emergency procedures, and participant guidance before program initiation. To prepare for technology-assisted translation into routine community care practice, 2 welfare center staff members—who were not specialists in cognitive or physical interventions—were intentionally included as facilitator trainees, reflecting the typical workforce of community-based older adult care settings. Their operational needs were elicited through qualitative interviews and incorporated into the program design, including adjustable difficulty levels, automated game modules, and instructional videos demonstrating each task to support independent program delivery. Intervention fidelity was monitored through session checklists completed by research assistants and weekly supervision meetings. Adherence was tracked through individual session attendance records and game completion rates documented automatically by the Brain Step system.

As shown in Table 1, the main trial program was structured into 3 progressive phases. Phase 1 (weeks 1-4) focused on single-task training, including weight-shift exercises with real-time center of pressure feedback and side-reaching exercises (single- and double-foot stepping) to strengthen ankle mobility and lower limb muscle function. Phase 2 (weeks 5 and 6) introduced measurement system level 2, combining physical exercises with location memory tasks and learning system games to increase task complexity. Phase 3 (weeks 7-16) emphasized dual-task training through multidomain cognitive training targeting image association, arithmetic, and recognition. Participants selected answers by stepping on designated target zones among the 8 positions on the pressure sensor mat, thereby integrating cognitive decision-making with weight-shifting movements.

The software comprised 3 components (Figure 1): a balance assessment system (Figure 1B) providing real-time center-of-pressure visualization, a weight-shift training system (Figure 1C), and a cognitive-motor training system (Figure 1D) featuring 7 exergames inspired by classic arcade games from the 1980s and 1990s to enhance engagement through nostalgic familiarity. Detailed descriptions of each game are provided in the Methods S1 in Multimedia Appendix 1.

Table 1. Table1. Brain step program structure and progression.

Phase	Weeks	Training focus	Tasks	Task type
1	1-4	Ankle mobility and lower limb strengthening	Center of gravity training and side reach (single/double foot stepping)	Single task
2	5 and 6	Memory and spatial cognition	Maze navigation, stepping stones, and mole catching	Increased complexity
3	7-16	Cognitive-motor integration	Cognitive training quizzes (image association, arithmetic, and recognition) with proprioceptive-motor movements	Dual task

Control Group

Participants in the control group received no intervention during the 16-week study period and attended only the 3 assessment sessions (baseline, 8 weeks, and 16 weeks). A passive (no-contact) control was selected at this feasibility stage to establish whether the intervention could be delivered and whether participants would engage with it in the real-world Public Community Care setting. As the intervention was delivered on-site within the existing infrastructure of the community welfare center, an active or attention-matched comparator was not logistically feasible at this stage. Limited space availability and a shortage of on-site staff precluded implementation of a parallel active-control program. Our priority was to evaluate the real-world applicability of the intervention.

Risk Stratification

Participants were stratified into high-risk (n=17) and low-risk (n=14) groups based on initial screening assessments. High-risk classification required the presence of 2 or more of the following: a history of recurrent falls, gait abnormalities, or cognitive test scores indicating mild cognitive impairment (K-MMSE ≤21 and Montreal Cognitive Assessment [MoCA] <23). This stratification was prespecified during the study design phase. Community stakeholders requested the inclusion of participants at the highest cognitive and sensorimotor risk, and the pilot study findings of differential response patterns informed the decision to classify participants by risk level using pretest screening (K-MMSE and fall history).

Outcome Measures

Comprehensive health outcomes were assessed to provide individualized feedback within the digital-human integrated personalized care framework. Outcomes were organized into 3 tiers: primary outcomes for which intervention effects were hypothesized, secondary outcomes to capture more detailed functional changes, and self-reported health outcomes routinely monitored in Community Care services. Primary outcomes included cognitive function (K-MMSE total and subscale scores), physical function (BBS and TUG), and sarcopenia indicators (ASM, ASMI, and grip strength). The K-MMSE [30] evaluates orientation, recall, attention/calculation, language, and visuospatial function (total score 0-30). Balance was measured using the Korean version of the BBS (14 items; total score 0-56) [31,32]. The TUG measured the time (in seconds) required to rise from a chair, walk 3 m, turn, return, and sit down [33]. Sarcopenia-related measures were assessed according to the Asian Working Group for Sarcopenia 2019 criteria [34]. ASM was measured using bioelectrical impedance analysis (InBody 370), and ASMI was calculated as ASM/height^2 (kg/m^2). Grip strength was measured using a dynamometer (CAMRY EH101) [35,36], with the highest value from 3 trials of the dominant hand used for analysis.

Secondary outcomes were complementary, hypothesis-generating measures, including cognitive function (Korean Montreal Cognitive Assessment [MoCA-K] total and subscale scores), physical fitness (Figure-8 Walk Test, 30-second Sit-to-Stand, and 2-Minute Step Test [36,37]), and fall incidence. The MoCA-K [38,39] was included as a secondary cognitive measure because the K-MMSE has known ceiling effects in detecting subtle cognitive changes in individuals with mild cognitive impairment [40]. The MoCA-K provides greater sensitivity for mild cognitive impairment through more demanding assessments of executive function, visuospatial ability, and attention (total score 0-30) [39].

Fall incidence was assessed at 3 time points. At baseline, participants completed a screening question (Have you experienced a fall in the past year?). At the immediate postintervention assessment, they were asked, “Have you experienced a fall during the past 16 weeks?” At the 1-year postintervention follow-up, fall incidence was determined from community caregiver fall incident reports shared by the municipal welfare center as part of routine Public Community Care service monitoring. Fall incidence was included as a secondary outcome to complement the primary balance and mobility measures.

Other outcomes included sleep quality (Pittsburgh Sleep Quality Index [PSQI]; total score 0-21, with higher scores indicating poorer sleep quality) [41], depressive symptoms (Geriatric Depression Scale-Short Form [GDS-SF]) [42], and pain-related functional limitations (Western Ontario and McMaster Universities Osteoarthritis Index [WOMAC]) [43].

Game Performance Metrics

Game performance data were automatically recorded throughout the 16-week intervention for all participants in the intervention group (n=16). A total of 63 performance indicators were generated across 9 games, including play count, average score, play time, reaction time, and game-specific metrics.

Statistical Analysis

Baseline characteristics were compared between groups to assess randomization balance using *t* tests (unpaired and 2-tailed) for continuous variables and chi-square or Fisher exact tests for categorical variables. The primary analysis examined intervention effects on primary, secondary, and other health

XSL•FO
RenderX

outcomes using GEEs to account for the correlation among repeated measures within participants. GEE models specified an exchangeable working correlation structure with robust SEs. All randomized participants were analyzed according to their assigned groups (intention-to-treat). Missing observations were handled at the observation level using available-case analysis without imputation, with all 31 randomized participants retained in their originally assigned groups and each contributing all available time points to the estimation [44-46]. For grip strength, 1 participant could not be assessed because of hand surgery unrelated to the intervention and was therefore excluded from the grip strength model (n=30). All other outcomes included all 31 randomized participants (see the "Data Exclusion and Missing Data" section).

The full model included group (intervention vs control), time (baseline, 8 weeks, and 16 weeks), and the group × time interaction to examine whether intervention effects were significant. Risk-stratified analyses were also conducted, as prespecified during the study design phase. Years of education were included as a covariate in the models for cognitive function to account for potential confounding. Given the number of outcome variables tested, the Benjamini-Hochberg false discovery rate (FDR) correction was applied within the 6 primary outcomes (K-MMSE total, BBS, TUG, ASM, ASMI, and grip strength; 6 comparisons) at q=0.05. Secondary outcomes (MoCA-K total, Figure-8 Walk, 30-second Sit-to-Stand, 2-Minute Step Test, and fall incidence) and other outcomes (PSQI, GDS-SF, and WOMAC) were reported with unadjusted P values only. Subscale scores were reported descriptively without FDR correction. These analyses were distinguished by both outcome tier and inferential status. Confirmatory inference was restricted to the 6 prespecified primary outcomes with FDR correction. The secondary and other outcomes, the K-MMSE subscale analyses, and the prespecified risk-stratified subgroup analyses were exploratory and hypothesis-generating and were reported with unadjusted P values without confirmatory interpretation. The only post hoc, data-driven analyses were the exploratory correlations between game performance metrics and clinical outcomes (Figure S1 in Multimedia Appendix 1).

An exploratory analysis examined the associations between game performance metrics and significant changes in outcome measures in study 2, with P<.05 applied as the exploratory threshold for identifying significant outcome changes in the intervention group. Pearson correlation coefficients were calculated between game performance metrics and nominally significant changes in primary outcomes (pre-to-post and mid-to-post; for ASM, pre-to-post change, P=.04). For K-MMSE Recall (P=.01) and ASMI (P=.05), analyses were conducted in the high-risk subgroup (n=8) based on significant group × risk × time interactions. For ASM, analyses were conducted in the full intervention group (n=14).

Statistical significance was set at P<.05 (2-tailed). The FDR correction described above was applied to account for multiple outcome comparisons. The study was not powered to detect intervention effects for all outcomes or subgroup effects. All risk-stratified and correlation analyses were exploratory and hypothesis-generating. Effect sizes were calculated as Cohen d based on the between-group differences in pre-to-post change scores divided by the pooled SD of the change scores, with 95% CIs [27]. Analyses were performed using Python 3.12 (Python Foundation) with the statsmodels package for GEE models and SciPy for correlation analyses. Additional statistical details, including the analysis of fall incidence outcomes, are provided in Methods S1 in Multimedia Appendix 1.

Data Exclusion and Missing Data

Of the 31 randomized participants, all completed the baseline assessment except for 1 intervention participant who declined the grip strength measurement because of a history of bilateral hand surgery. This participant subsequently withdrew before the 8-week assessment. By the 8-week midpoint, 5 participants had withdrawn (2 intervention and 3 control), leaving 26 participants with data at that time point. By the 16-week postintervention assessment, 1 additional control participant had withdrawn because of scheduling conflicts, leaving 25 participants with data at that time point. The full longitudinal data set thus comprised 82 participant-by-time point observations across the 3 assessments.

Missing data resulted primarily from participant attrition rather than item-level nonresponse and were not imputed. All GEE analyses used available-case analysis at the observation level. Each participant-by-time point record was included when the outcome value was nonmissing, whereas records missing key covariates (group assignment or baseline risk stratum) were excluded. This approach leverages GEE's ability to accommodate unbalanced repeated-measures data without listwise deletion at the participant level [45,46], such that all 31 randomized participants were retained in their originally assigned groups, with each contributing all available observations to the estimation.

Results

Study 1: Pilot Study Results

The pilot study results are presented in Table 2. Among the primary outcomes, significant pre-post changes that survived FDR correction were observed for the BBS (P<.001, FDR-adjusted P=.002) and TUG (P<.001, FDR-adjusted P=.002). ASM (P=.04) and ASMI (P=.047) showed modest decreases but did not survive FDR correction (FDR-adjusted P=.07). The K-MMSE Visuospatial subscale showed a significant uncorrected pre-post change (P=.02). Among the secondary outcomes (Table S2 in Multimedia Appendix 1), all 3 measures survived FDR correction: Figure-8 Walk (P=.002, FDR-adjusted P=.006), 30-second Sit-to-Stand (P=.007, FDR-adjusted P=.01), and 2-Minute Step Test (P=.02, FDR-adjusted P=.02).

Risk-stratified analyses revealed nominally significant time × risk interactions for the K-MMSE Memory (P=.04) and Attention (P=.006) subscales, with differential patterns according to risk group (Figure 2).

Based on the pilot findings and participant feedback, the intervention protocol was refined for study 2. Instructional videos were added, real-time feedback was enhanced, the

XSL•FO
RenderX

program duration was extended from 12 to 16 weeks, and a midpoint assessment was added at 8 weeks.

Table 2. Comparison of cognitive and sensorimotor frailty over time for pilot testing.[a]

Variable	Intervention group (n=15)		*P* value	FDR[b] *P* value

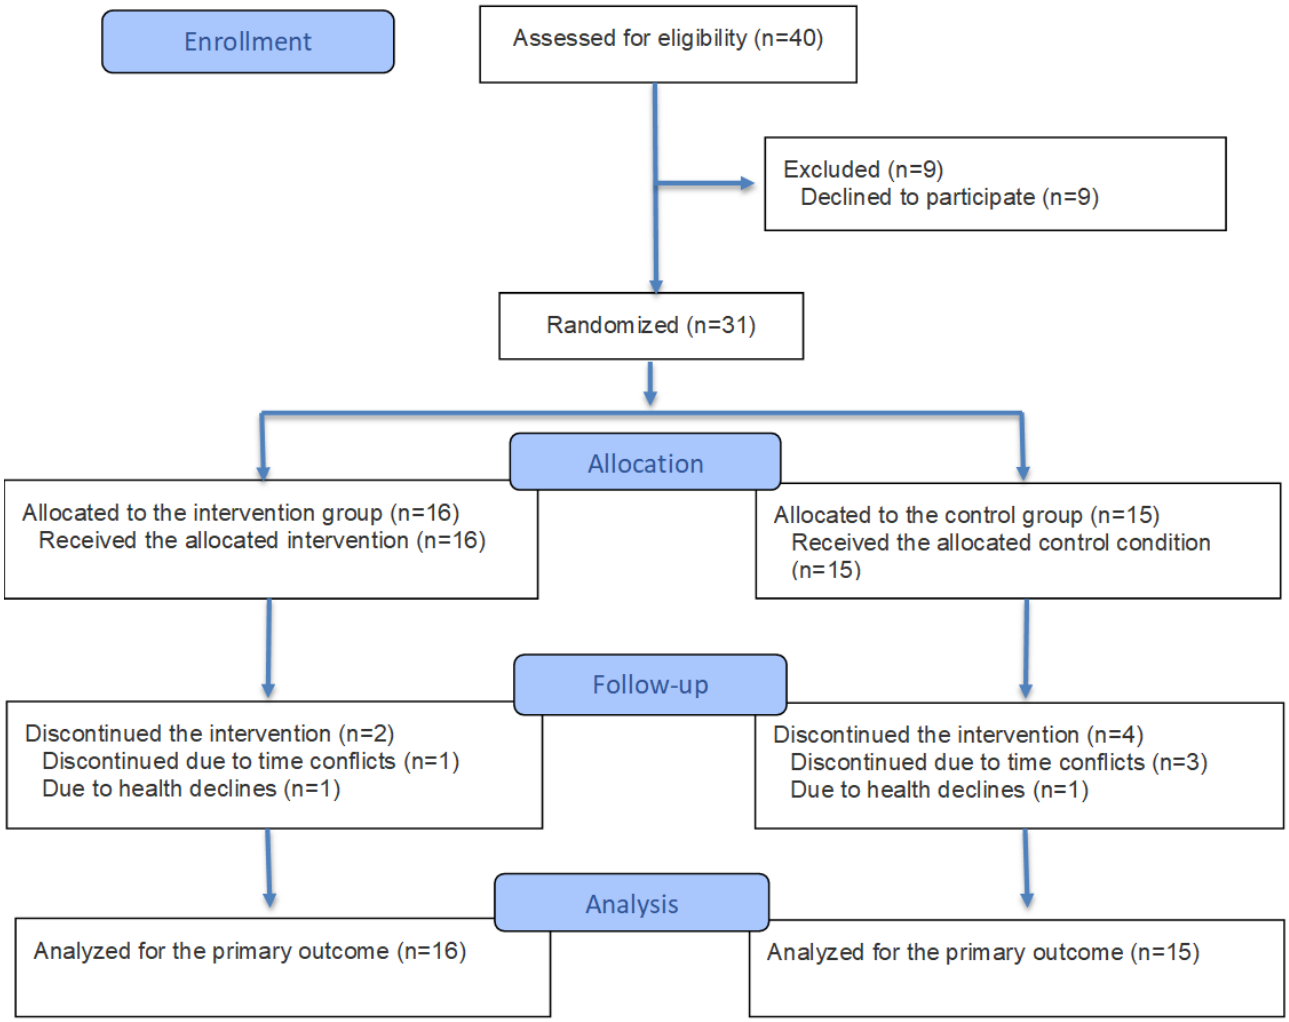
Study 2: The Main RCT Results



Participant Characteristics

Participant flow is presented in Figure 3. Of the 40 older adults screened, 31 were randomized to the intervention (n=16) or control (n=15) group. Six participants withdrew during the study. All 31 randomized participants were included in the intention-to-treat analysis (82 total observations across 3 time points). See Multimedia Appendix 2 for the study's CONSORT-EHEALTH (Consolidated Standards of Reporting Trials of Electronic and Mobile Health Applications and Online Telehealth) checklist.

XSL•FO
RenderX

Baseline characteristics are presented in Table 3. Participants (mean age 81.5 years; 26/31, 84%, female) were low-income older adults living alone who were receiving Public Community Care services. The groups were comparable at baseline (see Table 3 for *P* values).

[a]US $1=1344 Korean won (KRW).

Intervention Effects on Primary Outcomes

As shown in Table 4, there were no significant group × time interactions for cognitive function. The K-MMSE total score showed no significant interaction (*P*=.27, FDR-adjusted *P*=.38). No significant interactions were observed for the K-MMSE subscales (Orientation, *P*=.36; Recall, *P*=.09; Attention, *P*=.37; Language, *P*=.27; and Visuospatial, *P*=.12).

A nominally significant group × time interaction was observed for the sarcopenia-related index ASM (*P*=.04; Cohen *d*=0.39, 95% CI −0.41 to 1.18). The intervention group maintained ASM over the 16-week period (baseline: 15.35 kg; postintervention: 15.77 kg), whereas the control group showed a decline (baseline: 17.03 kg; postintervention: 15.48 kg; Table 4). The group × time interaction for ASMI did not reach statistical significance (*P*=.05; *d*=0.38, 95% CI −0.41 to 1.18). This pattern is consistent with possible preservation of muscle mass, although the finding did not survive FDR correction. The BBS showed a marginally significant group × time interaction (*P*=.05; *d*=−0.27), likely reflecting a ceiling effect given the high baseline scores in both groups (intervention: 52.88; control: 52.73 of a maximum score of 56). No significant group × time interactions were observed for the other sensorimotor frailty measures (Timed Up and Go, *P*=.65; for grip strength, *P*=.32).

After FDR correction, none of the group × time interactions remained statistically significant (all FDR-adjusted *P*>.16; see Table 4). However, effect sizes are presented to provide context for the observed differences. Before correction, the nominally

XSL•FO
RenderX

significant findings showed small-to-medium effect sizes (ASM *d*=0.39; ASMI *d*=0.38), and the risk-stratified analyses revealed medium-to-large effect sizes among high-risk participants for K-MMSE Recall (*d*=0.73) and ASMI (*d*=0.90), warranting confirmation in larger trials with risk-enriched samples.

Table 4. Comparison of cognitive and sensorimotor frailty outcomes between intervention and control groups over time (n=31).

Variable	Intervention (n=16)		Control (n=15)		Group × time[a]		*d*[b]

[a]Group × time interaction effects were analyzed using generalized estimating equations with exchangeable correlation structure.

[b]Cohen *d* was calculated from between-group differences in change scores divided by pooled SD.

[c]FDR: false discovery rate.

[d]The Benjamini-Hochberg FDR correction (*q*=0.05) was applied within the 6 primary outcomes (Korean Mini-Mental State Examination total, Berg Balance Scale, Timed Up and Go, appendicular skeletal muscle mass, Appendicular Skeletal Muscle Mass Index, and grip strength). No outcomes reached significance after FDR correction.

[e]The Korean Mini-Mental State Examination models were adjusted for years of education.

[f]N/A: not applicable.

[g]*P*<.05.

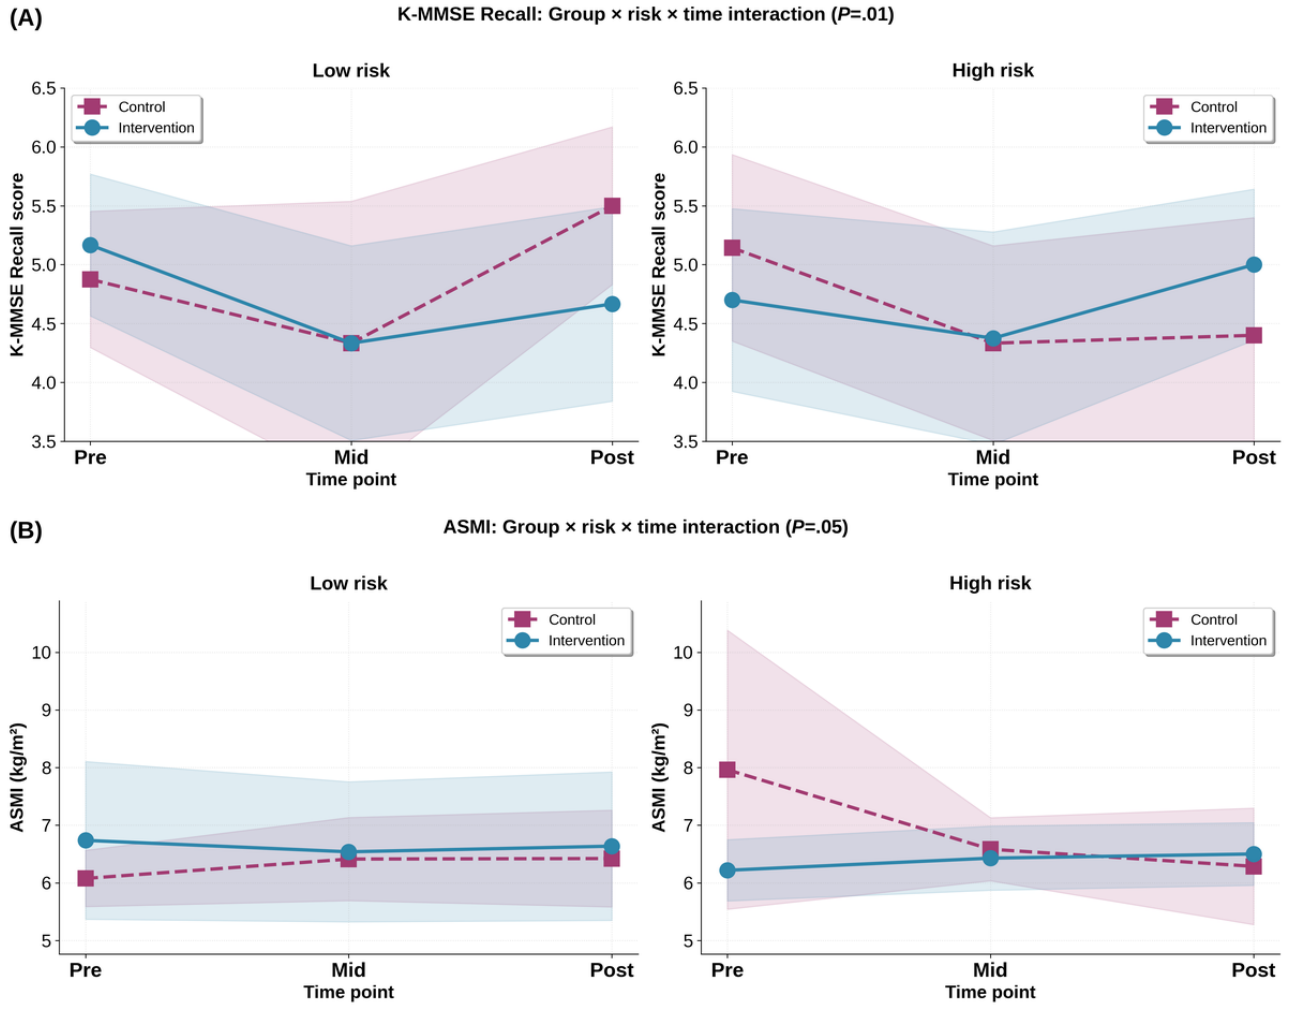
Intervention Effects on Secondary and Other Health Outcomes

As a secondary outcome, self-reported fall incidence was examined at 3 time points (Table S5 in Multimedia Appendix 1). The group × time interaction for pre-post fall incidence was not statistically significant (Wald χ^2_1=0.66, *P*=.42; odds ratio [OR] 0.47, 95% CI 0.07-2.94). At the postintervention assessment, fall incidence was numerically lower in the intervention group than in the control group (5/14, 35.7% vs 7/11, 63.6%; OR 0.32, 95% CI 0.06-1.64). Although this between-group difference did not reach statistical significance (Fisher exact *P*=.24), the direction and magnitude of the effect favored the intervention group. As a secondary outcome, this finding should be interpreted as hypothesis-generating only.

A 1-year postintervention follow-up assessed fall incidence through community caregiver reports collected as part of routine Public Community Care service monitoring. No fall events were reported for any participant in either the intervention or control group during the 12-month follow-up period (intervention, 0/14; control, 0/14). A separate GEE model comparing baseline with the 12-month follow-up also showed no significant group × time interaction (Wald χ^2_1=0.13, *P*=.71; OR 1.39, 95% CI 0.24-8.05), although this model should be interpreted with caution because of quasi-complete separation resulting from the absence of events at follow-up. Although the absence of falls during follow-up is notable for this population with elevated fall risk, the floor effect precluded between-group comparisons, and the absence of a nonparticipating comparison group limited causal interpretation.

No significant group × time interactions were observed for the secondary outcomes (MoCA-K, *P*=.12; Figure-8 Walk, *P*=.65; 30-second Sit-to-Stand, *P*=.72; and 2-Minute Step Test, *P*=.62; Tables S3 and S4 in Multimedia Appendix 1) or the self-reported health outcomes (PSQI, *P*=.19; GDS-SF, *P*=.55; and WOMAC, *P*=.68).

XSL•FO
RenderX



Risk-Stratified Analysis

Figure 4 presents outcomes with risk-level interactions. These analyses are exploratory and hypothesis-generating because of the small subgroup cell sizes (n=5-8 per cell). High risk was defined as meeting the criteria for cognitive impairment (K-MMSE ≤21 or Montreal Cognitive Assessment [MoCA-K] <23) combined with a history of recurrent falls.

A significant uncorrected 3-way interaction (group × risk × time) was observed for K-MMSE Recall (Wald χ^2_2=6.16, *P*=.01; Figure 4A). Among the high-risk participants, the intervention group showed an improvement in Recall (4.70-5.00; *d*=0.73), whereas the control group declined (5.14-4.40). The low-risk participants showed the opposite pattern (*d*=−0.99), suggesting that cognitive effects may be concentrated among individuals with greater baseline impairment.

The 3-way interaction for ASMI reached borderline significance (Wald χ^2_2=6.00, *P*=.05; Figure 4B). Among the high-risk participants, the between-group effect size was large (*d*=0.90): the control group showed a substantial decline (8.0-6.3 kg/m^2), whereas the intervention group maintained ASMI levels (6.2-6.5 kg/m^2). No other outcome variables showed significant uncorrected 3-way interactions (group × risk × time), including the MoCA-K total (*P*=.71) and subscale scores (Memory, *P*=.83; Attention, *P*=.71; Language, *P*=.71; Visuospatial, *P*=.75; Orientation, *P*=.89), K-MMSE total (*P*=.71) and other subscale scores (Recall, *P*=.37; Orientation, *P*=.85; Attention, *P*=.75; Language, *P*=.71; Visuospatial, *P*=.75), and sensorimotor function measures (BBS, *P*=.82; TUG, *P*=.83; Figure-8 Walk, *P*=.75; grip strength, *P*=.81; 30-second Sit-to-Stand, *P*=.70; 2-Minute Step Test, *P*=.70; and ASM, *P*=.70).

Figure 4. Risk-stratified intervention effects on cognitive and sensory-motor frailty outcomes. (A) Korean Mini-Mental State Examination (K-MMSE) Recall scores: a significant uncorrected group × risk × time interaction was observed (*P*=.01). In the high-risk subgroup, the intervention group showed improvement in Recall from mid- to postintervention, whereas the control group continued to decline. (B) Appendicular Skeletal Muscle Mass Index (ASMI): a group × risk × time interaction reached borderline significance (*P*=.05). In the high-risk subgroup, the intervention group maintained relatively stable muscle mass, whereas the control group showed continued decline. Lines represent estimated marginal means, and shaded areas indicate 95% CIs.

Exploratory Game Performance Analyses

Post hoc exploratory correlations between game performance metrics and clinical outcomes (Figure S1 in Multimedia Appendix 1) suggested potential associations between cognitive challenge during gameplay and cognitive outcomes, although the small subgroup sizes require cautious interpretation.

Discussion

Principal Findings

This study examined the effects of a pressure sensor–based exergame intervention on cognitive and sensorimotor frailty in socially vulnerable older adults through 2 sequential studies. In the pilot RCT, no primary outcomes survived FDR correction, indicating that the present findings do not establish efficacy and should be interpreted as preliminary. Within this cautious framework, the pilot study (study 1), an uncontrolled single-arm design, showed pre-post improvements in balance and mobility that survived FDR correction. It also showed an uncorrected pre-post improvement in the K-MMSE Visuospatial subscale. This finding is consistent with evidence that proprioceptive training can enhance visuospatial processing through sensorimotor integration in the posterior parietal cortex [47,48]. In the RCT (study 2), nominally significant uncorrected signals were observed for ASM preservation. In exploratory risk-stratified analyses based on small subgroup cell sizes, comparable uncorrected signals emerged for K-MMSE Recall and ASMI among the high-risk participants. These exploratory patterns are hypothesis-generating only. They suggest that older adults with mild-to-moderate impairment may represent a potentially more responsive subgroup in whom the residual capacity for improvement is greater. Confirmation in adequately powered, risk-enriched trials is required.

Comparison With Prior Work

The uncorrected preservation of ASM, together with trends toward greater grip strength, may reflect the functional loading produced by the repeated weight-shifting and stepping movements in the Brain Step program. A meta-analysis of 24 RCTs reported that exercise interventions produced a significant increase in appendicular muscle mass (+0.4 kg) among community-dwelling older adults [49], and a recent exergame RCT similarly demonstrated significant improvements in ASM following exergame-based training in residents of long-term care facilities [50]. However, these findings should be interpreted cautiously given the lack of statistical significance after FDR correction in our study.

Although the intervention group showed numerically higher BBS scores and shorter TUG times, no significant group × time interaction was observed. Participants were independently ambulatory older adults with high baseline functional levels (BBS approximately 52-53 of 56; TUG approximately 7-8 seconds). At these baseline levels, the BBS and TUG had limited capacity to detect further improvement, indicating ceiling effects. This likely reflects a mismatch between the selected outcome measures and the functional level of the sample rather than definitive evidence of no benefit. Therefore, the lack of significant effects on balance and mobility should not be interpreted as evidence of no intervention benefit because these measures may have been insufficiently sensitive to detect change in this high-functioning sample. Consistent with this interpretation, previous studies have reported limited sensitivity of the BBS for detecting subtle balance changes in high-functioning older adults [51,52] and reduced responsiveness of the TUG in individuals with preserved mobility [53]. Conventional clinical assessments such as the BBS and TUG may not adequately capture subtle changes in dynamic balance or real-world mobility, particularly under complex or dual-task conditions [54,55]. These findings underscore the need to select outcome measures that are both sensitive and ecologically valid and that are appropriately matched to the baseline functional level of the target population.

The K-MMSE Recall pattern among the high-risk participants was consistent across both studies, aligning with exergame RCTs reporting cognitive effects in individuals with MCI [19,20,56] but not in healthy [57,58] or severely impaired [59] populations. The concurrent preservation of muscle mass alongside improved recall in the high-risk participants is consistent with growing evidence that lower limb muscle function and cognitive function are bidirectionally linked [60,61] and that dual-task training engaging both motor and cognitive systems may produce benefits across both domains [12,62]. However, these concurrent patterns were observed in small, underpowered subgroups and should be regarded as hypothesis-generating signals requiring confirmation in adequately powered trials.

Self-reported fall incidence showed a nonsignificant directional reduction favoring the intervention group at the postintervention assessment (intervention, 35.7% vs control, 63.6%; d=−0.42). At the 12-month follow-up, no falls were reported in either group. This likely reflects the shift from retrospective self-report to prospective caregiver monitoring rather than a true treatment effect [63]. Whether proprioceptive-motor training can attenuate fall risk warrants investigation in a larger sample with longer follow-up.

Implications for Digital Health Equity

The target population—low-income older adults living alone who were receiving Public Community Care services—is systematically underrepresented in digital health research. The successful completion of an RCT with this population, facilitated by a participatory research committee that endorsed randomization, demonstrates the feasibility of conducting rigorous evaluations within community care settings. This study completes a 3-phase research program progressing from digital health monitoring [24] through community care–mediated intervention, in which caregivers identify needs and lay workers deliver services [25], to targeted cognitive-motor training, suggesting that the standardized Public Community Care infrastructure offers a scalable platform for embedding technology-based interventions. The high retention rate despite the participants' advanced age (mean 81.5 years), low-income status, and living alone suggests that welfare center–based delivery is a feasible model for reaching underserved populations. From a policy perspective, pressure-sensor mat systems may offer a potentially cost- and resource-efficient option for community care settings.

Limitations

Several limitations should be considered. The small sample size (n=15 for the pilot study; n=31 for the pilot RCT) limited statistical power, and no findings survived FDR correction. The small sample size and the inclusion of outcomes across multiple

XSL•FO
RenderX

domains reflected 2 design priorities: embedding the intervention within the welfare center's existing infrastructure and adopting a multidimensional monitoring framework [24,25]. The risk-stratified subgroup analyses involved very small cell sizes (n=5-8 per subgroup), substantially limiting the reliability of subgroup effect estimates and increasing the risk of inflated type I error and unstable estimates. Although the observed effect sizes were small-to-medium overall (d=0.38-0.50) and medium-to-large in the high-risk subgroups (d=0.73-0.92), these findings should be interpreted as exploratory and hypothesis-generating and require confirmation in adequately powered trials with prespecified subgroup hypotheses. Nonetheless, low-income older adults receiving Public Community Care services constitute a hard-to-reach and underrepresented population that is rarely included in digital health research. We therefore deliberately examined the high-risk subgroup pattern that recurred from the single-arm pilot study (study 1) to the pilot RCT (study 2) and present it strictly as exploratory and hypothesis-generating to inform hypotheses, outcome selection, and sample enrichment for other investigators studying similarly constrained, hard-to-recruit populations.

Relatedly, the selected balance and mobility outcome measures were not well matched to the sample's baseline functional level. Several balance and mobility measures, particularly the BBS and TUG, exhibited ceiling effects because participants were already highly functional at enrollment. These ceiling effects limited the sensitivity of the measures to detect change; accordingly, the null findings for balance and mobility should be interpreted as inconclusive rather than negative. Future trials should select outcome measures that are matched to the target population's functional level and incorporate more sensitive, ecologically valid measures (eg, instrumented gait analysis or dual-task assessments).

Despite randomization, the control group had numerically higher baseline K-MMSE scores than the intervention group (25.73 vs 24.44). This minor imbalance raises the possibility of regression to the mean for cognitive outcomes. The use of a passive (no-contact) control group constitutes a key limitation of internal validity. Without an active or attention-matched comparator, any observed differences cannot be attributed unambiguously to the cognitive-motor training itself because the effects of attention, social contact, novelty, and facilitator engagement remain confounded with the intervention. Although passive control groups are often used in feasibility-stage studies, particularly when the primary objective is to evaluate delivery feasibility within an existing care infrastructure, definitive trials should employ active or sham-exergame controls [28] to strengthen causal inference.

Cognitive outcomes were limited to global screening measures (K-MMSE and MoCA-K) rather than comprehensive neuropsychological batteries, and practice effects cannot be fully excluded. Generalizability is limited by the single-site recruitment context. Multisite replication across populations with diverse socioeconomic characteristics is needed. For independently ambulatory older adults, the 1-year follow-up period may not have been sufficient to detect meaningful differences in fall incidence. The 16-week intervention period also represents a limitation for evaluating durable cognitive and sensorimotor changes.

Conclusion

The 2 sequential studies demonstrate the initial feasibility of delivering a pressure sensor–based exergaming intervention through the existing Public Community Care infrastructure as an engaging, community-based program for socially vulnerable older adults experiencing age-related cognitive and sensorimotor decline. Designed to operate within the limited resources of a community welfare center using nonspecialist staff as facilitators, the Brain Step program offers a scalable template for multisite expansion. However, the current evidence is preliminary. The observed effects did not survive FDR correction, and the preliminary signals for muscle mass preservation and cognitive improvement were concentrated among participants with mild-to-moderate impairments, suggesting that this subgroup may benefit most from movement-mediated cognitive-motor training. Adequately powered multisite trials with longer follow-up are needed to confirm these findings and to evaluate the integration of exergame-based interventions within personalized digital health care frameworks that combine wearable-based monitoring of daily functional changes with adaptive intervention delivery.

Acknowledgments

We are very grateful to the older adults and care service providers for their participation and to the staff and community caregivers at the Seongbuk Municipal Senior Welfare Center for their support. We are also deeply grateful to the late Mr. Jong-hoon Kim, father of Junesun Kim, for generously serving as the first pretester of the Brain Step system; his early contribution helped lay the foundation for this work. During manuscript preparation, the authors used Claude (Anthropic) to assist with English grammar correction, reference formatting and reordering, and general manuscript formatting. All artificial intelligence–assisted content was reviewed and edited by the authors, who take full responsibility for the content of this publication.

Funding

This study was supported by the ANCHOR through the Seoul ANCHOR Center, funded by the Ministry of Education (MOE) and the Seoul Metropolitan Government (2026-ANCHOR-01-003-01), the Pioneer Research Center Program (RS-2022-NR067566) through the National Research Foundation of Korea, and the Basic Science Research Program through the National Research Foundation of Korea (NRF), funded by the Ministry of Science and ICT (MSIT) (RS-2024-00348012).

Abstract

Background: Falls are a major cause of morbidity among older adults, yet fall risk may begin to emerge during midlife. Physical performance measures may identify early functional vulnerability associated with later-life health outcomes.

Objective: This study examined whether midlife gait speed and muscle performance were associated with recurrent falls later in life.

Methods: This study was a secondary analysis of prospectively collected data from the Midlife in the United States (MIDUS) cohort. Independent adults (n=309) aged 45 to 64 years at wave 2 (2004-2009) who completed physical performance assessments were followed to wave 3 (2013-2021). Baseline measures included gait speed from a 50-foot walk test, grip strength, sit-to-stand time, and calculated lower-extremity power. The primary analysis examined associations between baseline physical performance and recurrent falls at follow-up (≥2 falls in the previous 12 months). A sensitivity analysis repeated the primary models but was restricted to participants without a baseline history of recurrent falls.

Results: At follow-up, 20.4% (63/309) of participants reported recurrent falls. Slower midlife gait speed was associated with higher odds of recurrent falls (odds ratio 1.43, 95% CI 1.05-1.95; *P*=.02), whereas muscle performance measures were not associated with falls in the primary analysis. The association between slower gait speed and recurrent falls remained significant in the sensitivity analysis. Over follow-up, muscle performance declined, whereas gait speed remained stable.

Conclusions: Slower midlife gait speed was associated with higher odds of recurrent falls, suggesting that fall vulnerability may be detectable as early as midlife. Given the exploratory nature of this study, further studies are warranted to confirm these findings.

KEYWORDS

middle age; mobility; fall risk; subjective age; physical performance

Introduction

Maintaining locomotor ability across the adult lifespan is a central goal of healthy aging. In many cases, increased life expectancy is not accompanied by preserved functional capacity, making mobility-related outcomes in later life a major health concern [1]. At the individual level, mobility limitations in older adulthood are associated with reduced participation, loss of independence, and increased fall risk [2]. Falls represent a substantial public health burden, contributing to substantial health care use, economic costs, and mortality among older adults [3].

Fall prevention efforts focus on identifying risk factors in clinical and research settings. Among these, markers of physical function are particularly informative because they reflect mobility capacity and physiological reserve and have been associated with increased fall risk and adverse health outcomes [4]. Recurrent falls, defined as 2 or more falls within 12 months, are of particular concern because they are more strongly associated with frailty, hospitalization, and mortality than

XSL•FO
RenderX

isolated falls [3]. Despite extensive research and prevention initiatives, population-level progress remains limited, with increasing fall-related mortality among US adults aged 65 years and older [5,6], and annual fall prevalence remaining approximately 1 in 4 [6].

Importantly, falls are not limited to older adulthood, and midlife may represent a critical window for prevention. Recent harmonized cohort analyses across multiple countries report an annual fall prevalence of 17% to 28% among community-dwelling middle-aged adults. Fall rates increase markedly across midlife, nearly tripling from early (45-54 years) to late (55-64 years) midlife [7,8]. Furthermore, approximately 1 in 5 middle-aged adults report mobility limitations despite the absence of overt clinical conditions [9]. These impairments are often unrecognized in routine care, highlighting the importance of early detection of mobility decline to enable timely preventive interventions [8,10]. Screening physical performance during midlife may therefore provide insight into early functional vulnerability.

To better understand functional aging dynamics, several population-based cohorts initiate assessments in midlife to support a life-course perspective on aging [8,11-14]. One such example is the Midlife in the United States (MIDUS) study, a national longitudinal cohort that integrates objective assessments of physical function with psychosocial and health measures [12,13]. These include fall prevalence as well as self-rated health and subjective age, indicators that have been independently associated with subsequent physical decline, frailty, disability, and mortality [15-17]. Together, this multidimensional framework enables the examination of physical function alongside health perceptions in midlife and their relevance to aging-related outcomes.

Among the wide range of physical function variables available in MIDUS, gait speed and muscle performance capture distinct yet complementary aspects of physical function and mobility. These domains have been widely used to elucidate mechanisms and predictors of age-related decline [14,18-22]. Gait speed is an integrative marker reflecting multisystem physiological function, including musculoskeletal, cardiorespiratory, neurological, and cognitive domains, and is widely recognized as a “sixth vital sign” for aging and frailty [23]. Muscle performance specifically quantifies neuromuscular capacity and is a direct indicator of sarcopenia and physical reserve [20,24].

Several studies have demonstrated that slower gait speed and reduced muscle performance are associated with recurrent falls. However, most prior research has focused on older and often more functionally impaired populations [22,25-27]. Studies including middle-aged adults have shown that these measures are associated with mobility difficulties [14,28], whereas a study of community-dwelling adults aged 50 to 65 years reported no association with adverse events, including falls [14]. Evidence specifically examining the relationship between physical performance and falls in middle-aged populations therefore remains limited. Examining this association in independent, community-dwelling, middle-aged adults may help identify risk factors that emerge before overt functional decline.

Using longitudinal MIDUS data, this study primarily examined whether midlife gait speed and muscle performance were associated with recurrent falls later in life. In addition, longitudinal changes in gait speed and muscle performance from midlife onward were examined to characterize their trajectories across adulthood. Secondary analyses assessed whether these same measures were associated with subjective age and self-rated health at follow-up.

Methods

Study Design and Participants

We conducted a longitudinal analysis using data from the MIDUS cohort, focusing on wave 2 (baseline, 2004-2009) [12] and wave 3 (follow-up, 2013-2021) [13]. Although MIDUS is a prospective cohort study, the present investigation represents a secondary analysis linking midlife physical performance at wave 2 with outcomes assessed at wave 3. This study is reported in accordance with the STROBE (Strengthening the Reporting of Observational Studies in Epidemiology) guidelines [29], and the completed checklist is available in Table S1 in Multimedia Appendix 1.

The analytic sample was defined based on eligibility at wave 2 and was restricted to relatively healthy, independent adults aged 45 to 64 years who did not use walking aids and were able to complete the 50-foot walking test. To minimize confounding and strengthen internal validity, participants with conditions likely to influence physical performance or fall risk were excluded. Specifically, participants were excluded if they reported a history of stroke or transient ischemic attack, head injury requiring an overnight emergency department or hospital stay, neurological disorder or cancer, blindness in one or both eyes, prior antiepileptic medication use, or opioid use at wave 2.

Physical performance measures (gait speed and muscle performance) obtained at wave 2 were examined in relation to the primary outcome of recurrent falls reported at wave 3. At wave 3, participants were asked to report the number of falls experienced during the previous 12 months. Responses were recorded as a count variable and subsequently categorized as recurrent falls (≥2 falls) versus nonrecurrent (0-1 falls). In addition, we examined changes in physical performance between the 2 waves. Secondary exploratory analyses examined associations between baseline physical performance and subjective age and self-rated health at follow-up. All MIDUS data are fully deidentified and anonymized, ensuring compliance with ethical research standards.

Physical Performance Measures

As part of the MIDUS data collection, participants completed the 50-foot timed walk test twice. They were instructed to walk at their usual comfortable speed from a standing start to a designated turnaround point and back. For the present analysis, gait speed (m/s) was calculated by dividing the total distance (50 feet; 15.24 m) by completion time in seconds. The average of the 2 trials was used in all analyses.

During the MIDUS assessment, handgrip strength was measured using a handheld dynamometer and recorded in kilograms

XSL•FO
RenderX

(equivalent to kilogram-force). Participants performed 3 maximal-effort trials. For the present analysis, the mean value across the 3 trials of the dominant hand was used.

Participants also completed the 5-repetition sit-to-stand test as part of the MIDUS protocol. For the present analysis, 2 indicators of lower-limb muscle performance were derived from this test: the total sit-to-stand completion time (seconds) and lower-extremity muscle power. Sit-to-stand completion time was obtained directly from the MIDUS dataset, whereas lower-extremity muscle power was calculated for the present analysis using an established allometric equation incorporating body mass, height, chair height (approximated as 45 cm), and total sit-to-stand duration [30]:

Self-Perceived Age and Health

Subjective age was measured across MIDUS waves by asking, "Many people feel older or younger than they actually are. What age do you feel most of the time?" Participants reported the age they felt in years as an open-ended numeric response, which was treated as a continuous variable in subsequent analyses. Self-rated health was assessed using 2 ordinal items: general physical health ("In general, would you say your physical health is excellent, very good, good, fair, or poor?"; 1=excellent to 5=poor) and comparative health relative to age peers ("Compared to others your age, would you say your health is much better, somewhat better, about the same, somewhat worse, or much worse?"; 1=much better to 5=much worse).

Statistical Analysis

Descriptive statistics are presented as mean (SD) or median with IQR, as appropriate. Continuous variables were assessed for distribution using visual inspection of histograms and Q-Q plots. Several complementary modeling approaches were used to address the study objectives. For the primary analysis, logistic regression examined whether midlife gait speed and muscle performance (grip strength, sit-to-stand completion time, and lower-limb muscle power) were associated with recurrent falls (≥2 falls in the preceding 12 months) at follow-up. Except for sit-to-stand completion time, all physical measures were directionally inverted prior to modeling so that odds ratios (ORs) reflected the effect of poorer performance. Age-related changes in gait speed and muscle performance between MIDUS waves were examined using linear mixed-effects models with random intercepts for participant ID and adjustment for baseline age and follow-up interval to estimate within-person change over time.

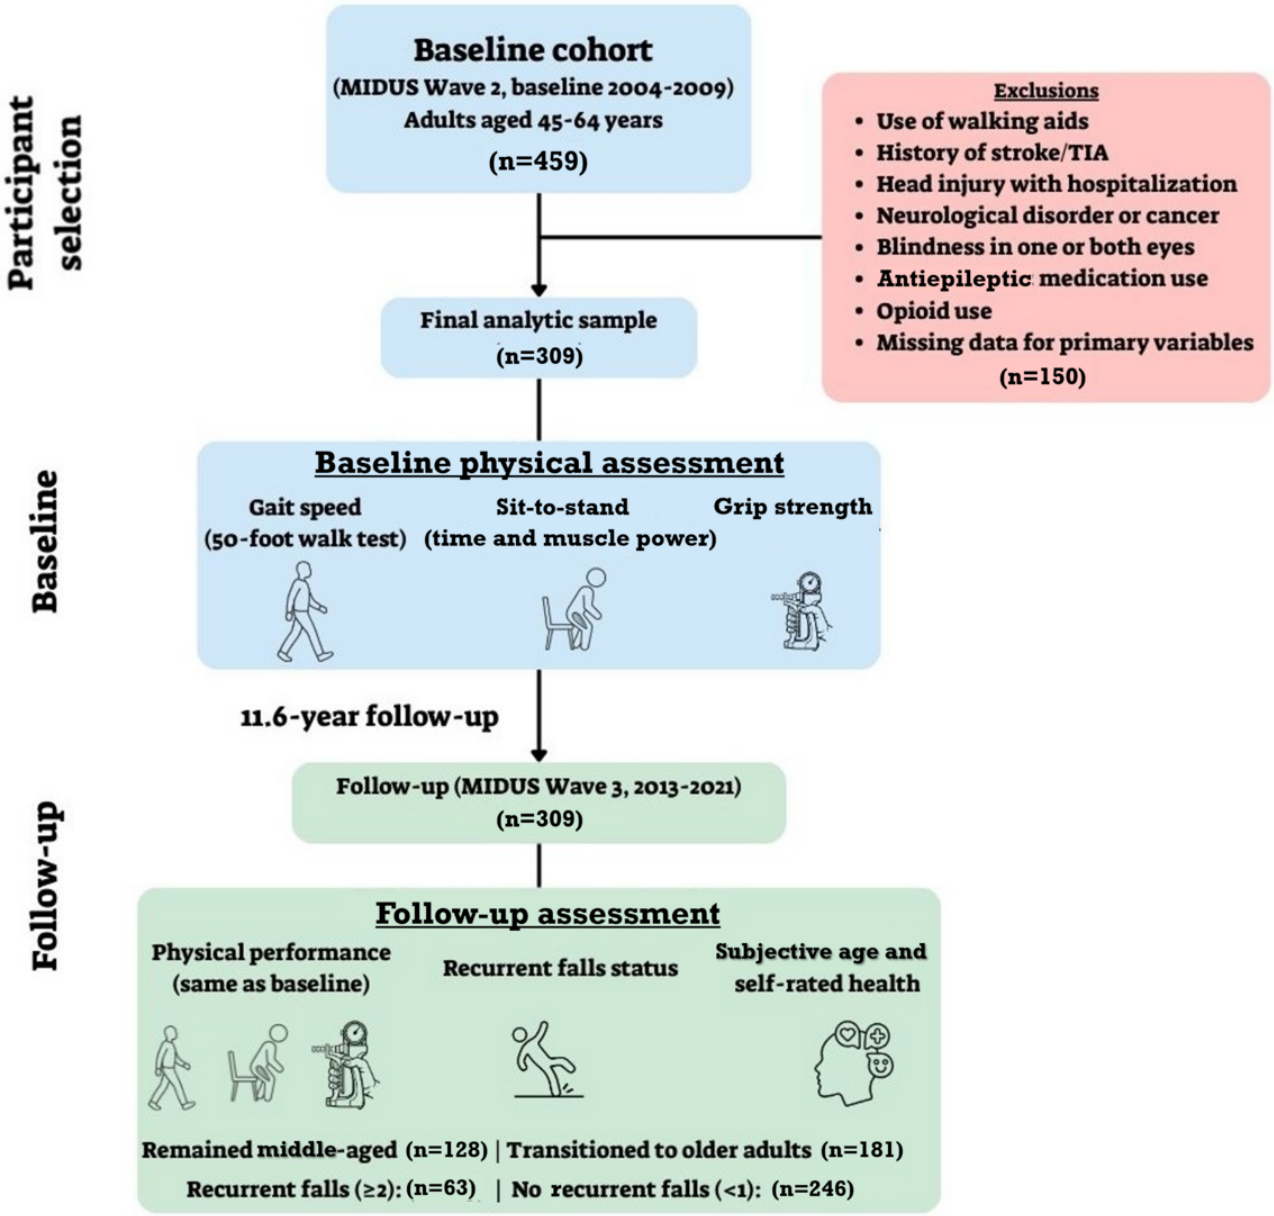
Secondary analyses evaluated associations of physical measures with subjective age and self-perceived health at follow-up, using linear regression for subjective age and ordinal regression for both self-perceived health measures (general physical health and comparative health). Primary and secondary regression models were adjusted for follow-up interval, baseline age, sex, BMI, height, baseline symptom burden (count of self-reported symptoms and chronic conditions), and the baseline value of the respective dependent variable.

Additionally, subgroup analyses were conducted by stratifying participants by age at follow-up (<65 or ≥65 years). The magnitude of associations in linear models was assessed using standardized regression coefficients (β), with values of 0.1, 0.3, and 0.5 denoting small, medium, and large effects, respectively [31,32]. For multiple testing, separate domains were defined in advance. Consistent with the literature, gait speed and muscle performance were treated as distinct domains. Gait speed is an integrative measure of multisystem physiological function [23], whereas grip strength, sit-to-stand time, and sit-to-stand power together index neuromuscular capacity [20,24]. The significance threshold was therefore adjusted within the muscle performance domain (P<.016) but not for gait speed, and unadjusted P values with 95% CIs are reported throughout.

As a sensitivity analysis, each primary adjusted and unadjusted model, for gait speed and each muscle performance measure, was refitted in participants free of recurrent falls at baseline (wave 2). This tested whether midlife performance was associated with newly emerging, rather than persistent, recurrent falls at follow-up. These sensitivity analyses were not adjusted for multiplicity and were interpreted as supportive rather than confirmatory. Statistical analyses were conducted in R (version 4.3.0; R Foundation for Statistical Computing) using the *tidyverse* and *lme4* packages [33-35].

Ethical Considerations

This study is a secondary analysis of deidentified data from the MIDUS Biomarker Project. The original data collection received ethics approval from the institutional review board at the University of Wisconsin-Madison, and informed consent was obtained from all participants by the MIDUS investigators.



Results

Overview

The participant selection process and the final analytic sample are shown in Figure 1. The initial dataset included 459 middle-aged participants at baseline (MIDUS wave 2). After applying prespecified exclusion criteria and removing cases with missing data, the final analytic sample consisted of 309 participants, 45% (n=141) of whom were male. The mean age was 54.62 (SD 5.60) years at baseline and 66.26 (SD 5.66) years at follow-up. At follow-up, 181 (58.6%) participants were 65 years or older. The mean interval between waves was 11.64 (SD 1.25) years. The median baseline count of self-reported symptoms and chronic conditions was 3 (IQR 2-4). A total of 63 (20.4%) participants reported recurrent falls (≥2 falls) at follow-up; of these, 15 (23.8%) had already been recurrent fallers at wave 2, and 48 (76.2%) were newly recurrent at follow-up. Demographic characteristics, health indicators, and physical performance measures at MIDUS waves 2 and 3 are presented in Table 1.

Table 1. Sample characteristics in wave 2 and wave 3.

Variable	MIDUS wave 2 (baseline)	MIDUS wave 3 (follow-up)
General characteristics (N=309)		
Age (y), mean (SD)[a]	54.62 (5.60)	66.26 (5.66)
Female, n (%)	168 (54.4)	168 (54.4)
BMI (kg/m^2), mean (SD)	29.25 (5.85)	29.74 (6.43)
Reported symptoms and chronic conditions, median (IQR)	3 (2-4)	4 (2-6)
Recurrent fallers[b], n (%)	55 (17.8)	63 (20.4)
Physical performance, mean (SD)		
Gait speed[c] (m/s)	1.11 (0.20)	1.11 (0.20)
Grip strength (kg)	36.40 (12.15)	30.99 (10.56)[d]
STS[e] time (s)	9.24 (3.21)	10.52 (4.10)[d]
STS mean power (W)	360.55 (163.47)	312.96 (141.26)[d]
Self-perceived age and health (n=280)		
Subjective age (y), mean (SD)	42.28 (10.80)	49.57 (9.59)
Differences between true age and subjective age, mean (SD)[f]	9.36 (9.42)	11.35 (8.40)
Self-perceived general physical health, median (IQR)[g]	2 (2-3)	2 (2-3)
Self-perceived health compared with age peers, median (IQR)	2 (1-3)	2 (1-2)

[a]Chronological age (n=309) and subjective age (n=280) are reported for different analytic samples.

[b]Recurrent falls were defined as the self-reported occurrence of 2 or more falls in the 12 months preceding each assessment.

[c]Gait speed was calculated from the 50-foot walk test as distance divided by completion time.

[d]*P*<.001 for changes in physical performance between waves, analyzed using linear mixed-effects models adjusted for baseline age and the time interval between assessments.

[e]STS: sit-to-stand.

[f]The age-difference values represent the mean within-person differences between chronological and subjective age calculated within the n=280 subsample and therefore do not equal the differences between the means reported above.

[g]Self-perceived general and comparative health were measured on a 1 to 5 scale, with higher scores indicating worse perceived health.

Association of Physical Performance Measures at Wave 2 With Recurrent Falls at Wave 3

Among the physical performance measures examined, only gait speed was significantly associated with recurrent falls. Slower gait speed was associated with higher odds of 2 or more falls at follow-up in the total sample (OR 1.43, 95% CI 1.05-1.95; *P*=.02), corresponding to a 43% increase in the odds of recurrent falls per 1 SD decrease in gait speed. In the age-stratified adjusted models, the association was stronger among participants who were 65 years or older at follow-up (OR 1.72, 95% CI: 1.11-2.74; *P*=.02), whereas no significant association was observed among participants younger than 65 years at follow-up (OR 1.15, 95% CI 0.73-1.86; *P*=.55). Figure 2 illustrates the predicted probability of recurrent falls at follow-up according to baseline gait speed in the total sample and age-stratified analyses. In contrast to gait speed, no statistically significant associations were observed between sit-to-stand time, calculated sit-to-stand power, and grip strength and recurrent falls in the total sample or in the age-stratified analyses. Results from the unadjusted and adjusted models are presented in Table 2. In a sensitivity analysis restricted to the 254 participants who were not recurrent fallers at baseline, slower midlife gait speed remained significantly associated with recurrent falls in the total sample (adjusted OR 1.48, 95% CI 1.05-2.13; *P*=.03), and this association was stronger among participants 65 years or older (adjusted OR 1.89, 95% CI 1.16-3.17; *P*=.02). Grip strength also showed a stronger association with a narrower 95% CI, most pronounced among participants 65 years or older, where lower grip strength was significantly associated with becoming a new recurrent faller (adjusted OR 2.13, 95% CI 1.02-4.67; *P*=.049). This finding was not seen in the unadjusted model or the primary, nonrestricted analysis. However, this result did not meet the Bonferroni-corrected threshold (*P*<.016). Results of the sensitivity analysis are summarized in Table S2 in Multimedia Appendix 1.

[a]Age category represents the participant's chronological age at the time of follow-up (MIDUS wave 3).

[b]OR: odds ratio.

[c]Adjusted models controlled for baseline covariates measured at MIDUS wave 2, including age, sex, BMI, height, baseline fall count, aggregate count of self-reported medical diagnoses and chronic conditions, and the time interval (years) between MIDUS waves.

[d]For all physical performance measures except sit-to-stand time, variables were coded so that higher odds ratio indicate poorer performance.

Longitudinal Changes in Gait Speed and Muscle Performance

Gait speed did not show a statistically significant change between MIDUS waves, remaining stable at 1.11 (SD 0.20) m/s at both baseline and follow-up. In contrast, all muscle performance indicators declined over time. Grip strength showed the largest standardized decline, decreasing from 36.40 (SD 12.15) kg at baseline to 30.99 (SD 10.56) kg at follow-up, corresponding to an approximately 15% reduction (β=−0.47, 95% CI −0.53 to −0.40; *P*<.001). Sit-to-stand time increased from 9.24 (SD 3.21) seconds to 10.52 (SD 4.10) seconds, indicating slower task completion and worsening performance (β=0.34, 95% CI 0.21-0.48; *P*<.001). Sit-to-stand power

XSL•FO
RenderX

decreased from 360.55 (SD 163.47) W to 312.96 (SD 141.26) W, indicating reduced lower-extremity power (β=−0.31, 95% CI −0.41 to −0.21; *P*<.001). Together, these findings indicate that muscle performance measures were more sensitive to age-related change across the follow-up period than gait speed.

Association of Physical Performance Measures at Wave 2 With Subjective Age and Self-Rated Health at Wave 3

This analysis included 280 participants. In unadjusted models, slower gait speed was associated with poorer self-rated health on both follow-up health measures. Each SD decrease in gait speed was associated with 32% higher odds of poorer self-perceived physical health in the total sample (OR 1.32, 95% CI 1.05-1.64; *P*=.02) and 39% higher odds among participants younger than 65 years at follow-up (OR 1.39, 95% CI 1.06-1.82; *P*=.01). A similar pattern was observed for health compared with age peers in the total sample (OR 1.49, 95% CI 1.19-1.89; *P*<.001) and among participants younger than 65 years (OR 1.56, 95% CI 1.19-2.08; *P*=.001), whereas no significant associations were observed among participants aged 65 years or older. However, after adjustment for baseline covariates, these associations were no longer statistically significant.

Gait speed was not associated with subjective age in unadjusted analyses (β=−0.03, 95% CI −1.34 to 0.93; *P*=.59). However, in fully adjusted models, faster gait speed was independently associated with a younger subjective age at follow-up, corresponding to an approximately 1-year younger subjective age for every 0.20 m/s increase in gait speed (β=−0.10, 95% CI −0.20 to −0.006; *P*=.04). This association did not reach statistical significance in either age-stratified subgroup.

No significant associations were observed between the other physical performance measures and either self-rated health or subjective age in the total sample or age-stratified analyses.

Discussion

Principal Findings

This longitudinal analysis of the MIDUS cohort examined whether midlife gait speed and muscle performance were associated with recurrent falls later in life. Slower midlife gait speed was associated with a 43% increase in the odds of recurrent falls at follow-up, whereas none of the muscle performance measures showed a significant association with future falls.

The association between gait speed and recurrent falls emerged despite the cohort maintaining high functional status, as indicated by a stable mean walking speed between waves (1.11, SD 0.20 m/s) that remained, on average, above commonly referenced geriatric risk thresholds (0.8-1.0 m/s) [4,26,27], and despite adjustment for fall history at baseline. Other longitudinal cohorts have similarly reported relative stability of gait speed across midlife and early older adulthood, consistent with our findings [36,37]. Although this average gait speed suggests preserved mobility at the group level, it may obscure meaningful between-individual differences in walking performance. Thus, the observed association with future falls likely reflects differences already present during midlife rather than progressive age-related decline, supporting the potential role of slower midlife gait speed as an early marker of future fall vulnerability.

Prior research also indicates that gait speed reflects broader biological and functional processes already present in midlife. For example, Rasmussen et al [19] reported that slower gait speed at age 45 was associated with poorer physical and neurocognitive function. Similarly, findings from the Baltimore Longitudinal Study of Aging demonstrated that multiple motor impairments are linked to slow gait speed in mid-to-late life [28].

Evidence from longitudinal studies in midlife, however, remains limited and somewhat inconsistent. In a cohort of community-dwelling adults aged 50 to 65 years, Segaux et al [14] reported that gait speed was not associated with subsequent adverse events, including nonaccidental falls. Several methodological differences may explain this discrepancy. First, participants in the study by Segaux et al [14] had exceptionally high functional status, with a median gait speed of 1.43 m/s and very few participants meeting criteria for slowness (<1 m/s). Second, the follow-up period in that study was considerably shorter than in the present analysis, which followed participants for more than a decade. Finally, differences in gait assessment may also contribute, as the MIDUS 50-foot walk includes a turning phase that places greater demands on dynamic balance than the straight-path walking tests [38,39] used in the Segaux et al [14] study. Together, these differences may explain the contrasting findings and highlight the need for further longitudinal research focusing on midlife populations to clarify the role of gait speed in predicting later fall risk. It would also be informative for future studies to examine midlife populations stratified into early and late midlife groups.

Consistent with previous studies reporting differences between younger and older middle-aged adults [40,41], our age-stratified analyses showed that the association between midlife gait speed and recurrent falls was primarily evident among participants who were 65 years or older at follow-up, whereas no statistically significant association was observed among those younger than 65 years. Nevertheless, these findings should be interpreted cautiously and require confirmation in larger longitudinal cohorts.

In contrast to gait speed, muscle performance indices, including sit-to-stand time, lower-extremity power, and grip strength, are considered particularly sensitive to age-related changes during midlife [24,30,37,42,43], and declined significantly over follow-up. However, none of these measures were associated with recurrent falls in the present cohort. Falls in community-dwelling adults commonly occur during walking [44], a complex task that requires continuous dynamic balance supported by sensorimotor integration and cognitive processing [19,45]; thus, gait speed likely reflects the integrity of multiple physiological systems involved in maintaining stability. In comparison, isolated aspects of muscular capacity assessed under relatively controlled conditions may be less sensitive to the complex demands underlying walking stability, particularly

XSL•FO
RenderX

during midlife when substantial muscle deconditioning is often absent [46].

Unlike our findings, the China Health and Retirement Longitudinal Study (CHARLS) reported that weak grip strength was associated with increased fall risk over a 4-year follow-up period that included middle-aged adults [22]. However, the CHARLS cohort included participants with conditions such as stroke, rheumatoid arthritis, and kidney disease that independently increase fall risk [22], whereas the present study excluded participants with major neurological and mobility-impairing conditions. In addition, mean midlife grip strength in our cohort was 45 kg for men and 28 kg for women, whereas CHARLS identified weaker grip strength (<30 kg for men and <20 kg for women) as a fall risk factor [22]. These differences in participant characteristics and grip strength distribution likely contributed to the discrepant findings. Therefore, our findings suggest that slower midlife gait speed may reflect early vulnerability to future fall risk, even when conventional measures of muscle performance remain within normal ranges. These findings underscore the need for further longitudinal studies to identify indicators of fall risk before overt functional decline.

A secondary exploratory aim of the present investigation was to examine whether midlife physical performance was associated with subjective age and self-rated health later in life. Faster midlife gait speed was associated with younger subjective age at follow-up after accounting for baseline participant characteristics; however, the estimated magnitude was small, corresponding to approximately a 1-year younger subjective age for a 0.20 m/s increase in gait speed. Associations between gait speed and self-perceived health were observed only before baseline characteristics were accounted for. Although these secondary findings should be interpreted as complementary to the primary fall-related outcomes, they are in line with previous research showing that gait speed correlates with self-reported physical limitations, lower self-rated health, and poorer scores on health-related quality of life instruments such as the 36-Item Short Form Survey [19,47]. Together, these findings suggest that walking performance may relate not only to future fall risk but also to subjective perceptions of health and aging.

Notably, participants in both MIDUS waves generally reported feeling younger than their chronological age, with a mean subjective age approximately 10 years lower, a pattern often interpreted as reflecting psychological resilience [48]. This pattern may also reflect the relatively healthy composition of the analytic sample. Associations between objective gait performance and perceived aging have rarely been examined in such healthy midlife populations, making this a potentially novel observation that warrants further investigation. To obtain a more comprehensive understanding of subjective and objective functioning during midlife, future studies should examine the relationship between objective physical performance and midlife-specific self-perception tools, such as the 16-item Mobility in Middle-Age Questionnaire [49].

Limitations

Several limitations should be considered when interpreting our findings. First, the primary gait speed association should be interpreted in the context of the multiplicity approach used in this study. Although gait speed and muscle performance were defined in advance as separate domains, if a single Bonferroni correction had been applied across all 4 physical performance measures (P <.0125), the association between gait speed and recurrent falls would not have met that threshold. Second, the observational design and reliance on self-reported falls and health conditions may introduce recall bias. Third, although exclusion criteria were applied to restrict the analytic sample to generally independent participants and strengthen internal validity, they also limit generalizability to the broader middle-aged population and reduce the sample size and number of recurrent fall events, particularly in analyses stratified by age category. Because MIDUS is an established closed cohort and the sample size was fixed by the number of eligible participants with complete data at both waves, no a priori power calculation was applicable. Although participants with major neurological conditions were excluded, residual confounding from unreported or undiagnosed health conditions cannot be ruled out and may have influenced performance on the physical tests. In addition, sit-to-stand muscle power was estimated using a validated equation rather than measured directly. Although this approach is established [30], the assumption of a standard chair height may have reduced individual-level precision and potentially obscured subtle associations. Finally, baseline subjective measures were collected during the MIDUS telephone interview, which preceded the biomarker assessment by approximately 2 to 3 years. This temporal gap may have introduced some measurement misalignment between subjective and objective variables, potentially affecting the precision of model adjustment. Despite these limitations, the study benefits from a longitudinal design with over a decade of follow-up and the use of objective physical performance measures within a well-characterized population-based cohort, providing a valuable opportunity to examine early functional markers of fall risk beginning in midlife.

Conclusions

Using data from the MIDUS cohort, this study provides evidence that vulnerability to recurrent falls may be detectable as early as midlife. Slower self-selected walking speed was associated with higher odds of recurrent falls at follow-up, despite stable average gait speed over time. In contrast, muscle performance indices declined with age but were not significantly associated with recurrent falls in the primary analysis. Further longitudinal studies in larger midlife cohorts are warranted to confirm these findings.

Abstract

Background: Undiagnosed cognitive impairment poses a global challenge, prompting recent interest in ultra-brief screening questionnaires (comprising <2 to 3 items) to efficiently identify individuals needing further evaluation. However, evidence on ultra-brief questionnaires remains limited, particularly regarding their validity across diverse literacy levels.

Objective: This study aimed to develop an ultra-brief questionnaire that performs well in detecting mild cognitive impairment or dementia (MCI/dementia) across diverse literacy levels and to compare its performance with an established questionnaire (the 8-item Informant Interview to Differentiate Aging and Dementia [AD8]).

Methods: This diagnostic study involved 1856 participants aged ≥65 years (median education 10 y, range 0 - 23 y), prospectively recruited from community settings in Singapore. Participants and informants completed 15 cognition-related questions. MCI/dementia was diagnosed via a comprehensive assessment and consensus conference. The sample was randomly split 70/30—the training sample (70%) was used to derive an ultra-brief questionnaire from the 15 cognition-related questions (using an exhaustive search approach), and the test sample (30%) evaluated the area under the receiver operating characteristic curve (AUC).

Results: The new questionnaire comprised 2 informant questions (ie, *assistance with medications* and *worry about cognition*), plus age and years of education. It demonstrated excellent performance in detecting MCI/dementia (AUC 85%, 95% CI 80% - 90%), significantly better (P=.003) than a nested baseline model (comprising age and years of education; AUC 78%, 95% CI 73% - 83%). In contrast, the AD8 had an AUC of 76% (95% CI 70% - 83%), not significantly different (P>.99) from the baseline model. The questionnaire's performance was consistent across education subgroups and varying prevalence scenarios. Two optimal cutoffs were used—the lower cutoff provided 80% sensitivity and 96% negative predictive value, and the upper cutoff provided 99% specificity and 81% positive predictive value. A web-based calculator is available for public use.

Conclusions: This ultra-brief questionnaire enables rapid screening for cognitive impairment (in <1 min) by family members or as part of community geriatric assessments. Its excellent performance across literacy levels supports its utility for case finding in diverse populations, including underserved communities and lower- and middle-income countries.

Introduction

Undiagnosed cognitive impairment is a global challenge [1], with 60% to 90% of affected individuals never receiving a formal diagnosis [2,3]. Those who remain undiagnosed miss out on timely clinical care [4], including management of reversible causes, prescription of cognitive enhancers, behavioral management, caregiver support, and advanced care planning [4-9]. All these can impact well-being [10,11] and increase the risk of premature nursing home placement [12-14]. Furthermore, undiagnosed individuals often do not receive adequate support to manage and coordinate care for their chronic diseases [15,16], resulting in suboptimal disease management, inappropriate health care utilization, and higher health care costs [17,18]. As an example, a modeling study estimated that timely management of cognitive impairment could potentially yield annual cost savings of US $13 to $41 billion in the United States [15]. Recently, the importance of early diagnosis has been heightened by emerging evidence supporting early interventions for cognitive impairment [19,20], such as risk factor modification [21,22] and antiamyloid monoclonal antibodies [23,24].

To address the challenge of undiagnosed cognitive impairment, various international bodies (eg, the Alzheimer's Disease International [25] and the International Association of Gerontology and Geriatrics) [26] have advocated for a systematic approach to case finding among high-risk individuals in the community [26]. In particular, a 2-stage strategy [27-29] has been proposed in recent literature to address resource constraints for community case finding. In the first stage, subjective reports (eg, Functional Activities Questionnaire and AD8 [the 8-item Informant Interview to Differentiate Aging and Dementia]) [30,31] are used to identify individuals with potential cognitive impairment. In the second stage, these individuals undergo brief cognitive tests (eg, Mini-Cog and short variants of Montreal Cognitive Assessment) [4,32-34] to confirm the presence of cognitive impairment. This 2-stage strategy is efficient and scalable—the first stage relies solely on subjective reports and does not draw on scarce health care resources for administration of cognitive tests, whereas the second stage reserves brief cognitive tests for a smaller subset of individuals [27]. Moreover, combining subjective reports and brief cognitive tests has been shown to improve the detection of subtle cognitive changes [27], making this approach optimal for case finding of early cognitive impairment.

In 2019, the 2-stage strategy was adopted by the World Health Organization (WHO) within the Integrated Care for Older People assessment tool to identify cognitive impairment, alongside assessments of other key components of intrinsic capacity (ie, mobility, nutrition, hearing, vision, and mood) [29]. For the first stage (subjective report), the WHO adopted an ultra-brief questionnaire based on a single question: "Do you have problems with memory or orientation (such as not knowing where one is or what day it is)?" [29] The decision to embed an ultra-brief cognitive questionnaire within Integrated Care for Older People is understandable, as it balances the need to assess a wide range of intrinsic capacity domains against the scarcity of community resources for comprehensive assessments. However, the validity of such ultra-brief questionnaires (ie, those comprising fewer than 2 - 3 items) remains unclear in the literature [28], especially when used across diverse levels of literacy [26,35]. This concern can be critical, as questionnaires with fewer items tend to have increased measurement variability and may be more susceptible to confounding factors such as educational attainment [36].

In this study, we sought to strengthen the evidence base supporting the use of ultra-brief questionnaires across diverse levels of literacy, potentially enhancing their utility in diverse populations across lower-, middle-, and higher-income countries. Specifically, we aimed to: (1) derive an ultra-brief questionnaire with high performance for detecting cognitive impairment (ie, the presence of mild cognitive impairment or dementia [MCI/dementia]) across diverse levels of literacy, using a contemporary, computationally intensive approach to identify the questions most discriminative of MCI/dementia; and (2) compare the performance of the new ultra-brief questionnaire to the well-established AD8 across participants with lower and higher educational attainment. We selected the AD8 as the benchmark because it is a widely used and extensively validated informant-based questionnaire, as demonstrated in recent systematic reviews [37,38]. Its use has been recommended by various international bodies, including the International Association of Gerontology and Geriatrics [26], the Gerontological Society of America [39], the US Alzheimer's Association [40,41], and the National Institute on Aging workgroup [42].

Of note, this study was conducted in Singapore, a city-state in Southeast Asia that provides a unique testbed of literacy diversity for developing the ultra-brief questionnaire. The current generation of older Singaporeans witnessed the country's transformation from a traditional, lower-income, Asian society to a more westernized, higher-income country [43]. Consequently, this cohort encompasses a wide range of educational backgrounds, from minimal formal education to tertiary education. By validating the ultra-brief questionnaire in such a heterogeneous population, we sought to demonstrate its potential for broader implementation in other literacy-diverse settings beyond Singapore, including populations across East and South Asia, and potentially, in some lower- and middle-income countries (LMICs).

Methods

Study Procedures

This study involved community-dwelling older persons recruited between March 2022 and September 2024, as part of a nationally funded project in Singapore aimed at developing artificial intelligence tools to detect early cognitive impairment in the community (Project PENSIEVE) [44]. Community-dwelling individuals were invited to participate if they met the following criteria: (1) higher risk of cognitive impairment (ie, aged ≥65 y [26]) and had at least one of the 3 chronic diseases (ie, diabetes mellitus, hypertension, or hyperlipidemia); this criterion was included a priori to focus on individuals with at least some risk of cognitive impairment, in line with current literature suggesting the limited benefit of screening among low-risk individuals) [26,45]; (2) ability to follow simple instructions in

XSL•FO
RenderX

English or Mandarin (due to limitations in the available assessment language); and (3) presence of an informant (eg, family member or friend) who knew the participants well. Individuals were excluded if they had severe visual impairment that would affect their ability to complete neuropsychological assessments (to ensure generalizability, participants were included as long as they could see pictures on a piece of paper held in front of them). No participants were excluded for reasons related to missing data, as we implemented strict data collection procedures (eg, mandatory data field) and routine data audits throughout the study.

Sources of recruitment included 14 community roadshows conducted by the study team, clients of our community partners, home visits by community volunteers who partnered with us, media publicity (radio, online articles, and posters), and word-of-mouth referrals from participants who had completed research assessments. To ensure the recruited samples were representative of the community, the study's publicity materials emphasized the key message of "detect dementia early" (along with direct referrals to memory clinics in the event of significant findings), rather than the conventional invitation to participate in research (which may inadvertently attract a distinct group of individuals). Examples of these publicity materials (eg, study banner, poster, and brochure) are provided in Method S1 in Multimedia Appendix 1.

All participants received comprehensive assessments, which included semistructured interviews with both participants and their informants, detailed neuropsychological testing, and observational notes of participants' behavior during assessments. Full descriptions of the comprehensive assessments are available in Method S2 in Multimedia Appendix 1, with further details on each assessment tool provided in Method S3 in Multimedia Appendix 1. Diagnoses of MCI and dementia were determined via consensus conference by 3 dementia specialists. Dementia was diagnosed using the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition*, criteria [46], which require the presence of cognitive concerns (reported by the individual or a knowledgeable informant), impairment in instrumental activities of daily living (eg, managing money or medications), and objective cognitive deficits. MCI was diagnosed using the modified Petersen criteria [47], which require the presence of cognitive concerns (reported by the individual or a knowledgeable informant), absence of impairment in instrumental activities of daily living, and the presence of objective cognitive deficits. Normal cognition was diagnosed when participants did not meet criteria for dementia or MCI.

Measures

AD8 [30] is an 8-item, informant-based questionnaire that assesses changes in a participant's cognition and function over the past few years. For each item, the informant rates whether there has been a change in the participant: 1=yes (a change) and 0=no (no change) or don't know. Responses to the 8 items are summed to provide a total score, with higher scores reflecting greater cognitive problems. AD8 has been shown to be useful in detecting varying severities of cognitive impairment [37,38]. Informant AD8 has also been previously validated in Singapore [48].

To derive an ultra-brief questionnaire, the study team focused on candidate questions that assess the two key criteria for diagnosing MCI/dementia [46,47]: (1) the presence of cognitive concerns as reported by the individual or a knowledgeable informant; and (2) impairment in instrumental activities of daily living (iADL). The presence of cognitive concerns was evaluated using validated questions related to subjective cognitive decline (SCD), by asking participants or informants: "Do you feel like your (or your family member's) memory is becoming worse?" and "Are you *worried* that your (or your family member's) memory is becoming worse?" These 2 sets of questions have been validated in previous studies [49,50] and have been shown to be useful for capturing early symptoms of cognitive decline [51-55].

Impairment in iADL was assessed using the locally validated modified Lawton scale [56], with informants asked about difficulties in various domains (public commuting, grocery shopping, managing money, using the telephone, taking medications, preparing meals, doing housework, and doing laundry). The original responses on the modified Lawton scale included 4 options (ie, unable to do at all, needs some help, needs no help, and never needed to do this), which were collapsed in this study into two options: (1) yes and (2) no/never needed to do this.

In total, 15 candidate questions were considered for the ultra-brief questionnaire: 12 cognition-related items and 3 basic demographic variables (eg, age, sex, and years of education), given their potential correlation with cognition. The exact wording and response options for all 15 items are provided in Table 1.

XSL•FO
RenderX

Table . A preselected list of 15 question items that are potentially related to cognition.

Question category [a]	Question item [a]	Response options
SCD[b] question—informant	Do you feel like your family member's memory is becoming worse?	1=yes; 0=no/not sure
Worry about cognition—informant	Are you *worried* that your family member's memory is becoming worse?	1=yes; 0=no/not sure
SCD question—participant	Do you feel like your memory is becoming worse?	1=yes; 0=no/not sure
Worry about cognition—participant	Are you *worried* that your memory is becoming worse?	1=yes; 0=no/not sure
iADL[c]—commute	Does your family member need help to take public transport or drive a car?	1=yes; 0=no/never needed to do this
iADL—grocery	Does your family member need help to do grocery shopping?	1=yes; 0=no/never needed to do this
iADL—money	Does your family member need help to manage money?	1=yes; 0=no/never needed to do this
iADL—telephone	Does your family member need help to use the telephone?	1=yes; 0=no/never needed to do this
iADL—medications	Does your family member need help to take medications?	1=yes; 0=no/never needed to do this
iADL—meals	Does your family member need help to prepare meals?	1=yes; 0=no/never needed to do this
iADL—housework	Does your family member need help to do housework?	1=yes; 0=no/never needed to do this
iADL—laundry	Does your family member need help to do laundry?	1=yes; 0=no/never needed to do this
Age	What is your family member's age?	Continuous variable
Sex	What is your family member's sex?	1=male; 0=female
Years of education	What is your family member's years of education?	Continuous variable. Count the years of full-time education, starting from elementary/primary school.

[a]Items in the list were selected to assess the 2 key criteria in the diagnosis of mild cognitive impairment and dementia: (1) the presence of cognitive concerns as reported by the individual or a knowledgeable informant and (2) impairment in iADL [46,47]. The presence of cognitive concerns was evaluated using validated questions related to SCD, given prior literature on the usefulness of SCD to reflect early symptoms of cognitive decline [51-55]. Impairment in iADL was assessed using the locally validated modified Lawton scale [56], with informants asked about difficulties in various domains of iADL. Three basic demographic variables (ie, age, sex, and years of education) were also included, given their potential correlation with cognition.

[b]SCD: subjective cognitive decline.

[c]iADL: instrumental activities of daily living.

Statistical Analyses

The study sample was randomly split into a 70% *training sample* and a 30% *test sample*. The *training sample* was used to develop an ultra-brief questionnaire that best distinguished MCI/dementia from normal cognition, whereas the *test sample* was used to evaluate the actual performance of this questionnaire.

In the *training sample*, a best-subset approach [57] with 5-fold cross-validation was used to select the optimal combination of items from the 15 candidate questions. The best-subset approach is an efficient, computationally intensive method for variable selection [4,20,58,59] in which logistic regression is used to exhaustively evaluate all possible combinations of the candidate questions, identifying models with the lowest prediction errors. Five-fold cross-validation was then used to select the most parsimonious model within 1 SE of the best-performing model. After identifying the optimal model from the best-subset approach, we further refined the model by considering potential inclusions of quadratic terms for continuous variables (eg, age and years of education); quadratic terms with $P<.05$ were incorporated into the final model to improve fit. The final selected model was then applied to the test sample to generate predicted probabilities of cognitive impairment (ie, MCI/dementia), with the model variables constituting the new ultra-brief questionnaire.

Predicted probabilities were computed from logistic regression using the following equation:

Predicted probability=eLogit1+eLogit

XSL•FO
RenderX

where

$$\text{logit} = \beta 0 + \beta 1 \cdot (\text{Variable } 1) + \beta 2 \cdot (\text{Variable } 2) + \beta 3 \cdot (\text{Variable } 3) + \ldots$$

with each β representing the regression coefficient for its respective variable in the model.

In the *test sample*, the predicted probabilities were used to compute the area under the receiver operating characteristic curve (AUC), thereby assessing the actual performance of the ultra-brief questionnaire in discriminating MCI/dementia from normal cognition. In general, an AUC of 0.7 to 0.8 is considered acceptable discrimination, 0.8 to 0.9 is considered excellent, and more than 0.9 is considered outstanding [60]. Comparisons of AUC were conducted using the nonparametric method proposed by DeLong et al [33,59,61,62], with analyses stratified by education subgroups (ie, ≤10 and >10 y of education based on median split). A 2-cutoff approach [63-67] was adopted for the ultra-brief questionnaire. The first cutoff was chosen to yield high sensitivity and negative predictive value (>80% each) and was used to rule out MCI/dementia (ie, when probability scores fell below the first threshold). The second cutoff was selected for high specificity and positive predictive value (>80% each), identifying those very likely to have MCI/dementia. This 2-cutoff approach is recommended in recent literature [67], as it enhances the performance of cognitive assessment tools [63-66], reduces the effects of prevalence on tool performance [64], and allows prioritization of scarce health care resources for individuals who truly require further cognitive assessments [63].

As a secondary analysis, the performance of the ultra-brief questionnaire was also evaluated for distinguishing dementia from nondementia. Additionally, 2 sensitivity analyses were conducted in the test sample to evaluate the robustness of results when the prevalence of MCI/dementia was readjusted to reflect the average prevalence in most communities:

- Prevalence of MCI/dementia was artificially readjusted to 20% based on prior meta-analytic findings that community prevalence is ~15% for MCI [68-70] and ~5% for dementia [71-73]. Readjustment of prevalence was done by randomly selecting a subset of participants with MCI and normal cognition—for each participant with dementia, 3 participants with MCI and 16 participants with normal cognition were randomly selected (ie, so that the final dataset corresponded to 5% prevalence for dementia and 15% prevalence for MCI).
- Prevalence of MCI/dementia was artificially readjusted to 35% based on prior meta-analytic findings that community prevalence could be as high as ~25% for MCI [69,70] and ~10% for dementia [72,73]. Readjustment of prevalence was done by randomly selecting only a subset of participants with MCI and normal cognition—for each participant with dementia, 2.5 participants with MCI and 6.5 participants with normal cognition were randomly selected (ie, so that the final dataset corresponded to 10% prevalence for dementia and 25% prevalence for MCI).

The best-subset approach was performed with the "bestglm" [57] package in R (version 4.4.0; R Foundation for Statistical Computing). All remaining analyses were conducted in Stata (version 18; StataCorp LLC). No a priori sample size calculation was performed; the final sample size was determined pragmatically based on participants recruited between March 2022 and September 2024. Post hoc power analyses confirmed that the test sample provided robust power (90%) to distinguish MCI/dementia from normal cognition (α=.05, two-sided test). Power was also reasonably sufficient for participants with ≤10 years of education (72%) but was limited in those with >10 years of education (19%) due to fewer positive cases. The power calculations were conducted using PASS software (version 15.0.5; NCSS, LLC) and the Hanley and McNeil formula [74], with further details provided in MethodS4 in Multimedia Appendix 1.

Ethical Considerations

The study received ethical approval from the SingHealth Centralized IRB of Singapore (reference number: 2021/2590). Informed consent was obtained from all participants. Before obtaining informed consent, the mental capacity of participants was briefly assessed in accordance with the Mental Capacity Act of Singapore [75]. In the event of concerns about mental capacity, informed consent by proxy was then obtained from the legally authorized next-of-kin. Participants who completed the research assessments received Singapore Dollar $80 as compensation for their time, inconvenience and transportation costs.

Results

Overview

A total of 1856 participants were included, of whom 255 (13.7%) had MCI/dementia. Participant characteristics are presented in Table 2, with a median age of 72 years and a median education of 10 years (range 0-23 y). Corresponding informant characteristics are provided in Table S1 in Multimedia Appendix 1, with informants primarily comprising spouses (897/1856, 48.3%) and children (506/1856, 27.3%). The sample was randomly split into a *training sample* (1299/1856, 70%) and a *test sample* (557/1856, 30%). Table S2 in Multimedia Appendix 1 shows that the training and test samples had comparable demographic characteristics (P>.05 across covariates).

[a]MCI: mild cognitive impairment.

[b]Test of difference across diagnoses: chi-square test for categorical variables and Kruskal-Wallis test for continuous variables.

[c]MoCA: Montreal Cognitive Assessment.

[d]NTB: neuropsychological battery.

[e]CDR: clinical dementia rating.

Development of the Ultra-Brief Questionnaire

Table 3 presents the top models identified through the exhaustive search method in the *training sample* (n=1299). *iADL–medications* and *worry about cognition–informant* were among the most useful items in detecting MCI/dementia, whereas *iADL–meals* and *iADL–grocery* were among the least useful. Following 5-fold cross-validation, the model with 4 items was identified as the most parsimonious among the top models (Figure S1 in Multimedia Appendix 1). This model included 2 informant questions (*iADL–medications* and *worry about cognition–informant*), plus 2 demographic variables (*age* and *years of education*). These items were then selected to constitute the new ultra-brief questionnaire, henceforth denoted as IQ2+ (Informant Questionnaire for cognitive impairment–2 items plus demographics). Further model refinement considered the inclusion of quadratic terms for *age* and *years of education*, resulting in the addition of a quadratic term for years of education (*P*=.004) in the final model. Thus, the final IQ2+ model comprised five predictors: iADL–medications, worry about cognition–informant, age, years of education, and the quadratic term for years of education. Responses from the IQ2+ questionnaire can be converted to predicted probabilities using an interactive web-based calculator we have created [76]. A screenshot of the calculator is shown in Figure 1.

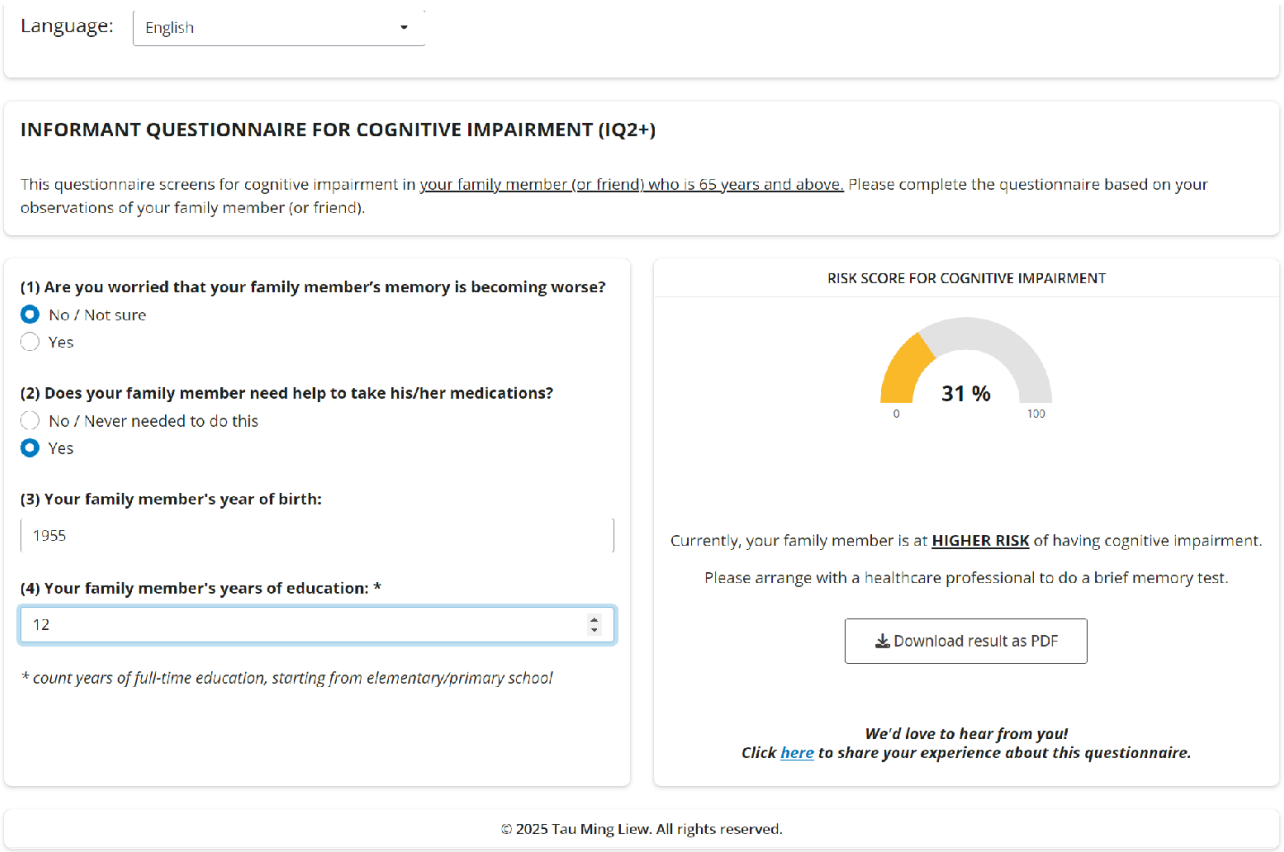
[a]MCI/dementia: mild cognitive impairment or dementia.

[b]A full description of each item is available in Table 1. Briefly, items in the list were selected to assess the 2 key criteria in the diagnosis of mild cognitive impairment and dementia: (1) the presence of cognitive concerns as reported by the individual or a knowledgeable informant and (2) impairment in iADL [46,47]. The presence of cognitive concerns was evaluated using validated questions related to SCD, given prior literature on the usefulness of SCD to reflect early symptoms of cognitive decline [51-55]. Impairment in iADL was assessed using the locally validated modified Lawton scale [56], with informants asked about difficulties in various domains of iADL. Three basic demographic variables (ie, age, sex, and years of education) were also included, given their potential correlation with cognition.



[c]The 4-item model was identified as the most parsimonious among the top models. Further details on model selection are available in Figure S1 in Multimedia Appendix 1.

[d]iADL: instrumental activities of daily living.

[e]N/A: not applicable.

[f]SCD: subjective cognitive decline

Figure 1. A sample screenshot of the interactive web-based calculator. The web-based calculator can be accessed at [76].

Performance of the Ultra-brief Questionnaire

Table 4 presents the AUC results for IQ2+ and AD8 in the *test sample* (n=557). Predicted probabilities from the new IQ2+ demonstrated excellent performance in distinguishing MCI/dementia from normal cognition (AUC 85.3%, 95% CI 80.4% - 90.2%), which was significantly better (P=.003) than a nested baseline model (comprising age, years of education, and the quadratic term of years of education; AUC 78.0%, 95% CI 72.6% - 83.4%). In contrast, AD8 had an AUC of 76.1% (95% CI 69.6% - 82.6%), which was not significantly different (P>.99) from that of the baseline model. For the detection of dementia, both IQ2+ and AD8 had AUCs >90%, which were significantly higher (P<.05) than the baseline model (83.2%). AUC results remained largely similar across education subgroups and in the 2 sensitivity analyses where the prevalence of MCI/dementia was increased to reflect average prevalence in most communities (ie, 20% [68-73] and 35% [69,70,72,73], respectively).

context of multiple testing.

[d]MCI/dementia: mild cognitive impairment or dementia.

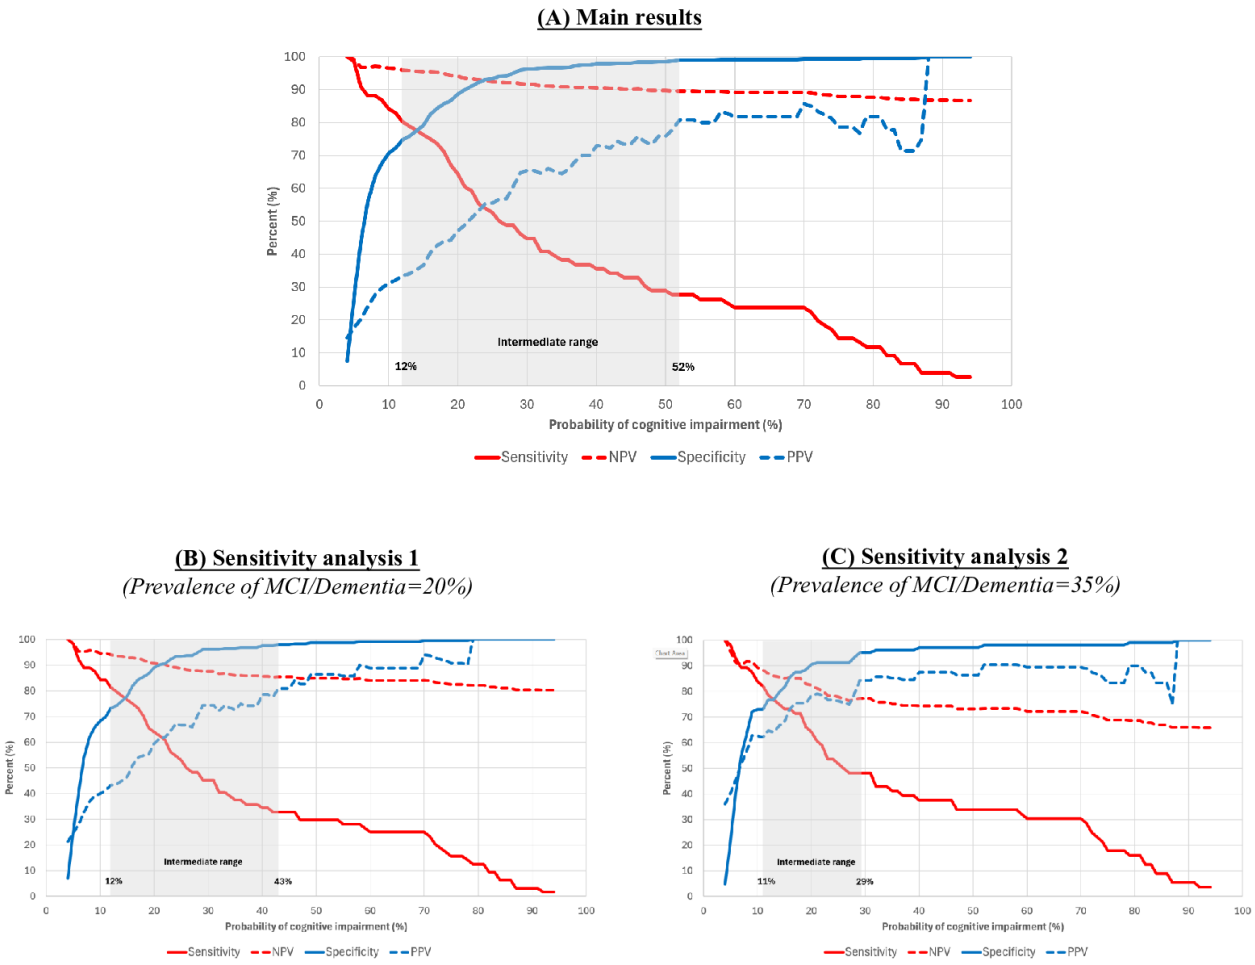
[e]This baseline model was provided mainly for comparison purposes, by omitting IQ2+'s 2 core questions (ie, *assistance with medications* and *worry about cognition*) to examine the incremental utility of the 2 core questions beyond those provided by the demographic information of age and education. The baseline model was generated in the training sample using a logistic model with the dependent variable of MCI/dementia and with the independent variables of age, years of education, and the quadratic term of years of education. This baseline model was then applied to the test sample to generate predicted probabilities of MCI/dementia, with the predicted probabilities used for AUC comparisons.

[f]Ref: reference.

[g]IQ2+: the Informant Questionnaire for cognitive impairment–2 items (plus demographics).

[h]AD8: the 8-item Informant Interview to Differentiate Aging and Dementia.

[i]Prevalence of MCI/dementia was readjusted to 20% in the test sample based on prior meta-analytic findings that community prevalence was ~15% for MCI and ~5% for dementia. In the test sample, a subset of participants with MCI and dementia was randomly selected to readjust the prevalence in the dataset (see Methods section for further details). The resulting dataset comprised 256 participants with normal cognition (80%), 48 participants with MCI (15%), and 16 participants with dementia (5%).



[j]Prevalence of MCI/dementia was readjusted to 35% in the test sample based on prior meta-analytic findings that community prevalence could be as high as ~25% for MCI and ~10% for dementia. In the test sample, a subset of participants with MCI and dementia was randomly selected to readjust the prevalence in the dataset (see Methods section for further details). The resulting dataset comprised 104 participants with normal cognition (65%), 40 participants with MCI (25%), and 16 participants with dementia (10%).

Optimal Cutoffs of the Ultra-Brief Questionnaire

Test statistics for IQ2+ are plotted in Figure 2A. Adopting a 2-cutoff approach, the lower cutoff (probability ≥12%) had 80.3% sensitivity and 96.0% negative predictive value and was used to rule out MCI/dementia (for individuals with probability scores below the cutoff), whereas the upper cutoff (probability ≥52%) had 99.0% specificity and 80.8% positive predictive value and identified those likely to have MCI/dementia (ie, to rule in MCI/dementia). These 2 cutoffs provide an intermediate range between them (grayed area in Figure 2A), identifying those who warrant further assessment. The optimal cutoffs varied slightly with changing prevalence of MCI/dementia, as shown in Figure 2B and 2C. Detailed results on test statistics for IQ2+ are also available in Tables S3–S5 in Multimedia Appendix 1.

XSL•FO
RenderX

Figure 2. Plot of sensitivity, specificity, NPV, and PPV based on probabilities of cognitive impairment generated from IQ2+ in the test sample (n=557). This plot is intended to demonstrate the 2-cutoff approach. The lower cutoff identifies sensitivity and NPV (red lines), which are >80% each and are used to rule out MCI/dementia (when probability scores fall below this threshold). The upper cutoff identifies specificity and PPV (blue lines), which are >80% each, and are used to rule in MCI/dementia (when probability scores exceed this threshold). The grayed area (demarcated by the lower and upper cutoffs) represents the intermediate range, identifying those who may warrant further assessment. Plot (A) was based on the main results from all the test samples (n=577). Plot (B) was based on results from sensitivity analysis 1, whereby the prevalence of MCI/dementia was readjusted to 20% in the test sample based on prior meta-analytic findings that community prevalence was ~15% for MCI and ~5% for dementia (in the test sample, a subset of participants with MCI and dementia were randomly selected in the test sample to readjust the prevalence in the dataset; see Methods section for further details). Plot (C) was based on results from sensitivity analysis 2, whereby the prevalence of MCI/dementia was readjusted to 35% in the test sample based on prior meta-analytic findings that community prevalence could be as high as ~25% for MCI and ~10% for dementia (in the test sample, a subset of participants with MCI and dementia were randomly selected in the test sample to readjust the prevalence in the dataset; see Methods section for further details). IQ2+: the Informant Questionnaire for Cognitive Impairment–2 Items (plus demographics); MCI/dementia: mild cognitive impairment or dementia; NPV: negative predictive value; PPV: positive predictive value.

Result Interpretation for the Ultra-Brief Questionnaire

The 2 cutoffs of IQ2+ effectively identified three risk categories for cognitive impairment: (1) less likely to have cognitive impairment, (2) higher risk of cognitive impairment, and (3) likely to have cognitive impairment. These 3 categories, along with their cross-tabulation with the final diagnoses, are presented in Table 5. In the first category (ie, less likely to have cognitive impairment), 88% to 96% of individuals had normal cognition. In the second category (ie, higher risk of cognitive impairment), 25% to 45% of individuals were diagnosed with MCI. In the third category (ie, likely to have cognitive impairment), 81% to 84% of the individuals had MCI/dementia, with a large proportion having dementia (47%-54%). Distinctions between these 3 risk categories of IQ2+ are also visible in the box plots in Figure 3A–3C. The first category (white region with probability scores below the lower cutoff) identified those with normal cognition, the third category (dark gray region with probability scores above the upper cutoff) identified almost all individuals with dementia, and the second category (light gray region between the lower and upper cutoffs) mostly captured those with MCI. In contrast, AD8 showed poorer discrimination between normal cognition and MCI, with discernible floor effects in the normal cognition and MCI groups as seen in the box plots in Figure 3D–3F. This is also reflected in the test statistics of AD8 (as presented in Tables S6–S8 in Multimedia Appendix 1), which demonstrated low sensitivity across its cutoff scores (with maximum sensitivity of 69.6% - 73.4%).

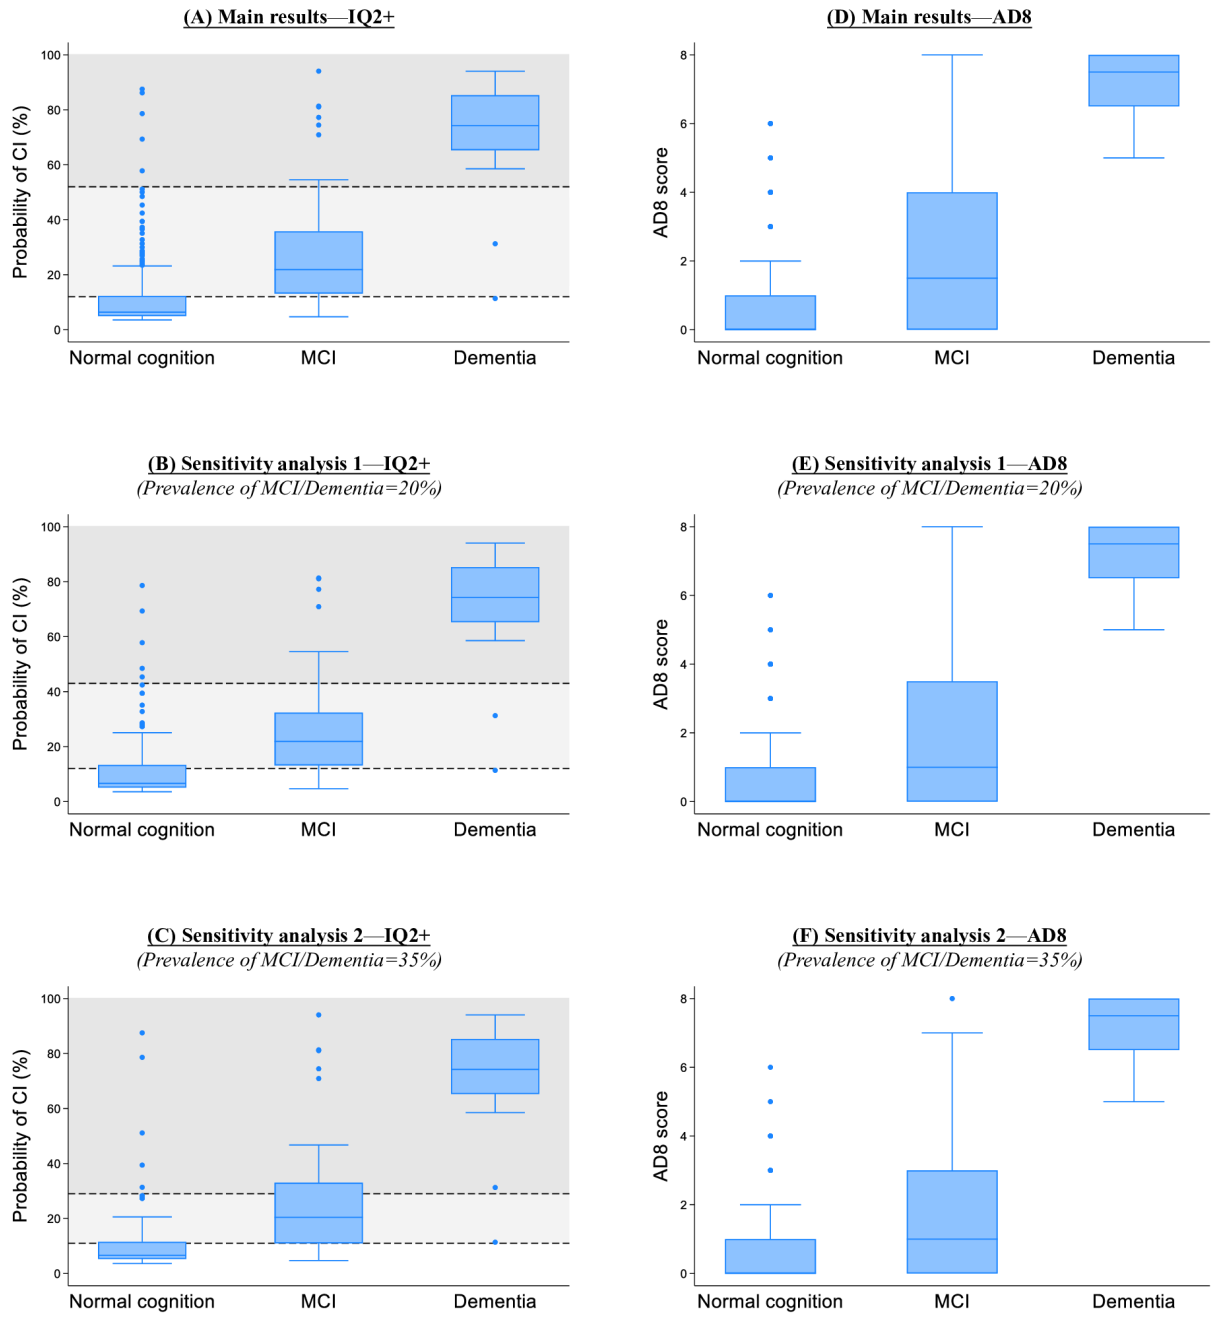
[a]IQ2+, the Informant Questionnaire for cognitive impairment–2 items (plus demographics).

[b]Two-cutoff approach was adopted for IQ2+. The lower cutoff has high sensitivity and negative predictive value (>85% respectively) and is used to rule out MCI/dementia (for individuals with probability scores below the cutoff). The upper cutoff has high specificity and positive predictive value (>85% respectively) and identifies those who are likely to have MCI/dementia. These 2 cutoffs provide an intermediate range between them, identifying those who may be at higher risk and require further monitoring or assessment.

[c]MCI: mild cognitive impairment.

[d]Probability cutoff for the main results (ie, prevalence of MCI/dementia=14%):<12% (less likely to have CI), 12% to 51% (higher risk of CI), and ≥52% (likely to have CI).

[e]Prevalence of MCI/dementia was readjusted to 20% in the test sample based on prior meta-analytic findings that community prevalence was ~15% for MCI and ~5 % for dementia. In the test sample, a subset of participants with MCI and dementia was randomly selected to readjust the prevalence in the dataset (see Methods section for further details).



[f]Probability cutoff for the first sensitivity analysis (ie, prevalence of MCI/dementia=20%):<12% (less likely to have CI), 12% to 42% (higher risk of CI), and ≥43% (likely to have CI).

[g]Prevalence of MCI/dementia was readjusted to 35% in the test sample based on prior meta-analytic findings that community prevalence could be as high as ~25% for MCI and ~10% for dementia. In the test sample, a subset of participants with MCI and dementia was randomly selected to readjust the prevalence in the dataset (see Methods section for further details).

[h]Probability cutoff for the second sensitivity analysis (ie, prevalence of MCI/dementia=35%):<11% (less likely to have CI), 11% to 28% (higher risk of CI), and ≥29% (likely to have CI).

Discussion

Principal Findings

In this study, we developed and validated an ultra-brief informant questionnaire (IQ2+) for the detection of cognitive impairment in literacy-diverse communities. Using a rigorous best-subset approach with cross-validation, we identified a parsimonious 4-item model that was most useful in detecting MCI/dementia, comprising 2 informant-based questions (*assistance with medications* and *worry about cognition*), along with *age* and *years of education*. In the independent test sample, IQ2+ achieved an AUC of 85.3%, outperforming the widely used AD8 (AUC=76.1%) and a baseline demographic model (AUC=78.0%). In contrast, AD8 was not significantly better than the baseline demographic model. The robust performance of IQ2+ was consistent across education subgroups and under varying prevalence scenarios, highlighting its potential utility for case finding in diverse community settings. Adopting 2 optimal cutoffs [63-67], IQ2+ demonstrated high sensitivity, specificity, negative predictive value, and positive predictive value.

Interpretation of Findings

Despite being widely recommended [26,39-42], the AD8 performed poorly in detecting MCI/dementia and was not substantially better than a basic demographic model comprising age and education. This finding aligns with recent literature, which demonstrates AD8's lower performance for detecting early cognitive impairment (AUC 61% - 69%) compared to its performance in clear-cut dementia cases (AUC 89% - 93%) [48,77]. AD8 was originally developed for the purpose of detecting dementia [30], and its items tend to focus on identifying conspicuous changes in iADL (ie, hallmarks of the onset of dementia) [46]. As a result, AD8 may possibly not be as sensitive or consistent in detecting subtle changes associated with early cognitive impairment [30,78]. In contrast, the 2 informant questions in IQ2+ may plausibly be more sensitive to early cognitive changes. Worry about cognition—especially when reported by a knowledgeable informant—has been shown to be an early symptom of cognitive decline [51]. This item requires informants to compare current abilities with previous premorbid abilities, making it more likely to detect subtle cognitive decline over time. It also prompts informants to apply a "threshold" to decide whether they are worried about the cognitive decline, which serves as a filter to identify individuals with meaningful changes. Similarly, the ability to manage one's medications is a complex task that possibly involves multiple cognitive domains [16], such as language (for understanding medication instructions), executive function (for scheduling medication intake and problem-solving when medications are not taken on schedule), and memory (for tracking medication intake). A subtle decline in any of these domains may potentially manifest as increasing difficulty in managing medications independently, serving as an early symptom of cognitive decline [79].

Implications

At the population level, IQ2+ can serve as a quick and efficient risk stratification tool, facilitating appropriate triage for further assessment. As summarized in Table 6, low-risk individuals (<12% probability of MCI/dementia) may be reassured and advised to repeat the test in 3 to 5 years or if circumstances change (eg, appearance of new symptoms). Intermediate-risk individuals (~25% - 45% probability of MCI/dementia) can be directed to further assessments using brief cognitive tests [4,32-34] to provide more conclusive evidence of cognitive impairment [27]. High-risk individuals (>80% probability of MCI/dementia) may benefit from direct referral to memory clinics for further clinical management. This approach, as summarized in Table 6, aligns with the 2-stage strategy for active case finding of cognitive impairment (ie, subjective reports, followed by brief cognitive tests) [27,28]. It offers a scalable approach to case finding in large populations by conserving resources for cognitive testing and reserving them for individuals who truly need further verification [27]. To ensure that IQ2+ remains useful in diverse populations, its optimal cutoffs can also be adjusted depending on the prevalence of MCI/dementia in different populations (as shown in Figure 1), thus providing a more tailored solution for identifying individuals at varying risk levels.

Table . Potential clinical implications based on the result from IQ2+.

Result from IQ2+[a]	Risk communication	Potential implications
Less likely to have CI[b]	<12% chance to have CI	• Repeat IQ2+ in 3 to 5 years or when circumstances change (eg, appearance of new symptoms)
Higher risk of CI	~25% to 45% chance to have CI	• Arrange with health care professionals to do brief cognitive tests
Likely to have CI	>80% chance to have CI	• Referral to memory clinic for further assessment and management

[a]IQ2+: the Informant Questionnaire for cognitive impairment–2 items (plus demographics).

[b]CI: cognitive impairment.

Essentially, IQ2+ may have 2 plausible use cases in the community. First, it allows family members who have concerns about a loved one's cognition to complete the questionnaire online (accessible at [76]), providing an immediate result with risk score and a brief interpretation of its implications. The results can also be downloaded as a PDF file for further

XSL•FO
RenderX

discussion with health care providers. This approach mirrors a well-established practice in the field of diabetes mellitus, where the public is encouraged to complete an online risk test [80] as an initial screening to determine the need for further diagnostic tests [81]. By enabling self-appraisal, this use case of IQ2+ leverages family members for efficient case finding and empowers them to proactively support the brain health of older persons.

Second, IQ2+ can also be used by health care workers who routinely conduct comprehensive geriatric assessments in the community. Since 2019, the WHO has advocated for routine assessment of intrinsic capacity among community-dwelling older persons, which requires comprehensive evaluations of cognition, mobility, nutrition, hearing, vision, and mood [29]. Given the extensive range of components to cover, it can be challenging to include routine cognitive testing in all geriatric assessments. IQ2+, which can be completed in <1 minute, is well-suited to be embedded within initial geriatric assessments to prioritize individuals who require further cognitive testing. Given its excellent performance across education subgroups (Table 4), IQ2+ offers a practical tool that may potentially be broadly implemented in diverse populations, including in underserved populations in LMICs, which currently have the largest number of undiagnosed cognitive impairment [82]. This is also in line with the 2024 Lancet Commission's call to address the unmet need for cognitive screening tools that are also suited for individuals with lower literacy in LMICs [35].

Limitations

Several limitations are notable. First, IQ2+ was developed for older individuals aged ≥65 years. It is unclear whether IQ2+ would be useful for individuals aged <65 years. Second, IQ2+ would benefit from further validations in other cultures and languages, as cultural differences may affect how informants respond to its items and could potentially modify its performance in different settings. Third, IQ2+ requires the use of a web-based calculator to determine the probability of cognitive impairment. This approach leverages technology to automate test scoring, result visualization, and interpretation. However, it may limit accessibility compared to pen-and-paper tests that use raw scores as a cutoff (eg, AD8), particularly in settings with limited access to technology. Fourth, one of the core questions of IQ2+ involves difficulty managing medications. This item was identified as the most useful item in our exhaustive search (Table 3) and has some face validity (as it detects subtle changes in a complex task of managing medications [16,79], and the need to take regular medications may also be a proxy for higher risk due to the presence of chronic diseases). However, this question may be less useful among healthier older individuals who do not need to take medications regularly. Fifth, although IQ2+ can be a useful case finding tool, it is not intended to replace comprehensive clinical and neuropsychological assessments, which provide more definitive diagnoses as well as granular information on specific cognitive deficits [20,83,84].

Conclusions

Using rigorous methodology, this study developed an ultra-brief questionnaire that enables untrained laypersons to screen for cognitive impairment in <1 minute. Despite its brevity, the questionnaire demonstrated excellent performance in detecting MCI/dementia, outperforming the well-established AD8. The questionnaire can be completed by members of the public who have concerns about a family member's cognition (accessible at [76]) or embedded within community geriatric assessments to prioritize cognitive testing. Its excellent performance was consistent across education subgroups and varying prevalence scenarios, supporting its utility for case finding in diverse populations, including underserved communities and LMICs.

Acknowledgments

The authors would like to thank the following persons for their assistance in recruiting study participants: Yanling Tan, Alcantara Leicester Shawn, Kai Xin Choo, Megan Cheng Mun Choy, Xin Tong Tan, Lydia Jia En Cheong, Jane Mee Chin Liew, Xiao Hui Ng, and Spencer Peng Ming Yuen. The authors would also like to thank the following community organizations for their support in participant recruitment: Thye Hua Kwan Moral Charities (AMK 645, Bukit Merah View, Beo Crescent), Kreta Ayer Senior Activity Centres, NTUC Health Active Ageing Centre (Lengkok Bahru), Agency for Integrated Care (Caregiving & Community Mental Health Division), Silver Generation Office, People's Association, Precious Active Ageing Centre, Montfort Care, Yong-en Care Centre, Presbyterian Community Services, Lions Befrienders Service Association Singapore.

Funding

This research is funded by the Singapore Prime Minister Office's Smart Nation and Digital Government Office (grant I_20092346). Separately, TML is supported by the Singapore Ministry of Health's National Medical Research Council (grant HCSAINV23jul-0001, NMRC/CG2/005e/2022-SGH, and MOH-SEEDFD22apr-0001). The funders had no role in the design and conduct of the study; collection, management, analysis, and interpretation of the data; preparation, review, or approval of the manuscript; and decision to submit the manuscript for publication.

Data Availability

The data used in this study contain sensitive information about the study participants, and they did not provide consent for public data sharing. The current approval by the SingHealth Centralized IRB of Singapore (reference number: 2021/2590) does not include data sharing. A minimal dataset could be shared by request from a qualified academic investigator for the sole purpose of replicating the present study, provided the data transfer is in agreement with Singapore's legislation on the general data protection regulation and a data sharing agreement has been signed. Abstract

Background: Life expectancy and age are frequently considered factors to assess perioperative and postoperative mortality risks in patients affected by aortic pathologies, which can affect the decision whether to suggest invasive treatment.

Objective: This study aims to investigate the association between age and all-cause mortality after invasive aortic treatment.

Methods: Unsupervised clustering (k-means) using data from the UK Biobank was conducted for patients with aortic pathologies (*International Classification of Diseases, Tenth Revision* [ICD-10] group I71) receiving endovascular or open surgical treatment. Clustering variables encompassed demographic and clinical parameters. Survival analyses (postoperative survival time in days to all-cause death) between clusters and cluster-derived age groups were conducted.

Results: The study included 1801 individuals undergoing surgical or endovascular repair for aortic aneurysms. Unsupervised cluster analysis identified distinct groups primarily based on age, both in models using 2 or 3 clusters. Clusters with older patients at surgery exhibited lower postoperative survival, with perioperative mortality disproportionately affecting these groups. While age was significantly associated with postoperative mortality overall (hazard ratio 1.07, 95% CI 1.05 - 1.08), this association diminished in older clusters after excluding perioperative deaths, a trend confirmed in analyses adjusted for relevant confounders.

Conclusions: Unsupervised cluster analysis revealed age as the primary factor distinguishing patient groups undergoing invasive treatment for aortic pathologies. However, age at surgery appears to have different consequences in certain age brackets, indicating a complex nonuniform relationship.

aneurysm; aortic aneurysm; cluster analysis; survival analysis; outcomes

Introduction

Aortic aneurysms (AAs) encompass a group of pathologies affecting the aorta in any of its segments from the ascending aorta to the infrarenal abdominal aorta, which is the most prevalent type [1]. Apart from true degenerative aneurysms, dissections are commonly included in this group of conditions or summarized as aortic syndromes due to a similar enlargement of diameter and treatment options [2]. The aorta is now considered an organ rather than a simple conduit to other tissues due to its complex structure and function [3]. Considering the high rate of adverse outcomes during acute ruptures, preemptive treatment is favored when possible in elective settings and is associated with significantly lower rates of perioperative morbidity and mortality [4]. Over the past 2 decades, shifts in global cardiovascular risk factors, the establishment of national screening programs, and the widespread adoption of endovascular aneurysm repair have significantly altered the epidemiology and management of AA [5-7]. Most high-income countries have experienced a marked decline in both incidence and mortality rates for elective and ruptured AA. However, demographic changes and expanded treatment options for older and frail patients have introduced new challenges [5,8].

Estimated life expectancy is frequently considered to be a relevant factor in clinical decision-making as the risks and benefits of treatment options may be assessed differently for patients with varying life expectancies. It is broadly suggested that younger and healthier patients can reasonably be exposed to the higher perioperative risks of open surgical repair to balance out limitations of endovascular strategies including concerns with durability and imaging surveillance [4,9]. The tradeoff between short-term survival advantages of endovascular repair and potential long-term disadvantages is not yet fully elucidated and, in general, is more nuanced and influenced by

XSL•FO
RenderX

patient characteristics, expectations, anatomy, and comorbidities [10].

Analyses of large population-based datasets and administrative registries have identified several risk factors associated with adverse perioperative outcomes and impaired long-term survival. However, predicting mortality and serious adverse events is complex, and traditional association studies alone may not be sufficient [11-14].

Unsupervised clustering algorithms can be used to identify patterns within complex clinical data, enabling a different approach to risk stratification by grouping patients with similar phenotypes. Unlike traditional regression models, which isolate independent effects and may produce high hazard ratios for rare but extreme risks, cluster analysis can identify clinically coherent patient archetypes where multiple low and moderate risk factors can accumulate to define high-risk subgroups. This is particularly valuable in surgical cohorts, where multimorbidity, rather than selective patient factors, frequently determines outcomes.

In this work, we investigated whether an unsupervised cluster analysis based on demographic and clinical patient characteristics and naïve to postoperative outcomes can be leveraged to identify distinct postoperative survival patterns for specific patient groups.

Methods

Study Design and Dataset

In this retrospective observational analysis, an unsupervised cluster analysis was conducted using data from the UK Biobank [15]. The UK Biobank is a large population cohort study with 502,488 participants aged 40 to 69 years, with a recruitment phase from 2006 to 2010, spanning over 22 assessment centers in the United Kingdom. During recruitment, participants consented to synchronizing their UK Biobank patient file with their electronic medical records from the National Health Service (NHS) [16]. The World Health Organization (WHO)'s *International Classification of Diseases, Tenth Revision* (ICD-10) *codes* were used to code clinical diagnoses of hospital inpatient data. The *Office of Population, Censuses and Surveys: Classification of Interventions and Procedures* (OPCS-4) codes were used to code operations and procedures. Data from the NHS Information Center for participants from England and Wales and from the NHS Central Register Scotland for participants from Scotland were used to obtain date and cause of death [17,18]. The investigation was conducted in all patients with the ICD-10 group I71 (AA and dissection). Included OPSC-4 codes to classify procedures were: L18*, emergency replacement of aneurysmal segment of aorta; L19*, other replacement of aneurysmal segment of aorta; L25.4, operations on aneurysm of aorta, not elsewhere classified (NEC); L26.6, transluminal aortic stent graft with fenestration, NEC; L26.7, transluminal aortic branched stent graft, NEC; L27*, transluminal insertion of stent graft for aneurysmal segment of aorta; and L28*, transluminal operations on aneurysmal segment of aorta.

Ethical Considerations

This study accessed UK Biobank data. Ethical approval for the UK Biobank was obtained from the North West Multi-Centre Research Ethics Committee (11/NW/03820). All enrolled participants gave written informed consent prior to enrollment in accordance with the tenets of the Declaration of Helsinki.

Cluster Analysis

Cluster analysis was performed using the k-means clustering algorithm. Optimization of k was performed using the NbClust function (*NbClust* package [19]) in R (version 4.4.1; R Foundation for Statistical Computing), which uses 30 different indices. Clusters were formed based on 14 features, encompassing demographics and comorbidities. The list of variables included: sex, age at surgery, coronary heart disease, hypertension, heart failure, cardiac dysrhythmia, chronic kidney disease, BMI, smoking, peripheral aneurysms, history of cancer, aortic pathology type, aortic rupture, and type of surgery. Comorbidities and treatment were binary coded, sex was one-hot encoded, and aortic pathology was ordinal structured (dissections, thoracoabdominal, thoracic, and abdominal). Variables were chosen based on their effects on outcomes in aortic surgery [4] and life expectancy in general. Optimization suggested different k-values using the *NbClust* package with the same level of recommendation (5 metrics suggested 2 or 3 clusters each). Clusters were generated with the centers set to 2 and nstart set to 25. Optimization of k and cluster formation was carried out with a set seed. Since clustering requires no missing data, 18 (1%) out of the 1819 patients with aortic pathologies undergoing invasive treatment had to be excluded from the dataset. This was considered reasonable with a low risk of introducing significant selection bias.

Sensitivity Analyses

Multiple steps were included in the analytical workflow to ensure the robustness of our findings. First, 2 different cluster analyses were conducted fitting 2 and 3 clusters to investigate whether the same set of variables would separate clusters from each other. Second, age cutoffs used in the cluster analyses were shifted to 65/75 years to investigate the consistency of the cluster-derived results. Third, survival analyses were done using different subsets of the study population, stratifying by clusters and after removing deaths within the perioperative period (30 d). Fourth, varying sets of covariates were introduced to adjust survival models and establish a set of parameters for the final model. Potential confounders included demographics such as age at surgery and sex, comorbidities used during clustering, smoking history, aortic pathology, as well as type and year of surgery.

Statistical Analysis

Descriptive statistics were used to summarize baseline characteristics, with continuous variables reported as mean (SD) or median (IQR), depending on their distribution, and categorical variables presented as frequencies and percentages. Survival analyses (postoperative survival in days to all-cause death) were conducted using the Kaplan-Meier curves to estimate survival, stratified by clusters or indices derived from the clustering analysis. Log-rank tests were used to compare survival curves

XSL•FO
RenderX

between groups. Cox regression models were used to fit survival models with varying covariates as mentioned above and Wald Test *P* value and 95% CI were assessed for each covariate. Statistical significance was defined as *P* value <.05. Cubic splines (4 degrees of freedom) were fitted based on the survival models to calculate and visualize age-related hazard ratios. All analyses were conducted using R. Multimedia Appendix 1 illustrates the analytic workflow and included packages [20-25]. The code outline can be accessed at the public GitHub repository [26] or in Multimedia Appendix 1. The actual analyses were conducted in the UK Biobank Research Analysis Platform.

Results

Study Population

The study included 1801 individuals, predominantly male (n=1500, 82.3%) with a median age at surgery of 69 (IQR 65 - 74) years. Coronary heart disease and arterial hypertension were highly prevalent, affecting 56.6% (n=1019) and 81.5% (n=1468) of participants, respectively. Heart failure and cardiac dysrhythmia were observed in 36.7% (n=661) and 53.1% (n=956) of cases. Peripheral aneurysms occurred in 12.3% (n=222), and 82% (n=1477) reported a history of smoking. AAs were primarily abdominal (n=1204, 66.9%), followed by thoracic (n=394, 21.9%) and thoracoabdominal (n=9, 0.5%), with dissections reported in 10.8% (n=194). Ruptures were noted in 9.9% (n=179) of cases (Table 1). In summary, 29.5% of patients did not survive the observational period.

Table . Demographic and clinical characteristics of the study population (N=1801).

Characteristics	Total (N=1801)
Sex, n (%)	
Female	301 (16.7)
Male	1500 (82.3)
Age at surgery, mean (IQR)	69 (65-74)
Coronary heart disease, n (%)	1019 (56.6)
Arterial hypertension, n (%)	1468 (81.5)
Heart failure, n (%)	661 (36.7)
Cardiac dysrhythmia, n (%)	956 (53.1)
Chronic kidney disease, n (%)	726 (40.3)
BMI, median (IQR)	28.0 (25.6 - 30.9)
Peripheral aneurysms, n (%)	222 (12.3)
Smoking (ever), n (%)	1477 (82)
History of cancer, n (%)	229 (12.7)
Aortic aneurysm, n (%)	
Abdominal	1204 (66.9)
Thoracic	394 (21.9)
Thoracoabdominal	9 (0.5)
Dissection	194 (10.8)
Rupture	179 (9.9)

Unsupervised Cluster Analysis

Cluster analysis was performed fitting 2 and 3 cluster solutions (see “Methods” section). When fitting 2 clusters, age appeared to be the primary factor separating groups. Cluster 1/2 had a younger median age at surgery (62, IQR 58-65 y) compared to cluster 2/2 (73, IQR 70-76 y). Both clusters had similar rates of arterial hypertension (approximately 81%) and smoking (approximately 82%). Differences included a higher prevalence of cardiac dysrhythmia and chronic kidney disease in cluster 2/2 (55% and 42.8%, respectively) compared to cluster 1/2 (49.3% and 35.5%, respectively), corresponding to the higher age. Abdominal aneurysms predominated in both clusters, but cluster 1/2 showed a higher frequency of dissections (14.7% vs 8.7%) and strictly thoracic aneurysms (26.8% vs 19.3%), while ruptures were comparable (approximately 10%; Table 2)

XSL•FO
RenderX

Table . Fitting 2 clusters to the study population. Cluster 1/2 consists of younger patients (at the time of surgery) with more thoracic pathologies.

Variable	Cluster 1/2 (n=612)	Cluster 2/2 (n=1189)
Female (%), proportion (95% CI)	14.9 (12.0 - 18.4)	17.7 (15.6 - 19.9)
Age at surgery, median (IQR)	62 (58-65)	73 (70-76)
Coronary heart disease (%), proportion (95% CI)	58.8 (54.8 - 62.7)	55.4 (52.5 - 58.2)
Arterial hypertension (%), proportion (95% CI)	81.2 (77.8 - 84.2)	81.7 (79.4 - 83.8)
Heart failure (%), proportion (95% CI)	37.7 (33.9 - 41.7)	36.2 (33.5 - 39.0)
Cardiac dysrhythmia (%), proportion (95% CI)	49.3 (45.3 - 53.4)	55 (52.1 - 57.8)
Chronic kidney disease (%), proportion (95% CI)	35.5 (31.7 - 39.4)	42.8 (40.0 - 45.6)
BMI, median (IQR)	28.1 (25.5 - 31.3)	2 (25.6 - 30.6)
Peripheral aneurysms (%), proportion (95% CI)	12.7 (10.1 - 15.9)	12.1 (10.4 - 14.1)
Smoking (ever) (%), proportion (95% CI)	80.4 (76.9 - 83.5)	83.7 (81.5 - 85.7)
Connective tissue disease (%), proportion (95% CI)	3.1 (1.9 - 5.0)	3.4 (2.5 - 4.6)
Aortic aneurysm		
Abdominal, %	57.8	71.5
Thoracic, %	26.8	19.3
Thoracoabdominal, %	0.7	0.4
Dissection, %	14.7	8.7
Rupture (%), proportion (95% CI)	9.2 (7.0 - 11.9)	10.3 (7.0 - 11.9)

When grouped into 3 clusters, age differences were more pronounced: cluster 1/3 (n=700; median age at surgery 75, IQR 73-78 y), cluster 2/3 (n=811; 68, IQR 65-69 y), and cluster 3/3 (n=290; 57, IQR 53-60 y). Cluster 3/3 had the highest rates of heart failure (43.8%) and thoracic aneurysms (34.1%) and the lowest smoking prevalence (73.5%). Cluster 1/3 had the highest aortic rupture rate (12%), with abdominal aneurysms being most common (73.9%). Cluster 2/3 displayed intermediate characteristics across many variables, including rupture rate (8.8%) and the distribution of aortic pathologies (Table 3). Due to the predominant separation between clusters by age, this was further evaluated. It was identified that the first cluster analysis split patients at age 66/67 years, while the second cluster analysis used 61/62 years and 71/72 years as thresholds. All patients below or above the respective thresholds were exclusively grouped in the corresponding clusters.

XSL•FO

Cluster Survival Analyses

Survival analyses were conducted for each cluster analysis. In both cases (2 or 3 clusters), age at death was higher in patients undergoing treatment at a later age, reflective of the selection bias of age at treatment. However, postoperative survival was significantly lower in these clusters (clusters 1/3 and 2/2; Figures 1A and 1B). It appeared that the main phase of separation in both cases lay within the perioperative period, where older clusters were associated with a higher all-cause mortality. Especially when comparing clusters 2/3 and 3/3, differences in long-term mortality appeared to stabilize between clusters.

XSL•FO
RenderX

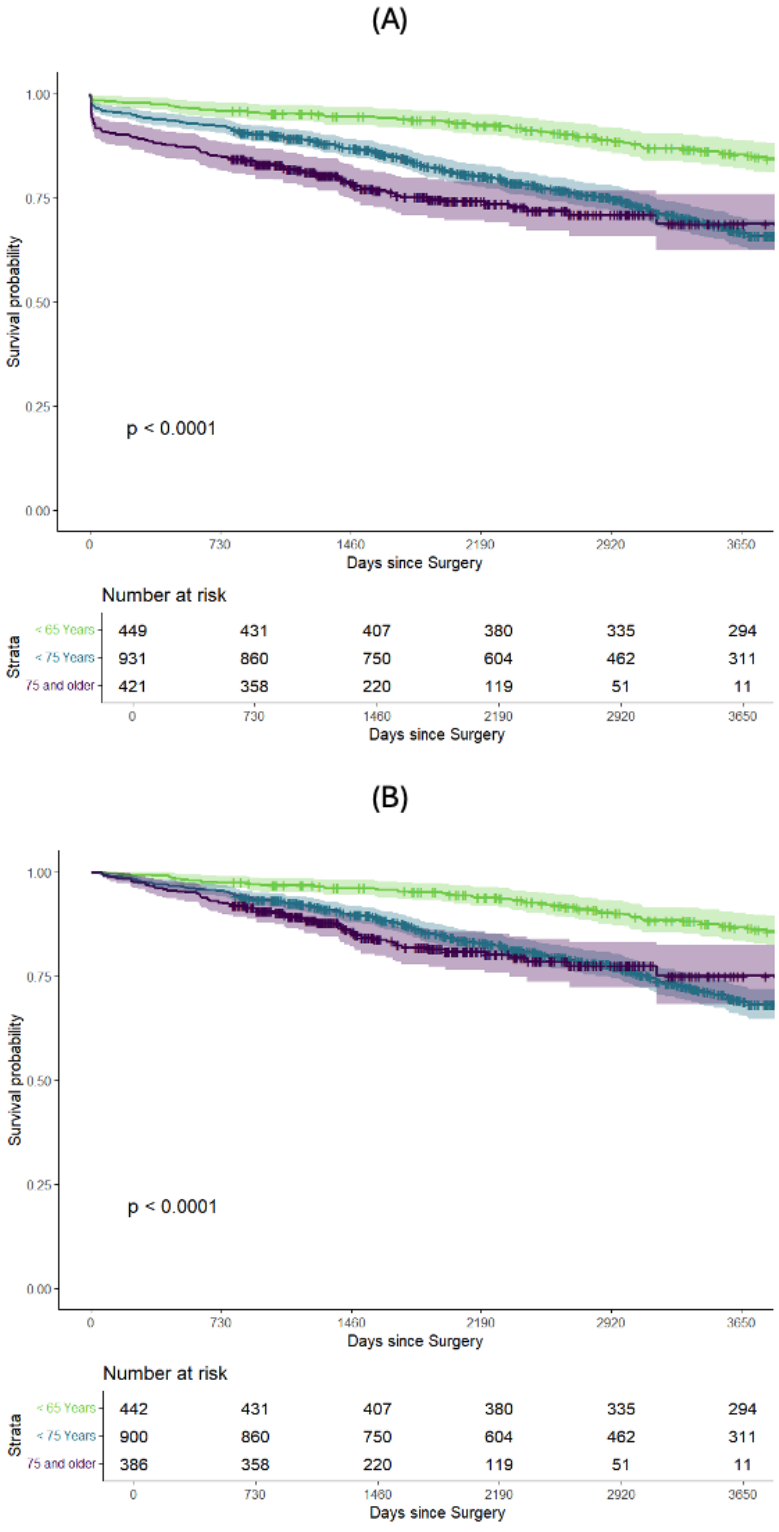

Figure 1. Kaplan-Meier curves illustrating postoperative survival for each cluster. Clusters with older patients at surgery had lower postoperative survival rates. (A) 3 clusters and (B) 2 clusters. The depicted *P* value refers to a log-rank test.

To explore whether these observations would remain constant after shifting age brackets, the study population was divided into 3 subgroups at 65 and 75 years. Postoperative survival was repeatedly lower in older age groups that were characterized by a higher perioperative mortality (Figure 2A). However, after removing deaths within the first 30 postoperative days, the survival estimates of all groups not only converged but, especially regarding the 2 older age groups, there was no evidence for a difference in all-cause mortality rates (Figure 2B).

XSL•FO
RenderX

Figure 2. Kaplan-Meier curve illustrating postoperative survival stratified by age. Patients with higher age at surgery have lower postoperative survival rates. (A) Full observational period and (B) after removing the first 30 postoperative days. The depicted *P* values refer to a log-rank test.

Age and Mortality

To further explore the relationship between age and postoperative survival, univariate survival analyses were conducted in different subsets of the study population (Table 4). In the full study population, age was significantly associated with increased all-cause mortality after invasive aneurysm treatment. When stratifying by clusters, this association faded for the cluster with the oldest patients (cluster 1/3), indicating that in very old patients, additional years of age do not significantly increase mortality risks. However, since the perioperative period was associated with disproportionate mortality in older people, the analyses were repeated removing patients who died during the first 30 postoperative days. Now, there was no evidence for an association between all-cause

XSL•FO
RenderX

mortality and age in both cluster analyses for the oldest clusters (cluster 2/2 and cluster 1/3).

Table . The association between age at surgery and mortality in varying patient groups in a single-predictor survival analysis (N=1801).

Cluster 3/3 (without first 30 d)	285	1.08	1.03 - 1.13	.003

[a]The *P* value is derived from the Wald test.

Subsequently, the analyses were repeated adjusting for the year of surgery since overall mortality rates have decreased over time and this was therefore considered a relevant confounder (Table 5). There was again strong evidence for an association between age and post-operative mortality, except for cluster 1/3 after deaths were removed in the perioperative period. To fit a final model, varying sets of confounders were introduced, and nonsignificant parameters were removed. The final analyses adjusted for year of surgery, chronic kidney disease, heart failure, and type of aortic pathology (Table 6). However, there was strong evidence for an association between postoperative mortality and age in most subgroups. However, after excluding perioperative deaths, age was no longer statistically significantly associated with all-cause mortality in either cluster 1/3 or cluster 3/3 (the youngest cohort).

Figure 3. Age-specific hazard ratios (HRs) for (A) all-cause mortality after invasive aortic treatment for the whole study population, (B) after removing deaths in the perioperative period (first 30 d), and (C) concerning mortality in the first 30 days after surgery. The shaded area indicates the 95% CI.

Discussion

The study analyzed 1801 individuals undergoing open surgical or endovascular repair for AAs. The majority were male (82.3%) with a median age of 69 years. Cardiovascular comorbidities and smoking were highly prevalent. AAs were primarily abdominal (66.9%). Overall, 29.5% of patients did not survive the observational period. Unsupervised cluster analysis revealed distinct groupings exclusively based on age. In a 2-cluster model, the clusters were separated at a median age of 62 and 73 years. A 3-cluster model further stratified the population, with median ages of 57, 68, and 75 years. Survival analyses highlighted lower postoperative survival in older clusters relative to treatment, with perioperative mortality disproportionately impacting these clusters. There was strong evidence that age was significantly associated with all-cause mortality overall but showed diminished significance in older clusters after excluding perioperative deaths. Adjusting for confounders confirmed this observation, with age losing significance in the youngest and oldest clusters in later analyses.

That clusters were primarily fitted based on age is not necessarily intuitive from a physician's perspective. We would have expected the presence of ruptures and the specific type of pathology to exert a larger influence on cluster formation, as these factors all have a relevant influence on clinical practice. Interestingly, the strictly data scientific approach of the analysis attributed heterogeneity between the included patients predominantly to age at the time of surgery. We hypothesize that a combination of collinearity, for example, a higher rate of dissections on younger patients, and homogeneity, with similarly distributed comorbidities, could explain this finding. Furthermore, aortic surgery, which is by definition a high-risk

XSL•FO
RenderX

procedure, may homogenize the investigated patient sample (at least for the electively treated patients) as patients must prove a certain level of health to qualify for such an operation. Age is strongly associated with postoperative mortality following invasive treatment of aortic pathologies, but there is solid evidence that this relationship varies across age groups. In the older clusters, the diminished association between age and all-cause mortality after excluding perioperative deaths suggests that perioperative risk plays a critical role in the age-related mortality disparity. Specifically, older patients demonstrated disproportionately higher all-cause mortality within the first 30 days after surgery, implying that the perioperative period is a key driver of mortality in this subgroup. This complies with previous evidence that reported a perioperative survival disadvantage after invasive aneurysm treatment in older patients [27,28].

This differential impact across age groups highlights the complexity of the relationship between age and mortality risk, which does not appear to be linear. While overall mortality increases with age, the cluster analysis revealed thresholds or transition zones in risk rather than a simple uniform progression. The higher perioperative mortality in older patients might reflect their greater vulnerability to surgical stress, emphasizing the importance of targeted perioperative management in this group. Additionally, the lack of a strong age-mortality association in the older clusters after the perioperative period suggests that factors beyond age, such as the type of aneurysm or co-existing conditions, may have a greater influence on long-term survival in these populations. Overall, the data support a nuanced interpretation of age as a risk factor, driven largely by perioperative mortality. Investigating nonlinear relationships between age and outcomes such as mortality in biomedical research has been of growing interest in the previous years [29-32]. This work contributes to the cumulative body of evidence that might gradually induce a paradigm shift in patient risk stratification.

From a statistical perspective, the findings reflect a nonlinear association in which the hazard function for age is dominated by early postoperative events in older patients, leading to attenuation of the age-mortality relationship once perioperative deaths are removed. This pattern is consistent with threshold-like behavior rather than a single global linear term, suggesting that conventional models assuming proportional and constant age effects may obscure important variation across the age distribution.

The clinical implications of this work emphasize the need for tailored perioperative management strategies that account for age-related differences in mortality risk. The necessity to identify solutions for an aging population is not confined to the field of healthcare, but is a subject of considerable interest within it. It is estimated that by 2050, 129.8 million individuals in Europe will be aged 65 years or older [33], with significant implications for the demand on national health care systems and the surgical workforce [34-36]. Therefore, the question of age as a limitation for operative procedures such as AA repair has attracted increasing attention in vascular surgery [27] but is discussed in other fields such as orthopedics with knee arthroplasty [37] as well. A substantial body of research has indicated an elevated risk of perioperative complications for older patients across various fields, including common abdominal [38-40] and vascular procedures [41,42]. In addition to adverse outcomes, surgical treatment in older patients has been demonstrated to be more resource-intensive, characterized by prolonged hospital stays [35,43]. The unsupervised cluster analysis identified distinct age thresholds at surgery, providing a framework for stratifying patients into risk groups. This approach moves beyond arbitrarily defined age-based subgroups, such as octogenarians or nonagenarians, which have traditionally been used as proxies for elderly populations in surgical research and have been previously questioned regarding their use [44].

However, the sensitivity analysis showed that alternative age cutoffs at 65 and 75 years produced similar Kaplan-Meier survival curves, suggesting that the transitions between age-based clusters are fluid rather than strictly defined. Consequently, these thresholds should not be interpreted as rigid cutoffs but rather as approximate transition zones that may guide clinical decision-making. For example, patients in the older age groups are at increased risk for perioperative mortality, highlighting the need for enhanced perioperative care, such as optimization of cardiovascular and respiratory function, and close monitoring during the immediate postoperative period. Similarly, younger patients may benefit from strategies aimed at mitigating long-term risk factors, such as smoking cessation and management of hypertension.

The identification of fluid but meaningful thresholds by the cluster analysis provides a valuable tool for clinicians, balancing the need for structured risk stratification with the recognition of patient-specific variability. From a group-level perspective, comorbidities were rather homogenously distributed among clusters. This may be due to case selection, as the analysis included only patients deemed suitable for surgery. As a result, eligibility for surgical treatment could have a homogenizing effect on this patient sample. Nevertheless, on an individual scale, this is certainly not the case and also requires attention when evaluating invasive treatment for a given patient. Age at surgery can give some guidance when evaluating perioperative and postoperative risks, and they vary for distinct age groups, but other factors still impose meaningful effects on survival as well.

The reliance on observational data introduces the potential for selection bias, particularly evident in the older clusters, where longer median survival age after surgery may simply reflect the fact that these patients underwent surgery at a later age. This delayed treatment may be indicative of slower disease progression, possibly due to reduced exposure to risk factors such as smoking or poorly controlled hypertension, but it complicates direct comparisons between age groups. Additionally, the UK Biobank lacks detailed information on aneurysm morphology, including diameters and growth rates, which are critical for understanding disease severity and progression. Such missing data may limit the granularity of risk stratification and affect the interpretation of clinical outcomes. Data from the UK Biobank are also subject to a volunteer selection bias. Furthermore, the use of administrative and diagnostic coding introduces the possibility of errors or misclassification in identifying aneurysm type, surgical

XSL•FO
RenderX

interventions, and comorbid conditions. Future studies incorporating more comprehensive clinical data and prospective designs could address these limitations and further refine the understanding of age-related risks in aortic aneurysm surgery. This will also address the need for further external validation of these findings.

This study highlights age as one of the key factors in postoperative all-cause mortality following AA surgery, with older patients experiencing higher perioperative mortality. Unsupervised cluster analysis revealed age thresholds that guide risk stratification reflecting transitions in age-related mortality risk.

Abstract

Background: The relationships among circadian rhythm syndrome, physical function, and muscle strength remain unclear.

Objective: This study aimed to demonstrate the separate and combined deleterious effects of solid fuel use and circadian rhythm syndrome on physical function and muscle strength.

Methods: We used data from the China Health and Retirement Longitudinal Study cohort. The study population consisted of participants who underwent comprehensive assessments of metabolism, circadian rhythm, indoor air pollution, physical function, and muscle strength at the initial evaluation. Muscle strength was assessed using repeated grip strength measurements, and physical function was assessed using a composite score of muscle strength, physical performance, and balance. Circadian rhythm syndrome was derived from the 5 diagnostic components of metabolic syndrome combined with sleep duration and depression. Logistic regression and linear mixed models were used to assess the relationships among solid fuel use, circadian rhythm syndrome, physical function, and muscle strength. Furthermore, we analyzed the mediating role of circadian rhythm syndrome and its combined effect with solid fuel use on physical function and muscle strength.

Results: A total of 7934 participants were included in the study, most of whom used solid fuels. Solid fuel use was positively associated with circadian rhythm syndrome (odds ratio [OR] 1.078, 95% CI 1.031-1.125; P<.05). Circadian rhythm syndrome was found to be a significant risk factor for impairment of physical function (β=−0.475; P<.05) and muscle strength (β=−0.304; P<.05). Participants who used solid fuels and had circadian rhythm syndrome needed to pay more attention to changes in physical function (β=−0.698; P<.05) and muscle strength (β=−0.332; P<.05). A significant interaction was observed between solid fuel use and circadian rhythm syndrome on physical function ($P_{interaction}$=.03) and muscle strength ($P_{interaction}$=.02). Circadian rhythm syndrome partially mediated the association between solid fuel use and physical function, accounting for 2.51% of the total effect.

Conclusions: Circadian rhythm syndrome exacerbates the adverse effects of solid fuel use on physical function and muscle strength. Fuel cleanliness and regular work and rest habits are crucial for the health of middle-aged and older adults.

KEYWORDS

age-related health decline; circadian rhythm syndrome; household air pollution; muscle strength; physical function

Introduction

Physical function assesses the ability to perform basic behavioral activities in terms of muscle strength, upper and lower extremity function, and balance [1]. Maintaining adequate physical function preserves the ability to live independently, optimizes quality of life, improves social participation, and reduces the risk of disability [2]. Low muscle strength and reduced physical function are associated with frailty, an increased risk of falls and fractures, and consequently, high morbidity and mortality [3-5]. Given that there are currently no effective pharmacological treatments to delay age-related decline in physical function [6], it is important to explore the risk factors associated with declining physical function and identify high-risk populations that are more likely to benefit from interventions to mitigate the decline in physical function.

The circadian rhythm is a biological rhythm with a cycle of approximately 24 hours that adapts to environmental changes and maintains stable physiological functions [7]. The suprachiasmatic nucleus of the hypothalamus is the central pacemaker of circadian rhythms and maintains synchronization with the external environment through neurohumoral signals in coordination with molecular oscillators in peripheral tissues [8]. Circadian rhythm is highly tissue-specific; each tissue of the human body, including the musculoskeletal system, has its own unique biological clock, which maintains physical function to meet daily demands by regulating the transcription and translation of clock genes [9]. The robustness of circadian rhythms decreases with age and the disruption of circadian rhythms; this is known as circadian rhythm syndrome and is a mechanism that potentially leads to an increased risk of various diseases [10,11]. Although maintaining a normal circadian rhythm is critical for skeletal muscle metabolic homeostasis, muscle fiber number and volume, and joint health [12], the impact of circadian rhythm syndrome on physical function and muscle strength lacks high-quality epidemiological studies for confirmation. As such, it is necessary to elucidate the relationship between circadian rhythm syndrome, physical function, and muscle strength and to identify special populations susceptible to circadian rhythm syndrome.

Household air pollution from solid fuel use is a common environmental safety problem worldwide [13]. According to statistics, the use of solid fuels is more common in developing countries. In China, approximately 450 million people rely heavily on solid fuels [14]. Numerous studies have shown that solid fuel use significantly increases the risk of physical and mental illnesses, such as cardiovascular disease and depression [14,15]. Additionally, our previous research also found adverse effects of solid fuel use and a combined adverse effect of solid fuel use and airborne particulate matter on physical function [1]. However, the association between solid fuel use and circadian rhythm syndrome remains unclear. Furthermore, solid fuel use and circadian rhythm syndrome are both risk factors for aging [16], and their combined effects on physical function and muscle strength require further elucidation.

To address these gaps, we performed a nationwide population-based cohort study to assess the independent and combined associations of solid fuel use and circadian rhythm syndrome with physical function and muscle strength in middle-aged and older adults. This study further aimed to explore the potential role of circadian rhythm syndrome in the relationship between solid fuel use and functional outcomes. The findings are expected to provide evidence relevant to public health strategies targeting environmental and lifestyle risk factors in aging populations.

Methods

Study Design and Data Source

This study used data from the China Health and Retirement Longitudinal Study (CHARLS), a large nationally representative cohort study of middle-aged and older adults in China [17]. CHARLS randomly selected 150 counties from 28 provinces in China, with a total of 17,708 participants as baseline and followed up every 2 years using face-to-face computer-assisted personal interviews (wave 2 in 2013, wave 3 in 2015, wave 4 in 2018, and wave 5 in 2020).

In the CHARLS survey, comprehensive assessments of circadian rhythm syndrome, physical function, and muscle strength were available only in the 2011, 2013, and 2015 waves. Therefore, data from 17,708 participants in 2011 (wave 1) were used as the baseline, with longitudinal analyses conducted using data from 2015 (wave 3). Exclusion criteria were: (1) being aged younger than 45 years (n=321); (2) no information on circadian rhythm syndrome (n=6067), physical function (n=2712), or household fuel use (n=674); and (3) no follow-up data (n=2916), comprising participants with missing information on circadian rhythm syndrome (n=929), physical function (n=1681), and household fuel use (n=306). A total of 7934 participants were finally included in the cross-sectional study, and 5018 participants in the longitudinal analysis (Multimedia Appendix 1). As shown in Multimedia Appendix 2, all participants in this study were distributed across 126 cities in 28 provinces in China, with the majority located in southern, central, and western China.

Household Solid Fuel Use Measurement

Household solid fuel use was assessed using a structured questionnaire. Participants were considered to use solid fuels when they answered “coal,” “crop residue/wood burning,” or “other” for heating and/or cooking, and clean fuels were considered to be used when they answered “natural gas,” “marsh gas,” “liquefied petroleum gas,” “solar,” or “electricity” for heating and/or cooking. Of note, due to the lack of data on the type of heating fuel used during follow-up, we conducted a longitudinal analysis of cooking fuels only and used participants using clean fuels as a reference to assess the impact of solid fuel use on circadian rhythm syndrome, physical function, and muscle strength. For the cross-sectional analysis, since data on both cooking and heating fuels were available, we adopted a

XSL•FO
RenderX

3-category classification to comprehensively reflect household fuel use patterns: clean fuel (reference group), partial solid fuel use (solid fuel used for at least 1 of cooking or heating), and solid fuel use.

Circadian Rhythm Syndrome Assessment

Based on previous studies, we used circadian rhythm syndrome as assessed by a combination of the 5 variables of the International Diabetes Federation assessing metabolic syndrome (elevated blood pressure, blood glucose, triglycerides, waist circumference, and lowered high-density lipoprotein cholesterol), combined with sleep duration and depression [11,18]. Detailed diagnostic criteria are shown in Multimedia Appendix 3 [19,20]. Participants were diagnosed with circadian rhythm syndrome if they met 4 of the 7 components [11,18].

Physical Function Assessment

Grip strength is a validated proxy for overall skeletal muscle strength and is widely used for sarcopenia screening in middle-aged and older adults [21-23]; therefore, it was used to assess muscle strength in this study. Each participant held the TM WL-1000 dynamometer (Nantong Yuejian Physical Measurement Equipment Co Ltd) in both hands successively at full strength for 2 separate measurements. The maximum of the 4 recordings was used and normalized by body weight [24]. If the participant was unable to perform the test with 1 hand due to special reasons, the maximum value of the other hand was recorded. In addition, the physical performance of each participant was assessed using gait speed and the chair stand test [23]. The above 3 tests were assigned a score of 1 to 4 to the participant based on the results from the first quartile to the fourth quartile. If the participant was unable to complete the test, the test was assigned a score of 0. Physical function was assessed using the above 3 tests plus the balance test [1]. For the balance test, participants were asked to stand and hold for 10 seconds in 3 increasingly difficult positions with their feet side-by-side, in semi-tandem, and in full-tandem. Scores were assigned based on the results of the tests (0: side-by-side <10 seconds; 1: side-by-side ≥10 seconds but semi-tandem <10 seconds; 2: semi-tandem ≥10 seconds and full-tandem <3 seconds; 3: semi-tandem ≥10 seconds and full-tandem between 3 and 10 seconds; 4: semi-tandem ≥10 seconds and full-tandem ≥10 seconds). Based on these assessments, the total physical function score was calculated as the sum of 4 domains: muscle strength, gait speed, chair-stand performance, and balance. Muscle strength, gait speed, and chair-stand test were each scored from 0 to 4 according to quartile-based performance, while balance was scored from 0 to 4 based on predefined criteria. Accordingly, the composite physical function score ranged from 0 to 16, with higher scores indicating better overall physical function [25-27].

Covariates

The following basic characteristics were included in the main analysis [1,11,18]: age, gender, education level, marital status, urbanization level, smoking status, drinking status, annual income, indoor temperature, housing type, BMI, and a comprehensive set of chronic diseases. Detailed information is provided in Multimedia Appendix 4.

Statistical Analysis

Statistical Summary of Participant Characteristics

The baseline characteristics of the participants were summarized based on the types of cooking and heating fuels used. Continuous variables are presented as mean (SD), while categorical variables are expressed as frequencies (percentage). Differences between groups were assessed using 2-tailed *t* tests for continuous variables and chi-square tests for categorical variables.

Cross-Sectional and Longitudinal Analysis of Separate Effects

We examined the relationships among solid fuel use, circadian rhythm syndrome, and physical function scores in both cross-sectional and longitudinal studies. Detailed information is provided in Multimedia Appendix 4. The missing rate for most individual characteristics was <5%; thus, missing values were imputed using a predictive mean-matching method to avoid excessive sample loss [18,28]. Upon comparing the summary statistics of the imputed dataset with those of the original dataset, no significant differences in the basic characteristics were observed (Multimedia Appendix 5). All statistical analyses were performed using R (version 4.3.1; R Foundation for Statistical Computing). Two-sided tests with a *P* value <.05 were considered significant.

Combined Effects and Interaction Analysis

We created a new variable by combining fuel type and circadian rhythm syndrome, resulting in 4 categories (2 × 2): fuel type (clean or solid fuels) and circadian rhythm syndrome (yes or no), to explore the collective effects of the 2 exposures on physical function scores. Moreover, we added multiplicative interaction terms to the model to analyze the interaction effect of solid fuel use and circadian rhythm syndrome on physical function scores. A *P* value <.05 for the interaction indicated the presence of a multiplicative interaction.

Stratified Analysis

Concurrently, we stratified by fuel type and circadian rhythm syndrome to explore the impact of other exposures on physical function scores, as well as the scores of the 4 tests.

Mediation Analysis

Finally, we conducted a mediation analysis using the R package *mediation* to assess whether circadian rhythm syndrome mediates the association between solid fuel use and physical function scores. Detailed information and sensitivity analyses are provided in Multimedia Appendix 4.

Ethical Considerations

Ethical approval was obtained from the Ethics Review Committee of Peking University (approval number IRB00001052-11015), and all participants consented to participate in this study.

Results

Statistical Summary of Participant Characteristics

Table 1 shows the baseline characteristics of the 7934 participants enrolled in the study. The findings revealed that solid fuel was the predominant household fuel, with 4820 (60.8%) and 4827 (60.8%) participants using it for cooking and heating, respectively. Participants who used solid fuels were generally older (aged 59.6, SD 8.9 years), female (2522/4820, 52.3%), less educated (4563/4820, 94.7%), living in rural areas (3827/4820, 79.4%), married (4078/4820, 84.6%), never smokers (3240/4820, 67.2%), never alcohol drinkers (3231/4820, 67%), with lower annual household incomes (3372/4820, 70%), and living in low-rise buildings (3639/4820, 75.5%) with unsuitable indoor temperatures. In terms of health status, participants who used solid fuels were more likely to have various chronic conditions, had a higher prevalence of circadian rhythm syndrome (1923/4820, 39.8%), and had lower physical function (12, SD 2.4), muscle strength (2.5, SD 1.1), gait speed (3.3, SD 1.1), chair stand test (2.4, SD 1.1), and balance (3.9, SD 0.5) scores. Characteristics of the participants in the longitudinal analysis are presented in Multimedia Appendix 6. Multimedia Appendix 7 illustrates the national distribution of solid fuel use, prevalence of circadian rhythm syndrome, physical function, and muscle strength. Northern China exhibited a higher prevalence of circadian rhythm syndrome and solid fuel dependency than Southern China, whereas physical function and grip strength scores were lower in the North.

Cross-Sectional and Longitudinal Analysis of Separate Effects

Figure 1A displays the separate effects of solid fuel use, circadian rhythm syndrome, and physical function at baseline. Regarding solid fuel use and circadian rhythm syndrome, participants who used solid fuels for cooking and those who used solid fuels for heating exhibited an elevated risk of circadian rhythm syndrome by 18.8% (odds ratio [OR] 1.188, 95% CI 1.069 to 1.32) and 19.8% (OR 1.198, 95% CI 1.082 to 1.326), respectively. Compared with participants using clean fuels for cooking and heating, those partially or entirely reliant on solid fuels experienced an increased risk of circadian rhythm syndrome by 17.2% (OR 1.172, 95% CI 1.024 to 1.341) and 31.5% (OR 1.315, 95% CI 1.155 to 1.499), respectively. Additionally, we examined the influence of solid fuel use on physical function and observed a negative correlation between the use of solid fuels for cooking (β=–0.189, 95% CI –0.282 to –0.097) and heating (β=–0.317, 95% CI –0.406 to –0.228) and physical function compared with clean fuels. Partial and complete reliance on solid fuels led to reductions in physical function scores by 0.175 (95% CI –0.293 to –0.057) and 0.386 (95% CI –0.5 to –0.272) points, respectively. Further analysis revealed significant decreases in muscle strength (β=–0.061, 95% CI –0.117 to –0.005) and chair stand test scores (β=–0.273, 95% CI –0.335 to –0.211) among participants who used solid fuels for cooking and heating (Multimedia Appendix 8). After adjusting for all covariates, we found a negative correlation between circadian rhythm syndrome and physical function (β=–0.552, 95% CI –0.641 to –0.462). Patients with circadian rhythm syndrome experienced decreased muscle strength, balance, and chair stand test scores (β=–0.378, 95% CI –0.421 to –0.335; β=–0.032, 95% CI –0.053 to –0.01; and β=–0.123, 95% CI –0.172 to –0.073, respectively; Multimedia Appendix 8).

Consistent with the results of the cross-sectional analysis, as shown in Figure 1B, our longitudinal analyses revealed a positive correlation between solid fuel use and the risk of circadian rhythm syndrome (OR 1.078, 95% CI 1.031 to 1.125). Additionally, participants who used solid fuel (β=–0.212, 95% CI –0.298 to –0.133) and had circadian rhythm syndrome (β=–0.475, 95% CI –0.555 to –0.394) had notably lower physical function scores. Multimedia Appendix 9 further demonstrates that these participants also had notably lower chair stand test and balance scores. Although no correlation was detected in the analyses examining the impact of solid fuel use on muscle strength, lower muscle strength scores were observed in participants with circadian rhythm syndrome (β=–0.304, 95% CI –0.342 to –0.265).

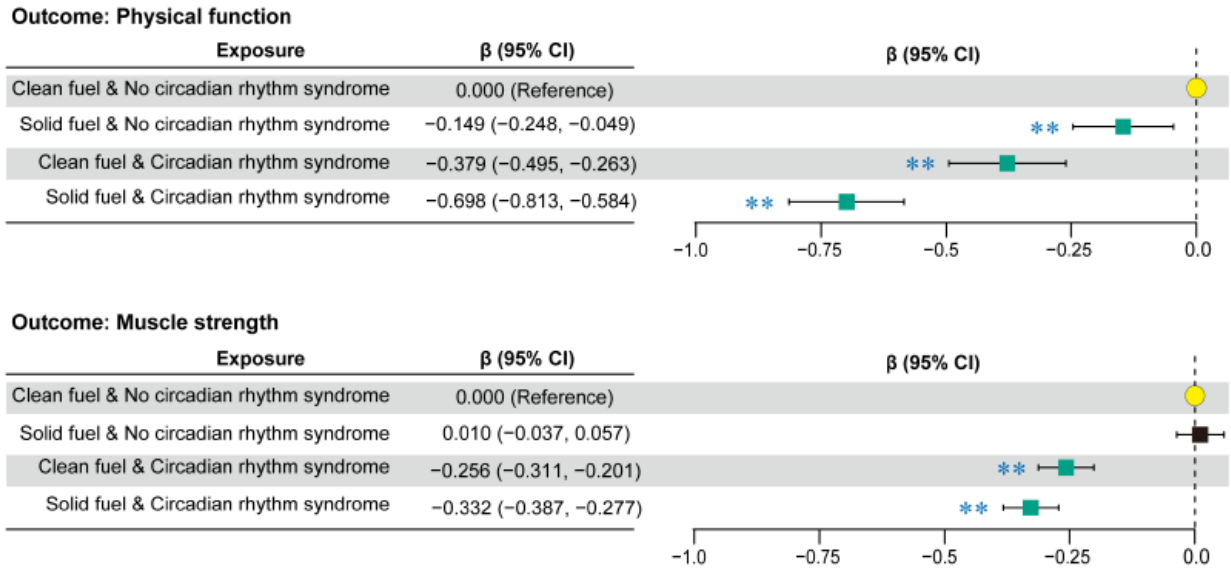
Figure 1. Associations among solid fuel use, circadian rhythm syndrome, and physical function in (A) cross-sectional and (B) longitudinal analyses. Estimates were derived from multivariable regression models (binary logistic regression for circadian rhythm syndrome, linear models for cross-sectional analyses, and mixed-effects linear models for longitudinal analyses). Results shown are from model 4, adjusted for age, gender, BMI, urbanization, education level, marital status, smoking status, drinking status, housing type, indoor temperature, and chronic diseases. A single asterisk (*) indicates $P<.05$ and double asterisks (**) indicate $P<.01$. OR: odds ratio.



Combined Effects and Interaction Analysis

Figure 2 illustrates the combined effects of solid fuel use and circadian rhythm syndrome on physical function and muscle strength. Specifically, participants who used solid fuels and had circadian rhythm syndrome concurrently (solid fuels + circadian rhythm syndrome group) had the most pronounced reduction in physical function (β=–0.698, 95% CI –0.813 to –0.584) and muscle strength (β=–0.332, 95% CI –0.387 to –0.277) compared with those who did not use solid fuels or had only one of the risk factors.

XSL•FO
RenderX

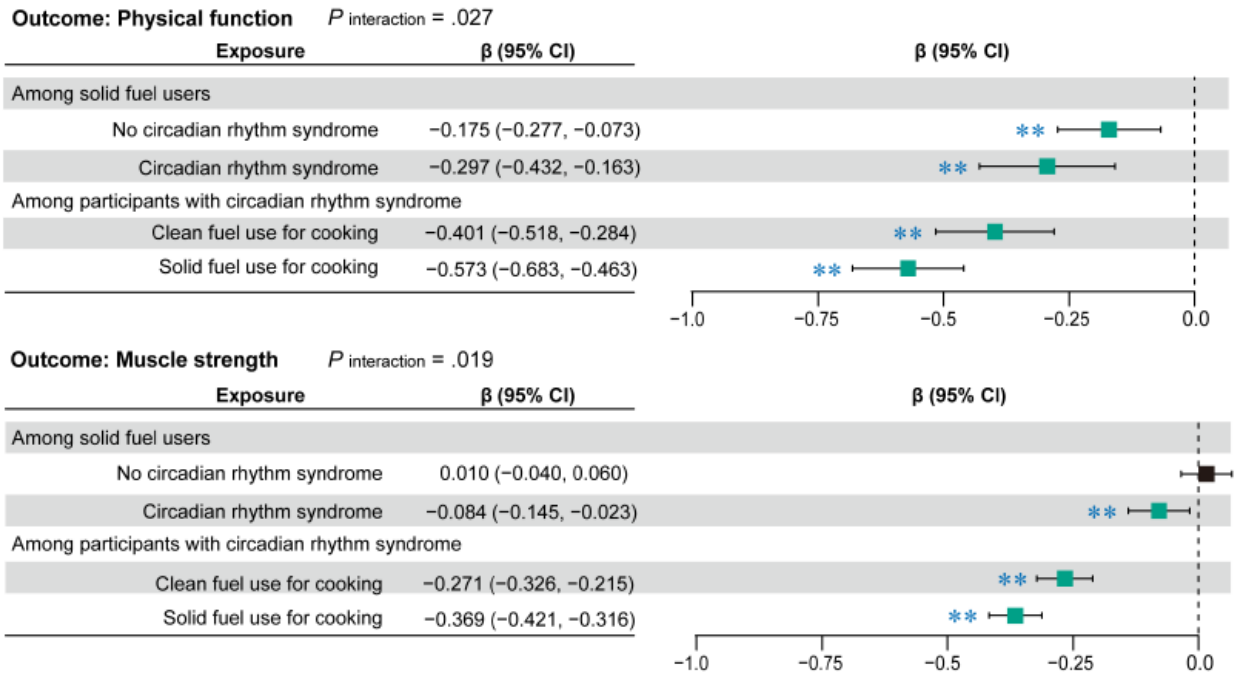


Figure 2. Combined effects of solid fuel use and circadian rhythm syndrome on physical function and muscle strength. Estimates were derived from multivariable linear regression models including a 2 × 2 combined exposure variable (fuel type × circadian rhythm syndrome) and a multiplicative interaction term to assess interaction effects. Adjusted for age, gender, BMI, urbanization, education level, marital status, smoking status, drinking status, housing type, indoor temperature, and chronic diseases. A single asterisk (*) indicates P<.05 and double asterisks (**) indicate P<.01.

Stratified Analyses

As we detected a multiplicative interaction between solid fuel use and circadian rhythm syndrome on physical function ($P_{interaction}$=.03) and muscle strength ($P_{interaction}$=.02), we conducted further stratified analyses (Figure 3). Our findings indicated that individuals with circadian rhythm syndrome were more vulnerable to the effects of solid fuel use on physical function (β=–0.297, 95% CI –0.432 to –0.163) and muscle strength (β=–0.084, 95% CI –0.145 to –0.023). Similarly, the negative correlation between circadian rhythm syndrome and physical function (β=–0.573, 95% CI –0.683 to –0.463) and muscle strength (β=–0.369, 95% CI –0.421 to –0.316) was more pronounced in participants who used solid fuels.

Figure 3. Stratified analyses were conducted separately for circadian rhythm syndrome and household fuel types. Estimates were derived from multivariable linear regression models stratified by fuel type and circadian rhythm syndrome. Adjusted for age, gender, BMI, urbanization, education level, marital status, smoking status, drinking status, housing type, indoor temperature, and chronic diseases. A single asterisk (*) indicates P<.05 and double asterisks (**) indicate P<.01.

Mediation Analysis

The results of the mediation analysis are depicted in Figure 4. Circadian rhythm syndrome served as a significant mediator of the positive association between solid fuel use and physical function, with a mediation effect of 2.51%.

Figure 4. Mediation analysis of the association among solid fuel use, circadian rhythm syndrome, and physical function. Mediation analysis was conducted using the R package mediation to examine whether circadian rhythm syndrome mediated the association between solid fuel use and physical function scores. Regression models were fitted for both the mediator and the outcome, adjusting for age, gender, BMI, urbanization, education level, marital status, smoking status, drinking status, housing type, indoor temperature, and chronic diseases. Direct, indirect, and total effects were estimated using 1000 bootstrap simulations to derive 95% CIs. A single asterisk (*) indicates $P<.05$.

Sensitivity Analyses

Multiple sensitivity analyses were performed to verify the reliability and validity of the findings. When examining the association between solid fuel use and the number of circadian rhythm syndrome components, we found that participants who used solid fuels for both cooking and heating exhibited a 5.5% increase in the number of syndrome components compared with those using clean fuels (Multimedia Appendix 10). We also examined the effects of different types of solid fuels on physical function and circadian rhythm syndrome and found that coal use was more strongly correlated with both physical function (β=–0.276, 95% CI –0.411 to –0.141) and circadian rhythm syndrome (OR 1.221, 95% CI 1.02 to 1.463), whereas crop residue/wood burning was only significantly associated with physical function (β=–0.198, 95% CI –0.286 to –0.11) (Multimedia Appendices 11 and 12). The results of the subgroup analyses, shown in Multimedia Appendix 13, indicate that older adults are more susceptible to the impact of circadian rhythm syndrome on physical function scores, highlighting the importance of maintaining regular work and rest habits in this population. We excluded participants who reported “other” as their fuel type and reexamined the main associations among solid fuel use, circadian rhythm syndrome, and physical function in both cross-sectional and longitudinal analyses. The results were consistent with the primary findings (Multimedia Appendices 14-16), supporting the robustness of the observed associations.

Discussion

Principal Findings and Comparison With Prior Works

This study found that solid fuel use was positively associated with circadian rhythm syndrome, and that both solid fuel use and circadian rhythm syndrome were independently and jointly associated with poorer physical function and lower muscle strength. A significant multiplicative interaction was observed, indicating that the associations between solid fuel use and these functional outcomes were stronger among participants with circadian rhythm syndrome. In addition, circadian rhythm syndrome partially mediated the association between solid fuel use and physical function, suggesting that circadian rhythm disruption may represent one potential pathway underlying the observed associations.

To the best of our knowledge, this is the first study to investigate the relationship between household air pollution from solid fuel use and circadian rhythm syndrome, making it difficult to compare our results with those of previous studies. Although previous studies have not reported a direct link between solid fuel use and circadian rhythm syndrome, associations between solid fuel use and various components of the circadian rhythm syndrome have been demonstrated. Results from a cross-sectional study involving women suggested that household

XSL•FO
RenderX

air pollution from burning biomass fuel is associated with an increased risk of metabolic syndrome [29]. Studies from different regions have consistently confirmed the association between household air pollution and components of metabolic syndrome, such as blood pressure, blood glucose, and lipid profile, highlighting the potential risk of metabolic disorders that can be reduced by mitigating household air pollution [30-32]. The use of solid fuels also affects the mental health of older adults, with the results of a cohort study showing that using solid fuels for heating and cooking increases the risk of depression by 45% [33]. Similarly, the sleep-related health of middle-aged and older adults is affected by the use of solid fuels, especially in rural areas, where the vast majority of households rely on the combustion of biomass fuels for nighttime heating in winter. Studies from different regions have shown a significant positive association among solid fuel use, poor sleep quality, and reduced sleep duration [34,35]. Metabolic homeostasis, social stress, and sleep significantly affect the stability of the circadian clock, and exploring the effects of solid fuel use on one of them alone is one-sided. Therefore, this study examined the comprehensive impact of household air pollution on circadian rhythm disorders and revealed the importance of household fuel cleanliness on circadian rhythm homeostasis in middle-aged and older adults (OR 1.315, 95% CI 1.155 to 1.499 at baseline; OR 1.078, 95% CI 1.031 to 1.125 at follow-up). We also further analyzed the impact of household air pollution on circadian rhythm syndrome components; participants who used solid fuels for heating and cooking showed greater accumulation of circadian rhythm syndrome components than participants who used clean fuels. Cooking and heating are 2 common and often coexisting household activities; therefore, examining the independent and combined use of solid fuels in these settings is of particular relevance. We found that, compared with the use of clean fuels for both purposes, using solid fuels for either cooking or heating, as well as for both, was associated with a higher likelihood of circadian rhythm syndrome (either cooking or heating: OR 1.172, 95% CI 1.024 to 1.341; both: OR 1.315, 95% CI: 1.155 to 1.499) and lower physical function scores (either cooking or heating: β=–0.175, 95% CI –0.293 to –0.057; both: β=–0.386, 95% CI –0.5 to –0.272) in a graded manner. These findings suggest that different patterns of household fuel exposure may exert additive adverse effects on circadian regulation and physical function.

Disturbances in the circadian rhythm pose a major threat to the health of the musculoskeletal system in middle-aged and older adults. Real-life problems faced by older adults, such as a reduced metabolic rate, sleep disturbances, and depression caused by loneliness, affect the stability of circadian rhythms and impair muscle, joint, and bone health [9,36]. Pathophysiological changes in the musculoskeletal system significantly affect mobility and muscle strength and accelerate aging, which in turn leads to the disruption of circadian rhythms [3,37]. Although the vicious cycle of circadian rhythm syndrome and reduced physical function and muscle strength is detrimental to the health of middle-aged and older adults, no high-quality epidemiological studies have confirmed this association. Using a large nationwide cohort, we observed a significant inverse association among circadian rhythm syndrome, physical function (β=–0.386, 95% CI –0.5 to –0.272 at baseline; β=–0.475, 95% CI –0.555 to –0.394 at follow-up), and muscle strength (β=–0.061, 95% CI –0.117 to –0.005 at baseline; β=–0.304, 95% CI –0.342 to –0.265 at follow-up). We also evaluated the impact of circadian rhythm syndrome on physical performance (assessed by gait speed and chair stand tests) and showed that disruption of the circadian rhythm impairs mobility in middle-aged and older adults.

The decline in muscle strength and mobility due to aging causes most middle-aged and older adults to stay indoors for long periods. Therefore, it is important to explore the comprehensive impacts of indoor environmental factors and lifestyle. We found that solid fuel use and circadian rhythm syndrome had a synergistic effect on the impairment of physical function (β=–0.698, 95% CI –0.813 to –0.584) and muscle strength (β=–0.332, 95% CI –0.387 to –0.277). There was a multiplicative interaction between solid fuel use and circadian rhythm syndrome ($P_{interaction}$<.05), with circadian rhythm syndrome exacerbating the effects of solid fuel use on physical function (β=–0.297, 95% CI –0.432 to –0.163) and muscle strength (β=–0.084, 95% CI –0.145 to –0.023). Since middle-aged and older adults, especially in rural areas, mostly use solid fuels for nighttime heating, sleep disorders caused by circadian rhythm disorders are more likely to be exposed to household air pollution caused by solid fuels, which in turn leads to a more significant negative correlation with physical function and muscle strength. Furthermore, we elucidated the mediating role of circadian rhythm syndrome, whereby solid fuel use impaired physical function in part by increasing the risk of circadian rhythm syndrome (mediation effect: 2.51%).

Mechanistically, disruption of central and peripheral circadian regulatory networks may underlie the associations observed among solid fuel use and impaired physical function and muscle strength. The combustion of solid fuels generates particulate matter and toxic gases, which have been shown to enter systemic circulation and may affect the central nervous system, potentially disrupting the coordination between the central pacemaker in the suprachiasmatic nucleus and peripheral clocks through neurohumoral pathways [38-40]. In addition, household air pollution has been associated with increased systemic inflammation and oxidative stress. Air pollutants can stimulate the production of inflammatory cytokines and reactive oxygen species while impairing antioxidant defense systems [41,42]. These processes may contribute to circadian dysregulation, as both inflammation and oxidative stress have been implicated in altering clock gene expression and circadian homeostasis. Furthermore, chronic inflammation and oxidative stress are known to adversely affect joint integrity and muscle function, thereby contributing to declines in physical function [12]. Metabolic pathways may also play a role in linking circadian disruption to functional impairment. Experimental studies have shown that disturbances in skeletal muscle circadian rhythms can lead to metabolic dysregulation, including increased reliance on anaerobic glycolysis, reduced mitochondrial function, and increased apoptosis [9,43]. Such changes may accelerate muscle degradation and contribute to sarcopenia. Taken together, although the precise mechanisms remain to be fully elucidated, existing evidence suggests that household air pollution from solid fuel use may influence circadian regulation through

XSL•FO
RenderX

interconnected pathways involving neurohumoral disruption, systemic inflammation, oxidative stress, and metabolic imbalance, ultimately contributing to impaired physical function and reduced muscle strength. Consequently, although the precise mechanisms remain unclear, the relationship between household air pollution due to solid fuel use, circadian rhythm syndrome, physical function, and muscle strength warrants further investigation.

This study has several strengths: (1) novel findings, we identified an association between solid fuel use and circadian rhythm syndrome, with both solid fuel use and circadian rhythm syndrome separately and synergistically associated with declines in physical function and muscular strength; (2) representative and reliable results, we used a large national cohort of 126 cities across 28 provinces to conduct meticulous sensitivity analyses; (3) rigorous analytic methods, to minimize the recall and social desirability biases inherent in self-report measures, we used repeated-measures tests focusing on physical function, muscular strength, and physical performance in middle-aged and older adults; (4) guiding insights, mediation analyses revealed that solid fuel use affected physical function and muscular strength by increasing the risk of circadian rhythm syndrome, emphasizing the importance of household fuel cleaning and regular work and rest habits for the health of middle-aged and older adults.

Limitations

However, some limitations of this study should be noted. The CHARLS is a representative cohort study of middle-aged and older individuals. We only evaluated the impact of circadian rhythm syndrome on the health of middle-aged and older adults. The differences between the different age groups warrant further exploration. In addition, information on household solid fuel use was self-reported by participants, which may be subject to recall bias or reporting bias. This study relied solely on information on household fuel use for heating and cooking to assess indoor air pollution and may have overlooked other factors, such as ventilation efficiency and weather conditions. The degree of dependence on solid fuels varies seasonally. For example, in winter, the dependence on solid fuels for heating is higher. It is necessary to pay attention to the differences in the use of solid fuels in different seasons with respect to circadian rhythm syndrome, physical function, and muscle strength. Moreover, given the observational nature of this study, the identified associations among solid fuel use, circadian rhythm syndrome, and physical function or muscle strength should be interpreted with caution. Although we adjusted for a wide range of potential confounders, residual confounding cannot be completely ruled out, and causal relationships cannot be definitively established.

In conclusion, this nationwide prospective cohort study revealed a positive association between solid fuel use and circadian rhythm syndrome and found negative effects of solid fuel use and circadian rhythm syndrome, separately and jointly, on physical function and muscle strength. Disturbances in the circadian rhythm exacerbate the decline in physical function and muscle strength caused by solid fuel use. Circadian rhythm syndrome is an important mediator in the relationship between solid fuel use and physical function. This study highlights the combined impact of indoor environmental factors and lifestyle on middle-aged and older adults and recommends the use of clean fuels and the development of regular work and rest habits to improve physical health.

Acknowledgments

The data for this study come from the CHARLS dataset, and we sincerely thank the CHARLS research team and each of the participants.

Funding

This study was supported by the Joint Fund Project General Support Program Project of Liaoning Provincial Department of Science and Technology (grant number 2023-MSLH-386 to YW) and the 345 Talent Project of Shengjing Hospital of China Medical University (grant number M0271 to YW).

Abstract

Background: Population aging and rapid digitalization have intensified concerns about older adults' digital participation. Although access disparities have narrowed, older adults continue to differ from younger groups in how they use digital technologies, with their use skewed toward instrumental rather than hedonic purposes. Technophobia is a salient psychological barrier; yet, its distinct fear dimensions and their links to different forms of technology use remain insufficiently differentiated. Daily technical support (DTS) may provide an important sociotechnical context for understanding these relationships.

Objective: This study aimed to test how DTS promotes older adults' instrumental and hedonic technology use by reducing multidimensional technophobia (fear of inconvenience, fear of personal failure, and human-machine ambiguity) and whether these mechanisms differ by gender.

Methods: A cross-sectional survey was conducted among Chinese adults aged ≥55 years recruited via online platforms and offline communities in Nanjing (June-October 2024). A total of 212 valid responses were included (mean age 66.96, SD 6.96, range 55 - 86 years; 142/212, 68.4% women). Measures assessed day-to-day technical support, 3 dimensions of technophobia, instrumental versus hedonic technology use, and demographic variables. We used partial least squares structural equation modeling (PLS-SEM) with 5000 bootstrap resamples to test direct, indirect, and moderated mediation effects, reporting 95% bias-corrected and accelerated (BCa) CI.

Results: DTS significantly reduced fear of inconvenience (β=−0.455, 95% BCa CI −0.632 to −0.229; *P*<.001) but did not significantly affect fear of personal failure (*P*=.12) or human-machine ambiguity (*P*=.26). Fear of inconvenience and human-machine ambiguity negatively predicted instrumental use (IU; β=−0.215, 95% BCa CI −0.410 to −0.009; *P*=.05 and β=−0.211, 95% BCa CI −0.389 to −0.001; *P*=.04). DTS had a positive direct effect on IU (β=0.104, 95% BCa CI 0.009 to 0.203; *P*=.04) but not on hedonic use (HU; β=0.075; *P*=.11). The indirect effect of DTS on IU through fear of inconvenience was significant (β=0.097, 95% BCa CI 0.020-0.204). Gender moderated the effect of DTS on fear of inconvenience (β=0.287, 95% BCa CI 0.052-0.518; *P*=.02), and such conditional indirect effect was significant for men (β=0.098, 95% BCa CI 0.001-0.219) but not for women (β=0.036, 95% BCa CI −0.002 to 0.116).

Conclusions: DTS was associated with greater instrumental technology use among older adults through lower fear of inconvenience, with a stronger indirect association among men, whereas no comparable pathway emerged for HU. This suggests that gender may shape how older adults benefit psychologically from technical support rather than reflect general differences in support needs. Interventions should move beyond one-size-fits-all approaches by providing targeted, task-oriented support that addresses older adults' specific technological fears and practical barriers.

Introduction

Background

Population aging is accelerating worldwide, with the proportion of people aged 60 years and older projected to nearly double from 12% in 2015 to 22% by 2050 [1]. Meanwhile, with the rapid development of information and communication technologies (ICTs), digital technologies have become increasingly embedded in older adults' everyday lives, mediating routine activities such as banking, shopping, health management, and social interaction and making digital competence increasingly comparable to foundational literacy [2,3]. The first-level digital divide, which refers to inequalities in access to digital technologies [4], has narrowed substantially with the widespread diffusion of internet-enabled devices and improved connectivity [5-7]. In China, for example, the number of internet users aged 60 years and older increased from 119 million in December 2021 to approximately 173 million in December 2025, an increase of approximately 45.4% over 4 years [8,9]. Nevertheless, older adults remain disproportionately disadvantaged in digital access, with an internet penetration rate of 53.7%, compared with 80.1% for the population as a whole [8]. In addition, despite the narrowing first-level digital divide, substantial inequalities persist at the second and third levels, reflected in disparities in how older adults use digital technologies and in the digital skills and competencies needed for effective and meaningful engagement [10,11]. Indeed, older adults' online engagement remains markedly skewed toward instrumental uses (IUs; eg, online services and communication) rather than hedonic uses (HUs; eg, entertainment, gaming, and social media) [11-13]. For instance, in the United Kingdom, 58% of older internet users (ages 65 - 74 years) shop online and 65% bank online, whereas only about 32% play online games [14].

Barriers to ICT adoption among older adults are multifaceted, encompassing health-related limitations, inadequate digital skills, resource constraints such as cost and connectivity, insufficient support networks, and psychological factors [15]. While many of these barriers primarily limit older adults' opportunities or capacity to engage with technology, psychological factors may exert a more immediate influence on adoption decisions by shaping how older adults perceive their technological capabilities, evaluate the benefits and demands of technology, and respond to difficulties encountered during use. Accordingly, psychological barriers—particularly technophobia—are salient for older adults. Technophobia is commonly defined as a fear or anxiety about technology, and it is associated with delayed or hesitant adoption, especially among individuals with limited digital literacy or inaccurate beliefs about technology [11,16]. Although scholars have called for conceptualizing technophobia as multidimensional, much of the literature continues to treat it as a unidimensional construct, limiting fine-grained insight into how distinct fears map onto different forms of technology use [16-19]. Moreover, while prior research has examined demographic correlates of technophobia and shown that structured interventions (eg, training and intergenerational mentoring) can alleviate it [20,21], evidence remains scarce on whether and how spontaneous day-to-day technical support—more typical of naturalistic settings—shapes technophobia within a broader sociotechnical context.

To address these gaps, this study examines how daily technical support (DTS) influences older adults' instrumental versus hedonic technology use through multiple fear-related dimensions of technophobia. We further test whether these indirect effects vary by gender, given documented gender differences in support-seeking motivations and technology-related stereotypes [22]. By clarifying which dimensions of technophobia are most responsive to everyday support—and for whom—this research advances digital divide scholarship and informs more targeted, age-friendly support and training strategies.

Literature Review and Hypotheses Development

The Multidimensionality of Technophobia

Originated from the concept of computer anxiety, technophobia was initially conceptualized as a unidimensional construct capturing negative psychological responses to technology in general [23,24]. This early view closely resembles technology anxiety or digital anxiety, which refers primarily to restlessness or apprehensive tension when one has to use or learn a new technology [25]. Subsequent research has refined this perspective, arguing that technophobia is not merely a simple emotional reaction (ie, anxiety); rather, technology anxiety constitutes only 1 facet of technophobia [17,26]. Accordingly, technophobia is better understood as an umbrella, higher-order phenomenon comprising multiple dimensions that reflect the cognitive appraisals and beliefs underlying the sources of fear during technology adoption.

Some studies have approached technophobia from an affective perspective, conceptualizing it primarily in terms of anxiety, discomfort, or other negative emotional responses to technology [27-29], with measures including techno-anxiety, techno-paranoia, and privacy concerns [26]. A different line of research has focused on the specific sources from which such fear arises. Sinkovics et al (2002) [19] proposed 3 dimensions of technophobia from the perspective of the underlying sources of fear; it distinguishes self-related, internal sources of fear from externally situated concerns embedded in the usage context. Fear of personal failure refers to the anticipated threat to one's competence and self-worth when engaging with technology—specifically, the concern that one may be unable to use it correctly, may make errors, or may be perceived as incapable. Fear of inconvenience reflects a more instrumental concern about whether the effort required to use a technology is justified by its anticipated benefits. Human-machine ambiguity captures discomfort rooted in one's preferences and beliefs about everyday action and interpersonal exchange, particularly when human contact is substituted by machine-mediated interaction. Subsequent research has further reinforced the view of technophobia as a multidimensional construct. For example, Khasawneh (2018) [17] identified 5 dimensions of technophobia, including techno-anxiety, techno-paranoia, techno-fear, techno-cybernetic revolt, and communication device avoidance. Although more differentiated, broadly capture fear sources similar to those represented in Sinkovics et al [19] 3D framework.

XSL•FO
RenderX

Prior empirical work has consistently shown that older adults tend to report higher levels of technophobia than younger cohorts [16,18]. Technophobia has also been associated with avoidance and reduced technology engagement, such that older adults may use digital technologies less frequently, limit themselves to a narrower range of applications, and show less willingness to adopt unfamiliar technologies [30]. However, much of the existing literature has treated technophobia as a global or unidimensional construct, providing limited insight into which specific sources of fear are associated with particular technology-use behaviors. By differentiating among distinct fear sources, Sinkovics et al [19] framework offers a more fine-grained basis for identifying the psychological barriers underlying older adults' technology use and for considering forms of support that are better matched to those barriers. Accordingly, the current study adopts this 3D, fear-specific framework to examine how different forms of technophobia are associated with older adults' technology use.

The Instrumental Versus HU of Technology

Scholars of information systems commonly distinguish 2 types of IT according to their primary purposes and functional orientations, utilitarian (instrumental) systems that support productivity and task accomplishment, and hedonic systems that foreground enjoyment, entertainment, and self-expression [31,32]. This typology draws on the hedonic consumption tradition that differentiates utilitarian from hedonic products and experiences [33]. It underscores that information systems are embedded not only in work or education settings for job and study-related activities, but also in domestic and leisure contexts where technology use itself can provide enjoyment and experiential value. Correspondingly, users' purposes for daily technology use tend to cluster into 2 broad motivation-driven categories: instrumental purposes (eg, banking, information search, and health management) and hedonic purposes (eg, streaming, gaming, and social media). Although some digital technologies can serve both instrumental and hedonic purposes, this dichotomy remains analytically useful because the psychological beliefs underlying technology acceptance may differ depending on the primary purpose for which a technology is used.

The Technology Acceptance Model (TAM) provides the primary theoretical foundation for understanding why individuals adopt and use technology. TAM proposes that technology acceptance is largely determined by 2 key beliefs: perceived usefulness and perceived ease of use [32,34]. These 2 beliefs reflect different motivational considerations underlying technology use. Perceived usefulness is closely associated with extrinsic motivation because users adopt a technology in anticipation of instrumental outcomes, such as improved performance, greater efficiency, or task accomplishment [35]. Perceived ease of use, in contrast, reflects the effort required to interact with a technology and is more closely related to the experiential process of technology use; by reducing effort and facilitating a more fluent interaction, ease of use can support intrinsically motivated experiences such as enjoyment and playfulness [36]. Importantly, the relative importance of these motivational mechanisms varies across technology-use contexts. In instrumental contexts, technology is primarily used as a means to accomplish an external goal. Consequently, extrinsic motivation is particularly salient, and perceived usefulness becomes a central determinant of adoption because users evaluate whether the technology helps them perform tasks more effectively or efficiently. In hedonic contexts, by contrast, technology use is more strongly driven by intrinsic rewards derived from the use experience itself, such as enjoyment, pleasure, playfulness, and immersion. Accordingly, perceived enjoyment becomes particularly important, while ease of use facilitates hedonic motivation by reducing interactional effort and allowing users to experience these intrinsic rewards more readily [32,35]. Thus, from a TAM perspective, the distinction between instrumental and hedonic technology use reflects not merely differences in technological functions, but differences in the motivational beliefs that become most salient across use contexts.

The Impact of Technophobia on Different Use of Technology Among Older Adults

Building on TAM, which suggests that different technology-use contexts may be driven by different motivational beliefs, we further draw on the multidimensional view of technophobia proposed by Sinkovics et al [19] to examine how distinct sources of technological fear may map onto extrinsic versus intrinsic motivational orientations toward technology use [37,38]. In particular, fear of inconvenience aligns with extrinsic motivation, such that perceived usefulness from the TAM represents rational skepticism about the effort-benefit balance of using technology [35]. Older adults with a heightened fear of inconvenience perceive technology as overly burdensome, thereby reducing perceived value and discouraging adoption. Conversely, fear of personal failure relates closely to perceived ease of use and self-efficacy, which echoes the intrinsic motivation in TAM, where low self-confidence leads to anxiety about technological mistakes or inadequacies [34,39]. Older adults with a heightened fear of personal failure avoid technologies that require adaptation or learning, thus reinforcing digital exclusion [6,18]. In Sinkovics et al [19], the human-machine ambiguity dimension captures deep-seated preferences and beliefs about everyday action, particularly individuals' comfort with human interaction when the "human element" is replaced by a machine. Recent research suggests that such substitution can undermine perceived autonomy, thereby threatening intrinsic motivation [40-42].

We build on the foregoing review to argue that the fear of inconvenience, which is a rational, extrinsic, effort-benefit appraisal, should most strongly depress iIU, where perceived usefulness is decisive. By contrast, fear of personal failure, as well as human-machine ambiguity, which erodes competence beliefs and undermines intrinsic engagement, should strongly curb HU, where perceived enjoyment and comfort are pivotal. This distinction motivates our domain-specific expectation that different technophobia dimensions map onto different adoption purposes rather than exerting uniform effects across all forms of technology use. Therefore, we propose the hypotheses mentioned below.

XSL•FO
RenderX

Hypothesis 1

Specific dimensions of technophobia will be negatively associated with older adults' technology use, with different fear dimensions expected to be more relevant to different types of technology use. Specifically, (1) fear of inconvenience will be negatively associated with instrumental technology use, (2) fear of personal failure will be negatively associated with hedonic technology use, and (3) human-machine ambiguity will be negatively associated with hedonic technology use.

Technical Support and Its Positive Effects

In gerontological research, social support is widely recognized as a key social determinant of healthy aging, and it generally refers to the resources and assistance provided through social relationships, which help individuals feel cared for, valued, and part of a mutually obliging network [43]. It typically distinguishes between structural and functional dimensions of support. The structural aspect refers to the existence and quantity of social relationships, such as living arrangements, network size, and frequency of social interaction [44]. The functional aspect refers to the specific supportive functions that relationships serve, and 2 primary functional forms are studied. Emotional support involves empathy, caring, love, and someone to confide in during stress. Instrumental support, which is usually tangible, refers to practical help or services, such as assistance with daily tasks or financial aid [45]. A robust body of evidence suggests that a strong social support network of any functions is associated with better outcomes in late life, including improved health and longevity [46], better mental health (eg, reduced stress, loneliness, and depression) [47,48], and greater well-being (eg, life satisfaction and overall quality of life) [49,50].

Technical support, which often provides immediate resolution and encourages continued technology use, is primarily recognized as instrumental support. Such support can be structured through formal workshops, training sessions, or digital learning programs led by instructors; it can also be informal and embedded in daily life through ad-hoc help from peers, family, or volunteers [11,51]. Previous research has consistently demonstrated that technical support is a powerful facilitator for new technology adoption among older adults because it enables the immediate resolution of technical issues, thus underscoring the general importance of assistance in overcoming initial adoption hurdles [11,52]. Therefore, we propose hypothesis 2.

Hypothesis 2

DTS will promote the instrumental and HUs of technologies among older adults.

On the other hand, it is also found that daily family support that focuses on digital tasks helps to reduce older users' overall digital anxiety [25]. A set of intervention studies demonstrate that technical support from internet training programs effectively reduced older adults' technology anxiety while improving confidence [53], and similar improvements have been observed in collaborative peer-learning contexts [54]. With this basis, we argue that ongoing DTS can positively influence all 3 dimensions of technophobia. First, practical assistance alleviates the fear of inconvenience by simplifying the learning process and demonstrating that technology can make life easier [55]. Second, frequent support helps counter the fear of personal failure—knowing that mistakes can be fixed with help boosts self-efficacy through repeated successful experiences. Older adults particularly prefer assistance from trusted family or friends, as this reduces embarrassment and enhances comfort [56]. Third, having a human intermediary eases human-technology ambiguity, transforming a solitary, intimidating process into an interactive, supportive experience [57]. Therefore, we further proposed hypothesis 3 mentioned below.

Hypothesis 3

DTS will mitigate each dimension of technophobia among older adults, including (1) fear of inconvenience, (2) fear of personal failure, and (3) fear of human-machine ambiguity.

The Mediation Effect of Technophobia

While the direct positive impact of technical support on both perception and behavioral reaction toward technologies is well documented, research also suggested that this effect is often indirect and operates through users' perceptions of the technology. As articulated in the TAM, external factors (such as training or support available in one's environment) do not directly cause someone to adopt a technology; instead, they influence key perceptual drivers of adoption, such as the technology's perceived ease of use and perceived usefulness [39,58]. For instance, workplace studies have found that when support is available, employees report high ease-of-use and usefulness beliefs about new IT systems, which then predict great adoption and usage [39]. Therefore, we further proposed the mediation effect of technophobia (hypothesis 4).

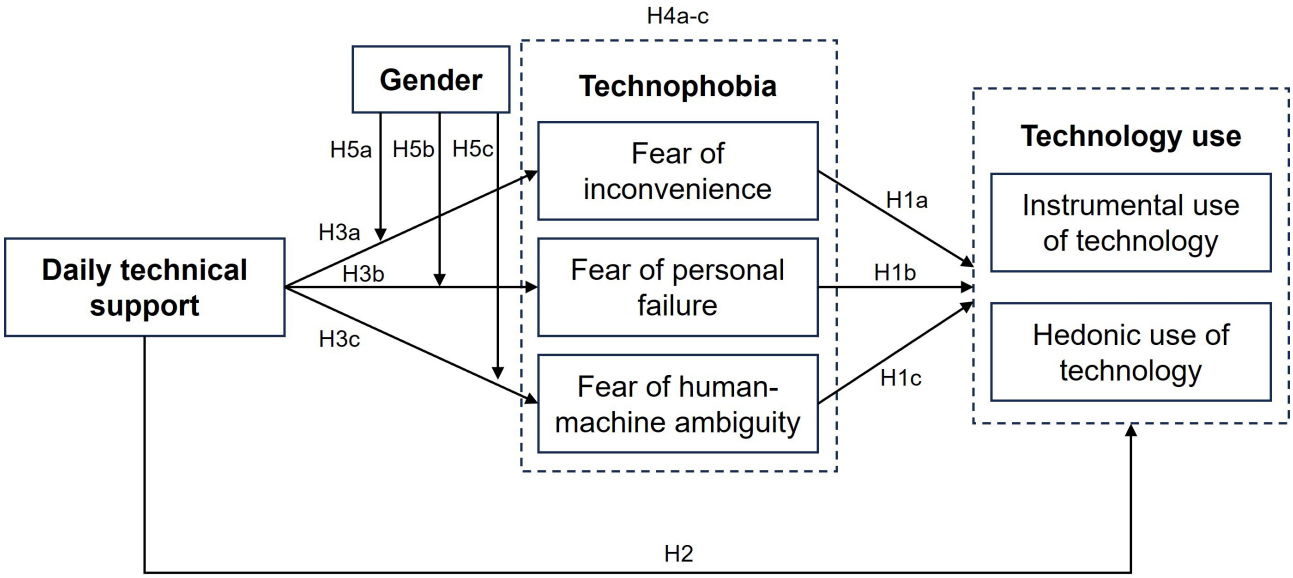
Hypothesis 4

Each dimension of technophobia will mediate the effect of DTS on both HU and IU of technologies. Specifically, (1) fear of inconvenience, (2) fear of personal failure, and (3) human-technology ambiguity will mediate the effect of DTS on both IU and HU of technologies among older adults.

The Moderation Effect of Gender

Social role theory posits that societally prescribed gender roles shape help-seeking tendencies and coping behaviors [59,60]. Across cultural contexts, masculinity norms emphasize competence, making help-seeking or admitting difficulty potentially threatening to a "competent man" identity; consequently, men are often more reluctant to seek assistance and report higher self-efficacy and lower anxiety than women [61]. Men's achievement- and task-oriented roles further heighten their focus on performance payoffs and instrumental attributes [59]. In contrast, women are frequently stereotyped as less competent in masculine-typed domains such as technology and with comparatively lower self-efficacy may place greater value on environmental and interpersonal support to reduce anxiety and maintain positive self-perceptions [62]. Supporting evidence further showed that men's technology adoption is more strongly driven by extrinsic motivation (perceived usefulness), whereas women are more responsive to perceived ease of use and internalized social norms [63,64].

XSL•FO
RenderX



On this basis, older adults, who were often socialized under more traditional gender norms, may differ in how they respond to DTS [22]. Because older men may view seeking help from others as a threat to their competence and treat support mainly as an instrumental fix, DTS may be more likely to reduce extrinsic, cost-related fears such as fear of inconvenience, but less likely to alleviate intrinsic, self-efficacy related fears such as fear of personal failure [65]. By contrast, older women may be more inclined to rely on social support when coping with difficult tasks; such support can reduce anxiety and bolster confidence as learners [66]. Thus, DTS may more effectively address women's fear of personal failure. Finally, because fear of human-machine ambiguity reflects not only the interaction experience but also relational beliefs in everyday activities, and because women tend to be more attuned to internal feelings and social norms, technical support may more strongly reduce this fear among older women than older men. In sum, we propose hypothesis 5 as mentioned below.

Hypothesis 5

Gender moderates the effect of DTS on technophobia. Specifically, (1) technical support will likely reduce the fear of inconvenience among older men (vs women). By contrast, (2) technical support will likely reduce the fear of personal failure, and (3) the fear of human-machine ambiguity among older women (vs men).

Figure 1 shows the overall conceptual model of this research.

Figure 1. Conceptual model.

Methods

Sample and Procedures

We recruited Chinese adults aged 55 years and older through online platforms and offline communities in Nanjing, China. Inclusion criteria were (1) age of ≥55 years, (2) sufficient cognitive ability to complete the questionnaire independently or with assistance, and (3) the ability to understand the questionnaire content. The target sample size was determined based on recruitment feasibility during the predefined data collection period. To further evaluate whether the achieved sample size was adequate for the proposed moderated mediation analyses, we conducted a sensitivity analysis using G*Power 3.1 (Franz Faul). Because the hypothesized involved first-stage moderation, the analysis focused on the incremental variance explained by the interaction term in a linear multiple regression model (fixed model, R^2 increase). Each first-stage regression included 3 predictors and 9 covariates, resulting in a total of 12 predictors. With the final sample of 212 participants, α=.05, and power=.80, the study was capable of detecting an incremental interaction effect of approximately f^2=.037 or larger. Thus, the achieved sample provided sufficient sensitivity to detect relatively small moderation effects in the proposed model.

A total of 230 questionnaires were collected between June and October 2024, thus yielding 212 valid responses for analysis after data screening. No missing data were present in the final dataset, as all items were set as mandatory in the online questionnaire, while trained volunteers assisted participants with questionnaire completion during offline data collection.

Ethical Considerations

This study was approved by the Research Ethics Committee of the School of Aging Services and Management, Nanjing University of Chinese Medicine (number 20240523) and was conducted in accordance with the Declaration of Helsinki. All participants provided written informed consent before participation. No personally identifiable information was collected, thereby protecting participant privacy and confidentiality. Participants received either RMB 7 (approximately US $1) or a small gift of equivalent value as compensation for their participation.

Variables and Measures

All measures were adapted from validated scales and translated via forward-backward translation to ensure linguistic and cultural validity for Chinese older adults. Full item wording, outer loadings, reliability and validity statistics for all constructs are reported in Table 1. DTS was assessed using 3 items with

XSL•FO
RenderX

5-point ordered category and 6-point Likert-type response formats; scores from the 6-point scale were linearly rescaled to a 5-point metric for comparability, with higher scores indicating greater DTS. Instrumental and hedonic technology use were each measured using 2 items based on the frequency of use over the past week, with responses recorded on 5-point scales and higher scores indicating more frequent use. Technophobia was measured using Sinkovics et al [19] 13-item scale with a 6-point Likert-type agreement scale. Reverse-coded items were recoded prior to analysis, with higher scores indicating greater technophobia. All constructs were modeled as latent variables in the subsequent analyses. Covariates included age, marital status, residence, education, economic status, functional status, subjective health, number of children, and social activity participation, with their coding and categories reported in Table 2. Gender was coded as 0 for men and 1 for women.

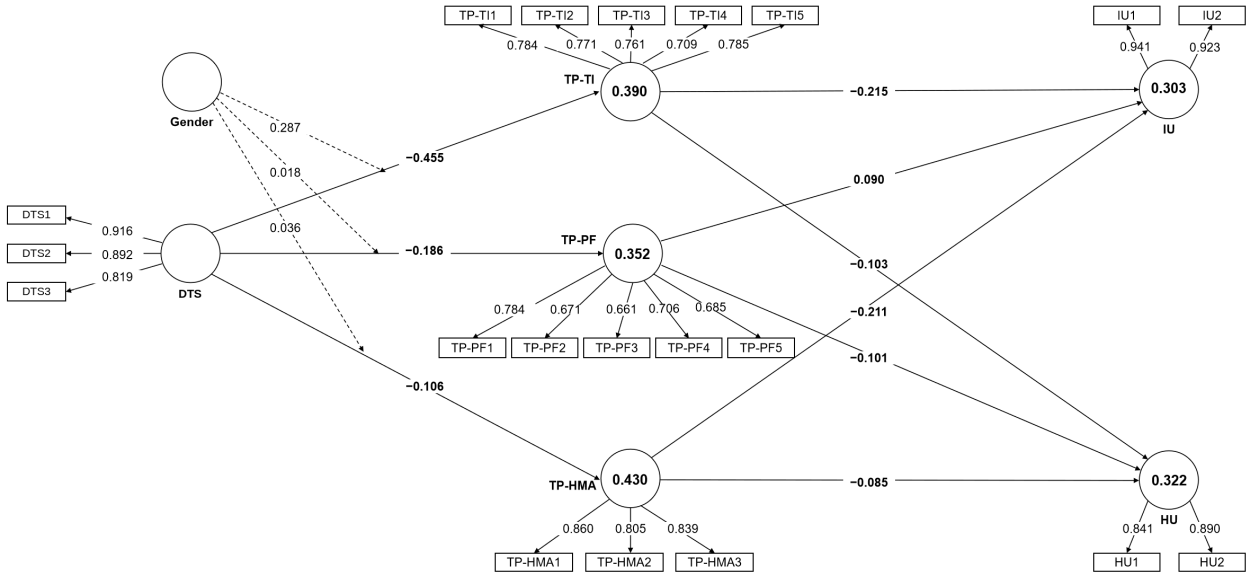
[a]Percentages do not sum to 100% because participants could select more than one device type.



Common Method Bias

Procedural and statistical controls were implemented to address potential common method bias that might arise from self-reported data. Procedurally, a pilot test with older adults improved item clarity and reduced bias. The questionnaire items were phrased in neutral language to avoid leading responses. Statistically, Harman single-factor test was performed via exploratory factor analysis with all measurement items. The results indicated that no single factor accounted for more than 50% of the total variance. Interconstruct correlation coefficients ranged from 0.154 to 0.814 with all values being below the 0.90 threshold [67]. Variance inflation factors (VIFs) for all constructs were between 1.054 and 3.261, which were below the critical value of 3.3 [68], thus eliminating severe multicollinearity.

Figure 2 illustrates the final partial least squares structural equation modeling (PLS-SEM) model with standardized path coefficients.

XSL•FO
RenderX

Figure 2. PLS-SEM results. Standardized path coefficients are shown on structural paths, and values inside endogenous constructs represent explained variance (R^2). Outer values represent indicator loadings. Dashed lines indicate moderation effects of gender. HU: hedonic use; IU: instrumental use; DTS: daily technical support; TP-HMA: technophobia-human-machine ambiguity; TP-PF: technophobia-personal failure; TP-TI: technophobia-technology inconvenience.

Data Analysis

PLS-SEM was conducted in SmartPLS version 4.1.1.4 (SmartPLS GmbH) to estimate the measurement and structural models examining how DTS and technophobia shape older adults' technology engagement. PLS-SEM is well suited to this study because it accommodates complex models with multiple latent constructs, is robust to nonnormal survey data, and performs well with relatively small samples. Therefore, model parameters were first obtained using the partial least squares (PLS) algorithm. Statistical inference for all hypothesized effects—including direct paths, the moderation and indirect (mediated) effects—was then performed via a nonparametric bootstrapping procedure with 5000 resamples. For the moderated mediation hypothesis, conditional indirect effects were computed at different levels of the moderator, and their significance was evaluated using 95% bias-corrected and accelerated (BCa) bootstrap CIs. Effects were considered significant when the corresponding 95% CI did not include zero. This approach is consistent with recent applications of moderated-mediation designs examining sex or gender-differentiated pathways in health-related outcomes [69,70].

Results

Participants' Demographic Profile

Participants' demographic characteristics are reported in Table 2. The sample (N=212) had a mean age of 66.96 (SD 6.96; range 55 - 86) years and was predominantly women (142/212, 68.4%). Most respondents lived in urban areas (203/212, 95.8%) and were married or cohabiting (192/212, 92.9%). In addition, 68.9% (146/212) reported having volunteer service experience, indicating active social participation among the sample. Regarding family structure, most reported having 1 or 2 children. Overall health was generally moderate, with over 40% (95/212) reporting no or minimal limitations in daily activities and most rating their health as fair or good. Educational attainment was relatively low, with nearly 60% (126/212) reporting fewer than 12 years of schooling and about one-fifth having completed higher education. The digital devices used by participants varied, with smartphones being the most commonly owned device (187/212, 88.2%), followed by smart televisions (48/212, 22.6%) and smartwatches or wearable devices (26/212, 12.3%). Regarding DTS, participants reported support from both same-age peers and younger adults, with 25.9% (55/212) reporting more than 10 same-age technical supporters and 26.4% (56/212) reporting more than 10 younger-adult technical supporters; only 12.7% (27/212) and 14.6% (31/212), respectively, reported having no such supporters.

Measurement Model Analysis

Table 1 reports factor loadings, reliability, and convergent validity. Most outer loadings exceeded the recommended threshold of 0.708, ranging from 0.661 to 0.916, indicating adequate indicator reliability [71]. Convergent validity was supported, with Cronbach α ranging from 0.668 to 0.929, composite reliability (CR) from 0.832 to 0.946, and average variance extracted (AVE) from 0.508 to 0.779; all CR values exceeded 0.70 and AVE values exceeded 0.50 [72]. Discriminant validity was established using the Fornell–Larcker criterion and Heterotrait-Monotrait ratio (HTMT). As shown in Table 3, the square roots of AVE exceeded interconstruct correlations, and all HTMT ratios were below 0.90 [67].

Structural Model Analysis

Structural Model Evaluation

Before hypothesis testing, the structural model was assessed for collinearity, explanatory power, and predictive relevance (Table 4). Inner VIFs ranged from 1.009 to 3.404, indicating no serious multicollinearity concerns. The model explained 16.5% of variance in technophobia-technology inconvenience (TP-TI), 11.6% in technophobia-personal failure (TP-PF), and 10.6% in technophobia-human-machine ambiguity (TP-HMA), indicating modest levels of explained variance, and 27% of the variance in IU and 29.5% in HU, reflecting moderate explanatory power [71]. Effect size (f^2) results showed that technical support had its largest impact on TP-TI (f^2=0.126, small-to-moderate), with small effects on TP-PF (f^2=0.034) and TP-HMA (f^2=0.036), while effect sizes for instrumental and HU were negligible (all f^2<0.03). All Q^2 values were above zero, indicating adequate predictive relevance.

XSL•FO
RenderX

Table . Structural model evaluation[a].

Endogenous construct	R^2	f^2	Inner VIF[b] range	Q^2
TP-TI[c]	0.165	DTS[d] (0.126)	1.009 - 2.956	0.092
TP-PF[e]	0.116	DTS (0.034)	1.009 - 2.956	0.073
TP-HMA[f]	0.106	DTS (0.036)	1.009 - 2.956	0.067
IU[g]	0.270	TI[h] (0.029)	1.082 - 3.404	0.141
HU[i]	0.295	TI (0.007)	1.082 - 3.404	0.162

[a] VIF <5 (with most values <3.3) indicates no multicollinearity; f^2=0.02, 0.15, and 0.35 denote small, medium, and large effect sizes; Q^2>0 indicates predictive relevance.

[b]VIF: variance inflation factors.

[c]TP-TI: technophobia-technology inconvenience.

[d]DTS: daily technical support.

[e]TP-PF: technophobia-personal failure.

[f]TP-HMA: technophobia-human-machine ambiguity.

[g]IU: instrumental use.

[h]TI: technology inconvenience.

[i]HU: hedonic use.

Path Analysis

To further test the hypothesis, path analysis was conducted. As shown in Table 5, the effects of each dimension of technophobia on technology use (H1) showed that TP-TI significantly reduced IU (β=−0.215, 95% BCa CI −0.410 to - 0.009; *P*=.045), while TP-HMA also negatively predicted IU (β=−0.211, 95% BCa CI −0.389 to 0.001; *P*=.04). By contrast, TP-PF did not significantly predict either IU or HU, as the corresponding 95% BCa CI included zero. Human-machine ambiguity was also significantly negatively associated with IU (β=−0.211, 95% BCa CI −0.389 to −0.001; *P*=.04). Next, DTS was found to exert a significantly positive direct effect on IU (β=0.104, 95% BCa CI 0.009 to 0.203*; P*=.04), but its direct path to HU was not significant, with the 95% BCa CIs including zero, which partially supports H2. In addition, results showed that DTS negatively predicted the dimension of perceived TP-TI (β=−0.455, 95% BCa CI −0.632 to −0.229; *P*<.001), while the effects of DTS on TP-PF and on TP-HMA were not significant, as both CIs crossed zero. Hence, only H3a is supported.

XSL•FO
RenderX

Table . Hypothesis testing[a].

Hypotheses and paths	β[b] (95% BCa[c] CI)	*t* test[d]	*P* values	Supported
H1a				
TP-TI[e] → IU[f]	−0.215 (−0.410 to −0.009)	2.01	.05	Yes
H1b				
TP-PF[g] → HU[h]	−0.101 (−0.351 to 0.132)	0.82	.41	No
H1c				
TP-HMA[i] → HU	−0.085 (−0.273 to 0.145)	0.80	.43	No
TP-HMA → IU	−0.211 (−0.389 to −0.001)	2.10	.04	Yes
H2				
DTS[j] → IU	0.104 (0.009 to 0.203)	2.06	.04	Yes
DTS → HU	0.075 (−0.018 to 0.166)	1.58	.11	No
H3a				
DTS → TP-TI	−0.455 (−0.632 to −0.229)	5.47	.00	Yes
H3b				
DTS → TP-PF	−0.186 (−0.400 to 0.073)	1.57	.12	No
H3c				
DTS → TP-HMA	−0.106 (−0.286 to 0.075)	1.14	.26	No
H5a				
DTS × Gender→TP-TI	0.287 (0.052 to 0.518)	2.40	.02	Yes
H5b				
DTS × Gender→TP-PF	0.018 (−0.274 to 0.268)	0.13	.90	No
H5c				
DTS × Gender→TP-HMA	0.036 (−0.198 to 0.255)	0.32	.75	No

[a]CI values not including zero indicate statistical significance.

[b]β: standardized path coefficient.

[c]BCa: Bias-corrected and accelerated CI.

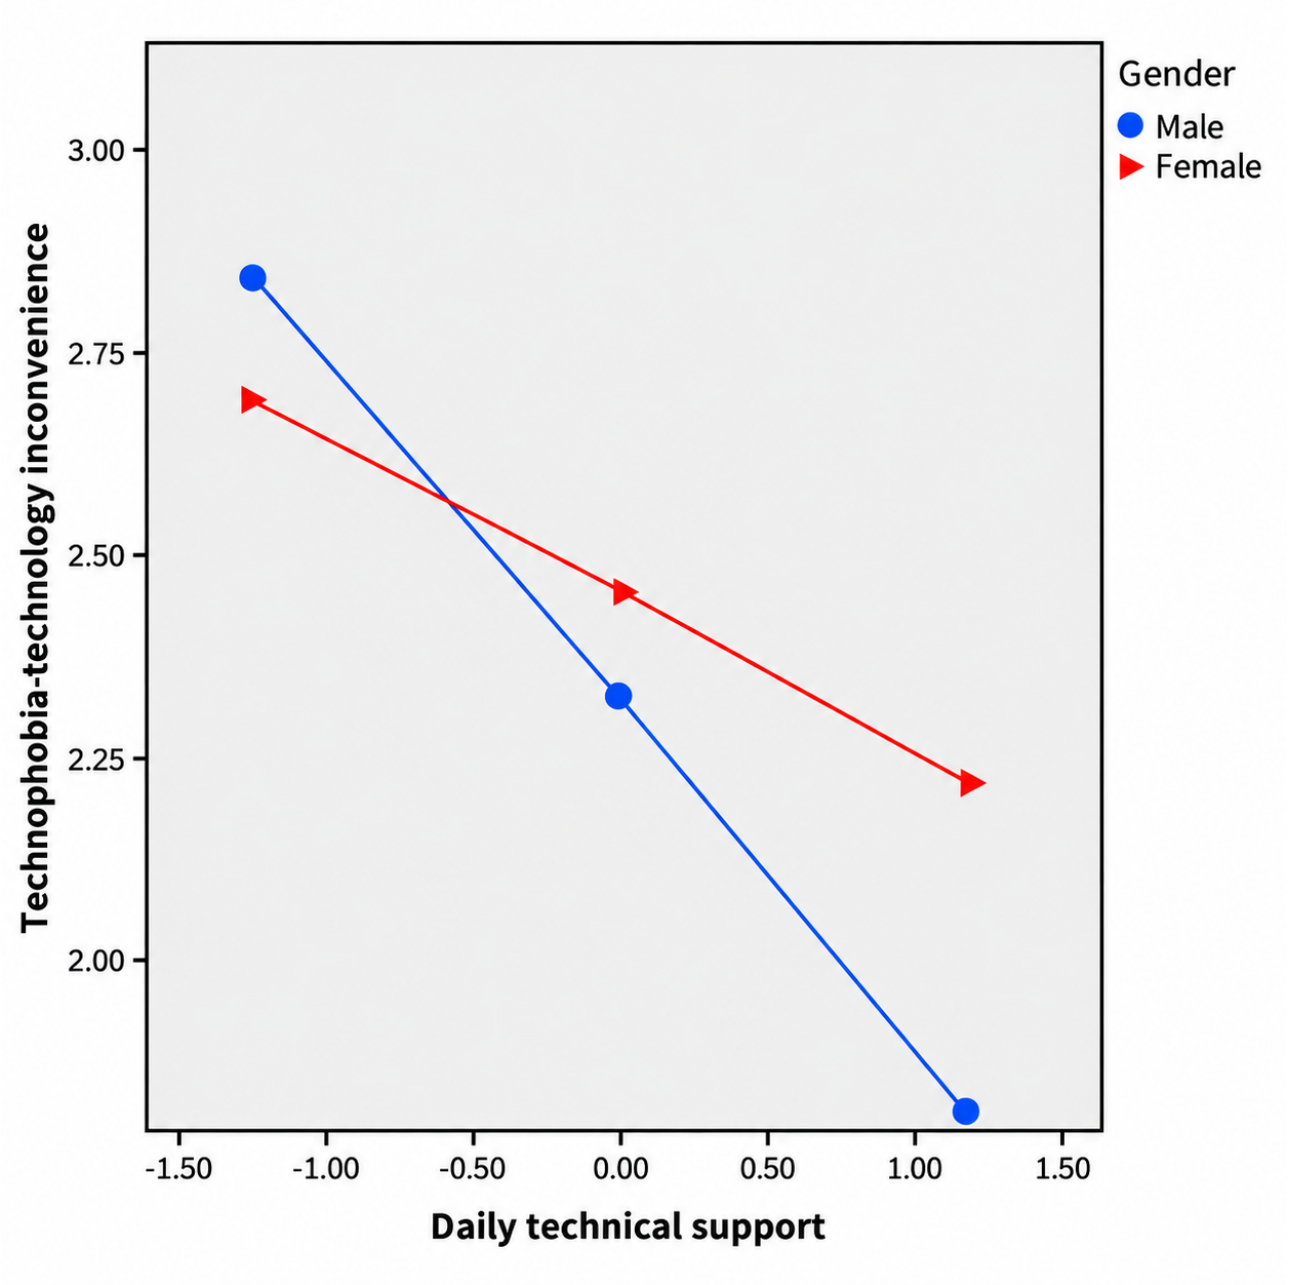
[d]*t* values were derived from PLS-SEM bootstrapping (5000 resamples); df is not applicable.

[e]TP-TI: technophobia-technology inconvenience.

[f]IU: instrumental use.

[g]TP-PF: technophobia-personal failure.

[h]HU: hedonic use.



[i]TP-HMA: technophobia-human-machine ambiguity.

[j]DTS: daily technical support.

Lastly, the interaction effect between DTS and gender was significant only for TP-TI (β=0.287, 95% BCa CI 0.052-0.518; *P*=.02), but not for TP-PF or TP-HMA, as the corresponding CIs included zero. We further conducted the simple slope analysis. Figure 3 presents that fear of inconvenience declined with increasing DTS for both genders. However, the decline was substantially steeper among males, indicating that daily support more effectively reduced perceived inconvenience for men (β=−0.455; *P*<.001) than for women (β=−0.168; *P*=.07). H5a is therefore supported.

XSL•FO
RenderX

Figure 3. Simple slopes analysis.

Additional moderation analyses were conducted to examine whether gender moderated the overall associations between DTS and the 2 forms of technology use. Neither the interaction predicting IU (β=0.116, SE .115, *t*=1.014, 95% BCa CI −0.107 to 0.334; *P*=.31) nor that predicting HU (β=0.165, SE .114, *t*=1.444, 95% BCa CI −0.056 to 0.391; *P*=.15) was significant.

Moderated Mediation Effect Analysis

Furthermore, bootstrap analysis (5000 resamples, bias-corrected) was conducted to examine the moderated mediating effects of technophobia in the interaction effect between DTS and gender on 2 types of technology use (H4, H5). Gender was coded as 0=men (reference category) and 1=women (comparison category). The results indicated that only TP-TI significantly mediated the effect of DTS on IU (β=0.097, 95% BCa CI 0.020-0.204), thus suggesting that part of the positive influence of DTS on goal-oriented use operates through reducing perceptions of inconvenience. By contrast, the indirect effects through TP-PF (β=–0.017, 95% BCa CI –0.059 to 0.150) and TP-HMA (β=0.009, 95% BCa CI –0.046 to 0.146) were not supported, as the corresponding CIs included zero (Table 6). These findings indicate that among the 3 dimensions of technophobia, only TP-TI acts as a significant mediator that links DTS and instrumental technology use.

XSL•FO
RenderX

Table . Moderated mediation analysis[a].

Hypothesis	Group	β[b] (95% BCa CI[c])	Supported
Overall indirect effects			
H4a

[i]TP-PF: technophobia-personal failure.

[j]TP-HMA: technophobia-human-machine ambiguity.

Conditional indirect effect analysis showed that the indirect effect of DTS on IU through TP-TI was significant for men (β=0.098, 95% BCa CI 0.001-0.219) but not significant for women (β=0.036, 95% BCa CI −0.002 to 0.116). All other indirect effects were nonsignificant for both genders, as the corresponding 95% BCa CI included zero.

Discussion

Principal Findings

Using a cross-sectional survey of community-dwelling older adults and PLS-SEM for hypothesis testing, the current research found that DTS lowers the technology-inconvenience dimension of technophobia, and this reduction subsequently promotes

XSL•FO
RenderX

instrumental—though not hedonic—technology use, especially among older men. By contrast, DTS was not significantly related to the personal-failure or human-machine ambiguity dimensions, but higher human-machine ambiguity was indeed linked to lower IU. These results refine theory by specifying a dimension-specific and gendered mechanism, and offer practical guidance to bridge the digital divide.

Distinct Fear Sources Linked to Instrumental Technology Use

The first finding of this research is that not all fears under the umbrella of technophobia equally predict older adults' actual technology use. Older individuals' instrumental (vs hedonic) use of technology was significantly influenced by their fear of inconvenience and by human-machine ambiguity but not by their fear of personal failure. Our finding is consistent with other research that has shown that extrinsic motivations, especially technology usefulness, often outweigh intrinsic motivations in determining the usage of involuntary technologies [73,74]. On the other hand, the finding from the dimension of human-machine ambiguity aligns with Smrke et al [27] findings, that older adults who are uneasy about technology's role tend to stay away from new health technologies.

Fear of personal failure did not significantly predict either instrumental or hedonic technology use among older adults in our study. One possible explanation is that our survey captured a general, self-reported belief about technological competence rather than a contextually primed perception [75]. Research on age stereotypes suggests that the activation of negative self-stereotypes is often context dependent and more likely to occur when salient age-related cues are present [76]. As a result, older adults may not explicitly endorse negative self-evaluations in a generic survey setting, which could attenuate observed associations with actual technology use.

The Role of DTS Among Older Adults

The key finding is that the effect of DTS on technophobia varies by dimension and gender. Daily support significantly reduced fear of inconvenience but did not significantly change fear of personal failure or human-machine ambiguity. These latter 2 dimensions are more closely related to internal psychological concerns than to the instrumental difficulties captured by fear of inconvenience. Previous research has indicated that fear of personal failure is often rooted in internalized age stereotypes about older adults' technological incompetence [6] and typically requires the development of self-efficacy through structured learning [77]. The nonsignificant association observed in the current study differs from findings reported in some intervention studies [53,54]. One possible explanation is that older adults may respond differently to different forms of technical support [53,54]. Informal, immediate help may function primarily as instrumental problem-solving, whereas structured programs may be more capable of changing underlying confidence and motivation [74,78]. Similarly, human-machine ambiguity reflects broader attitudinal or ideological concerns about technology and its potential to replace or reduce human interaction [42]. Because TS typically targets immediate operational issues rather than these deeper beliefs, its lack of a significant association with human-machine ambiguity is understandable.

More importantly, this research uncovered that the effect of DTS on reducing the fear of inconvenience is more salient among older men than among older women. Our research resonates with existing findings, that men are more likely to address the instrumental aspect of social support than women, thus the extrinsic motivation-related fear is affected [59]. However, our research did not yield significant gender differences in the effect of technical support on fear of personal failure [63,64]. This outcome may also support the point proposed above that older adults generally seek technical support primarily to solve problems (ie, extrinsic motivation) rather than to obtain internal psychological relief (ie, intrinsic motivation). Notably, additional analyses provided no evidence that gender moderated the overall associations between DTS and either instrumental or hedonic technology use. This pattern suggests that gender may function more specifically as a boundary condition of older adults' psychological responses to technical support rather than as a general moderator of its behavioral association with technology use.

On the other hand, DTS has a significantly positive effect on older adults' IU of technology but no significant effect on HU. This finding is consistent with prior observations that many older adults view technology, such as mobile apps, primarily as a tool for social engagement rather than a source of entertainment [79]. Therefore, DTS, by increasing technology accessibility and decreasing frustration, demonstrates the concrete utility of technology in everyday tasks [12]. Meanwhile, many older people have well-established leisure routines outside of digital technology; even with daily assistance available, they may not be motivated to explore new entertainment technologies [79].

Moderated Mediating Effect of Fear of Inconvenience

The gender-specific finding demonstrated that DTS boosts instrumental technology use by reducing fear of inconvenience to a greater extent among older men than among older women. This result is in line with the established TAM; that is, technical support serves as an external environmental factor that affects one's perception toward technology per se, which is further a key driver of technology adoption [34]. It bridges 3 dimensions of technophobia and 2 classic focal predictors of technology use (ie, technology usefulness and ease of use), as well as incorporates gender as a moderator. As such, it generalizes TAM into older adults and enables a nuanced understanding of how the social environment can influence older men and women's technology adoption behavior differently.

Implication and Limitation

Our findings suggest a shift in how interventions to promote technology use among older adults are designed. Older adults are often stereotyped as technophobic and lacking confidence in their ability to use technology, and interventions have therefore tended to emphasize intrinsic empowerment (skills training and confidence building). Our findings indicate that more instrumental forms of support may also be important, particularly for technologies that have become difficult to avoid

XSL•FO
RenderX

in everyday life. By reducing the inconvenience, effort, and practical burden associated with technology use, DTS may help older adults recognize the functional value of technology and facilitate IU. Accordingly, interventions could place greater emphasis on readily accessible, task-oriented assistance, such as just-in-time support, simplified workflows, default configurations, and age-friendly interface design with larger fonts and icons, simplified navigation, and fewer steps required to complete common tasks [80].

The stronger indirect association observed among men further suggests that older adults may not benefit from the same form of technical support to the same extent. Rather than treating gender itself as the basis for intervention, this finding highlights the importance of identifying the specific barriers that users experience and tailoring support accordingly. For individuals whose technology use is particularly constrained by perceived inconvenience, immediate and task-focused assistance may be especially effective, whereas those whose difficulties stem from other sources of technophobia may require different forms of support, such as structured learning, confidence-building, or greater reassurance about human-technology interaction. Gender may therefore serve as 1 contextual indicator of heterogeneity in how technical support is experienced, but intervention decisions should ultimately be guided by users' specific needs and sources of technological fear [22]. Such a barrier-specific approach may provide a more precise and sustainable way to promote technology engagement among older adults.

Despite these findings, our research is not without limitations. First, the survey sample was small and skewed toward urban older adults, thus limiting the generalizability of our findings to diverse socioeconomic and rural populations. As the sample was drawn from one country, the magnitude and relative salience of these associations may also vary across cultural and social settings. Second, the cross-sectional design precludes strong causal inference about the proposed relationship between variables. Third, measures relied on self-reports, which are susceptible to recall and social desirability biases. For instance, older men may underreport technophobia because of gendered norms about technological competence. Future research should use larger and more diverse samples, including cross-cultural comparisons, and longitudinal designs. Complementing surveys with objective behavioral indicators, such as smartphone or app usage logs and passively sensed interaction traces, could also provide fine-grained evidence on how daily support translates into reduced technophobia and sustained technology use. Future studies could further examine how emerging forms of online and real-time technical support can translate these findings into practice. As older adults increasingly engage with digital technologies as everyday users, platforms could potentially use user profiles and interaction data to provide more timely and tailored support, including gender-sensitive prompts or assistance. Finally, we failed to find a significant predictor of older adults' HU of technology; future research can focus on this specific technology domain.

Conclusion

This study examined how DTS relates to older adults' instrumental and hedonic technology use, with fear-specific technophobia as a mediating mechanism and gender as a moderator. TA was associated with lower fear of inconvenience, which in turn was associated with greater instrumental technology use, and this indirect effect was stronger among men than women. No comparable pathway was found for HU. Theoretically, these findings advance a more differentiated understanding of technophobia by highlighting the importance of examining specific sources of technological fear rather than treating technophobia as a unitary barrier. The absence of a comparable pathway for HU further suggests that different forms of technology use may be shaped by distinct psychological mechanisms and therefore warrant more use-specific investigation. Practically, the findings underscore the value of moving beyond one-size-fits-all approaches to digital inclusion by matching support strategies to the particular barriers older adults experience. Efforts to reduce technophobia should therefore complement generic skills training with targeted assistance that addresses specific sources of fear, practical barriers that can be alleviated through daily support, and differences in how older adults psychologically respond to such support. Such a more targeted approach may help improve the effectiveness of interventions designed to promote sustained and meaningful technology engagement in later life.

Abstract

Background: Health care systems increasingly offer services to citizens through online portals, which have been found to be associated with patient satisfaction and better management of health concerns. Few studies have compared self-reported use with objectively documented portal use, especially among older adults.

Objective: This study aimed to examine differences between documented and self-reported health portal use, and their associations with background variables and digital health literacy (DHL) among older adults.

Methods: A cross-sectional telephone survey was conducted among 600 participants aged 60 years and older, who were sampled from a registry of members of a national health maintenance organization (HMO). The participants reported their use of the HMO's portal, their DHL, and demographic and background variables. Participants' use of the portal was retrospectively retrieved from the HMO's administrative database.

Results: A large gap between self-reported use and documented use of the health portal was found: for example, while only 8.1% (46/566) reported not using the portal, the HMO's records indicated that 62% (372/600) did not make use of the portal. However, a positive correlation was found between self-reported use and documented use (r=0.22; P<.001). Significant positive associations were found between administrative and physician-related online services, both reported use (r=0.41; P<.001) and documented use (r=0.56; P<.001). A multivariate analysis, where documented use was the dependent variable, explained 12.5% of the variance. Experience with computers (β=0.13; P=.02) and ethnicity (β=−0.22; P<.001) were significantly associated with documented use. DHL, though significantly associated with documented use at the bivariate level (r=0.09; P=.04), was not significantly associated with documented use in this analysis (β=0.02; P=.97).

Conclusions: The findings indicate that users tend to overestimate their health portal use. Interpretations vary from measurement issues, such as social desirability bias regarding digital functioning or the perception that assisted use also constitutes usage, to signaling their identity as engaged digital health consumers. Future studies on digital health use should also include measures of electronically documented use and not only self-reported use.

KEYWORDS

digital health literacy; ethnicity; portal use; online portal; older adults

Introduction

Digital transformation in health care, and its potential for improving patient outcomes, operational efficiency, and care quality, is fundamentally contingent on users' active engagement and their digital competencies. Consistent evidence demonstrates that the success of digital health technologies critically depends on users' willingness to participate in and effectively use these systems [1,2]. Individuals need sufficient digital health literacy (DHL) to access, understand, appraise, and apply health information from electronic sources to realize the benefits of digital health solutions [3]. The evidence indicates that without adequate user engagement and digital skill development, digital health technologies often produce limited clinical impact [4].

XSL•FO
RenderX

A patient health portal is a digital health application, defined as a secure, web-based platform through which patients can access and manage their personal health services, including, for example, communication with health care providers (telehealth), medical records, laboratory results, appointment scheduling, prescription requests, and referrals. The Danish national health portal, sundhed.dk, exemplifies the use of these platforms for understanding laboratory results and treatment plans, with the authors reporting on actual patient use [5]. Systematic reviews from recent years on the use of health portals and their outcomes [6-8] surveyed the different metrics, reported on positive associations with health processes (monitoring, interactions with health care providers, and health behaviors), and noted that patient portals are increasingly integral to health systems, offering functionalities that support patient engagement. Still, the quality of evidence on the effects of service use (eg, health care workers' workload, emergency department use, and hospitalization) and clinical outcomes was rated as low to moderate.

When discussing patient portal use, it is important to distinguish between self-reported use and documented use, and the current study focuses on the gap between the two. Reported use refers to data gathered directly from patients through surveys, interviews, or questionnaires, where they self-report their portal activities, perceptions, attitudes, or intentions [9]. Numerous studies have focused on reported use of portals in conjunction with self-reported eHealth literacy [10,11]. Documented use, on the other hand, refers to objective data tracked directly from patient portal systems, such as login frequency, session duration, specific functionalities accessed (eg, viewing test results and sending messages), digital health outcomes (health behaviors and clinical outcomes), and health care use patterns (interactions with health care providers) [12].

Few studies have reported on both documented and reported use. For example, Woods et al [10] examined patient factors associated with documented use among patients (n=270) who registered with a portal and self-identified as users and reported the percentage of documented users among those reporting use. It should be noted that studies in a related field of DHL, which assessed both reported and actual literacy levels, found a low to medium association between the two [11-13]. A comparison of self-reported use to documented use may serve as a form of validation of self-reported use. The question is, to what degree does self-reported use of portal services represent actual or documented use, as measured by computerized measures of use?

A related research effort that focused on the factors associated with adoption and engagement by patients with their portals categorized these factors into demographic (age, gender, and race/ethnicity), socioeconomic (education, income, insurance, and geography), health-related (chronic conditions/health status and patient activation), and technology-related characteristics (health literacy, digital access/skills, and DHL). There is considerable heterogeneity in the findings, and a systematic review [7], which analyzed 32 studies on this subject, identified only women's gender and age (older, though depending on the population studied) as consistently associated with portal use. Another umbrella review [6] did not find strong evidence of an association between patients' characteristics and portal use, and assessed the quality of the evidence (regarding private insurance, higher illness burden, race [White], age, and income) as moderate.

Studies that examined both self-reported and documented use of health portals are scarce and are often based on small samples, presenting a research gap. The objective of the present study was to address this gap by examining both types of use in a medium-sized sample, assessing the association between the two, and examining patient characteristics associated with documented and self-reported use. We focused on the population of older adults (aged >60 years), who represent a growing demographic that often faces challenges in managing complex and multiple chronic conditions, leading to a high demand for health care services. Due to their increased health care needs and frequent interactions with the health care system, they are also considered among the populations that may benefit significantly from patient portals for improved access to care, self-management, communication, and health information [14]. In addition to demographic and socioeconomic characteristics, we also included the often-studied skill of DHL, which has been found to be associated with engagement and use [15].

We hypothesized the following:

- H1: Reported use of the health portal will be higher than documented use, and the two use measures will be positively associated with each other to a weak-to-medium degree.
- H2: Patient characteristics will be associated with both reported and documented use. Based on the cited reviews, we hypothesize that, in the restricted age group of those older than 60 years, age will be negatively associated with use measures, while women will have higher documented and reported use than men.
- H3: DHL will be positively associated with both reported and documented use.

In addition, we explored the following research question (RQ): Are there associations between portal-documented use and socioeconomic status, self-rated health, and prior use of the internet and computers?

Methods

Sample

The eligibility criteria for the study included being a member of "Clalit" Health Services (CHS) in Israel, being aged 60 years or older, and being fluent in Hebrew, Arabic, or Russian.

CHS is Israel's largest health maintenance organization (HMO), serving more than half of the country's population. It is a nonprofit organization, sanctioned by Israel's National Health Insurance Law of 1994, operating a comprehensive network of community and hospital services throughout the country, and, over the past several decades, has maintained electronic health records that support clinical care, quality improvement, and both clinical and population-based research [16,17]. CHS has a digital portal that includes a large, diverse range of services and can be accessed from any type of digital device (mobile

XSL•FO
RenderX

phone, personal computer, laptop, or tablet). Access to the portal—for both patients and health care providers—is availed by using the patient's personal identification number.

A random list of potential participants (names and phone contact details) was generated by CHS, assigned a serial number, anonymized, and securely transferred to a survey company. The target number of 600 (actually, N=601) was reached after phone contact was initiated with 5688 individuals. The overall response rate was 20.4%, with a sampling error of 2.04%, discounting phone numbers with no response after at least 3 attempts. The phone interviews were conducted in Hebrew, Arabic, or Russian, according to the preference of the interviewee. There was no requirement for prior experience using the portal, as all CHS members are entitled to access the digital resources.

Design and Procedure

The telephone survey's design was cross-sectional, while the data on documented portal use were retrospective for the year 2024. The outcome (dependent) variables were the documented and reported use of the health portal. The independent variables were demographics, DHL, and use of digital resources and devices. The survey was conducted from June to September 2024. Following the telephone survey, information on the documented use of the CHS portal was extracted from the national CHS information system on "no-queue" services, matched to each individual who responded to the survey, and anonymized for analysis.

Measures

Documented Portal Use

CHS collects information on the use of its website/mobile application through which digital health services are provided. Service use is recorded upon completion of each service transaction. Portal use pertains to information regarding the types of services. We grouped services (with equal weights) into medical/health, administrative, and overall services. The medical/health services include medical authorizations/certificates (eg, sick leave) and clinical summaries; results of tests/procedures and referrals; and requests for prescriptions (eg, refills of routinely taken medications). The administrative services include consultations with clinic administrators/service staff, authorizations for funding of medical procedures implemented outside the CHS system, and payment refunds.

Reported Portal Use

Respondents were asked about the level of use of the above-mentioned services on the CHS portal during the past 6 months (Multimedia Appendix 1). The list of services was read out to the respondents, who estimated the number of times they accessed the portal. The 6-month time frame was chosen as this is a time frame widely used in health care use, found to produce more accurate reporting (than 12 mo) and lower the chances of recall bias [18]. Responses were recorded on a 5-point scale (not at all, less than once in this time period, 1‐2 times, 4‐6 times, and more than once in a given month). We included the response option "less than once in this time period" to convey the possibility that respondents have used the activity sometime in the past, but not in the time period asked about, as distinct from "not at all." Three indices of reported portal use were constructed by averaging across service items: reported medical/health-related use (Cronbach internal reliability was α=0.71), reported administrative use (Cronbach internal reliability was α=0.59), and overall reported use.

DHL

DHL was measured using the HLS_{19}-DIGI instrument [19] of the World Health Organization Action Network on Measuring Population and Organizational Health Literacy, which comprises 8 items assessing the difficulty or ease of the following skills: accessing, understanding, appraising, and applying online health information. The internal reliability (Cronbach α) was 0.89 in the current study.

As a correlate of DHL, an additional module (HLS_{19}-DIGI-DD), comprising 6 items, assessed the frequency of using digital health resources. Participants reported the frequency (ranging from 1="Not relevant or less than once per week" to 5="More than once per day") of using the following resources: websites, social media, digital devices, mobile health apps, digital communication with health services, and "other digital resources."

Demographic Characteristics

Participants provided information on gender, age, country of birth, ethnicity/religion (Jewish, Muslim, Christian, Druze, and other; grouped such that Muslims, Christians, and Druze were classified as Arab, and Jews and others were classified as Jewish), religiosity, education (grouped into less than high school, completed high school, and completed more than high school), perceived social status (the MacArthur Scale [20]), difficulty covering the cost of medications, employment status, marital status, household size, and self-rated health [21].

Ethical Considerations

This study was approved by the institutional ethics review boards of both the University of Haifa (#298/25) and CHS (#0101‐23-COM2). All respondents expressed explicit consent before their participation, and their consent was orally recorded; they were notified that any publication of the study would contain no identifying information. All data were anonymized for data analysis purposes. No compensation was offered or given to participants.

Statistical Analysis

Participants' characteristics and the study's primary measures (reported and documented portal use) were calculated for descriptive analysis. Categorical variables were analyzed using frequency and percentage distributions, while continuous variables were examined using means and SDs.

Indices of reported and documented use were computed by averaging the medical/health and administrative items. Bivariate associations between reported use and documented use of the health portal were computed, as well as the associations of these with explanatory (independent) variables (demographics and DHL). Bivariate associations were also computed between all

XSL•FO
RenderX

subindices (medical/health, administration, and overall) of reported and documented use.

For comparison between reported and documented use of services, both indices were aligned to qualitative ranges: none, low, and high. In the case of documented use, the transformation was none to none, ≥1 and ≤2 to low, and >2 to high. In reported use, the transformation was none to none, "less than once in this time period" and "1 to 2 times" to low, and "4 to 6 times" and "more than once in a given month" to high.

Lastly, we conducted linear hierarchical regressions to assess the association between documented and reported use and explanatory variables. Only variables that were significant in the bivariate analysis with either documented or reported use were entered. As years of computer use and using computers at work were highly correlated (r=0.50; P<.001), only the former was entered. The variables entered in the first step included the following: age, ethnicity, education, household size, self-rated health, and experience with computers. DHL was entered in the second step. We also reversed the order of the steps. Ethnicity was coded so that Jewish was 0 and Arab was 1. R^2 and coefficients were reported.

Results

Participant Characteristics

Of 600 study participants, 314 (52.3%) were women and 286 (47.7%) were men, with a mean age of 70.45 (SD 7.54) years, ranging in age from 60 to 80 years. Over half (n=351, 58.5%) were Jewish and were married or cohabiting (n=378, 63%). Over half (n=365, 61%) completed more than a high school education, ranked themselves in the upper half of the social ladder (6 and above on a 10-point McArthur scale: n=449, 74.8%), and a quarter of the sample (n=150, 25%) found paying for medications difficult or very difficult. Nearly a third (n=179, 29.8%) rated their health as very good and good, 41.5% (n=249) as average, and nearly one-third (n=172, 28.6%) as bad or not so good. Most people lived either with another person in their household (n=258, 44%), or lived in larger households (n=198, 33%) and the rest, about a quarter (n=144, 24%), lived alone. Lastly, 65% (n=114) of the sample reported regularly using/used computers in their work, with an average of 18.35 (SD 15.53) years of experience using computers, and 58.3% (n=349) endorsed being very good at surfing the internet (see Table 1 for more details).

Documented and Reported Portal Use

Documented and reported use are presented for each service (Multimedia Appendix 2) and for the averaged indices: medical/health, administrative, and overall.

The overall reported and documented indices were aligned for comparative purposes, so that both reported and documented use included 3 categories: none, low, and high. The frequency scale of the averaged documented use of the types of services on the portal (measured as the number of times, continuous) was transformed into categories: none, low (≥1 and ≤2), and high (>2). Categories on the scale of reported use were transformed into none, low (including "less than once in this time period" and "1 - 2 times"), and high (the 2 upper response options). The documented and reported use of the portal is presented in Table 2.

Table . Reported and documented use of the HMO portal[a].

Percentage of portal use by services	Reported[a], n (%)	Documented, n (%)
None	46 (8.1)	372 (62.0)
Low	123 (21.7)	223 (37.2)
High	397 (70.1)	5 (0.8)

[a]There was missing data on the reported use for 34 respondents.

The data indicate that reported use is higher than documented use. The data from the HMO portal indicate that the majority of the participants (n=372, 62.0%) did not use the portal at all in the past year, whereas only 8.1% (n=46) reported not using it in the past 6 months. An opposite pattern was observed for use defined as low: documented use of the portal under this category was about a third (n=223, 37.2%), but only a fifth of participants reported using the portal at this use level (n=123, 21.7%). Most participants reported using the portal at high levels (n=397, 70.1%), whereas documented high use was reported for only a few participants (n=5, 0.8%). The data on specific types of services used (Multimedia Appendix 2) also consistently showed higher reported use than documented use.

The association between documented and reported use of the portal was positive and significant (r=0.22; P<.001), such that higher documented use was positively associated with higher reported use (significant associations are given in Table 3). This association was also found at the service-use level, both for medical/health-related services between documented and reported use (r=0.16; P<.001) and for administrative services between documented and reported use (r=0.19; P<.001), such that greater engagement in one activity was associated with greater use of the other activity. Table 3 also indicates a significant positive association between the 2 types of services in the portal, medical/health-related and administration-related, in both the reported (r=0.41; P<.001) and documented use (r=0.56; P<.001).

Bivariate Associations With Portal Use

The association between documented portal use and background variables is displayed in Table 1 in the third column (with significant associations/differences mentioned in Table 1). Pearson coefficients were computed for continuous variables, and a 2-tailed *t* test or ANOVA was used for categorical variables. Age (r=−0.08; P=.03), higher education (r=0.14; P<.001), and ethnicity (being Jewish, $F_{4,595}$=7.13; P<.001) were significantly associated with documented portal use, as well as household size (r=−0.08; P=.04) and using or having used computers at work ($F_{1,172}$=5.85; P=.02). Documented portal use was not significantly associated with gender, marital status, being able to cover the expense of medications, and self-rated health (all P values >.05).

A somewhat similar pattern emerged between reported portal use and background variables (last column in Table 1): higher education (r=0.12; P=.003), ethnicity (being Jewish, $F_{4,561}$=6.45; P<.001), and years of experience with computers (r=0.22; P<.001) were significantly associated with reported portal use; unlike documented use, self-rated health was associated with reported use, with participants reporting worse health reporting more portal use (r=−0.11; P=.01).

We also examined all portal use indices in relation to DHL (both the cognitive capacities and the use of digital devices; Table 3). Documented portal use indices (administrative and medical-related indices, and the overall index) were significantly associated with DHL, but not with the use of various digital devices (all P values >.05), except for the association between digital device use and medical-related services in the portal (r=0.11; P=.02).

Multivariate Associations Explaining Portal Use (Reported and Documented)

We regressed background and DHL variables on reported and documented portal use across services. We included only variables that were significantly associated with combined services—either reported or documented—at the bivariate level. Only one variable, “using or having used computers at work,” was excluded from the analysis due to high shared variance with the related question of “experience with computers” (r=0.50; P<.001). Table 4 presents the results of the 2 regressions.

XSL•FO
RenderX

Table . Hierarchical linear regression on documented and reported portal use.

Characteristics	*B*	SE(*B*)	β	*P* value
Outcome: documented portal use[a]				
Age	0	0	−0.09	.04
Ethnicity	−0.17	0.04	−0.22	<.001
Education	0.01	0.01	0.05	.37
Household size	0.01	0.01	0.05	.36
Self-rated health	0	0.02	0.01	.86
Experience with computers	0	0	0.13	.02
DHL[b]	0.01	0.01	0.02	.97
Outcome: reported portal use[c]				
Age	0	0	0.04	.43
Ethnicity	−0.1	0.1	−0.06	.32
Education	0	0.03	0.01	.83
Household size	0	0.02	−0.01	.79
Self-rated health	-0.12	0.04	-.15	<.001
Experience with computers	0.01	0	.23	<.001
DHL	0	0.002	.04	.46

[a]R^2 for the documented portal use outcome is 12.5%.

[b]DHL: digital health literacy.

[c]R^2 for the reported portal use outcome is 7.1%.

As shown in Table 3, the documented use of the portal was explained better (adjusted R^2=12.5%) than reported use (adjusted R^2=7.1%), with documented use significantly explained by the ethnicity of patients (with higher use among patients who identified as Jewish than among those who identified as Arab) and reported experience with computers (the more experience, the more use), while reported use was significantly explained by experience with computers and self-rated health, with education, ethnicity, and DHL not significantly associated with reported use. Notably, DHL, while significantly associated at the bivariate level, did not reach significance at the multivariate level in both analyses, possibly due to shared variance with other explanatory variables (eg, r=0.46; P<.001, r=0.49; P<.001, and r=0.31; P<.001, for education, experience with computers, and self-rated health, respectively).

Discussion

Principal Results

This study focused on portal use—documented and reported—among a relatively vulnerable, growing in numbers, and highly relevant population segment—older adults. The design of the study—relying on both sources of information—allowed the researchers to identify and quantify a significant gap between patients' perceptions of their activity and their documented behavior. The study found a significant discrepancy between patients' self-reported use of services on their health portal and the documented use of these services by the HMO, supporting H1 that reported use will be higher than documented use. While only 8.1% (n=46) of participants reported not using the portal at all, the retrospective analysis of the CHS database indicated that 62% (n=372) did not use the services on the portal at all. This substantial gap underscores a potential overestimation of use of services when relying solely on self-reported data, suggesting that both indicators should be used in studies recording and explaining portal use.

Despite this disparity, a positive correlation was found between self-reported use and documented use of the portal (r=0.22; P<.001). This positive association suggests that although not compatible, each measure represents a different aspect of use of services. When examining factors associated with portal use in multivariate analyses, the hypotheses on age and gender (H2: negative association with age and more use among women) were not supported (though the age component of H2 was supported in a bivariate analysis). Key predictors of documented portal use included ethnicity (higher use among participants who identified as Jewish than among those who identified as Arab) and reported experience with computers (more experience correlated with greater use, addressing the RQ). In contrast, reported use was significantly explained by self-rated health (increased use among participants reporting worse health) and by reported experience with computers. Additionally, the model for documented use demonstrated better explanatory power (adjusted R^2=12.5%) compared to reported use (adjusted R^2=7.1%). DHL was associated with most use indices in a

XSL•FO
RenderX

bivariate analysis, but was not significantly associated with either type of use in multivariate analyses, thus lending mixed support for H3. Lastly, both medical/health-related and administrative services within the portal were positively correlated in both reported (r=0.41; P<.001) and documented use (r=0.56; P<.001).

Comparison With Prior Work and Interpretation

The substantial gap observed between self-reported and documented portal use in this study is a major finding, echoing concerns highlighted in previous literature regarding the accuracy of self-reported use of digital health services. Studies have consistently shown that self-reported data can often reflect an overestimation of portal use. For instance, Beal et al [8] indicated that measurements of patient portal use in research often vary widely, with inconsistent definitions and a reliance on simplified metrics, such as "at least one login," which may not reflect meaningful engagement or use of services. Tavares and Oliveira [22] also noted that awareness and registration do not necessarily translate to frequent use, finding that only 30% of users regularly checked their electronic health records portal. The current study's finding of 62% (n=372) documented nonuse compared with 8.1% (n=46) reported nonuse attests to the limitations of self-report and the need to augment self-reports with objective, tracked data to better understand patient engagement. The disparity between perceived and recorded measures is analogous to the low concordance between self-reported and externally measured DHL/eHealth literacy [23] as well as between self-reported and documented health care use for periods exceeding a month [23]. Another relevant comparison is the assessment of stress, which overwhelmingly encompasses both self-reported stress and physiological measures. These two are also only moderately correlated and are considered to capture different, distinct aspects of the stress response, each considered valid [24]. Other examples are smoking or physical activity, assessed by both self-reports and objective measures (accelerometers and the presence of cotinine [a metabolite of nicotine], respectively).

As there was no incentive for high reported use, interpretations can vary, ranging from measurement explanations, cognitive-motivational explanations, and broader identity signaling or symbolic engagement explanations. Measurement explanations address the possibilities that participants perceived surrogate/assisted use (clinic staff or family members) as their own use; that respondents may have experienced recall bias or estimation bias, so that they genuinely believe they use the portal more frequently than they actually do; or that an acquiescence bias occurred, whereby some respondents tended to answer "yes" to an interviewer. Conversely, database records may be incomplete because of the definition of a completed transaction or errors in linking activity to individual participants. Therefore, electronic records should not necessarily be regarded as an error-free gold standard, and thus the gap could be interpreted as measurement disagreement, as neither self-report nor database documentation necessarily captures precisely the same construct.

A more social-psychological interpretation pertains to constructs such as self-efficacy and self-perception. Self-efficacy theory could suggest that individuals with high digital health self-efficacy may report portal use partly based on confidence, perceived competence, or familiarity, rather than documented frequency [25]. Relatedly, Bem's Self-Perception Theory proposes that people infer attitudes and identities from observations of themselves, constructing narratives about who they are. Specifically, respondents may infer that portal use is consistent with a self-image of caring about their health, being engaged with their health, and using modern technology. Under this interpretation, over-reporting is identity-consistent self-description [22]. The technology acceptance model could also explain the findings through the intention-behavior gap: respondents may have reported intended use, expected use, or favorable attitudes, instead of documented behavior. Valuing and intending to use the portal may have become using the portal [26]; respondents understood something other than what was intended.

The reported-documented use gap may be broadly interpreted through identity signaling theory or digital participation/symbolic technology use research. Identity signaling theory proposes that behaviors communicate desired identities to others and even to oneself [27]. Digital health technologies increasingly function as symbols of responsibility, proactivity, health consciousness, and technological competence. Thus, respondents may have reported portal use in a manner consistent with their identity as an engaged, responsible, and digitally connected person, even when objective use remains low. While identity signaling has not been studied in patient portals specifically, it was used to explain other digital health behaviors, such as health-app adoption and wearable use [28].

The perspective of digital participation views portal use as part of a broader digital inclusion and citizenship [29]. Under this perspective, the central question becomes: "Does an individual feel they participate in digital health care?" rather than "How many times have they logged in?" Hence, portal use may function as a marker of digital inclusion, and respondents who see themselves as digitally connected may report higher use because they either identify as digitally engaged, feel connected to modern health care, or find that portal membership itself becomes meaningful. Thus, reporting use reflects perceived participation in digital health care ecosystems rather than observed activity.

In conclusion, on the interpretations of the reported-documented use gap, rather than viewing self-reported portal use solely as a proxy for behavior, "use" may be more appropriately understood as a multidimensional construct that reflects both documented engagement and participants' self-perceptions, identity signaling, and symbolic affiliation with digital health care, thereby explaining why subjective reports and objective usage metrics do not necessarily converge.

The identified demographic disparities in documented portal use align with, and also nuance, existing research. The finding that older age was associated with less documented portal use in the bivariate analysis is largely consistent with numerous studies reporting that older adults generally trail the general population in adopting digital health technologies. However, some literature presents mixed findings on age, with Carini et

XSL•FO
RenderX

al [7] noting both increasing use with age and a lack of homogeneity in results, while Woods et al [10] found no significant differences in portal logins by age among already enrolled users. The current study, focusing on an older adult population (mean age 70.45 y), records the challenge faced by this demographic group in portal use.

Regarding ethnicity, our finding of higher documented use among Jewish participants compared with Arab participants supports the broader understanding that patient portal use is often lower among racial and ethnic minorities. Previous research suggests that White patients are generally more likely to use patient portals and that patients' race and ethnic backgrounds are associated with perceptions of need for, and access to, portal services [2,6,30]. However, it is also important to note that some national studies [10,31], after adjusting for other factors, have not identified significant associations between patients' race and ethnic backgrounds and patient portal access or use. The significant association between ethnicity and *documented* portal use observed in our multivariate model (as opposed to no significant association of ethnicity with *reported* use) may be due to different degrees of acquiescence bias in reporting among the groups [32,33] or to differences in actual use associated with reduced internet infrastructure and resources available in rural areas, inhabited more by Arabs.

The significant association of reported experience with computers for both self-reported and documented portal use is well-supported in prior studies, either reviews or empirical work. Limited digital literacy, computer skills, and internet access are frequently cited as significant barriers to patient portal adoption [7,10,13,14]. This consistency across studies on prior experience with computers underscores the fundamental importance of previously developed digital skills for effective portal engagement.

Our findings on DHL—association with reported and documented use only at the bivariate level and not in a multivariate analysis—align with the mixed results in the literature. For example, van der Vaart et al [13], who examined documented portal use, found it associated with eHealth literacy, as well as other works [34,35] which identified eHealth literacy as positively associated with *reported* portal use. However, Xie concluded in her review [36] that the evidence is inconclusive, as other studies point to no association [37,38]. Still, this result could stem from the shared variance with other related variables in the multivariate analysis.

The difference in explanatory power between models for documented vs reported use (R^2=12.3% vs R^2=5.3%) could reflect a measurement issue or a substantive difference. Measurement-wise, documented portal use is an objective measure with relatively low noise, whereas self-reported use is subjective and likely contains greater measurement error. These differences in measurement properties alone can influence R^2 values, independent of any true discrepancy. Alongside, this result may indicate that objective measures capture a different angle of user behavior and its drivers. It should be noted that studies using the technology acceptance model and its extensions [22,34] explained higher variance than that found in our study, though they addressed reported usage and not documented usage. Still, most variation in portal engagement remains unexplained.

Strengths and Limitations

This study demonstrates methodological strengths. A primary strength is its robust dual-data approach, which directly addresses a paucity in the literature by comparing both self-reported portal use and objective, documented use data retrieved directly from the HMO database. Furthermore, the study strategically focused on a vulnerable, growing, and highly relevant population segment—older adults—and used a medium-sized sample of 600 individuals aged 60 years and older. This demographic is critical to study because older adults often need to manage complex chronic conditions, have high health care needs, and stand to benefit significantly from portal functionalities, yet often face unique challenges with technology adoption. Finally, the study moves beyond basic demographics by incorporating specific digital variables, such as DHL and reported experience with computers, into its analysis.

Several limitations should be considered when interpreting these findings. First, the nonidentical temporal frames and scales used for documented (frequency during the year of 2024) and reported use (addressed past 6 months, ranging from "not at all" to "more than once a month") should be considered. The latter time frame (6 months) was intended to reduce recall bias, yet it may have made direct comparisons difficult and introduced measurement bias. However, we did not compare exact quantities but rather qualitative ranges, and when comparing reported and documented use we focused on the category of no use, which was identical in both measures. Relatedly, though the time frame was constructed to be shorter to facilitate the accuracy of reported use (6 months rather than a year), some degree of recall error or forgetfulness may be attributed to age-related memory challenges among people aged 60 years and older. Second, while the study directly addressed the gap between self-reported and documented use, it relied on self-reported data for some variables, such as computer experience and DHL. Additionally, some participants might have had clinic staff or family members use the portal on their behalf (surrogate/assisted use), which could influence their self-perception of "use" without actual personal operation. Notably, this interpretation of surrogate use would emphasize the gap between reported and documented use even more. Third, the cross-sectional design of the survey limits the ability to establish causality or observe changes in portal use patterns and their explanatory variables over time. Longitudinal studies are essential for understanding the evolution from initial awareness to sustained adoption of patient portals. Fourth, the study was conducted within a single HMO in Israel, which—though serving more than half the country's population—may limit the generalizability of findings to other health care systems or populations with different cultural, socioeconomic, or technological contexts. Fifth, the response rate of 20.4% may be considered relatively low. Though this response rate is not uncommon in a population sample with no paid incentive [39], it may have introduced selection bias, which in turn may have biased estimates. Furthermore, the study analyzed the population aged 60 years and older as one homogeneous sample with regard to age. Further studies could

XSL•FO
RenderX

contribute more in-depth analyses of stratified age groups among the older population.

Conclusions

This study reveals a substantial gap between patients' perceptions of their health portal use and their documented use, with self-reported use significantly higher than documented use. This highlights a critical challenge for health care systems and reinforces the necessity of also using objective metrics to comprehensively assess patient engagement. The identification of background variables associated with documented portal use underscores the persistent digital divide, which affects vulnerable populations, including older adults and certain ethnic minority groups.

Bridging this divide and enhancing patient engagement calls for integrating interventions in health care that are culturally sensitive, tailored to specific demographic needs and digital experience levels, including DHL. By addressing these factors, health care systems can move toward more equitable and effective patient portal use, ultimately leveraging these tools to improve health outcomes for all.

Acknowledgments

We would like to acknowledge the contribution of Talish Razi from "Clalit" Community Medical Branch for her support regarding the data used in the study.

The first author (EN) used Microsoft Copilot (Microsoft Corp) during manuscript preparation to improve grammar, clarity, and readability. All AI-generated suggestions were reviewed, edited, and verified by the author, who takes full responsibility for the final content of the manuscript.

Funding

The study was funded by a grant from the Israeli Ministry of Science and Technology for a joint bi-national study with Taiwan.

Data Availability

Due to Clalit Health Services' data privacy regulations and per the institutional Helsinki and data utilization committee approvals for this study, the data used for this study cannot be shared.

Authors' Contributions

EN, DL-Z, PWSC, TVD, and OB-E conceived and planned the study. EE coordinated data collection, supported by DL-Z. EN conducted the data analysis and wrote the first draft. All authors commented on the drafts.

Abstract

Background: Studies performed in urban communities with access to technology suggest high patient satisfaction with telehealth. While virtual visits can increase the reach of clinical practice in rural communities, technological barriers may reduce patient satisfaction.

Objective: This study aimed to compare satisfaction with telehealth visits between patients living in rural and urban communities.

Methods: A telephone survey was developed and administered to hepatology patients seen at outpatient clinics from March 2020 through March 2021. Patient characteristics and survey responses were compared by urban and rural location as defined by the census tract based on zip code using univariable and multivariable logistic regression.

Results: Of 400 patients, 164 (41%) completed the survey. Compared with urban patients, rural patients had twice the transportation time to clinic (mean 59, SD 35 vs mean 30, SD 15 min) and were more likely to cancel due to transportation issues (21/48, 46% vs 15/116, 13%). Rural patients reported less proficiency with technology and more technical difficulties, including an inability to log on to the portal or access the camera or microphone (35/48, 75% vs 29/116, 25%) and less comfort with their devices (26/48, 54% vs 10/116, 9%). Overall, urban patients were more likely to prefer telehealth (adjusted odds ratio 5.20, 95% CI 2.15 - 13.7) and were more satisfied with telehealth vs in-person visits than rural patients (72/116, 62.1% vs 10/48, 20.8%).

Conclusions: Rural patients reported more technical challenges with telehealth and more transportation issues than urban patients but favored in-person hepatology visits. Urban patients were more satisfied with telehealth visits compared with in-person visits. Research is needed to improve telehealth delivery and satisfaction for rural patients.

KEYWORDS

technology literacy; hepatology; patient experience; broadband; technological barriers

Introduction

Telehealth provides an alternative to in-person appointments, and the number of these visits soared during the COVID-19 pandemic [1]. Potential benefits of telehealth include eliminating the need for transportation and reducing the amount of time associated with office visits, which can increase patient convenience and reduce health care costs. Previous research showed high patient satisfaction with telehealth visits, but most of these studies were performed in urban communities [1-3]. Despite the benefits, patients may experience difficulties with these visits related to internet connectivity and technological demands [1,4]. These difficulties are noted to be increased in patients with low technology literacy. Between 55% and 85% of households have broadband internet access, with lower rates in rural communities [5,6]. Our hepatology practice covers a wide geography with clinics throughout the state of Illinois, including patients in both rural and urban communities. Given the disparity in access to broadband in rural areas, our objective was to examine patient satisfaction with telehealth between rural and urban communities.

Methods

Ethical Considerations

This study was reviewed and approved by the institutional review board at Loyola University Medical Center (IRB#LU 214739; approval date October 21, 2021). All participants were adults and provided verbal informed consent prior to participation in the telephone survey. Participants were informed of the voluntary nature of the study, that refusal to participate would not affect their medical care, and that they could withdraw at any time. No protected health information was collected beyond data necessary for study objectives. Survey responses were deidentified and securely stored to maintain confidentiality, in accordance with institutional and ethical guidelines.

Survey Development

A survey tool was developed to assess patient satisfaction with telehealth visits in addition to technology literacy and broadband internet access (Multimedia Appendix 1). Survey questions were identified from a literature search focusing on 4 main themes: demographic information, geographic information, telehealth literacy, and telehealth satisfaction. Telehealth literacy questions were developed to test similar concepts asked in prior validated questionnaires including the eHealth Literacy Scale [7] and the Mobile Device Proficiency Questionnaire [8]. Telehealth satisfaction questions were developed to test similar concepts asked in the Telehealth Usability Questionnaire and asked on a 5-point Likert scale [9].

Patients were approached for participation in this study if they had both a telehealth visit and an in-person appointment between March 2020 to March 2021, when our telehealth program was most active. We excluded patients who were liver transplant recipients and those with hepatocellular carcinoma, as their appointment criteria may require more frequent in-person visits with a multidisciplinary care team and therefore may bias the result. Patients were contacted by telephone by an investigator. Informed consent was obtained over the phone via a script. The survey was then read to these patients and responses were recorded in Research Electronic Data Capture (REDCap) software. For patients who were non–English speaking, a certified interpreter was used over the phone. Information on rural-urban commuting area code was calculated via the most recent US Department of Agriculture data by zip code for the 2010 census [10]. Demographic information was collected from the electronic medical record including age, gender, race, diagnosis, and zip code. Our primary outcome was patient satisfaction with the visit, measured on a 5-point Likert scale. Secondary outcomes included internet access, difficulties with telehealth use, device used, and preference for type of visit in the future.

Statistical Analysis

Descriptive variables were compared using Student *t* tests (2-tailed) for continuous variables and chi-square or Fisher exact tests for nominal variables by location (urban vs rural as defined by census tract) and visit preference (in person or telehealth). Univariable and multivariable analyses with logistic regression models were used to determine odds ratios (ORs) for patient characteristics associated with telehealth preference. Certain questions in the survey used the Likert scale to assess characteristics associated with satisfaction with telehealth which were analyzed with proportional odds logistic regression models. Analyses were performed using the R programming language (version 4.4.1; R Foundation for Statistical Computing).

Results

Of 400 patients who were contacted, 164 (41%) completed the survey. The mean age was 64 (SD 10) years, more than half were male participants (n=88, 53.7%), and three-quarters were non-Hispanic White (122/163, 74.8%). The most common causes of liver disease were alcohol (51/162, 31.5%), metabolic dysfunction–associated steatotic liver disease (49/162, 30.2%), and hepatitis C (36/162, 22.2%; Table 1).

Using univariate analysis, rural patients (n=48) compared with urban patients (n=116) had double the transportation time to the clinic (mean 59, SD 35 vs mean 30, SD 15 min; *P*<.001), were less likely to reliably attend appointments (36/48, 75% vs 110/116, 96%; *P*<.001), and were more likely to cancel visits due to transportation issues (21/48, 46% vs 15/116, 13%; *P*<.001; Table 2). Rural patients also reported more technical difficulties (35/48, 75% vs 29/116, 25%; *P*<.001), less comfort with their devices (26/48, 54% vs 10/116, 9%; *P*<.001), and less frequent computer use (14/48, 29% vs 78/116, 67%; *P*<.001). Despite these differences, similar proportions of rural and urban patients were willing to have telehealth visits in the future (38/48, 79% vs 100/116, 86%; *P*=.26).

[a]Data were available for 163 participants (overall).

[b]Data were available for 162 participants (overall).

[c]Data were available for 161 participants (overall).

Multivariate analysis showed that 54% (88/164) of all participants reported a preference for in-person visits and 46% (76/164) for virtual visits. Furthermore, 81% (39/48) of rural patients preferred in-person visits compared with only 42% (49/116) of urban patients (*P*<.001). More urban patients were satisfied with telehealth visits compared with rural patients (72/116, 62% vs 10/48, 20%; *P*<.001). Both rural and urban patients had predominantly Medicare insurance (20/32, 63% vs 67/129, 51%); however, the proportion of Medicaid patients was greater in the urban population (26/129, 20% vs 4/32, 13%).

XSL•FO
RenderX

Patients with Medicaid insurance preferred virtual visits to in-person visits (19/30, 63% vs 11/30, 37%, *P*=.03). Even with shorter travel times and fewer barriers to in-person visits, urban patients were more likely to prefer virtual visits compared with rural patients (OR 5.93, 95% CI 2.73 - 14.1) and were more satisfied with telehealth visits compared with in-person visits (OR 6.22, 95%, CI 2.91 - 14.3; Table 3). Other factors associated with patient satisfaction with telehealth visits included age (OR 0.96, 95% CI 0.93 - 0.99) and comfort with their device (OR 6.08, 95% CI 3.75 - 10.9). However, after adjusting for age, sex, location, and comfort with the device in a multivariable logistic regression, comfort with the device was the only significant predictor of patient satisfaction with telehealth visits compared with in-person visits (adjusted OR 5.80, 95% CI 3.30 - 11.3; Table 3).

Table . Association of patient characteristics with telehealth satisfaction and preference.

	Prefers virtual visits, OR[a] (95% CI)		More satisfied with telehealth than in person, OR (95% CI)		Satisfaction with virtual visit, OR (95% CI)

Discussion

Rural patients in our study reported more difficulty attending in-person visits due to double the transportation time and were more likely to cancel these appointments due to transportation issues. Despite these challenges, rural patients reported higher satisfaction with in-person visits compared with urban patients. In contrast, rural patients experienced more technical difficulties during telehealth visits, reported less comfort with their devices, and used their smartphones less frequently. Notably, comfort with device use emerged as the strongest predictor of telehealth satisfaction, suggesting that lower technological literacy may underlie the lower preference for telehealth observed among rural patients.

Telehealth use has expanded rapidly, particularly during the post–COVID-19 pandemic era, due to its advantages in convenience, access, and timeliness [3,11,12]. Prior studies have demonstrated high satisfaction among both patients and health care providers, supporting telehealth as a viable alternative to in-person care [11,13,14]. Within the field of gastroenterology and hepatology, telehealth has been successfully integrated into inflammatory bowel disease clinics, with associated improvements in patient satisfaction and disease-specific quality of life [15]. In hepatology specifically, telehealth interventions have also been used to help support sleep, stress management, and nutrition [16-18]. Within academic gastroenterology and hepatology practices, factors associated with higher satisfaction have included younger age, race, and type of visit [14]. However, broader socioeconomic factors are increasingly recognized as important contributors [19,20]. Prior reviews have demonstrated that income and education level are key determinants of telehealth accessibility and are closely linked to lower electronic health literacy [3,21,22]. Consistent with this literature, our study found that preference for virtual visits was associated with younger age, urban location, smartphone or tablet use, and greater comfort with technology. We also observed significantly lower telehealth satisfaction among rural patients, which appeared to be primarily driven by reduced comfort with devices and lower technology literacy. Although age alone was not independently associated with visit-type preference in multivariable analysis (OR 0.97; *P*=.20), patients with Medicaid insurance, used as a proxy for income, were more likely to prefer virtual visits (*P*=.03), highlighting the complex interaction between socioeconomic factors and telehealth preferences.

Telehealth has been shown to increase access to care through methods of improving availability and affordability [23]. However, persistent challenges remain, particularly related to infrastructure limitations such as broadband access and gaps in technology literacy. Our results show that rural patients are disproportionately affected by both barriers. While the Infrastructure Act of 2021 promised US $65 billion toward improving broadband access, addressing connectivity alone may be insufficient. Targeted efforts to improve technology literacy are likely necessary to fully realize the benefits of telehealth in rural populations.

To better understand potential solutions, our survey asked patients to identify resources that might help them with their visits in the future. Proposed interventions included a step-by-step “how-to” guide for accessing visits, a loaned tablet with a preloaded telehealth app, and a hospital-based app for tracking weight or medication management. A total of 80%

XSL•FO
RenderX

(131/164) of patients expressed interest in additional resources, with the most endorsed intervention being a “how-to” guide focusing on accessing visits. These findings suggest that relatively low-cost educational interventions may meaningfully improve telehealth satisfaction. Future studies should focus on implementing such interventions, particularly in rural communities, to assess whether targeted technology training and assistance can help improve health care access and patient satisfaction.

The Veterans Affairs (VA) health care system was an early adopter of telehealth and provides a useful model. Through initiatives led by the VA Office of Connected Care, established in 2015, the VA has addressed common telehealth barriers by providing loaned devices and offering structured support to improve technology literacy [24]. These investments in telehealth have allowed the VA to reach a broader patient population [25]. Whether other health care systems and private insurers will adopt similar programs to address these barriers remains an important area for study.

Several limitations should be considered when interpreting our findings. This was a single-center study conducted during the COVID-19 pandemic, and some patients may have favored telehealth visits due to concerns about infection risk with in-person visits. Although our survey was not validated externally, it was based on prior studies and reviewed by our hepatology colleagues and statistician to ensure appropriate content. Visit types were not stratified by routine follow-ups and acute visits, which may have played a role in satisfaction. In addition, patient-physician relationships may have confounded satisfaction ratings, as patients’ comfort with a physician may have biased their opinion on visit type. Furthermore, given the complexity of our patient population, those who answered the survey may have had higher technology literacy at baseline, potentially limiting generalizability to the broader hepatology patient population. Finally, our study did not address health care provider burden or perceived quality of care [26]. Health care provider concerns regarding limitations of physical examinations during telehealth visits were not evaluated, nor were objective clinical outcomes assessed. Future studies should incorporate both patient- and health care provider–reported outcomes to better characterize the impact of telehealth on quality of care.

In conclusion, this study demonstrates lower satisfaction with telehealth among rural patients compared with urban patients. Our findings suggest that efforts to improve broadband access, provide appropriate devices, and enhance telehealth literacy may increase satisfaction and reduce barriers to care, including travel time and associated costs, for patients in rural areas.

Abstract

Background: The swift pace of digital transformation has heightened individuals' dependence on digital technologies. This makes it imperative to explore how individual factors such as digital self-efficacy and social capital affect satisfaction with the daily life changes stemming from digital transformation. This investigation is particularly essential among middle-aged and older adults because they encounter numerous challenges and opportunities from digital transformation.

Objective: This study examined the moderating effect of social capital on the relationship between digital self-efficacy and satisfaction with the daily life changes stemming from digital transformation among middle-aged and older adults.

Methods: This study used data from the 2022 Digital Divide Survey conducted by the National Information Society Agency in South Korea. The sample included 4155 individuals aged 40 years or older, of whom 71.8% (n=2985) were classified as middle-aged (40 - 64 y) and 28.2% (n=1170) as older adults (65 - 96 y). Data were analyzed using multiple linear regression models with IBM SPSS (version 27.0) and the PROCESS macro.

Results: Compared with the middle-aged group, the older adult group showed lower levels of digital self-efficacy, social capital, and satisfaction with the daily life changes stemming from digital transformation. The interaction term between digital self-efficacy and social capital was significant in the middle-aged group (B=−0.11, *P*=.002) and the older adult group (B=−0.24, *P*<.001). There was a positive association between digital self-efficacy and satisfaction in both groups, and this association was stronger among those with low social capital. Furthermore, this effect was more pronounced in the older adult group (B=0.71, *P*<.001 for low and B=0.47, *P*<.001 for high social capital) than in the middle-aged group (B=0.55, *P*<.001 for low and B=0.46, *P*<.001 for high social capital). Education level and digital competence were positively associated with satisfaction in both age groups; higher household income was positively associated with satisfaction only in the middle-aged group.

Conclusions: Individuals with low social capital showed a stronger association between digital self-efficacy and satisfaction with the daily life changes stemming from digital transformation. Enhancing digital self-efficacy among older adults, especially those with low levels of social capital, may improve their satisfaction with the daily life changes stemming from digital transformation.

Introduction

Background

The COVID-19 pandemic expedited digital transformation, increasing the adoption of digital technology-based public and private services and accelerating innovation in information and communication technologies (ICTs) [1,2]. As of 2023, approximately 5.16 billion people (constituting 64.4% of the global population) were using the internet, and approximately 5.44 billion (or 68% of the global population) were using mobile phones [3]. South Korea is at the forefront of this global trend.

XSL•FO
RenderX

According to the Organisation for Economic Co-operation and Development (OECD) Digital Government Index published in 2025, South Korea ranked first overall, with a composite score of 0.94, substantially higher than the OECD average of 0.61 [4]. This reflects an environment in which digital platforms are no longer optional but function as essential infrastructure for daily life. This pervasive digitalization has fostered the development of a well-connected society in South Korea. However, this rapid digitalization coincides with an unprecedented pace of population aging.

The global proportion of individuals aged 65 years and older is projected to rise to 1 in 6 by 2050 [5]. Notably, South Korea is experiencing the world's most rapid pace of population aging and is expected to become one of the world's most aged societies by 2050, with older adults comprising approximately 40% of the total population [5]. In this context, where rapid digital transformation and population aging are occurring simultaneously, the digital divide extends beyond access to resources to include disparities in digital skills and perceptions of digital technologies [6].

The digital divide refers to the disparity between individuals with access to modern ICTs and those without such access [7]. It contributes to digital exclusion [2], particularly in societies where technology and the internet govern various aspects of daily activities [8,9]. This technological shift brings about changes in daily life that individuals perceive as either beneficial or burdensome. When individuals are digitally excluded, barriers to accessing information and services, as well as maintaining social participation, can undermine everyday autonomy, thereby reducing satisfaction with the daily life changes stemming from digital transformation [9].

While internet adoption has accelerated across all ages in recent years, middle-aged and older adults continue to account for a large proportion of those experiencing the digital divide [10,11]. This population is often less familiar with digital technologies, which makes them more vulnerable to the digital divide and increases their risk of digital exclusion [2,8-12]. Given that digital exclusion can detrimentally affect the quality of life and social participation [13,14], it is essential to address digital divide concerns among middle-aged and older adults. However, the digital divide is not a uniform phenomenon, as its underlying mechanisms and consequences often vary across life stages. From a life-course perspective, middle-aged adults often face strong demands to use digital technologies for work, family responsibilities, and social roles, whereas older adults may encounter more complex barriers due to retirement-related transitions, changes in social ties, and health or functional limitations [15,16].

Previous research suggests that digital technology adoption processes differ between middle-aged and older adults, particularly in how key adaptive resources such as digital self-efficacy and social capital are developed and used. Middle-aged adults, who have higher levels of participation in the workforce, tend to strengthen their digital self-efficacy through task-related experiences, training, and repeated ICT use in both occupational and everyday contexts [17]. In contrast, older adults are more likely to encounter digital technologies later in life and tend to rely more on relational support, such as encouragement, demonstration, and guidance from family members or social networks during the adaptation process [18]. The use of social capital in digital environments also differs across age groups. Middle-aged adults often use broader and more diverse networks, including professional and extended social ties, to access information and resources. In contrast, older adults tend to depend on close ties, such as family members and familiar contacts, for instrumental assistance and emotional support [19,20]. Taken together, structural differences in the formation of digital self-efficacy and the usage of social capital between middle-aged and older adults support distinguishing these groups to capture heterogeneity in digital adaptation processes across life stages.

The impact of digital transformation on daily life extends beyond technology use and reflects individuals' experiences of changes in the digital environment. Recent studies have shown that digital transformation is associated with a range of subjective life outcomes, including life satisfaction [21], quality of life [22], subjective well-being [23], and overall well-being [24]. These indicators capture general life outcomes and assess the effects of digital transformation only indirectly, without reflecting individuals' evaluations of specific changes in their daily lives. In this study, the dependent variable was measured as "satisfaction with the daily life changes stemming from digital transformation." This variable reflects how individuals evaluate the impact of accelerated digital changes across key domains of everyday life, including leisure opportunities, access to information and knowledge, social connection and exchange, and work and study efficiency.

This conceptualization is consistent with the third-level digital divide perspective, which emphasizes that digital inequalities are not limited to differences in internet access (the first-level digital divide) and digital skills (the second-level digital divide) [25], and are ultimately reflected in differences in the tangible benefits individuals derive from using technologies [26]. Previous studies further demonstrate that digital transformation is closely associated with key domains of everyday life. Digital transformation facilitates access to information and knowledge by enhancing opportunities for learning and information seeking [27], promotes social connection and exchange by reducing social isolation and supporting social well-being [14,28], and contributes to improved learning experiences and work-related productivity in educational and occupational contexts [29]. Furthermore, digital transformation has extended into leisure, reshaping recreational activities and influencing individuals' daily experiences [30,31]. Collectively, the dependent variable captures a theoretically grounded measure of perceived satisfaction with digital transformation–related changes in everyday life as a key outcome of digital engagement.

Digital self-efficacy refers to an individual's belief in their capability to use digital systems effectively [32]. It promotes the long-term use of digital devices, thereby reducing the digital divide and boosting the quality of life [33-35]. According to the self-efficacy theory, self-efficacy is one's belief in their ability to plan and successfully perform the activities needed to achieve a specific goal [36]. Self-efficacy acts as a resource in task attainment, as individuals regulate their effort and

XSL•FO
RenderX

perseverance based on their self-efficacy [37]. Insufficient digital self-efficacy can hamper the ability of middle-aged adults and older adults to effectively use technologies to address later-life needs, such as financial management, health care, and retirement planning [8,38]. Addressing the barriers to technology use and enhancing digital self-efficacy may improve their engagement and proficiency with digital devices, which can, in turn, aid them in achieving successful aging [33,39].

Social capital is defined as networks and relationships among individuals that are underpinned by the norms of reciprocity and trust. It encompasses two key functions: (1) bonding, which creates strong emotional connections; and (2) bridging, which produces weaker but broader connections [40]. As individuals transition from middle age to older adulthood, events such as retirement, the loss of spouses and close connections, limited educational opportunities, and mobility limitations diminish social capital. Specifically, there is a gradual reduction in one's social networks and the capacity to use social resources [41-43]. Social capital is a significant contributor to the use of digital devices and the maintenance of online engagement [38]. Additionally, it can function as a contextual resource that moderates the relationship between digital self-efficacy and satisfaction with the daily life changes stemming from digital transformation [44]. When social capital is high, individuals can access support that facilitates digital engagement and reduces reliance on their own digital self-efficacy, whereas when social capital is low, limited support increases dependence on digital self-efficacy for digital engagement [45]. Accordingly, the effect of digital self-efficacy on satisfaction with the daily life changes stemming from digital transformation may vary depending on the level of social capital.

According to the conservation of resources (COR) theory [46], individuals experiencing resource loss tend to protect and preserve their remaining resources. In technology-dependent societies, individuals with low social capital have limited access to external support, increasing their vulnerability to resource loss. In this context, digital self-efficacy may function as a key internal resource that compensates for the lack of external support. Specifically, higher digital self-efficacy may enable individuals to more effectively navigate digital environments despite constrained support, thereby facilitating a more adaptive appraisal of digital transformation as manageable rather than threatening [47]. Such appraisal may reduce maladaptive responses and enhance satisfaction with the daily life changes stemming from digital transformation. Taken together, these considerations suggest that digital self-efficacy may serve as a compensatory resource among middle-aged and older adults with limited social capital, with important implications for supporting adaptation to evolving digital environments and reducing the digital divide.

Purpose

This study aimed to evaluate the relationship between digital self-efficacy, social capital, and satisfaction with the daily life changes stemming from digital transformation. Specifically, it focused on how social capital moderates the relationship between digital self-efficacy and satisfaction with the daily life changes stemming from digital transformation among both middle-aged and older adults.

Methods

Data and Study Population

We used cross-sectional data from the 2022 Digital Divide Survey, an annual nationwide survey conducted by the Ministry of Science and ICT and the National Information Society Agency in South Korea. In this study, analyses were based on the general population subsample aged 40 years or older (n=4155). Adults aged 40 - 64 years were classified as the middle-aged group (n=2985, 71.8%), and those aged 65 - 96 years as the older adult group (n=1170, 28.2%), based on the official life-stage age classification used in Korea's national administrative statistics [48]. In 2022, the survey was conducted from September to December using standardized face-to-face interviews and used a stratified probability-proportional-to-size sampling design to ensure national representativeness. The survey assessed the effectiveness of policies aimed at reducing the digital divide and included a total of 15,000 respondents from the general population, along with additional samples from vulnerable groups such as older adults, individuals with disabilities, individuals in low-income households, immigrant women in international marriages, North Korean defectors, and individuals engaged in agriculture or fishing. The official methodology report of this survey did not provide an overall response rate; however, the analytic dataset contained no missing values for study variables.

Variables

Dependent Variable

Satisfaction with the daily life changes stemming from digital transformation was determined using 4 items rated on a 5-point Likert scale from 1 ("strongly disagree") to 5 ("strongly agree"). The items were as follows: (1) "The digital transformation has increased opportunities for leisure activities and made them more enjoyable (for instance, through online content and mobile applications)"; (2) "The digital transformation has enabled quicker access to new information or knowledge (for instance, through remote learning and online content platforms)"; (3) "The digital transformation has increased opportunities to engage with new people and exchange opinions"; and (4) "Efficiency in work or academic pursuits has improved due to practices like remote work and mobile learning." The total score was calculated as the mean of 4 items, with higher scores indicating greater satisfaction levels [49]. In this study, the scale exhibited excellent internal consistency, with a Cronbach α of 0.90.

Construct validity was examined using confirmatory factor analysis (CFA) in the total sample and separately in middle-aged and older adults, given that this 4-item measure was newly added to the 2022 survey. Model fit was evaluated using the comparative fit index (CFI), Tucker-Lewis index (TLI), and standardized root-mean-square residual (SRMR). The chi-square statistic was excluded from model fit evaluation because it is overly sensitive to large sample sizes [50]. Acceptable model fit was indicated by CFI and TLI≥0.90 and SRMR<0.08 [51],

XSL•FO
RenderX

with more stringent cutoffs of CFI and TLI≥0.95 suggested [52]. In addition to CFI, TLI, and SRMR, root-mean-square error of approximation (RMSEA)<0.08 is commonly used as a criterion for acceptable model fit; however, RMSEA tends to be upwardly biased in models with small dfs [53]. Since our measurement model for the 4-item scale has a small df (df=2), model fit was primarily evaluated using CFI, TLI, and SRMR, which are more robust in such cases [53]. Construct reliability was assessed using composite reliability (CR; ≥0.70) [54], and convergent validity was assessed using average variance extracted (AVE; ≥0.50) [55].

Independent Variable

Digital self-efficacy was assessed using 4 items rated on a 4-point scale ranging from 1 (“strongly disagree”) to 4 (“strongly agree”). These 4 items have been widely used in past studies [56-58]. The items are as follows: (1) “I am confident that I can learn about digital devices”; (2) “I am confident in using digital devices”; (3) “I can quickly learn how to use new digital devices”; and (4) “I want to use digital devices more frequently.” The digital self-efficacy score was calculated based on the average score on the 4 items, with higher scores reflecting higher digital self-efficacy. In this study, the scale demonstrated excellent internal consistency, with a Cronbach α of 0.88.

Moderating Variable

Social capital was measured with an abbreviated version of Williams’s social-capital scale [59] developed by the agency that conducted the 2022 Digital Divide Survey. It comprises 10 items—5 items each for bonding and bridging social capital. The items for bonding social capital were (1) “I know someone who can help me solve my problems”; (2) “I know someone who I can ask for advice when I have to make important decisions”; (3) “I know someone who I can talk to about my private matters”; (4) “I know someone who I can trust with important work”; and (5) “I know someone who can help me fight injustice.” The items for bridging social capital were (1) “I feel connected to a bigger world as I interact with people online and offline.”; (2) “I feel that everyone in the world is connected as I interact with people online and offline.”; (3) “I am willing to spend time on community activities”; (4) “Online and offline interactions allow me to communicate with new people”; and (5) “Online and offline interactions allow me to meet new people.” The items are rated on a 4-point scale that ranges from 1 (“strongly disagree”) to 4 (“strongly agree”). We used a combined social capital score (bonding plus bridging) to capture overall accessible social resources, consistent with previous research [44,58,60]. This operationalization aligned with our focus on moderation by overall social support and information pathways. The average of the scores on the 10 items indicates the total social capital score. Higher scores indicate greater social capital. This scale has been extensively adopted in previous studies [44,58,60]. In this study, the scale had a Cronbach α of 0.84, indicating great internal consistency.

Covariates

The general characteristics of the study population and digital competence were included as covariates. The general characteristics were age, sex, education level, living arrangements, the presence of disability, monthly household income, self-rated health, and digital competence. These covariates were selected based on previous studies [32,61,62]. The exchange rate in 2022 was KRW 1=US $0.000774, based on the average annual exchange rate reported by the World Bank [63]. Self-rated health was captured with a single question on how satisfied participants felt about their physical and mental health, with responses ranging from 1 (“not satisfied at all”) to 4 (“very satisfied”) [64]. Digital competence was measured with 14 items assessing personal computer and mobile phone use skills, each rated from 1 to 4, where higher scores indicated greater digital competence [65]. In this study, the scale exhibited a Cronbach α of 0.96, suggesting excellent internal consistency.

Ethical Considerations

This was a secondary analysis study that used publicly available data without any personally identifiable information. Therefore, this study was exempt from review by the Institutional Review Board (IRB 4-2023-1516).

Statistical Analysis

We compared the general characteristics of the study population and the study variables between middle-aged and older adults using chi-square tests and 2-tailed independent *t* tests. To examine the associations between digital self-efficacy, social capital, and satisfaction with the daily life changes stemming from digital transformation, we used multiple linear regression analyses. Three separate regression models were developed for the total sample, for middle-aged adults, and for older adults. All regression models were adjusted for covariates. The continuous variables were mean-centered before the regression models were constructed, and no variables were standardized. The moderation effect of social capital was assessed using an interaction term (digital self-efficacy×social capital) in the models. The PROCESS macro in IBM SPSS Statistics was used to determine significant interaction effects. Unstandardized simple slopes were calculated at 1 SD above (+1 SD) and below (−1 SD) the mean score for social capital.

Considering the potential heterogeneity across the dependent variable’s subdimensions, we performed an additional analysis using a multiple indicators multiple causes (MIMIC) model, a specific form of structural equation modeling (SEM) [66]. In this model, the dependent variable was specified as a latent factor indicated by 4 reflective items, while observed covariates were included as causal predictors [67].

Statistical analyses were performed using SPSS Statistics for Windows (version 27.0). The CFA and SEM models were estimated in R (version 4.5.1; R Core Team) using the *lavaan* package, using robust maximum likelihood estimation [68]. We evaluated normality by inspecting absolute skewness values for all continuous variables (with values ≥3 indicating substantial deviation from normality) and visually reviewing histograms and quantile-quantile (Q-Q) plots. All absolute skewness values were <1.5, and no marked deviations from normality were observed in the histograms or Q-Q plots. No missing values were present for any variables included in the analytic sample; therefore, no exclusions or imputations were required. No

XSL•FO
RenderX

multicollinearity issues were observed in any of the models because the variance inflation factor remained under 10.

Results

General Characteristics of the Study Population

The average age of middle-aged adults was 52.42 (SD 6.80) years, while that of older adults was 71.33 (SD 5.05) years (Table 1). The proportion of individuals with high school or higher educational attainment was higher in the middle-aged group (2814/2985, 94.3%) than that in the older adult group (510/1170, 43.6%). The proportion of individuals living with others was lower in the older adult group (927/1170, 79.2%) than that in the middle-aged group (2786/2985, 93.3%). Furthermore, older adults had lower household incomes, poorer self-rated health, and weaker digital competence than middle-aged adults.

Differences in Digital Self-Efficacy, Social Capital, and Satisfaction With the Daily Life Changes Stemming From Digital Transformation Between Middle-Aged and Older Adults

The older adult group (mean 1.93, SD 0.68) exhibited lower levels of digital self-efficacy than the middle-aged group (mean 2.67, SD 0.62; $t_{4,153}$=32.13; P<.001; Table 1). The former (mean 2.65, SD 0.50) demonstrated lower levels of social capital than the latter (mean 2.89, SD 0.41; $t_{4,153}$=14.76; P<.001). The former (mean 2.44, SD 0.88) also reported lower levels of satisfaction with the daily life changes stemming from digital transformation than the latter (mean 3.23, SD 0.75; $t_{4,153}$=27.17; P<.001).

CFA Results for the 4-Item Measure of the Dependent Variable

CFA supported a unidimensional structure of the 4-item measure of satisfaction with the daily life changes stemming from digital transformation in the total sample and both age groups (Table 2). Standardized factor loadings were high (total: 0.82 - 0.86; middle-aged: 0.75 - 0.82; and older adults: 0.84 - 0.88), and fit indices indicated acceptable to excellent fit overall (CFI and TLI≥0.95; SRMR<0.08). Construct reliability and convergent validity were well-supported across groups (CR≥0.7; AVE≥0.5).

Associations Between Digital Self-Efficacy, Social Capital, and Satisfaction With the Daily Life Changes Stemming From Digital Transformation

Higher levels of digital self-efficacy were associated with higher levels of satisfaction with the daily life changes stemming from digital transformation in the middle-aged group (B=0.50, *P*<.001) and in the older adult group (B=0.59, *P*<.001; Table 3). Similarly, higher social capital was significantly associated with higher satisfaction with the daily life changes stemming from digital transformation among both middle-aged (B=0.28, *P*<.001) and older adults (B=0.12, *P*=.01).

Moderating Role of Social Capital

The interaction effect of digital self-efficacy and social capital was significant among both middle-aged (B=−0.11, *P*=.002) and older adults (B=−0.24, *P*<.001; Table 3). We estimated the unstandardized simple slopes of these relationships (Figure 1). High and low levels of social capital were determined using SD, and values 1 SD above and 1 SD below the mean indicated high and low levels of social capital, respectively. In both the middle-aged and older adult groups, digital self-efficacy displayed a stronger positive relationship with satisfaction with the daily life changes stemming from digital transformation (satisfaction) when social capital was low. Additionally, this relationship was stronger in the older adult group (B=0.71, *P*<.001 for low and B=0.47, *P*<.001 for high social capital) than in the middle-aged group (B=0.55, *P*<.001 for low and B=0.46, *P*<.001 for high social capital). Among covariates, education level and digital competence were positively associated with satisfaction in all groups; household income was positively associated with satisfaction only in the total sample and middle-aged adults, and age was negatively associated with satisfaction only in the total sample.

These results were largely consistent in additional SEM analyses using a MIMIC model (Multimedia Appendices 1-3), particularly with respect to the effects of digital self-efficacy and the digital self-efficacy×social capital interaction term across groups. The direct effect of social capital was significant in the total and middle-aged samples, but was attenuated and not statistically significant among older adults in SEM.

To further examine age heterogeneity, we conducted age-stratified analyses (40 - 50 y: n=1189, 51 - 64 y: n=1796, 65 - 74 y: n=872, and ≥75 y: n=298; Multimedia Appendix 4). In the 65 - 74 years group, digital self-efficacy was positively associated with satisfaction with the daily life changes stemming from digital transformation (B=0.60, *P*<.001), and the interaction effect was negative and statistically significant (B=−0.27, *P*<.001). In the ≥75 years group, the interaction term did not reach statistical significance (B=−0.21, *P*=.18), whereas the direct effect of digital self-efficacy remained significant (B=0.54, *P*<.001).

Discussion

Principal Findings

This study examined the moderating effect of social capital on the relationship between digital self-efficacy and satisfaction with the daily life changes stemming from digital transformation among middle-aged and older adults. In both groups, digital self-efficacy was positively linked to satisfaction, and the effect was stronger among individuals with low social capital compared with those with high social capital. Notably, this positive relationship was more pronounced among older adults than among middle-aged adults. These results offer valuable insights into the challenges of digital transformation in aging populations. Importantly, satisfaction with the daily life changes stemming from digital transformation remains underexamined compared with broader outcomes such as quality of life. Focusing on this transformation-specific outcome helps capture individuals' subjective adaptation to rapidly changing digital environments, which may not be fully reflected in broader well-being indicators. This study extends previous research by demonstrating that social capital moderates the association between digital self-efficacy and satisfaction with the daily life changes stemming from digital transformation, with clear differences across age groups.

Our findings revealed that for individuals with low social capital, digital self-efficacy was more strongly associated with satisfaction with the daily life changes stemming from digital transformation. This was particularly evident among older adults, who may face greater challenges in adapting to digital advancements. These findings suggest that older adults with limited social connections may rely more heavily on their own digital self-efficacy to maintain social engagement, access services, and maintain satisfaction with the daily life changes stemming from digital transformation. Enhancing digital self-efficacy may support more positive perceptions of digital transformation, particularly among socially vulnerable groups, consistent with the COR theory [46]. Similarly, past studies have shown that the positive effect of frequent internet use on life satisfaction is stronger among older adults living alone compared with those living with others [61]. Likewise, the autonomy benefits of active internet use have been reported to be greater among older adults with poorer functional health than among those with better functional health [69].

The moderation effect of social capital reached statistical significance among adults aged 65 - 74 years but not among those aged ≥75 years. However, among the old-old (≥75 y; n=298; B=−0.21; *P*=.18), the coefficient was comparable in direction and magnitude to that observed in the young-old (65 - 74 y; n=872; B=−0.27; *P*<.001). This suggests that the nonsignificant finding in the old-old group may reflect limited statistical power rather than the absence of a meaningful moderating pattern. Although the directional pattern was broadly consistent across older adult subgroups, these age-stratified findings may also indicate heterogeneity within the older adult population. The young-old (65 - 74 y) often experience major life transitions such as retirement, accompanied by shifts in social roles and available resources; thus, digital self-efficacy may function more prominently as a compensatory resource [70]. In contrast, among adults aged ≥75 years, satisfaction with the daily life changes stemming from digital transformation may be shaped not only by digital self-efficacy and social capital but also by structural and functional constraints, such as physical limitations, cognitive burden, poorer health, and accessibility barriers [20,71].

The observed age-related differences may also be interpreted in light of a potential digital cohort effect, whereby digital adaptation is shaped more by the timing and context of initial exposure to digital technologies than by chronological age alone [25,72]. Earlier and sustained exposure to digital technologies may strengthen digital self-efficacy and its influence on satisfaction, whereas later or limited exposure may constrain digital skills and self-efficacy, making it more difficult to effectively use social capital in digital contexts. This interpretation is consistent with previous research emphasizing the role of experience and cumulative engagement with digital technologies in shaping the digital divide among older adults [20]. Although the moderation effect was not statistically significant in the old-old group, digital self-efficacy remained significantly associated with satisfaction. This suggests that digital self-efficacy still plays an important role in this group, consistent with previous findings showing that it continues to influence behavioral intention to use the internet in old-old age [73].

Our results highlight the importance of self-efficacy, as also suggested in social cognitive theory [36]. Self-efficacy is particularly relevant in later life, as this stage is characterized by resource losses [74]. Strategies such as persuasion, observational learning, and mastery experiences can effectively enhance self-efficacy, enabling individuals to balance their actions and acquire new skills [36]. Notably, previous research has consistently identified digital self-efficacy as a key factor in digital proficiency, learning outcomes, and life satisfaction [56,74,75]. Therefore, improving digital self-efficacy may foster acceptance of digital services and confidence in navigating them, supporting greater satisfaction with the daily life changes stemming from digital transformation.

Building upon theoretical foundations, our findings suggest that policy and program designs can benefit from differentiated strategies for middle-aged and older adults. For middle-aged adults, who are often required to engage with digital technologies in occupational and administrative contexts, interventions should focus on enhancing the efficient and context-specific use of digital services. Program impact may be strengthened by long-term outreach that enhances exposure and awareness, alongside a shift toward skill-building-based empowerment and low-barrier service pathways.

For older adults, particularly those with low social capital, interventions could prioritize strengthening digital self-efficacy through tailored support, including dedicated one-on-one mentorship to provide guided mastery experiences. Such support can emphasize confidence-building, achievable goal setting, and the development of organizational and self-management skills. In addition, heterogeneity within older adults should be considered. The young-old may be more likely than the old-old

XSL•FO
RenderX

to have previous experience with digital technologies before retirement, and such experience has been shown to be a strong predictor of internet use in later life [20]. Previous experience may facilitate continued learning and make the young-old more responsive to structured, skill-building support such as one-on-one mentorship, enabling the translation of existing familiarity into effective skills and rapid mastery. Therefore, interventions for the young-old may benefit from focusing on such skill-oriented, experience-based support. In contrast, interventions for the old-old should prioritize reducing barriers to access and use, such as simplifying interfaces and providing assistive support. They may also benefit from approaches that enhance digital self-efficacy through personalized, family-integrated support, with attention to accessibility, usability, and functional limitations, including visual and hearing impairments [20,71]. In South Korea, government initiatives to promote digital literacy have included kiosk usage training at senior welfare centers, along with efforts to transform over 2000 senior centers into smart facilities by 2024 [76]. Nonetheless, older adults continue to report low digital self-efficacy and limited awareness of online government services [77], indicating that further expansion and active dissemination are needed to enhance program reach and impact. These efforts may further prioritize subgroups facing compounded barriers, such as individuals with lower education or income, those living alone, people with disabilities, and rural residents. Targeted and accessible support for these groups may further enhance equity in digital adaptation.

Satisfaction with the daily life changes stemming from digital transformation may facilitate individuals' openness to engaging with digital environments and, in turn, may help them realize the potential benefits of digital technologies. The active usage of digital technology provides middle-aged and older adults with access to resources and services such as information, entertainment, shopping, and banking, thereby improving their independent living, health, and life satisfaction [78-80]. The use of digital services can also predict health outcomes [78]. Based on data from 5 international longitudinal cohort studies, Li [11] found that middle-aged and older adults who use the internet reported lower levels of frailty, fewer health deficits, and better overall health. Additionally, the networks formed online can foster social connections among individuals experiencing a gradual reduction in their social roles and relationships, thereby contributing to decreased loneliness and improved well-being [19,38,81,82]. This suggests a reciprocal relationship where active digital engagement not only requires social resources but also provides opportunities to maintain or enhance them, particularly for those with limited social networks [83]. Within this framework, improving digital self-efficacy does more than facilitate technical adaptation; it may empower socially isolated individuals to manage and expand their social capital through digital means.

By examining individuals' satisfaction with the daily life changes stemming from digital transformation, this study highlights the evolving challenges of the digital era. These challenges are particularly relevant in the post–COVID-19 period, as digital competencies have become essential for life satisfaction. South Korea provides a unique context for this study, as it is the fastest-aging society among the OECD countries [84] and is undergoing rapid digital transformation [6]. Our findings not only contribute to the literature on aging and digitalization but also provide actionable insights for addressing similar challenges worldwide.

Strengths and Limitations

This study used nationally representative survey data from 2985 middle-aged and 1170 older adults in South Korea. The survey was conducted by reputable organizations and government agencies, including the Ministry of Science and ICT in collaboration with the National Information Society Agency. Trained interviewers visited participants' residences to administer the questionnaires in a standardized manner. In addition, the dataset contained no missing values for the variables used in this study, eliminating the need for casewise deletion or imputation. Therefore, the large sample size and rigorous data collection methods enhance the reliability and generalizability of our findings, offering valuable insights for the older adult population.

Nevertheless, this study has several limitations. First, this study focused on the general population and did not include specific groups such as people with disabilities or those living alone, who may experience distinct challenges in digital integration. Future research should explicitly include these populations and use accessibility-focused measures, tailored digital interventions, or subgroup-specific analyses to better understand digital integration across diverse groups. Second, the instrument used to measure social capital assessed both online and offline social capital, and it was not possible to differentiate between the two in the results. Therefore, the findings reflect overall social capital rather than mode-specific resources, and future research should disentangle offline and online dimensions to examine whether their moderating roles differ. Third, the cross-sectional design precludes the establishment of a clear causal relationship between digital self-efficacy and satisfaction with the daily life changes stemming from digital transformation. It remains unclear whether higher levels of digital self-efficacy lead to greater satisfaction or vice versa. Future studies should use a longitudinal design to explore these causal relationships. Fourth, key variables were measured using self-reported questionnaires, which may be subject to recall or social desirability bias. Fifth, although we adjusted for digital competence, some conceptual overlap between digital competence and digital self-efficacy may remain. Future studies should further disentangle these constructs using more refined measures or alternative model specifications. Sixth, because this study was conducted in South Korea, which is characterized by rapid digital transformation and distinct sociocultural features, generalizability to other countries or cultural settings may be limited. Additionally, most participants had completed high school or above (approximately 80%), which may further limit generalizability to individuals with lower educational attainment. Seventh, although our study focused on digital self-efficacy in relation to digital transformation–related satisfaction, we should also consider the possibility of problematic internet use and addiction. Previous studies have also shown that spending excessive time on online activities increases the risk of depressive symptoms [85], sleep disturbance [86], and musculoskeletal pain [87] in this

population. Accordingly, future research should assess not only the benefits of digital engagement but also its negative consequences, such as digital burden, fatigue, and cognitive load, to provide a more balanced understanding of its impact on well-being.

Conclusion

The findings of this study demonstrate the important role of digital self-efficacy in improving satisfaction with the daily life changes stemming from digital transformation, particularly among older adults with low social capital. This study not only contributes to the literature on aging and digitalization but also offers practical insights for reducing the digital divide. The results emphasize the importance of fostering digital self-efficacy through strategies such as mentorship programs, observational learning, and tailored educational interventions. These strategies can empower vulnerable populations to adapt to digital transformation.

Acknowledgments

We thank the Ministry of Science and ICT and the National Information Society Agency (NIA) for sharing the data with the researchers.

We confirm that no generative AI tools were used in the preparation of this manuscript.

Funding

This study was supported by the Basic Science Research Program through the National Research Foundation of Korea (NRF), funded by the Ministry of Education (No. 2020R1A6A1A03041989) and the Ministry of Science and ICT (MSIT) (RS-2025-00520935) to HL. JC received a scholarship from Brain Korea 21 FOUR Project fundedby NRF of Korea, Yonsei University College of Nursing.

Data Availability

This data is publicly available, and the authors do not have the authority to share it.

Authors' Contributions

JC, HC, and HL contributed to the conceptualization, study design, data interpretation, manuscript drafting, and manuscript revision. JC performed the data analysis. All authors have read and approved the final version of the manuscript.

Abstract

Background: Rapid population aging and the intensifying digitalization of everyday life are unfolding simultaneously in China. While prior studies have largely examined pairwise associations among digital inclusion, social engagement, mental health, and overall health status, few have evaluated an integrated, theoretically grounded pathway linking these domains in later life.

Objective: This study aims to quantify the direct and indirect pathways through which digital inclusion influences older adults' overall health status, social engagement, and mental health, specified as sequential mediators.

Methods: We analyzed the newly released, nationally representative data from the 2023 wave of the China Longitudinal Aging Social Survey, comprising 9918 adults aged 60 years or older. Overall health status was assessed using 3 self-rated health (SRH) indicators: current SRH, SRH relative to age peers, and SRH relative to last year. Digital inclusion was measured through digital access, device proficiency, and digital ability. Social engagement captured social support, frequency of participation in community or voluntary activities, and nononline activities. Mental health included depressive symptoms, social adaptation, and life satisfaction. Analyses included descriptive statistics, multivariable hierarchical linear regressions, and structural equation modeling to estimate direct and mediated effects (2-sided; α=.05).

Results: Older age, chronic disease, and functional limitations were associated with poorer overall health status, whereas higher education and current employment were associated with better health status. Digital inclusion was positively associated with social engagement (β=.50), which in turn was positively associated with mental health. Mental health showed the strongest association with SRH (β=.74). The direct path from social engagement to overall health status was nonsignificant (*P*=.34), indicating that participation influences health primarily through psychological pathways. In regression analyses, digital inclusion modestly improved model fit for health status outcomes, while adding mental health produced a greater increase.

Conclusions: Digital inclusion promoted active aging indirectly, by expanding social engagement and enhancing mental health, thereby improving overall health status. Policy efforts should prioritize narrowing the digital divide by improving digital skills and capability, rather than access alone. Meaningful opportunities for social engagement should also be expanded to strengthen community-based mental health support. In addition, strategies should be tailored to the differing needs of urban and rural settings.

KEYWORDS

digital inclusion; social engagement; mental health; overall health status; healthy aging; active aging; older adults; China

Introduction

Background

Population aging has become one of the most consequential demographic shifts worldwide. In China, this transition is particularly rapid: by the end of 2024, adults aged 60 years or older accounted for 22% of the national population [1], accompanied by rising multimorbidity, functional decline, and widening social and health disparities. As chronic disease burden and long-term care needs increase, understanding the mechanisms that support health and well-being in later life has become a central scientific and policy priority [2].

To guide global responses, the Active Ageing Framework of the World Health Organization (WHO) emphasized that healthy aging is not only about disease prevention but also about creating an environment that enables older adults to remain

XSL•FO
RenderX

healthy and socially engaged [3]. This perspective aligns with core gerontological theories: the activity theory highlights the importance of meaningful participation for psychological and social well-being [4], while the socioemotional selectivity theory underscores the increasing value of emotionally meaningful social ties in later life [5]. China has integrated these principles into national strategies, illustrated by the 2025 *Guiding Opinions on Supporting Elderly People's Social Participation and Promoting the Realization of a Proactive Age*, which call for the need to mobilize older adults' capacities, enhance opportunities for social engagement and overall health, and reduce psychosocial risks [6].

Meanwhile, the rapid digitalization of everyday life has profoundly reshaped how older adults access services, maintain social ties, and engage with community resources. By 2024, China had 157 million internet users aged 60 years or older, yet their online participation remains disproportionately low [7,8]. Digital inclusion today extends beyond access to encompass skills, motivation, trust, and the ability to meaningfully participate in digital environments. The digital divide theory conceptualizes these disparities as layered barriers—spanning access, ability, and confidence—that structure opportunities for social interaction and integration [9,10]. For many older adults, insufficient digital competence, low usability of platforms, and the absence of age-friendly design restrict meaningful digital participation and may exacerbate social and health inequalities.

An integrated theoretical perspective suggests that digital inclusion can influence well-being through psychosocial pathways [11]. The removal of access and skill barriers expands older adults' capacity to obtain information and mobilize social support, forming the structural basis for the participation mechanisms described by the activity theory. Technology acceptance frameworks explain how perceived usefulness, ease of use, and digital self-efficacy determine whether digital access translates into sustained digital engagement [12]. The biopsychosocial model further posits that psychological well-being—shaped in part by social engagement—is a central determinant of both perceived and actual health [13]. Together, these perspectives imply a sequential logic in which digital inclusion facilitates social engagement, which enhances mental health, ultimately contributing to better overall health [14].

However, most existing studies examine these components in isolation—for example, exploring associations between digital use and social connectedness, or between social engagement and mental health—without testing how these elements interact as part of a continuous mechanism [11]. The absence of an integrated analytic framework limits both theoretical coherence and the development of targeted interventions to promote active aging within increasingly digital environments. Empirical validation of the full pathway linking digital inclusion, social engagement, mental health, and their overall health is therefore essential for understanding how digitalization intersects with aging and for informing policy efforts that support healthy, meaningful, and socially integrated later life [15].

Literature Review

Existing research provides substantial but fragmented evidence on the individual links within the broader connecting digital inclusion to health in later life. Studies commonly assess digital inclusion across access, skills, use frequency, and trust and report significant positive effects on social interaction and meaningful forms of participation [16-18]. Digital engagement extends beyond leisure use to include health information seeking, online consultations, communication with family, and participation in community activities [19]. These digitally enabled interactions have been shown to reduce social isolation, strengthen support networks, and enhance older adults' ability to mobilize social resources. Subgroup analyses further indicate heterogeneous effects, with women, urban residents, and younger segments of the older adult population benefiting more from digital inclusion [20]. While literature consistently affirms the positive association between digital engagement and social participation, most studies examine direct associations and rarely evaluate how digital inclusion may activate deeper psychosocial processes that ultimately shape well-being.

Research on the linkage between social engagement and mental health provides equally strong evidence yet remains similarly limited. Social engagement is widely recognized as a cornerstone to active aging. Numerous empirical studies demonstrate that greater frequency and diversity of participation are associated with lower depressive symptoms, reduced loneliness, improved social adaptation, and higher life satisfaction [21-25]. Engagement enhances psychological resources by offering meaningful roles, reinforcing identity and purpose, and strengthening emotional connections—all of which align with core propositions of the biopsychosocial model. Mental health, in turn, as the central determinant of overall health and self-rated health (SRH), exerts substantial influence through mechanisms such as stress buffering, resilience, and positive cognitive appraisal [21-27]. Although these findings underscore mental health as a pivotal conduit between social participation and health outcomes, prior studies rarely embed mental health within a continuous pathway that begins with digital inclusion and culminates in overall health [17,28]. Consequently, the literature lacks an integrated explanation of how digitalization interacts with social processes and psychological well-being to shape health trajectories in later life.

To address these gaps, this study draws on the 2023 wave of the China Longitudinal Aging Social Survey (CLASS), the most recently released and nationally representative dataset on Chinese older adults. Importantly, the data were collected in the immediate post–COVID-19 period, during which digital technologies became deeply embedded in daily life and the digital divide among older adults intensified. This context offered a unique opportunity to examine the mechanisms through which digital inclusion influences social engagement, mental health, and overall health. By constructing and testing an integrated pathway model, this study offers timely empirical evidence to inform more precise and actionable strategies for promoting digital inclusion and active aging in China's rapidly aging society.

Methods

Study Design and Participants

This study used a cross-sectional design and analyzed data from the CLASS 2023. The CLASS project is a national, large-scale social survey conducted by the National Survey Research Center at Renmin University of China. The survey covered 28 provinces, 134 districts, and 462 villages across China, excluding Hong Kong, Taiwan, Macao, Hainan, Xinjiang, and Tibet. The survey collected detailed information on respondents' health status, family structure, social background, and economic conditions.

Ethical Considerations

The study of the CLASS database was approved by the ethics committee at the Capital University of Physical Education and Sport (ChiCTR-IOR-ChiCTR2200063177). All participants provided informed consent before, and for individuals with limited literacy skills, consent was obtained from their legally authorized representatives. Participants were informed of the study purpose and their right to withdraw at any time. All data were deidentified, stored securely, and accessible only to authorized research team members to ensure privacy and confidentiality. No financial compensation was provided, and the study involved minimal risk.

Survey Procedures

Data collection for the CLASS project was carried out using the China Social Survey Network. The survey used a stratified, multistage probability sampling method. County-level regions, including counties, county-level cities, and districts, were selected as primary sampling units. Villages and neighborhood committees served as secondary sampling units. With each secondary sampling unit, sample households were randomly selected, and 1 eligible older adult was interviewed per household. Data were collected through structured interviews and standardized questionnaires. To ensure data quality, on-site supervision and call-backs were employed as part of the quality control measures implemented by CLASS.

Variables

The dependent variable was older adults' overall health status, proxied by SRH using 3 items: current SRH (respondents rate their present health status, scores of 0 - 5), SRH relative to age peers (scores of 0 - 5), and SRH relative to last year (scores of 0 - 3). Item scores were summed (range 3 - 13), with higher scores indicating better overall health.

Independent variables included measures of digital inclusion and active aging indicators. Digital inclusion comprised 3 dimensions as follows:

- Digital access: This dimension reported whether the respondent could connect to the internet via available infrastructure and devices, measured by three items—network availability at the dwelling; current internet use; and ability to access the internet via a mobile phone, tablet, or computer. Summed scores reflected overall access, with higher scores indicating greater access.
- Device proficiency: This dimension reported self-rated proficiency in operating devices such as mobile phones and tablets, rated from 1 ("very unskilled") to 5 ("very skilled"). Higher summed scores indicated stronger digital skills.
- Digital ability: This dimension reported the performance of 11 common online activities (eg, voice or video chat, SMS text messaging, online shopping, and reading news), each scored from 0 to 1. Total scores (range 0 - 11) reflected functional digital competence.

Active aging comprises health, engagement, and security; because security is primarily a macro-level construct [29], this study focused on individual-level with health and engagement. Social engagement included 3 components as follows:

- Social support and network: This component was a six-item scale measuring (1) the number of family or relatives contacted or met at least monthly, (2) the number of family or relatives with whom one can confidently discuss private matters, (3) the number of family or relatives available to help when needed, and (4-6) the same three items for friends. Each item was scored from 0 to 5; total scores ranged from 0 to 30, with higher scores indicating stronger support and denser network.
- Activity participation frequency: This component measured involvement in 7 community or voluntary activities (community patrols, caring for older adults or children, environmental protection, dispute mediation, companion chatting, professional volunteering, and caring for the next generation). Each item was scored from 0 to 4 (0="never" to 4="almost daily"); total scores ranged from 0 to 28.
- Nononline activities: This component measured participation in 6 offline activities (religious activities; senior college or training courses; watching television, listening to the radio, reading newspapers or books, or watching an opera; singing or playing instruments; mahjong, chess, or cards; and square dancing). Each item was scored from 0 to 4; total scores ranged from 0 to 24, with higher scores indicating greater offline engagement.

Mental health included 3 measures as follows:

- Depressive symptoms: This component was measured using the 9-item short form of the Center for Epidemiologic Studies Depression Scale [30]. Items were scored from 1 to 3 (1="no," 2="sometimes," and 3="often"). Except for items 1, 4, and 9, all items were reverse-scored, producing a total score that ranged from 9 to 27, with higher scores indicating fewer depressive symptoms.
- Social adaptation: This component was measured using 8 items (eg, willingness to participate in village or neighborhood committee work, desire to contribute to society again, current enjoyment of learning, feeling useful to society, difficulty adapting to rapid social change, difficulty accepting more viewpoints, difficulty accepting new social policies, and perception that social change is increasingly unfavorable to older adults). Items were scored from 1 to 5 (1="strongly disagree" to 5="strongly agree"); total scores range from 8 to 40, with higher scores indicating better adaptation.

XSL•FO
RenderX

- Life satisfaction: This was a single global item measuring overall life satisfaction (1="very dissatisfied" to 5="very satisfied").

Following prior studies [18,31], this study included a set of covariates to control for demographic and health-related factors, including age, sex, educational level, marital status, number of coresidents, household registration (*hukou*), chronic disease (yes or no), and current employment status (yes or no). Functional status measures included as follows:

1. Activities of daily living (ADL): 11 items scored from 1 to 3 (1="independent," 2="needs some help," and 3="unable"); total scores ranged from 11 to 33.
2. Instrumental activities of daily living: 9 items scored from 1 to 3 (same as ADL); total scores range from 9 to 27, where lower scores indicated better instrumental functioning.

Statistical Analysis

Power

Data were curated in SPSS version 26.0 (IBM Corp). We conducted descriptive analyses, chi-square tests, correlation analyses, and multivariable hierarchical regression. Structural equation modeling (SEM) was specified in AMOS version 28.0 (IBM Corp); model fit was evaluated and modified as appropriate. It also compared pathways by which digital inclusion, social engagement, and mental health influence older adults' overall health status. Statistical significance was set at a 2-sided α of .05.

Data Exclusion

The 2023 CLASS dataset contains 11,670 valid cases. Based on the requirements of the research design, variables unrelated to the study aims were excluded, and missing data were processed accordingly. A final analytic sample of 9918 respondents was obtained.

Results

Descriptive Analysis

Table 1 showed significant differences in SRH across all demographic groups (P<.001). Younger respondents and those with higher education, smaller household sizes, nonrural *hukou*, absence of chronic diseases, and current employment all reported higher SRH. Men also showed slightly better SRH than women. Overall, health status was consistently better among individuals with greater socioeconomic resources and fewer health limitations (Figure 1).

Figure 1. Data exclusion flowchart.

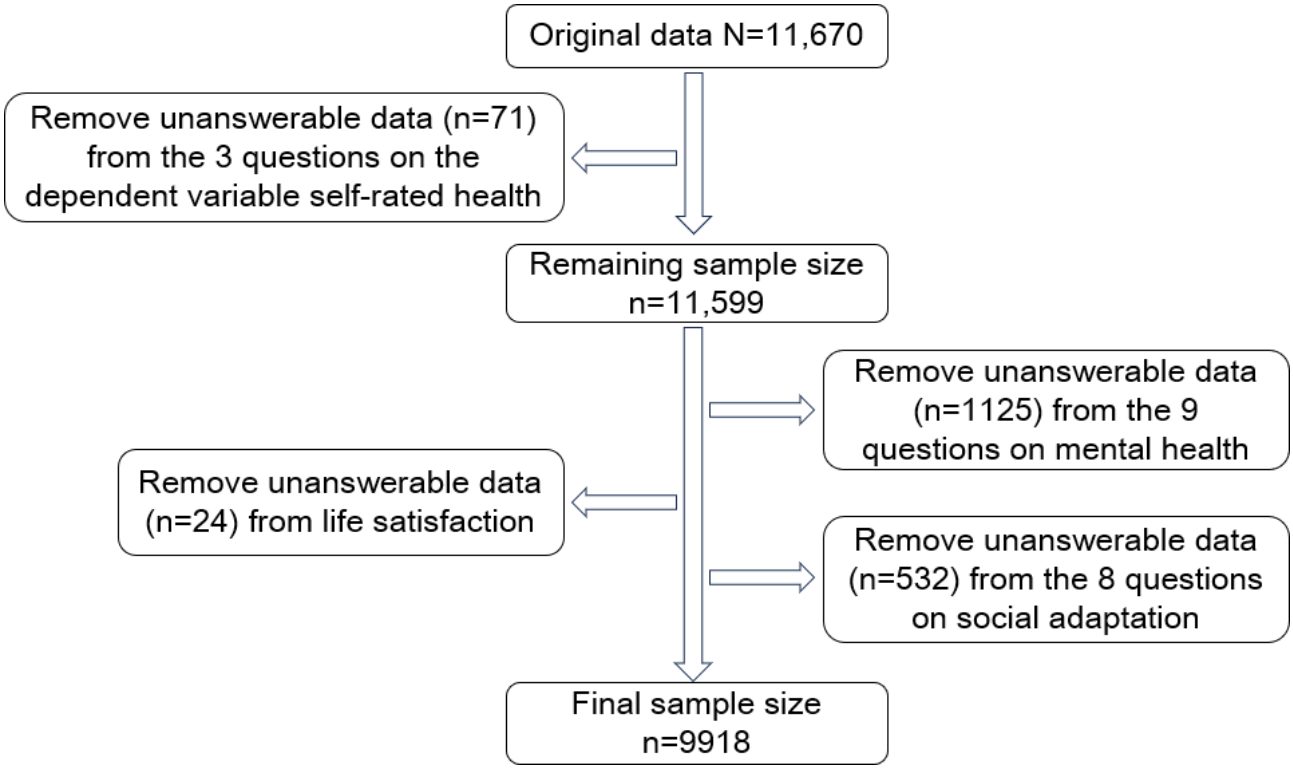

Table 2 presented descriptive statistics for the main study variables. Mean ADL and instrumental activities of daily living scores were 11.38 and 9.58, respectively. SRH measures (3.59, 3.23, and 1.92) showed moderate levels of perceived current and comparative health. Digital inclusion indicators (access, proficiency, and ability) displayed relatively low mean scores with wide variability. Social engagement levels were modest overall, while social support was relatively higher. Mental health indicators showed moderate depressive symptoms, average social adaptation, and relatively high life satisfaction.

[e]Higher scores indicate fewer depressive symptoms (lower depressive tendency).

Results of Regression Analysis

Table 3 presented the hierarchical regression results for overall health. Model 1, which included demographic and baseline health variables, explained 16.4% of the variance in overall health (ΔR^2=0.164). Older age, being unmarried, larger household size, poorer functional status, and having chronic conditions were all negatively associated with health, whereas higher education and being employed showed positive associations. Model 2 added digital inclusion variables and modestly increased explanatory power (ΔR^2=0.173). Digital proficiency and digital ability—rather than mere access—were positively associated with better perceived health. Model 3 incorporated social engagement indicators but did not meaningfully improve model fit (ΔR^2 unchanged). Model 4 added mental health variables and substantially increased explanatory power to 29.4% (ΔR^2=0.294). Lower depressive symptoms, higher life satisfaction, and better social adaptation emerged as strong predictors of overall health.

To verify the robustness of the baseline regression results, a sensitivity analysis was also conducted. As some areas may introduce bias to the estimated digital inclusion effects, respondents from 3 regions with the highest levels of internet development during the survey period (Guangdong, Shanghai, and Beijing) were excluded. Using the remaining sample, we re-estimated the pathway linking digital inclusion, social engagement, mental health, and overall health. The results of the revised model were highly consistent with models in Table 3, indicating strong robustness of the estimated relationships (Table 4).

SEM Analysis Outcomes

Figure 2 showed that the structural equation model identified multiple significant pathways linking digital inclusion, social engagement, mental health, and overall health status. Digital inclusion strongly predicted social engagement (β=.45) and influenced overall health indirectly through its effects on engagement and, subsequently, mental health. Although the direct path from social engagement to overall health was negligible (β=.01), its effect on mental health was significant (β=.04). Mental health had the strongest predictive power in the model (β=.74). Surprisingly, digital inclusion had a small negative direct effect on overall health (β=–0.15), although the indirect pathways through engagement and mental health were positive. Model fit indices indicated acceptable fit (goodness-of-fit index=0.956, adjusted goodness-of-fit index=0.931, and root mean square error of approximation=0.073).

Figure 2. Structural equation model linking digital inclusion, social engagement, mental health, and overall health status. DF: degree of freedom; GFI: goodness-of-fit index; AGFI: adjusted goodness-of-fit index; RMSEA: root mean square error of approximation; SRH: self-rated health.

Discussion

Principal Results

This study elucidated how demographic characteristics, digital inclusion, and social engagement and mental health jointly shape older adults' perceptions of overall health. First, results showed that advancing age, chronic disease burden, and functional limitations were associated with poorer SRH, consistent with longitudinal evidence from multiple countries. Specifically, SRH declines with age—likely reflecting physiological deterioration, cumulative adverse life events, and shifting social roles—and age is a robust predictor of SRH among older adults [32]. Chronic diseases also weakened perceived overall health, reinforcing findings that multimorbidity served as a risk factor for poor SRH [33]. Internationally, analyses using the Health and Retirement Study (HRS) and the English Longitudinal Study of Ageing (ELSA) showed that a higher number of conditions was tightly linked to lower SRH, even after psychological factors were considered [34]. Functional limitations further depressed health perceptions from a capability standpoint. By contrast, higher educational attainment and current employment operated as stable protective factors, suggesting that education22 and work [22] not only improved health literacy and economic resources but also expanded social support networks that buffer the health costs of aging. These associations aligned with cumulative advantage theory and underscore how late-life health inequalities reflect long-term disparities in socioeconomic and social resource accumulation.

Second, the findings clarified the mechanism of digital inclusion as one of "limited direct effects but substantial indirect effects." Despite high factor loadings for digital access, device proficiency, and digital ability—and a clear positive effect of digital inclusion on social engagement—digital inclusion did not directly translate into better overall health. This mirrors evidence that where uptake of digital health services (eg, teleconsultation and health management apps) remains modest, digital skills training without integrated health education or health intervention yields limited direct health gains. Survey of Health, Ageing and Retirement in Europe (SHARE) data indicated that internet use had only a weak direct association with SRH. Its benefits are realized mainly through enhanced social connectedness and life satisfaction [35]. US studies similarly suggested that digital technology improved health indirectly via enriched social interaction, greater information access, and increased cognitive stimulation. Moreover, internet use benefited older adults' mental health, with social capital partially mediating the effect [36]. In China, a persistent digital divide, especially in rural and low-education groups, further dampened any direct health effect [37].

What was notable in this study was the negative direct path from digital inclusion to overall health. This may reflect information overload, increased exposure to health misinformation [16], health perfectionism, driven social comparison, and health anxiety, all of which may exacerbate anxiety and offset positive spillovers transmitted through social engagement and mental health [25]. These findings emphasize that digitalization is not inherently health-promoting, while

XSL•FO
RenderX

containing both enabling and burdensome properties. Policy should therefore prioritize not only access but also content quality, digital safety, and age-friendly platform design, embedding digital literacy within broader behavioral and psychosocial intervention strategies to unlock the genuine health-promoting potential of digital inclusion.

Third, the study verified that social engagement mediated between digital inclusion and perceived health, while mental health was the core bridging mechanism. This underscores the pivotal role of mental health in shaping health perceptions. The mechanism suggested is that positive experiences derived from social support, activity participation, and social interaction are re-processed psychologically—via reduced depressive symptoms, greater social adaptation, and higher life satisfaction—before they translate into better SRH. Thus, social engagement serves as an upstream facilitator of psychological well-being, whereas mental health functions as the final common pathway through which digital inclusion affects overall health.

This mechanism accorded with the WHO Active Ageing chain of "social connectedness → mental health → overall health" [38] and was supported by diverse empirical evidence. For example, the longitudinal Chinese Longitudinal Healthy Longevity Survey showed that the lack of participation predicted declines in mental health, whereas active participation was linked to better psychological well-being [10]; leisure-oriented participation could improve mental health broadly and significantly [39]. Additionally, the Australian Longitudinal Study on Women's Health found that persistent or rising loneliness was closely tied to deterioration in mental health–related quality of life, highlighting the long-term protective value of social ties [40]. Korean aging panel studies showed that multimorbidity and disability depressed SRH, whereas social engagement partially mitigated these effects through psychological pathways [41]. In rural China, research on "empty-nest" older adults indicated that internet use directly raised life satisfaction and indirectly improved mental health by boosting participation, thereby further elevating health perceptions [42]. Moreover, a recent cross-national systematic review of digital interventions (randomized controlled trials) showed that online socialization and digital interaction significantly reduced loneliness and depressive symptoms, indirectly enhancing subjective health and life satisfaction [25]. These findings indicated that the dual mediation of social engagement and mental health is the key mechanism through which digital inclusion delivers health benefits.

Although the SEM results revealed significant links among digital inclusion, social engagement, mental health, and SRH, these pathways should not be interpreted as causal. The cross-sectional design prevents verification of temporal ordering, and reverse or bidirectional influences remain possible—for example, older adults with better health or stronger social ties may be more inclined to adopt digital technologies. Unobserved factors, such as cognitive status or personality traits, may also contribute to the associations observed. Thus, the mediation pathways identified here reflect theoretical plausibility rather than confirmed causal processes. Longitudinal analyses using future waves of CLASS will be necessary to assess whether these mechanisms hold over time.

Finally, the study revealed cross-national differences. Compared with high-income Western settings, the health benefits of digital inclusion among Chinese older adults relied more on indirect pathways (via social engagement and mental health) than on direct effects. Variations in social structure, welfare systems, and digital health ecosystem maturity likely contribute to these differences. In Europe and North America, digital tools were more deeply embedded in daily life and were closely integrated with community health services, social welfare, and family care, forming a "digital + in-person" support network that yielded more immediate perceived health gains [27]. In China, limited penetration of digital health services, uneven distribution of community digital resources, and the predominance of offline group activities among older adults meant that participation—although beneficial for mental health—had weaker direct links to concrete health behaviors (eg, screening, exercise, and self-management) [43]. Gaps also remained in the availability and quality of mental health services. Although mental health sat at the center of the causal chain, under-identification of emotional disorders in community settings and limited access to age-appropriate professional interventions likely attenuated its potential health benefits. By contrast, many high-income countries have embedded mental health supports within primary care and community systems, amplifying the health gains from both participation and digital technology.

Limitations

This study had several limitations. First, SRH was a subjective measure without objective clinical or biomarker data. As it was susceptible to cognitive frames and momentary affect, potentially biasing associations and attenuating the precision of mediation estimates among digital inclusion, social engagement, and mental health. Second, the negative direct effect of digital inclusion on SRH may partly reflect perceptual or cognitive mechanisms—such as upward social comparison, exposure to idealized health information online, or heightened health anxiety—rather than a true adverse effect of digital engagement. This analysis was unable to fully disentangle these psychological influences from structural digital factors. Third, this study relied on cross-sectional data; thus, the directionality of associations cannot be conclusively established. The mediation effects suggested by SEM may partially reflect reverse causality or unmeasured confounding. Future research using multiwave CLASS data will allow for longitudinal validation of these mechanisms and more rigorous evaluations of causal ordering.

Implications

On the basis of these findings, several implications emerge for policy, practice, and the design of future interventions. First, digital inclusion initiatives must extend beyond access provision to emphasize skills, usability, and sustained engagement, particularly for rural, low-education, and less digitally confident older adults. Integrating digital literacy with health education and psychosocial support may help ensure that digital engagement translates into meaningful health benefits rather than information overload or anxiety. Second, expanding opportunities for diverse and age-appropriate social

XSL•FO
RenderX

participation—both online and offline—is essential, as participation serves as an upstream determinant of psychological well-being and a conduit through which digital inclusion exerts its influence on health. Community organizations, social service agencies, and primary care institutions should co-develop engagement platforms that are socially meaningful, culturally appropriate, and accessible to older adults with varying functional capacities.

Conclusions

This study shows that digital inclusion shapes older adults' health perceptions primarily through indirect pathways, operating first by enhancing social engagement and subsequently by improving mental health. While demographic and health-related vulnerabilities such as aging, chronic diseases, and functional limitations remain dominant predictors of poorer SRH, digital competence and meaningful participation represent actionable levers that can mitigate health disadvantages in later life. Mental health emerged as the pivotal link in the causal chain, underscoring the need to position psychological well-being at the center of healthy aging strategies. These findings highlight the importance of moving beyond infrastructure-focused digital policies to approaches that build skills, support sustained social participation, and integrate mental health services within both community and digital ecosystems. As population aging and digital transformation continue to accelerate, coordinated interventions that align technological, social, and psychological resources will be essential for promoting active, equitable, and healthy aging.

Abstract

Background: Internet use may support cognitive health in aging populations, but the digital divide in access and use might worsen inequalities.

Objective: This study aimed to examine whether internet use mediates the long-term relationship between broadband access and cognitive function among middle-aged and older adults in China.

Methods: Using 3-wave data (2015 - 2020) from the China Health and Retirement Longitudinal Study (N=6063), we applied parallel-process latent growth curve models to analyze trajectories of broadband access, internet use, and general cognition, adjusting for sociodemographic and time-varying covariates.

Results: Baseline broadband access predicted initial internet use (β=0.453; *P*<.001), and broadband access increases strongly forecasted rises in internet use (β=0.625; *P*<.001). Increased internet use was associated with improved baseline general cognition (β=0.470; *P*<.001) and more significant cognitive improvements over time (β=0.444; *P*=.006). Older age, lower educational level, and rural residence were correlated with lower initial digital engagement; however, participants from rural areas demonstrated a greater adoption rate. Health status and social activities initially positively influenced outcomes; however, their impact diminished by the final wave.

Conclusions: These findings demonstrate that internet use mediates the longitudinal relationship between broadband access and cognitive resilience. The observed cascading growth trajectories suggest that gradually bridging the digital divide may help mitigate cognitive decline.

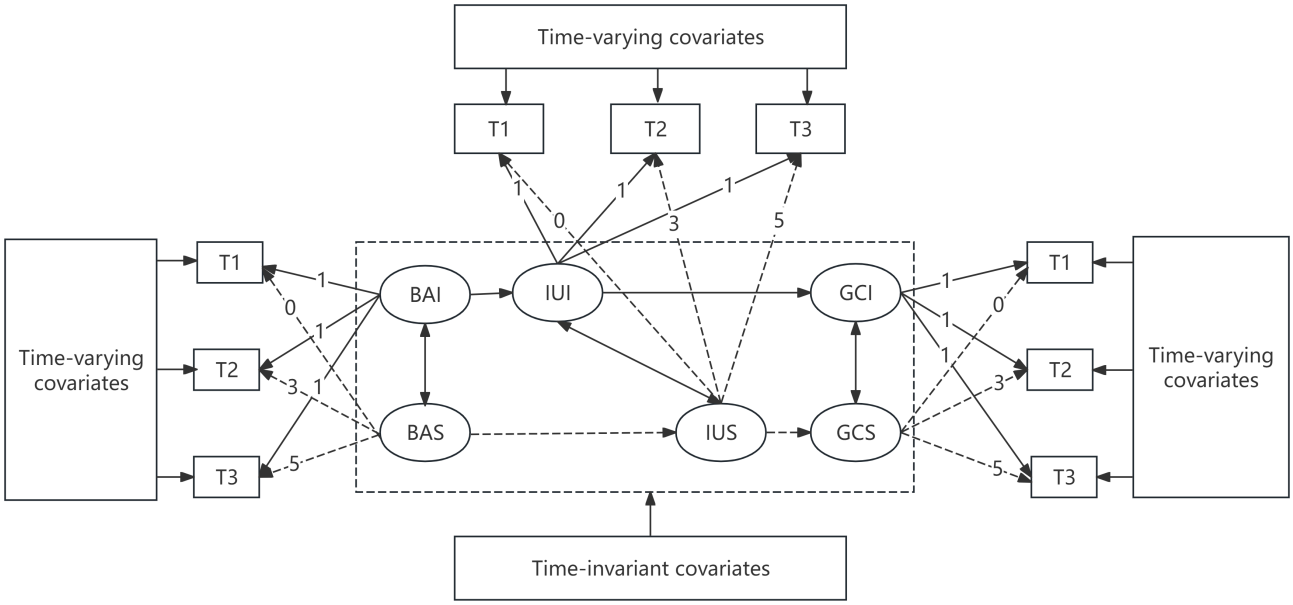
Introduction

In the digital age, the internet is essential for accessing information, maintaining social connections, and managing daily tasks [1]. Approximately 2.6 billion people worldwide (32% of the population) remain offline as of 2024 [2]. The benefits of digital innovation are unevenly distributed, leading to a persistent "digital divide" [3]. The definition of "digital divide" has shifted from a simple binary notion of connectivity in the 1990s [4] to a 3-level framework of coverage and access, use, and real-world consequences [5,6], with significant effects on individual health and societal well-being [7,8].

Cognitive decline is one of the most substantial challenges faced by the older adult population in health and social care systems [9]. Cognitive decline, which can start as early as the age of 45 years [10], is a significant risk factor for disability, dementia, and death [11-13]. A notable increase in cognitive decline after the age of 65 years has been documented [14]. China, with the world's largest older adult population, faces an increasing challenge: almost 20% of adults aged >60 years have mild cognitive impairment, with 6% developing dementia each year [15-18].

Since 2015, China's Internet Plus initiative has rapidly improved digital infrastructure, especially broadband access [19,20]. Despite this progress, age remains a significant factor of inequality: older adults, particularly those living in rural areas, with less education, or lacking digital skills, often face exclusion from meaningful internet use [21-23]. A 2024 cohort study in Beijing revealed that nearly half of older adults experience an "internet use divide," which correlates with reduced processing speed and overall cognitive performance [24].



XSL•FO
RenderX

This challenge aligns with a vital global goal: the United Nations Decade of Healthy Ageing (2021 - 2030) [25]. The first progress report [26] highlights that, although many countries, including China, have developed laws and infrastructure for age-friendly environments, more than two-thirds still lack sufficient resources to fully implement their action plans. This problem is especially severe in low- and middle-income areas, where nearly 80% of the world's older adults are expected to live by 2050 [26,27]. The World Bank states that increasing access alone is insufficient to bridge the digital divide as technological progress may exclude the targeted populations [28]. Therefore, digital inclusion should be regarded as an ongoing process incorporated into age-inclusive communities and an essential component of healthy aging [29].

Empirical studies increasingly suggest that internet use—not merely access—is an active factor influencing cognitive outcomes in later stages of life. An ecological analysis found that higher broadband coverage correlates with lower prevalence of cognitive disorders, suggesting that digital infrastructure may help mitigate cognitive health disparities among older adults [30]. However, broadband access is commonly associated with an area's economic resources, enabling internet use and social interactions. For instance, one longitudinal study in Europe found that older adults who regularly used the internet exhibited slower cognitive decline over 2 years independent of baseline connectivity [31]. Similarly, research using nationally representative data from the United States demonstrated that changes in internet use had asymmetric effects on cognitive decline in older adults: initiating use slowed decline, whereas discontinuing use accelerated it [32]. Further supporting this distinction, another investigation using data from the China Family Panel Study found that the frequency and variety of internet activities positively contributed to cognitive functions [33]. These findings align with 2 complementary theoretical perspectives. First, a widely cited model of digital inequality posits that material access to technology constitutes only the initial layer of inclusion; its benefits emerge only when individuals acquire the skills, motivation, and opportunities to engage meaningfully with digital tools [5]. Second, the cognitive reserve hypothesis proposes that participation in cognitively stimulating activities builds neural resilience against age-related cognitive decline [34]. Thus, internet use—as a dynamic, interactive, and often socially embedded behavior—may serve as the behavioral bridge through which structural access translates into sustained cognitive benefit.

We hypothesize that internet use mediates the longitudinal association between household broadband access and cognitive function among middle-aged and older adults in China such that growth in access predicts increased use, which in turn predicts more favorable cognitive trajectories over time as shown in Figure 1. However, most existing research examines only isolated links. These include the relationships between broadband access and cognitive outcomes, and between technology use patterns and cognitive development. Most of this research relies on cross-sectional data. Few studies use longitudinal designs capable of modeling how disparities in digital infrastructure spread through behavior to affect cognitive aging. Using China's rapid digitization and population aging as a natural experiment, this study applied parallel-process latent growth curve modeling (PP-LGCM) with nationally representative panel data to estimate trajectories of broadband access, internet use, and general cognition simultaneously and test whether internet use changes mediate the relationship between digital infrastructure and cognitive outcomes among middle-aged and older Chinese adults.

Figure 1. The hypothesized model of the digital divide across 3 waves. In this model, intercept factors—broadband access intercept (BAI), internet use intercept (IUI), and general cognition intercept (GCI)—capture baseline levels of broadband access, internet use, and cognitive function, respectively. Slope factors—broadband access slope (BAS), internet use slope (IUS), and general cognition slope (GCS)—represent the rates of change in these outcomes over time. T1: 2015; T2: 2018; T3: 2020.

Methods

Ethical Considerations

This study conducted a secondary analysis of deidentified, publicly available China Health and Retirement Longitudinal Study (CHARLS) data, exempt from additional ethics review. The original CHARLS was approved by Peking University's Biomedical Ethics Review Committee (IRB00001052-11015), obtained written informed consent from all participants, and complied with the Declaration of Helsinki and China's Personal Information Protection Law. All procedures adhere to CHARLS protocols.

Participants

Participants were enrolled in 3 follow-ups of the CHARLS from 2015 to 2020. It is a nationally representative sample of the middle-aged and older adult population (aged ≥45 years) in China, a community-based longitudinal study conducted by the China Center for Economic Research at Peking University [35]. The CHARLS used a multistage, probability proportional to size sampling technique to select participants. The primary sampling units were administrative villages in rural areas and urban neighborhoods. The CHARLS data can be accessed through its official website [36]. It is designed to better understand the socioeconomic determinants and consequences of aging.

Data were drawn from 3 waves (2015 [T1], 2018 [T2], and 2020 [T3]) of the CHARLS. The baseline cohort included 23,459 participants. Of these 23,459 participants, we excluded individuals aged <45 years or >100 years and those with household consumption per capita equal to 0 at baseline (n=10,026, 42.7%), yielding 13,433 (57.3%) eligible respondents. From this group, we further excluded those with missing data on broadband access, internet use, or cognitive function (362/13,433, 2.7%) and those with a total cognitive score of 0 (143/13,433, 1.1%). An additional 1.1% (153/13,433) of the participants were excluded due to missing values for key time-invariant covariates (employment status, self-rated health, or household consumption per capita) at baseline. Of the remaining 12,775 participants with at least one valid cognitive measure, 6712 (52.5%) were lost to follow-up across the 3 waves, resulting in a final analytical sample of 6063 (47.5%) participants with sufficient longitudinal data for modeling.

Measurements

Dependent Variables

Cognitive function assessment tools included an adapted Chinese version of the Mini-Mental State Examination [37]. Four specific dimensions were assessed at each wave: orientation, episodic memory, calculation ability, and constructability. Orientation was measured by naming the date (day, month, season, and year) and day of the week (score range 0-5). For episodic memory, participants were first asked to immediately repeat as many as possible of 10 Chinese nouns that were read to them and then to recall the same list 5 minutes later (score range 0-10). Calculation ability was evaluated using the serial sevens subtraction task, which required participants to subtract 7 from 100 and continue subtracting 7 from each subsequent number 5 times (score range 0-5). Constructability was evaluated through a drawing task that assesses visuospatial skills and motor coordination (score range 0-1). General cognition was the sum of cognitive scores (range 0-21) [14] and was considered the digital outcome.

Independent and Mediating Variables

The primary independent variable was household broadband access. The digital divide was operationalized using 2 indicators aligned with the multilevel model by van Deursen and van Dijk [5] and Scheerder et al [38], measured using the question "Does your residence have a broadband internet connection?" (yes=1; no=0). The mediating variable was internet use, measured using the question "Have you accessed the Internet in the past month?" (yes=1; no=0).

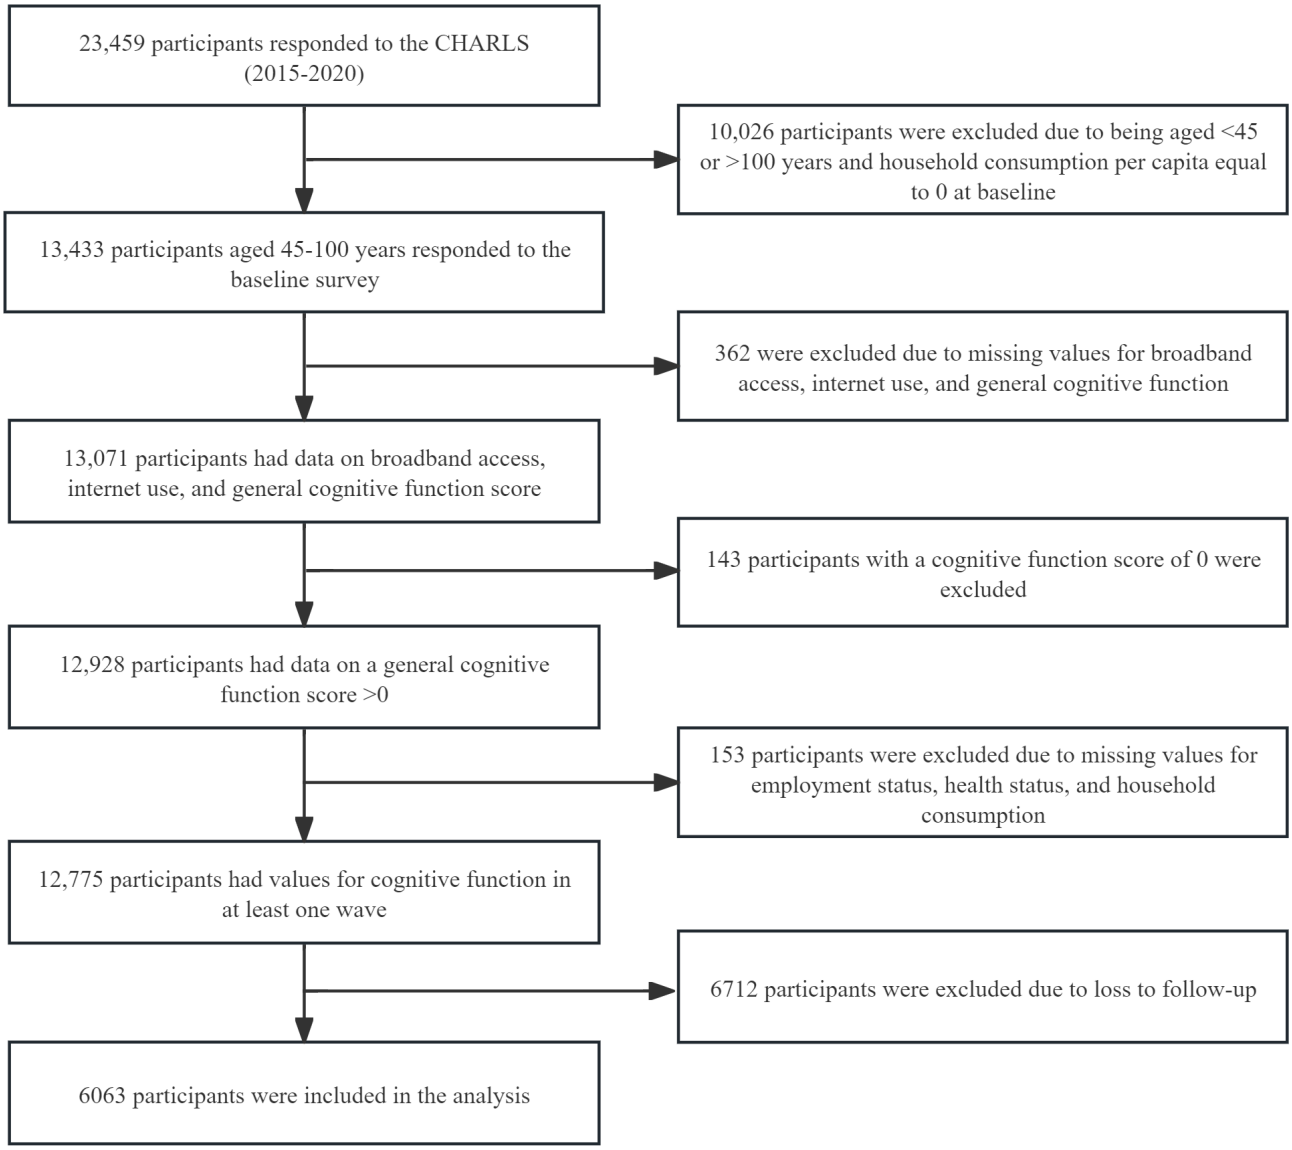
Covariates

There were time-invariant sociodemographic factors (age, sex, educational level, rural residence, marital status, and household consumption per capita) and time-varying characteristics (self-rated health, social activity participation, and employment status) included, all measured at each wave.

Statistical Analysis

R (version 4.1.0; R Foundation for Statistical Computing) was used for the purposes of descriptive and correlational analyses. Descriptive statistics were used to summarize the characteristics of the participants, specifically frequencies with percentages for categorical variables and medians with IQRs for continuous variables. The *lavaan* package in R was used to perform structural equation modeling. PP-LGCM was implemented to investigate the cascading effects of digital divides on trajectories of cognitive function. For each domain, the baseline level (intercept) and the rate of change over time (slope) were modeled [39]. The cascade effect framework suggests that broadband access influences internet use, which subsequently affects the intercepts and slopes of cognitive function. Full information maximum likelihood was applied to address missing data by leveraging all available information from each participant. The following fit indexes were evaluated: the comparative fit index (CFI), Tucker-Lewis index (TLI), root mean square error of approximation (RMSEA), and standardized root mean square residual (SRMR). Conventional thresholds stipulate that CFI and TLI values above 0.90 are acceptable, with values exceeding 0.95 indicating a good fit. For RMSEA and SRMR, values below 0.05 indicate a good fit, whereas values between 0.05 and 0.08 are acceptable [40]. In the conditional latent growth curve modeling and PP-LGCM analyses, demographic variables were incorporated as covariates.

Results



Descriptive Statistics

A total of 6063 Chinese middle-aged and older adults were included in this study (Figure 2). Table 1 shows significant sociodemographic disparities in digital access and use. Individuals with broadband access and internet use were significantly younger, more educated, and more likely to reside in urban areas; reported better health; engaged in social

XSL•FO
RenderX

activities; and had a higher household consumption (P<.001 in all cases). Men were more likely to be internet users (P<.001) but not among broadband owners (P=.79). Marital status and employment status showed minimal or no association with internet use (P=.10 and P=.29, respectively), although both differed slightly by broadband subscription (P<.001). Those who had broadband access and internet use also exhibited significantly higher cognitive function scores (median 15.5, IQR 14.5-16.5 vs median 12.5, IQR 10-14.5; P<.001), although the difference for broadband access was less pronounced (median 14.0, IQR 12-15.5 vs median 12.5, IQR 9.5-14.5; P<.001).

Bivariate Correlations Regarding the Digital Divide

The correlation matrix presented in Table 2 delineates the relationships among broadband access, internet use, and general cognition at 3 distinct time points. The findings demonstrate moderate stability within each construct over time, with autocorrelation coefficients ranging from 0.30 to 0.62. Conversely, cross-construct correlations were consistently weaker, typically below 0.40, thereby providing evidence of adequate discriminant validity among the constructs. This pattern of associations indicates that the 3 constructs may be

XSL•FO
RenderX

validly treated as separate latent variables in longitudinal modeling, such as latent growth curve analyses.

Conditional Latent Growth Curve Models for Each Element of the Digital Divide

The fit indexes presented in Table 3 strongly support the measurement models for each domain. Overall, these results indicate that the latent construct representations were adequate over time, confirming the validity of the developmental trajectories studied.

Table 4 shows that sociodemographic factors influenced initial levels and changes over time in broadband access, internet use, and cognitive function. Older age correlated with lower baseline levels (β=–0.327 to –0.144) and slower growth in internet use (β=–0.356) and general cognition (β=–0.151). Male individuals reported slightly less broadband access (β=–0.032) but higher baseline internet use and general cognition (β=0.107), with steeper declines over time (β=–0.152 and –0.160). Higher educational level boosted initial general cognition (β=0.518) but predicted slower growth in internet use (β=–0.332) and slightly faster cognitive gains (β=0.123). Rural residents started lower (eg, broadband; β=–0.220) but showed accelerated growth in broadband access (β=0.170) and internet use (β=0.202). Health status and social activity predicted higher levels of digital inclusion early on. For example, at T2, better health status was associated with greater broadband access (β=0.066), increased internet use (β=0.081), and higher general cognition scores (β=0.039). Social activity demonstrated a stronger link

XSL•FO
RenderX

specifically with internet use (β=0.122). By T3, these effects were weakened. Employment status reduced broadband access (β=–0.062 to –0.041 across waves) but had minimal impact on internet use and a small positive association with general cognition (β=0.034 at T3).

Table . Model fit indexes for conditional latent growth curve models.

Variable	Chi-square (*df*)	CFI[a]	TLI[b]	RMSEA[c]
Broadband access	93.0 (24)	0.973	0.997	0.020
Internet use	115.3 (24)	0.931	0.991	0.024

PP-LGCM Model for the Digital Divide

The PP-LGCM model demonstrated an excellent fit (χ^2_{97}=335.1; *P*<.001; CFI=0.976; TLI=0.991; RMSEA=0.020; SRMR=0.026). This finding revealed a significant mediating pathway connecting broadband access to cognitive function through internet use, as illustrated in Table 5 and Figure 3. Consistent with our hypothesized cascade model, baseline broadband access strongly predicted initial internet use (β=0.453; *P*<.001), and increases in broadband access over time forecasted steeper growth in internet use (β=0.625; *P*<.001). In turn, higher baseline internet use was associated with better initial cognition (β=0.470; *P*<.001), and greater increases in use were associated with slower cognitive decline (β=0.444;

XSL•FO
RenderX

P=.006). Although older age, lower educational level, and rural residence were associated with lower initial digital engagement, rural participants exhibited significantly faster adoption rates (broadband slope: β=0.163; internet slope: β=0.102; *P*=.10), suggesting a partial narrowing of the use gap. Educational level boosted broadband access (β=0.238), internet use (β=0.337), and general cognition (β=0.299; *P*<.001 in all cases); and older age negatively affected broadband access (β=–0.324) and internet use (β=–0.167; *P*<.001 in both cases) and slowed internet use growth (β=–0.338; *P*<.001), with no significant impact on cognitive slope. Men reported higher baseline internet use (β=0.119; *P*<.001) and general cognition (β=0.071; *P*<.001), although they experienced steeper declines in internet use over time (β=–0.149; *P*=.02). Household consumption predicted higher baseline broadband access (β=0.203) and internet use (β=0.116; *P*<.001 in both cases) but was negatively related to their slopes. Social activity had a consistent association with internet use, with β coefficients of 0.117 at T1, 0.122 at T2, and 0.109 at T3. Furthermore, it positively predicted cognitive function (β=0.037 at T1, β=0.040 at T2, and β=0.035 at T3). Health status demonstrated a positive relationship with both internet use and cognition at T1 and T2; however, this association did not persist at T3. Employment displayed a negative correlation with broadband access across all waves (β=–0.062 at T1, β=–0.073 at T2, and β=–0.041 at T3), indicating lower adoption rates among employed individuals. Its influence on cognition remained negligible.

Figure 3. Digital divide in cognitive function using parallel-process latent growth curve modeling. For latent variables, solid lines denote intercept relationships, while dashed lines represent slope relationships. Numerical values indicate loadings from latent variables to items. For regressions of sociodemographic variables, solid lines denote statistically significant paths with |β| ≥0.20; dotted lines denote statistically significant paths with |β| <0.20; nonsignificant paths are omitted. All the coefficients are standardized. ***P<.001; **P<.01; *P<.05; BAI: broadband access intercept; BAS: broadband access slope; GCI: general cognition intercept; GCS: general cognition slope; IUI: internet use intercept; IUS: internet use slope; T1: 2015; T2: 2018; T3: 2020.

Discussion

Principal Results

The findings of this study demonstrated that the cascading potential influence of household broadband access predicts internet use and subsequent codevelopment of this prediction, both of which are associated with a possible slower decline in cognitive trajectories among middle-aged and older Chinese adults. The PP-LGCM model confirmed the 3-level digital divide framework and extends the perspective from static views to a process-based approach, emphasizing how disparities in infrastructure could influence actual internet use and cognitive aging through codevelopmental pathways. Our findings substantially enhance the discussion of digital inclusion as a vital component of healthy aging, emphasizing the importance of not only physical access but also creating supportive environments that enable older adults to thrive.

This aligns with the first progress report of the United Nations Decade of Healthy Ageing, which underscores the vital role of digital engagement in sustaining intrinsic capacity in later life [26]. The report cautions that, despite investments in connectivity, the resources for engagement remain insufficient, especially among older adults in low- and middle-income countries. Van Dijk [41] similarly argues that access alone is insufficient; individuals require motivation, digital skills, and supportive opportunities to translate connectivity into benefit. Our results support this view: China's infrastructure expansion from 2015 to 2020 narrowed the rural-urban gap in broadband access, yet this did not translate into comparable gains in internet use or cognitive outcomes among rural respondents. Early advantages among urban and highly educated individuals likely reflect the Matthew effect [42,43], in which initial resources accumulate over time. However, what appears to be a cumulative advantage may stem from persistent conversion gaps [44,45]: the failure to translate access into meaningful use, especially in mid to late life, when cognitive resilience is more vulnerable [46,47].

Moreover, the association between internet use and cognitive resilience is plausibly mediated by neurocognitive mechanisms aligned with the cognitive reserve hypothesis [48,49]. Internet use is positively associated with cognitive stimulation and cognitive reserve [50,51]. Activities such as seeking health information, comparing services, or navigating digital interfaces engage executive functions, working memory, and attention [52,53]. Social relationship factors are correlated with cognitive

XSL•FO
RenderX

function and its decline, and engaging in social activities via calls or messaging may reduce social isolation, which is identified as a risk factor for cognitive decline [54,55]. The internet offers problem-solving opportunities through online tasks such as navigating websites, managing banking, or learning, which demand cognitive effort and decision-making, helping maintain mental agility [56] and thereby stimulating cognitive abilities [57]. Although our binary measure of internet use limits granularity, the findings are consistent with those of research linking online behaviors to delayed recall and processing speed [58], indicating that continuous engagement activates these neural pathways [59].

Structural inequalities shape both digital and cognitive trajectories [60]. Age is a predictor of disadvantage [23,43]: older adults tend to have less broadband access, lower internet use, and slower progress in these domains. Educational level functions as a lifelong enabler, increasing broadband access, internet use, and cognitive capacity [60]. Men in this study reported higher initial levels of internet use and general cognition. However, there is a significant decline in internet use over time, rather than in cognitive function, aligning with previous research [18,61], some of which is potentially attributable to cohort attrition in men. Household consumption predicted higher initial digital engagement but also correlated with slower growth, implying saturation among more advantaged individuals [22]. Self-rated health and social activity were associated with better outcomes in the initial wave but lost significance in later waves, potentially due to survivor bias or the stabilization of digital habits [32]. Employment status consistently showed a negative relationship with broadband access across waves, likely reflecting work-related constraints or measurement limitations.

While our PP-LGCM model supports a directional cascade from access to use to general cognition, we acknowledge the plausibility of reverse causation: individuals with higher baseline cognitive capacity may be more likely to adopt and sustain internet use [32]. Future studies using cross-lagged panel models or instrumental variables are recommended to further elucidate the causal direction.

Limitations

This study has several limitations. First, attrition (6712/12,775, 52.5%) may introduce bias if those lost to follow-up were disproportionately cognitively impaired or digitally excluded. Second, our binary measures of internet use could not distinguish between passive (eg, scrolling) and cognitively stimulating activities (eg, learning and problem-solving)—a key nuance for future research. Third, although the Mini-Mental State Examination cognitive composite is widely used in surveys among large aging populations, it has limited ceiling effects in high-functioning individuals, sensitivity to early or specific decline, and possible cultural or educational biases in literacy or numeracy items [62,63].

Conclusions

This study provides longitudinal evidence that internet use mediates the association between broadband access and general cognition among middle-aged and older Chinese adults. The growth trajectory in broadband access predicted increased internet use, which in turn predicted slower cognitive decline. These results argue for integrating digital literacy and socially engaging online opportunities into public health strategies for healthy aging.

Abstract

Background: Digital platforms disseminating health information and providing support for the experience of non-memory-led dementias (NMLDs) are invaluable. However, the factors influencing engagement with these resources in people affected by NMLDs are poorly understood. We conducted the world's largest survey exploring the experience of digital access in NMLDs to learn directly from people with a diagnosis, their care partners, and NMLD health care professionals (HCPs).

Objective: This study aimed to determine factors associated with digital health and well-being resource use in people with NMLD and their care partners and investigate differences in digital health and well-being resource use according to NMLD subtype.

Methods: Individuals diagnosed with NMLD—for example, those with frontotemporal lobar degeneration, posterior cortical atrophy (PCA), and primary progressive aphasia (PPA)—their care partners, and NMLD HCPs (N=450) responded to the survey. A subset of care partners provided two responses (carer-related and proxy), generating 4 survey groups with responses (N=538). The survey included demographics and basic clinical information, the outcome measure of usage behavior, and factors including constructs from the Short Senior Technology Acceptance Model (Short STAM) and additional constructs informed by a combination of previous literature and consultation with NMLD experts-by-experience (anxiety and depression [Patient Health Questionnaire–4-item], instrumental activities of daily living, web-related privacy and security concerns, and digital health literacy). Separate multiple linear regressions were run for each survey group to elucidate which variables predicted higher use of digital health and well-being resources. The use of digital resources for health and well-being was also explored across 3 NMLD subtypes: frontotemporal dementia (FTD), PPA, and PCA.

Results: Attitudinal belief was consistently the strongest predictor of digital health and well-being resource use in people with NMLD as well as caregivers and proxy respondents. Control belief was significantly associated with higher digital health and well-being resource use in the NMLD and proxy groups; a trend was observed in the carer group. The adjusted R^2 range (63.0% - 70.8%) denotes the variance in digital health and well-being resource use accounted for in the 3 models. Lower digital health and well-being resource use was associated with FTD diagnosis and caregiver groups relative to PPA and PCA.

Conclusions: Collectively, these findings indicate several factors are critical to consider when designing digital health and well-being resources for people with NMLD and their caregivers, in particular targeting practical and emotional perceptions of digital resource use for health and well-being. This should be undertaken in combination with design considerations that address condition-specific cognitive profiles encountered by those living with NMLD diagnoses and those who care for them.

Introduction

Background

Dementia is an umbrella term encompassing several diseases that cause progressive cognitive and functional decline, affecting over 57 million people worldwide, with 10 million new cases diagnosed each year [1]. While pharmacological therapeutic interventions are available for some forms of dementia, access remains inconsistent, and many individuals living with a dementia diagnosis—as well as their caregivers—rely heavily on psychosocial support and community-based services. eHealth and digitally delivered services designed for people affected by dementia are both an appealing way to disseminate relevant information and provide virtual opportunities for dementia care in the context of stretched resources (thus reducing reliance on geographical proximity to in-person services). The COVID-19 pandemic catalyzed a rapid shift toward digital health and well-being tools, accelerating the transition from paper-based and in-person community support provision to virtual platforms [2]. This shift opened numerous possibilities for dementia care, including increasing accessibility to dementia-related support groups [3]. Emerging evidence suggests that individuals with dementia and their caregivers engage with technology in similar ways, indicating that both audiences benefit from digital health and well-being provision [4].

The most common form of dementia is Alzheimer disease, with the majority of individuals presenting with episodic memory impairment as an early symptom [5]. However, a substantial proportion of people with dementia present with initial symptoms other than memory complaints. For example, individuals with an atypical variant of Alzheimer disease, posterior cortical atrophy (PCA), exhibit early visual dysfunction [6]. Changes in behavior and personality are characteristic of behavioral variant frontotemporal dementia (bvFTD [7]); language production and comprehension are a hallmark of the primary progressive aphasias (PPA [8]); and sudden-onset mood disorders are often accompanied by hallucinations in dementia with Lewy bodies [9]. These atypical presentations, collectively referred to as non–memory-led dementias (NMLDs), pose unique challenges for individuals with a diagnosis and their caregivers. In addition, symptoms often emerge before the age of 65 years (considered a young-onset dementia) with consequent implications for finances, work, and family [10]. The relative rarity of these conditions contributes to limited postdiagnostic service provision and low primary care professional and public awareness [11], while their geographical dispersion further complicates access to relevant face-to-face services [12]. Many of these challenges can be mitigated through virtual platforms, which can enable expert-led interventions [13] and peer support across geographical regions [14]. Capacity for digital engagement is high in people with NMLD as well as caregivers, owing to the fact that many affected individuals are younger than 65 years; in 2019, 73.9% of individuals aged between 50 and 64 years in England used the internet every day [15].

While digital services are a promising platform to meet the specific needs and reach of people affected by NMLDs, the factors influencing engagement with digital health and well-being resources—specifically among people living with NMLDs and their caregivers—remain underexplored, representing a critical gap in the literature. While digital platforms (eg, websites and videoconferencing) offer promising avenues for support, their usability may be directly affected by specific clinical and neuropsychological profiles associated with NMLDs. For example, anosognosia (lack of insight), which is characteristic of bvFTD, may influence likely engagement with condition-specific health and well-being materials if the individuals do not perceive themselves as having a disease. NMLD caregivers, too, face distinct potential barriers to digital health and well-being engagement. These include limited time to source and access digital health and well-being information due to demanding caregiving roles, often compounded by a lack of recognition or support from professionals and the broader public; insufficient privacy to participate in virtual support groups; and the emotional strain of navigating complex and frequently misunderstood symptoms. Understanding the specific factors associated with NMLD digital health and well-being resource use will optimize NMLD-specific digital resource and intervention design, maximizing subsequent engagement and uptake from the audiences with NMLD they aim to support.

Previous models explaining variance in technology use and behavioral intention to use technology have sought to do so in a consumer context, such as the Unified Theory of Acceptance and Use of Technology (UTAUT [16]), the revised version of which explains up to 74% of behavioral intention to use technology and 52% of actual use [17]. Combining this with another predominant model for workplace technology use (Technology Acceptance Model [18]), Chen and Chan [19] developed a 38-item seniors-focused model to understand gerontechnological acceptance by older people from Hong Kong. Alongside original constructs pertaining to attitudinal beliefs and control aspects, Chen and Chan [19] included additional constructs of age-related health and independent capabilities, revised in a shortened version of the Short Senior Technology Acceptance Model (14-item; Short STAM), which demonstrated its accuracy in relation to assessing the propensity of individuals older than 55 years to engage with new technology, appropriate for dementia populations with a lower age of onset and their caregivers [20]. Low variance for the Short STAM (14-item) explaining technology usage behavior in subsequent studies [21] indicates other population-specific factors that may be important to consider when examining factors contributing to technology-use behavior in NLMDs. Qualitative work focusing on technology use in older adults with hypertension, for example, highlights other factors potentially influencing engagement, such as privacy concerns [22]. This factor may even be arguably more pertinent for studies exploring technology usage behavior in dementia populations, owing to acknowledged vulnerability to financial and technological scams and for people with NMLDs in the necessity to divulge sensitive category data by virtue of explaining symptoms (eg, a person living with posterior cortical atrophy disclosing their clinical phenotype to allow for reasonable adjustments to be made). Additional aspects influencing digital health and well-being resource use in people with NMLDs may include factors related to major neurocognitive changes (eg,

XSL•FO
RenderX

changes in instrumental activities of daily living), shared experiences between people with dementia and their caregivers (eg, anxiety and depression), and more recently identified constructs such as digital health literacy that were not included in the Short STAM (14-item) model. Informed by these current models of technology use, we conducted the first quantitative study to our knowledge exploring these and additional constructs in people living with NMLDs and their caregivers (see Figure 1). We included subconstructs and item numbers from the Short STAM, the selection for which was derived from a sequential item-reduction strategy and confirmatory factor analysis of prior models (original STAM–38 items [19]). Standardized parameter estimates for interconstruct correlations for the Short STAM (14-item) are reported in full in the study by Chen and Lou [20]. The right-hand block indicates additional constructs added to the digital access survey in this study, with variable selection guided by technology-use investigations in other clinical cohorts [22] and patient and public involvement (PPI) consultation with NMLD experts-by-experience. Aligned with our focus on flexible health care provision, we focused on technology use relating to digital platforms providing resources in the domains of health and well-being (eg, websites, Zoom [Zoom Video Communications]) and remained agnostic to mode of access (eg, whether accessed via smartphone, tablet, or computer).

Study Objectives

To address this gap, the following research questions were formulated:

1. What are the factors associated with digital health and well-being resource use in people with NMLD and their care partners?
2. Is there a difference in digital health and well-being resource use according to NMLD subtype?

Methods

Participant Characterization

Background demographic variables previously reported to influence usage (eg, age in years, gender, and ethnicity [17,23]) were collected alongside clinical characteristics such as NMLD type (eg, primary progressive aphasia, posterior cortical atrophy, and frontotemporal dementia), time since first symptoms, and formal dementia diagnosis.

The final sample comprised 450 participants with 538 survey responses, collected between March 2023 and March 2024. This exceeded our initial power calculations for analysis of participation issues affecting people with NMLD, which was computed at n=385 (assuming 10 predictors; power=90%; R^2=0.33; α=.05). Taking a conservative approach, the minimum sample size for the 10 candidate predictor variables would be 385 (assuming outcome prevalence=50%, margin of error in intercept estimation =5%, 5% acceptable difference in apparent, and adjusted R^2 of 0.2). Survey response N exceeds sample size owing to a group of carers providing 2 responses, one relating to their own experiences and proxy responses for the person with NMLD. Participants included 63 people with a diagnosis of NMLD, 269 carer reporting on their own digital health and well-being resource use, 105 proxy responses, and 101 health care professionals (HCPs).

Survey Design and Measure Selection

The study was based on a cross-sectional questionnaire, using a participant-report approach. The survey was carefully designed to consider ease of administration and reduce participant burden where possible, in consultation with HCPs experienced in working with people with NMLD as well as caregivers and proxy respondents (eg, consultant neurologists, clinical psychologists, academic researchers, and support workers), and the Rare Dementia Support PPI group, comprising people living with and alongside NMLDs.

The theoretical constructs proposed for the survey were based on a rapid scoping review of studies exploring information and communication technology adoption and usage among older adults. Three theoretical models were identified as relevant for this study: (1) the UTAUT [16], (2) the Technology Acceptance Model [18], and (3) the Senior Technology Acceptance Model (STAM [19,20]). A variety of proposed measures were initially circulated in full to HCPs with relevant expertise in NMLD, PPI leads from two NMLD research studies, and the Rare Dementia Support PPI group. Following PPI consultation and feedback relating to length and potential participant burden, scale selection was finalized with the objective of balancing research requirements with participant burden and accessibility for people living with NMLDs. The questionnaire was available in English. The finalized survey scale items are outlined in full in the Table S1 in Multimedia Appendix 1 and described further below.

Outcome Measure: Usage Behavior

Usage behavior (UB) was measured using participant-reported technology use (TU) and behavioral intention to use. TU was measured by establishing frequency of use within the 3 months prior to data collection (7-point Likert scale, ranging from “not at all” [0] to “multiple times a day” [6]). Behavioral intention reflected a measure of usage behavior validated in previous work via participant report of 3 questions relating to intention to use technology, responses to which were established using a 10-point Likert scale (“disagree strongly” to “agree strongly” [17]). Usage behavior was calculated as a composite score of TU scores (where 0 - 6 frequency scores were rescaled as dummy variables) and behavioral intention to use scores (total score range$_{BI}$: 3 - 30), resulting in a total UB score range of 3 - 36 reflecting past use frequency and intention to use in the future. Higher scores indicate greater usage behavior of digital resources for health and psychological well-being in the surveyed population. Summing user variables to compute a composite outcome measure and subsequently treating this as a continuous outcome aligns with previous approaches in the literature using the UTAUT2 [17] and STAMs to assess smartphone and technology use in older adults [17,19,23].

Factors and Constructs

Predictors comprised constructs validated in the Short STAM 14-item (attitudinal beliefs, n=3; control beliefs, n=4; gerontechnology anxiety, n_{items}=2; health, n_{items}=5), which has been shown to explain up to 81.5% variance of actual technology usage in older adults [20]. Additional measures of depression and anxiety (Patient Health Questionnaire–4-item [PHQ-4]; [24]), instrumental activities of daily living [25], web-related privacy and security concerns (n_{items}=6 [26]) and the Digital Health Care Literacy Scale (n_{items}=3 [27]) were added to this survey following consultation of other technology-use studies in clinical older adult cohorts [22] and PPI consultation with NMLD experts-by-experience to further characterize the sample and explore their potential influence on technology use in people with NMLD as well as caregivers and proxy respondents. Likert scales were used for all scale responses, preserving the parameters and scale numbers according to each scale’s administration instructions.

Adaptation and Procedure

PPI consultation resulted in several adaptations being incorporated into the final survey. This included using the standardized phrase “web-based resources (eg, Zoom and websites) for your health and psychological well-being” across the scales, replacing varying terms such as “mobile Internet,” “ICT,” and “technology,” to create an accessible term that captured the digital platforms of interest in this study and reduce the number of questions. In addition, online survey branching was introduced to ensure participants would view only the

XSL•FO
RenderX

questions relevant to their experience, thus reducing completion time and participant burden.

The finalized scales were uploaded to Qualtrics and replicated in a hard-copy version where preferred. Four survey types were developed to tailor the questions to different possible NMLD experiences:

1. NMLD: for people living with a diagnosis of NMLD;
2. Proxy NMLD: for family members or friends of individuals with NMLD who provided proxy responses;
3. Proxy HCP: for HCPs who provided a proxy response on behalf of a person with NMLD who had capacity to access online resources;
4. Care partners: for family members or friends of those with a diagnosis of NMLD.

All electronic surveys were tested for technical functionality before data collection took place. Surveys were administered to individuals with experience of the following non–memory-led and young-onset dementias: Frontotemporal lobar degeneration (behavioral variant frontotemporal dementia; primary progressive aphasias [semantic variant primary progressive aphasia; nonfluent variant primary progressive aphasia]), atypical Alzheimer disease (posterior cortical atrophy; logopenic variant primary progressive aphasia); dementia with Lewy bodies, inherited dementias (familial frontotemporal dementia; familial Alzheimer disease) and young-onset Alzheimer disease.

Variable Derivation and Statistical Analysis

Data cleaning and item scoring were undertaken in SAS (SAS Institute) and RStudio (Posit). For analysis purposes, clinical phenotypes were pooled to reflect broad similarities in the presenting symptoms' cognitive domains. For example, the primary progressive aphasia subtypes (semantic, logopenic, and nonfluent variants, where specified) were subsumed under the label "PPA" to characterize digital health and well-being resource use for individuals with predominant language impairments. Where non–memory-led conditions were either reported to be copresenting (eg, frontotemporal dementia with dementia with Lewy bodies), individuals presented with other syndromes such as young onset Alzheimer disease or vascular dementia, or group sizes precluded condition-specific analyses (eg, individuals living with progressive supranuclear palsy; n=2), these were labeled as "Other."

Demographic information stratified by survey group is outlined in Table 1. To facilitate comparison across scales, composite scores were normalized, creating *z* scores for outcome and predictor variable responses. To elucidate which factors may be associated with higher usage of digital health and well-being resources, a linear multiple regression was fitted using the UB composite variable as an outcome. Separate multiple regressions were undertaken for each survey type (NMLD, Proxy, HCP, and Carer). To understand whether FTD, PCA, and PPA subtypes were associated with different usage behavior, a robust linear model was undertaken using the UB composite variable as the outcome, with diagnostic category as the main predictor variable and age and gender as covariates. This model was run twice; once collapsing the NMLD and proxy groups and once modeling FTD, PPA, and PCA carers only. Standardized coefficients, 95% CIs, and related significance values (where $P<.05$) are reported for each predictor. The default approach within the lm function in R (R Foundation for Statistical Computing) handles missing data by performing listwise (complete case) deletion. Therefore, cases with any missing data on the predictors were excluded from the regression model. The number of observations for each group is outlined in Multimedia (Table S2 in Multimedia Appendix 1). Acknowledging the smaller sample size, particularly in the NMLD group, model residuals were assessed for normality using statistical tests (Kolmogorov-Smirnov) and visual inspection via Q-Q plots. Testing for multicollinearity by calculating variance inflation factors for variables within each model confirmed that all variance inflation factor values were satisfactory (<5).

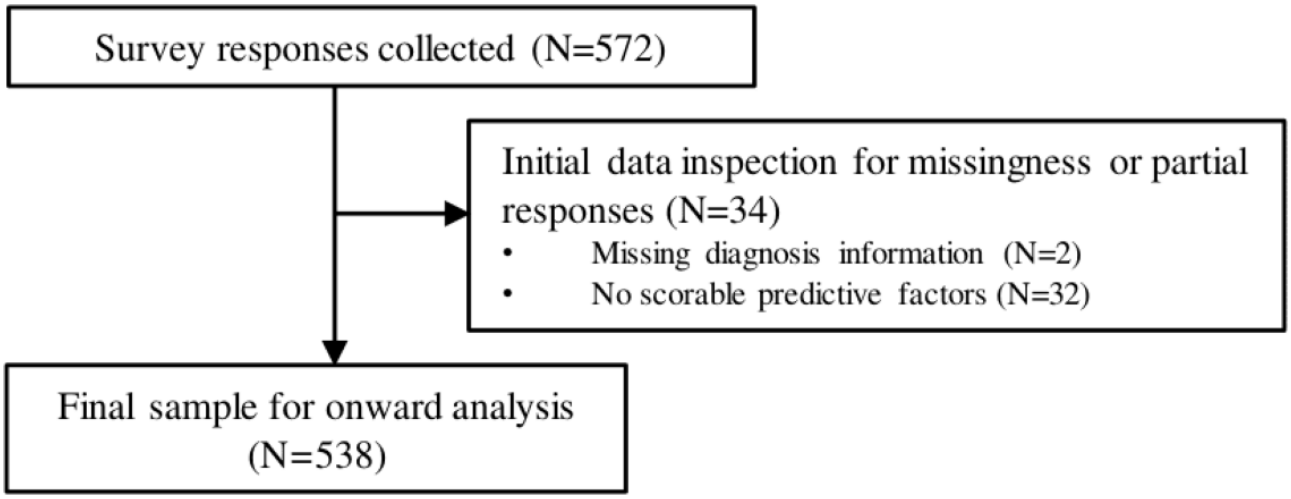
Ethical Considerations

Ethical approval was obtained from the University College London (UCL) Research Ethics Committee (8545/004: Rare Dementia Support Impact Study [28]). Potential participants were identified by one of two mechanisms: (1) membership of the UCL-led Rare Dementia Support [29], or (2) membership of the Dementia Research Center participant database. Members of both received email correspondence containing a link to the participant information sheet, online consent form, and survey.



XSL•FO
RenderX

To ensure we included individuals who may not use digital health and well-being resources, the e-invitation was supplemented by brief research reminders in several in-person support group meetings, where attendees had the opportunity to read the participant information sheet and ask clarifying questions to the research team, provide written informed consent, and complete a hard copy version of the questionnaire (including a version adapted for posterior cortical atrophy in consultation with a specialist NMLD neuropsychologist).

Results

The final sample comprised 538 responses from 450 individuals (354 women, 92.9% White; mean age 60.75, SD 13.29 years; see Figure 2). All collected entries were used to calculate the overall survey completion rate (94.1%). A small proportion (0.74% - 3.39%) of data were missing in the remaining survey group datasets, the highest proportion observed for people living with an NMLD response data. Full characteristics of the sample are shown in Table 1, split by NMLD condition and participant group.

Figure 2. Flowchart depicting response exclusion and final sample selection.

Model outputs are available in Table S2 in Multimedia Appendix 1. A higher use of digital resources for health and well-being for NMLD responders was moderately associated with higher attitudinal beliefs (eg, thinking that digital resources might be helpful) (β=.43, 95% CI 0.24-0.63; *P*<.001), followed by control beliefs (eg, perceived ease of use; β=.30, 95% CI 0.05-0.54; *P*=.02). Adjusted R^2 values indicated the model accounted for 69.3% of the variance in use of health and well-being digital resources.

Proxy NMLD diagnoses were provided in 97.1% of caregiver responses by either a spouse or partner (67.6%) or first-degree relative (parent, child, or sibling; 29.5%). The proxy model output broadly recapitulated the predictors of digital health and well-being resources as reported by individuals living with a diagnosis (attitudinal beliefs β=.66, 95% CI 0.52-0.80; *P*<.001; control beliefs β=.20, 95% CI 0.05-0.35; *P*=.009). In contrast to the NMLD model, proxy PHQ-4 score was additionally associated with proxy digital health and well-being resource use (β=.15, 95% CI 0.03-0.26; *P*=.01), with the overall model accounting for 70.8% of the variance in proxy-reported digital health and well-being resource use.

Responses from HCPs working with people with NMLD demonstrated a range of disciplines, namely NMLD clinicians (neurologists, psychiatrists, and clinical neuropsychologists), nurses, occupational and speech and language therapists, academic researchers, dementia support workers, care home managers, and social workers. One observation in the HCPs' model, corresponding to an outlier, was identified as deviating from the theoretical normal distribution by approximately 1.0 in the upper tail of the Q-Q plot. No remarkable changes in results were observed when rerunning this model after having excluded this observation, at which point normality assumptions were upheld. The model's ability to account for the variance of digital health and well-being resource use in the proxy HCPs' responses was greatly reduced relative to the two previous groups (Adjusted R^2=0.284). Nevertheless, the proxy HCP model was consistent with the findings above in that control beliefs were moderately associated with proxy digital health and well-being resource use (β=.38, 95% CI 0.12-0.64; *P*=.005).

Carers responding to the survey about their own use of digital health and well-being resources were consistent with other models in reporting a strong association between digital health and well-being resource use and attitudinal beliefs (β=.70, 95% CI 0.61-0.79; *P*<.001). A small association was demonstrated between digital health and well-being resource use and control beliefs (β=.13, 95% CI −0.001 to 0.25; *P*=.05). Distinct from previous models, carers' perception of better health was associated with digital health and well-being resources (β=.12, 95% CI 0.02-0.23; *P*=.03). Adjusted R^2 values indicated the model accounted for 63.0% of the variance in use of digital health and well-being resources.

To provide further insight into clinical phenotype associations with digital health and well-being resource use, we conducted exploratory analyses profiling associations of diagnosis (FTD, PPA, and PCA phenotypes) with digital health and well-being resource use. Given the relative concordance between the NMLD and carer-proxy profiles, we considered it appropriate to pool data from these 2 groups and stratify this aggregated

XSL•FO
RenderX

group (NMLD+proxy) by clinical phenotype, alongside carer scores for each group (see Table 2). All observations were retained (n=147) for onward analysis. Controlling for covariates age and gender, a robust linear regression indicated that diagnosis category was associated with digital health and well-being resource use for self- and proxy-reported NMLD. Compared to participants with FTD (reference group), higher digital health and well-being resource use were associated with the PCA (β=.75, 95% CI 0.33-1.16) and PPA groups (β=.55, 95% CI 0.06-1.03). This was recapitulated in the carer groups; higher digital health and well-being resource use was associated with the PCA (β=.51, 95% CI 0.23-0.78) and PPA (β=.27, 95% CI 0.01-0.54) carer groups relative to FTD carers.

Table . Demographic, basic survey information, and outcome measure scores depicted for the subgroup of the initial sample, stratified by clinical phenotype of behavioral variant frontotemporal dementia, primary progressive aphasia, and posterior cortical atrophy.

Clinical phenotype	bvFTD[a]	PPA[b]	PCA[c]
Living with NMLD[d] diagnosis and proxy combined	n=45	n=36	n=66
Age (years), mean (SD)	63.9 (12.4)	71.3 (8.1)	65.4 (8.1)
Female:male (N)	15:30	16:20	42:24
Ethnicity (White), n (%)	43 (95.5)	33 (91.7)	65 (98.5)
Time since diagnosis (years), mean (SD)	3.5 (3.3)	3.1 (1.8)	2.9 (2.6)
Time since symptoms noticed (years), mean (SD)	6.6 (4.2)	5.5 (2.8)	5.3 (3.5)
Online, n (%)	44 (97.8)	31 (86.1)	56 (84.9)
Digital resource use (composite), mean raw score (SD)	9.80 (10.25)	14.44 (12.67)	16.91 (11.34)
Carers	n=88	n=74	n=72
Age (years), mean (SD)	61.5 (13.3)	63.6 (11.3)	59.8 (14.6)
Female:male (N)	75:12[e]	54:20	39:31[e]
Ethnicity (White) n (%)	83 (94.3)	67 (90.5)	68 (94.4)
Time since diagnosis (years), mean (SD)	3.6 (3.2)	4.0 (2.9)	3.5 (2.5)
Time since symptoms noticed (years), mean (SD)	7.3 (4.2)	7.2 (5.5)	5.8 (2.9)
Online, n (%)	67 (76.1)	55 (74.3)	56 (77.8)
Digital resource use (composite), mean raw score (SD)	19.91 (9.02)	22.14 (9.39)	24.10 (8.47)

[a]bvFTD: behavioral variant frontotemporal dementia.

[b]PPA: primary progressive aphasia.

[c]PCA: posterior cortical atrophy.

[d]NMLD: non-memory-led dementia.

[e]Does not reflect total N owing to missing data or respondents preferring to self-describe.

Discussion

Principal Results

This work was conducted with the aim of understanding the factors associated with digital health and well-being resource use in people with NMLD as well as caregivers and proxy respondents. The findings provide insight for HCPs who seek to maximize engagement with NMLD-specific health and well-being support and underscore considerations for digital NMLD resource design and dissemination. Our findings characterize the extent to which theoretically derived technology use factors associate with digital health and well-being resource use in people with NMLD as well as caregivers and proxy respondents. Here, we report a consistent association between digital health and well-being resource use and control and attitudinal beliefs, regardless of whether it is proxy- or self-reported for people living with NMLDs. Caregiver-proxy reports additionally identified that increased feelings of anxiety and depression in the person with NMLD are associated with their engagement with digital health and well-being resource use. For carers' own digital health and well-being resource use, perception of better health was an additional predictor of higher use. Carer-reported proxy responses estimated NMLD resource use was lower relative to the reports received directly from individuals with an NMLD diagnosis, and individuals with FTD and their carers demonstrated lower digital health and well-being resource use relative to their PPA and PCA counterparts.

RenderX

Interpretations

Controls' beliefs were positively associated with digital health and well-being resource use across NMLD self-reported and proxy models. Examining the subordinate items within this construct, the likelihood of NMLD engagement with digital health and well-being offering is increased with a platform's perceived ease of use, the user's self-efficacy, and facilitating conditions being met (eg, accessibility factors and financial means). Promoting a user's self-efficacy maximizes the potential of digital platforms for health and well-being. Practically, this finding highlights the importance of training opportunities for people with NMLDs to optimize their experience with any bespoke digital health and well-being resource. This could be achieved by virtue of a tutorial or demonstration by another individual. Training may, for example, involve incorporating initial "onboarding" sessions, which aim to acclimatize the person affected by NMLD to a new digital health and well-being offer. These findings support previous research investigating videoconference-delivered support for people with dementia and their caregivers, whereby integrated technological support and training facilitated ongoing access by participants and users [30-33]. Digital provision of mental health support is available at the time of this writing in the United Kingdom for people with NMLD as well as caregivers if the need of the individuals is deemed to be low in complexity [34]. Evidence suggests that people with NMLD as well as caregivers benefit from accessing such services, therefore underscoring a critical need for NMLD-specific onboarding training as part of this and other digitally mediated mental health provisions [34,35]. In addition, the findings relating to control beliefs highlight the influence of basic accessibility factors in digital health and well-being engagement, which emphasizes the importance of designing for open access for people with NMLD as well as caregivers. Capitalizing on accessibility opportunities, such as working in partnership with community groups and institutions that offer tablet devices and computer access to the general public, will increase equity for individuals affected by NMLD who may otherwise be unable to access specialist digital resources. Taken together, these findings reflect recently reported themes from semistructured interviews exploring technology use in older adults with intellectual disabilities, resulting in recommendations around providing structured, repetitive, and gradual training opportunities for individuals with cognitive challenges, as well as promoting distribution of digital resources in rural areas [36].

Attitudinal beliefs were consistently the strongest predictor of digital health and well-being resources, arguably playing a crucial role in determining whether people living with dementia and their caregivers engage with these resources. This was demonstrated to a greater extent relative to the usability barriers outlined above. This construct reflects the individual user's perception of these resources being beneficial (eg, enhancing daily effectiveness) and whether they find their use appealing. For people with NMLD as well as caregivers and proxy respondents, the perceived functional value of digital health and well-being resources is critical, perhaps owing to this population seeking digital resources that specifically respond to their unique challenges, which often differ from amnestic dementia experiences. Practically, these findings point to a need for effective communication strategies at the point of offering these resources, which (1) provide a clear scaffold and framing of the digital resource in question and (2) emphasize the positive role that digital resources can play in supporting the navigation of NMLD symptoms, caregiving guidance, or health and well-being support for caregivers.

An additional insight from the NMLD-proxy group indicated that carer-perceived increased digital health and well-being resource use was associated with the person with NMLD's higher anxiety and depression. Acknowledging that causality may not be inferred from the study design and analysis approach, we venture a range of factors that may explain this finding. For example, depression and anxiety symptoms may be linked to digital health and well-being engagement by virtue of a different profile of help-seeking behavior, either in relation to the person with NMLD consulting the internet for potential mood-related symptom treatment or management through mental health and well-being platforms aimed to target these experiences; or, more broadly, to quell other non–dementia-specific concerns or worries that are exacerbated by virtue of increased anxiety and depression as a result of navigating the challenges dementia brings. Additionally, caregivers providing proxy responses may be aware of their own prompting behaviors, perhaps suggesting that a loved one displaying anxiety and depression may find online resources beneficial for managing their distress. Without further qualitative investigation; however, the mechanisms mediating this association remain speculative.

NMLD caregiver–specific findings indicated that higher self-reported health status predicted higher use of digital health and well-being resources. This differs from previous findings relating to dementia caregiver internet use, whereby caregivers of people primarily with Alzheimer disease or vascular dementia who appraised their own physical health as worse reported significantly more frequent internet use relative to those who appraised their physical health to be similar to a noncaregiver peer of the same age and gender [37]. This contrast may, however, reflect some specificity of the interplay of NMLD caregiver health and digital health resources relative to the same factor's influence for those caring for individuals with typical dementia variants. This supports the justification for stratifying the needs of these caregivers through bespoke post-diagnostic support and signposting as they form their own distinct profile of factors influencing digital health and well-being technology use.

The distinct cognitive hallmarks of FTD may explain the heterogeneity observed between NMLD phenotypes in relation to digital health and well-being resource use in the self- and proxy-reported group. The most common form of FTD, bvFTD, is characterized by changes in personality and behavior, coupled with early apathy and lack of insight into these symptoms [7]. The lower use of health and well-being digital resources relative to others presenting with different non–memory-led symptoms (as in PCA or PPA) may either reflect a lack of motivation to engage, a failure to even acknowledge or recognize there may be a health problem to consult about, or a combination. Addressing these 2 condition-specific barriers may be key in engaging people with FTD in health and well-being resources related to their condition. For FTD individuals in particular

XSL•FO
RenderX

(relative to PPA or PCA), it may be important to explore digital health and well-being resource use design that harnesses methods aiming to increase intrinsic motivation to engage, such as gamification approaches. Unequal diagnostic group sizes resulted in unequal precision as indicated by wider 95% CIs with lower bounds for PPA, consistent with a smaller group size and implying lower sensitivity to detect small effects. We, therefore, interpret this finding with caution. An interesting finding related to the recapitulation of these condition-specific web resource use profiles in the FTD carer groups in relation to the PCA and PPA groups. One potential explanation for this could be reflecting higher care demands specifically in bvFTD, with higher reports of caregiver stress and lower perceived control observed in this caregiver group relative to Alzheimer disease carers [38] and those caring for people with other NMLDs such as PPA [39]. This increase in stress and caregiver burden is likely to diminish FTD carers' dedicated time and resources to digital use in relation to their own health and well-being needs, in turn reflecting lower use relative to other NMLD caregiver peers.

Taken together, these findings highlight the utmost importance of condition-specific considerations when designing health and well-being digital materials for individuals living with and caring for individuals with NMLDs. However, as a recent systematic review of participatory methods in digital health interventions for dementia caregivers highlighted, subtyping is relatively rare, and many interventions are designed for the typical array of caregiver needs [40]. Approaches to adapt existing support platforms designed with more prevalent dementias in mind (eg, iSupport; World Health Organization) to cater to the specific needs of individuals with NMLDs included several co-design stages to enable iterative changes, including focus groups and validation surveys [41]. Similar approaches have been adopted for the co-development of forthcoming digital health interventions specifically designed by, with, and for specific dementia caregiver subtypes from the outset [13]. Co-design of digital resources and interventions with individuals living with or caring for NMLD is likely critical for ensuring ongoing engagement and interaction with digital provisions designed with people with NMLD as well as caregivers and proxy respondents in mind [42].

Limitations

Our health care professional model demonstrated far less predictive value of health and well-being digital resource use (only 28% of the variance). This may reflect the instruction given to HCPs to "imagine clients you have worked with," which does not give ample opportunity for HCPs to share the complexity or breadth of their experience when trying to engage NMLD audiences in digital health and well-being offers. This contrasts with the good explanatory power demonstrated by the NMLD, carer, and proxy models, perhaps reflecting the selective focus of these groups, who were instructed to respond in reference to only one individual (either themselves or one other in the proxy report). Given the HCP group comprised a multidisciplinary group, there is also the potential for differing frames of reference to have impacted model fit. A variability in the professional role within the HCP group, and therefore the clients or service users envisaged when HCP participants completed the survey, may have introduced greater heterogeneity, which in turn would weaken the predictive capacity of the HCP model in contrast to the other models reported here. We acknowledge that the quantitative format of the survey may have also restricted the potential for HCPs to share the depth of expertise that professionals working in this space have to offer. This reflection emphasizes the importance of mixed methods approaches incorporating qualitative inquiry with HCPs to harness the benefits of their range of experiences in this area and to elucidate any discipline-specific observations. This work has been undertaken, and findings are described in a separate publication (Fearn et al, forthcoming).

The definition of technology use in this study was intentionally narrow, concentrating specifically on digital health and well-being resources in order to capture information relating to engagement with NMLD digital offers that are currently available, such as virtual support groups and digital platforms (eg, Rare Dementia Support and Dyscover). This survey did not capture particular devices NMLD users preferred to access these resources, which may be mediated by NMLD audience (persons living with vs carers) or syndromic group and which may have notable influence on whether or not these digital resources are engaged with. FTD populations, for example, exhibit lower smartphone battery usage relative to clinically neurotypical controls [43], which may necessitate other means of presenting health and well-being information for these groups that seem not to engage with smartphone interaction. Together, these findings must also be considered alongside other contextual factors at play, including mediating factors that can influence telehealth success in these individuals, such as the engagement of the communication partner, which has been found to associate with functional outcomes in videoconference-delivered PPA speech and language therapies [44].

Although we endeavored to collect data using both hard-copy paper questionnaires and a complementary digital survey option to capture a broad range of digital access experiences, we acknowledge that the invitations for both formats were distributed electronically. As a result, this sample may overrepresent digitally literate older adults relative to the wider dementia and caregiver populations. Relatedly, internet use is associated most strongly with individuals with dementia specifically from middle-income backgrounds with high educational attainment, characteristics that are also prevalent in membership of specialist support services such as the one from which our sample was derived [45]. Socioeconomic factors similarly associate with internet access in caregiver populations; for instance, individuals with private health insurance are 8 times more likely to have internet access than those without [46]. Furthermore, our sample comprised a very high proportion of White participants, which did not provide the opportunity for exploring potential digital-access patterns and associated factors in more ethnically diverse people with NMLD as well as caregivers and proxy respondents. Our findings and their generalizability should therefore be considered in this context. As awareness for NMLDs grows, there may be opportunities for future research studies to use recruitment strategies that identify participants from more community-based or primary

XSL•FO
RenderX

care settings who, in turn, are likely to increase the representativeness relative to this sample. Finally, despite the large overall sample size, we acknowledge that in order to examine group-specific profiles, the number of available observations per group and number of predictors resulted in regressions that may be overfitting. While assumptions were upheld through normality testing with little evidence for multicollinearity, the findings should be interpreted with the understanding that these models are exploratory in nature.

Conclusions

Collectively, these findings provide insight into several factors that are critical to consider when designing digital health and well-being resources for people with NMLD and their caregivers. The insights from this work underscore the importance of marketing and resource design that resonate with NMLD audiences in terms of targeting practical and emotional perceptions of digital health and well-being offers. This should be undertaken in combination with design considerations that address technical and logistical barriers to access, as well as considering the specific intended audience in terms of specific cognitive and symptom profiles.

Acknowledgments

The authors would like to thank all our participants, without whom this work would not have been possible. We are also grateful to Mrs Valerie Mansfield as Co-Lead (PPI), Mrs Roberta McKee-Jackson, and the Rare Dementia Support PPI group for reviewing the surveys and providing feedback on drafts.

Abstract

Background: Digital eldercare services are promoted to address gaps in traditional care provision, yet actual uptake among older adults remains limited. Prior research has largely focused on technological attributes, with less attention to older adults' context-specific behavioral attitudes toward digital services.

Objective: This study aimed to identify the multidimensional structure of older adults' behavioral attitudes toward digital meal assistance services and to examine their associations with usage intention and actual use.

Methods: A mixed-mode survey was conducted in 2020 among adults aged 60 years or older in a large metropolitan city in China. A total of 1019 valid questionnaires were collected (n=405 online and n=614 offline). Exploratory factor analysis was used to identify attitudinal dimensions, followed by binary logistic regression analyses conducted separately for online and offline samples, controlling for sociodemographic characteristics.

Results: Five attitudinal dimensions were identified, explaining 60.38% of the variance. Regression analyses showed that associations between attitudinal dimensions and service use differed by usage stage and sample type. Digital trust was the most consistent predictor, significantly associated with intention to use in both samples—particularly online (odds ratio [OR] 1.351, 95% CI 1.054 - 1.732; *P*=.02)—and with actual use in the offline sample (OR 1.068, 95% CI 1.011 - 1.128; *P*=.02), with a marginal association online (OR 1.347, 95% CI 0.986 - 1.840; *P*=.06).

Conclusions: Older adults' adoption of digital meal assistance services is shaped by multidimensional and context-dependent attitudes that extend beyond technological considerations. Policy efforts should therefore emphasize trust-building, affordability, and differentiated strategies tailored to diverse groups of older adults.

KEYWORDS

digital meal assistance services; older adults; behavioral attitudes; usage intention; actual use; China

Introduction

Digital older care services are increasingly viewed as an important approach to addressing population aging and alleviating shortages in traditional eldercare provision. Prior studies indicate that digital technologies, such as the internet and big data, can integrate service resources through smart platforms. These platforms enable the delivery of diverse services tailored to older adults' needs, including home-based care, remote medical consultation, rehabilitation guidance, and health management [1,2]. In China, national policies have further promoted the integration of digital technologies and eldercare services. The Smart Health and Elderly Care Industry Development Action Plan (2021 - 2025) explicitly encourages the digitalization and age-friendly application of services such as meal delivery and household assistance, aiming to narrow the digital divide among older adults [3]. Despite these policy efforts and technological advances, the actual use of digital eldercare services among older adults remains limited [2,4].

Digital meal assistance services represent a key component of digital eldercare by linking daily nutritional support with the broader eldercare service delivery system through platform-based models. Meals on Wheels services were initially designed for older adults with difficulties in meal preparation and have gradually expanded to serve broader populations [5,6]. Existing research suggests that meal assistance services can improve nutritional intake and health outcomes, reduce family caregiving burden, and promote social interaction [7-9]. With digitalization, these services have evolved into multiple forms, including online meal delivery platforms and food delivery applications [10-12]. However, empirical evidence indicates that such services have not been widely adopted by older adults,

XSL•FO
RenderX

potentially undermining food security and health outcomes [2,7,10].

Previous studies have mainly relied on the Andersen behavioral model, the Technology Acceptance Model (TAM), and the theory of planned behavior (TPB) to explain digital service use, highlighting the roles of perceived usefulness, perceived ease of use, and behavioral attitudes in shaping usage intention [13-16]. Nevertheless, 2 gaps remain. First, many studies focus on the general population and give insufficient attention to older adults, who differ markedly in digital skills and risk perceptions [10,17]. Second, although behavioral attitudes are frequently emphasized, their underlying structure among older adults remains insufficiently specified, and the mechanisms through which attitudes translate into actual service use—the intention-behavior gap—are not fully understood [14,16,18].

To address these gaps, this study examines digital meal assistance services in urban China using survey data collected from older adults in 2020. We aim to (1) identify the structure of older adults' behavioral attitudes toward digital meal assistance services through exploratory factor analysis (EFA); (2) examine differences in attitudinal structures across population subgroups; and (3) assess the associations between different attitudinal dimensions, usage intention, and actual service use. By adopting a behavioral attitude perspective, this study seeks to clarify the mechanisms underlying digital eldercare service adoption among older adults and to provide empirical insights for service design and policy development.

Methods

Study Design and Setting

This study used data from a questionnaire survey examining older adults' intention to use smart eldercare services. The survey was conducted over a 2-month period in 2020 in 2 districts of a large metropolitan city in China. The survey collected information on respondents' sociodemographic characteristics and their awareness and use of digital meal assistance services (ie, online food ordering services). Given potential systematic differences between online and offline surveys in digital skills and service access, a mixed-mode design was adopted. Descriptive and regression analyses were conducted separately for online and offline samples. The final analytic sample comprised 1019 valid responses (n=405 online and n=614 offline). Additional details on the sampling framework and survey implementation are provided in Multimedia Appendix 1.

Offline Survey Procedures

The offline survey used a 2-stage stratified random sampling strategy. Streets within each district were first selected using simple random sampling. Communities within selected streets were then stratified by geographic accessibility to community eldercare service stations (approximately 15-min walkability, defined as about 1.0 - 1.2 km based on navigation distance) and randomly sampled within each stratum. Eligible older adults were recruited through intercept surveys, yielding 614 valid questionnaires. Further procedural details are provided in Multimedia Appendix 1.

Online Survey Procedures and Quality Control

The online survey was administered via the Wenjuanxing platform and yielded 405 valid responses. Survey links were primarily distributed by community staff, with additional responses collected through the platform's mutual-assistance service. No incentives were provided. Eligibility was ensured through an automated age-screening item (≥60 y), and duplicate submissions were prevented by restricting 1 response per IP address. Participation was voluntary, and informed consent was implied by questionnaire submission. Additional quality control details are provided in Multimedia Appendix 1, and the completed CHERRIES (Checklist for Reporting Results of Internet E-Surveys) checklist is provided in Checklist 1.

Measures

Behavioral Attitudes Toward Digital Meal Services

According to the TPB, behavioral attitudes are derived from individuals' beliefs about behavioral outcomes and are influenced by perceived behavioral control [19]. When individuals perceive that they have sufficient ability and resources to perform a behavior, they are more likely to develop positive attitudes. The TAM further posits that perceived usefulness and perceived ease of use are core mechanisms underlying attitude formation, with external factors influencing attitudes indirectly through these perceptions [20-22]. Building on the TPB and the TAM, this study incorporates the digital divide experienced by older adults as well as the family-oriented eldercare context in China [23-25]. Behavioral attitudes are defined as older adults' overall evaluations of the value, acceptability, and safety of digital meal assistance services within a specific service context, as well as their perceived impacts on themselves and their families. From this perspective, attitudes toward digital meal assistance services encompass evaluations of usefulness and convenience. They also involve judgments related to family roles and caregiving responsibilities, trust-related risk assessments, and perceived constraints associated with resources and affordability.

Measurement items were developed based on a systematic review of prior studies on eldercare service use, digital technology adoption, and digital inequality. The initial item pool primarily covered perceived service value, service acceptance, safety concerns, and perceived impacts on individuals and families. To reduce social desirability and self-presentation bias, some items were framed in a projective manner (eg, asking how "older adults around you" perceive digital meal services). Reverse-coded items were also included to minimize acquiescence bias. All items were measured using a 5-point Likert scale ranging from 1 ("strongly disagree") to 5 ("strongly agree"). Following semantic refinement and standardization prior to the formal survey, a total of 19 items were retained for analysis.

Based on the results of EFA, composite indices were constructed for each behavioral attitude dimension. Scores for each dimension were calculated as the mean of the corresponding items, with higher scores indicating more positive attitudes. Internal consistency for each attitudinal dimension was assessed using Cronbach α.

XSL•FO
RenderX

Outcome Variables

To assess the effects of behavioral attitudes, 2 outcome variables were examined: intention to use digital meal assistance services and actual service use. Usage intention was measured using the item "Would you (continue to) order meals through internet-based platforms?" on a 5-point Likert scale (1="definitely would not use," 5="definitely would use") and dichotomized as 1 for responses of 4 or 5 and 0 otherwise. Actual service use was measured by the frequency of online food ordering and coded as 1 for any reported use and 0 for "never."

Ethical Considerations

This study involved an anonymous questionnaire survey administered online (via Wenjuanxing) and offline face-to-face. No personally identifiable information (eg, names, contact details, identification numbers, or precise addresses) or sensitive personal data (eg, medical or financial information) was collected, and no intervention, clinical procedures, or biological sample collection was involved. Under Article 32 of the Measures for Ethical Review of Life Sciences and Medical Research Involving Human Subjects, research using anonymized information data that does not cause harm to participants and does not involve sensitive personal information or commercial interests may be exempt from ethics review. Accordingly, this anonymous, minimal-risk survey study met the criteria for exemption from institutional ethics review.

Participants were informed about the study purpose, procedures, voluntary participation, and data protection. For the online survey, consent was implied by submission of the completed questionnaire; for the offline survey, oral informed consent was obtained prior to participation. Participants could withdraw at any time without consequences. No compensation was provided for participation.

Data Privacy and Security

All survey data were collected anonymously. Online responses were exported and stored in password-protected files, and offline paper questionnaires (if applicable) were securely stored and then digitized. Only the research team had access to the data.

Data Analysis

EFA was conducted to identify the latent structure of older adults' behavioral attitudes toward digital meal assistance services. Prior to analysis, questionnaires with missing values on key variables or substantial nonresponse were excluded. The final analytic sample consisted of 1019 complete questionnaires; therefore, no imputation was applied.

EFA followed standard procedures of item screening, factor extraction, rotation, and interpretation. Factors were extracted using principal component analysis, with the number of factors determined by the Kaiser criterion (eigenvalues >1). Varimax orthogonal rotation was applied. Items with factor loadings below 0.50 were considered for removal; items with cross-loadings (loading differences <0.20 across factors) or communalities below 0.40 were also evaluated and excluded when appropriate.

Binary logistic regression models were used to examine associations between behavioral attitude dimensions and both usage intention and actual service use. Given differences between online and offline samples, all models were estimated separately for each subsample. The general model specification was

$$(1)\log(pi1-pi)=\beta0+\beta1Xi+\beta2Zi$$

where pi denotes the probability that individual i reports a higher usage intention or actual service use; Xi represents behavioral attitudes (or specific attitudinal dimensions); and Zi includes control variables (gender, age, education, and income). Results were reported as odds ratios (ORs) with 95% CIs. Given the sensitivity of the Hosmer-Lemeshow test in large samples, pseudo-R^2 and the Akaike information criterion were also reported as supplementary fit indicators.

Results

Participant Characteristics

Table 1 summarizes the sociodemographic characteristics of the sample. Overall, the age distribution was skewed toward younger older adults, with participants aged 60‐69 years accounting for 569 of 1019 (55.8%) of the sample, which may limit generalizability. Compared with the offline sample, the online sample was younger on average, whereas the offline sample included a higher proportion of the oldest-old (aged ≥80 y). In terms of socioeconomic characteristics, the online sample had higher educational attainment than the offline sample, with 272 of 405 (67.2%) reporting a high school education or above compared with 297 of 614 (48.4%) in the offline sample. The online sample also had a higher proportion of high-income respondents (≥8000 CNY, 1 CNY=US $0.14), whereas the offline sample included a relatively larger share of middle-income respondents (4000‐7999 CNY). Overall, the offline sample more closely resembled community-dwelling older adults, whereas the online sample was more likely to represent younger and more digitally skilled individuals. Accordingly, the findings were more applicable to younger and older adults and those with greater digital capacity, and caution was warranted when generalizing to the oldest-old or to older adults with limited digital skills; these limitations are discussed in the Limitations section.

Behavioral Attitude Structure

EFA was conducted to identify the latent structure of older adults' behavioral attitudes toward digital meal assistance services. Data suitability was confirmed by a significant Bartlett test of sphericity (χ^2=286.67, P<.01) and a Kaiser-Meyer-Olkin value of 0.894, indicating adequate interitem correlations. After excluding 3 items based on predefined criteria, 16 items were retained for analysis. Five factors with eigenvalues greater than 1 were extracted, with initial eigenvalues of 6.01, 2.43, 1.82, 1.39, and 1.03. Following Varimax orthogonal rotation, the 5 factors explained 14.60%, 14.13%, 11.64%, 11.09%, and 8.92% of the total variance, respectively, yielding a cumulative explained variance of 60.38%. Detailed results are presented in Table 2.

Table 3 presents the standardized factor loadings and communalities for each retained item. All items showed strong loadings on their corresponding factors, and each factor was represented by at least 3 items, indicating a clear and stable factor structure. Reliability analysis showed that the overall scale demonstrated good internal consistency, with a Cronbach α of 0.879. In addition, correlations between the mean scores of individual behavioral attitude dimensions and the overall scale mean ranged from 0.414 to 0.762, suggesting that the dimensions were moderately correlated while maintaining adequate discriminant validity (Multimedia Appendix 2).

I avoid using online meal ordering services because I am concerned about making operational mistakes or being scammed	—	—	—	0.704	—	0.711
I avoid using online meal ordering services because of concerns about food quality or hygiene during preparation	—	—	—	0.691	—	0.606
I avoid using online meal ordering services if my children have to pay for the cost	—	—	—	—	0.652	0.662
I am more likely to use online meal ordering services when government subsidies are available	—	—	—	—	0.583	0.584
I am willing to use online meal ordering services only when my pension income is sufficient to cover the cost	—	—	—	—	0.671	0.681

[a]Only factor loadings with absolute values ≥0.50 are reported. Factor extraction was based on principal component analysis with Varimax rotation.

[b]Not reported (factor <0.50).

Based on the content characteristics of items with high factor loadings, 5 factors were labeled. Alleviating burden (F1) reflects value-based judgments regarding whether digital meal assistance services were worth using, particularly in terms of their potential to reduce the caregiving burden on adult children in daily life. When such services were perceived as helping to alleviate family caregiving pressure, older adults tended to hold more positive attitudes toward their use. Enhancing convenience (F2) captures perceived evaluations of the extent to which digital meal assistance services improve convenience in older adults' daily lives. This factor reflected the functional use of the service, consistent with perceived usefulness in the TAM. Service acceptance (F3) represented older adults' evaluations of the social meaning of digital meal assistance services. When service use was interpreted as indicating that adult children had not adequately fulfilled their caregiving responsibilities, attitudes toward the service tended to be negative. Digital trust (F4) reflected older adults' attitudinal judgments regarding the safety and reliability of digital meal assistance services. Funding sources (F5) captured older adults' perceived affordability of digital meal assistance services, consistent with perceived behavioral control in the TPB. Lower perceived affordability was associated with a lower likelihood of service use.

Notably, perceived ease of use, as defined in the TAM, did not emerge as an independent attitudinal dimension in the identified factor structure.

Differences in Behavioral Attitudes Across Groups

Table 4 summarizes mean scores across behavioral attitude dimensions by participant characteristics. Overall, older adults reported relatively higher evaluations on alleviating burden (F1) and enhancing convenience (F2). Middle- and higher-income groups generally scored higher on enhancing convenience (F2), service acceptance (F3), and digital trust (F4), whereas lower-income older adults reported higher scores on funding sources (F5) and alleviating burden (F1). Higher educational attainment was associated with more positive evaluations of alleviating burden (F1), enhancing convenience (F2), and service acceptance (F3), as well as lower concern regarding funding sources (F5). By contrast, differences in digital trust (F4) were modest across education groups. By survey mode, the online sample consistently reported higher scores across most attitude dimensions—particularly enhancing convenience (F2)—whereas differences in digital trust (F4) between online and offline samples were relatively small.

Table . Mean scores of behavioral attitude dimensions across different groups of older adults.[a]

Behavioral attitude dimension	Total sample	Middle- or high-income[b]	Low-income[b]	Higher education	Lower education[c]	Offline sample[d]	Online sample[d]
Alleviating burden (F1), mean (SD)	3.668 (1.412)	3.278 (1.357)	3.816 (1.602)	3.700 (1.288)	3.346 (1.492)	3.278 (1.525)	3.417 (1.064)
Enhancing convenience (F2), mean (SD)	3.588 (1.500)	3.763 (1.410)	3.237 (1.762)	3.604 (1.287)	3.251 (1.650)	3.054 (1.682)	3.611 (0.784)
Service acceptance (F3), mean (SD)	3.334 (1.890)	3.411 (1.999)	3.146 (1.35)	3.551 (2.029)	3.228 (1.681)	3.209 (2.00)	3.441 (0.784)
Digital trust (F4), mean (SD)	3.022 (1.226)	3.082 (1.023)	2.927 (1.79)	2.962 (1.228)	3.002 (1.219)	2.989 (1.32)	3.132 (1.063)
Funding sources (F5), mean (SD)	3.010 (1.947)	2.711 (1.953)	3.132 (1.812)	3.002 (2.140)	3.359 (1.703)	2.796 (1.961)	3.364 (1.807)

[a]Values represent mean scores on a 5-point Likert scale (1=strongly disagree, 5=strongly agree).

[b]Low-income refers to a monthly income of 0-3999 CNY; middle- or high-income refers to ≥4000 CNY; 1 CNY=US $0.14.

[c]Lower education refers to junior high school or below; higher education refers to high school or above.

[d]Offline and online samples were collected using different survey modes as described in the Methods section.

Associations Between Behavioral Attitudes, Usage Intention, and Actual Use

Tables 5 and 6 present logistic regression results examining associations between the 5 behavioral attitude dimensions and both intention to use and actual use of digital meal assistance services, estimated separately for the online and offline samples. All 4 models were statistically significant (P<.001), with pseudo-R^2 values ranging from 0.156 to 0.240 and Akaike information criterion values from 800.001 to 1002.470, indicating acceptable model fit. Hosmer-Lemeshow tests did not suggest a significant lack of fit (P value range .055-.062).

Hosmer-Lemeshow goodness-of-fit (*P* value)[g]	.06	.06	.06	.06

[a]OR: odds ratio.

[b]*P*≤.001.

[c]*P*≤.05.

[d]*P*<.10.

[e]NA: not applicable.

[f]AIC: Akaike information criterion.

[g]The Hosmer-Lemeshow goodness-of-fit test is sensitive to large sample sizes; therefore, pseudo R^2 and Akaike information criterion are reported as complementary indicators of model fit.

Table . Control variables included in all models (definitions, distinctions, and coding).

Control variables[a]	What it means (to distinguish similarly named variables)	Coding/categories[b]
Gender	Binary indicator	Male=1; female=0
Education level	Highest attained education category (not y of schooling)	No formal education=1; primary school=2; junior high school=3; high school and above=4
Age group	Categorical age bands (not continuous age in y)	60-69=1; 70-79=2; ≥80=3
Self-rated health	5-point subjective health rating	Very poor=1 to very good=5
Marital status	Current marital status	Married=1; unmarried/widowed=0
Monthly household income (CNY)[c]	Household-level total monthly income (not personal income)	0-3999 CNY=1; 4000-7999 CNY=2; ≥8000 CNY=3

[a]Control variables were included in all models reported in Table 5.

[b]For binary variables, the reference category is coded as 0 (female; unmarried/widowed). For ordinal variables entered as numeric scores (education level, age group, self-rated health, and monthly household income), odds ratios represent the change in odds per 1-level increase in the coded category.

[c]Exchange rate for interpretation (study period Jul-Aug 2020): 1 CNY=US $0.14.

In the online sample, alleviating burden (F 1) was positively associated with both usage intention and actual use. A 1-unit increase in F1 was associated with a 61.8% increase in the odds of intending to use the service (OR 1.618, 95% CI 1.235 - 2.118; *P*<.001) and a 74.2% increase in the odds of actual use (OR 1.742, 95% CI 1.286 - 2.359; *P*<.001). In addition, digital trust

XSL•FO
RenderX

(F4) was positively associated with usage intention, with each 1-unit increase corresponding to a 35.1% increase in the odds of intention to use (OR 1.351, 95% CI 1.054 - 1.732; *P*=.02), and showed a marginal association with actual use (OR 1.347, 95% CI 0.986 - 1.840; *P*=.06). Service acceptance (F3) was not significantly associated with usage intention (*P*=.10) but demonstrated a marginal positive association with actual use (OR 1.250, 95% CI 1.000 - 1.557; *P*=.05).

In the offline sample, alleviating burden (F1), service acceptance (F3), and digital trust (F4) were all positively associated with usage intention. Notably, a 1-unit increase in digital trust (F4) was associated with a 22.1% increase in the odds of intention to use (OR 1.221, 95% CI 1.083 - 1.376; *P*<.001). In contrast, funding sources (F5) showed a marginal negative association with usage intention (OR 0.806, 95% CI 0.642 - 1.020; *P*=.07). With respect to actual use, digital trust (F4) was the only attitude dimension that remained significantly associated with service use in the offline sample, with a 1-unit increase corresponding to a 6.8% increase in the odds of actual use (OR 1.068, 95% CI 1.011 - 1.128; *P*=.02). Although the odds ratio for alleviating burden (F1) in predicting actual use appeared large in the offline sample, this association did not reach statistical significance, likely reflecting limited statistical power and greater heterogeneity in offline respondents.

Discussion

This study uses digital meal assistance services as a case to explain the phenomenon of "adequate supply but insufficient use" of digital eldercare services. Based on survey data from 1019 older adults in a large metropolitan city in China, we examined service adoption from a behavioral attitude perspective. The results show that older adults' attitudes toward digital meal assistance services have a multidimensional structure. Different attitudinal dimensions play distinct roles in shaping usage intention and actual service use. Evaluations of digital eldercare services are not determined by technology alone. They are also influenced by family caregiving contexts, perceived social norms, risk perceptions, and financial constraints. In addition, the effects of behavioral attitudes differ across the transition from intention to actual behavior. These findings provide empirical evidence to inform the promotion of digital services in an aging society.

Older adults' behavioral attitudes toward digital meal assistance services exhibited a clear multidimensional structure. Five dimensions were identified: Alleviating burden (F1), enhancing convenience (F2), service acceptance (F3), digital trust (F4), and funding sources (F5). These findings indicate that evaluations of digital eldercare services extend beyond functional attributes. Family caregiving relationships, perceived social norms, risk perceptions, and financial constraints also shape these evaluations. This pattern is consistent with prior studies showing that older adults' technology adoption is influenced by broader social and contextual factors [26-28]. A purely technology-rational framework that emphasizes usefulness or ease of use alone may therefore be insufficient to explain service choice. Notably, no independent factor of perceived ease of use emerged in this study. Ease of use appears to be embedded within broader evaluations of convenience, trust, and affordability. This suggests that, in specific eldercare service contexts, older adults' attitudinal structures toward technology may differ from those proposed in classical TAMs.

Attitudinal priorities toward digital meal assistance services varied across older adult groups. Most older adults focused on whether these services could help alleviate caregiving burdens, whereas younger-old adults placed greater emphasis on support for daily convenience. As shown in Table 4, the offline sample scored higher on alleviating burden (F1) than on other dimensions, indicating that many older adults tend to view digital meal assistance services as a supplement to the family caregiving system. This pattern is consistent with the Chinese eldercare context, in which limited family caregiving resources, particularly from spouses and adult children, have been an important foundation for the development of formal eldercare services [29,30]. Accordingly, the perceived ability of digital meal assistance services to reduce family caregiving pressure serves as a key reference in older adults' attitude formation. By contrast, the online sample scored higher on enhancing convenience (F2), consistent with previous studies [31-33]. This finding indicates that younger old adults place greater value on digital eldercare services that improve daily convenience and support autonomy. It also suggests that future cohorts of older adults may increasingly emphasize the role of digital services in enhancing quality of life and independent living.

Insufficient digital trust represents a key barrier to the use of digital meal assistance services, particularly among lower-income older adults. The findings show that although low-income older adults expressed relatively high levels of service acceptance (F3), their scores on digital trust (F4) were lower than those of other income groups. This attitudinal pattern is consistent with the regression results, which showed that digital trust was significantly associated with usage intention and selected aspects of actual service use. These findings align with previous research indicating that the use of eldercare services tends to be concentrated among middle- and high-income groups [34-36]. They also shed light on the mechanism through which the digital divide operates. Limited digital skills and resources not only constrain older adults' capacity to use digital services but may also weaken trust, thereby influencing usage decisions. When individuals face simultaneous deficits in digital skills and resources, psychological strain may increase, including reduced trust, which can further limit service use and exacerbate digital inequality [37,38]. Notably, regardless of income level, overall scores on digital trust remained relatively low among older adults, consistent with the distribution shown in Table 4. This pattern highlights trust as a fundamental condition that requires particular attention in the broader promotion of digital eldercare services.

Behavioral attitudes played an important but uneven role in the translation of usage intention into actual behavior. Although the TPB posits behavioral intention as a key predictor of behavior, prior studies have reported inconsistencies in how attitudes relate to intention and actual use [39,40]. In the online sample, alleviating burden (F1) was significantly associated with both usage intention and actual service use. Service

XSL•FO
RenderX

acceptance (F3) was associated only with actual use and showed no significant relationship with usage intention. This pattern suggests that some attitudinal dimensions may be less salient during intention formation but exert a more direct influence on usage decisions. By contrast, in the offline sample, multiple attitudinal dimensions, including alleviating burden (F1), service acceptance (F3), and digital trust (F4), were significantly associated with the usage intention, whereas only digital trust was further translated into actual service use. Funding sources (F5) primarily influenced usage intention and showed no significant association with actual behavior. Overall, behavioral attitudes toward digital eldercare services show clear context dependence across intention and behavior. This provides empirical evidence for the intention–behavior gap in older adults' use of digital services.

These findings have important implications for policy and practice. Greater attention should be given to the vulnerability of low-income older adults in digital environments. Public digital spaces and smart communities can improve access to digital technologies for groups affected by the digital divide [41,42]. Community-based courses and remote assistance programs can support tailored digital skills training [43]. Digital platforms should also reduce barriers through age-friendly interface design, such as larger fonts and simplified procedures [41,44]. In addition, efforts are needed to reduce technology-related anxiety among older adults [45-47]. Trust-enhancing mechanisms, including service quality certification, data security standards, and transparent pricing, can strengthen perceived safety and confidence. Finally, digital eldercare services should better match the needs of different groups. Services should emphasize burden reduction for most older adults and highlight independence and convenience for younger-old or higher-income groups. For low-income older adults, establishing basic trust remains a critical condition for service uptake.

This study has several limitations. First, the sample was skewed toward younger older adults, with relatively few participants aged 80 years or older. The findings may therefore be less representative of the oldest-old population. Second, differences between the online and offline samples may have introduced selection bias. Although key control variables were included, the results reflect associations rather than causal relationships. In addition, the sample was drawn from a single region, which may limit generalizability. Future studies should include larger and more diverse samples, increase representation of the oldest-old, and apply methods such as sample weighting or sensitivity analyses to better assess potential sampling bias.

Abstract

Background: Intrinsic capacity (IC) refers to the sum of the physical and mental capacities of an individual. Conventional IC assessment requires substantial temporal and human resources. Digital twin (DT) technology emerges as a promising solution for efficiently mapping ICs.

Objective: This study aims to explore older adults' perspectives on the DT technology and their perceptions of how it could effectively represent their ICs.

Methods: A qualitative study was used. Face-to-face semistructured interviews with 23 older adults were conducted. The interviews were transcribed verbatim and analyzed via content analysis approach.

Results: The analysis identified five themes and 16 subthemes: (1) "opt for or not my digital twin," revealing the older adults' decisions regarding whether to use DT technology for mapping ICs; (2) "my ideal digital avatar," describing the older adults' preferences for personalized digital avatar appearances; (3) "my digital twin maps my intrinsic capacity," highlighting how multimodal reminders and synchronized avatar changes enhanced their comprehension of ICs; (4) "the benefits my digital twin can deliver," emphasizing the potential of the DT system to provide feedback services to older adults; (5) "some expectations for my digital twin," outlining their expectations for DT technology. Based on the above insights, a conceptual model, "windmill" model, was further developed to better understand how to build DTs of older adults and map their ICs.

Conclusions: DT technology was a promising tool for mapping ICs of older adults. Furthermore, the "windmill" model provided a framework to build tailored DTs. The findings of this study could provide references to develop DT model to support IC management.

intrinsic capacity; IC; aging; digital twin; DT; avatar; qualitative research

Introduction

As the global population continues to age, promoting healthy aging has become an increasingly urgent public health goal. The meta-analysis indicated that only 22% of the global older adults were expected to achieve healthy aging status by 2023 [1]. To address this issue, the World Health Organization (WHO) developed a health care pathway program—integrated care for older people (ICOPE) [2]. The primary focus of ICOPE was to optimize the trajectory of intrinsic capacity (IC) [3]. IC refers to the sum of the physical and mental capacities of an individual, comprising 5 domains, namely cognitive, locomotive, sensory, vitality, and psychological capacities [4]. The prevention of IC decline plays a vital role in promoting healthy aging. The rate of decline in IC of older adults has been found to reach as significant a proportion as 76.1% [5]. Furthermore, it was hypothesized that changes in IC preceded the process of disability development [3]. Therefore, it is essential for screening and assessing IC and implementing interventions to reverse IC decline, with the goal of fostering healthy aging.

Both the first and second versions of the ICOPE framework emphasized the importance of IC assessment [6,7]. IC assessment was typically conducted by health care providers. Specifically, assessment for IC was recommended to be carried out once every 4 to 6 months [8]. However, this approach was time-consuming and labor-intensive. Therefore, the exploration

XSL•FO
RenderX

of new assessment tools was warranted. Technological advancements suggest that digital devices might assist in screening and assessing IC [3]. For instance, ICOPE Monitor (IHU Health Age), a digital tool, has been applied to ICOPE implementation [9,10]. Additionally, conversational robots have been used to assist in screening the older adults for IC [8]. Despite these efforts, current digital devices remained limited in their ability to automatically transmit IC-related data, presenting challenges for older adults who faced difficulties in operating digital devices. In contrast, digital twin (DT) technology, with its potential for real-time data integration and predictive analytics [11], might offer a more efficient and comprehensive approach to the screening and assessment of IC.

DT refers to the integration of data from physical models, sensors, and operational history into a multidisciplinary, multiphysical, multiscale, and multiprobabilistic simulation process, which maps the entire lifecycle of the corresponding physical entities in virtual space [12]. The DT facilitated bidirectional data flow between physical and virtual entities to continuously optimize physical counterparts and leveraged historical data to acquire knowledge, predict outcomes, simulate behaviors, and provide valuable insights into the future performance of physical systems [13]. DT has been applied across various fields, including architecture, industry, and aerospace [12]. In recent years, DT has also been applied to the field of health care, demonstrating significant potential for the realization of precision medicine [14]. One representative example is human DT, which can dynamically reflect an individual's molecular profile, physiological status, emotional and psychological states, and lifestyle evolution [15]. In addition, the study showed DT models could simulate and replicate the wound healing process to facilitate wound management [16]. Within cardiovascular disease, DT technology seeks to predict disease risk and progression in patients and to help clinicians forecast how pathology will evolve against a particular environmental background [17]. Furthermore, the artificial intelligence–enabled DT technology was a lifestyle medicine intervention that results in significant improvements in hypertension [18]. These applications highlighted the versatility and potential of DT in health care.

The 5D DT model can be used to guide the implementation of DT technology. It was proposed in 2018, incorporating physical entities, the model of physical entities in the virtual space, data, services, and connections [19]. This 5D DT model is a general framework that has been applied across various fields [20]. However, existing studies have mainly focused on technical applications and system construction, with limited exploration of how this model can be tailored to represent the IC of older adults. To bridge this gap and adapt the 5D DT model to a health-related framework, this study proposed a preliminary customization based on the IC context. Accordingly, the preliminary design of each component in the customized 5D DT model was structured as follows. First, the physical entity referred to the older adults and their IC levels. Second, the data dimension covered all data related to the IC of older adults, including historical, real-time, and predictive data, involving the collection, storage, management, and analysis processes. Third, services represented the various functions provided within the DT, illustrating how real-world services could be supported and enhanced through digital means. Fourth, connections described the interaction and communication among different components. Finally, the model of physical entities in the virtual space specifically refers to the digital avatar of an older person, designed to accurately reflect his or her level of IC in this study.

This study represents a step toward developing a customized 5D DT model, with a specific focus on exploring the perspectives of older adults. When designing the customized 5D DT model, it is crucial to ensure that the model not only accurately reflects the assessment results of their ICs but also aligns with the self-perception of older adults. Moreover, the DT model must be designed in a way that is both comprehensible and acceptable to older adults, addressing their specific needs and preferences. To translate these theoretical considerations into a practical model, we conducted semistructured face-to-face interviews to explore older adults' perspectives on the DT concept and their views on how their ICs could be effectively represented within such a model. The findings from these interviews provide the foundational evidence that informs the construction of the customized 5D DT model tailored to map the ICs of older adults.

Methods

Study Design

This study used descriptive qualitative research design, which followed the principles of naturalistic inquiry [21]. Face-to-face semistructured interviews with the older adults were conducted between November 2024 and December 2024.

Study Setting and Participants

Participants were recruited from urban parks and leisure clubs for older adults in Beijing, China, where they engaged in regular recreational and social activities. These sites were chosen because they are popular gathering places for community-dwelling older adults, making them ideal for reaching individuals with diverse levels of ICs. However, we acknowledged that such sampling might introduce a selection bias toward relatively active older adults who are more socially involved. Purposive sampling was used in this study, which enabled researchers to select experienced participants based on the aims of the study [22]. The maximum variation sampling technique was also applied simultaneously to recruit heterogeneous samples of older adults with different levels of ICs, education, sex, and age [23]. The participants had different levels of ICs which were measured by traditional assessment methods (Table S1 in Multimedia Appendix 1), and the educational attainment of participants included primary, secondary, and higher education, to ensure diversity in cognitive and experiential perspectives, offering a wealth of diverse perspectives that could enrich the research topic.

Potential participants were selected according to the following criteria: (1) aged 60 years or older, (2) completed the IC assessment (Table S1 in Multimedia Appendix 1), (3) able to communicate effectively in daily life, and (4) informed consent and voluntary participation in this study.

XSL•FO
RenderX

Data Collection

Older adults were invited to participate in both the assessments of ICs and qualitative interviews. The IC assessment was conducted using a tablet computer, with specific measurement tools and scoring rules detailed in Table S1 in Multimedia Appendix 1. Interviews were scheduled with individuals who agreed to participate after completing the IC assessment. All participants were assured that their participation was entirely voluntary, and written informed consent was obtained prior to data collection.

Before the interview, the interviewer fully introduced the objective of this study to the older adults. The researcher prepared textual and graphic materials to explain the study to the older adults, helping them understand their ICs and DT technology. In addition, a short video introducing DT technology and the concept of a digital avatar was shown to enhance participants' comprehension. Everyday examples and scenario-based demonstrations were used to ensure comprehension, and participants were asked to restate their understanding before the discussion began. The older adults were encouraged to actively share their understanding of the applications of the avatar and DT technology, as well as to voice their perspectives and related knowledge during the discussion. Afterward, the older adults were invited to ask any questions they had about the avatar or DT technology, and the researchers provided clear and comprehensive responses to their inquiries. The participants were also told they could withdraw at any point during the interview. The interviews were conducted in a quiet and relaxed cafe environment that allowed for open and comfortable conversation. The interviews were conducted through Chinese conversations. The participants were encouraged to express themselves based on the interview guide. Audio recordings were made with the consent of the participants.

All of the interviews were conducted by the same researcher (YN) to ensure consistency. The researcher was trained by qualitative research experts and practiced interviews to refine their interviewing skills. The interviews were conducted using a semistructured interview guide (Table S2 in Multimedia Appendix 2), which was initially designed based on self-construal theory, providing a deeper understanding of individuals' self-perception [24]. Then, experts in qualitative research, IC, and DT technology were organized to discuss the interview guide, and the interview guide was revised based on feedback. One participant, who met the inclusion criteria, was selected for a preinterview, and the interview outline was modified based on the results of this preinterview. The data obtained from the preinterview were not included in the analysis. The principle of data saturation was a recognized criterion for determining sample size in qualitative research designs [22]. In this study, data collection and analysis processes were carried out simultaneously, and data collection was stopped when no new data was generated related to the topic of study. Specifically, after interviewing 21 participants, no additional themes related to the study topic were identified, and 2 further interviews were conducted to confirm saturation. Therefore, data collection was stopped once thematic redundancy was observed.

Data Analysis

The interview recordings were transcribed and organized verbatim within 24 hours of the end of each interview. NVivo 12.0 software (QSR International Pty Ltd) was used for coding and analysis, and data analysis was conducted in Chinese. This study adopted the content analysis approach [25]. The interviewer reviewed the text multiple times to ensure comprehensive understanding of its content. Subsequently, open coding was conducted to identify key ideas and concepts within the material. To ensure comprehensive capture of information, open coding was conducted in a line-by-line, sentence-by-sentence format. Then, similar and related codes were classified into categories and subcategories. Furthermore, themes and subthemes were generated based on categories and subcategories. This process was iteratively repeated until saturation was reached, with no new themes or subthemes emerging, and was independently conducted, confirmed, and discussed by 2 researchers. Finally, the themes and subthemes were translated into English using both direct translation and back-translation methods.

Rigor

Rigor focuses on 4 key dimensions: credibility, transferability, dependability, and confirmability [26]. The credibility was strengthened by the researcher's establishment of trusting relationships with older adults, which facilitated authentic self-expression during the interview process. The results of the study were also fed back to the participants, enabling them to confirm and add to the results. Additionally, the researcher used reflexive journaling to track the research process and identify potential biases, thereby enhancing credibility. To enhance transferability, a purposive sampling method was adopted to ensure that participants had rich perspectives. Moreover, rich interview data enhanced transferability by documenting participants' context, enabling evaluation of results' applicability to other settings. The dependability was addressed through regular discussions among the researchers. These discussions allowed for the resolution of disagreements and confusion during the analysis process. Finally, the confirmability was established by providing a description and rationale for the decisions made based on the results.

Ethical Considerations

This study was approved by the ethics committee of the Capital Medical University (batch: Z2023SY138). Informed consent was obtained from all participants, and the study adhered to all relevant privacy and confidentiality protocols. All patient-related information has been fully anonymized and de-identified. No compensation was provided to the participants. All procedures were conducted in accordance with the guidelines of the Institutional Review Board (IRB) and Research Ethics Board (REB).

Results

Participant Characteristics

A total of 23 older adults were interviewed face-to-face, with participant selection considering the age, sex, degree of education, and the level of IC. Interviews lasted between 27.75

XSL•FO
RenderX

and 49.58 minutes (mean 37.57, SD 6.77 min). The demographics were outlined in Table 1. Of the 23 older adults, 12 were women and 11 were men, with an average age of 68.30 (SD 5.45; range: 61-84) years. 17 had a high school education or higher, including 6 with a bachelor's degree or higher. The average score for IC was 4.04 (SD 0.98; range: 2-5).

Summary of Themes

Overview

The study identified five key themes related to build DTs of older adults to map their ICs: (1) “opt for or not my digital twin,” explored the willingness of older adults to adopt DTs as a means to reflect their ICs; (2) “my ideal digital avatar,” in which older adults depicted the characteristics of their ideal digital avatars; (3) “my digital twin maps my intrinsic capacity,” focused on how DTs could effectively represent and monitor the ICs of older adults; (4) “the benefits my digital twin can deliver,” in which older adults expressed their beliefs regarding the potential benefits that DTs could offer to them; and (5) “some expectations for my digital twin,” expressed the expectations that older adults had for the future development of DTs. From these insights, we further developed a conceptual model to better understand how to build DTs of older adults to map their ICs.

Theme 1: “Opt for or Not My Digital Twin”

DT technology, being an emerging concept, was unfamiliar to the majority of older adults. When older adults understood the concept of DT, they were presented with the option to use this technology for monitoring and reflecting on their levels of IC. This decision-making process yielded 4 response outcomes:

Subtheme 1: “Health Mirror”—Optional

Some older adults recognized and believed that DTs were optional as health mirrors. They believed that DTs were just like mirrors that could reflect their IC levels and health status. The presentations of DTs were real-time, with changes synchronizing with the IC levels of older adults:

> *If one day digital twins could become a reality and come into my life, that would be quite nice, I reckon.* [N3]

> *Digital twin is my soul, the soul that represents my physical body and health status. The digital twin is perfectly in sync with me, like two hearts beating as one.* [N9]

Subtheme 2: “Multidimensional Advantages”—Worthwhile

Some older adults believed that DTs were well worth choosing because of their multidimensional advantages in terms of convenience, intuitive visibility, scientific rigor, and timely alerts. Moreover, from the perspective of older adults, DTs might be better than physicians. The results generated by DTs were based on real data, which provided a rational basis for accuracy and reliability. However, it was possible for the physicians to selectively disclose certain information to older adults:

> *Digital twins can bring a lot of convenience to my life. It can remind you before you are in danger. It’s very useful, isn’t it? My son is not around me, and my health is poor. I am afraid that one day something bad will happen. No one reminds me. No one is around me. It will be much more convenient to have the digital twins* [N12]

> *Doctors, they have their own emotions and thoughts, and mixing them in with the process (clinical care trajectory) is very bad. Digital twins, they have no emotions. They just do what they are supposed to do, and you know what? They are based on data. Well, they are true.* [N2]

Subtheme 3: “Unknown and Unbelievable”—Nonessential

There remained a group of older adults who believed that constructing a DT to reflect their ICs and health status was of little consequence. Many demonstrated limited familiarity with DT and had no practical experience in its use, leading to skepticism or ambivalence toward its adoption. Additionally, a segment of the older adults perceived DT as being overly futuristic and unattainable, particularly within the near-term timeframe. For technologies perceived as infeasible, the question of choice was deemed irrelevant:

> *I didn’t know anything about digital twins before, and even now, I’ve only heard a little bit about it. I’ve never actually used it, so I can’t really say much*

XSL•FO
RenderX

about it. And as for using it? Well, I wouldn't have a clue how to. [N3]

Well, how should I say it? For someone like me, at this age, even talking about this stuff—digital twin technology—seems like wishful thinking. I don't waste my time on it because this kind of technology is not going to be ready anytime soon. This thing won't be around for at least a decade or two. It has nothing to do with me, so whether I choose it or not doesn't really matter. [N10]

Subtheme 4: "Proliferation Concerns"—Rejected

Not all older adults actively accepted new technologies, with a subset expressing opposition to the adoption of DTs. They argued that advancements in technology might reduce the need for human labor, leading to job losses or unemployment among younger generations. Without stable employment and income, young people might delay or forgo marriage and childbearing, ultimately contributing to a decline in fertility rates. These adverse outcomes caused by the development of technology could affect human survival and reproduction:

I surely don't wish to see such a thing come to pass. If this technology was applied, a few people could take care of all the older adults. What about other young people? How should they survive? Let me tell you this, the more advanced technology becomes, the more people find themselves out of work. But people must have a work and live on. Then they will choose to get married and have children. Why are there so many DINK families coming out? Because technology is too advanced." [N15]

Theme 2: "My Ideal Digital Avatar"

The appearance of the digital avatar served as the end point for the presentation to older adults and directly affected the effectiveness and adherence of the application. According to the concept of DT technology, the digital avatars were replicas of physical entities that synchronized with the changes in real older adults. Unexpectedly, they voiced some perspectives that were outside the box.

Subtheme 5: "Mirror Mapping" and "Visual Refinement"

To better understand their IC and health conditions, some older adults desired the digital avatar to be an exact replica of themselves, reflecting a mirror-image relationship. To avoid negative emotions, such as sadness or self-abasement, that might arise from confronting the realities of aging and poor health, others preferred the digital avatar to embody an idealized, glorified version of themselves. A feasible solution might be to show the real appearance to physicians and a beautified version to the older adults:

I don't want the real one. When you look at yourself against this appearance at home, it's necessary to have an appearance that's more pleasant to look at. You could design two versions—one that shows the real appearance to the doctors, and another that shows a more comforting and pleasant appearance to us. [N1]

Subtheme 6: Self-Preference Projection

The ideal digital avatar for older adults varied significantly based on personal preferences. Some chose representations that mirrored themselves, including their current appearance, an enhanced version, or a rejuvenated younger self. Moreover, some older adults said the digital avatar was portrayed as a young person of the opposite sex, which they found more visually appealing and engaging. Others indicated that the digital avatar represented specific organs, enabling them to better understand health conditions. Interestingly, idols, cute pets, and favorite cartoon characters were also regarded as their ideal digital avatar:

Everyone likes handsome men and beautiful women, don't they? If you're a man, of course you'd want a beautiful woman, especially as you get older, right? And for us old ladies, it's such a delight to see something pleasing to the eye - it just makes us happy! [N8]

Well, if that digital avatar looked like Daoming Chen (an actor), I'd be using it all the time, I tell you! I'd follow every suggestion he makes. [N20]

Theme 3: "My Digital Twin Maps My Intrinsic Capacity"

DT technology can map the ICs of older adults, and the shape and changes of the digital avatar indicate the level and changes in their ICs. The expectations among older adults regarding how DT should reflect the diversity and dynamics of their ICs vary widely.

Subtheme 7: Multimodal Presentation

The manifestation of IC variations in DTs of older adults was multimodal, encompassing auditory, visual, animated, and textual modalities. Some older adults indicated that auditory alerts from the DTs were considered an adequate response to IC variations, dimensional changes, or risk factor detection, and visual representations through images or animations were generally well-received among the older adults. Textual presentations, though beneficial for maintaining the privacy of IC results, were not user-friendly for older adults with vision loss:

My motor function is down. The digital twin of mine is just like the avatar in virtual game—when its energy runs low, it slowly starts to shrink away. It's like a little nudge, reminding me to get moving and recharge my batteries. [N14]

All I need is for it to show me in plain writing—what's the test about, what's the perfect score, how many points I got, what's considered normal range, and where exactly I stand. Just lay it out simple and clear for me. [N18]

Subtheme 8: Matching Behavior Mapping

Older adults tend to monitor external changes that align with the 5 dimensions of IC, using these changes as indicators to

XSL•FO
RenderX

identify potential issues (Table 2). For example, assistive devices indicated declining motor functions, lateral ear orientation suggested hearing loss, and squinting eyes represented visual impairment. There were still some older adults who said they did not need to have extrinsic changes when their IC levels changed:

> *When I can't move like I used to, my digital twin shows it too—starts walking slower, takes smaller steps, kind of shuffling along like my feet are stuck to the floor.* [N23]

> *Even if my IC decreased, I'd still want my digital twin to look happy and cheerful. You see, when the people around me are smiling and in good spirits, it makes me feel better too. But if they look sick and miserable, it just brings me down.* [N11]

Table . Digital avatar's external changes linked to intrinsic capacity abnormalities.

Dimension and abnormal outcomes	External changes
Cognition	
Cognitive decline	• Dull eyes • Forgetting behavior • Speech delay • Look unsure • Dementia-like behavior • Fixed posture • Unresponsive
Psychological capacity	
Mild depressive symptoms	• Less communication • Moodiness
Severe depressive symptoms	• Expression of fear • Expression of irritability • Expression of anger • Expression of giving up • Abnormal behavior • Social avoidance
Sensory	
Vision failed	• Wearing glasses • Squinting
Hearing failed	• Wearing hearing aids • Lean in to listen • Unresponsive
Vitality	
Malnutrition or risk of malnutrition	• Slim • Pale complexion • Listless • Increased wrinkles • Activity reduction
Locomotive capacity	
Decline	• With the aid of assistive devices • Stride reduction • Flustered gait

Theme 4: "The Benefits My Digital Twin Can Deliver"

From the perspective of older adults, DT offers the following potential benefits.

Subtheme 9: Health Advisor

Some older adults regarded DTs as personalized health advisors, capable of enhancing their IC through proactive interventions. Moreover, DTs could perform comprehensive health monitoring, provide early disease detection, support medical treatment, and facilitate health management:

> *Every morning when I open my phone and see my digital twin, it's like getting a little preview of how my day might go. It tells me what I should watch out for, if something's not quite right with my health, giving me a heads-up before any real trouble starts.*

XSL•FO
RenderX

It's like having a little guardian angel in my pocket. [N21]

Subtheme 10: Life Assistant

Beyond the medical applications, DT was also recognized as a comprehensive life assistant, offering support across various aspects of daily living, such as essential reminders, practical life guidance, and tailored solutions to address the unique challenges faced by seniors living independently:

In the future, if I am left alone, I will get such a digital twin. It'd be a real help. Like when I feel like cooking, it could show me recipes. And when I want to do my exercises, it could lead me through them. [N7]

Subtheme 11: Spiritual Mentor

Some older adults not only found joy in engaging with their DTs but also saw them as spiritual mentors in favor of their psychological well-being:

Sometimes we old folks aren't too keen on socializing with others. Maybe we don't quite get along with real people, but chatting with our own digital twin gives us something to do. What's more, the mental state of my digital twin is exceptionally good, and I consider it to be my role model. [N1]

Subtheme 12: Role Complement

DT was poised to become an important supplement to the lives of older adults, such as their children, caregivers, or health advisors. For instance, for a group of older adults experiencing geographical separation from their children or those belonging to childless households, DT offered comprehensive solutions by providing both practical assisted living services and essential emotional companionship, thereby effectively supplementing traditional filial support roles:

My children can't really take care of me, bless their hearts - they've got their own families to look after, and they live so far away. But I've got this digital twin of mine, it's been a real lifesaver. Whether it's helping me in life or giving me health guidance, it's always there for me. Honestly, it's just like having one of my own children by my side. [N9]

Theme 5: "Some Expectations for My Digital Twin"

Older adults expressed some expectations for their DTs, notably the following subthemes.

Subtheme 13: Intelligence and Knowledge Integration

The DT technology used to reflect the IC of older adults was expected to be intelligent and knowledge-integrated, enabling automated data transfer, rich functionality, and remote operation. The intelligence and knowledge integration of the DT technology were not only applied in health care, but also extended to various facets of older adults' daily life, encompassing daily assistance, entertainment, and so on:

All my information and data just get sent up there automatically—I don't have to bother with typing anything in myself. [N10]

My digital avatar can even dance and sing for me. When I'm in the mood for some Beijing opera, it can belt out those classic tunes too. It's got all sorts of little entertainment tricks up its sleeve. [N13]

Subtheme 14: Positive Feedback

Timely positive feedback could help motivate older adults to persist in using DT technology to improve their ICs and health status:

Every day, my digital avatar gives me exercise guidance. After the workout, it shows me all my vital signs right then and there, making me feel like I'm getting better. Getting this instant feedback really keeps me motivated to stay active and healthy. [N16]

Subtheme 15: Multisubjective Bond

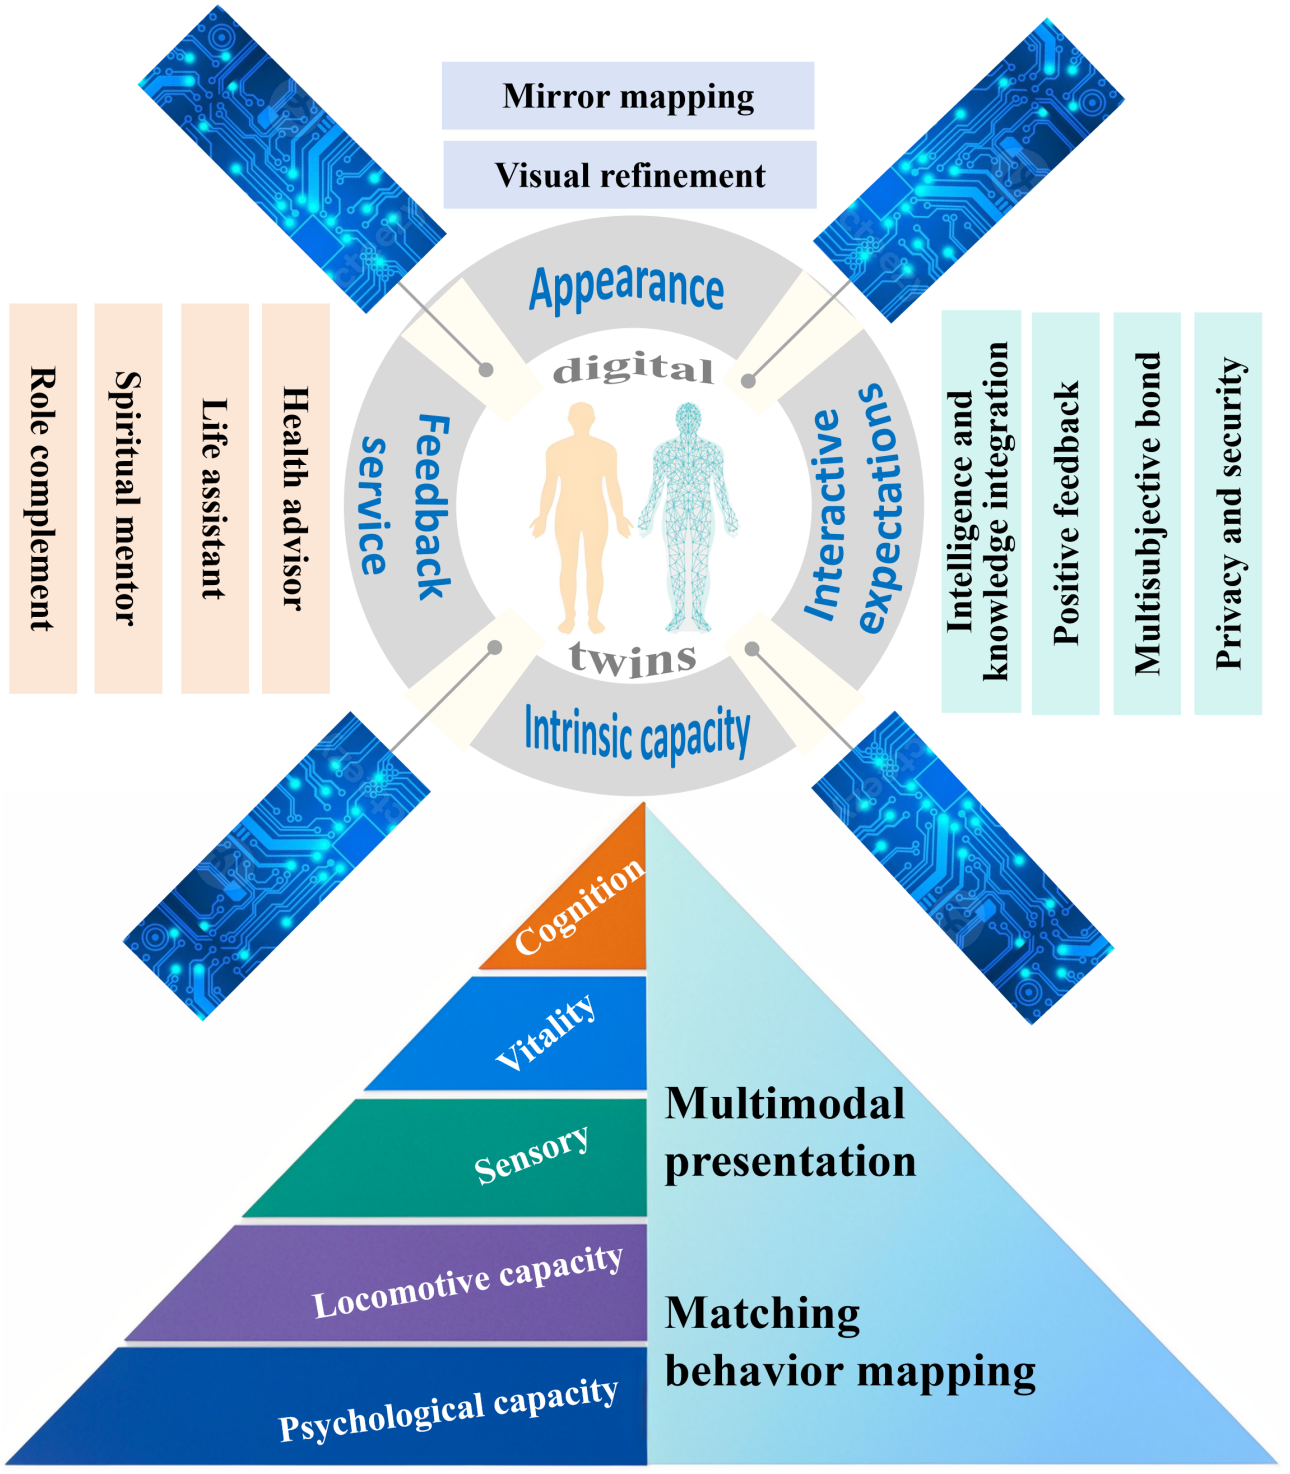
DTs for older adults were anticipated to function as interconnected systems with multiple entities, serving as bonds that facilitated integration across domestic, community, and hospital networks:

If the doctor notices my digital avatar 's head turning red—that means my blood pressure's up—they can just send me a message right away, telling me what to do about it. [N6]

Let me give you an example—my digital avatar here, it's not just saw by me, but my spouse too. My son can check in on me anytime, through this system. [N14]

Subtheme 16: Privacy and Security

The assessment and management of older adults' IC using DT technology necessitated the huge sensitive personal data. This process should be private and secure:



The digital twin should have proper security measures. If they go leaking all our private information, we seniors would lose trust in them. [N12]

Conceptual Model

Based on the insights, we further developed a conceptual model, the "windmill" model, to better understand how to build DTs of older adults to map their ICs (Figure 1). Centered on the evaluation of IC, the "windmill" model integrated DT technology and comprised 4 key components. First, the appearance of the DT, which reflects 2 main preferences: "mirror-like" and "idealized" forms. Second, the mechanism of mapping IC, which enables dynamic visualization of older adults' IC levels and changes through multimodal presentation and behavioral mapping. Third, feedback service, which includes 4 functional roles: health advisor, life assistant, spiritual mentor, and role supplement. Fourth, interactive expectations, which emphasize intelligence and knowledge integration, the provision of positive feedback, effective coordination among families, communities, and health care institutions, and ensuring the security of personal privacy information. Grounded in the perspective of older adults, this "windmill" model provided support for the application of DT technology in IC assessment.

XSL•FO
RenderX

Figure 1. Digital twins focusing on intrinsic capacity of older adults—windmill model.

Discussion

Principal Findings

The integration of DT technology into IC assessment held the potential to transform how older adults' IC was monitored and supported. Incorporating the perspectives of older adults, this study offered an initial exploration of how DT technology might be leveraged to support IC assessment. As for avatar appearance, the participants have demonstrated diverse perspectives regarding their envisioned characteristics of an ideal DT. They also described how the DT should represent and map their IC levels, highlighting the importance of multimodal reminders for enhancing IC comprehension. In addition, participants expected the DT to offer feedback services that could help maintain or improve IC. Based on these findings, a preliminary framework—the "windmill" model—was developed, incorporating 4 core components: appearance, intrinsic capacity, feedback services, and interactive expectations. The "windmill" model offered potential pathways for guiding the design of DT-supported IC assessment tools for older adults.

The appearance of digital avatars played a pivotal role in user engagement and acceptance, which was conducive to helping

XSL•FO
RenderX

older adults understand and maintain their ICs. The findings of this study emphasized the importance of personalized digital avatars, consistent with existing literature that indicated superior self-identity recognition with personalized digital representations versus generic avatars [27]. The digital avatars might be one-to-one reductions of physical entities. Individuals might demonstrate an inherent desire to protect avatars that mirrored themselves [28,29], which was beneficial for them to maintain their internal abilities. Digital avatars representing older adults were also expected to take other forms, such as younger versions of themselves, specific organs, or even their idols. It has been shown that whether or not digital avatars resemble the individuals themselves, both can have an impact [30]. Effective interaction, rather than mere personification, might be the key to the success of digital avatars [31]. Therefore, the design of digital avatars should be tailored to the unique characteristics and preferences of older adults to enable effective interactions, rather than strictly replicating their physical appearance.

DT technology realized the dynamic mapping of the ICs of older adults. DT technology could effectively reflect ICs in the following ways: (1) current IC levels and trends, presented through multimodal methods such as voice, text, images, and animations, which cater to diverse user preferences and cognitive abilities; and (2) synchronous changes between digital avatars and the older adults they represent, which were more easily understood. By bridging the gap between complex health data and actionable information, DT technology had the potential to empower older adults to better understand and manage their ICs, which could compensate for the health inequalities caused by the digital divide [32].

The digital avatar had a dual identity—"from avatars to agents" [27]. In this study, digital avatars functioned not only as visual representations to display the ICs of older adults but also as interactive agents capable of providing feedback services. These feedback services focused on health support, life support, and psychological and social support. In terms of health support, digital avatars could provide health status monitoring, early warning, and health education [14]. Additionally, when interacting with digital avatars representing themselves, individuals could adopt an interventionist perspective, leading to a more objective self-assessment [33]. Digital avatars were also expected to provide assistance in daily life for older adults, thereby increasing user engagement and stickiness. Regarding emotional and social support, older adults could identify with their digital avatars, experience meaningful emotions, and form authentic attachments with them. Digital avatars created a beneficial psychological distance that facilitated more objective self-reflection while maintaining emotional engagement [34]. Compared to interactions with real people, individuals perceived digital avatars as more private and secure, making them more willing to express themselves [34,35]. Avatar therapy has been used for the treatment of psychosocial diseases [35-37]. In summary, digital avatars were expected to serve as multifunctional tools.

Older adults expressed some expectations for DT technology in mapping their ICs. First, the process should be intelligent and equipped with sufficient knowledge. In addition to the foundational technologies such as sensors, Internet of Things, machine learning, and deep learning, the intelligence of DT can be further advanced through the integration of multisensor fusion, edge-cloud computing synergy, virtual reality or augmented reality interactive technologies, and generative adversarial networks for data augmentation [38,39]. In the future, DT could be further enhanced by integrating knowledge graphs [40] and expert knowledge [11] to ensure sufficient knowledge support. Second, older adults need positive feedback from DT. Positive feedback has been proven to improve self-efficacy and intrinsic motivation [41]. Third, the DT technology, as a multisubjective bond, connected the older adults, families, communities, and hospitals. From the perspective of older adults, remote health care services become more accessible. For families, it provides a clearer and more comprehensive understanding of older adults' well-being. Meanwhile, communities and hospitals can achieve batch management of older adults. Finally, the privacy and security of DT technology can be guaranteed by blockchain technology, federated learning, and other methods [11].

Overall, the "windmill" model provided insights from older adults on the construction of the virtual entity, the mapping of IC, the mechanisms of interaction between the virtual entity and his or her twin, and the types of services that a DT system should deliver. It also encompasses the core components of a DT system—the physical entity, its virtual twin, and the mapping relationship linking the two [42]. Compared with the 5D DT model, the "windmill" model offered a distinct theoretical contribution by integrating older adults' perspectives into the conceptualization of DT-based IC assessment. This user-centered orientation was absent from the 5D DT model, which primarily emphasized system architecture, data flows, and computational mechanisms but offered limited consideration of older adults' acceptance, perceptions, and needs. However, the "windmill" model presented a notable limitation in that it did not address the data and connectivity dimensions included in the 5D DT model. To enhance its comprehensiveness, future work should incorporate expert consultations to refine these technical dimensions and integrate them with the older adults-centered components.

The IC assessment based on DT technology guided by the "windmill" model showed considerable promise. The IC assessment is grounded in multidimensional data collected from older adults, such as physiological parameters, handgrip strength, and daily activity [43-46]. By integrating general population-level knowledge with real-time individual data from wearable devices, DT technology enabled personalized and continuously refined IC assessments for older adults [47,48]. The entire process of data collection and IC assessment results presentation through DT technology reflects the ongoing transition in modern medicine towards a data-driven paradigm [49]. Beyond assessment, DT technology informed by the "windmill" model also showed strong potential for IC-oriented interventions. The study demonstrated that personalized digital coaching presents a highly promising approach for interventions targeting IC [50]. Virtual entity could also be seen as a form of coaching. The study had shown that a virtual entity equipped with expert-level medical knowledge could serve as a personal physician capable of answering patients' questions around the

XSL•FO
RenderX

clock [51]. In addition, an older adult's DT could serve as a platform for computer-simulated therapeutic experiments, enabling the design of precisely tailored and personalized treatment plans [51].

However, the application of DT to the IC assessment in older adults still faces several major challenges, such as high implementation costs [52], limited usability for individuals with low digital literacy [53], and ethical concerns regarding data privacy and consent [54]. To overcome these limitations, future DT systems are expected to incorporate generative artificial intelligence–based interfaces to simplify user interaction and adopt low-cost wearable sensors and privacy-preserving data protocols to mitigate financial and ethical constraints [51,55,56]. These technological advances also provide a foundation for practical implementation in real-world settings. Take the Chinese community setting as an example, older adults could wear basic wearable sensors, and the collected data would automatically update their individual DTs. Based on these real-time data streams, the DT model could provide targeted guidance for daily IC management, while community health professionals could remotely assess and manage older adults' IC through the DT system.

There were several limitations to this study. First, this qualitative study sample involved participants from parks and leisure clubs for older adults but did not include older adults from homes, nursing homes, or hospitals. This limited the generalizability of our findings to the broader population of older adults. Second, all interviewees were from urban areas and had some level of familiarity with DT technology. This might have influenced their perceptions and suggests that the findings might not fully represent older adults living in rural areas or those with limited exposure to DT technology [57]. In the future, a more diverse sample should be considered, including participants from different regions and with varying levels of technological experience, to improve representativeness and capture a wider range of perspectives.

Conclusions

To integrate DT technology for mapping the ICs of older adults and enable comprehensive management of ICs, a preliminary conceptual model, termed the "windmill" model, was proposed. According to the "windmill" model, the ideal digital avatars of older adults had diverse personalized characteristics. To help older adults understand their ICs, multimodal reminders and synchronous changes of digital avatars were essential. Furthermore, the DT system was believed to provide various feedback services to older adults in terms of health, daily life, psychology, and society. Older adults also had some expectations for DT technology, such as intelligence, knowledge integration, and positive feedback. These findings provided guidance for the development of DT systems tailored to effectively support IC mapping in older adults, ultimately contributing to healthy aging.

Acknowledgments

The authors would like to express their deepest appreciation to all the older adults who participated in this study for their valuable involvement.

Funding

This study was supported by a grant from the National Key R&D Program of China (2023YFC3605200 and 2023YFC3605201).

Abstract

Background: Globally, the older population is increasing rapidly, becoming one of the most significant demographic trends of the 21st century. This growth poses important social, health, and technological challenges for societies that must adapt their environments and services to promote independent and healthy aging. In Spain, the population aged 65 years and older reached 18% of the total population in 2020, and projections indicate that this proportion will continue to rise in the coming decades. Within this context, smart homes have emerged as one of the most promising avenues to support aging in place and improve the quality of life. Smart homes encompass a wide variety of functions, including environmental control, safety monitoring, communication, and other assistive technologies, that may help older people stay healthy, safe, and independent in their own homes. However, older people are not a homogeneous group. Their lifestyles, health conditions, and technological experiences differ substantially, which means that, as with any assistive technology, smart home functions must match the real and perceived needs of the target users to ensure acceptance, adoption, and long-term use.

Objective: In this study, as a step forward toward the adaptability of smart home technology, we present a method to analyze the practical needs of smart home functions for older people. Specifically, we aim to understand the Spanish older population's readiness and needs for smart homes and to provide insights that can guide the design of more adaptive and user-centered solutions.

Methods: We conducted an online survey focusing on residentially based lifestyles, health conditions, and preferences for smart home functions, targeting older adults living in Spain. The survey collected information about participants' demographic profiles, daily activities, health self-assessment, and attitudes toward technology. A total of 102 valid responses were analyzed. We then classified the older adults according to their residentially based lifestyles using clustering techniques and analyzed the preferences and needs for smart home functions in each identified group.

Results: Four clusters emerged based on the information provided by the participants: (1) high quality of life and independent life, (2) poor quality of life, (3) social-centered life, and (4) creative and personal-centered hobbies at home. On the basis of this classification, we explored each group's specific needs for smart homes and estimated their readiness to embrace different aspects of technology. As a result, the top-priority smart home functions for each group were identified and compared.

Conclusions: This research contributes to understanding the practical user needs of smart homes as assistive technologies for older people. It provides a methodological approach to anticipate and prioritize functions according to user characteristics, supporting the development of personalized, adaptive, and more acceptable smart home solutions for aging populations.

KEYWORDS

older people; smart homes; assistive technology; user needs; user segmentation; residentially based lifestyles

Introduction

Population aging is a global challenge [1]. It is of utmost importance for older people to stay healthy and independent in their homes, where they feel comfortable. To support independent living, technology that can quickly detect hazards and respond appropriately in emergency situations becomes crucial for older people living in their own homes [2].

Smart home technology has made significant advances in the fields of remote management and older adult assistance [3]. Smart home services improve comfort, safety, and security at home with Internet-of-Things technology and allow older adults to receive medical treatment or check their health at home [4]. It is becoming a very important technology to support healthy and independent lives for older people [5]. Ultimately, this

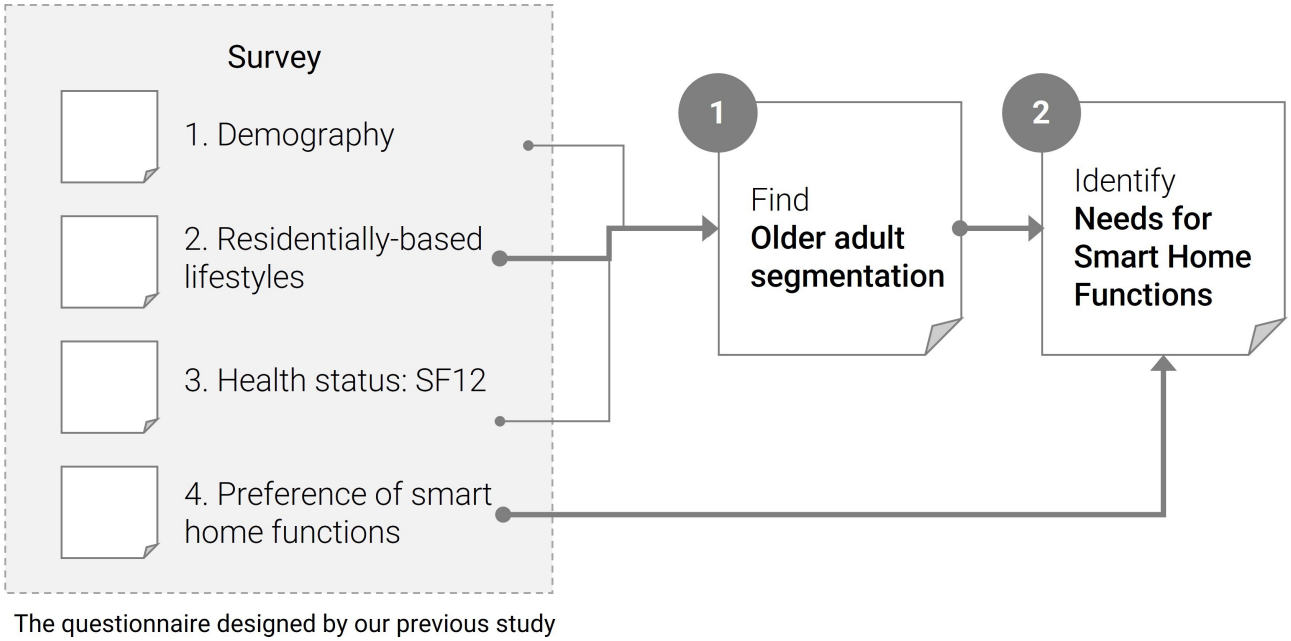
XSL•FO
RenderX

technology can help improve the quality of life in the older population [6].

However, most older adults perceive smart technologies to be difficult to use, and there may be many barriers to adopting the technology in real life. In addition, older people may not even be aware of how smart home functions can meet their needs. For these reasons, it is expected that commercialization and widespread use of smart homes for older adults will take still some time [6]. In order for this technology to pervade their lives, older users should not be classified into a single group but should be subdivided according to the service purpose, so their specific needs can be identified and satisfied accordingly [7].

To address this challenge, we segmented older people according to their lifestyles within residential facilities, where smart homes are used. Our segmentation was based on residentially based lifestyles (RBL). Some studies claim that lifestyles related to a specific domain can provide meaningful results for segmentation of the population under study [8]. For example, Thøgersen [9] considered food-related lifestyles for analysis related to food consumption, and Sanquist et al [10] proposed the use of energy-related lifestyles as a domain to identify patterns of energy consumption.

In this study, we used a questionnaire on RBL and smart home needs that we have previously developed and validated in a Korean population, in which we confirmed that this is a tool that can lead to meaningful results [11]. Building upon that prior work, the present research applies the instrument to a sample of older adults in Spain, with the aim of proposing a segmentation method and analyzing the smart home requirements of each subgroup. This approach enables the assessment of both readiness and specific needs, thereby generating insights that can inform strategies to enhance the adoption and usability of smart home technologies among older adults.



The remainder of the paper is organized as follows. The *Methods* section presents the study process, the participants, the questionnaire used, and the data analysis. Then, the *Results* section presents the principal component analysis (PCA) of the RBL, the segmentation, and the needs for the smart home functions. The *Discussion* section states first the main findings, comparing them with related works, and then it discusses the limitations. Finally, the *Conclusions* section closes the paper with the main contribution and future research.

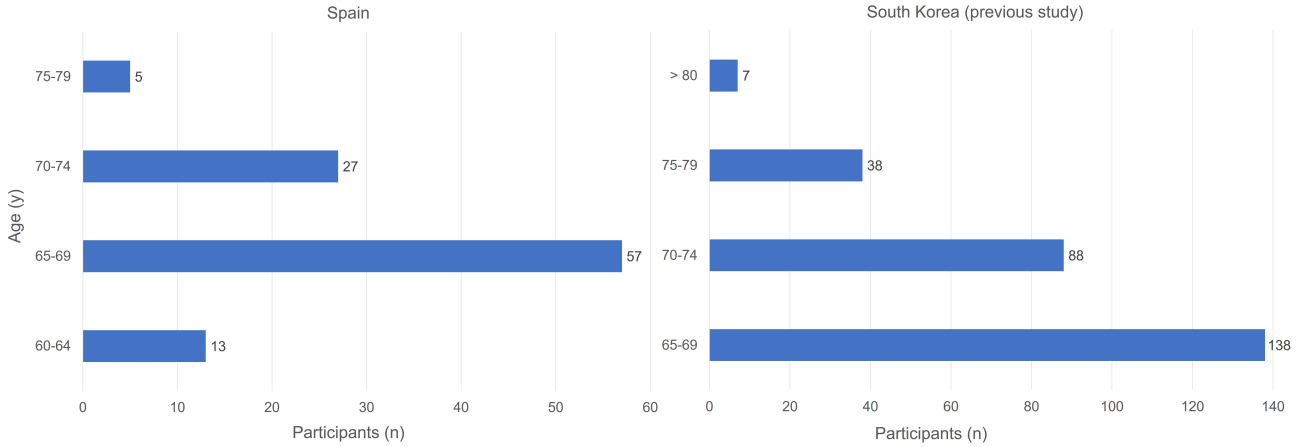
Methods

Process

Figure 1 presents the study process. The resulting outcomes are (1) RBL-based segmentation of older adults in Spain and (2) analysis of the needs of smart home functions for each segment. This study proves that segmentation according to RBL and analysis of smart home needs through the questionnaire and method presented are useful to analyze the perception and detailed needs of smart homes, which are essential as assistive technologies for older adults.

Figure 1. Study process. SF12: 12-item Short-Form Health Survey.

Participants



This study targeted older adults in Spain, a representative country facing an aging society. In the previous Korean study, the survey was conducted with older adults aged 65 years or older. Considering that the internet usage of older adults in South Korea decreases at higher ages than in Spain [12,13], we set the lower age limit at 60 years, 5 years below that of South Korea.

Therefore, the survey participants were designated as senior citizens aged 60 years and over, living in Spain (Figure 2). The criteria for a valid response were (1) age of 60 years or older, (2) no missing answers to questions, and (3) responses received within the specified survey period. We collected a total of 102 valid answers over 5 consecutive weeks. Regarding the

XSL•FO
RenderX

proportion of women and men, our sample included 41 men and 61 women (40.2% vs 59.8%), similar to that of Spain (45% vs 55%) [14]. The average age of the respondents was 68 (SD 3.8) years.

Figure 2. Age comparison of participants in 2 countries.

Instruments

We used a questionnaire that was developed and used in our previous Korean study [11], which consisted of a total of four sections: (1) demographics, (2) RBL, (3) health status, and (4) smart home function preferences. The demographics section consisted of eight questions: gender, age, marital status, residence type, caregiver, time spent out of the home, education, and monthly income. Questions for RBL were constructed by analyzing existing relevant studies [15-23] and explored the following: (1) quality of home life and needs for daily life, (2) daily home activities, and (3) social events at home.

In addition, the health status was checked through the Short-Form Health Survey of 12 items, so that the physical and mental health of each group could be compared after segmentation by RBL questions. With proven reliability and validity, the 12-item Short-Form Health Survey was developed to measure the health status of respondents in a short time. This survey calculates a physical component summary (PCS) and a mental component summary (MCS), which can be assessed based on the US average of 50 points. A high score means good status of physical or mental health [24].

Finally, regarding smart home function preferences, functions considered were based on a systematic review of smart home research [25]. On the basis of the results of this study, we could extract 26 functions in 8 categories. This section of the questionnaire demands the participant to select from 1 (not necessary) to 5 (most necessary) how much each of the 26 smart home functions is needed.

All questionnaires were carefully revised by experts in gerontology research and smart home technology.

Procedure

Data collection was conducted as an online survey, a non-face-to-face survey tool. This survey used convenience sampling, which is one of the nonprobability sampling methods. The questionnaire was distributed among older adults in different areas of the Madrid region via day care centers. The questionnaire was translated into Spanish, and it was distributed via Google Forms, together with a guide on the purpose of the study and the information that the survey responses would not be used for any other purpose except for research. Responses were collected over 5 weeks.

Ethical Considerations

We did not gather any personal data that could be linked in any way to the identity of the respondents; therefore, according to the rules of our ethical committee at Universidad Politécnica de Madrid [26], there was no need to request the prior approval of the committee. The survey does not require any personally identifiable data (eg, name, phone, email, and personal address) and does not require going through a log-in process in which personal information may be collected. In addition, respondents could voluntarily choose whether to participate in the survey or not; therefore, starting the survey constitutes a valid consent to participate. The collected responses were stored and analyzed anonymously. Moreover, the collected answers were not used for any purpose other than research analysis, and all initial data from the survey were deleted after analysis. No interventions, compensation, or treatments were included in this research.

Data Analysis

The items on RBL were dimensionally reduced to main factors through PCA. By applying PCA before clustering, the original 17 survey items were reduced to five interpretable dimensions: (1) independent living and quality of life, (2) social events at home, (3) regular life routine, (4) creative and healthy, and (5) time spent alone. This dimensional reduction served 2 main purposes. First, it minimized noise by removing items with low communalities and condensed correlated items into coherent factors, thereby improving the stability of the clustering solution. Second, it enhanced interpretability, as clusters could be explained in terms of meaningful lifestyle dimensions rather than raw questionnaire items. In high-dimensional spaces (many variables), distance metrics become less discriminating, and clustering algorithms such as K-means can perform poorly or yield unstable clusters. Compared to direct clustering on the original 17 variables, clustering on the 5 extracted components provided clearer group separation and yielded more distinct, interpretable lifestyle-based clusters. In contrast, clusters formed directly on all 17 items would be harder to interpret because

XSL•FO
RenderX

each cluster's distinguishing features would involve possibly many items with varying contributions. Moreover, parsimony in model building (ie, fewer variables) tends to generalize better when replicating or applying to new data. It is important to highlight that PCA does sacrifice some information present in the original variables, especially if lower variance components (or items with unique variance) are dropped; some cluster-defining features might lie in those discarded dimensions. In addition, PCA assumes linear relationships among items and may not capture complex nonlinear interactions.

For reliability analysis of the resulting factors, internal consistency was verified with Cronbach α value. K-means clustering based on these RBL factors could segment Spanish older respondents with similar patterns of RBL and characteristics. After segmentation by RBL, the demographics and health status of each group were compared. Then, through the questions on smart home function preferences, the needs for smart home functions for each group were measured.

To verify significant differences among groups, chi-square test validation was applied to the demographic data, and ANOVA analysis was used on the health status scores (PCS and MCS) and smart home needs scale.

Results

PCA of RBL

The mean Kaiser-Meyer-Olkin value for the RBL items was 0.604. After removing factors with commonalities of low scores, PCA was performed. Bartlett's test of sphericity was significant (χ^2_{136}=455.893; P<.001), indicating that the correlation matrix was not an identity matrix and was therefore suitable for factor analysis. PCA was selected to reduce the dimension to the main factors of each assessment item and analyzed by Varimax rotation. Table 1 presents the PCA results of the RBL items. Five principal factors were extracted by allowing factor loadings greater than 0.4: (1) independent living and quality of life, (2) social event at home, (3) regular life routine, (4) creative and healthy, and (5) time spent alone.

Regular life routine (factor loadings)					
My diet is varied and balanced.	—	—	0.732	—	—
I am not sleepy during the day.	—	—	0.707	—	—
Take care of my house	—	—	0.489	—	—
Creative and healthy (factor loadings)					
Cook or bake	—	—	—	0.732	—
Creative and artistic activities	—	—	—	0.646	—
Do light exercise	—	—	—	0.539	—
Time spent alone (factor loadings)					
Use a computer or smartphone or tablet at home	—	—	—	—	0.775
Read books, newspapers or magazines	—	—	—	—	0.626
Sum of squares loadings	3.051	2.034	1.674	1.625	1.593
Proportion variance	17.949	11.965	9.847	9.56	9.372
Cumulative variance	17.949	29.914	39.761	49.32	58.692
Cronbach α	0.8	0.651	0.489	0.424	0.449

[a]Not applicable.

XSL•FO
RenderX

The reliability of each factor was confirmed by the Cronbach α value. Although Cronbach α values of 3 factors were measured somewhat lower, those were accepted considering that the questionnaire was newly developed in the previous study and the survey was conducted with a limited number of people. Each factor has at least an eigenvalue of 1, and the total variance explained by these 5 factors is 58.69%. According to methodological studies in the social sciences, cumulative explained variance values of approximately 50% to 60% are considered adequate for survey-based instruments.

Segmentation Based on RBL

On the basis of 5 RBL factors, a hierarchical cluster analysis via the Ward method was conducted, and it was judged that classification into 4 clusters was the most stable and convincing. After that, final clustering was performed through K-mean cluster analysis. Table 2 presents the clustering results segmented into the 4 groups. ANOVA analysis was conducted to explore differences in RBL factors by clusters. The analysis shows that all factors are significantly different: (1) independent living and quality of life (50.80; P<.001), (2) social event at home (6.83; P<.01), (3) regular life routine (21.29; P<.001), (4) creative and healthy (5.98; P<.01), and (5) time spent alone (25.43; P<.001). Figure 3 shows the differences among the factors for each cluster.

The lifestyle patterns and characteristics of each group were defined according to the 5 factor values in the RBL.

- Cluster 1: “High quality and independent life” is a group that shows the highest quality of life and independent living ability.
- Cluster 2: “Poor quality of life” has the lowest quality of life compared to other groups and the least amount of time spent on hobbies at home alone. It also displays the most regular life routine.
- Cluster 3: “Social-centered life” has a lifestyle with the most frequent visits by friends and family to their homes and the least regular life routine.
- Cluster 4: “Creative and personal-centered hobbies at home” is a group of people who have many creative hobbies and activities that they can do alone.

Table . Cluster analysis for residentially based lifestyles (RBL) of older people.

	Cluster 1 (n=47), factor scores (mean)	Cluster 2 (n=5), factor scores (mean)	Cluster 3 (n=25), factor scores (mean)	Cluster 4 (n=25), factor scores (mean)	*F* test (*df*)

Figure 3. Clusters for older people by the residentially based lifestyles.

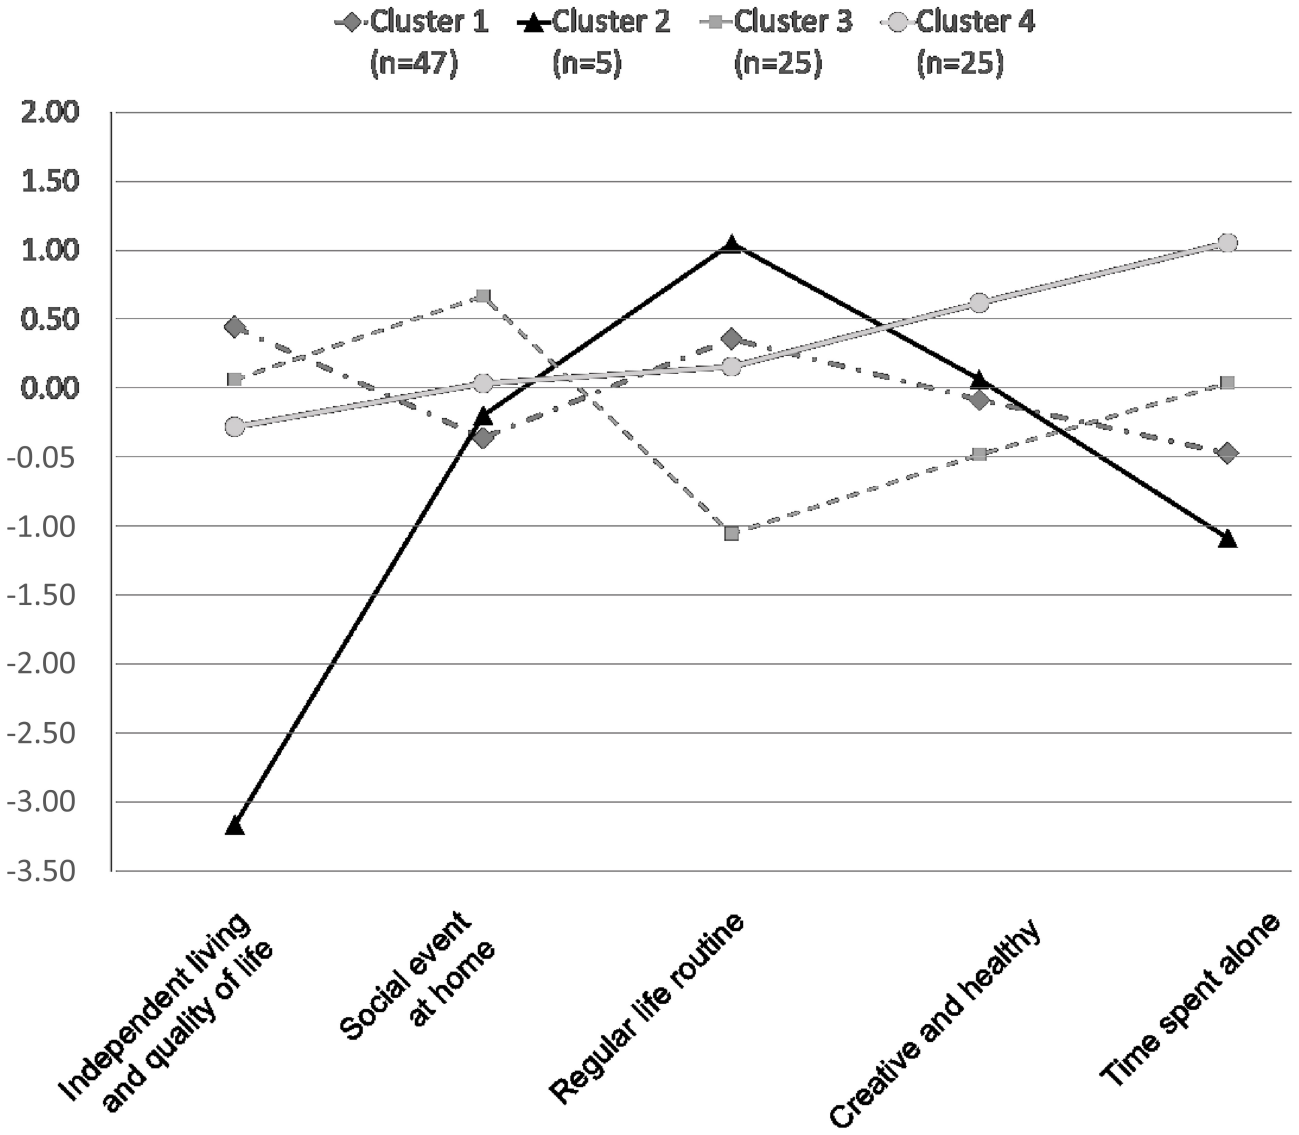

Table 3 presents the demographic characteristics of each group. There is a significant difference in gender of each group. Clusters 1 and 4 had more females with a male-to-female ratio of approximately 1:2, and cluster 2 is made up of 100% females. Cluster 3 was the only group in which the proportion of men was higher.

The MCS score of cluster 1 “high quality and independent life” was the highest, and the PCS score of cluster 4 “creative and personal-centered hobbies at home” is the highest. On the other hand, cluster 2 “poor quality of life” had the lowest both PCS and MCS ().

A one-way analysis of variance was conducted to examine differences in health status across the four residentially based lifestyle clusters. The results indicated statistically significant differences in physical component scores among the clusters (P=.01). The mean physical component scores were 50.33 for Cluster 1 (high quality of life and independent), 25.73 for Cluster 2 (poor quality of life), 47.74 for Cluster 3 (social-centered life), and 50.45 for Cluster 4 (creative and personal-centered hobbies at home). Specifically, Cluster 2 demonstrated substantially lower physical component scores compared with the other clusters, whereas Clusters 1, 3, and 4 showed relatively higher and comparable scores.

In contrast, differences in mental component scores did not reach statistical significance (P=.15). The mean mental component scores were 52.88 (SD 8.42) for Cluster 1, 43.48 (SD 10.12) for Cluster 2, 52.87 (SD 7.95) for Cluster 3, and 51.66 (SD 9.03) for Cluster 4, suggesting that mental health status was relatively similar across clusters.

Needs for Smart Home Functions

In this section, we compared the needs for smart home functions of each cluster. The respondents could choose from 1 (not necessary) to 5 (most necessary) for 26 detailed smart home functions in 8 categories. Higher numbers should be interpreted to mean "more necessary functions" for their lives (Table 4). As a result of ANOVA, there was a significant difference in the preference—F(3, 98)—of the *sensors you can wear as clothes* function. The smart home needs of cluster 2 "poor quality of life" are the highest, with an average score of 2.06 for a total of 26 functions, while the needs of cluster 1 "high quality of life and independent life" are the lowest, with an average score of 1.75.

We compared the needs of smart home functions above the median, based on the Spanish responses (value=2) (highlighted in italic in Table 4 and ordered by decreasing priority in Table 5). Cluster 2 "poor quality of life" needed more smart home functions compared to other groups. On the other hand, "high quality and independent life" and "social-centered life" had relatively few needs for the smart home functions.

There was also difference in the most essential functions for each group. Cluster 1 "high quality and independent life" required the *gas leak detection or smoke detection* function the most, cluster 2 "poor quality of life" required the *telehealthcare* function, cluster 3 "social-centered life" required the *remote-controlled electricity* function, and cluster 4 "creative and personal-centered hobbies at home" required the *automatic heating* function the most.

However, it is important to highlight that there are three functions—*automatic heating*, *telehealthcare*, and *call the family in case of emergency*—which are essential in all 4 groups. This indicates that the Spanish older population is ready to adopt such services. On the other hand, we observed the functions that were not considered important in any of the groups: *automatic watering in the garden*, *automatically checked postbox*, *monitoring in your absence*, and *robot like a friend*. Table 5 lists which smart home functions are needed according to the perceived priority in each group.

5	Remote-controlled electricity	Smart washing machine	Measure sleep health	Remote-controlled lights

Discussion

Principal Findings

This study identifies the smart home needs of older adults in Spain through a segmentation according to RBL. Through this approach, we can assess the readiness of older people to use and adopt concrete smart home functions. Concretely, we found 4 clusters of the Spanish older adults, identified the smart home functions that each group considers important, and analyzed how the smart home needs of older users relate to RBL.

To derive meaningful lifestyle clusters from the original 17 survey items, we first applied PCA to reduce dimensionality before performing K-means clustering on the extracted component scores. Specifically, after removing items with low communalities, PCA with Varimax rotation yielded 5 interpretable components (ie, independent living and quality of life, social events at home, regular life routine, creative and healthy, and time spent alone), each having an eigenvalue of 1 or greater. These 5 components explained approximately 58.7% of the total variance in the data.

Using these components for clustering rather than the full set of original variables offers several methodological advantages:

1. Reduction of redundancy and noise: Some of the 17 items are correlated and share underlying variance; PCA consolidates that shared variance and filters out items or variance that contribute less to the common structure. This reduces noise (ie, irrelevant or weakly contributing variation) that might obscure true cluster structure.
2. Mitigation of the curse of dimensionality: In high-dimensional space (many variables), distance metrics become less discriminating, and clustering algorithms such as K-means can perform poorly or yield unstable clusters. By reducing dimensions to those that capture the majority of variance and represent interpretable dimensions, we improve the cluster algorithm's ability to separate groups meaningfully.
3. Improved interpretability: Clusters defined on principal component scores are easier to characterize: each component is labeled (eg, "regular routine," "social at home," etc), so the resulting clusters can be described in terms of these meaningful dimensions. In contrast, clusters formed directly on all 17 items would be harder to interpret because each cluster's distinguishing features would involve possibly many items with varying contributions.
4. Stability and parsimony: Working with fewer, more stable dimensions tends to improve the reliability of clustering; clusters are less likely to be driven by measurement error or idiosyncratic items. Also, parsimony in model building (ie, fewer variables) tends to generalize better when replicating or applying to new data.
5. Facilitation of validity checks: Components allow checking internal consistency (Cronbach α) for each extracted dimension, which helps ensure that the reduced dimensions are coherent constructs. Additionally, when the components are reliably measured, using them in clustering gives more confidence in subsequently interpreting differences among clusters.

In our case, after PCA, we used K-means clustering on the 5 component scores and identified 4 clusters with distinct lifestyle profiles. Compared to what clustering on the full 17 variables would likely have yielded, the component-based clustering produced more coherent, stable, and interpretable clusters. For example, rather than clusters being defined by numerous item-specific idiosyncrasies, each cluster's profile can be described in terms of high or low scores on the 5 factors.

XSL•FO
RenderX

It should be noted that PCA does sacrifice some information present in the original variables, especially if lower variance components (or items with unique variance) are dropped; some cluster-defining features might lie in those discarded dimensions. Also, PCA assumes linear relationships among items and may not capture complex nonlinear interactions. Nonetheless, given our sample size and the moderate Kaiser-Meyer-Olkin (~0.60), the approach of PCA followed by K-means was judged appropriate.

Visutsak and Daoudi [27] attempted to identify the perceptions, accessibility factors, and needs of the older adults for smart homes through a survey. They asked about 7 smart home features in total and received responses from 20 stakeholders (doctors, nurses, the older adults, and their adult children). In a study on perception of smart home technologies [4], a survey was conducted with the general population, including working people in hospitals and nursing homes, to identify awareness of 6 smart home technologies for the older adults and concerns for using. This identified perceptions of usefulness for key technologies and their concerns from 18 respondents. Unlike previous studies, our study focuses on the older adults who will be the actual primary users. In addition, our questionnaire asked about the needs and perceptions of 26 detailed functions in a total of 8 categories of smart homes, covering a wider range of functions than previous studies. In addition, we compared and analyzed the particular needs of each group by segmentation based on the RBL.

In this study, rather than targeting older adults with a specific status (cognitive level and health status), the participants were segmented according to RBL. In addition, after segmentation, the average physical and mental health status of each group could be analyzed in connection with smart home needs. Although smart home technology could have great benefits for older people who need physical assistance or have mild cognitive impairment, we believe that smart home technology will help maintain independent living both for the healthy older adults and those with poor health.

Four segmented groups were identified in Spain: (1) high quality of life and independent life, (2) poor quality of life, (3) social-centered life, and (4) creative and personal-centered hobbies at home. We figured out the priority of smart home functions for each group and found that the priority of each group and the number of required functions were different. Although the 4 clusters provided meaningful and interpretable lifestyle profiles, 1 cluster (cluster 2, n=5) was substantially smaller than the others. At first glance, such a small subgroup may raise concerns about representativeness and the robustness of comparisons across clusters. However, several factors justify retaining this cluster in the analysis. First, the emergence of a small cluster was not an artifact of the analytic procedure but rather a reflection of genuine heterogeneity within the data. Even after multiple reclusterings, cluster 2 consistently appeared, suggesting that it represents a stable and reproducible pattern rather than a random byproduct of the algorithm. Second, the value of clustering lies not only in identifying large, dominant groups but also in revealing smaller, distinctive subgroups. In many areas of social science and consumer research, rare or niche groups play a crucial role in theory development and practice, despite their limited size [28,29]. Third, prior work in clustering methodology emphasizes that the interpretability and stability of clusters are more critical than their absolute size [30]. From this perspective, the consistent detection of cluster 2 across replications strengthens its validity as a meaningful subgroup. Finally, while the small number of respondents in this cluster warrants caution in generalization, its unique profile provides important insight into lifestyle heterogeneity. Future research with larger and more diverse samples can further verify the existence and characteristics of this subgroup, but its inclusion in this study enhances rather than detracts from the comprehensiveness of the clustering solution.

Cluster 2 “poor quality of life,” which is the group with the weakest mental and physical health, required more smart home functions than the other clusters. Their top priority is *Telehealth*, a system that allows them to receive medical care without going to a hospital. Besides that, they valued almost all categories of features as important; especially, they considered the *automation of daily routines* category and the *assist mobility* category as more important than the other groups. Also, as they spend more time at home than other groups, it was confirmed that they were interested in setting up TV programs and movie modes to enjoy at home.

Although only a limited number of functions showed statistically significant differences across the 4 clusters, this does not necessarily diminish the value of the segmentation. Clustering methods aim primarily to uncover underlying heterogeneity in patterns rather than to maximize between-group statistical significance on individual variables [28,31]. Even when differences in specific functions are not statistically significant, the cluster solution may still provide meaningful insights.

First, the overall profiles of the clusters reflect distinct combinations of lifestyle and technology needs that are not captured when examining single variables in isolation. Prior work has emphasized that segmentation should be evaluated on interpretability and theoretical coherence, rather than significance tests alone [29,32]. Second, the relatively small sample size in some clusters may have limited statistical power to detect differences. This limitation is particularly relevant for cluster 2, but the stability of this subgroup across repeated clustering iterations supports its substantive validity.

Thus, while statistical tests provide one form of validation, the meaningful differentiation in the patterns of technology needs across clusters—combined with theoretical plausibility and methodological robustness—justifies the retention and interpretation of the 4-cluster solution. Comparing these results with the segmentation and smart home needs analyzed previously in the Korean study [11], we noticed that the median value of smart home needs in South Korea was 3 (IQR 1-4), which is higher than in Spain (2, IQR 1-2). We believe that the difference in the popularization of smart homes in the 2 countries [33,34] and the internet use among the older adults can affect overall smart home perception and needs. It is possible to establish some parallels between clusters in Spain and in Korea. For instance, cluster 1 “high quality of life and independent life” in Spain and Korea’s “high quality of life and healthy” have similar RBL and had the lowest demands for

XSL•FO
RenderX

smart home functions compared to other groups. However, we can highlight that although Spain and Korea have similarities, the segmentation extracted different clusters and needs. This difference arises because instead of imposing a top-down classification, we obtained the clusters in a bottom-up fashion, maintaining in this way the particularities of each country. We believe this is a very useful tool to understand the idiosyncrasy of each culture and to better design smart home technologies that satisfy older adults' needs.

Limitations

A first limitation can be pointed out regarding the number and heterogeneity of participants: Due to the characteristics of the non–face-to-face survey, we could not target all the older adults in Spain but only those older adults who could respond to an internet survey. Also, the number of responses collected is related to unfamiliarity with online surveys for the older adults in this country. However, the use of information and communication technologies is increasing year by year in Spain. In particular, the daily internet usage rate among those aged 65 to 74 years increased to 50.7% in 2020, compared to 43.3% in 2019 [35,35]. We believe it is a practical method to quickly gather data and reach conclusions for the older population, and we are confident that it will become a more effective method in Spain.

The channel for the distribution of the survey may also have an impact on the educational level of respondents. We collected 78.43% of responses from older people with university education, which is significantly higher than the percentage of Spanish adults who have reached tertiary education (approximately 38%). In addition, because participants were able to complete this online survey alone, we acknowledge there could be a bias in our sample to older adults with good cognitive status, familiarity with technology, and possibly a higher willingness to adopt smart home technologies. This can pose a threat to the representativeness of the sample, which is important, as smart home technology could especially benefit older adults with cognitive decline. In future research, we aim to collect feedback from older adults with lower educational levels and more varied cognitive status, to increase the representativeness of the results. Further, given that the survey was anonymous, and we were not controlling who the person answering the questionnaire was, there was a risk of collecting responses from participants who do not meet the target profile. However, the channels that we used for the distribution of the questionnaire increase our confidence in effectively being able to reach the target population.

Another issue to be highlighted is the low number of respondents who were classified into cluster 2 "poor quality of life" (n=5). As a result, the demographic characteristics and responses of each individual member have a considerable influence in the definition of the cluster. We were concerned about the small dimension of cluster 2, so we tested grouping in various ways, but these 5 adults could not be tied to other groups. Although the cluster with 5 people was a small group, we think it is a meaningful group because of their distinct characteristics and RBL. In addition, small but stable clusters have been shown in prior literature to capture unique patterns or extreme profiles that larger clusters cannot reveal [29]. Retaining this cluster therefore enhances our ability to reflect the full heterogeneity of the data, even if statistical generalizations must be made with caution. Following established recommendations [36], we decided to keep the 4-cluster solution, while explicitly noting the interpretive limitations associated with the small sample size of cluster 2.

We believe the reduced number of participants in this group may be due to limited internet access of older people with this profile. We observe that the proportion of members aged older than 75 years in this cluster is the highest (20%), whereas the representation of this age segment in the other 3 clusters is much lower (with a maximum of 8%). Considering that the quality of life tends to decrease with age, this cluster might be biased to be defined by the low quality of life of its members. We would like to explore this issue by collecting more responses on the older age segment.

A more fundamental limitation of this study (but also one of its strengths) is that the results are inherently dependent on the target population. Spanish RBLs may differ from those in other countries and cultures. Being a data-driven research process, the factors that emerge through PCA are different, and the clustering process also leads to groups that are not necessarily comparable to the ones in another population. Direct generalization of the conclusions to another population should therefore be avoided. However, we consider this as a major strength of our method. The independent results of the segmentation by countries (Spain and South Korea) are evidence that smart home technology must be tailored to each specific context. This method may help to investigate the context and guide the tailoring process in technology development and deployment. This is also an interesting tool to guide policymakers in deciding concrete actuations to foster the integration of smart home technologies with existing services.

Conclusions

A smart home is an assistive technology that can improve the quality of life in old age and lead to an independent life. In order for this rapidly growing technology to fulfill its role in the lives of older people, it is necessary to first identify and analyze the actual needs of potential users. Older people are generally going through stages that may be physically and mentally debilitating, but their lifestyles at home cannot be defined as homogeneous. If the specific needs of older people are met by analyzing and segmenting life patterns at home, this assistive technology can fully perform its role. Our main contribution is a method that can be applied to any older adult group to analyze their smart home needs. In this study, we applied previously defined methods and questionnaires in a different geographical context. As confirmed through the analysis results, there was a difference in the priority of smart home functions and the number of functions required according to segmentation by RBL. It was also confirmed that RBL-based smart home needs analysis is meaningful even for studies conducted in different countries with different cultures. This second study demonstrates that the proposed questionnaire and research method are generally useful and not limited to specific countries or contexts. The results of this study and the previous study in South Korea showed that

XSL•FO
RenderX

this method can be used to investigate the perception of smart home technology in older adults and identify the actual needs of the groups that emerge.

Future research may explore a more sophisticated yet comprehensive categorization of smart home features, exploring the possibility of hierarchically grouping the 26 individual smart home functions into function categories or themes, to improve the interpretation of the preferences of different user groups.

Abstract

Background: Major neurocognitive disorders (MNCDs) frequently lead to difficulties in performing activities. Several studies have shown that people living with an MNCD benefit from the use of learning optimization methods from cognitive rehabilitation, such as error-free learning, motor encoding, spaced retrieval, and fading, which promote the safe pursuit of their meaningful activities. However, while the principles of learning optimization methods are relatively straightforward, the personalized application of these methods to the specific situations encountered can be more difficult.

Objective: The aim of this study was to describe the codevelopment process, including the validation of a web application called "Aide-Mémoire-Interactif (AMI)," a tool to help in personalizing learning optimization methods.

Methods: To design the web application, participatory action research based on a codevelopment and validation process was carried out. The various stages leading to the codevelopment of the AMI web application were grouped into 3 phases: (1) assessment of caregivers' needs (identification of situations frequently encountered by people living with an MNCD); (2) production of the first version of the AMI web application; and (3) validation of the AMI application. Individual interviews and workshops were conducted with 20 participants (caregivers, health and social service professionals, and community organization workers) to obtain a diversity of viewpoints and application contexts of use.

Results: The AMI web application was developed through an iterative, participatory process involving caregivers and professionals. Participants identified daily situations requiring the use of learning optimization methods and provided feedback that guided successive refinements to the content, answer choices, navigation, and personalization features. The logical architecture was built according to the rationale underlying learning optimization methods. The final version enables users to generate tailored strategies for specific situations, access educational capsules, and save personalized strategies. Participants reported improved clarity, usability, and relevance.

Conclusions: This participatory action research enabled the codevelopment and validation of the AMI web application to support the operationalization of learning optimization methods for people living with an MNCD by personalizing them to the situations encountered daily as well as to the underlying cognitive difficulties. By involving caregivers, professionals, and users, this process contributed to the development of a web application that meets user needs and their appreciation.

web application; major neurocognitive disorder; family caregivers; intervention; learning-optimizing methods; qualitative research

Introduction

Major neurocognitive disorders (MNCDs) frequently lead to difficulties in performing activities [1]. These difficulties can be attributed particularly to the deterioration of certain cognitive functions, which hinders the learning of new tasks or the maintenance of known tasks [2]. These difficulties increase as the MNCD progresses, ranging from difficulties in performing complex activities such as managing finances and planning meals to activities of daily living such as hygiene and eating. However, procedural memory and implicit retrieval processes are relatively well preserved compared to other cognitive functions, enabling the continuation of automatic, well-integrated sequences of actions in everyday life. Learning methods that build on these preserved capacities and compensate for the cognitive difficulties arising from MNCDs have been shown to be effective in maintaining the ability to perform activities [2,3].

Several studies have shown that people living with an MNCD benefit from the use of learning optimization methods from cognitive rehabilitation, such as error-free learning, motor encoding, spaced retrieval, and fading, which promote the safe pursuit of their meaningful activities [3-8]. These learning optimization methods provide successful experiences by ensuring that the right challenge is offered [3], thus helping to foster their engagement in the pursuit of meaningful activities and increasing the sense of competence of the caregiver of a person living with an MNCD [7]. These learning optimization methods rely on the cognitive capabilities generally preserved in people living with MNCDs, namely procedural memory and implicit retrieval processes [9]. These methods focus on the automation of correct action sequences during learning (errorless learning and motor encoding [10,11]), the gradually spaced repetition of these sequences (spaced retrieval [12,13]), and the progressive reduction of motor, visual, and verbal cues provided during their performance (vanishing cues [14]). To integrate these learning optimization methods, the involvement of a caregiver or an intervener is necessary to ensure consistency in the sequence of activities and to enable learning [15]. Since the integration of these methods, supported by the caregiver, supports the pursuit of meaningful activities, it fosters a positive relationship within the dyad, which may explain why the introduction of these methods does not increase caregiver burden [16].

However, while the principles of learning optimization methods are relatively straightforward, the personalized application of these methods to specific situations encountered can be more difficult [12,17]. In addition to considering the person's specific cognitive difficulties (eg, difficulty sequencing tasks, forgetting to eat, or missing appointments), caregivers must also take into account the person's habits and daily routine [16]. It is therefore essential to offer support or tools to caregivers to help them apply learning optimization methods to the specific situations experienced daily by the person living with an MNCD [17]. Support and tools for caregivers in the personalized application of learning optimization methods could optimize the pursuit of meaningful activities by people living with an MNCD by promoting the use of their preserved abilities.

Many support resources and tools are available for caregivers of people living with MNCDs. According to a recent comprehensive meta-review of systematic reviews and meta-analyses, many face-to-face, nonpharmacological interventions are beneficial for caregivers [18]. This category of intervention includes psychoeducation, psychotherapy, occupational therapy, mindfulness interventions, and multicomponent interventions (eg, combining psychoeducation and psychotherapy components). Positive effects on depression, quality of life, sense of mastery, and communication skills have been attributed to various nonpharmacological interventions [18]. Although face-to-face interventions are effective, caregivers do not always use them and often find them difficult to access. This can be due to challenges such as being unable to leave the person alone, difficulty traveling, believing they do not need help, reluctance to seek services, limited knowledge of available resources, lack of time, or concerns about sharing personal information about their loved one [19].

To reduce some of these barriers, studies recommend that technological tools could make certain types of support more accessible to caregivers [20]. Among these, online interventions are effective and cost-effective and could favor accessibility [21,22]. A systematic review of online support interventions (eg, websites) for caregivers, including 12 studies [23], showed that these interventions can have positive effects on caregivers' well-being. Among the interventions included in this systematic review, those that combine information, personalized strategies, and contact with other caregivers could increase caregivers' knowledge and skills for caring for a loved one living with an MNCD, their confidence and self-efficacy, and reduce their stress, burden, and depressive symptoms [24-29]. Online interventions can easily incorporate a variety of formats (eg, videos, graphics, text), as well as support (eg, specific recommendations) [30]. The use of health information technologies can be relevant to family caregivers if adapted [31]. These technologies make it possible to reach isolated and stigmatized groups, reduce health care costs, and access information and advice at any time [32]. Among online support interventions, personalized ones (based on responses to a questionnaire or feedback following the intervention) show greater positive effects than nonpersonalized intervention [23,33,34].

In addition to online interventions, several technology applications (eg, sensors, wristwatches, cameras, voice recorders, calendars, automatic night lamps, gas cooker devices, picture button telephones, alarms, and electronic pillboxes) can support caregivers and people living with MNCDs [35]. In their scoping review, Huisman et al (2022) found that these technology applications help to reduce the burden and social isolation of caregivers and consequently promote better sleep. Technology applications for caregivers are mainly designed to

XSL•FO
RenderX

provide information and resources, offer general practical tips for frequently encountered problems (eg, managing behavioral problems or medication), or help coordinate care among multiple caregivers (eg, sharing calendars or to-do lists) [36].

Although online interventions and technology applications have shown benefits and have many advantages when compared with face-to-face interventions, caregivers may find it difficult to personalize the content and translate the information provided into concrete strategies that fit specific everyday situations [37]. For example, the transposition of methods based on analysis of the situation encountered can represent a challenge [17]. Thus, to our knowledge, no tool that enables caregivers to learn how to use learning optimization methods to support the realization of meaningful activities by building on the person's preserved abilities.

A previous study from our team highlighted the difficulty caregivers had in appropriating learning optimization methods, as well as their need for support tools to use these methods [38]. Based on this previous study, a knowledge mobilization study was carried out to codevelop a variety of support tools, including a web application, which is the scope of the present article. These support tools were designed to help caregivers learn, understand, and use learning optimization methods (eg, error-free learning). More precisely, the project aimed to support caregivers in adapting these methods to specific situations encountered daily and underlying difficulties to help people living with an MNCD maintain autonomy in meaningful activities by building on preserved abilities. This article describes the codevelopment and iterative steps involved in the design and validation process of a web application called "Aide-Mémoire-Interactif (AMI)," a support tool developed as part of this knowledge mobilization study.

Methods

Participatory Action Research Approach

To design the AMI web application, participatory action research based on a codevelopment and validation process was carried out. In the health care field, the codevelopment of such a web application requires a partnership among health care professionals, the people who will use the application, and the team of researchers and designers [39]. Caregivers, health and social service professionals, and workers from community organizations providing support to caregivers were involved in identifying situations frequently encountered by people living with an MNCD [16] and throughout the process of codeveloping and validating the AMI web application. The stages of this codevelopment were overseen by at least 1 coinvestigator with expertise in the stage in question and the principal investigator. For example, during the computer coding stage to operationalize the application, 2 project coinvestigators with expertise in this field supervised the computer programming work, and the principal investigator took part in all meetings with these coinvestigators and the computer scientist to ensure that user needs were met. The various stages leading to the codevelopment of the AMI web application can be grouped into 3 phases: (1) assessment of caregivers' needs (identification of situations frequently encountered by people living with an MNCD) [16]; (2) production of appropriation tools, including the first version of the AMI web application [40]; and (3) validation of the tools, leading to the final version of the AMI application. Caregivers, health and social service professionals, and workers from community organizations experimented with the first version of the application during workshops with an occupational therapist and have made suggestions that contributed to revisions as the codevelopment progressed.

Participants, Recruitment, and Data Collection

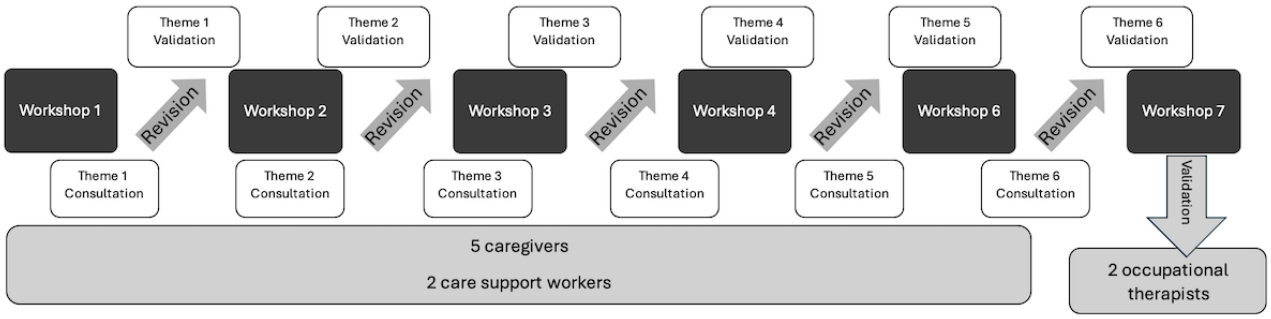
For the first stage of the project (ie, the identification of frequently encountered situations), 20 participants (caregivers, health and social service professionals, and community organization workers) were targeted to obtain a diversity of viewpoints and application contexts and data saturation [41]. Participants were recruited by one of the coinvestigators, a practitioner from the partner community organization. An interview guide for individual semistructured interviews (preplanned duration of approximately 60 min) was developed to identify meaningful activities and lived situations in which the cognitive difficulties of people living with an MNCD cause difficulties and would thus benefit from learning optimization methods. The results of this stage are reported in a previously published article [16].

For the 2 subsequent stages (ie, codevelopment and validation of the support tools), a target number of 8 to 10 participants was set for the learning optimization methods appropriation workshops. To ensure diversity of viewpoints in terms of application contexts while keeping the workshop group small enough to promote interactions, 3 participant groups were targeted: family caregivers, stakeholders from community organizations working with family caregivers, and occupational therapists in health and social services who work with people living with an MNCD in a variety of daily situations. A purposive sampling strategy was used to recruit women and men from different age groups and whether they were cohabiting or not with a person living with an MNCD. For family caregivers, inclusion criteria were (1) providing day-to-day support to a person living with an MNCD and (2) not having an MNCD as perceived by the referring caregiver. For occupational therapists and caregivers from community organizations, to meet the inclusion criteria, they had to work with people living with MNCDs and their caregivers. Occupational therapists were recruited by the head of the home care department based on their knowledge of home care issues. The coresearcher from the partner organization (Société Alzheimer des Maskoutains–Vallée des Patriotes) recruited community workers and caregivers by contacting caregivers who attended the organization's activities and who, he felt, could contribute to the development of the appropriation tools by experimenting with and critiquing them.

Production of Appropriation Tools

Several tools for appropriating learning methods were designed during the project, including workshops for caregivers [34], the AMI web application, companion leaflets, and video capsules showing examples of putting learning optimization methods into action, to support their operationalization in specific situations and contexts encountered. This study describes more

XSL•FO
RenderX



specifically the codevelopment of the AMI application using a software development process based on the Agile Scrum methodology [42]. The Agile Scrum method is a project management methodology that follows an iterative process with users to adjust to changing objectives and needs. It is divided into short cycles, called "sprints," which enable features to be developed progressively while adjusting priorities based on feedback from stakeholders (caregivers, occupational therapists, stakeholders from partner organizations, coresearchers, and research assistants). This methodology requires teams with the necessary complementary expertise and an operating structure based on defined roles to ensure communication and ongoing project progress. The design is therefore based on principles of user friendliness and accessibility to provide a practical and effective solution for specific contexts [43]. To promote accessibility, the application is accessed via a web browser, making it available on different devices and operating systems. Moreover, platform independence reduces development effort and costs involved in supporting multiple user installations. Finally, updates and the addition of new functionalities are possible, enabling the application to evolve in line with emerging needs.

The Agile Scrum methodology chosen was built around 4 elements targeted by the team. First, an ordered list of features for the AMI application was created based on the developed logic algorithm and usage requirements. Second, planning of the functionalities to be programmed was divided into subtasks per 2-week period. Third, daily meetings between the programmer and 2 coinvestigators (an occupational therapist and a computer scientist) were held to identify problems and find solutions, which were implemented by the programmer. Finally, demonstrations of developed functionalities and reviews of the latest iteration were carried out by the programmer and the 2 coinvestigators during the first workshop with caregivers and occupational therapists, enabling participants to experiment with the AMI application, criticize it, and validate the changes made as they experimented during the series of workshops.

Tool Validation

A first version of the AMI web application was designed by the research team, followed by several feedback loops aimed at adjusting the application according to the comments received (Figure 1). Before the experimentation by caregivers, the application was tested by members of the research team and representatives of partner organizations. This allowed us to clarify some terms and add some answer choices. During the trial period, caregivers participating in the workshops provided feedback during demonstrations at each of the workshops and by trying out the application for themselves at home with their loved one afterwards [36]. After each workshop on a specific theme (eg, memory or executive function difficulties), feedback on the use of the AMI web application was collected, and modifications were made on an ongoing basis. For example, caregivers were asked to provide specific situations they wanted to be included in the app. For each situation, they answered the questions asked by the AMI web application and reviewed the suggested strategy. Participants were invited to provide feedback on various aspects of the app, including the variety of situations or suggestions for additional or missing ones, answer choices that could be missing for specific situations, cognitive difficulties encountered for a specific situation, and the actions included in the learning sequence. Modifications were then validated with participants during the following workshops, leading to the final version of the application after the workshop series. This approach, which included several iterations, made it possible to quickly adjust the development according to needs. Each caregiver had the opportunity to provide suggestions for the application based on specific situations they had encountered. The approach of valuing diversity and the richness of complementary or divergent points of view was presented right from the first workshop. It was specified that everyone's experience was essential to the codevelopment of a relevant web application. Opposing comments were discussed as a group to identify a solution that would meet the needs of all participants. The principal researcher, who cofacilitated the workshops, took note of the participants' comments and then discussed their implementation with the programmer and the information technology coresearcher.

Ethical Considerations

This study was approved by the CIUSSS de l'Estrie-CHUS Research Ethics Committee (MP-31-2019-3211). Written informed consent was obtained from all participants. To ensure privacy, any information that could lead to identification was removed. Information gathered was kept confidential. No financial compensation was given to the participants.

Results

Process and Participants

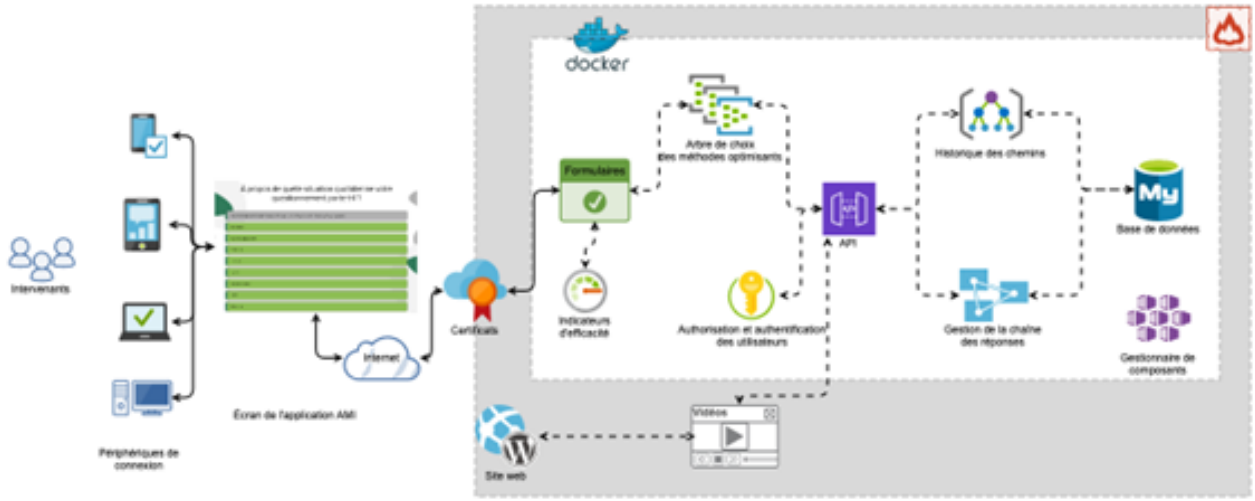
This section describes the different steps that led to the development of the AMI web application and focuses on 2 complementary aspects: the participatory process through which the application was developed and the adjustments made to the tool based on users' feedback. These elements illustrate how the final version of the application, which is described in detail, emerged through iterative refinement.

For the first part, caregivers (n=11), health and social service professionals (n=7; social workers and occupational therapists), and community organization workers (n=7) participated in identifying situations for which the AMI web application should support the operationalization of learning optimization methods. For the subsequent codevelopment and validation of the AMI web application, caregivers (n=5), caregiver support workers from community organizations (n=2), and occupational therapists working with people living with MNCDs (n=2) were recruited. The application was designed to be easy to navigate for users who are mainly caregivers or health care professionals working with people living with an MNCD [44]. The application home page (Figure 2) provides summary information on navigation, its various functionalities, and contact details for training in its optimal use. Indeed, the AMI web application, designed to support the operationalization of learning optimization methods, requires a basic understanding of the difficulties present in neurocognitive disorders and of these methods.

Figure 2. Aide-Mémoire-Interactif web application home page.

Codevelopment of the AMI Web Application: Logical Architecture

Technological choices were made to ensure that the web application would be easy to adapt to the realities of partner environments. Thus, the logical architecture was built according to the rationale underlying learning optimization methods and is structured around the following questions: considering the specific situation in which the difficulty occurs, (1) What is the difficulty that can explain it? (2) What is the desired action? (3) After which action should the desired action be done? (4) What action is performed instead of the desired action? The application was codeveloped based on real-life situations requiring the use of learning optimization methods [39]. Question 1 asks the caregiver to identify, based on their perception, the primary cognitive difficulty that may explain why learning optimization methods are needed for this specific situation. The cognitive difficulty guides how the 4 learning optimization methods are combined to rely on preserved abilities. Question 2 requires the caregiver to analyze the sequence of actions, identify the usual error, and specify which action should be learned through motor encoding to replace this error. Question 3 also draws on the analysis of the action sequence and, in line with errorless learning principles, identifies the action that immediately precedes the error as well as the action that needs to be integrated using learning optimization methods. Finally, question 4 is essential to prevent the error before it occurs, supporting the errorless learning method. The strategy suggested by AMI includes a progression that integrates fading and spaced retrieval methods.



Being user-centered, the AMI web application is built to offer each user dynamic interaction with the generated content so that the strategies generated are personalized to the situation encountered and the specific context. To optimize accessibility, the application is accessed using a web browser via a computer, tablet, or smartphone. As illustrated in Figure 3, AMI is

XSL•FO
RenderX

organized around modular, adaptable software components comprising the following:

- a server secured by an SSL (Secure Sockets Layer) certificate, enabling access to data when the user interacts with the application, regardless of the device used;
- an API (application programming interface) that offers flexibility to integrate new components based on needs expressed by users during validation and scaling in different types of environments and with people with different levels of impairment;
- a Docker-type application virtualization environment, enabling the application to be used on any device;
- a MySQL database to store data for later access to customized strategies;
- a centralized Keycloak authentication and authorization component to facilitate user management [39] and ensure access to personalized strategies;
- an HTML interface for visualizing situation and context information entered by users;
- a ReactJS framework for rapid updating of suggested strategies based on user input;
- a high-performance, open-source FastAPI engine, enabling development, particularly with the Python language, to facilitate integration of new components and easily evolve the application in line with user needs.

Figure 3. Logical architecture diagram of the Aide-Mémoire-Interactif web application.

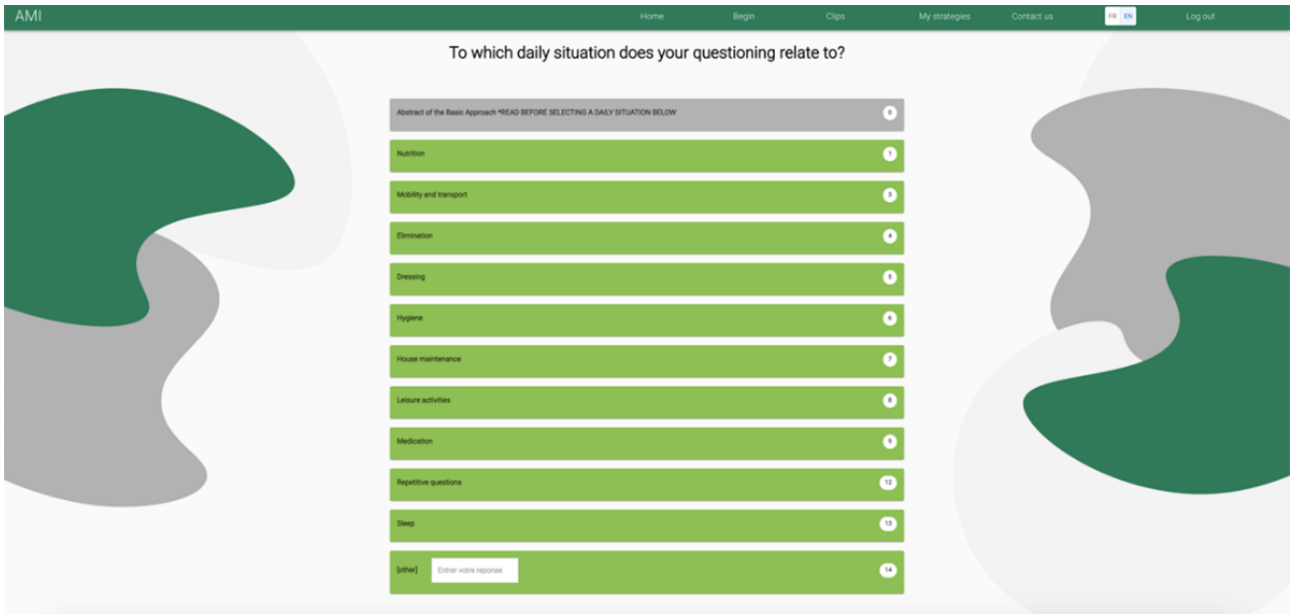
The application is composed of scripts written in several programming languages. This plurality of programming languages allows greater modularity based on the requirements of each tool for programming learning methods. A 4-GB RAM server with 4 cores covers all application needs.

Validation of the Tools: Perceptions and Feedback From Participants

As the workshops progressed, participants provided feedback that directly informed several modifications to the tool. Their suggestions mainly concerned the following: (1) formulation of everyday situations to make them easier to understand and choose from; (2) formulation of the difficulties underlying the problems in everyday situations to make them easier to understand and choose from; (3) addition of frequently encountered answer choices for desired actions and actions performed in place of desired actions; and (4) visual presentation for navigating questions, choices, and proposed strategies.

Following systematic verification of the vocabulary used in each situation category by participants, clarifications were made to facilitate understanding. Regarding the difficulties underlying the problems in everyday situations, certain categories of cognitive difficulties initially established were subdivided into 2 distinct categories to facilitate understanding and more direct application to the difficulties encountered. Regarding desired actions and actions performed in place of the desired action, additions were made to the answer choices to cover a wider range of contexts for operationalization in everyday situations. Additions were made to the list of answer choices, and if none of the options corresponded to the person's situation, an "other" button led to an answer box for entering the context-specific element subsequently used by the AMI web application for personalized operationalization of learning optimization methods.

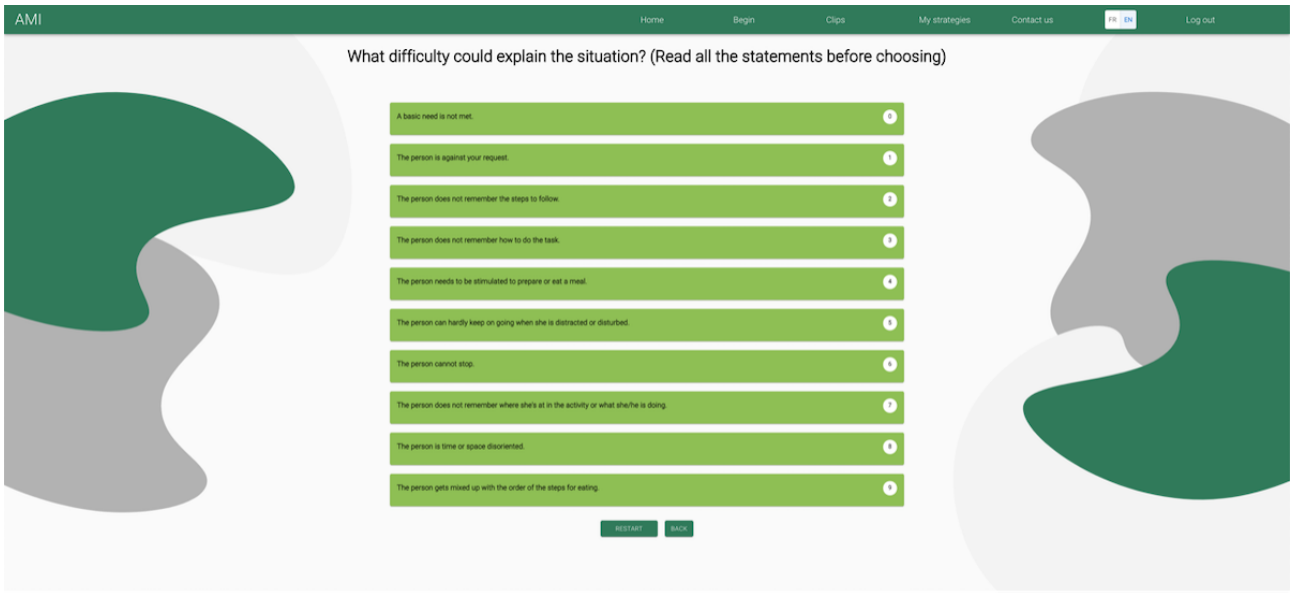
Some participants reported that certain dichotomous "yes or no" questions did not fit their situation, so they did not know which option to select. As a result, the "not applicable" option was added. Regarding the visual presentation of the AMI web application, feedback from participants helped to make navigation more intuitive (eg, replacing the "questionnaire" button with "start"). In response to participants' request for the opportunity to save the strategies proposed for a specific situation, a "Favorites" button was created to save the individual history of strategies based on the individual answers provided to the questions. The AMI web application underwent refinements to support its ongoing improvement. Enhancements included the ability to save personalized strategies using the initials of both the caregiver and the care recipient. A printable version of the strategy, with editable sections to tailor intervention sequences, was also implemented. In parallel, visual and technical adjustments were made to optimize system performance, streamline navigation, and improve clarity for



XSL•FO
RenderX

users. Participants confirmed that the latest version, shaped through iterative feedback, better met their needs.

Final Version of the Application: Description of Functionalities



The home page of the final version of the AMI web application lets the user choose among the following: (1) starting navigation to operationalize learning optimization methods in a specific situation, (2) viewing video capsules describing these methods, or (3) consulting strategies saved from previous navigations. By selecting the Start option, users can select a daily situation from a range of possible options (Figure 4).

Figure 4. List of daily situations.

Once a situation is selected, users identify the difficulty that could explain it. For example, for the Nutrition situation, 10 difficulties are presented (Figure 5). For each situation, questions and response options vary depending on the difficulty encountered.

Figure 5. List of difficulties that could explain the situation.

Depending on the answers given about the situation (activity, cognitive difficulties) and the context in which it occurs, the user obtains suggestions for possible solutions to the situation (Figure 6).

XSL•FO
RenderX

Figure 6. Example of a possible solution related to the situation.

Users can obtain a reminder of the theoretical foundations by clicking on Capsules. Twelve capsules are available, covering the following topics: (1) basic needs; (2) approaches (communication, validation, diversion, refusal); (3) methods to promote learning (error-free learning, motor encoding, spaced retrieval, blurring); (4) reminders of how memory, praxis, and executive functions work; (5) preserved abilities; and (6) complementarity with compensatory measures.

Finally, the *My Strategies* option in the drop-down menu includes 2 tabs: Lately, which allows the user to view the most recent sequences he or she has performed, and Favorites, which saves the operationalization of preferred strategies.

Discussion

Main Results

This participatory action research enabled us to codevelop and validate the AMI web application to support the operationalization of learning optimization methods for people living with an MNCD, by personalizing them to situations encountered daily as well as to the underlying cognitive difficulties. It enabled the reformulation of everyday situations and their underlying difficulties, the addition of frequently encountered answer choices for desired actions and actions performed in place of desired actions, and finally a visual presentation facilitating navigation. By involving caregivers [45], professionals, and users, this research contributed to the development of a web application that aligns with their needs and preferences.

Comparison With Previous Studies

To date, a number of applications have been developed specifically for caregivers, with a variety of functions to meet the diverse needs of this population [20,31,32]. For its part, the AMI application is, to our knowledge, the first that facilitates the use of learning optimization methods by caregivers and that proposes solutions adapted to the specific context of everyday situations by promoting the use of the preserved abilities of people living with an MNCD. Indeed, when caregivers find themselves in a situation where they do not know how to deal with the impact of MNCDs on the performance of daily activities, the AMI web application provides them, after a series of questions on the specific context, with a strategy adapted to the problematic activity, the underlying cognitive difficulty, and the context in which it is performed [16]. Considering that several negative effects on physical and mental health can be caused by the role of caregiver, such as chronic stress and depression [46], feelings of burden [47], and poor-quality sleep [48], the possibility of having a web application that supports their role can help foster a positive aspect of the caregiver role.

The difficulties and activities performed by people living with MNCDs are highly variable, as are the coping skills of their caregivers, justifying the relevance and superior effectiveness of personalized interventions [23]. Warmoth et al [49] developed a personalized cognitive rehabilitation intervention and found that people living with MNCDs and their caregivers appreciated the personalized approach to intervention and that the flexibility allowed by this approach played an important role in their appropriation of learning optimization methods. Personalization is essential when using learning optimization methods, given the difficulty caregivers have in transposing these methods to

XSL•FO
RenderX

another context [17]. The inclusion of users in studies aimed at developing services offered to them is essential [50] so that they can contribute to improving the products that meet their needs [51]. In the present study, the involvement of caregivers at all stages of the research enabled the application to be developed in line with the situations they encounter daily. In this way, the AMI application fills a gap for caregivers, enabling them to support the pursuit of day-to-day activities of people living with MNCDs.

Although the application is adapted to the situations encountered, studies report that lack of time and low digital literacy can limit the use of web applications by caregivers [52,53]. Since it can be difficult for some caregivers to find information [54], easy navigation and recording of information can be supportive. Clarity of language is also essential [52]. This participatory action research, which led to the codevelopment of the AMI application and involved seniors at every stage, enabled us to take these potential issues into account and make the necessary adjustments based on feedback from caregivers, mainly by adding the My Strategies feature to enable easy retrieval of personalized strategies.

Finally, studies tend to show that peer support and psychosocial support are also important elements in the interventions offered to caregivers [55]. Although the AMI web application was created to meet another equally important need of caregivers, the workshops held to help them appropriate the web application enabled several caregivers in similar situations to interact. This enabled them to share their experiences and possibly feel less alone, a feeling often experienced by people in this role [54]. In fact, 1 caregiver had recommended the addition of a function that would enable caregivers to obtain psychosocial support or communicate with other caregivers. Due to the extent of the research and programming required, which went beyond the primary objective of codevelopment, this recommendation could not be integrated into the current version of the application, despite its great relevance. These additional functionalities would be relevant given that the mobile web applications currently available for caregivers rarely address their personal needs, such as their health, financial security, or the problems they may encounter at work [56].

It would also fill a gap in web applications that currently do not offer support for caregivers' emotional well-being, notably for stress and anxiety management, as well as depression [23-25,29].

Strengths and Limitations

One of the main strengths of this study is the codevelopment process to ensure that the application meets needs and is user-friendly [37]. All types of potential users contributed to the codevelopment, including health care professionals and caregivers who worked in partnership with the team of researchers and designers (occupational therapy, social work, leisure, and information technology). Caregivers and health care professionals were involved throughout the process, from the definition of needs to the final validation of the application. Codevelopment ensures that the needs, preferences, and functionalities required by users are considered, and that the result is finally tailored to them [56]. Participants were caregivers and health care professionals mainly involved in home care. Although some have experience of intervention in a residential setting, the application answer choices are mainly based on situations occurring at home, in the community. Caregivers and interveners of people living with MNCDs in residential settings whose situations are not included in the application's answer choices can, however, choose the *Other* option for the various questions and enter the contextual elements specific to their situation to obtain a personalized strategy proposal. These situations have not yet been validated. Although the number of caregivers involved was small, the multiple iterations allowed for the inclusion of a wide variety of situations. Future studies may adapt the application to other practice contexts (eg, hospital settings) or living environments (eg, residential resources offering long-term care) for people living with MNCDs. Although recruitment by reasoned choice targeted a diversity of experience, as caregivers and care providers were linked to a community organization and to health care network stakeholders working in collaboration with this organization, cultural representativeness and socioeconomic status were not present. More, since the caregivers were recruited targeting people who would be critical for a web application, since they had good digital literacy, they are not representative of all caregivers who may have more difficulty using technological tools. During implementation, introductory tools will have to consider the low digital literacy of some caregivers to guide their use of the web application. Although caregivers shared positive comments regarding the usefulness, accessibility, and effects of the AMI web application on autonomy and quality of the caregiving relationships, these effects were not assessed. Future studies should therefore assess the effects and usefulness of the AMI web application for caregivers and health professionals in supporting the performance of activities using the preserved abilities of people living with MNCDs. Future studies could evaluate the application's implementation and its effects on caregivers, health professionals, and people living with an MNCD.

Recommendations and Avenues of Research

The aim of this study was to describe the codevelopment process of the AMI web application, which supports the operationalization of learning optimization methods using the preserved abilities of people living with MNCDs. Suggestions received from caregivers and health care professionals have enabled us, in an iterative process, to improve the application so that it meets the specific needs of using preserved abilities in daily activities, thus compensating for difficulties encountered at home. Considering the physical and mental impacts of the caregiver role mentioned above, it would also be relevant to measure whether daily use of the AMI application has an impact on caregivers, particularly on their sense of burden. In the same way, the impact on the person living with an MNCD would also be interesting to assess. Second, it would also be relevant to look at the prolonged use of the AMI application to assess the sustainability of its use daily and to evaluate its long-term effectiveness [57], particularly in view of the progression of difficulties in daily activities attributable to the evolution of MNCD. Finally, as mentioned, additions to the web application would be relevant to make in future studies, such as offering peer support and psychosocial support via the application [53,58]

XSL•FO
RenderX

and adding features that would support the personal needs of caregivers [55].

Conclusions

This study details the steps that led to the development of the AMI web application, which enables caregivers to appropriate learning optimization methods for the specific situations encountered daily. The AMI application stands out for its ability to be customized to everyone's context and for its codevelopment process, which involved caregivers, health care professionals, community workers, and researchers with expertise in the field. The AMI application was developed to provide a practical, high-performance solution for managing interventions. Its user-friendly interface, flexible web architecture, and advanced functionalities make it a valuable tool for professionals working in this specific field. What's more, the technology used to develop the AMI web application has enabled optimal scalability and performance, guaranteeing a fluid user experience even with many simultaneous users. The chosen methodology favors the development of a web application that meets the needs of all those involved and thus optimizes its day-to-day use.

Acknowledgments

The research team thanks caregivers and support workers who generously contributed to the codevelopment of the Aide-Mémoire-Interactif (AMI) application by sharing examples of their experience to optimize the application's response to their needs. The team also thanks the Ordre des ergothérapeutes du Québec for its involvement and pertinent comments. A special thank you to the DOMUS team for its information technology contribution, through the contribution of several people with specific expertise at different stages of codevelopment.

Abstract

Background: eHealth literacy is important for older adults to be able to seek and evaluate online health information. However, there is a scarcity of large-scale data on their eHealth literacy levels, particularly among the oldest older individuals (aged >75 years) in unique, high-income Asian regions such as Hong Kong. A comprehensive understanding of how eHealth literacy is associated with specific health behaviors, mental well-being, and physical health outcomes in this population is lacking.

Objective: This study aims to assess the level of eHealth literacy and its associations with health behaviors and health-related outcomes among older adults in Hong Kong.

Methods: We conducted a cross-sectional analysis of baseline data from the Generations Connect Project. This is an ongoing large-scale community-based project, where we trained university students to conduct home visits and assess the health status of older adults (N=6704) in Hong Kong. eHealth literacy was measured using the eHealth Literacy Scale (eHEALS; score: 8 - 40). Health behavior measurements included physical activity levels (metabolic equivalent of task minutes per week) and smoking, drinking, and eating habits. Mental well-being was measured using the World Health Organization-Five Well-Being Index (percentage score: 0 - 100) and UCLA 3-item Loneliness Scale (score: 3 - 9). Physical health was assessed on the basis of self-reported medical diagnosis of noncommunicable diseases (yes/no), including hypertension, diabetes, cardiovascular disease, and stroke. Adjusted unstandardized coefficients (b) and odds ratios (ORs) were calculated to determine the associations between variables.

Results: Among the 6704 participants (mean age 77.8, SD 7.0 years), the mean eHEALS score was 18.2 (SD 10.2), and 44.1% (2897/6566) of the participants had inadequate eHealth literacy (score: 8 - 15.99). Increasing age (adjusted b −0.32, 95% CI −0.35 to −0.28; *P*<.001), support from the Comprehensive Social Security Assistance Scheme (adjusted b −1.49, 95% CI −2.04 to −0.95; *P*<.001), and living in public housing (adjusted b −1.60, 95% CI −2.69 to −0.50; *P*=.004) were associated with a lower eHEALS score. Participants with moderate eHealth literacy (score: 24 - 31.99) were less likely to be current smokers (adjusted OR 0.60, 95% CI 0.38-0.95; *P*=.04), more physically active (adjusted b 39.83, 95% CI 2.04-77.62; *P*=.04), more likely to be community health center members (adjusted OR 1.52, 95% CI 1.30-1.77; *P*<.001) and to have healthy diets (adjusted b 0.034, 95% CI 0.006-0.063; *P*=.04), and less likely to have a medical diagnosis of diabetes (adjusted OR 0.73, 95% CI 0.62-0.85; *P*<.001). Moreover, they had a higher score on the World Health Organization-Five Well-being Index (adjusted b 2.89, 95% CI 1.42-4.36; *P*<.001) and a lower score on the UCLA 3-item Loneliness Scale (adjusted b −0.26, 95% CI −0.37 to −0.15; *P*<.001).

Conclusions: The level of eHealth literacy was low among older adults in Hong Kong. eHealth literacy was associated with positive health behaviors and health-related outcomes. Interventions are warranted to boost their eHealth literacy in the future.

Introduction

Older adults (aged >60 years) accounted for 5% of the global population in the last few decades, and this estimate is projected to rise to 16% by 2050 [1]. In China, the population aged ≥80 years reached 36 million in 2020 and will increase to 115 million in 2050 [2]. This global demographic shift toward an older population is accompanied by an increased burden of noncommunicable diseases (NCDs) [3] and mental illnesses [4], which places immense strain on public health care systems. More than 20% of older adults in the world have 1 or more mental illnesses [4], and the prevalence increases with population size. In 2017, 8.6% of older adults in Hong Kong (N=4368) had depression and anxiety [5]. Mental illnesses among older people remained underrecognized and undertreated, which accounted for 10.6% of the total loss of disability-adjusted life years in older adults [6]. In response, and in line with the World Health Organization's call for primary health care reform [7], there is an urgent need for innovative strategies to support healthy aging. The rapid development of digital technologies, accelerated by the COVID-19 pandemic, offers a key opportunity. Digital tools have the potential to support older adults' intrinsic capacity, promote active and healthy aging, and alleviate the economic burden on health care sectors, making them an increasingly recognized priority in geriatric care [8].

The emergence of digital health offers a new avenue for improving individuals' quality of life. Rapid advances in information and communications technology contribute to the increasing innovation and upgrading of health service modes [9]. Digital health enables low-cost, timely health care services for older adults and supports their physical and mental health by providing access to reliable health information, self-monitoring tools for chronic conditions, and social connection platforms [9]. Although accessing online medical services and information is convenient, the quality of online information varies [10]. Older adults need eHealth literacy to navigate and evaluate the accuracy of medical information, especially in the context of primary health care reform in Hong Kong, where the government is committed to enhancing digital primary health care services to shift the emphasis from tertiary to primary care.

eHealth literacy is defined as the ability of an individual to find and evaluate health information from online platforms and apply health-related knowledge to address health problems [11]. Although smartphone ownership has increased among older adults [12], they often possess lower technological skills than the younger generations and are consequently less likely to use these devices to search for health information [12]. eHealth literacy impacts how older adults search for health information online, which might influence health-related decisions [12]. With the rapid and continuous development of eHealth resources, it is crucial to assess older adults' eHealth literacy and examine its association with health-related outcomes.

Previous studies suggested that higher eHealth literacy was associated with some healthy aging components (eg, less cognitive impairment and functional limitation) in older adults [13]. However, database searches in PubMed and CINAHL (using keywords such as "eHealth literacy," "older adults," "aging population," "health behavior," "smoking," and "physical activity") suggest that studies on the association of eHealth literacy with specific health behaviors (eg, smoking, drinking, and physical exercise) and health status are scarce. Only 1 recent meta-analysis showed a positive association between eHealth literacy and general health-related behaviors (overall estimate of the correlation: 0.31, 95% CI: 0.25 - 0.34), with a similar effect size observed in older adult populations [14]. Another systematic review showed that higher eHealth literacy was associated with better health knowledge and attitude in older adults, but the associations with physical and psychosocial outcomes were still inconsistent [15]. The relationships between eHealth literacy and specific health-related outcomes (eg, mental and physical well-being) need to be assessed to further explore their underlying mechanisms. In addition, studies on digital health often recruit participants from more accessible, community-dwelling populations [16], potentially underrepresenting the most vulnerable, such as homebound or socioeconomically disadvantaged older adults, who may face the greatest digital divide.

While existing research provides a foundational understanding of eHealth literacy, several critical gaps remain, limiting the development of effective, evidence-based interventions for older adults. First, eHealth literacy levels are known to vary significantly across different sociocultural and demographic contexts, with studies in the United States [16], South Korea [17], and Norway [18] reporting higher average scores than those reported in mainland China [19]. However, there is a scarcity of large-scale, representative data from Hong Kong, a unique high-income region characterized by extreme longevity, high digital penetration, and a government-led push for digital primary care reform. Second, much of the existing literature focuses on younger older populations (eg, those aged 60-65 years); however, the challenges and capabilities of the oldest older individuals (ie, those aged ≥75 years) may differ substantially. Third, while a study has confirmed a general positive association between eHealth literacy and composite health-related behaviors [14], there is a lack of research examining the associations between eHealth literacy and a comprehensive suite of specific, modifiable behaviors (eg, smoking, physical activity, and diet) and health service use. Finally, outcomes are often studied in silos. A holistic understanding requires a simultaneous investigation of the links between eHealth literacy and a broad spectrum of outcomes, including health behaviors, mental well-being, social connectedness, and physical health status.

To address these gaps, this study aimed to (1) assess the level of eHealth literacy in a large, community-based sample of underprivileged older adults in Hong Kong, with a particular focus on the oldest older population and (2) comprehensively examine the associations of eHealth literacy with specific health behaviors, mental health outcomes (well-being and loneliness), and physical health outcomes (prevalence of multiple NCDs).

Methods

Study Design

This study used a cross-sectional design, using baseline data from the Generations Connect Project. The parent project is an ongoing, large-scale, community-based, quasi-experimental pre-post study that trained over 1000 nursing students to provide home visits and perform a baseline health assessment and to deliver a health intervention (face-to-face and digital) to older adults in Hong Kong. The present study focused on the analysis of the baseline data collected before any intervention took place.

Older adults were recruited through collaborations with 20 local nongovernmental organizations covering 18 districts across Hong Kong. Between November 2022 and December 2024, we recruited participants aged ≥65 years who could read and communicate in Chinese and were cognitively and physically capable of understanding and answering survey questions. Older adults who were bedbound and had a history of mental illnesses were excluded. The exclusion of older adults with self-reported mental illness was to minimize potential confounding effects on the mental health outcomes measured in this study. In contrast, older adults with physical limitations (eg, visual or hearing impairments) were not excluded, as these conditions are prevalent in the target population, and their inclusion is crucial for the generalizability of our findings regarding the digital divide among the oldest older population. We recruited University of Hong Kong students to be student ambassadors through open recruitment via internal university emails and on-campus promotional materials (eg, posters and flyers) as well as selected curriculum (medical, nursing, dental, and common core courses) integration. Before making a home visit, all student ambassadors received a 3-hour training to ensure the intervention's fidelity and data quality during the data collection process. Details of the training session and intervention are reported elsewhere [20].

Ethical Considerations

Ethical approval was sought from the Institutional Review Board of the University of Hong Kong/Hospital Authority Hong Kong West Cluster (IRB/REC reference: UW 22 - 693). The institutional review board also allowed secondary analysis without additional consent. The reporting of this study strictly followed the STROBE (Strengthening the Reporting of Observational Studies in Epidemiology) guidelines (Checklist 1). The funder of the study had no role in the study design, data collection, data analysis, data interpretation, or writing of the report.

Informed consent was obtained using comprehensive information sheets and verbal explanations, and signed consent forms were obtained from participants before any procedures began. The consent form included information about the study's purpose and procedures and the participant's right to withdraw at any time without penalty.

Participants enrolled in the study received gift bags worth HK $50 (US $6.44) as an incentive during the initial student visits.

All data collected during the study were deidentified to protect the participants' privacy, with all identifying information removed. Access to the data was restricted to the research team, and all data were stored securely.

Measurements

We collected and analyzed the baseline data on the sociodemographic characteristics (eg, sex, age, highest educational attainment, marital status, and family monthly income), health behaviors, mental health, physical health, and eHealth literacy of participants.

Health behaviors included physical activity levels in metabolic equivalent of task minutes (MET min) per week (measured using the International Physical Activity Questionnaire Short Form) [21], number of days of vegetable and fruit consumption in the past week, smoking status (never smoker, ex-smoker, and current smoker), intention to quit within 30 days (yes/no) for current smokers, and drinking frequency in the past year (never, monthly or less, 2-4 times per month, 2-3 times per week, and ≥4 times per week).

Mental health and perceived level of loneliness were assessed using the World Health Organization-Five (WHO-5) Well-Being Index [22] and UCLA 3-item Loneliness Scale, respectively [23]. The raw score on the WHO-5 ranges from 0 to 25, and the percentage score ranges from 0 to 100 (raw score multiplied by 4). A percentage score of 0 represents the worst possible mental health status, and 100 represents the best possible mental health status [22]. The WHO-5 has been validated for the Chinese population [24]. In our sample, the scale demonstrated good internal consistency, with a Cronbach α of 0.89. The UCLA 3-item Loneliness Scale measures 3 dimensions of loneliness (relational and social connectedness and self-perceived isolation) with a score ranging from 3 to 9, where a higher score indicates a higher level of loneliness [23]. The UCLA 3-item Loneliness Scale was validated for older Chinese adults [25]. The scale showed high reliability in the present study, with a Cronbach α of 0.88. Physical health was assessed by asking whether the participants had been medically diagnosed with each NCD (yes/no), including hypertension, diabetes, cardiovascular disease, and stroke. A multimorbidity variable was constructed (defined as having been medically diagnosed with ≥2 of the following 4 conditions: hypertension, diabetes, cardiovascular disease, and stroke).

eHealth literacy was measured using the eHealth Literacy Scale (eHEALS) [11]. The scale measures participants' perceived skills, knowledge, and comfort toward eHealth [11]. The scale consists of 8 items, which are rated on a 5-point Likert scale ranging from 1 (strongly disagree) to 5 (strongly agree). The total score ranges from 8 to 40, with higher scores indicating higher self-perceived eHealth literacy [11]. On the basis of the score, the respondents can be categorized into 4 groups: inadequate eHealth literacy (score: 8 - 15.99), low eHealth literacy (score: 16 - 23.99), moderate eHealth literacy (score: 24 - 31.99), and high eHealth literacy (score: 32 - 40) [26]. The scale has high internal consistency, with a Cronbach α of 0.96 [26], and has been validated for Chinese older adults, with a Cronbach α of 0.88 [26].

Statistical Analysis

Inverse probability weighting based on the sex distribution of Hong Kong older adults in 2023 (from the census) was conducted to make the sample more representative of Hong Kong's older adult population. Descriptive statistics were used to describe the participants' sociodemographic characteristics, eHealth literacy, health behaviors, mental health, and physical health at baseline.

The associations of sociodemographic characteristics (sex, age, highest educational attainment, family monthly income, Comprehensive Social Security Assistance [CSSA] Scheme status, type of housing, and living with family members) with the eHEALS score were analyzed using multivariable linear regression (adjusted unstandardized coefficient [b]) with mutual adjustment for baseline sociodemographic characteristics.

Multiple logistic regression (adjusted odds ratio [AOR]) was used to analyze the associations of the level of eHealth literacy with smoking and drinking status (yes/no), District Health Center member status (yes/no), multimorbidity of NCDs (yes/no), and medical diagnosis of NCDs (yes/no). Multivariable linear regression (adjusted unstandardized coefficient [b]) was used to examine the associations of the level of eHealth literacy with total physical activity (MET min/week), the WHO-5 Well-Being Index score, and the UCLA 3-item Loneliness Scale score. The associations of the level of eHealth literacy with the number of days of vegetable and fruit consumption in the past week were analyzed using Poisson regression. The models were adjusted for baseline sociodemographic characteristics. All analyses were conducted in Stata (version 15.1; StataCorp LLC). A 2-sided *P* value <.05 was considered statistically significant.

Results

Between November 2022 and December 2024, a total of 7087 potential participants were screened and found eligible, and 6704 agreed to participate and were included in the baseline analysis. The mean time to conduct baseline assessments and deliver interventions was 102 (SD 7.3) minutes.

Table 1 shows that the mean age of the participants was 77.8 (SD 7.0) years, and 26.9% (1805/6704) of the participants were men. Most participants had primary education or below (4003/6676, 60.0%), were married (3173/6626, 47.9%), and had a family monthly income of HK $25,000 (US $3205.9) or less (5127/6653, 77.1%). Moreover, 25.4% (1691/6650) of participants were supported by the CSSA Scheme. Most participants were retired (6460/6694, 96.5%), living in public housing (4829/6696, 72.1%), and living with family members (3479/6696, 52.0%). In total, 71.2% (4774/6704) of participants were not District Health Center members. The mean eHEALS score of participants was 18.2 (SD 10.2), and most participants (2897/6566, 44.1%) had inadequate eHealth literacy (score: 8 - 15.99).

Characteristic	Participants, n (%)
High (score: 32 - 40)	1165 (17.7)

[a]The proportions were weighted by sex distribution of older adults in Hong Kong 2023. The observations (n) were unweighted.

[b]Reported as mean (SD).

[c]eHealth literacy is measured on a 5-point eHealth Literacy Scale (eHEALS), with ratings ranging from 1 (strongly disagree) to 5 (strongly agree). The overall score ranges from 8 to 40, with a higher score indicating more perceived skills in finding, evaluating, and using electronic information to make health decisions.

Table 2 shows that the participants' mean total physical activity was 628.7 (SD 542.9) MET min per week. The mean number of days on which vegetables and fruits were consumed in the past week was 6.6 (SD 1.3) and 5.9 (SD 2.0), respectively. In total, 3% (198/6686) of participants were current smokers, and 91% (163/179) had no intention to quit. Moreover, 8.5% (570/6704) of participants were current drinkers. The mean percentage score on the WHO-5 Well-being Index was 68.1 (SD 21.3), and the mean score on the UCLA 3-item Loneliness Scale was 4.0 (SD 1.6). Notably, 45.2% (3020/6674) of participants had multimorbidity of NCDs (medically diagnosed with ≥2 NCDs). Of the 6704 participants, 60.5% (n=4059) were medically diagnosed with hypertension, 27.1% (n=1816) had diabetes, 13.3% (n=894) had cardiovascular disease, and 4.6% (n=309) had a medical diagnosis of stroke.

Table . Health behaviors, mental health, and physical health of participants (N=6704)[a].

Parameter	Outcome
Physical activity, IPAQ-SF continuous score (MET[b] min/week), mean (SD)[c]	
Walking	463.5 (443.8)
Moderate	139.9 (222.6)
Vigorous	25.2 (108.6)
Total	628.7 (542.9)
Number of days of vegetable consumption in the past week, mean (SD)	6.6 (1.3)
Number of days of fruit consumption in the past week, mean (SD)	5.9 (2.0)
Smoking status, n (%)	
Never smoker	5812 (86.9)
Ex-smoker	676 (10.1)
Current smoker	198 (3)
Intention to quit for current smokers, n (%)	
No	163 (91)
Yes	16 (9)
Drinking frequency in the past year, n (%)	
Never	6104 (91.5)
Monthly or less	289 (4.3)
2 - 4 times per month	129 (1.9)
2 - 3 times per week	46 (0.7)
>4 times per week	106 (1.6)
WHO-5[d] Well-Being Index percentage score (0 - 100)[e], mean (SD)	68.1 (21.3)
UCLA 3-item Loneliness Scale score: 3 - 9)[f], mean (SD)	4.0 (1.6)
Multimorbidity[g] of NCDs[h], n (%)	
No	3654 (54.7)
Yes	3020 (45.2)
Medical diagnosis of hypertension, n (%)	
No	2645 (39.5)
Yes	4059 (60.5)
Medical diagnosis of diabetes, n (%)	
No	4888 (72.9)
Yes	1816 (27.1)
Medical diagnosis of cardiovascular disease, n (%)	
No	5810 (86.7)
Yes	894 (13.3)
Medical diagnosis of stroke, n (%)	
No	6395 (95.4)
Yes	309 (4.6)

[a]The proportions were weighted by sex distribution of older adults in Hong Kong 2023. The observations (n) were unweighted.

[b]MET: metabolic equivalent of task.

[c]The International Physical Activity Questionnaire Short Form (IPAQ-SF) continuous scores are expressed in MET min/week: MET level × minutes of activity × events per week. The total physical activity is computed as the sum of walking, moderate, and vigorous scores (MET min/week).

XSL•FO
RenderX

[d]WHO-5: World Health Organization-Five Well-Being Index.

[e]The raw score, ranging from 0 to 25, is multiplied by 4 to obtain a percentage score. A percentage score of 0 represents the worst possible quality of life, whereas a score of 100 represents the best possible quality of life.

[f]The 3-point response scale for each item ranges from "hardly ever or never" (1 point) to "often" (3 points), and the total score is the sum of all items, which ranges from 3 to 9, with higher scores indicating a higher level of perceived loneliness.

[g]Multimorbidity was defined as having been medically diagnosed with ≥2 of the following 4 conditions: hypertension, diabetes, cardiovascular disease, and stroke.

[h]NCD: noncommunicable disease.

Table 3 shows that increasing age (adjusted b −0.32, 95% CI −0.35 to −0.28; *P*<.001), support from the CSSA Scheme (adjusted b −1.49, 95% CI −2.04 to −0.95; *P*<.001), and living in public housing (adjusted b −1.60, 95% CI −2.69 to −0.50; *P*=.004) were associated with a lower eHEALS score, after mutual adjustment for baseline sociodemographic characteristics. Secondary education (adjusted b 4.31, 95% CI 3.81-4.82; *P*<.001) and tertiary education (adjusted b 9.04, 95% CI 8.04-10.06; *P*<.001) were associated with higher eHEALS scores.

Table . Associations of sociodemographic characteristics with eHealth literacy of participants (N=6704).

Characteristic	Association with eHealth Literacy Scale score (8 - 40)			
	Crude b (95% CI)	*P* value	Adjusted b (95% CI)[a]	*P* value
Sex (reference: male)

Yes	0.99 (−0.78 to 2.76)	.95	−0.43 (−2.10 to 1.23)	.89

[a]The model was mutually adjusted for all sociodemographic characteristics listed in the table, including sex, age, highest educational attainment, family monthly income, Comprehensive Social Security Assistance status, type of housing, and living with family members.

Descriptive analysis showed that 93% (6227/6704) of participants were smartphone users. In total, 57.5%(3549/6173) used a smartphone for 1 hour or more daily, 91.5% (6135/6704) had instant messaging apps installed on the smartphone, and 60.2% (3992/6634) had not searched for health-related information from online sources using the smartphone (Multimedia Appendix 1). Table 4 shows that participants with moderate eHealth literacy (score: 24 - 31.99) were less likely to be current smokers (AOR 0.60, 95% CI 0.38-0.95; *P*=.04) and more likely to be District Health Center members (AOR 1.52, 95% CI 1.30-1.77; *P*<.001), and moderate eHealth literacy was associated with higher total physical activity levels (adjusted

XSL•FO
RenderX

b 39.83, 95% CI 2.04-77.62; *P*=.04) and a higher number of days of fruit consumption in the past week (adjusted b 0.034, 95% CI 0.006-0.063; *P*=.04). Participants with high eHealth literacy (score 32 - 40) were less likely to be current smokers (AOR 0.57, 95% CI 0.36-0.92; *P*=.03) and more likely to be District Health Center members (AOR 1.76, 95% CI 1.51-2.05; *P*<.001), and high eHealth literacy was associated with a higher number of days of fruit consumption in the past week (adjusted b 0.046, 95% CI 0.017-0.075; *P*=.003).

Table . Associations of eHealth literacy with health behaviors of participants (N=6704).

[a]eHEALS: eHealth Literacy Scale.

XSL•FO
RenderX

[b]OR: odds ratio.

[c]Adjusted for sex, age, highest educational attainment, family monthly income, living with family members, and District Health Center member.

[d]WHO-5: World Health Organization-Five Well-Being Index. The score ranges from 0 to 25, with 0 representing the worst possible and 25 representing the best possible quality of life. The score is multiplied by 4. A percentage score of 0 represents the worst possible quality of life, whereas a score of 100 represents the best possible quality of life.

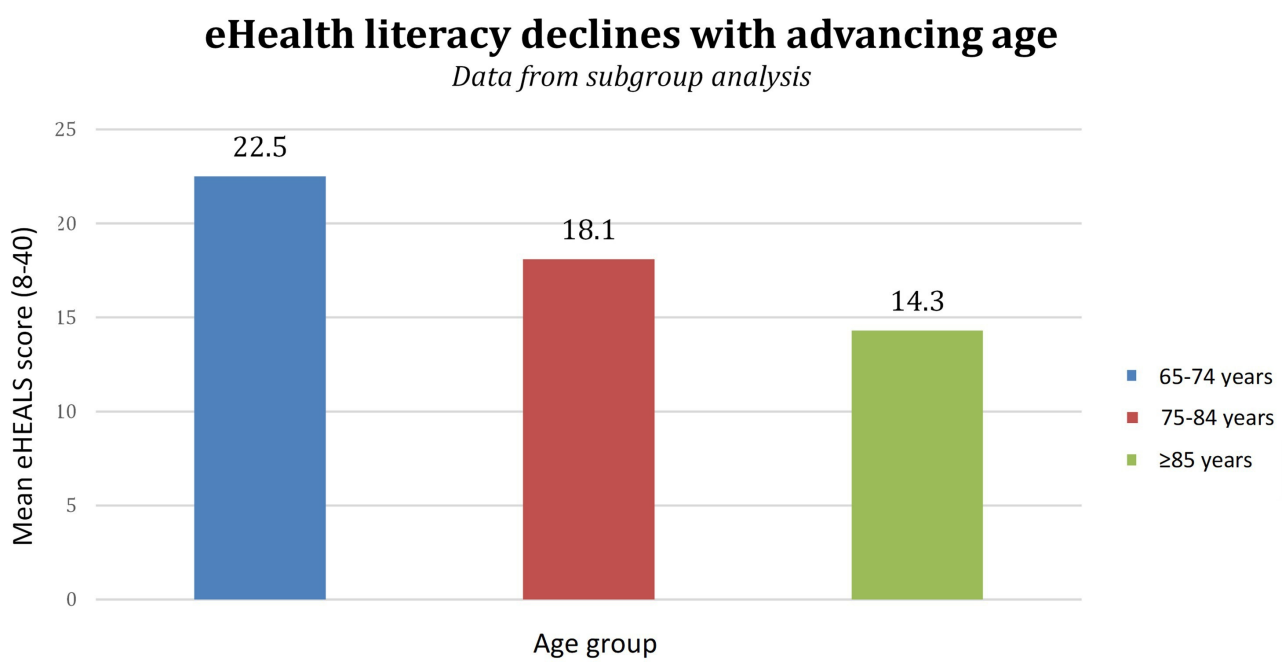
[e]The 3-point response scale for each item ranges from "hardly ever or never" (1 point) to "often" (3 points), and the total score is the sum of all items, which ranges from 3 to 9, with higher scores indicating a higher level of perceived loneliness.

[f]Multimorbidity was defined as having been medically diagnosed with ≥2 of the following 4 conditions: hypertension, diabetes, cardiovascular disease, and stroke.

[g]NCD: noncommunicable disease.

Discussion

Principal Findings



We analyzed the baseline data from an ongoing, large-scale, quasi-experimental, pre-post study to investigate the level of eHealth literacy and its associations with health behaviors, primary care service use, mental health, and physical health among Hong Kong Chinese older adults (N=6704). The results suggested that their eHealth literacy level was generally low. In addition, our findings showed that older adults with higher eHealth literacy were associated with positive health behaviors and better health-related outcomes at baseline. A key strength of this study is its examination of specific, modifiable health behaviors (eg, smoking, physical activity, and diet) and health outcomes (eg, mental health and NCD risks). This granular approach provides more actionable insights for public health interventions. For example, identifying a link between eHealth literacy and smoking status allows for more targeted health promotion campaigns. This specificity moves the field beyond broad associations toward evidence that can directly inform the content of programs that leverage digital tools for health improvement in aging populations.

The mean eHealth literacy score of the study participants was 18.2 (SD 10.2), which was lower than the scores reported in the United States (30.9) [16], South Korea (30.5) [17], Norway (25.7) [18], and China (21.4) [19]. The notably higher age (mean 77.8, SD 7.0 years) of our sample is likely a key contributor to this low average score, a conclusion supported by our finding that increasing age was the most significant demographic predictor of lower eHealth literacy. This suggests that interventions to enhance older adults' eHealth literacy are much needed. Our study indicated that 44.1% of older adults (mean age 77.8, SD 7.0 years) lacked eHealth literacy despite having a smartphone with internet access. This can be attributed to older adults' attitudes toward the internet, including self-efficacy in managing digital technology and a preference for in-person interaction with health practitioners [27]. eHealth literacy may also be lower due to age-related problems and cognitive decline [27]. These findings are relevant to delivering eHealth resources to older adults [27]. Overcoming these sociodemographic and psychological barriers may increase eHealth literacy and help older adults improve their general health. In addition, despite 93% (6227/6697) of participants owning a smartphone, 60.2% (3992/6634) reported never having used it to search for health information (Multimedia Appendix 1). This highlights a critical gap between device ownership and meaningful health-related use, underscoring that access to technology alone is insufficient. This "know-do" gap underscores the urgent need for interventions that build skills and confidence in searching for health information with technological devices among older adults.

Furthermore, we performed subgroup analyses of eHealth literacy by age group (65 - 74 years, 75 - 84 years, and ≥85 years) in our study sample (Figure 1). The results showed a stepwise decline in eHealth literacy across age strata. Older adults with increasing age had the highest burden of chronic disease and the greatest need for health care services, yet they are the most likely to be excluded from an increasingly digitized health care system. Our study's findings can serve as a data point for policymakers and health care providers, highlighting the urgent need for tailored, age-appropriate support systems to prevent the digital divide from becoming a health equity crisis.

XSL•FO
RenderX

Figure 1. Mean eHealth literacy Scale (eHEALS) score by age group in the study sample (N=6704).

Our findings showed that older adults with higher education were associated with higher eHealth literacy, and older adults with indicators of lower socioeconomic status (receiving support from the CSSA Scheme and living in public housing) were associated with lower eHealth literacy. Lower-income older adults may have poorer access to digital technology, such as limited computer and internet access, leading to skill disparity [28]. The relationship between socioeconomic status and eHealth literacy needs to be investigated in depth to prevent the potential loss of the silver economy in a digitalized society. It is important to consider the social disparities and the digital divide factors when promoting eHealth services to ensure that those needing these services are not left out [28]. Primary health care is the cornerstone of the health care system, and we should optimize the primary health care services to enhance older adults' eHealth literacy. In addition, training should be provided to carers and the younger generation (eg, university students) to guide underprivileged older adults in using electronic information technology and meeting their health needs in the digital age.

We found that older adults with moderate and high eHealth literacy were less likely to be smokers and more likely to engage in positive health behaviors. Higher eHealth literacy may enhance an individual's self-efficacy in managing their health. With an enhanced ability to find, evaluate, and apply online health information, older adults may feel more confident in making informed decisions [29], leading to better health behaviors such as improved diet or increased physical activity and more effective self-management of chronic conditions. In addition, greater access to eHealth resources increases the awareness of health maintenance and encourages older adults to adopt healthy lifestyles [30]. Older adults skilled in using digital health services will be able to communicate with health care professionals in advance and manage their health more efficiently, enabling them to receive more comprehensive NCD prevention services.

Our findings revealed a strong association between higher eHealth literacy and better mental health outcomes, specifically higher levels of well-being and lower levels of loneliness. This finding aligns with a growing body of literature demonstrating the positive role of digital engagement in the psychosocial health of older adults [31]. For instance, a study in Hong Kong during the COVID-19 pandemic found that the use of instant messaging apps was a key factor in mitigating loneliness [32]. Our results expand on this by suggesting that eHealth literacy, as a core component of digital competency, is a crucial enabler of such beneficial social connections. The mechanism is likely 2-fold. First, digitally literate older adults can more easily use technology to maintain contact with family and friends, thereby strengthening their social support networks. Second, those with low eHealth literacy may struggle to differentiate credible information from misinformation online [33], leading to increased anxiety and negative emotional states. The implication for practice is significant: interventions aimed at improving mental health in older adults should consider incorporating digital literacy training not merely as a technical skill but as a fundamental tool for fostering social connectedness and resilience in a digital world.

Implications and Future Directions

Based on the findings identified in this cross-sectional study, several avenues for future research are warranted to deepen our understanding and inform effective interventions. First, there is a critical need for longitudinal studies to establish temporal relationships between eHealth literacy and health outcomes. For instance, a recent 3-wave longitudinal study demonstrated that higher baseline eHealth literacy predicted a better health-promoting lifestyle over time among Chinese older adults [34]. Future research should build on this finding by following up older adults to determine whether improving eHealth literacy leads to sustained health behavior change and better long-term

XSL•FO
RenderX

health outcomes and to explore the mediating pathways (eg, self-efficacy) in these relationships.

Second, to move beyond association and test for causality, future work should include intervention studies, such as randomized controlled trials. These studies could evaluate the effectiveness of tailored eHealth literacy training programs on specific outcomes, including health behavior change, chronic disease self-management, and mental well-being in older adults. Such interventions should be multifaceted and co-designed with older adults, moving beyond basic technology access to build practical skills and confidence. Strategies could include (1) tailored, hands-on training workshops; (2) intergenerational peer-tutoring models; (3) the development of age-friendly user interfaces for health apps; and (4) the integration of eHealth literacy support within primary care settings and community centers.

Third, the measurement of eHealth literacy itself requires advancement. This study, similar to many others, relied on a self-report scale. Future research would benefit from incorporating objective, performance-based assessments. This would provide a more accurate measure of actual competency and help bridge the gap between perceived and demonstrated skills. Additionally, research is needed to validate eHealth literacy assessment tools and their cut-off scores for the older and oldest older populations.

Finally, to enhance generalizability, future research should include older adults with a history of mental illness. While they were excluded from our analysis to avoid confounding the mental well-being outcomes, research focus on this vulnerable group is essential for developing tailored interventions that address their specific barriers to digital engagement and health management [35], thus further narrowing the digital divide.

Limitations

This study has several limitations. First, the findings were based on an analysis of the baseline data, and causal relationships between variables could not be confirmed. Given the initial observational data, intervention studies (eg, randomized controlled trials) should be conducted to determine causal relationships between eHealth literacy, health behaviors, and health-related outcomes. Follow-up data and qualitative research may provide more insights into these mechanisms in the future. Second, our study excluded older adults with a self-reported history of mental illness (eg, depression and anxiety), and this exclusion may limit the generalizability of our findings. Mental health status may be associated with an individual's motivation and ability to engage with digital technology [31]. Further research is needed to investigate the relationships between eHealth literacy and health outcomes, specifically within this vulnerable subgroup of older adults. Third, individual eHealth literacy and health status are closely related to the local economic development level [36], and the study findings may not be generalizable to regions with different socioeconomic contexts, cultural backgrounds, or levels of digital infrastructure. In addition, the study was conducted in Hong Kong, a high-income region with advanced digital infrastructure. The observed levels of eHealth literacy and their associations with health outcomes may not be directly generalizable to older adults in low-income or middle-income settings, where access to technology and digital skills may be substantially different. Fourth, this study used the eHEALS to assess eHealth literacy. While widely used and validated, this scale has significant limitations. Developed in 2006 [11], eHEALS may not fully capture the complex skills required to navigate today's ecosystem of mobile apps and interactive health technologies [37]. Furthermore, newer instruments such as the Digital Health Literacy Instrument (DHLI) have been developed and show good utility in Chinese older adults [38]. Recent systematic reviews also highlight the need for more robust, performance-based tools, as eHEALS assesses self-perceived skills rather than actual competence, which may be subject to self-report bias [37,39]. Finally, the generalizability of our findings to the entire older adult population in Hong Kong may be limited. While our sample was large and weighted by sex distribution to match the Hong Kong census, the mean age of our participants was 77.8 (SD 7.0) years, which is higher than that of the general older adult population in Hong Kong [40].

Conclusions

eHealth literacy is an essential skill in a rapidly digitalizing world. The findings showed that the eHealth literacy of older adults in Hong Kong was low and needs improvement, especially in the context of global primary health care reform. We also observed that higher levels of eHealth literacy were associated with health-promoting behaviors, primary care service use, and better physical and mental health outcomes. With the application of the results from this study, tailored interventions should be implemented to improve eHealth literacy and narrow the digital divide among older adults.

Abstract

Background: Amid the convergence of global population aging and accelerating digital transformation, older adults' digital adaptability has emerged as a critical indicator of their quality of life, autonomy, and capacity for successful aging. However, digital disparities, technology-related anxiety, and insufficient support systems continue to hinder older individuals from fully participating in digital society. Particularly in modern family structures—where children often live apart from aging parents—the diminishing role of family support further underscores the importance of broader social influences.

Objective: This study aims to examine how environmental factors (family support and social influence) and psychological factors (digital anxiety and sense of achievement) are associated with older adults' intention to use Assistive Digital Tools and Services (ADTS), and how these relationships contribute to the development of digital literacy. Drawing upon an integrative framework that combines constructs from the Technology Acceptance Model, the Unified Theory of Acceptance and Use of Technology, and social cognitive theory, the study also investigates the mediating and moderating mechanisms underlying these effects, offering strategic insights to support older adults in moving from social isolation to digital empowerment.

Methods: A structured questionnaire survey was conducted using a convenience sampling method among adults aged 55 years and older in Shenyang, Liaoning Province, China, yielding 480 valid responses. Structural equation modeling, bootstrapping, and moderation analysis were used to test the proposed integrative framework.

Results: For both family support and social influence, their associations with digital literacy were fully mediated by ADTS. Higher family support was associated with lower digital anxiety, which in turn correlated with greater intention, while stronger social influence was directly associated with higher intention. Digital anxiety showed a strong negative association with intention; however, this relationship was significantly weaker among those reporting a higher sense of achievement. These findings highlight usage intention as a central pathway through which environmental and psychological conditions are related to digital competence.

Conclusions: Digital literacy in later life is more than a technical skill set—it represents a vital form of psychological and social capital that empowers autonomy, well-being, and social integration. Strengthening older adults' intention to engage with digital tools through emotional reinforcement, achievement-oriented experiences, and supportive social environments is key to narrowing the digital divide. Beyond its personal benefits, fostering digital competence contributes to successful aging, which in turn brings profound advantages for families, strengthens community cohesion, and supports national goals in public health, economic participation, and social sustainability. Intergenerational learning initiatives, community-based engagement programs, and leveraging social influence to offset weakened family support can create a more inclusive, resilient, and age-friendly digital ecosystem—one that benefits not only older individuals but society at large.

Introduction

Global Aging and the Challenge of Digital Inclusion

The intersection of rapid global population aging and accelerated digital transformation has rendered digital inclusion among older adults a pressing concern for researchers and policymakers alike. According to the United Nations [1], by 2050, the global population aged 65 years and older is projected to surpass 1.6 billion, accounting for nearly 16% of the total population. This demographic shift not only places strain on health care systems and labor markets but also redefines the societal roles and needs of aging populations in an increasingly digital world.

Within this context, digital literacy—encompassing not only operational skills but also digital confidence and information navigation—has been widely recognized as a key enabler for bridging this divide and promoting the effective use of Assistive Digital Tools and Services (ADTS) [2].

Prior studies have linked digital literacy to improved psychological well-being, life satisfaction, and learning motivation among older adults [3]. Yet, how digital literacy develops under the influence of environmental and psychological factors—especially in the context of aging—remains underexplored.

Digital exclusion exacerbates social isolation and loneliness among older adults, increasing the risk of depression and cognitive decline—while digital literacy offers a potential buffer against these outcomes [4]. In digitally mediated societies, older adults may experience compounded vulnerability—excluded not only socially but technologically.

Crucially, digital literacy holds promise as a remedy to both social and digital isolation. Older adults with strong digital competencies are more likely to engage in video communication, access health services remotely, and maintain active social networks [5,6]. In this sense, digital literacy is not merely a technical skill—it is a bridge to successful aging.

COVID-19: A Double-Edged Catalyst for Digital Transformation

The COVID-19 pandemic served as a global stress test for digital readiness, rapidly shifting key aspects of daily life—health care, communication, commerce—into digital spaces. While digital services such as telemedicine and online grocery delivery became lifelines for many, they also exposed and widened the digital gap among older populations [7].

Older adults demonstrated significantly lower intention to adopt digital services during and after the pandemic, largely due to digital anxiety, low confidence, and lack of digital trust [8]. Digital anxiety encompasses fears about making mistakes, information overload, and concerns about fraud and data breaches—factors particularly salient for older first-time users [9].

While digital literacy training can alleviate anxiety and improve adoption, sustained engagement often depends on ongoing emotional and environmental support—particularly from family and community contexts [10]. However, the long-term sustainability of digital engagement often depends on external support structures such as family guidance or community-based learning. Without sustained environmental and emotional support, even trained users may regress into avoidance behaviors. This underscores the importance of examining how family and social influences shape not only technology adoption but also digital confidence and persistence among older adults.

Research Gaps and Objectives

While widely adopted models such as the Technology Acceptance Model (TAM) and the Unified Theory of Acceptance and Use of Technology (UTAUT) have contributed significantly to understanding digital behavior, they were primarily developed for younger, working-age users [11]. As such, these models often overlook emotional vulnerabilities and contextual factors that are particularly salient among older adults—such as digital anxiety, family support, and social influence.

At the same time, the Digital Literacy Framework highlights competencies essential for navigating the digital world but does not explicitly address how these skills develop within psychosocial environments. Moreover, existing studies tend to examine these psychological and environmental variables in isolation, without a cohesive explanatory structure [5,11].

To address this gap, we propose an integrative framework that draws on TAM, UTAUT, and social cognitive theory (SCT) [12]. In this model:

- Family support and social influence reflect environmental enablers of technology adoption (UTAUT);
- Digital anxiety and sense of achievement represent emotional and cognitive mechanisms (SCT);
- Usage intention (from TAM) serves as a behavioral mediator;
- Digital literacy is positioned as a dynamic outcome representing both skill and empowerment.

Furthermore, we incorporate a moderated mediation structure, positing that sense of achievement may buffer the negative impact of digital anxiety on usage intention, thereby shaping digital literacy development [12].

This integrative approach also aligns with Successful Aging Theory, framing digital literacy as a form of “aging capital” that enhances autonomy, social participation, and psychological well-being.

Based on this framework, our study addresses the following research questions:

1. To what extent are family support and social influence associated with older adults’ intention to adopt ADTS?
2. Does digital anxiety negatively affect usage intention, and is this effect moderated by sense of achievement?
3. Does usage intention mediate the relationship between environmental/psychological factors and digital literacy?

By empirically validating this multilevel framework, we aim to offer new insights into how older adults move from digital exclusion to empowerment in an aging digital society.

XSL•FO
RenderX

In applying UTAUT as a guiding framework, we intentionally retained social influence and conceptualized family support as an environmental enabler, while excluding performance expectancy and effort expectancy. We do so for parsimony and contextual salience: (1) their predictive roles have been robustly established in prior work, so retesting them would add replication rather than novel insight; (2) prestudy interviews suggested many older adults lacked sufficient hands-on ADTS experience to meaningfully assess usefulness or ease of use; and (3) our theoretical focus is the age-specific psychosocial mechanisms (family support, social influence, anxiety, and achievement) that drive intention in later life. This selective adaptation contextualizes UTAUT rather than diluting it.

We also model digital literacy as an outcome—an accumulated form of "aging capital"—to trace how environmental and psychological conditions translate into competence via usage intention. While prior studies have treated literacy as an antecedent that can reduce anxiety and strengthen intention, our outcome-focused specification clarifies the developmental pathway we test here; it does not preclude reciprocal dynamics, which we note as an avenue for longitudinal research.

Literature Review

Family Support

Family support plays a critical role in facilitating older adults' digital engagement. Defined broadly, family support encompasses emotional encouragement, technical guidance, and intergenerational interaction that collectively enhance older adults' adaptation to digital life [13]. Caplan [14] viewed the family as a key provider of values and behavioral norms, offering essential mediation when individuals encounter challenges. Casper et al [15] further divided family support into instrumental, financial, and emotional dimensions, all of which contribute meaningfully to older adults' ability to learn and apply new technologies.

In the digital context, family members frequently act as facilitators in older adults' learning process, offering real-time help and reassurance [16]. Older adults are often influenced by their children's or grandchildren's attitudes toward technology, making family encouragement a significant determinant of their intention to engage with ADTS [17].

Empirical research supports this relationship. Xiong and Zuo [13] showed that emotional support and technical instruction from family members enhance digital literacy by reducing fear and uncertainty. Similarly, Meng et al [18] and Sosa Díaz [19] found that positive intergenerational communication increases digital confidence and learning motivation. Sosa Díaz [19] highlighted that assistance from younger family members strengthens adaptability, while Roman et al [20] emphasized how strong family bonds can boost learning confidence.

Thus, this study highlights family support as a foundational environmental factor influencing both psychological readiness and behavioral engagement in digital contexts. The focus on intergenerational interaction aims to deepen our understanding of how familial dynamics contribute to digital inclusion among older adults.

Social Influence

Social influence refers to the degree to which individuals' behaviors, attitudes, or decisions are shaped by those in their social environment—such as family, friends, or peers [11]. Rooted in the UTAUT, social influence is recognized as a key driver of technology adoption, particularly through normative pressure and perceived expectations from significant others [11,21].

From a broader psychological perspective, social influence encompasses beliefs, emotions, and behavioral patterns formed through interactions within social networks [21]. Morosan et al [22] highlighted that individuals' perceptions of others' expectations can significantly affect their own technology acceptance decisions. Karahanna et al [21] expanded this view by discussing how proximity, contact frequency, and interpersonal dynamics influence behavior, emphasizing that social structures can either facilitate or inhibit digital engagement.

Among older adults, social influence is particularly potent. Compared with younger individuals, older adults are more likely to rely on interpersonal cues and social norms when evaluating new technologies [11]. The impact of social influence is also more pronounced in collectivist cultures—such as in many East Asian societies—where conformity to group norms and maintaining social harmony are especially valued.

The role of social influence has become even more salient in the postpandemic digital era. During COVID-19, social distancing measures drove many older adults to adopt digital tools for health, communication, and daily tasks, often under the encouragement or guidance of their social circles [23]. Positive social reinforcement can lead to greater confidence and higher willingness to engage with digital services, whereas skepticism or lack of support may result in avoidance or anxiety [24-26].

Furthermore, recent studies show that social influence not only affects direct behavioral intention but also moderates psychological factors such as digital anxiety and self-efficacy [27]. These findings underscore the need to understand social influence as both an external motivator and a psychological buffer or amplifier in older adults' digital adaptation.

By focusing on the multifaceted nature of social influence—including social norms, peer encouragement, and perceived expectations—this study aims to clarify how social context shapes older adults' engagement with ADTS and the broader development of digital literacy.

Digital Anxiety: Concept and Development

Digital anxiety refers to the emotional discomfort, fear, or stress that individuals—particularly older adults—experience when interacting with digital technologies. Unlike simple unfamiliarity, digital anxiety reflects a deeper psychological resistance often rooted in low confidence, fear of failure, and perceptions of complexity or risk [26,28]. Wang and Zhang [29] defined it as a form of state anxiety, varying with task demands and context. Among older adults, this anxiety is

XSL•FO
RenderX

especially pronounced due to the widening digital divide and their limited prior exposure to emerging technologies.

Rook [30] highlighted that older individuals frequently report elevated anxiety when using ADTSs such as telemedicine platforms, smartphones, or mobile payments. This is compounded when they lack the digital self-efficacy or training needed to operate these tools confidently. Straub [26] found that prior experience and perceived self-efficacy can significantly reduce anxiety and increase willingness to adopt digital tools. Similarly, the TAM posits that perceived ease of use and usefulness directly shape user attitudes and behaviors.

From the perspective of Rogers' Diffusion of Innovations Theory, perceived complexity and compatibility with past experiences are key barriers for older adults. Even simple digital interfaces can feel cognitively taxing, potentially triggering avoidance behaviors rather than active engagement [31,32].

One of the most consistently supported buffers against digital anxiety is family support. Beyond emotional reassurance, family members often provide practical technical guidance and encouragement, helping older adults feel less overwhelmed and more motivated to engage with digital tools. Studies have shown that such support fosters emotional security, strengthens digital self-confidence, and decreases feelings of uncertainty in digital environments [33]. For instance, when family members offer direct assistance—such as walking through digital tasks step-by-step—older adults are more likely to persist in their learning process and overcome initial apprehension.

However, overly reliant support can have mixed effects. While moderate, empowering support improves outcomes, excessive dependence may inadvertently signal incompetence or fuel learned helplessness, thereby reinforcing anxiety [7,34]. Nevertheless, the preponderance of evidence suggests a net protective role of family involvement in alleviating digital stress, leading to the following hypothesis:

H1: Family support negatively influences digital anxiety.

In addition to family, broader social influence plays a crucial role in shaping digital anxiety. When older adults perceive positive expectations or encouragement from peers, neighbors, or community members, it can reduce fear and promote digital exploration. On the contrary, negative social feedback—such as expressions of doubt, impatience, or age-related stereotypes—can heighten self-doubt and anxiety. Recent studies have demonstrated that social environments that are judgmental or unsupportive intensify older adults' digital apprehension, especially when they fear being seen as "incompetent" or "too old to learn" [35,36].

Conversely, positive social modeling and group-based learning environments—such as community digital workshops—can boost older adults' digital confidence and reduce anxiety levels. Venkatesh et al [11] and Cambre and Cook [27] have also pointed out that perceived social expectations (a key dimension of UTAUT) can influence both emotional responses and behavioral intentions related to technology.

H2: Social influence positively influences digital anxiety.

In summary, digital anxiety among older adults is shaped not only by individual cognitive appraisals but also by the presence—or absence—of emotional and environmental support. Understanding how family support and social influence interact with psychological states like anxiety is essential for building more inclusive and effective digital interventions.

Usage Intention of Assistive Digital Tools and Services

The intention to use ADTS among older adults is a central construct in models of technology adoption. Usage intention refers to an individual's motivational readiness and willingness to adopt or engage with a specific technology [37]. In the context of aging populations, intention plays a critical intermediary role, linking psychological and environmental factors with actual digital behavior and literacy development.

Family Support and Usage Intention

Family support has been widely documented as a catalyst for technology acceptance among older adults. Beyond alleviating anxiety, supportive family environments contribute to a more proactive stance toward digital learning. Emotional encouragement, technical guidance, and shared experiences with family members strengthen older adults' belief in their own capability, thereby enhancing their readiness to use ADTS.

Studies suggest that family members who model digital behavior or provide hands-on help not only increase access but also shape attitudes of usefulness and ease of use—2 key predictors in the TAM [38]. For instance, Zhang [17] found that the opinions of close family members significantly influenced older adults' willingness to try new technologies. Likewise, Selwyn [16] and Park [39] noted that active family involvement enhances digital confidence and curiosity, which translates into a stronger intention to use tools like mobile banking or telemedicine services.

While over-dependence on family for digital engagement may hinder independent learning, moderate and empowering support appears to foster technology acceptance. Therefore, based on the strong empirical and theoretical link between family support and technology adoption, the following hypothesis is proposed:

H3: Family support positively influences older adults' intention to use ADTS.

Social Influence and Usage Intention

Social influence extends beyond the family unit to include peers, community members, and broader societal norms that shape older adults' willingness to engage with digital technologies. In UTAUT, social influence is considered a direct antecedent of usage intention, reflecting how individuals perceive the expectations and behaviors of others as relevant to their own decision-making [11].

Research demonstrates that when older adults observe peers successfully using ADTS, they are more likely to emulate those behaviors, especially in collectivist cultures where conformity and social approval are emphasized [40,41]. Additionally, informational and normative forms of social influence—such as digital learning groups, community workshops, or

XSL•FO
RenderX

word-of-mouth recommendations—play a crucial role in shaping perceived accessibility and relevance of digital services [42,43].

Moreover, positive social reinforcement enhances self-efficacy, reduces uncertainty, and increases perceived behavioral control—factors that strongly predict technology use. Conversely, negative perceptions within one's social network may lead to skepticism or hesitation. Given this evidence, we propose:

H4: Social influence positively influences older adults' intention to use ADTS.

Digital Anxiety and Usage Intention

Digital anxiety, as established in prior sections, serves as a psychological inhibitor that can undermine willingness to engage with ADTS. Fear of making mistakes, concerns over privacy, and low digital confidence create a barrier that suppresses both motivation and perceived ability.

Drawing from TAM and SCT, when anxiety increases, perceived ease of use diminishes, leading to lower adoption intention [3,9]. In real-world contexts, this means older adults who feel overwhelmed or unsupported are more likely to avoid digital tools, even when such tools offer substantial benefits.

Studies in health care technology and fintech show consistent negative correlations between digital anxiety and usage intention [44,45]. Lee et al [9] emphasized that enhancing digital self-efficacy can reduce anxiety and indirectly boost usage intention, but when anxiety remains unaddressed, intention significantly declines. Given this robust evidence, we hypothesize:

H5: Digital anxiety negatively influences older adults' intention to use ADTS.

Digital Literacy

Digital literacy is a multidimensional competency that encompasses not only the ability to use digital tools, but also to evaluate, create, and communicate digital content effectively [46,47]. It includes technical, cognitive, and socioemotional skills, all of which are crucial for navigating digital environments [48,49]. In aging populations, digital literacy has emerged as a key determinant of autonomy, participation, and well-being [50].

Research has shown that the intention to use digital tools often precedes and fosters the development of digital literacy. When older adults are motivated to use digital tools—such as smartphones, e-payment systems, or telehealth platforms—they are more likely to develop the necessary skills and confidence through experiential learning [51,52]. This iterative process suggests that usage intention is not merely an outcome but also a catalyst in digital literacy acquisition.

H6: Usage intention of ADTS positively influences digital literacy.

Beyond direct effects, usage intention also serves as a mediating mechanism through which environmental support influences digital literacy. For instance, when family members provide technical guidance and emotional encouragement, they boost older adults' confidence and motivation. This, in turn, leads to increased digital usage, which fosters skill development and digital empowerment [38,53].

H7: Usage intention of ADTS mediates the relationship between family support and digital literacy.

Similarly, social influence plays a significant role in digital skill development. Older adults who are embedded in digitally engaged social networks are more likely to receive informal training, tips, and positive reinforcement, which enhance both their usage intention and their digital competence [35,41,42]. This cascading effect suggests that social influence indirectly contributes to digital literacy via behavioral intention.

H8: Usage intention of ADTS mediates the relationship between social influence and digital literacy.

Sense of Achievement

Sense of achievement refers to the intrinsic satisfaction and psychological reward individuals experience upon successfully accomplishing a task, overcoming a challenge, or attaining a self-defined goal [54,55]. This construct is closely tied to self-efficacy, motivation, and emotional resilience—factors that are especially relevant when individuals are navigating unfamiliar or cognitively demanding environments.

For older adults adapting to digital life, a sense of achievement plays a pivotal role. Unlike younger users who often grow up immersed in digital environments, older adults frequently approach technology as late adopters. When they successfully use digital tools—such as conducting a video call, managing a mobile payment, or accessing web-based health services—this sense of accomplishment becomes a powerful motivator for further learning and sustained engagement [56]. It also fosters autonomy and contributes to their psychological well-being, aligning with key principles of successful aging.

However, the digital environment presents numerous barriers that can threaten or diminish this feeling of accomplishment. These include perceived complexity, lack of intuitive design, cybersecurity concerns, and insufficient support systems [57]. When older adults encounter repeated failure or confusion, their confidence may erode, reinforcing negative beliefs about their ability to master technology. In this context, a diminished sense of achievement can magnify digital anxiety and lead to avoidance behaviors.

Recent studies suggest that a strong sense of achievement can buffer the negative effects of digital anxiety. Older adults who perceive themselves as capable learners are more likely to persist through technological challenges and less likely to internalize failure as a reflection of their overall competence [9]. In contrast, those who lack this sense of accomplishment are more prone to technostress and self-doubt—factors that reduce usage intention [58].

Given these dynamics, this study positions sense of achievement as a moderator in the relationship between digital anxiety and the intention to use ADTS. Specifically, we propose that achievement-oriented individuals will experience a weaker negative effect of digital anxiety on usage intention, as their

XSL•FO
RenderX

internal sense of progress and mastery helps to offset fear and hesitation.

H9: Sense of achievement moderates the relationship between digital anxiety and usage intention of ADTS, such that the negative effect is weaker at higher levels of achievement.

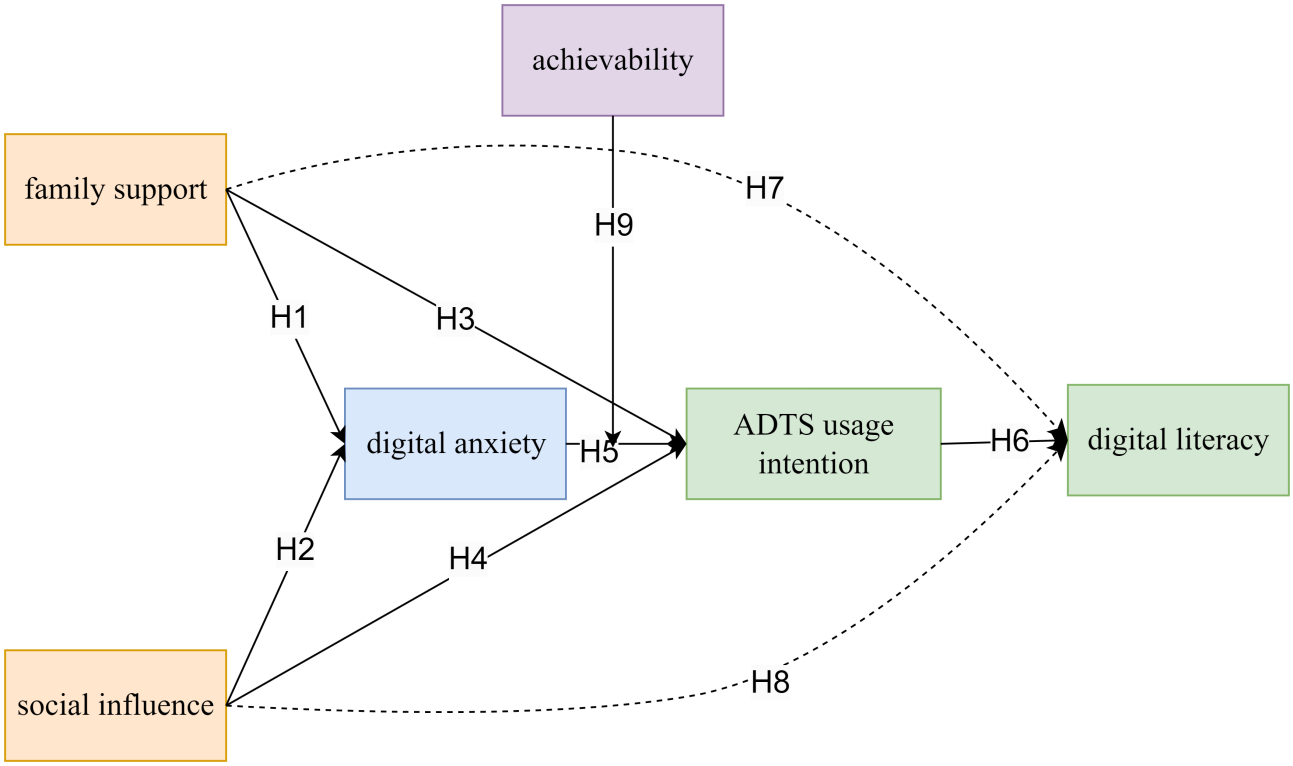
Methods

Participants

This study focuses on older adults in Shenyang, Liaoning Province, China, considering the region's demographic aging trends and digital adaptation status. As one of the major cities in Northeast China, Shenyang has a rapidly aging population, with individuals aged 60 years and older accounting for over 20% of its residents, meeting the United Nations' definition of a "deeply aging society"[96]. With the advancement of digital technologies, the internet behaviors and technological adaptation of older adults have become critical research topics. However, despite Shenyang's well-developed urban infrastructure, older adults in the region still face significant challenges in using ADTS (smartphones and e-services, etc).

Previous research has highlighted the existence of a digital divide among China's aging population, which is particularly pronounced in the northeastern region. Chu (2010) further pointed out that older individuals' digital learning and technology adaptation are influenced by educational background, social support, and technology anxiety, all of which contribute to lower adoption rates of e-services. These factors may limit older adults' ability to access web-based resources, subsequently affecting their digital quality of life [13].

The socioeconomic structure of Shenyang also plays a crucial role in shaping older adults' digital behaviors. As a traditional industrial city, Shenyang has a significant population of retirees from state-owned enterprises, whose social support networks and digital behavior patterns differ from those in coastal cities or rural areas [5]. Research by Chen et al [5] has further demonstrated a correlation between older adults' socioeconomic status, online activity types, and susceptibility to digital fraud, emphasizing the importance of digital literacy in ensuring their safety on the web. Given these factors, this study selects Shenyang as its research site to gain deeper insights into older adults' behavioral patterns and psychological influences in digital environments.



Additionally, this study includes individuals aged 55 years and older rather than limiting the sample to traditional older adult groups. There are 2 key reasons for this decision. First, individuals in this age group are rapidly adopting internet technologies, making them a highly relevant demographic for this study. Second, early retirement is common in China, with many individuals experiencing retirement before the official retirement age. By incorporating participants aged 55 years and older, this study effectively captures the early stages of aging and the transition into digital adaptation [5].

This study used a convenience sampling method, with surveys distributed across community centers, senior activity venues, and elderly care institutions in Shenyang. Individuals aged 55 years and older were invited to voluntarily complete the questionnaire. A total of 541 responses were collected. After excluding 61 incomplete questionnaires, 480 valid responses were retained, resulting in an effective valid completion rate among respondents of 88.7%. All participants were residents of Shenyang, Liaoning Province, China.

Demographic data were collected on participants' gender, age, education level, marital status, family structure, place of residence, and smartphone usage behavior. To ensure accurate comprehension and response quality, the research team provided detailed instructions and on-site assistance during the survey process. The conceptual framework guiding this study is presented in Figure 1.

Figure 1. Research Framework. ADTS: Assistive Digital Tools and Services.

Measures

This study primarily investigates the psychological states and digital behaviors of older adults. A 6-point Likert scale was used, ranging from "strongly disagree" to "strongly agree," to measure key variables, including social influence, family support, digital anxiety, digital literacy, adoption intention of ADTS, and sense of achievement. The measurement instruments were derived from well-established scales in the existing literature:

Family support was adapted from Wang and Wu [28], originally developed in the context of older adults' digital adaptation in urban China. The scale assesses 3 core dimensions of support provided by family members: emotional encouragement, technical assistance, and informational guidance. While Wang and Wu's [28] study focused on digital literacy outcomes, the psychometric properties of the family support scale were independently validated through confirmatory factor analysis (CFA) and internal consistency measures (Cronbach α=0.82). This scale was chosen for its cultural contextual relevance and conceptual alignment with our study focus. In our sample, Cronbach α was 0.802.

Social influence was adapted from Venkatesh et al [11] in the UTAUT. The scale evaluates the extent to which individuals perceive that important others—such as family members, peers, or community figures—believe they should use digital technologies. Each item was rated on a 6-point Likert scale. This construct has been validated in numerous technology acceptance studies across diverse populations, including older adults. In this study, the scale demonstrated good internal consistency (Cronbach α=0.798).

Digital anxiety was also adapted from Venkatesh et al [11]. The items reflect the UTAUT construct of anxiety, which captures individuals' apprehension, fear, or discomfort when interacting with digital technology. Although originally tested in younger user populations, the scale has been applied and adapted in aging research. In this study, internal consistency was acceptable (Cronbach α=0.762), supporting its reliability among older adult users.

Intention to use ADTS was adapted from the UTAUT model (Venkatesh et al [11]), assessing respondents' willingness to engage with digital services such as e-health platforms, digital payments, and digital communication tools. Each item was rated on a 6-point Likert scale. The original scale has been validated in both general and older adult populations. In this study, Cronbach α was .789, indicating acceptable reliability.

Digital literacy was evaluated using the eHealth Literacy Scale developed by Norman and Skinner [59], consisting of 8 items that measure perceived ability to find, understand, evaluate, and apply digital health information. This scale has been widely adopted in aging, health, and digital divide studies and has demonstrated strong psychometric properties across diverse populations. In our study, the scale yielded a Cronbach α of 0.871, indicating high internal consistency.

Sense of achievement was measured using a 3-item subscale from the achievement motivation framework developed by Janke and Lüftenegger [50]. The items reflect individuals' feelings of satisfaction and competence when overcoming digital challenges. The original instrument was validated in academic and motivational contexts and has since been adapted in studies of digital learning among older adults. The internal consistency for this scale in our sample was strong (Cronbach α=0.851).

XSL•FO
RenderX

To ensure the statistical adequacy of structural equation modeling (SEM), this study adhered to the sample size recommendations proposed by Bentler and Chou [60], which suggest that the sample size should be at least 5 times the number of estimated parameters. Additionally, data screening procedures, including missing data analysis and normality tests, were conducted to ensure the suitability of the dataset for subsequent analysis. Ultimately, a total of 480 valid responses were collected, meeting the theoretical requirements for robust statistical analysis.

Reliability (Cronbach α), CFA, and SEM were conducted using SPSS (version 26.0; IBM Corp) and AMOS (version 24.0; IBM Corp). Bootstrapping (n=5000) and PROCESS Macro (Model 1) were used to test mediation and moderation effects, ensuring robust statistical validity.

Ethical Considerations

This study utilized fully anonymized survey data that contained no personally identifiable information. As such, ethical approval and informed consent were not required under institutional and national research ethics regulations. All research procedures adhered to internationally recognized ethical standards, ensuring transparency, data integrity, and the responsible handling of anonymized information.

Results

Sample Profile

Regarding gender distribution, 69% (n=331) of respondents were male, and 31% (n=149) were female. In terms of age, the majority were aged between 60 and 65 years (263/480, 54.8%), followed by those aged 65 to 70 years (167/480, 34.8%), while only 1.0% (n=5) were aged 75 years and older. Residential distribution indicated that 60.4% (n=290) of participants lived in urban areas, whereas 39.6% (n=190) resided in rural regions. In terms of educational attainment, 57.1% (n=274) of respondents had completed middle school or below, 23.5% (n=111) held a university degree, and 1.5% (n=7) had attained a postgraduate degree or higher. Regarding marital status, 87.5% (n=420) of respondents were married, 4.8% (n=23) were unmarried, 2.9% (n=14) were divorced, and 4.8% (n=23) were widowed. As for family structure, 74.8% (n=359) lived with their spouse, 12.5% (n=56) lived with their children, and 12.7% (n=61) lived alone.

Regarding the usage of ADTS, 85.0% (n=408) of respondents primarily used smartphones for voice calls, followed by text messaging (381/480, 79.4%) and video calls (357/480, 74.4%). In contrast, mobile shopping (261/480, 54.3%) and digital payments (271/480, 56.5%) were less frequently used. Notably, only 53.4% (n=256) of participants used their smartphones for digital information retrieval, suggesting that a considerable portion of older adults remains unfamiliar with internet-based search functions.

Reliability Analysis

To assess the internal consistency of the measurement scales, this study calculated Cronbach α for each variable. The results, presented in Table 1, indicate that all Cronbach α values exceeded the recommended threshold of 0.7, demonstrating good reliability across the constructs.

Table . The results of reliability analysis (N=480). All constructs were measured on a 6-point Likert scale (1=strongly disagree, 6=strongly agree).

Variable	Values, mean (SD)	Values, Cronbach α
Social influence	2.850 (1.023)	0.798
Family support	4.960 (0.803)	0.802
Digital anxiety	4.980 (0.784)	0.762
ADTS[a] usage intention	5.030 (0.844)	0.789
Digital literacy	4.510 (0.919)	0.871
Achievability	5.380 (0.817)	0.851

[a]ADTS: Assistive Digital Tools and Services.

Among the variables, Digital Literacy exhibited the highest internal consistency, with a Cronbach α of 0.871, suggesting strong reliability. Meanwhile, Digital Anxiety had a Cronbach α of 0.762, which remains within an acceptable range, indicating sufficient internal consistency for further analysis.

Confirmatory Factor Analysis

To ensure convergent validity and discriminant validity of the measurement model, this study conducted CFA. Following the recommendations of Hair et al [61], composite reliability should exceed 0.7, and average variance extracted should be above 0.5 to confirm the internal consistency and validity of the measurement instruments.

As shown in Table 2, all constructs in this study met these criteria, with composite reliability values exceeding 0.7 and average variance extracted values above 0.5, indicating strong convergent validity. Additionally, all standardized factor loadings were statistically significant (>0.60), demonstrating that the observed variables effectively captured their respective latent constructs.

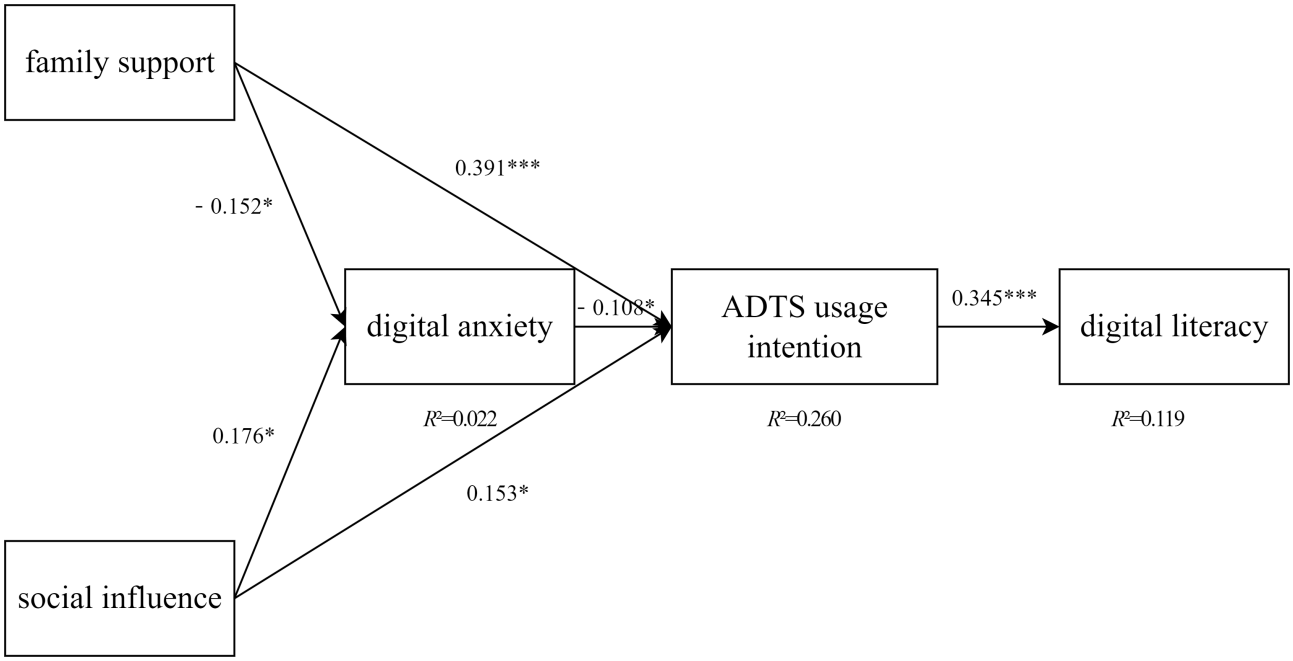
Overall, the results confirm that the measurement tools used in this study exhibit high reliability and validity, ensuring their suitability for further SEM analysis.



Structural Equation Modeling (SEM) Analysis

Model Fit Assessment

This study used SEM to validate the proposed research framework, as illustrated in Figure 2. Prior to conducting SEM analysis, we assessed the model fit indices to ensure the suitability of the model.

XSL•FO
RenderX

Figure 2. The model of structural equation modeling. ADTS: Assistive Digital Tools and Services. *P<.001, **P<.01, ***P<.05.

By examining the Modification Index, we identified and removed items with large residual discrepancies, including 2 items from the Family Support scale and items 1 and 3 from the Digital Literacy scale. After these modifications, the revised model exhibited improved goodness-of-fit indices, confirming its appropriateness for further SEM analysis (Table 3).

Structural Equation Modeling (SEM) Analysis

The SEM analysis in this study was conducted in 2 stages. First, we examined the overall model fit indices to ensure the model's suitability. Second, we tested the path coefficients to validate the research hypotheses.

By performing path analysis on the latent variables, we assessed the relationships among key constructs. The results are presented in Table 4 and Figure 2.

Table . The results of structural equation modeling path analysis.

Hypothesis	Independent variable	Dependent variable	β	SE	Composite reliability	*P* value
H1	F[a]	A[b]	−.152	0.080	–2.087	<.037
H2	SI[c]	A	.176	0.081	2.362	<.018

XSL•FO
RenderX

Mediating Effect

This study used the PROCESS macro in SPSS (version 26.0; IBM Corp) with the bootstrap method to examine mediating effects. The analysis tested whether usage intention of ADTS mediated the relationships between (1) family support and digital literacy, and (2) social influence and digital literacy.

For the family support → digital literacy pathway (Table 5), the indirect effect was 0.071, with a 95% CI of (0.095-0.262), indicating statistical significance as the interval did not include zero. In contrast, the direct effect was 0.397, with a 95% CI of (–0.130 to 0.082), which was nonsignificant. This pattern reflects full mediation, meaning that family support influences digital literacy entirely through its impact on usage intention.

Table . Mediating effect analysis (family support and digital literacy).

F→ADTS→D[a,b,c]	Effect	Bootstrapping (BC[d] 95% CI)
Indirect effect	0.071	0.095 to 0.262
Direct effect	0.397	–0.130 to 0.082
Total effect	0.468	0.003 to 0.052

[a]F: family support.

[b]ADTS: Assistive Digital Tools and Services.

[c]D: digital literacy.

[d]BC: bias-corrected percentile method.

For the social influence → digital literacy pathway (Table 6), the indirect effect was also significant (95% CI excluding zero), whereas the direct effect was −0.418 with a 95% CI of (−0.141 to 0.186), which was nonsignificant. This likewise indicates full mediation, suggesting that social influence affects digital literacy only indirectly via usage intention.

Table . Mediating effect analysis (social influence and digital literacy).

SI→ADTS→D[a,b,c]	Effect	Bootstrapping (BC[d] 95% CI)
Indirect effect	0.128	0.069 to 0.194
Direct effect	–0.418	–0.141 to 0.186
Total effect	0.086	0.014 to 0.186

[a]SI: social influence.

[b]ADTS: Assistive Digital Tools and Services.

[c]D: digital literacy.

[d]BC: bias-corrected percentile method.

Overall, these findings demonstrate that both family support and social influence enhance older adults' digital literacy not by directly improving their skills, but by strengthening their intention to use ADTS—thereby facilitating subsequent skill acquisition and competence development.

Moderation Effect

The moderating effect of sense of achievement on the relationship between digital anxiety and ADTS usage intention was examined using PROCESS Model 1 with 5000 bootstrap samples. The overall model was significant (R^2=0.389, $F_{1, 476}$=101.222, P=.003), and the interaction term (Digital Anxiety×Sense of Achievement) was also significant, indicating the presence of a moderation effect.

Simple-slopes analysis revealed that the negative association between digital anxiety and ADTS usage intention was weaker at higher levels of sense of achievement and stronger at lower levels. This suggests that a greater sense of achievement can buffer the detrimental impact of digital anxiety on the intention to use ADTS. Figures 3 and 4 depict the slope differences across varying levels of sense of achievement, providing visual confirmation of the moderation effect.

In line with Self-Determination Theory, these results indicate that perceived competence and mastery help sustain motivation when engaging in tasks that may provoke anxiety. Accordingly, H9 is supported: sense of achievement attenuates the negative effect of digital anxiety on ADTS usage intention.

Discussion

Summary of Key Findings

In an era marked by rapid digital transformation and global population aging, older adults' ability to adapt to digital technologies has become a critical determinant of quality of life, autonomy, and the trajectory of successful aging [2,3]. Grounded in the UTAUT and the Digital Literacy Framework, this cross-sectional study tested an integrated model that incorporated environmental, psychological, and behavioral factors. Specifically, it examined how family support, social influence, digital anxiety, and sense of achievement are associated with older adults' intention to use ADTS, and how these factors, in turn, relate to the development of digital literacy. The findings provide new insights into how digital engagement can be transformed into real-life competence and social connection.

XSL•FO
RenderX

Family Support and Social Influence Operate Through Intention

Both factors were positively associated with ADTS usage intention (β=.413 and β=.160, respectively, *P*<.05). Mediation analysis showed that their effects on digital literacy were fully mediated by usage intention, with nonsignificant direct paths after accounting for the mediator.

Family Support Was Associated With Lower Digital Anxiety

Family support was negatively associated with digital anxiety (β=−0.168, *P*<.05), which in turn was negatively associated with usage intention (β=−.103, *P*<.05). This suggests that family support may help older adults overcome apprehension toward technology, indirectly promoting adoption.

Sense of Achievement Attenuates the Association of the Negative Effect of Digital Anxiety

The interaction term (Digital Anxiety × Sense of Achievement) was significant, indicating that a higher sense of achievement attenuates the negative relationship between digital anxiety and usage intention.

Usage Intention Is a Central Behavioral Pathway

Across environmental and psychological predictors, usage intention emerged as the pivotal link to higher digital literacy scores (β=.345, *P*<.001).

Theoretical Implications

This study advances the literature by showing how psychosocial factors operate within an integrative, later-life adaptation of UTAUT. Specifically, it contributes three distinctive insights—each grounded in the SEM results:

1. Extending UTAUT with age-specific psychosocial mechanisms: Beyond utilitarian appraisals, digital anxiety exerts a negative effect on intention (β=−0.103, *P*<.05), while sense of achievement attenuates this link (significant interaction), indicating that affective constraints and motivational buffers are integral to older adults' adoption processes.
2. Unpacking the pathway from environmental enablers to competence: The effects of family support (β=.413) and social influence (β=.160) on digital literacy are fully mediated by usage intention (indirect effects with 95% CIs excluding zero), positioning intention as a necessary conduit from context to competence.
3. Reframing successful aging for the digital era: Digital literacy functions as aging capital—a capability accumulated through intentional engagement and shaped by psychosocial conditions—thereby warranting its incorporation into the theoretical core of successful aging in technology-mediated societies.

Practical / Managerial Implications

The findings translate into the following action priorities for policymakers, community organizations, and technology designers:

1. Leverage family and peer networks as complementary pillars: Given the stronger association of family support with intention (β=.413) relative to social influence (β=.160), intergenerational pairings can serve as high-impact entry points. To avoid over-dependence, pair these with peer-led workshops, senior tech clubs, and neighborhood "digital ambassadors" for continuity.
2. Design for progressive achievement to counter anxiety: Because achievement buffers the anxiety-intention link, use milestone-based modules, micro-goals (eg, a first mobile payment), and instant positive feedback to convert apprehension into mastery and sustained engagement.
3. Prioritize sustained, habitual use over one-off adoption: With literacy gains operating through intention, build reinforcement sessions, periodic "digital check-ins," and adaptive nudges (reminders, personalized suggestions, calibrated difficulty) to routinize use and consolidate skills. These recommendations move beyond generic calls for support, advancing age-sensitive, culturally grounded strategies that directly target the psychosocial dynamics revealed by our model.

Future Research and Practice Directions

Limitations and Future Directions

The cross-sectional design precludes causal inference; results reflect associations within one metropolitan sample, limiting generalizability. Demographic covariates (eg, age, education, marital status) were collected but excluded from the structural model to preserve parsimony; future work can incorporate them to refine estimates.

Modeling Choices

We intentionally excluded performance expectancy and effort expectancy to foreground later-life psychosocial mechanisms and avoid redundancy with well-established findings; future studies should reincorporate these UTAUT constructs to test robustness and generalizability. We also modeled digital literacy as an outcome to trace competence formation; longitudinal or cross-lagged designs should examine possible bidirectional effects whereby literacy reduces anxiety, enhances self-efficacy, and strengthens intention.

Next Steps

We recommend longitudinal/experimental designs, cross-cultural comparisons, and the inclusion of digital trust/privacy and emerging AI/IoT tools to evaluate scalable, age-friendly pathways to digital inclusion.

Conflicts of Interest

None declared.

Abstract

Background: The increasing use of smartphones among older adults offers new opportunities for social connection but may also pose risks associated with adverse mental health outcomes, including depression.

Objective: This study examined the relationship between smartphone use and depression among older adults in Guangzhou, China, to identify key predictors and complex configurations associated with depression.

Methods: Using a hybrid analytic approach applied to survey data from 2585 older adults in Guangzhou, machine learning methods first identified the strongest predictors of depression. Subsequent fuzzy-set qualitative comparative analysis delineated distinct configurations associated with depression.

Results: The analysis identified high levels of smartphone addiction and a low preference for interactive use as central configurations associated with depression. These patterns appeared to operate through 2 distinct mechanisms: structural exclusion related to resource limitations and agentic maladaptation associated with relational deficiencies. This underlying vulnerability, in combination with specific sociodemographic factors, delineated distinct depression-related typologies. High-risk profiles included unmarried men with limited educational attainment and socially withdrawn individuals with greater socioeconomic resources.

Conclusions: Problematic smartphone use, particularly when it displaces social interaction, is significantly associated with depression among older adults. Interventions should therefore promote healthier interactive digital behaviors and provide targeted support for high-risk groups.

KEYWORDS

depression; fuzzy-set qualitative comparative analysis; machine learning; smartphone addiction; smartphone use preference

Introduction

The rapid development of digital technologies, coupled with an aging population, has resulted in increasing smartphone use among older adults. The proportion of individuals aged 60 years and older in China increased from 14.9% in 2013 to 21.1% in 2023, reflecting the country's transition toward a moderately aging society [1]. According to the 56th Statistical Report on China's Internet Development, released in July 2025, the internet penetration rate among older adults in China reached 52%, with 161 million internet users aged 60 years and older [2]. These trends reflect the growing digital engagement of older adults in contemporary society.

The expanding prevalence of smartphone use has generated increasing scholarly interest in its implications for the mental health of older adults. Studies suggest that smartphones fulfill daily needs for communication, entertainment, and information [3]. However, problematic smartphone use has been associated with reduced social connectedness, intergenerational tension, and sleep disturbances [4], all of which may contribute to psychological distress. Thus, smartphone use presents both potential benefits and risks for older adults: moderate and purposeful engagement may support well-being, whereas excessive or maladaptive use may exacerbate mental health risks.

Despite a growing body of research, many studies on late-life depression tend to examine physiological, psychological, or social predictors in isolation, often underemphasizing the complex interaction among these dimensions and their combined effects. The limitation of single-factor studies constrains

XSL•FO
RenderX

understanding of how digital behaviors, social contexts, and individual vulnerabilities interact to produce divergent outcomes. The influence of smartphone use intensity and preference does not occur in isolation but is embedded within broader life circumstances. To address this theoretical and methodological gap, this study developed a configurational model to identify the most salient predictors and examine how these factors combined to form patterns associated with depressive outcomes. The findings provide empirically grounded insights to inform strategies aimed at promoting mental well-being and digital literacy among older adults.

Depression in Later Life

Late-life depression is a multifactorial condition influenced by physiological, psychological, and social factors. Physiological contributors include chronic illness and functional decline [5,6]. Psychological factors such as negative thinking and loneliness are also associated with increased risk [7,8]. Social support systems and community engagement play important roles. Social participation theory suggests that engagement in activities such as volunteering and recreational activities protects mental health by reducing loneliness and building supportive networks [9,10].

Smartphone Use and Depression Among Older Adults

In this study, smartphone addiction is defined as a behavioral addiction characterized by compulsive and excessive use that disrupts daily functioning and is associated with adverse psychological outcomes [11,12]. Smartphone addiction has been positively associated with depression, particularly with prolonged use [13]. Excessive reliance may create a cycle in which loneliness drives escapist use, further deepening social isolation [14].

Patterns of smartphone use are associated with mental health outcomes. Purposeful and socially oriented use—categorized as interactive functions (eg, social networking and online task engagement)—may enhance social connectedness [15]. In contrast, entertainment-driven use—categorized as self-entertainment functions (eg, playing games, scrolling social media, watching videos)—is linked to higher levels of depression and anxiety, often mediated by escapism [16,17]. Although much of the evidence derives from studies of younger populations [18-20], older adults may be particularly vulnerable due to cognitive decline, which may increase the likelihood of passive use reinforcing isolation and depressive symptoms.

Conceptual Framework

The conceptual framework of this study integrates socioemotional selectivity theory (SST) and the digital inequality theory (DIT). Socioemotional selectivity theory posits that older adults prioritize emotionally meaningful relationships, thus smartphone use may be beneficial only when it supports these goals rather than displaces them [21]. Digital inequality theory emphasizes that structural disadvantages limit digital literacy and access, potentially transforming technology into a source of exclusion rather than connection [22]. Together, these perspectives inform the hypotheses in this study regarding the conditions under which depression may arise among older adults. Accordingly, this study tested the hypothesis that depression among digitally active older adults is associated with maladaptive patterns of smartphone use. It further examined whether socioeconomic barriers limit beneficial engagement, contributing to exclusion and depressive symptoms, consistent with DIT, and whether individuals with greater socioeconomic resources substitute smartphone use for meaningful social participation, potentially resulting in emotional dissatisfaction despite material security, consistent with SST.

This study tested 3 hypotheses. First, high smartphone addiction was hypothesized to represent a necessary condition for high levels of depression. Second, high smartphone addiction in combination with low educational attainment and low preference for interactive use was hypothesized to constitute a sufficient configuration for depression. Third, high smartphone addiction combined with low social participation was hypothesized to form a sufficient configuration for depression, particularly among individuals with greater socioeconomic resources.

Methods

Data

Data were collected using a combined convenience and quota sampling strategy through a study-specific survey titled Smartphone Use and Mental Health Among Older Adults, administered between October and November 2024. To ensure data quality, structured, on-site assisted data collection was implemented across 87 social workstations in 5 districts of Guangzhou. Each workstation recruited 30 community-dwelling older adults. Social workers organized in-person sessions at community centers, guided participants through the questionnaires, clarified items, assisted with smartphone use, and reviewed responses for completeness. This assisted approach helped address technical and cognitive barriers, resulting in a high valid response rate and a consistent sample size.

Measures

Depression was measured using the 15-item Geriatric Depression Scale, adapted by Tang [23] for Chinese older adults. Items were answered in binary form (yes=1, no=0), yielding total scores ranging from 0 to 15. Following Tang's guidelines, scores were categorized as 0 to 4 (no depression), 5 to 9 (mild depression), and 10 points or more (clinical depression). Internal consistency was good (Cronbach α=0.790). Smartphone addiction was assessed using the 17-item Mobile Phone Addiction Index [24]. Items were rated on a 5-point Likert scale, with higher scores reflecting greater severity. In this study, the scale scores were summed and standardized. Reliability in this sample was excellent (Cronbach α=0.968).

Smartphone use preferences were assessed with 2 multiple-choice items: 1 captured the general smartphone functions used and another identified the 3 smartphone functions most frequently used. Exploratory factor analysis of 12 functions yielded three factors: (1) self-entertainment function use (eg, streaming and music; explained variance=3.627), (2) interactive function use (eg, WeChat, short videos; explained variance=1.264), and (3) basic telecommunication (eg, calls, texts; explained variance=1.122). Short video platforms, such as TikTok and Xiaohongshu, play an increasingly prominent role in fostering social connectivity and interaction. These

XSL•FO
RenderX

platforms enable users to share videos with family members and engage in interactive livestreams within local community contexts [25,26]. Self-entertainment use and interactive use were the 2 functions retained for analysis. The use of self-entertainment or interactive functions was operationalized as the occurrence of engagement with self-entertainment or interactive features, with higher counts indicating stronger preferences.

Social participation was measured using the 22-item scale developed by Ren et al [27]. Responses were recorded on a 5-point Likert scale, with higher scores indicating greater participation. In this study, scores were summed and standardized. Internal consistency was high (Cronbach α=0.946). Covariates included gender, age, education, employment, self-rated health, income, marital status, and average daily smartphone use. Multicollinearity diagnostics indicated no concerns (all variance inflation factors <2).

Methodological Approach

We used a multimethod strategy that combined machine learning and fuzzy-set qualitative comparative analysis (fsQCA). The integration of machine learning and fsQCA followed a predictive-explanatory sequence. Machine learning was used to handle high-dimensional feature selection and objectively identify factors most relevant for prediction, whereas fsQCA was used to uncover how these factors combine to produce depressive outcomes. This sequential design leveraged the strengths of both methods: machine learning identified the most influential predictors of depression, and fsQCA revealed complex configurations underlying depressive outcomes. Together, these provided a more nuanced understanding of complex relationships.

First, 4 machine learning algorithms—logistic regression, support vector machine, random forest (RF), and extreme gradient boosting—were applied using the web-based Python Jupyter Notebook development environment to identify salient predictors of depression. To prevent overfitting, 10-fold cross-validation was used, and performance metrics were reported as the mean across folds to provide stable and generalizable estimates. To enhance interpretability, the Shapley additive explanations algorithm was used, quantifying each variable's contribution to model predictions.

Following predictive modeling, fsQCA was conducted to test hypotheses on the necessary and sufficient conditions for depression. Fuzzy-set qualitative comparative analysis is a set-theoretic method that evaluates causal complexity by identifying configurations of factors, rather than the net effects of individual variables [28]. Based on fuzzy-set theory, it assesses necessary conditions, sufficient pathways, and conjunctural causation, allowing for equifinality (ie, multiple combinations of conditions leading to the same outcome). This approach is well-suited for exploring how structural vulnerabilities, smartphone use patterns, and social participation jointly shape mental health in later life.

Ethical Considerations

This study was conducted in accordance with the Declaration of Helsinki and approved by the Research Review Committee of the School of Public Administration, Guangdong University of Foreign Studies (2024003). Informed consent was obtained prior to survey administration. Participants were informed that participation was voluntary and anonymous, that they could withdraw at any time, and that measures were in place to ensure data confidentiality, such as deidentification, secure server storage, and restricted access to data.

Results

Of 2610 questionnaires distributed, 2585 were completed and deemed valid, yielding a 99% response rate. Demographic characteristics are presented in Table 1.

Predictive Analysis Using Machine Learning Models

A comparative analysis was conducted using logistic regression, support vector machine, RF, and extreme gradient boosting models to predict depression based on smartphone use variables, social participation, and sociodemographic covariates. The dataset was partitioned into a training set comprising 80% of the data and a test set comprising the remaining 20%. During feature engineering, the outcome variable was binarized and the predictor variables were standardized. This process transformed all features to a common scale; this ensured their influence was balanced and prevented certain features from having an excessive impact on the model due to differences in magnitude. To reduce the risk of model overfitting, bootstrapping was applied within the machine learning framework to generate training sets for each tree, resulting in 1740 additional resampled observations, which were used exclusively for model training; all subsequent analyses were conducted using the original dataset.

To address observed imbalances in the outcome variable (depression categories) within the training data, the synthetic minority over-sampling technique was applied to the training set only and not to the test set used for final area under the curve computation. After applying the synthetic minority over-sampling technique, the distribution of depression levels was fully balanced, providing a more equitable foundation for model training. Grid search with 10-fold cross-validation was used for hyperparameter tuning and model optimization. Among the 4 machine learning analyses conducted, the RF model demonstrated superior performance on the test set as shown in Table 2; therefore, RF was selected for feature importance analysis.

Table . Performance of machine learning models on the test set.

Model	Accuracy	Precision	Recall	F_1-score	AUC[a]
RF[b]	0.8483	0.8258	0.8258	0.8258	0.9261
XGBoost[c]	0.8186	0.7895	0.7955	0.7925	0.8742
SVM[d]	0.7585	0.7140	0.7424	0.7280	0.8103
LR[e]	0.6735	0.6130	0.6780	0.6439	0.7293

[a]AUC: area under the curve.

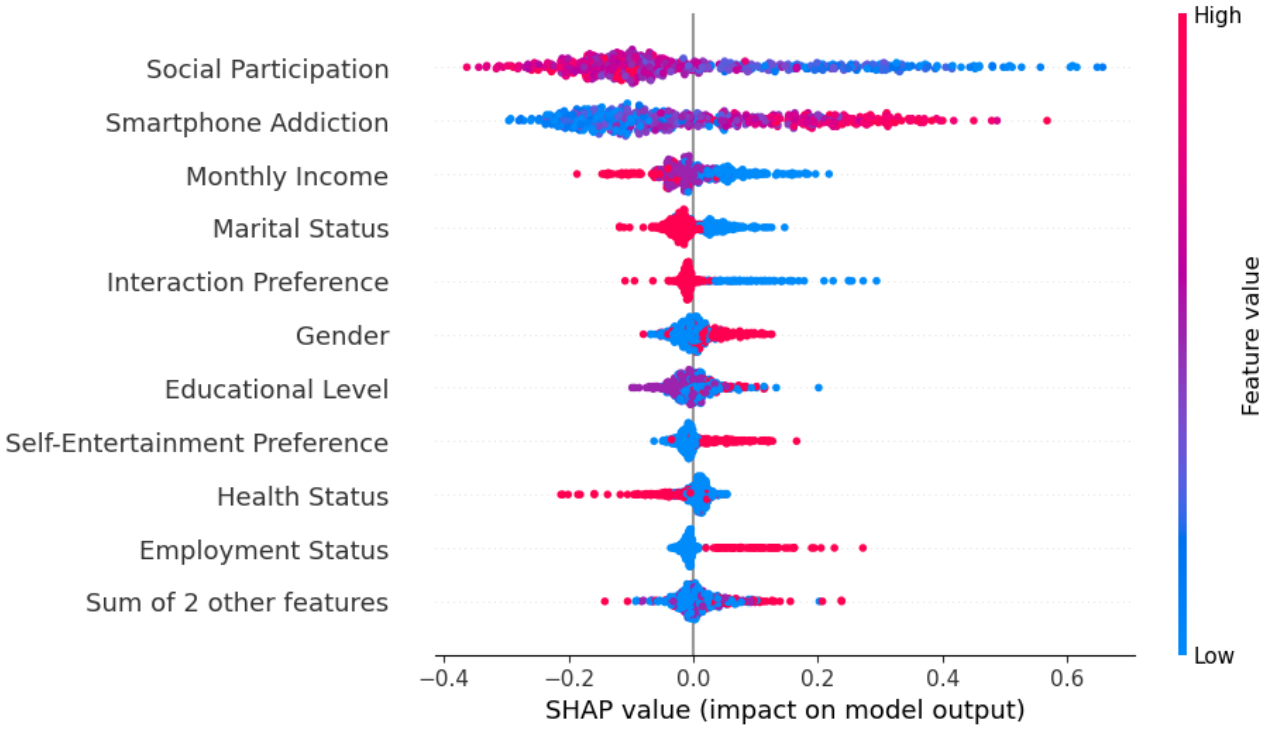
[c]XGBoost: extreme gradient boosting.

[d]SVM: support vector machine.

[e]LR: logistic regression.

Ranking the Importance of Features Across Different Variables



As shown in Table 3, the most influential predictors of depression, in descending order of importance, were social participation, smartphone addiction, monthly income, marital status, interaction preference (ie, the use of interactive functions), education level, gender, health status, self-entertainment preference (ie, the use of self-entertainment functions), and age, with social participation and smartphone addiction being the most salient factors. Figure 1 presents the Shapley additive explanations algorithm values, indicating that social participation had the strongest negative association with depression, whereas higher levels of participation were associated with a significantly lower probability of depression. Smartphone addiction was positively associated with depression. Higher income and being married were associated with a lower risk of depression, and use of interactive functions preference was also associated with reduced risk. Educational attainment showed a relatively modest association with a risk of depression. Female sex, poorer health status, a stronger preference for self-entertainment functions, and older age were each associated with a slight increase in depression risk. Because fsQCA typically examines 4 to 8 antecedent conditions, the top 7 predictors—social participation, smartphone addiction, monthly income, marital status, use of interactive functions, education, and gender—were selected as key conditions for configurational analysis of late-life depression.

FsQCA Analysis

This study used fsQCA 4.0 software to convert antecedent and outcome variables into fuzzy-set membership scores using the direct calibration method. Following the literature in FsQCA analysis, the 95th, 50th, and 5th percentiles were set as the 3 anchor points for full membership, the crossover point, and full nonmembership, respectively [29,30]. To address the issue that cases with a fuzzy membership score of exactly 0.5 cannot be included in the analysis, the method proposed by Fiss [31] was followed, replacing the 0.5 value with 0.501. Table 4 presents the results of the variable calibration.

XSL•FO
RenderX

Table . Calibration analysis.

Variables	Anchor points[a]		
	Full nonmembership	Crossover point	Full membership
Condition variables			
Social participation	–1.722	0.662	1.790
Smartphone addiction	–1.224	0.018	1.624
Monthly income	0	1	2
Marital status	0	1	1
Preference for interactive functions	0	1	1
Education level	0	1	2
Gender	0	0	1
Outcome variable			
Depression	0	0	2

[a]Anchor points were calibrated using the 5th percentile (full nonmembership), 50th percentile (crossover), and 95th percentile (full membership).

To test the first hypothesis, which posited that high smartphone addiction is a necessary condition for high depression, a necessity analysis was conducted. As shown in Table 5, the consistency score for smartphone addiction was 0.991, exceeding the commonly used threshold of 0.9. This suggests that nearly all cases of high depression also exhibited high smartphone addiction. Therefore, the first hypothesis is strongly supported. The consistency scores for the remaining variables were all below 0.9, indicating that none met the threshold for depression in individual cases. The combined effects of multiple variables warrant further examination using a configurational approach.

Table . Fuzzy-set qualitative comparative analysis necessity analysis.

The analysis identified 3 distinct configurations (Table 6), which collectively achieved a high overall fsQCA configurational (sufficiency) solution of 0.956. The first configuration, termed the digitally disconnected and vulnerable profile, is characterized by high smartphone addiction, low interaction preference, lower educational attainment, and male gender. The raw coverage was 0.499, indicating that approximately 49.9% of cases of depression were represented by this configuration. This finding supports the hypothesized risk pattern in contexts where structural constraints may amplify behavioral vulnerabilities. The second and third configurations highlight more complex, paradox-driven mechanisms. The socially withdrawn profile with greater socioeconomic resources was characterized by high smartphone addiction, low social participation, and no use of interaction functions, despite high educational attainment and high income. This configuration demonstrated a raw coverage of 0.560. This supports the hypothesis that greater socioeconomic resources may not necessarily protect against depression when digital use is maladaptive, suggesting a potential paradox among socioeconomically advantaged older adults. The third configuration, the emotionally isolated and digitally dependent profile, was specifically characterized by unmarried men with high smartphone addiction and low interaction preference, even when overall social participation appeared adequate. The raw coverage was 0.462. Collectively, these 3 configurations illustrated how smartphone addiction, in combination with specific socioeconomic and marital contexts, was associated with late-life depression.

The analysis revealed an additional sufficient configuration that was not prespecified in the hypotheses. This emergent configuration, termed the emotionally isolated and digitally dependent profile, demonstrated a consistency of 0.910 and unique coverage of 0.011. It was characterized by unmarried older men who, despite relatively high social participation, exhibited high smartphone addiction and no use of interaction functions. The identification of this configuration is an important finding. Whereas the initial second and third hypotheses focused on vulnerabilities associated with limited socioeconomic resources or low social participation, this configuration suggested a distinct pattern associated with relational and gender-related vulnerabilities. The theoretical implications of this unanticipated finding are discussed further in the Discussion section. The robustness of the solution was assessed by (1) raising the consistency threshold from 0.80 to 0.85, (2) tightening the proportional reduction in inconsistency cutoff, and (3) modifying the case frequency threshold. The core configurations for depression remained substantively unchanged, confirming the stability of the solution.

Discussion

Configurational Patterns of Late-Life Depression in the Digital Context

This study confirmed smartphone addiction as a foundational vulnerability and necessary condition for late-life depression. However, this individual-level risk factor appeared to operate through specific configurational pathways rather than in isolation. Thus, this study synthesized the findings into a dual-mechanism integrated framework of depression caused by digital technology to clarify heterogeneity in etiological patterns across different groups.

The first mechanism, structural exclusion and deficit, reflects a resource-deficit pattern of depression primarily observed among older men with low educational attainment. This pattern may be shaped by digital inequality and gender-related social norms [32]. Limited educational attainment may constrain digital literacy, contributing to a greater reliance on smartphone use to engage in passive entertainment rather than socially connective functions. In contrast to women, who often maintain broader kin-keeping networks, older men may rely more heavily on spouse-centered networks. Following widowhood or social isolation, no use of interaction functions and lower digital literacy may hinder the formation of online connections, while fewer kin-keeping practices may reduce social buffers against loneliness. These intersecting factors are associated with an elevated risk of depression in this subgroup [33,34]. In this context, smartphones may not function as bridges to social integration and instead may reinforce existing structural marginalization.

The second mechanism, agentic maladaptation and relational void, reflects a maladaptation-based pattern of depression observed among individuals with greater socioeconomic resources and unmarried men. For socioeconomically advantaged individuals, material resources such as income and education may not provide effective psychological protection in the absence of socially meaningful connections. Consistent with SST, passive digital consumption without interpersonal interaction cannot substitute for emotionally meaningful engagement, potentially leading to material abundance coexisting with emotional deprivation [35]. Among unmarried men, the absence of a primary attachment figure may create a unique emotional void. Even when overall social participation seems adequate, reliance on noninteractive smartphone use may represent an attempt to use technology for unmet emotional needs. In this configuration, depression was associated not with limited capability or access but with patterns of digital engagement that may reflect efforts to cope with offline relational deficits through compulsive digital escapism [36].

Theoretical and Practical Implications

This study contributes to DIT in two ways. First, it refines DIT by identifying gendered patterns among men with lower educational attainment. Second, it extends SST by specifying contextual conditions under which unmet social connection needs are associated with depression, even among groups with greater socioeconomic resources, highlighting the importance of meaningful engagement for well-being.

From a practical perspective, these findings suggest that interventions should be targeted and configuration-specific rather than uniform. For digitally disconnected older men at elevated risk, intervention strategies may extend beyond basic technical support to strengthen digital family connections. Community-based workshops (eg, grandparent-grandchild connection programs) can teach functional skills such as video calling and photo sharing, transforming passive screen time into active intergenerational engagement. Peer-led interest groups may also promote social engagement.

For socioeconomically advantaged but socially isolated older adults, greater resources may not prevent depression associated with a diminished sense of purpose. Meaning-oriented engagement, such as recruiting older adults as online mentors, may shift their role from passive consumer to active contributor. Among unmarried older men, the combination of unmarried status and high screen time may warrant proactive screening. Programs such as digital workshops for older men could create low-pressure online spaces that foster weak-tie networks, reduce loneliness, and decrease emotional dependency on smartphones. Finally, given that smartphone addiction was identified as a necessary condition across depressive profiles, technology developers should consider incorporating age-sensitive design principles and responsible algorithm practices to support digital well-being.

These findings should be considered alongside several limitations. First, the cross-sectional design and nonprobability sampling from Guangzhou limit causal inference and generalizability. Longitudinal studies are needed to clarify causality and reduce potential measurement overlap between smartphone addiction and depression. Second, the measure of social participation did not distinguish between online and offline engagement, which may obscure their distinct associations with mental health. Future research should use instruments that differentiate these modalities. Third, smartphone addiction in older adults may require more nuanced assessment. Behaviors resembling addiction may reflect limited digital literacy rather than true dependency. Mixed-methods studies could help distinguish between compulsive use and unskilled engagement. Fourth, the high internal consistency (Cronbach α=0.968) of the Mobile Phone Addiction Index in this sample suggests it may be perceived as a unidimensional construct by older adults; further validation of its factor structure in this population is warranted. Finally, this study did not account for medication use, a potential confounder. Future research should incorporate medication-related variables to better isolate the association between digital engagement and depressive symptoms.

Conclusion

This study suggests that late-life depression and the increasing use of smartphones is not a uniform condition but reflects complex interactions. Smartphone addiction was consistently associated with an increased risk of depression and appeared to operate through 2 distinct mechanisms: structural exclusion and maladaptive engagement. The former was characterized by

XSL•FO
RenderX

resource deficits among vulnerable men, whereas the latter was associated with relational isolation among individuals with greater socioeconomic resources or limited social integration. These results support the use of a configurational approach rather than single-factor explanations to promote healthy aging in an increasingly digital society.

Abstract

Background: While older adults' social media use has been widely studied for its instrumental benefits, such as accessing health information or maintaining family ties, research has largely focused on identity-based platforms that mirror offline social networks, leaving pseudonymous, interest-driven environments such as Reddit underexplored. Although older adults actively participate in these spaces to share personal narratives and engage beyond their existing social roles, the literature has yet to center their own voices, with most existing work focusing on caregivers or younger users discussing older adults rather than older adults speaking for themselves.

Objective: Integrating a life course perspective with the concept of subjective age cohort, this study examines how Reddit users who explicitly self-identify as being in their 50s, 60s, or 70s engage in self-expression and personal experience sharing within pseudonymous online spaces.

Methods: Using data collected via the Reddit application programming interface, this study analyzed posts and comments from 848 self-identified older Reddit users, including 488 future older adults in their 50s (57.5%) and 360 current older adults in their 60s and 70s (42.5%) identified through age-based flairs in the subreddit *r/AskOldPeople*. A fine-tuned large language model (BLOOM-560m; F_1-score=0.96) classified 4,055,275 sentences into three personal experience domains: (1) health and wellness, (2) personal relationships and identity, and (3) professional and financial life. Chi-square analysis compared domain distributions across age groups. BERTopic topic modeling identified thematic patterns within each domain.

Results: Of 569,107 personal experience sentences identified, personal relationships and identity comprised the largest share (n=268,212, 47.1%), followed by professional and financial (n=186,768, 32.8%) and health and wellness (n=114,127, 20.1%). Chi-square analysis revealed significant between-group differences (χ^2_2=34.7; P<.001): current older adults shared proportionally more about health and wellness, whereas future older adults shared more about relationships and identity. Topic modeling further revealed qualitatively distinct emphases within each domain. Future older adults' posts frequently discussed menopause, depression, and friendships, while current older adults more frequently addressed chronic illness, aging, and financial security. Both groups used pseudonymity to disclose sensitive or stigmatized topics.

Conclusions: This study demonstrates that older adults' personal experience sharing on pseudonymous platforms is shaped by the simultaneous interplay of life course stage, age cohort background, and platform affordances, rather than by any single factor. Pseudonymous environments such as Reddit enable disclosures of health vulnerabilities, contested social identities, and emotional experiences that are structurally discouraged on identity-based networks, and this has direct implications for how digital inclusion is conceptualized and practiced. Beyond operational literacy, supporting older adults' expressive inclusion in interest-based, pseudonymous online communities represents a meaningful yet underaddressed dimension of digital participation policy.

Introduction

Background and Research Gap

Older adults' use of social media is often examined through the lens of instrumental benefits, such as accessing health-related information or maintaining contact with family and friends [1-3]. Yet, this perspective largely centers on identity-based platforms that replicate offline social networks. A growing body of research distinguishes between platforms that sustain identity-based networks, such as Facebook or Instagram, and those that are pseudonymous and interest-based, such as Reddit (Reddit, Inc), where users connect with strangers through shared topics rather than preexisting ties [4,5]. Unlike social networking sites grounded in real-name connections, these interest-driven environments encourage interaction that is less constrained by existing social roles and expectations.

Despite growing recognition of older adults' digital participation, a critical gap remains in the literature: a distinct lack of research that prioritizes older adults' own voices and personal sharing within pseudonymous online environments. While some studies have examined aging-related discussions on these platforms, most have focused on caregivers or younger users talking about older adults [6,7]. Given that older adults actively participate in various online environments to learn from and interact with younger generations and to share their own narratives and reflections [8,9], such pseudonymous spaces allowing users to interact free from existing offline social roles may therefore provide meaningful yet overlooked contexts for older adults to communicate and sustain social contact in digital spaces. This study addresses this gap by shifting the focus to older adults' self-expression on Reddit, examining how they navigate and share personal experiences when untethered from identity-based networks.

Theoretical Framework

From a social relations perspective, the convoy model provides a rationale for why such spaces can matter in later life [10,11]. As individuals age, their social networks, or convoys, tend to shrink due to retirement, mobility limitations, or loss of peers. Supplementary, low-barrier online exchanges can partially compensate for this contraction by maintaining a sense of embeddedness and continuity. While the convoy model explains why older adults may be drawn to online pseudonymous platforms, a life course perspective is needed to understand how they engage with them. In this perspective, age is understood not only as biological age but also as a series of transitional life phases [12]. Rather than viewing age as fixed, the life course approach conceptualizes it as a dynamic process in which each stage is shaped by distinct social and developmental characteristics [13]. These age-related characteristics influence media use alongside changing social circumstances [14]. Unlike rigid biological age, the life course perspective attempts to capture the social dynamics of individuals in relation to their broader societal context [15]. An individual's current life stage, such as transitioning out of the workforce, brings specific social conditions that can influence the types of experiences they wish to discuss with others.

Self-Identification on Pseudonymous Platforms

In pseudonymous spaces like Reddit, the intersection of life course and age cohort becomes highly visible through self-identification. Because Reddit relies on anonymity, a user's age group is invisible unless they explicitly disclose it. This act of voluntary disclosure can be understood through the lens of subjective age identification, which examines the age group to which a person self-identifies, regardless of their strict chronological age [13]. Often referred to as "identity age," this self-categorization grounds age at a subjectively experienced level rather than an objective one [13]. In this sense, one's age cohort self-identified on Reddit signals the social realities of their life course stage.

Within this integrated framework, pseudonymous, topic-based platforms such as Reddit offer an important setting for examining how these identities are expressed in practice. Their affordances, namely, default anonymity, topic segmentation, and interest-based exchange, enable older adults to share personal experiences outside the boundaries of identity-based networks, creating new conditions under which age-group–related patterns of sharing can be reconsidered [16]. On Reddit, users who explicitly self-identify as "60-something" or "70-something" publicly articulate a sense of belonging to an age cohort within a pseudonymous environment. This study focuses on people who consciously identify with these groups and make that identity visible online. Such acts of self-identification involve 2 complementary processes: *individuation*, through which members recognize common traits and shared experiences within the group, and *differentiation*, through which they mark their distinction from other groups [9,17].

Research Objective

The primary objective of this study is to examine how older adults engage in self-expression and personal experience sharing in pseudonymous online spaces. Rather than treating older adults as a monolithic age group, this study moves beyond demographic categories by integrating a life course perspective with the concept of subjective age cohort. Specifically, it investigates how Reddit users who explicitly self-identify as being in their 50s, 60s, or 70s share personal experiences online. Focusing on users who make their age cohort membership publicly visible, this study interprets such disclosures as performative expressions of subjective age cohort identity. This framing illuminates how people navigating the later stages of midlife and early older adulthood draw on pseudonymous

XSL•FO
RenderX

platforms to adapt their modes of self-expression to the particular demands and transitions of their current life stage.

Methods

Platform Context

This study adopted a mixed methods approach combining large-scale computational text analysis, statistical comparisons, and topic modeling. The analysis focused on data from Reddit users who explicitly self-identify as being in their 50s, 60s, or 70s. Reddit is a large-scale, forum-based platform where users post and comment within topic-specific communities called *subreddits*. Each subreddit is user-created and moderated, with its own rules, culture, and norms. Users can join and participate in multiple subreddits, allowing diverse discussions across interests and experiences. As of 2024, Reddit ranked as the ninth-most-used online platform in the United States [18]. Unlike identity-based social networks, Reddit operates under pseudonymity, where users participate under consistent usernames that are not tied to real-world identities. This allows them to maintain a recognizable online presence while preserving privacy [19]. Subreddits also allow the use of user flairs, which are short labels that appear beside usernames within a given subreddit. These flairs can indicate characteristics such as age group (eg, "60-something"), experience level (eg, "newbie"), or location (eg, "NYC").

Data Collection

This study focused on *r/AskOldPeople*, a subreddit with a strong presence of older adults that facilitates intergenerational and peer discussions about aging and everyday life. As of June 2025, *r/AskOldPeople* had more than 800,000 members and ranked within the top 1% of all subreddits by size. To identify users' age groups in this pseudonymous environment, the study used the subreddit's flair system. In *r/AskOldPeople*, users may select flairs such as "50-something" or "70-something" to indicate their age. Data were collected via the Reddit Developer Platform application programming interface (API) in January 2024, retrieving users who posted or commented on the 1000 most recent posts, reflecting the limit imposed by Reddit's API. Although this constrained the historical range of data, it ensured the inclusion of recently active users with up-to-date age flairs and minimized overrepresentation of highly active users. A total of 848 users were identified for analysis: 360 (42.5%) current older adults ("60-something" and "70-something" flairs) and 488 (57.5%) future older adults ("50-something"). Of the 360 current older adults, 304 (84.4%) were in their 60s, and 56 (15.6%) were in their 70s. These 2 age groups were combined into a single category to ensure a comparable sample size with the future older adults' group.

Although *r/AskOldPeople* was used to identify older Reddit users, the analysis was not limited to that subreddit. Reddit's structure allows public posts and comments across all subreddits to be retrieved for a given user. Using the Reddit API in February 2024, up to 1000 of the most recent posts and 1000 of the most recent comments were collected for each identified user. To ensure comparability across varying content lengths, all text was tokenized into sentences using the Punkt sentence tokenizer, which detects sentence boundaries in natural language text. This process yielded a dataset of 4,055,275 sentences: 1,671,400 (41.2%) from current older adults and 2,383,875 (58.8%) from future older adults.

Personal Sharing Classification

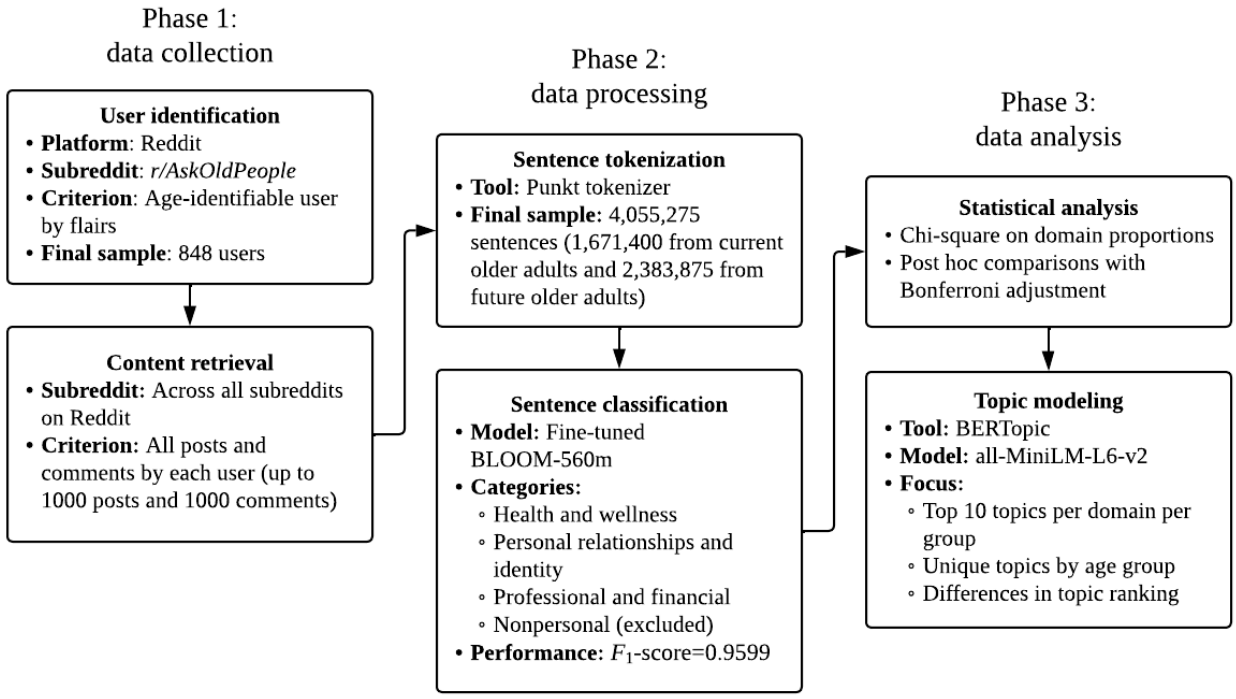
Given the dataset's scale, a machine learning model was fine-tuned to classify each sentence into one of four categories: (1) health and wellness, (2) personal relationships and identity, (3) professional and financial, or (4) not related to personal experience sharing. After excluding the sentences unrelated to personal experience sharing, only the first 3 categories were analyzed. The classification schema was adapted from Geetha et al [20] and refined to include only personally reflective sentences. When sentences referenced multiple domains, the dominant theme was selected. For example, "My wife was diagnosed with stage IV cancer" was classified as *health and wellness*, while "I kept talking to my therapist when I started dating again after I divorced" was classified as *personal relationships and identity*. Sentences not describing personal experiences (eg, "The International Lyme and Associated Diseases Society recommends 4-6 weeks of antibiotics" or "Thank you so much") were excluded.

The model used was BLOOM-560m [21], an open-source large language model available via Hugging Face. A balanced training set of 2000 manually labeled sentences (500 per category) was constructed through stratified random sampling and split into training (80%), validation (10%), and test (10%) subsets. The fine-tuned model achieved an F_1-score of 0.96 on the test set and was subsequently applied to label the full dataset. The fine-tuned model is publicly accessible at [22].

Ethical Considerations

This study used publicly available data collected via the official Reddit API. Data collection complied with the platform's Terms of Service, and the study qualified for an Institutional Review Board exemption due to the lack of direct human subject interaction. Any direct quotes used for illustration were carefully paraphrased to prevent reverse searches.

Analytic Strategy



To examine age cohort differences in personal sharing, the proportions for each domain were calculated for both groups. A chi-square test was performed to assess whether the distribution of domains differed between age cohorts, with Bonferroni-adjusted post hoc comparisons conducted when significant.

To further explore thematic variation within each domain, topic modeling was applied using BERTopic, which uses transformer-based embeddings to cluster semantically related sentences into interpretable themes [23]. The SentenceTransformer model *all-MiniLM-L6-v2* was used to generate embeddings. Topic modeling was conducted separately for each domain and group. For each group, the top 10 topics were identified by frequency, represented by characteristic keywords automatically extracted by the model. The analysis focused on identifying topics unique to one group and differences in topic prominence between current and future older adults. This approach enabled a detailed comparison of

XSL•FO
RenderX

how distinct groups of older adults share personal experiences across life domains in pseudonymous online contexts. A visual summary of the data processing and analysis workflow is provided in Figure 1.

Figure 1. Data collection and analysis process.

Results

Overview of Personal Experience Sentences

After excluding nonpersonal content, a total of 569,107 sentences were identified as related to personal experiences. Among these, the "personal relationships and identity" domain accounted for the largest proportion (n=268,212, 47.1%), followed by the "professional and financial" (n=186,768, 32.8%) and "health and wellness" (n=114,127, 20.1%) domains.

Chi-Square Analysis of Domain Distribution

A chi-square test revealed a significant difference in the distribution of domains between future and current older adults (χ^2_2=34.7; P<.001), with Bonferroni-adjusted post hoc comparisons indicating that the professional and financial domain did not differ significantly between groups. Current older adults in their 60s and 70s shared proportionally more about health and wellness (46,379/227,458, 20.4%; P<.001), whereas future older adults in their 50s shared more about personal relationships and identity (161,925/341,649, 47.4%; P<.001). Table 1 summarizes the domain distribution and standardized residuals.

Table 1. Distribution of personal experience domains by age group.

Age group	Health and wellness		Personal relationships and identity		Professional and financial	
	Values, n (%)	R [a]	Values, n (%)	R	Values, n (%)	R
Future older adults (50s; n=341,649)	67,748 (19.8)	–5.17[b]	161,925 (47.4)	4.94[b]	111,976 (32.8)	–0.84
Current older adults (60s and 70s; n=227,458)	46,379 (20.4)	5.17[b]	106,287 (46.7)	–4.94[b]	74,792 (32.9)	0.84
Total (n=569,107)	114,127 (20.1)	—[c]	268,212 (47.1)	—	186,768 (32.8)	—

[a]R represents standardized residuals from the chi-square test.

[b]Residuals with Bonferroni-adjusted significance levels P<.001.

[c]Standardized residuals are not applicable to marginal totals.

Thematic Patterns by Domain

Health and Wellness

Table 2 presents the 10 most frequent topics by domain and age group. In the health and wellness domain, leading themes for future older adults included *smoking and nicotine use* (615/41,134, 1.5%), *cancer experiences* (460/41,134, 1.1%), *hormonal changes* (335/41,134, 0.8%), mental health discussions, such as *depression* (326/41,134, 0.8%), and *health care access* (280/41,134, 0.7%). Sentences commonly described

XSL•FO
RenderX

experiences such as treatment side effects (“The estrogen patch stopped my hot flashes”) or emotional responses to illness (“I am much more lonely now and prone to depression”).

For current older adults, the most frequent themes were *smoking* (409/28,376, 1.4%), *keto diet* (365/28,376, 1.3%), *positive health reflections* (296/28,376, 1.0%), *vaccination* (254/28,376, 0.9%), and *aging awareness* (206/28,376, 0.7%). Additional frequent topics included *dental issues* (195/28,376, 0.7%) and *Parkinson’s disease* (190/28,376, 0.7%). Example sentences referenced daily management of age-related conditions (“As I get older, I feel tired and discouraged”) and lifestyle adjustments (“I transitioned from the Standard American Diet to keto gradually”). While some topics overlapped (eg, smoking, vaccination, and cancer), their relative prominence varied between groups.

Personal Relationships and Identity

Both groups frequently discussed hobbies and everyday interests, but the emphasis of the discussion differed. For future older adults, top-ranked topics were *biking* (604/83,150, 0.7%), *racial identity* (527/83,150, 0.6%), *LGBTQ+ identity* (445/83,150, 0.5%), *photography* (419/83,150, 0.5%), and *books and reading* (383/83,150, 0.5%). Additional themes included *hairstyles* (353/83,150, 0.4%), *friendship* (302/83,150, 0.4%), and *movies* (283/83,150, 0.3%). Sentences often included midlife reflections on friendships (“I have five friends in my inner circle, and it’s all I need”).

Current older adults similarly mentioned *biking* (597/62,124, 1.0%) and *reading* (364/62,124, 0.6%), but also featured *gun ownership* (232/62,124, 0.4%) and *cooking* (230/62,124, 0.4%) among top topics. Examples included sharing recipes or memories of learning to cook for family (“I’m putting together a cookbook for my sons”). Across both groups, discussions of racial and LGBTQ+ identities were frequent, indicating engagement with broader conversations about social identity on the platform.

Professional and Financial Life

Work, income, and retirement were common themes for both groups, though with different foci. Leading topics for future older adults included *ticketing and consumer transactions* (345/63,052, 0.5%), *legal issues* (302/63,052, 0.5%), *work attire* (263/63,052, 0.4%), *retirement planning* (246/63,052, 0.4%), and *tipping practices* (238/63,052, 0.4%). Additional topics involved *job interviews* (205/63,052, 0.3%) and *COVID-related work disruptions* (204/63,052, 0.3%). Example sentences included practical reflections on everyday financial activity and employment: “I already have my tickets for next year,” “I’m a big tipper, so I usually go closer to 30 percent,” and “I have not gotten one single interview this year.”

For current older adults, frequent topics were *legal matters* (326/42,626, 0.8%), *retirement* (312/42,626, 0.7%), *401(k) and pension savings* (241/42,626, 0.6%), *social security* (193/42,626, 0.5%), and *charitable giving* (181/42,626, 0.4%). Other topics included *gender at work* (157/42,626, 0.4%) and *air travel* (148/42,626, 0.3%). Example sentences included: “I am 67, retired in August, and most basic expenses are covered by Social Security and a pension,” “I donate to charities every year,” and “I used to fly weekly for work for many years.” Overall, both groups contributed extensive discourse around financial security and employment experiences, though the specific subthemes differed in prominence.

Across domains, both current and future older users produced diverse personal narratives on Reddit. The largest quantitative differences appeared in the health and wellness and personal relationships and identity domains, whereas professional and financial content showed similar proportions. Topic modeling further revealed that overlapping themes, such as health conditions, hobbies, and work, were framed through distinct emphases in frequency and rank, reflecting the breadth of personal sharing among older Reddit users.

Discussion

Principal Findings

This study investigated how self-identified older Reddit users share personal experiences across 3 domains (ie, health and wellness, personal relationships and identity, and professional and financial life) and found that age-group differences emerged both at the domain level and within specific topics. The central analytic contribution is not merely that the 2 groups discuss different things but that the nature of those differences points to distinct underlying forces: life course position most powerfully structures sharing in health and professional domains, while age cohort socialization more visibly shapes expression in the relationships and identity domain. Meanwhile, pseudonymous platform affordances function as an enabling condition across all 3 domains, facilitating disclosures that identity-based networks structurally discourage. Taken together, these patterns suggest that older adults' online self-expression cannot be adequately explained by any single framework; rather, it reflects the simultaneous, domain-specific interplay among aging, cohort, and platform.

Health and Professional Domains: Life Course Position as the Primary Driver

The sharpest between-group contrasts in health and professional content are best understood as reflections of where each cohort stands in the life course. In health and wellness, the topics that distinguish the 2 groups correspond closely to the physiological and institutional realities of their respective life stages: hormonal change, depression, and nursing interactions for those in their 50s; Parkinson disease, dental decline, and aging awareness for those in their 60s and 70s. This pattern is consistent with life course theory's premise that age-related transitions bring distinct social and bodily concerns that shape what individuals perceive as meaningful to communicate [24-28]. Crucially, neither group's health discourse is simply about illness; both articulate experiences of bodily negotiation, that is, managing a changing body and its social consequences. What differs is the temporal orientation: future older adults write from a position of midlife adjustment and medical navigation, while current older adults write from one of chronic management and embodied constraint. This temporal dimension suggests that health-related sharing on Reddit may serve less as information exchange and more as a form of life-stage sense-making.

A parallel logic applies to professional and financial content. Future older adults' emphasis on job interviews, workplace roles, and consumer transactions reflects continued embeddedness in the labor market, whereas current older adults' focus on Social Security, pensions, and charitable giving reflects the financial and moral landscape of postretirement life. Notably, the shift from employment-centered to giving-centered discourse among current older adults is not merely a change in topic. It signals a reorientation of economic identity from productivity to stewardship. This aligns with life course research on the transition from midcareer to later adulthood, in which individuals increasingly frame financial decisions through a lens of legacy and responsibility rather than accumulation [29-32]. The presence of this discourse on a pseudonymous platform is itself significant: it implies that Reddit serves not only as a space for practical information-seeking but also as a venue for working through identity transitions that are rarely voiced in face-to-face settings.

Relationships and Identity: Cohort Culture as the Primary Driver

If life course position explains health and professional differences, it is less adequate for understanding the divergences in personal relationships and identity. Their expressive content in this domain differs in ways that point more directly to age cohort socialization, which includes the enduring cultural habits, values, and media landscapes formed during each cohort's formative years [33]. Future older adults' more frequent discussions of friendships and film suggest that this cohort's sense of self is significantly organized around shared cultural memory and relational intimacy. This cohort, consisting of Generation X, came of age during an era of expanded media consumption and shifting norms around personal expressiveness, and these formative experiences appear to persist as frameworks for identity and connection in midlife [34]. Current older adults' greater emphasis on cooking and gun ownership is analytically distinct: rather than nostalgia or relational affirmation, these topics function as articulations of responsibility, continuity, and moral selfhood. Research on boomer generational culture documents a persistent orientation toward family stewardship and civic identity that was instilled during early socialization and continues to anchor self-narratives in later life [35-37]. On Reddit, these values are not merely expressed; they are performed for an anonymous audience, suggesting that even in pseudonymous spaces, generational identity remains a meaningful resource for self-presentation.

The cross-group similarities in this domain are equally important analytically. Both groups engaged substantively with race and LGBTQ+ identity, topics that carry heightened social risk for older cohorts in offline contexts. This convergence challenges assumptions that older adults' online engagement is primarily conservative or identity-confirming, and points instead to Reddit's capacity to elicit discursive engagement with contested social identities across age lines. This finding is better explained by platform affordance than by either life course or generational factors, which sets up the argument in the following section.

Pseudonymity as an Enabling Condition for Authentic Self-Expression

Across all 3 domains, the patterns of sharing observed in this study are not fully intelligible without accounting for Reddit's pseudonymous architecture. Pseudonymity lowers inhibitions and restructures the environment of self-disclosure, enabling users to share content that would carry social risk in identity-bound contexts [38,39]. This mechanism is most visible in health-related sharing in this study. Both age cohort groups disclosed experiences involving vulnerability, such as mental health struggles, bodily decline, and stigmatized conditions, topics that research consistently shows to be suppressed in face-to-face interactions and on real-name platforms due to stigma, self-restraint norms, and the fear of burdening others [40,41]. The willingness to share such content on Reddit is not simply a function of digital confidence; it reflects the structural

XSL•FO
RenderX

condition that pseudonymity enables disclosure without consequences for one's offline social standing. This aligns with the conceptualization of networked privacy by De Choudhury and De [42], in which users actively calibrate visibility and intimacy through selective, context-dependent disclosure, a practice that pseudonymous platforms uniquely support.

In the relationships and identity domains, pseudonymity's enabling role takes a different form. It expands the boundaries of moral and social expression, not only emotional disclosure. The engagement of both groups with race and LGBTQ+ identity, sensitive topics that generate social friction in many older adults' offline communities, suggests that Reddit functions as a low-risk venue for articulating positions and experiences that would otherwise be carefully managed in identity-tied settings. This expressive expansion extends to loneliness, marital life, nostalgia, and everyday frustration—contents that are affectively authentic but socially inadmissible on platforms where one's full social identity is visible [43,44].

Taken together, these patterns position Reddit not as a neutral medium but as a structurally distinctive space that actively reconfigures what older adults are willing to say, and to whom. The act of self-identifying with an age cohort through a flair compounds this effect as users are not merely anonymous individuals but members of a loosely assembled, voluntarily constituted community of peers—a social context that provides the dual affordance of relatability and anonymity. This combination may be especially consequential for older adults, whose offline social networks, as convoy theory predicts, are contracting precisely at the life stage when the need for resonant peer exchange may be intensifying [10,11].

Design and Policy Implications

These findings carry implications that go beyond platform research to inform *how digital environments are designed* and *how digital inclusion is conceptualized for older populations*. The results suggest that conventional digital inclusion frameworks, which tend to center operational literacy and family connectivity via identity-based platforms, leave a critical dimension unaddressed: what might be called *expressive inclusion*—the capacity to communicate authentically within a social frame that is not constrained by one's offline identity and relationships. The finding that pseudonymous spaces enable disclosures about mental health, physical vulnerability, and contested social identities suggests that access to such digital spaces constitutes a distinct and meaningful dimension of digital participation that identity-centric interventions cannot replace. This has practical implications for both platform design and community-based programming. Designers of eHealth platforms and digital aging services should consider integrating pseudonymous or semianonymous communication options alongside identity-tied profiles, particularly for forums addressing sensitive topics such as mental health, midlife transitions, or chronic illness. Evidence from this study suggests that such affordances may substantially increase candor and peer engagement among older users. For digital literacy practitioners, the implication is similarly concrete: curricula could incorporate "pseudonymous navigation," teaching older adults how to identify, evaluate, and safely participate in interest-based online communities alongside the operational and security competencies that currently dominate training programs. Equipping older adults to find resonant peer communities outside their immediate offline networks would directly address the social contraction that convoy theory associates with later life.

Limitations

Several limitations should be acknowledged when interpreting the findings. First, the study operationalizes age groups through user-selected age-based flairs. It is important to acknowledge that these labels reflect a voluntary self-categorization within a digital space, rather than objectively verified demographic membership. This choice may also bias the sample toward Reddit users who are both more digitally confident and more comfortable identifying publicly with their age. These individuals likely represent a distinctive subset of older adults. Findings should therefore be understood as characterizing active, self-identifying older Reddit users, who are a distinctive and probably more digitally agentic subset rather than older adults in general.

A second and more fundamental limitation is the cross-sectional design, which makes it impossible to disentangle life course effects from cohort effects. The differences observed between the 50s and the 60s and 70s groups could reflect either the distinct life-stage position of each group, the different generational cultures that shaped them, or their interaction. This study treats the two explanatory frameworks as complementary rather than competing but cannot empirically adjudicate their relative contributions. Doing so would require a longitudinal or cohort-sequential design capable of tracking how the same cohort's expressive patterns shift as it moves through subsequent life stages, and this is a methodologically demanding yet theoretically essential direction for future research.

Abstract

Background: Integrated Care for Older People (ICOPE), focused on monitoring and optimizing the intrinsic capacity (IC) of older adults, is a new model of geriatric care that is currently being accelerated globally. Digital health technologies are recommended for longitudinal IC monitoring to provide precise and timely interventions. However, little is known about the psychological intentions of engaging in digital monitoring of IC according to the profile heterogeneity of IC among older adults.

Objective: This study aims to map a set of customized personas to capture the profiles of IC and match psychological intentions that support personalized digital IC monitoring.

Methods: An explanatory sequential mixed methods study was conducted at 16 sites in Beijing, China. Older adults aged ≥60 years (n=481) were selected to complete the quantitative survey. Latent profile analysis, descriptive statistics, and logistic regression analyses were performed to cluster subgroups using Mplus (Muthén & Muthén) and SPSS (IBM Corp). A subsample of participants from each profile (n=25) was purposively sampled for semistructured interviews. An inductive-deductive content analysis was used to identify similar attributes and to affirm the personas gradually. A joint statistical and thematic visualization method was used to integrate the customized personas.

Results: Three profiles of IC patterns emerged: “multisubdomain decline–IC imbalance group,” “multisubdomain moderate–sensory deficit group,” and “multisubdomain robust–whole balance group.” The distribution of latent profiles was influenced by age, education, monthly per capita household income, self-rated health, and number of chronic diseases, while positively impacting older adults’ functional ability. The following customized personas were captured regarding established themes: “affects my mood—anxious evader,” characterized by avoidance and anxiety, low digital interest, and perceived social isolation; “capitalize on what comes—accommodative adopter,” pragmatically oriented toward disease detection, with moderate digital openness but limited self-efficacy; and “more autonomy—active improver,” who exhibited proactive engagement, high digital literacy, and motivation rooted in self-management and social participation.

Conclusions: This study is the first to integrate latent profile analysis with customized qualitative personas to link the heterogeneity of IC with the psychological intentions underlying digital monitoring. The resulting personas model provides an actionable framework for tailoring digital IC monitoring strategies in community-based integrated care. The findings emphasize the need to align monitoring approaches with older adults’ IC characteristics, psychological readiness, digital literacy, and social support to enhance engagement in digital IC monitoring.

Introduction

The Aging Challenge and the Centrality of Intrinsic Capacity

In the face of increasing aging trends, health care systems are confronted with a diverse and intricate array of geriatric care demands [1]. The transition from a model of health care that is centered on responding to diseases to one that focuses on maintaining functions is an urgent strategy for improving and coordinating health care services [2]. Intrinsic capacity (IC), commonly consisting domains of cognition, psychological capacity, sensory capacity (including vision and hearing), vitality, and locomotor capacity, is the physiological reserve of an individual's functional ability and plays an important role in quality of later life [3,4]. It is defined as "the composite of all the physical and mental capacities that an individual can draw on" [1]. To operationalize this concept, the World Health Organization (WHO) has released 2 editions of the "Integrated Care for Older People (ICOPE): Guidance for Person-centered Assessment and Pathways in Primary Care" handbook to guide the assessment and monitoring of older adults' IC in community settings [1,5].

IC, as a health metric reflecting the degree of healthy aging in a country or region, is of special reference value [6]. A systematic review stated that the global prevalence of IC decline among community-dwelling older adults was 67.8% [7]. In China, Ma et al [8] reported that 69.1% of participants showed a decline in 1 or more domains of IC. A longitudinal study of retired Chinese older adults revealed that 32.1% experienced a decline in IC over a 4-year follow-up period [9]. According to previous studies, IC is a robust predictor of adverse health outcomes, including frailty, falls, health care use, incident disability, hospitalization, and mortality [10,11]. In general, optimizing IC in older adults can enhance functional autonomy and predict adverse events. Consequently, dynamic monitoring of cognitive impairment is needed to identify risk factors that can be ameliorated and to develop individualized intervention strategies that delay or prevent the deterioration of IC.

Digital Health for IC Monitoring: Potential and the Challenge of Equity

Digital health technology is an efficient and manageable approach for expanding the study and monitoring of IC in older adults [12]. An ICOPE program in France used digital tools to establish a timely feedback mechanism and support network for early warning IC monitoring in community settings, enabling interaction between older adults and health care professionals and providing an interface for subsequent steps in ICOPE [13-15]. A qualitative study indicated that implementing eHealth interventions within the IC framework may promote the social participation of older adults and communication with physicians, enhancing subjective well-being and enriching the monitoring activities of medical staff [16]. Currently underway in China, the "Comprehensive Evaluation of Intrinsic Capacity in China Study" (HEALTHY) aims to develop a consolidated digital technology–based platform for assessing IC and tailoring personalized interventions to promote proactive health behaviors among Chinese older adults [12]. However, older adults' motivations for participating in digital health programs are complex and influenced by multiple factors [17]. Several studies have shown that older adults who engage in IC-focused digital health programs tend to be younger and healthier [13,14], which appears to conflict with the health equity goals advocated by ICOPE. The psychological intentions of older adults have a profound effect on their interaction with technology and their ability to use digital tools [18]. Therefore, establishing evidence-based links between IC heterogeneity and digital engagement patterns is an important process for scaling up the individual-centered ICOPE model and promoting equity in digital health for older adults.

A Persona-Based Design for Customized IC Monitoring Strategies

The concepts of people-oriented integrated care and user-centered digital design achieve similar purposes and effects, both of which aim to meet the specific needs and preferences of the target group and achieve a deep and intuitive understanding [19]. Personas are a valuable approach for capturing older adults' preferences, abilities, and attitudes toward self-management of health, particularly in the use of digital technology [20]. The novel paradigm of IC as a health criterion undoubtedly impacts the traditional disease-centered perceptions of older adults. Previous studies exploring the heterogeneity of IC subgroups have neglected to provide insight into older adults' psychological intentions regarding IC monitoring and management [21,22]. Strategies for adopting digital health technologies may be hindered by a lack of demand or skills if only the external characteristics of older adults are targeted and the underlying behavioral determinants of accepting IC monitoring are overlooked [23]. Customized personas, with the advantage of incorporating biopsychosocial characteristics that encompass needs, experiences, and expectations, are an important reference for clustering older adults for digital IC monitoring [24].

Study Purpose

Few studies have combined quantitative analysis with additional data to construct accurate customized personas, which are usually generated through gradual affinity grouping after labeling qualitative data [25,26]. To the best of the authors' knowledge, this study is the first to adopt a mixed methods approach aimed at exploring the psychological intentions of older adults to receive integrated care focused on digital IC monitoring, thereby supporting personalized monitoring activities for community health care providers.

Methods

Study Procedures

This study used an explanatory sequential mixed methods design, which was implemented in 2 consecutive phases [27]. First, a quantitative phase was conducted using structured questionnaires to collect objective data and identify key patterns or clinically significant issues. Subsequently, a qualitative phase followed, in which in-depth interviews were carried out with a purposively selected subgroup of participants to explore and interpret the underlying reasons and contextual meanings behind the quantitative findings [28]. The following hypotheses were proposed in this study: (1) by using the 5 domains of IC as observational indicators, older adults will be clustered into distinct groups, reflecting differences in IC levels and subdomain characteristics; and (2) older adults in differently characterized IC subgroups will express different motivations, goals, and concerns regarding digital monitoring of IC. A total of 3 PhD candidates in nursing jointly developed the research protocol under the guidance of 2 nursing professors, 1 associate professor, 1 lecturer, and 1 senior nurse practitioner, all of whom possesses extensive research or clinical practice experience in geriatric or community nursing. Figure 1 illustrates the 4 steps of the study [29], including: (1) the cluster: questionnaire survey on IC of older adults; (2) analysis of the cluster: to gain an initial understanding of differential characteristics and classification of subgroups based on latent profile analysis (LPA); (3) qualitative interviews to explore the attitudes, goals, needs, and potential concerns of older adults for digital monitoring under the different profiles of IC; and (4) integration and corroboration of quantitative and qualitative findings to portray a set of personas of older adults' IC profiles and matched digital monitoring intentions, laying the groundwork for the future development of personalized monitoring strategies. Reporting adhered to the Good Reporting of a Mixed Methods Study (GRAMMS) checklist (Multimedia Appendix 1) [30].

Figure 1. Study steps and integration process.

Quantitative Phase

Setting, Participants, and Recruitment

The study took place at a total of 16 sites, including 14 community committees, 1 nursing home, and 1 community health service center in 6 districts of Beijing, China, from March 2024 to October 2024. Convenience sampling was applied during the quantitative survey phase, as it aligns with the community-level screening and voluntary nature of IC assessment under the ICOPE framework. The authors coordinated and communicated with community workers and heads of health facilities before each questionnaire survey and recruited a consecutive sample of older adults by posting group notices and conducting onsite outreach after consent was obtained. Older adults who met the following inclusion criteria were eligible to participate in the survey: (1) aged 60 years or older; (2) with normal reading, writing, and comprehension skills; and (3) voluntarily participated in this survey after providing informed consent. The exclusion criteria were as follows: (1) participants with severe functional impairments that prevented them from safely completing an exercise test, (3) participants with medically diagnosed severe cognitive impairment, (3) participants with medically diagnosed serious psychiatric disorders, and (4) participants currently experiencing an acute or worsening illness.

The sample size was estimated based on 2 primary considerations. First, the initial target sample was calculated using the Kendall model, which recommended at least 5 to 10 times the number of variables [31]. With 17 variables in this study, and considering the possibility of 20% invalid questionnaires, the required sample size was 102 to 204 cases. Second, to ensure the stability and reliability of the subsequent LPA, a sample size exceeding the commonly recommended minimum of 300 is advised [32]. A final sample of 481 older adults therefore met both the adjusted recruitment target and the methodological requirement for robust LPA.

Variables and Instruments

Based on the literature review [33,34], a structured questionnaire was designed by the research team to collect general information

XSL•FO
RenderX

as predictor variables, including sex, age, education level, marital status, family structure, type of labor force before retirement, per capita monthly family income, self-rated health using a Likert scale, and the number of chronic diseases.

The functional ability of participants, which results from the interplay between an individual's IC, supportive environment, and personal characteristics [1], was assessed using 3 established scales as key outcome measures: the Barthel Index [35], Fried Frailty Phenotype [36], and HALFT scales [37] were used to assess activities of daily living, frailty, and social frailty, respectively.

The 5 key domains of IC were assessed following the instruments recommended in the new version of the WHO ICOPE guidelines [1]. The Mini-Mental State Examination [38], Geriatric Depression Scale-15 [39], WHO vision screening chart [1], whisper voice test [1], Mini Nutritional Assessment Short-Form [40], and Short Physical Performance Battery test [41] were used to assess cognition, psychological capacity, sensory capacity (vision and hearing), vitality, and locomotor capacity, respectively. The scoring rules of these instruments are summarized in Multimedia Appendix 2.

Data Collection

Before the formal questionnaire, the investigative team, comprising postgraduate nursing students, underwent a uniform offline training on the purpose of the study, assessment procedures, questionnaire content, assessment site setup, and language and behavioral norms. For participants who had difficulty completing the questionnaire, such as those experiencing presbyopia or slow reading speeds, the investigators helped them complete it after explaining the meaning of each item. The survey was conducted using either a paper version of the questionnaire or an application installed on tablet computers, with the content being the same in both formats. The paper version of the questionnaire was entered into the application after validity was established so that the data could be accessed for statistical analysis. At the end of the questionnaire survey, the authors invited older adults who were interested in this study to participate in follow-up qualitative interviews and retained their contact details.

Data Analysis

The IC of older adults is influenced by many factors and exhibits differential characteristics [42]. Therefore, we attempted to find a people-oriented clustering approach to provide an objective population classification basis for customized personas [32]. LPA is a statistical method that identifies characteristics between individuals based on the estimation of their response patterns on observed indicators, providing unique insights into the heterogeneity of the target population [43].

First, Mplus (version 8.3, Muthén & Muthén) was used to analyze the latent profiles of the IC of older adults. Starting with 1 category, categories were added progressively until the maximum likelihood method was used to determine the best solution. The main evaluation indices included Akaike information criterion (AIC), Bayesian information criterion (BIC), adjusted BIC (aBIC), and entropy. The lower the AIC, BIC, and aBIC are, the better the model fit [44]. Entropy ranges from 0 to 1; the closer the value is to 1, the more accurate the model classification is, and it is generally believed that values of 0.80 or greater indicate that the classification accuracy of the model reaches 90% [45]. The Lo-Mendell-Rubin likelihood ratio test (LMRT) and the bootstrapped likelihood ratio test (BLRT) were used to compare the fit of 2 adjacent models, where low and significant *P* values suggest a *k*-class model is superior to *k-1*−class model [46]. To visualize the latent profiles, the estimated class-specific means from the Mplus LPA model output were exported and plotted using line charts in Microsoft Excel version 16.1.

Second, latent profiles were named and assigned values to classify groups. Descriptive statistics were analyzed using SPSS (version 26.0, IBM Corp) to understand the data distribution characteristics of the profiles. Variables that conformed to a normal distribution were described as mean (SD), and comparisons between groups were made using 1-way ANOVA. Count data were described as frequency and percentage. Differences in sociodemographic and health-related factors between groups were assessed by chi-square tests. Finally, multivariate logistic regression analyses were performed with latent profiles of IC as the dependent variable and variables that were statistically significant in the univariate analyses as the independent variables. To avoid modeling errors, dummy variables were used for categorical data. The impact of the predictor variables and their statistical significance were assessed through regression coefficients (β), *P* values, odds ratios (ORs), and 95% CIs. A *P* value <.05 indicated a statistically significant difference.

Qualitative Phase

Setting and Participants

A naturalistic, descriptive qualitative design is well suited to mixed methods research [47], enabling older adults to provide a rich and direct description of the goals, needs, and concerns of digital monitoring regarding their IC level. Stratified purposive sampling based on the categorical results of the LPA ensured the representation of participants originating from different IC profiles. Given the sequential continuity of the mixed methods study, the inclusion and exclusion criteria established for the quantitative phase were likewise applied to this phase. The first author contacted the older adults who had accepted the invitation to be interviewed during the quantitative phase, while explaining the purpose, content, and methodology of the further study and setting the time and place of the interviews.

Data Collection

Semistructured interviews were conducted between October and December 2024 to collect data. In accordance with the objectives of the study and the literature review [48], the research team developed the following interview outline: (1) "What is your idea of IC?" (2) "How would you evaluate your IC? Can you share some stories from your daily life where you have felt IC come into play or decline?" (3) "What do you think about using digital health tools for IC monitoring?" (4) "What do you hope the use of digital health tools for IC monitoring will do for you?" (5) "Do you have any concerns and doubts

XSL•FO
RenderX

about using digital health tools for IC monitoring?" and (6) "Do you have any suggestions or expectations regarding the digital monitoring of IC?"

The first author reviewed the results of the quantitative phase of the IC assessment with the participants before the commencement of the interviews. Participants were interviewed in relaxed and comfortable parks, cafes, and clinic rooms. A total of 2 additional individual interviews were conducted via voice calls on the Tencent Conference platform. Each interview, led by the first author and assisted by another author for observation and field notes, lasted 20 to 68 minutes. Audio interviews were transcribed into text within 24 hours using Lark intelligent transcription. The first 2 authors (ZX and YN) and 2 qualitative experts (QX and YW) proofread the transcript and verified its contextual integrity. Data collection and analysis were synchronized in this study. Recruitment of participants was stopped when no further significant new information emerged, implying data saturation [49].

Data Analysis

The qualitative phase of data analysis was conducted with the main aim of obtaining the needs, intentions, and challenges of older adults regarding digital monitoring originating from the different IC profiles. Inductive combined with deductive content analysis was used to hand code the data to compare and integrate the similarities and differences between the different profiles horizontally [50]. Initially, the research team repeatedly reviewed interview transcripts to gain a holistic understanding of the data. Second, after interviewing 2 participants from each latent profile, the authors conducted open coding, assigning descriptive codes to meaningful text segments to develop a preliminary coding framework for guiding the remaining transcripts. Next, data from the same latent profiles were clustered and extracted contemporaneously by the first 2 authors (ZX and YN) following the attributes in the coding framework, which enabled the creation of customized personas. The framework was continuously refined and clarified throughout this process as new insights emerged or existing categories required redefinition. The final version of the framework constituted the thematic results. To capture the group-level commonalities within each persona, the primary author noted interview logs after each interview. These logs documented the author's immediate impressions and holistic understanding of the participants, which later played a pivotal role in identifying the shared attributes that define each persona. Finally, the research team collaborated to define and describe the customized personas, outlining the participants' differing attitudes, goals, needs, and available support that ultimately formed the subthemes for the 3 customized personas. Discrepancies between the first 2 authors (ZX and YN) during data analysis were addressed by an expert in qualitative nursing research to achieve harmonization of the results.

Data Integration Procedure

As mentioned above, this study achieved methodological integration in that a quantitative LPA identified subgroups of IC that guided the qualitative phase of cluster sampling. Furthermore, the joint statistical and thematic presentation was used as a visualization tool to integrate and cross corroborate the main quantitative and qualitative findings at the level of results interpretation [51], providing a reference for future digital personalized interventions. The integrated customized personas were described jointly by the first 2 authors and iteratively discussed and revised in regular meetings of the research team, and finally confirmed by all authors.

Ethical Considerations

This study was undertaken in accordance with the Declaration of Helsinki and approved by the Ethics Committee of Capital Medical University (approval number Z2023SY138). All participants enrolled in this study voluntarily and signed informed consent before the formal start of the assessment after being informed that they could withdraw at any time. Each older adult who participated in the quantitative survey received a gift worth approximately RMB 20 (US $2.81; a currency exchange rate of RMB 1≈US $0.1403 is applicable), while those who participated in the interviews received an additional gift worth RMB 40 (US $5.58). All data, audio recordings, and written records are stored on a password-protected laptop and backed up in the cloud; only the research team has access to them. In addition, all data were used for research purposes only and could not be disclosed without the participants' consent. To ensure privacy protection, the participants' personal information was anonymized and labeled "P1-P25."

Results

Quantitative Phase

Participant Characteristics

A total of 481 older adults, aged 60-97 years, with a mean age of 70.7 (SD 6.8) years, participated in the quantitative phase. The results in Table 1 show that most participants were female (320/481, 66.5%), aged 60-69 years (234/481, 48.6%), currently married (356/481, 74%), and living in a married couple's household (224/481, 46.6%). Most participants had a secondary education (318/481, 66.1%), a per capita monthly household income of RMB 3000-RMB 5999 (260/481, 54.1%), and engaged in light labor (241/481, 50.1%) before retirement. In addition, the majority of older adults rated their health as "very good or good" (258/481, 53.6%) and had 1 to 3 chronic diseases (323/481, 67.2%).

LPA Results

The scores in the 5 domains of IC were used as exogenous variables to model the latent profiles. The *z* score was used to eliminate the effects of different magnitudes on data analysis during data preprocessing. The fitting statistics for modeling 1-5 latent profiles sequentially are shown in Table 2. After comprehensive consideration of the latent profile metrics and clinical significance, we identified the 3-profile model as the best option for the following reasons: (1) the values of AIC, BIC, and aBIC decreased gradually as the number of profile subgroups increased, but beginning with the 4-profile model, the LMRT was greater than .05 and the minimum classification probability was less than 10%, signifying that this category may be spurious; (2) the LMRT and BLRT results were statistically significant ($P<.05$) for the 3-profile model, indicating that it was better than the 2-profile solution; and (3) the entropy value of the 3-profile model exceeded 0.8, indicating good model accuracy. Therefore, the 3-profile model was selected as the most appropriate model. To verify the reliability of the LPA, we calculated the average posterior probabilities for the 3 profiles. The results are shown in Multimedia Appendix 3, where the posterior probabilities were greater than 0.8, indicating that the model results for the 3 profiles were well separated [52].

Table 2. Latent profile analysis model fit of intrinsic capacity impairment patterns.

Model	Log(L)[a]	AIC[b]	BIC[c]	aBIC[d]	Entropy	LMRT[e]	BLRT[f]	Classification probability

Characteristics and Naming of Latent Profiles

Figure 2 illustrates a graphical presentation of the *z* score for the 5 domains of IC in the 3 impairment profiles. Each profile was named according to its characteristics. Profile 1, constituting 19.1% (92/481) of the sample, was designated the "multisubdomain decline–IC imbalance group." The most obvious characteristic of this group was the overall decline in IC, while only the sensory domain remained at a high level, resulting in an imbalance in IC. It should be noted that higher scores on the psychological domain indicated reduced psychological capacity. Profile 2, the "multisubdomain moderate–sensory deficit group," included 29.1% (140/481) of the participants. This group showed a moderate IC level that was higher than those in profile 1 and was characterized by significant sensory deficits, reflecting a pattern of decline with single deficits. Profile 3 was the most prevalent in the sample, accounting for 51.8% (249/481) of cases. It was designated the "multisubdomain robust–whole balance group" owing to its exceptional performance in IC, with no significant loss of ability.

XSL•FO
RenderX

Figure 2. Characteristic distribution of 3 latent profiles. Profile 1: multisubdomain decline–IC imbalance group; profile 2: multisubdomain moderate–sensory deficit group; and profile 3: multisubdomain robust–whole balance group.

Comparison of Predictive Variables in Each Latent Profile

As shown in Table 1, the findings derived from the univariate analyses provide insights into the differences among the 3 latent profiles by using sociodemographic and health-related factors as predictor variables. Among these variables, age, marital status, education level, type of labor force prior to retirement, per capita monthly household income, self-rated health, and number of chronic diseases differed significantly (P<.05) among the 3 IC impairment patterns. No statistically significant differences were observed in sex and family structure.

Only variables that were statistically different between the IC subgroups in the univariate analyses were included in the multivariate logistic regression analyses (Table 3). Using profile 3, the "multisubdomain robust–whole balanced group," as the reference group, older adults aged 80 years and older are more frequently found in either profile 1 (OR 9.190, 95% CI 2.986-28.284; P<.001) or profile 2 (OR 7.018, 95% CI 2.559-19.247, P<.001). As detailed in Table 3, as education levels rose, older adults were less likely to be categorized in profile 1 or profile 2. Those with a per capita monthly household income of ≥RMB 6000, indicating a higher quality of life and social status, were less likely to be attributed to profile 1 (OR 0.163, 95% CI 0.040-0.670; P<.05). Those with better self-rated health were more likely to belong to profile 3. For example, the probability of older adults rating their self-health as "very good" joining profile 1 (OR 0.037, 95% CI 0.005-0.265; P<.001) and profile 2 (OR 0.115, 95% CI 0.017-0.773; P<.05) was reduced. Older adults with no chronic diseases were less likely to be enrolled in profile 1 (OR 0.315, 95% CI 0.105-0.943; P<.05). The results, when viewed through profile 2 as the reference group, indicated a lower possibility of older adults with a per capita monthly household income ≥RMB 6000 (OR 0.219, 95% CI 0.061-0.782; P<.05) and self-rated health of "good" (OR 0.236, 95% CI 0.060-0.935; P<.05) belonging to profile 1.

Outcome Variables of Latent Profiles

As demonstrated in Table 4, there are significant differences in activities of daily living, frailty, and social frailty among the identified latent profiles of IC impairment. Subsequent post hoc comparisons revealed a gradual decline in functioning for latent profiles 3, 2, and 1, using the 3 functional abilities as the outcome variables.

Qualitative Phase

Interview Sample Characteristics

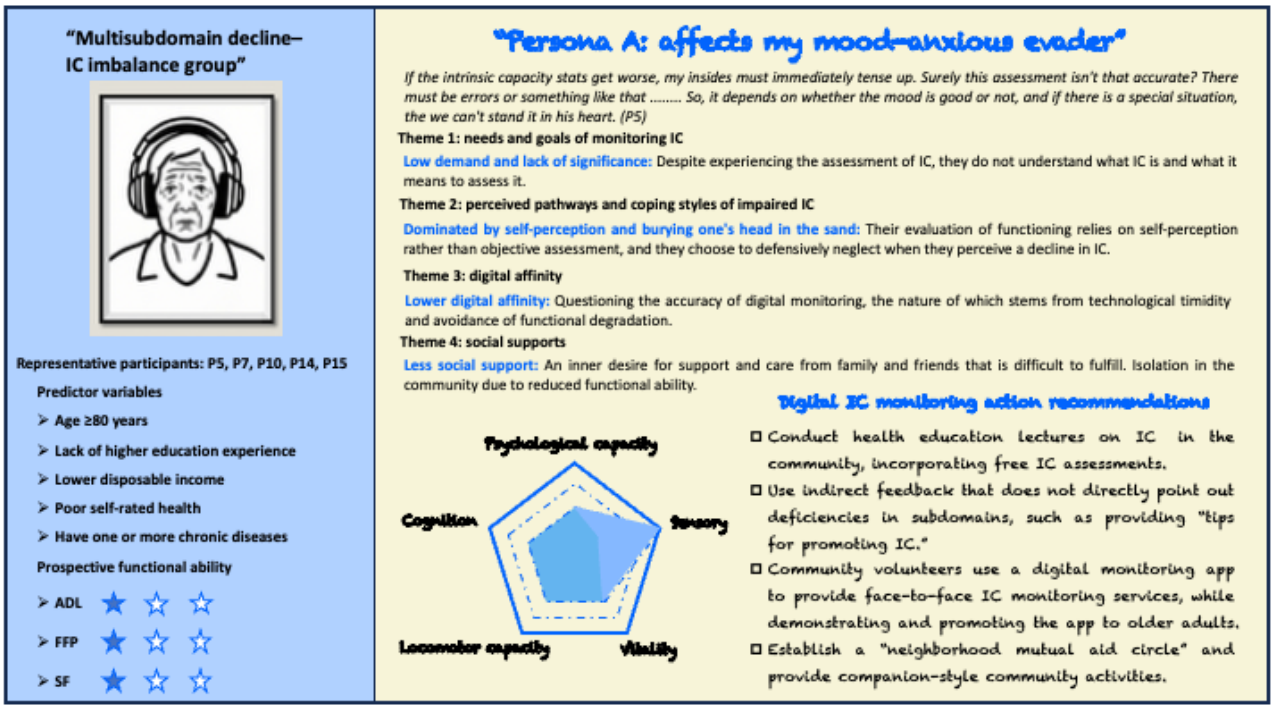
A total of 25 older adults volunteered to participate in the interviews, including 5 in profile 1, 10 in profile 2, and 10 in profile 3. Most participants were female (17/25, 68%). All participants had a mean age of 70.1 (SD 7.03, range 60-85) years, and had experienced between 0 and 4 IC domain declines. Detailed information is provided in Multimedia Appendix 4.

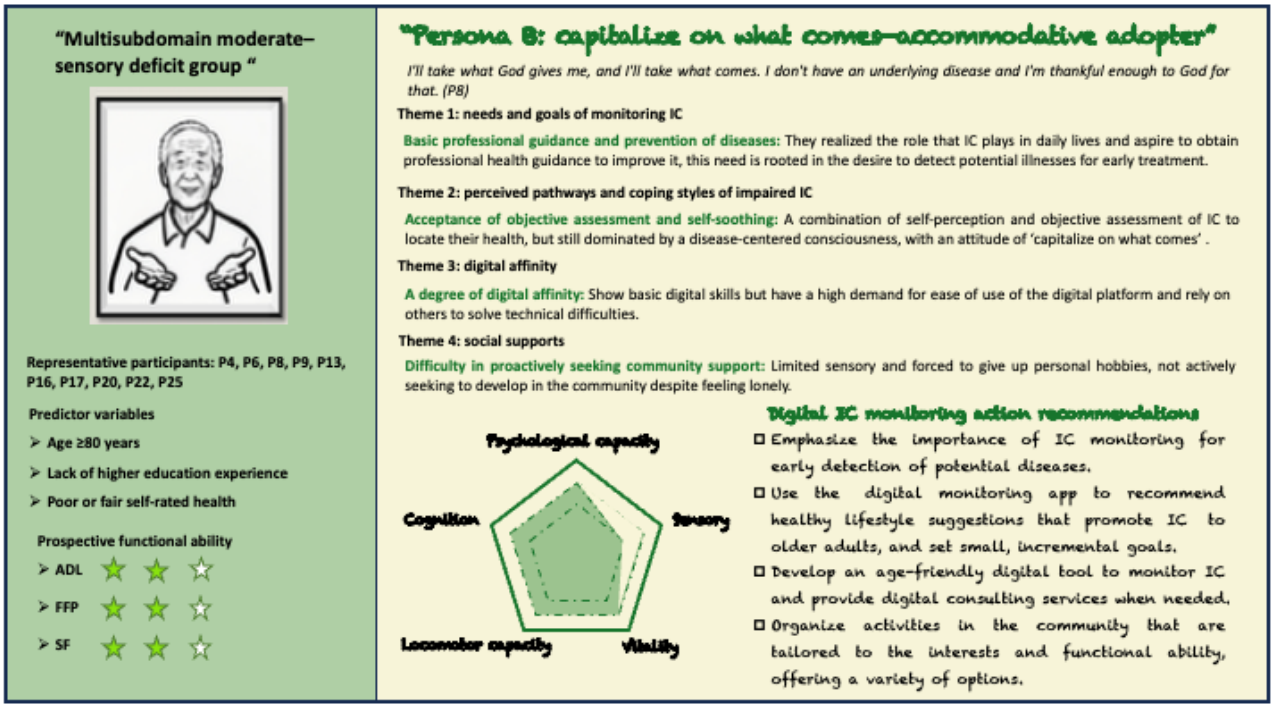
Developing Customized Personas

A total of 4 themes emerged in this study. In the hierarchical data analysis, 3 customized persons corresponding to different IC profiles were depicted, and subthemes under the themes that matched the persons were illustrated in Figures 3-5. Representative quotations were translated into English by the authors and confirmed by back-translation. In this section, the findings are reported as an integration of customized personas as follows.

XSL•FO
RenderX

Figure 3. Persona A: affects my mood—anxious evader.





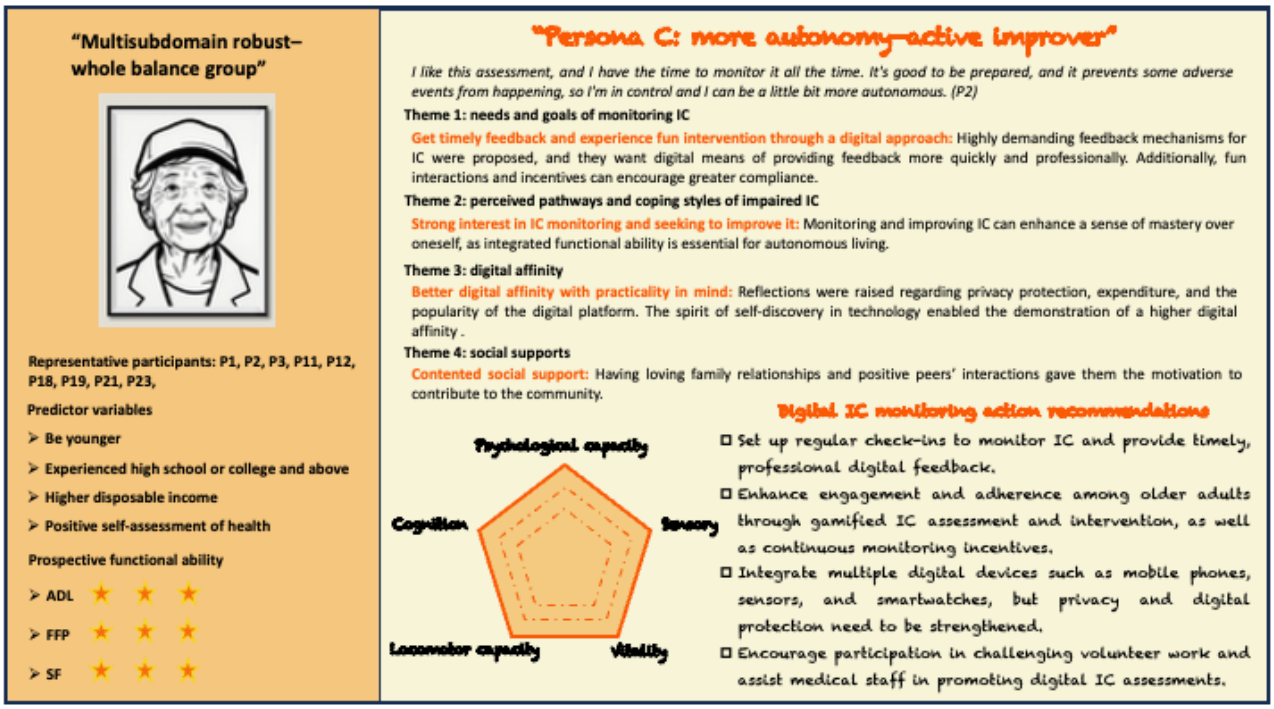


Figure 4. Persona B: capitalize on what comes—accommodative adopter.

XSL•FO
RenderX

Figure 5. Persona C: more autonomy—active improver.

Persona A: Affects My Mood—Anxious Evader

Narrative persona: affects my mood—anxious evader are female and belong to profile 1. They are older than those in other profiles, have lower education and disposable income, rate their health negatively, and are more likely to be chronically ill. Insights from the interviews suggest that they are psychologically fragile and stay away from anything that may bring about emotional stress. Moreover, the lack of social support for persona A, as evidenced by inadequate family care, a desire for companionship, and a neglected position in social groups, may further diminish their physical and psychological capacity in the face of potential stress. In addition, they were skeptical about using digital technology to assess IC and reluctant to ask for help based on past experiences. As a result, persona A showed less interest in digital monitoring of IC, which may have been a psychological coping mechanism that prompted the adoption of an avoidance strategy.

> *It certainly can't improve, this time this way, next time do better than this time, I don't think it can be done, people can only get older and worse.* [P15]
>
> *I know all about it, the results of this assessment are pretty much the same as how I feel about myself, the assessment is not very useful, and I'm doing enough to build muscle at home.* [P10]
>
> *I can type, but it might be difficult for other older adults. If I ask my child to help, she always tells me to take a break and not mess around. So, um..., but I don't want people to think I'm stupid if you ask for help, I'd be embarrassed and stressed.* [P14]
>
> *I used to be the lead dancer of the dance team, I thought I could still teach people how to dance when I got better, but I didn't realize that now I'm the most insignificant person in the dance team, and I can't dance .....I wish someone would tell me how to face society.* [P7]

Persona B: Capitalize on What Comes—Accommodative Adopter

Narrative persona: older adults in persona B, derived from profile 2, have a slight decline in IC, characterized by an impairment in sensory function. Compared to persona C, older adults in persona B were older, less educated, and more likely to rate their health as neutral or slightly negative. Participants expressed a desire to receive assistance from IC in the identification of potential illnesses and the acquisition of professional guidance, which was a passive strategy for treating illnesses. The acceptable attitude they displayed was derived from the Chinese proverb "capitalize on what comes," which implied that since illness is unavoidable, it should be accepted calmly. Seemingly, this was not consistent with the Healthy Aging Framework, which posited the maintenance of IC to promote functional ability and quality of life. Moreover, they were willing to take advantage of digital health technology to assess IC but were marginally deficient in digital literacy, resulting in greater demands for functionality and ease of use. Regarding social support, they reported feeling cared for by family and friends. However, the activities and hobbies that they were compelled to abandon due to declining functionality also engendered helplessness and isolation, echoing the findings that they may be in the prefrailty and presocial frailty stages.

> *I'd like to know, what I should eat, and what I should watch out for to make me cognitively aware if I've lost my ability in a certain area.* [P8]
>
> *The disease is inevitable, no one will not be sick, old age is sicker, this is also in the natural, normal. Of course, when things go wrong, maybe it's just a minor problem, who doesn't do that in life? I can still sing,*

XSL•FO
RenderX

my head is not confused, and I don't have any trouble recognizing people, so I'm very satisfied with myself. [P6]

In any case, it should be simplified. Technology is something that makes things simpler, it is 1 + 1 = 2, but why can't some older adults accept it? That's why I think it should be simplified; too many functions don't match the energy of the older adults. [P13]

I have to give up a lot of activities and interests because of declining physical abilities.……The last six months I've been feeling really lonely and unenergetic. When I get up early, I go out and sit for two hours, and then the afternoon is particularly torturous. [P16]

Persona C: More Autonomy—Active Improver

Narrative persona: participants in persona C are derived from profile 3 and represent older adults with high levels of IC. Compared to personas A and B, they are likely to be younger, more educated, have better disposable income, and a more positive assessment of their health. They showed a high level of interest in monitoring IC and were keen to maintain communication with their community health care team through age-friendly digital platforms for regular reminders, feedback on professional advice, and facilitation of functional improvement. Older adults in the technology-rich exploratory persona C also needed fun interventions and motivational approaches to help improve monitoring adherence, confidence, and sense of achievement. They suggested that free and community outreach is essential to increase access to IC monitoring. In addition, the interviews revealed that they were more likely to live in well-functioning family relationships and maintained good relationships with neighbors and peers through developing shared hobbies and were more autonomous and socially active.

After all, it needs to be assessed regularly, so could you design some mini-games? Design mini-games that exercise cognitive and finger dexterity and are similar to completing tasks. Older adults enjoy playing games just as much as children do. [P12]

I think vitality, cognition, psychology and so on make up a state of equilibrium, and good IC is the most appropriate balance. For example, sometimes we may encounter some things, and our mental ability may be reduced, but we can regulate and restore it through some methods. [P23]

Some of the digital stuff reflected ..... Actually, to the point where we use it quite simple. I have no difficulty at all, may have something to do with my previous work exposure to digital technology earlier. [P3]

I often participate in social activities and volunteer, and I want to do what I can. I have been instructing residents on rubbish sorting and participating in community work, which I am willing to do as long as I have enough time. [P11]

Discussion

Principal Findings

This study used an explanatory sequential mixed methods design to elucidate the data-driven link between heterogeneous IC profiles and psychological intentions toward digital IC monitoring in older adults. Specifically, an explanatory sequential mixed methods design was used, in which quantitative LPA provided the sampling framework and identified group-centered persona predictors. This informed subsequent qualitative interviews, which uncovered the underlying psychosocial narratives and specific digital monitoring intentions unique to each persona. “Persona A: affects my mood—anxious evader,” “persona B: capitalize on what comes—accommodative adopter,” and “persona C: more autonomy—active improver” represent differentiated IC characteristics among older adults and their digital monitoring intentions. These findings provide person-centered typology that can inform the development of tailored digital monitoring strategies within community-based integrated care for older adults.

While digital health tools offer efficient ways to monitor IC, it is vital that implementation strategies remain cautious and respect older adults’ willingness for digital engagement [29]. This caution is particularly pertinent to the “persona A: affects my mood—anxious evader” in this study, who was revealed to have the lowest level of IC and a negative willingness to engage in digital monitoring. They exhibited a higher prevalence of individuals aged 80 years or older, with low levels of education, low income, and poor self-rated health compared to the other 2 personas, echoing results reported in other studies showing a clear correlation between sociodemographic determinants and significant decline in IC [34,53]. A scoping review suggested that the 3 key factors contributing to digital exclusion among older adults are sociodemographic, physiological, and psychological factors, resulting in “unable” and “unwilling” attitudes [17], which further validate the trait of technological timidity in persona A.

The Health Belief Model can also provide an indirect explanation for this phenomenon, whereby older adults recognize that a decline in IC poses risks to their functional capacity and quality of life, yet the perceived benefits of digital IC monitoring are overshadowed by perceived barriers, including technological complexity, technophobia, and threats to self-esteem. As far as psychological states were concerned, the interview findings revealed that older adults within persona A exhibit a strong sense of self-protection, which is manifested in their avoidance of confronting their actual IC level. They expressed anxiety about the implication that an IC decline reflects age-related functional ability lapse, a condition that signifies aging. This phenomenon may be partially explained by Guo et al [54], who claimed that self-neglecting older adults are more exposed to delayed health actions and mental health damage and have a multisubdomain impairment of IC. Furthermore, social participation and family relationships are potential ameliorative factors in the decline of IC [53]. Persona A yearns for familial care and community engagement, though concerns about self-esteem and public image hinder proactive

XSL•FO
RenderX

action, resulting in unmet social needs such as reminders and companionship [55].

Therefore, intervention strategies for Persona A should still be initiated with traditional IC monitoring to build trust via stable, low-pressure collaborative relationships. Community care providers should conduct comprehensive assessments of older adults' daily living conditions, home environments, and social networks to design tailored supportive measures, which may involve gradual exposure to digital IC assessment tools and the provision of accessible social activities.

Persona B are characterized as "capitalize on what comes—accommodative adopter," who have made peace with the decline in IC and demonstrate a more pragmatic, disease-centered demand for digital monitoring. They believed that the IC could provide early warning of hidden diseases and guide them to seek timely medical treatment by obtaining professional advice from the community health care team. ICOPE, focused on monitoring IC, is a key practice in the shift from disease-centered to function-centered approaches to healthy aging [56]. It is an innovative model that not only facilitates the transformation of community health care models but also urges older adults to overcome the cognitive limitations of a disease-focused mindset.

However, older adults in persona B are subconsciously constrained by self-agism, whereby they perceive the decline in IC as inevitable, which may reduce their perceived benefits of digital IC monitoring and lead to passive technological application [57]. A further characteristic is a notable sensory deficit that may result in diminished self-efficacy during digital interactions. As one grows older, the sensory domain is where the prevalence of impaired IC is most evident [21]. A previous study confirmed that augmented digital access could help address unmet medical needs and increase use of preventive care [58]. As participants desired, digital platforms integrated with wearable devices for real-time monitoring, capturing metrics such as step speed and gait, may mitigate interaction challenges arising from visual impairment. Besides, a flat structure and clear interface design of the digital platform can reduce technological dependence and enhance adherence to long-term IC monitoring.

Therefore, while monitoring IC through digital platforms, it is also essential to recommend and track lifestyle factors such as nutrition, physical activity, and social engagement for persona B. These recommendations should be tailored rather than generic health advice to alleviate their concerns about disease risks and functional decline. By linking behaviors that support IC to the motivation of disease detection, digital monitoring of IC becomes more proactive.

Persona C is an active collaborator in the community integrated care team's use of digital IC monitoring; hence, it is designated as "more autonomy—active improver." They were characterized by relatively younger age, higher educational attainment, disposable income, and more positive self-assessments of health, in line with previous studies that found that older adults with these characteristics had better IC and lower risk of decline [59,60]. Older adults in this persona were particularly proactive in mastering their IC to seek autonomy in later life. They believed that maintaining self-management abilities is essential for older adults' health and independence, especially in the face of IC decline, and that it also moderates the relationship between quality of life and physical function [33]. Moreover, persona C showed higher digital literacy, as evidenced by their constructive comments on the needs for digital platforms, such as timely and professional feedback and interesting incentives and interventions to stimulate adherence and engagement in health management. As confirmed by prior practical experience studies, timely feedback mechanisms and support networks enhanced interactions between older adults and community integrated care teams, providing an efficient interface for subsequent steps in ICOPE [14,15]. Additionally, another characteristic of this persona was that they fully perceived and used social support and further contributed to society to the best of their ability. Similar findings indicated that when older adults had a greater sense of control, they were able to actively use perceived social support to achieve goals they deemed important [61]. On the other hand, these older adults unintentionally accessed more resources or strategies while participating in social activities, creating a positive feedback loop for the improvement of IC [62].

Consequently, digital monitoring of persona C's IC should incorporate motivational elements to encourage long-term engagement, thereby reinforcing a sense of competence and autonomy. To sustain engagement, the monitoring platform could incorporate gamification features such as progress tracking, challenge missions, and reward mechanisms for achieving IC-related goals, which could directly enhance a sense of accomplishment and confidence in self-management, aligning with their proactive approach to healthy aging.

Strengths and Limitations

The primary contribution of this study is the application of a data-driven persona framework to elucidate older adults' psychological intentions regarding digital IC monitoring. These personas synthesize quantitative predictors of IC profiles with qualitative insights into attitudes, goals, ability reserves, and support resources. Methodologically, the initial LPA established a sampling and analytical framework ensuring that interviews focused on revealing rich contextual narratives behind each statistically defined profile. This approach advances the discourse from describing subgroup characteristics to explaining psychological intentions, constructing personas that are both statistically grounded and vividly descriptive. Additionally, customized personas will inform targeted recruitment strategies and the development of IC monitoring systems oriented toward real abilities and goals, ensuring monitoring pathways align with the readiness and needs of diverse groups.

However, this study has several limitations. First, the participants in this study were recruited from urban communities in Beijing, China, and were selected through convenience sampling. Therefore, the findings may not be generalizable to older adults in rural or remote settings, where factors such as health care accessibility, digital literacy, socioeconomic status, and community support structures may present distinct profiles that could influence both IC trajectories and engagement with digital monitoring. Second, sex differences in the value of health

XSL•FO
RenderX

and social engagement resulted in a majority of participants being female, which has an unknown effect on depicting persona characteristics. Third, the interview sample based on the results of the quantitative phase has differences in the number of participants, which can be explained by the poorer health and lower interest of older adults in profile 1. The final limitation is that the 3 customized personas provide only a momentary sketch of a specific population. To keep the personas up to date, future studies will address this by collecting additional data through follow-up visits.

Conclusion

This study integrates quantitative feature analysis with qualitative narrative exploration to investigate the heterogeneous IC characteristics of older adults and their psychological intentions toward digital IC monitoring. Through a comprehensive review, 3 distinct IC profiles were identified, and corresponding customized personas were developed. These personas not only reflect the multidimensional nature of IC but also capture underlying attitudes, personal goals, digital affinity, and social support. The findings provide practical, persona-based tools for community health care providers to tailor communication, support, and technology adoption strategies, enhancing the acceptance and effectiveness of digital IC monitoring among older adults.

Abstract

Background: The "aged" filter has gone viral on TikTok. This filter leverages AI to superimpose signs of aging, such as wrinkles, crow's feet, and sagging skin, onto a user's face. Notably, several dermatologists have attested to the accuracy of this filter in simulating the effects of aging. Reactions among the TikTok community have been mixed, with some utterly dismayed but others wholeheartedly embracing the sight of their aged visages.

Objective: This study takes a deep dive into the ways in which TikTok users react to their aged selves through a content analysis of videos featuring the aged filter. Understanding how they respond to the filter can shed light on the types of meanings commonly attributed to old age as a social construct. The following research questions form the premise of our content analysis of videos on TikTok: (1) How do individuals react to the way their possible future selves look? (2) What types of attitudes toward old age are being conveyed in these videos? (3) What do these responses say about prevailing cultural beliefs, values, and attitudes toward old age?

Methods: To build a comprehensive dataset, we compiled all publicly available videos (N=2682) using the following hashtags as search queries: "#AgedFilter," "#OldFilter," and "#AgeFilter." Collectively, these hashtags amassed >2,068,100,000 views at the time of writing this manuscript. After applying our exclusion criteria, the dataset comprised 681 videos, which received a total of 34,382,236 likes, 1,204,741 favorites, and 211,006 comments. Both deductive and inductive approaches informed our content analysis.

Results: A total of 7 themes emerged from our content analysis. Half of the videos (n=342, 50%) fell under theme 1, "anxiety about aging." The second-largest theme (n=95, 14%) focused on the "pursuit of youthfulness" (theme 2). Theme 3 was about "aging with confidence" (n=84, 12%) and theme 4 was about the "beauty of aging" (n=54, 8%). Theme 5 examined the "privilege of aging" (n=48, 7%) and theme 6 examined "generational connections" (n=43, 6%). Theme 7 covered the "inevitability of aging" (n=15, 2%).

Conclusions: This study marks one of the first attempts to analyze videos using the aged filter on TikTok. Our findings suggest that ageist beliefs may be prevalent among some users. Going forward, there is value in adopting a definition of beauty that transcends age. By doing so, aging can be reframed as a natural part of life to be embraced rather than as a grim reality to be dreaded.

Introduction

TikTok boasts a presence in more than 160 countries and lays claim to approximately a billion monthly active users [1]. One defining characteristic that sets TikTok apart from other social media services is its extensive array of creative tools—filters, sounds, and stickers, among others—which users can experiment with when creating videos. In July 2023, the "aged" filter went viral on TikTok [2]. This filter essentially leverages AI to superimpose signs of aging, such as wrinkles, crow's feet, and sagging skin, onto a user's face. Notably, several dermatologists have attested to the accuracy of this filter in simulating the effects of aging [2]. Reactions among the TikTok community have been mixed, with some utterly dismayed and others wholeheartedly embracing the sight of their aged visages [2]. This study takes a deep dive into the ways TikTok users react to their aged selves through a content analysis of videos using the aged filter.

From a conceptual viewpoint, this study marks one of the first attempts to analyze videos using the aged filter on TikTok. Other gerontological studies that have dealt with social media focus on other topics such as stereotypes about older adults [3-7]. Understanding how individuals respond to the aged filter can shed light on their attitudes toward the physical changes that attend the aging process. From a practical viewpoint, this study can illuminate the types of meanings people attribute to old age as a social construct. It is well documented that TikTok is populated primarily by younger individuals. On the basis of data from July 2023, more than 37% of TikTok's global user base is composed of individuals aged 18 to 24 years. Those aged 25 to 34 years accounted for approximately 32% of the TikTok populace [8]. Insights from this study can support broader efforts to improve societal perceptions of old age.

In accordance with the theory of social constructionism, all human knowledge is produced, communicated, and sustained in social contexts [9]. To conceive of age as a social construct is to acknowledge that although aging itself is a biological fact, the meanings assigned to it are by no means cast in stone [10]. Rather, these meanings are colored by the values, attitudes, and narratives that prevail in society at a particular time [10].

In virtually all contemporary societies, standards of attractiveness are predicated on having a youthful appearance [11-13]. Specifically, youth has been constructed as the epitome of health, vitality, and beauty. In contrast, aging is typically associated with a loss of appearance-related assets, especially in terms of social and sexual desirability [11,14]. Perhaps the phenomenon that best exemplifies the hegemonic ideal of youthfulness is the enduring profitability of the antiaging industry, which purveys a plenitude of products, regimens, and services often peddled as elixirs of youth [15,16]. The global antiaging market was valued at approximately US $58.5 billion in 2020 and is forecast to experience a compound annual growth rate of 7% from 2021 to 2026 [17].

Critical feminists have censured the antiaging industry for the way it has problematized a natural transition, cast old age as the enemy, and ultimately engineered a climate of fear surrounding the aging process [18]. Many of them have argued that the construct of antiaging is a capitalistic framework designed to cash in on feelings of insecurity [19]. These feelings of insecurity are implanted through marketing that casts wrinkles and fine lines as issues to be "treated" or "prevented," and aging as a process to be "delayed," "repaired," or "inhibited" [20]. A striking example of how the antiaging industry instills a fear of aging is the way Elizabeth Arden advertised its PREVAGE moisturizer. Specifically, a fencing mask was used to symbolize the protective nature of the brand's antiaging skincare technology. One of the lines in the advertisement, "[p]repare yourself for the beauty battlefield," further underscores the message that aging ought to be fought and conquered [21].

Another camp emphasizes the need to pay attention to the role of agency when assessing one's reasons for conducting antiaging work. Some postulate that this qualifies as disidentification [22,23], an adaptive strategy that involves a reconceptualization of the self in a way that minimizes one's aging identity as a basis of self-evaluation. More precisely, in a society where beauty is frequently entwined with youthfulness, partaking in antiaging work can serve as a way to elevate one's self-esteem and confidence [24]. Research states that cosmetic treatments can enhance psychological well-being and ameliorate appearance-based distress [25]. Engaging in antiaging work may also function as a way to sidestep the marginalization that ensues when one is visibly older [12,26].

It is widely accepted that a sense of anxiety accompanies the notion of aging [27-29]. Lasher and Faulkender [30] define this anxiety as the anticipation of losses that aging brings about. They consider that anxiety about aging encompasses 4 distinct dimensions: physical, psychological, social, and transpersonal. Particularly apposite to this study is the physical dimension, which includes factors such as perceptions of one's health status, concerns about physical self-efficacy, as well as the physical changes that come with growing older. Anxiety about aging may manifest in 3 types of fears: fear of aging, fear of being old, and fear of older people [30]. Anxiety about aging is said to be intertwined with anxiety about death [31,32].

The perceived loss of physical attractiveness can pose a threat to one's self-esteem and psychological well-being, especially in a world where good looks constitute a form of social currency [33]. Additionally, as per the theory of stereotype embodiment [34], the negativity ascribed to societal meanings of old age can be hazardous to one's health. When assimilated as part of one's culture, age stereotypes may eventually become self-definitions that shape health outcomes in later life. Since the 1990s, research done in regions including America, Europe, and Asia has found that older adults who hold negative age stereotypes have a lower sense of efficacy, a higher risk of depression, and poorer cardiovascular health [34-36]. Conversely, those who embrace positive age stereotypes generally enjoy better functional health, enhanced well-being, and increased longevity [34,37,38]. There is also evidence that people who endorse negative age stereotypes in their younger years confront a greater likelihood of experiencing a cardiovascular event in later life than those who hold positive age stereotypes [34].

The following research questions form the premise of our content analysis of videos on TikTok: (1) How do individuals

XSL•FO
RenderX

react to the way their possible future selves look? (2) What types of attitudes toward old age are being conveyed in these videos? (3) What do these responses say about prevailing cultural beliefs, values, and attitudes toward old age?

Methods

Dataset

Consistent with previous research [39], a new TikTok (ByteDance Ltd) account was created to compile the videos. This was done to reduce bias since videos on the app are arranged based on a complex algorithm, which takes into account the popularity of the video (measured by views, likes, comments, and shares), the popularity of the creator (measured by followers and engagement), any previous content that was engaged with, and the geographic location of the device where the app was accessed [39]. No content was previously engaged with to ensure a regular user's experience when using the app [39].

The aged filter on TikTok is a type of visual effect designed to simulate an aged appearance. Several versions of this filter exist on the platform, but they all serve the same purpose. We compiled all publicly available videos (N=2682) using the following hashtags as search queries: "#AgedFilter" (n=901), "#OldFilter" (n=877), and "#AgeFilter" (n=904). Hashtags enhance the searchability of content by organizing it into categories. Collectively, these hashtags amassed >2,068,100,000 views at the time of writing this manuscript. Videos were compiled from August 21, 2023, to September 21, 2023. We removed (1) videos where the filter served purposes other than the self-examination of one's future appearance, such as role-playing or performing skits (n=745); (2) videos not in English (n=682); (3) videos where the filter was applied to participants other than the user, such as celebrities or animals (n=246); (4) videos with a different filter or without a filter (n=218); (5) videos where the user had no discernible reaction (n=90); and (6) videos that appeared more than once in the dataset, in which case only one was retained (n=20). After applying the exclusion criteria, our dataset consisted of 681 videos, which received a total of 34,382,236 likes, 1,204,741 favorites, and 211,006 comments. Table 1 shows the data collection process.

Table 1. Themes identified in TikTok content featuring the aged filter based on a content analysis of 681 videos.

Themes	Videos, n (%)
Anxiety about aging	342 (50)
Pursuit of youthfulness	95 (14)
Aging with confidence	84 (12)
Beauty of aging	54 (8)
Privilege of aging	48 (7)
Generational connections	43 (6)
Inevitability of aging	15 (2)

Content Coding of TikTok Videos

Following past research [40], the coding rubric was designed using both deductive and inductive modes of reasoning [41]. Analyses led by a directed or deductive approach begin with the identification of an initial set of codes based on past scholarship [41]. Meanwhile, in inductive content analyses, codes are derived directly from the data [41]. We used both deductive and inductive approaches to ensure certain pertinent assumptions informed the analysis, even as we were mindful that new categories would emerge inductively.

To develop a preliminary codebook, we identified categories based on scholarship concerning perceptions of physical appearance in later life [12,14,33]. All the videos were viewed twice by the authors to ensure familiarity with the data. The objective of the first reading was to ascertain the validity of the initial set of categories, as well as to modify the codebook until all variables were refined and defined clearly. During this first reading, a new category was added whenever a video featured a particular attribute that could not be suitably coded into any of the existing categories and appeared frequently enough to warrant its own category. The objective of the second reading was to ensure we had a framework sufficiently representative of the different types of videos to finalize the coding rubric.

To maintain analytic rigor, the 2 coders had regular discussions during which any discrepancies were reviewed and adjudicated. Areas of major overlap were identified and sectioned into broader themes. The percentage agreement between the 2 raters was 96.5% with a weighted Cohen κ of 0.93 (P<.001), showing high interrater reliability. Seven themes emerged from this iterative procedure. It must be highlighted that a video may be classified under more than one theme. As mentioned in previous research, categories in a content analysis need not be mutually exclusive, although they should be internally homogeneous (ie, coherent within themes) and externally heterogeneous (ie, distinct from each other) as far as possible [42,43].

Ethical Considerations

This study analyzed publicly available TikTok data and did not involve interaction with human participants. According to institutional guidelines, ethical review board approval was not required for this study. Informed consent was not obtained as all data were publicly accessible and anonymized prior to analysis.

Results

Summary of Insights From Content Analysis of TikTok Videos

Of the 681 videos, half (n=342, 50%) fell under theme 1, "anxiety about aging." The "pursuit of youthfulness" was the focal point of theme 2 (n=95, 14%). Theme 3 was about "aging with confidence" (n=84, 12%), while theme 4 was about the "beauty of aging" (n=54, 8%). The "privilege of aging" was discussed in 7% (n=48) of the videos. Theme 6, "generational connections," made up 6% (n=43) of the dataset. Theme 7 covered the "inevitability of aging" (n=15, 2%). Table 1 summarizes the themes.

Theme 1: Anxiety About Aging

In this theme, users reacted to their aged selves with varying levels of displeasure. "Shocked," "traumatized," "disturbed," "depressed," "devastated," "terrified," and "enraged" are but some of the words TikTokers used upon seeing themselves through the filter. Many were convinced the filter did them "dirty." One said the filter "lower[ed] [her] self-esteem," and another asserted that the creator of the filter essentially "amplified her body dysmorphia." An audio clip used by multiple users featured a woman uttering, "I need to buy a gun."

Some evoked death-related imagery to describe their future appearances. For instance, one TikToker likened herself to someone who had "just been dug up from the grave." Another bewailed, "It looks like I am [expletive] decaying, bro. I don't even look human, bro, I look like a [expletive] corpse, bro." One insisted he looked like he was "two seconds away from [his] final breath."

Comparisons to movie characters were commonplace. One referred to herself as a "wrinkly Voldemort," and another as the "after version of Rose from Titanic." One poster claimed she looked like "something from The Conjuring."

References to witches emerged in a couple of uploads. A case in point is a video where a user asked, "Why do I look like the witch in the [expletive] Bog that steals your firstborn child? Why do I look like I put a curse on the princess in the castle?" Another opined that she bore a resemblance to a "witch living in the woods."

There were posters who took issue with how fellow users seemed to age "well" or "gracefully." In particular, one individual lamented, "Some people age like fine wine, some people age like milk. I am of the milk variety."

Many were vexed by how old they appeared. "I look like I fought in World War II," exclaimed one user. Another griped, "I look like I am 110 years old and was left out in the sun for an amount of time." One user groaned, "I look like someone left me in the pool for ages."

A few TikTokers took a more dramatic approach, declaring their intent to withdraw from the aging process altogether. Statements that encapsulated this sentiment include "Old isn't for me, guys. Peace out," "So, youth is not in my future," "I need to die young," and "I will not be partaking in aging."

Some were discomfited by how unapproachable or unfriendly they appeared. For instance, one exclaimed, "I look like I eat children." Another complained that she looked like "she would bite the nursing home staff."

Theme 2: Pursuit of Youthfulness

Posts under theme 2 featured users attempting to stave off the aging process through enhanced skincare regimens, cosmetic procedures, or antiaging supplements. Such videos typically depicted individuals frantically applying sunscreen or moisturizer, occasionally using copious amounts for dramatic effect. Similar videos showcased users incorporating facial rollers into their skincare routines.

Many users conveyed a desire to undergo cosmetic procedures such as Botox (AbbVie Inc) or face-lifts. "Give me the botox right now. I want whatever Kris Jenner has.... Before you start commenting 'aging is beautiful', shut the [expletive] up, okay, this is not. This is hideous," commanded one user. Another video contained a text sticker stating, "Running to put on liquid botox and sunscreen [because] I refuse to believe this is what I will look like when I'm old."

One TikToker reached for a tub of collagen peptides and other supplements, vowing to "prove the filter wrong." Another shared that she would be "switching from 0.05% to 0.1% tretinoin" in order not to "age like spoiled milk."

Theme 3: Aging With Confidence

Videos in this category featured users feeling content or confident with their older selves. Some enthused over how "sophisticated" and "powerful" they looked. One effused unapologetically, "I'm gonna be such a hot granny." Another was certain of her ability to continue "luring men" in her advanced age. One proudly declared he was "aging like fine wine" and dubbed himself a "good-looking man." There was even a playful warning from one poster to "hide the abuelas," presumably because of his attractiveness. Several TikTokers called themselves "cute." For example, one commented, "I hope I age this good. I look like a cute old lady."

Theme 4: Beauty of Aging

This theme revolved around the positive aspects of aging, focusing on the personal growth and enrichment it brings.

Several users embraced aging as a path toward increased wisdom, inner strength, and personal fulfillment. "I can't wait to grow old...to have experienced so much life, hold powerful wisdom, and witness myself blossom and change over time. I get so emotional and filled with love seeing the older version of me," one remarked. Another shared, "In my family, wrinkles show laughter and grey hair means wisdom. Age is beauty. I'm so excited to meet her. She looks like she gives the best hugs and runs the local crafts store." One believed that her older self appeared fulfilled, affirming, "She looks like she's lived." Another individual volunteered that being able to reach old age means having "lived and survived."

A group of posters dwelled on the warmth radiated by their future selves. Some relished the prospect of becoming grandparents. One user mentioned that she looked like "she

XSL•FO
RenderX

gives the best hugs, is loved by all the grandkids, and always slips you money every time she sees you." Another focused on the pleasant demeanor of her aged self, saying, "I like her. She has kind eyes. She's lived a full life. She's the type of woman who will comfort you when you're sad. She deeply understands people."

Theme 5: Privilege of Aging

In these posts, users reflected on aging as a "gift," "blessing," or "privilege." A fair share of individuals spoke about how their struggles with mental illness made them grateful for the opportunity to envision life in the future. For example, one confessed, "I've been so mentally ill my whole life. I've genuinely never pictured living this long before." Similarly, a self-proclaimed cancer survivor announced that it would be the "greatest gift" to live till old age. A paramedic said the filter made him think about "all the people [he] was not able to save," believing these people would have desired to live a long life. He concluded, "Aging is a gift. It's a gift to be able to lead a fulfilled, long life."

Some TikTokers were disheartened by the overwhelming negativity surrounding the filter. One maintained that aging is a "privilege," not a "punishment." Another criticized the TikTok community for being "wildly ageist," stressing that anyone would be "lucky to live this long."

Theme 6: Generational Connections

Videos under theme 6 had users reveling in the fact that their aged selves were the spitting image of their parents or grandparents. A representative video contained a caption that read, "What's so wonderful about this is I immediately see my grandma, dad, mum, aunties, and uncles in my features. We are combinations of so many people."

A handful of posters had a deep sense of admiration for their parents or grandparents, which in turn fueled their excitement about growing older. For instance, one gushed, "I look like my grandma who I think is the most beautiful woman." Another anticipated "aging gracefully" like her grandmother. This sentiment was especially pronounced for those who had lost their parents or grandparents.

Theme 7: Inevitability of Aging

In this theme, users either normalized aging as a natural part of life or resigned themselves to the inevitability of its implications. One TikToker spoke reassuringly, "You're gonna age and that's okay." Another put forth, "We all have to get old one day."

One individual was upfront about becoming less attractive. "I wanna embrace the fact that we're all gonna look like this someday and nobody's gonna die looking sexy," she proclaimed.

Discussion

Principal Findings

In this study, we examined the reactions of individuals to the appearance of their possible future selves by performing a content analysis of videos using the aged filter on TikTok. Our analysis unveiled 7 themes: "anxiety about aging" (theme 1), "pursuit of youthfulness" (theme 2), "aging with confidence" (theme 3), "beauty of aging" (theme 4), "privilege of aging" (theme 5), "generational connections" (theme 6), and "inevitability of aging" (theme 7).

Collectively, themes 1 and 2 accounted for more than two-thirds of the videos, which underscores the widespread negativity surrounding the concept of aging among users. In particular, old age is perceived as entailing a loss of one's physical attractiveness [14,30]. An outsized number of users couched their future selves in words that were highly pejorative. Many also conveyed their intent to pay more attention to their skincare routines or to undergo cosmetic procedures to prolong their youthful countenance and quell the anxiety of growing older. These themes reflect deeply ingrained beliefs that equate youth with beauty and old age with undesirability. Such beliefs can exact a toll on one's self-esteem and overall psychological well-being [33]. Furthermore, through the lens of the theory of stereotype embodiment, these negative beliefs about aging can jeopardize one's overall health outcomes [34,37,38].

Theme 3 portrayed users with a positive self-image and sense of self-assurance regarding growing older, attributes that will likely stand them in good stead as they eventually advance into later life. Posts under this theme offer a powerful and refreshing counternarrative that reimagines old age as a period characterized by continued appeal. However, this sense of contentment or empowerment could very well be tethered to the perception of one's physical appearance. One person commented that he aged like "fine wine," insinuating that less appealing ways to age do exist. It is possible that their reactions would be less favorable had the filter presented a version of themselves with more pronounced signs of aging.

Posts under theme 4 reflect the belief that old age is a phase marked by the accrual of experience and wisdom, as well as the development of a mellower personality. Implicit in these posts is a recognition that aging is a multifaceted journey that goes beyond mere physical transformation. In particular, growing older involves certain emotional, social, and psychological changes [44]. Similarly, theme 5 illustrates that for some members of the TikTok population, the experience of aging is not so much a matter of one's changing visage as it is an opportunity to enjoy a long and fulfilling life. Both themes 4 and 5 substantiate findings showing that as people age, their priorities may evolve such that appearance no longer figures into their self-evaluations as prominently [45-47].

Videos under theme 6 depicted users getting emotional over the striking resemblance between their future selves and their parents or grandparents. A growing body of evidence documents that many individuals tend to perceive their grandparents more positively than the general older populace [48,49]. Moreover, being close to one's grandparents has been linked to more positive views of older adults [50,51]. The excitement expressed by certain individuals about being able to look like their older family members may be anchored in strong emotional ties.

Theme 7 demonstrated users having come to terms with the reality of the aging process. Cognizant of the fact that they would eventually deviate from the hegemonic ideal of youthfulness, some TikTokers adopted cognitive strategies that involved adjusting their expectations about their eventual selves

XSL•FO
RenderX

[47]. For instance, a user immediately reconciled herself to the fact that she would no longer be considered attractive by societal standards, thereby decoupling her self-worth from youth-based ideals and accepting her older self.

Implications

Our findings suggest multiple avenues for combating ageism. First, there is a need to step up efforts to reframe aging. Over the years, various social movements, such as the "body positivity" movement, have sprouted up to counter prevailing beauty standards deemed harmful. The principles of inclusivity underlying these movements could be extended to the way society perceives old age. Recently, a number of beauty companies have eschewed the term "antiaging." Instead, these companies now opt for seemingly anodyne alternatives, such as "regeneration," "renewal," and "vitality," which, at the end of the day, however, continue to promulgate the idea that aging skin is undesirable [52]. True inclusivity could involve accepting natural signs of aging. Even as some may rely on antiaging solutions as a way to cope with the aging process [12,24,26], the reality is that all individuals will eventually reach a point where physical signs of aging can no longer be camouflaged by cosmetic interventions [45].

Second, given its preponderant role in stigmatizing old age, the media bears significant responsibility for improving portrayals of older adults [12]. Proactive steps could be taken to increase their representation. For example, media outlets and advertising agencies could actively include older individuals in beauty-related content. This may help transmit the message that beauty is not the prerogative of youth and that aging is but a natural and inevitable part of life. It could also foster positive age stereotypes and lead to more favorable health outcomes [34].

Third, it is paramount that society unlearns the notion that aging brings with it a loss of physical attractiveness. Instead, aging should be recognized as a time of increased experience [53] and emotional intelligence [54]. More importantly, it should be seen as a privilege since not all individuals will live to see old age [55]. Promoting the idea of self-love and self-acceptance may be worthwhile as well [56].

Fourth, tapping into the deep emotional bonds that people share with their parents or grandparents may inspire a more positive outlook on aging [48,49]. When individuals discern aspects of their family members in themselves, they may navigate their own aging journey more favorably. Policymakers could involve grandparents or aging parents in interventions to combat ageism [57,58], harnessing them as proof that aging can indeed be a time of continued growth.

Finally, our findings make a case for implementing initiatives to reframe aging from an early age so that individuals are exposed to positive narratives on aging long before they reach later life. To this end, efforts to reframe aging could be integrated into schools and workplaces.

Limitations and Future Directions

This study is subject to several limitations. First, our findings are unique to a segment of TikTok users whose videos happened to be included in this study and are therefore not generalizable to the wider population. Second, as we did not have access to the motivations that drove users to create the videos, our interpretations were molded by our own thoughts and assumptions. It is worth noting that TikTok is a platform that thrives on entertaining content. Hence, some may have reacted in specific ways to bolster engagement. Third, we lacked information on the demographic characteristics of users, such as their gender. We also refrained from using automated recognition systems given their potential to perpetuate gender biases [59]. Thus, we could not comment on how demographic factors influence individuals' attitudes toward their older selves. It is well established that men and women are subject to different sets of expectations as far as aging is concerned [11,60]. This double standard of aging places women in a position where they contend with greater losses as growing older is often perceived to entail an erosion of their most valued social asset: their physical allure. Men, in contrast, are sometimes regarded as more attractive as they age [61]. Fourth, a substantial number of videos had to be excluded as they were not in English. Future studies could examine this topic in other cultural contexts [62]. Finally, although we recorded the overall number of videos for each theme, we did not track the number of videos associated with the various subthemes. Future research could adopt a quantitative approach [63] by noting down the number of videos for different subthemes. This would lay the groundwork for a regression analysis to explore potential relationships in the data [64, 65].

Other avenues for further gerontological inquiry include an investigation of the psychological effects of using the aged filter. In addition, there is room for an analysis of how reactions to one's aged self differ across age groups. Studying the comments section of videos that use the aged filter presents another promising direction for subsequent research.

Conclusions

This study has shed light on the prevalence of ageist beliefs among some users of TikTok. Going forward, there is value in adopting a definition of beauty that transcends age. By doing so, aging can be reframed as a natural part of life to be embraced rather than as a grim reality to be dreaded.

Abstract

Background: Stroke is a leading cause of global disability in the aging population, with cognitive impairments playing a significant role. Prior research has shown that subjective cognitive concerns (SCCs) can predict later dementia and serve as an essential indicator for poststroke functional rehabilitation. The use of smartphone-based ecological momentary assessment (EMA) in real-world environments may help us understand how SCCs relate to daily functioning in individuals aging with stroke, thereby guiding cognitive rehabilitation and prevention efforts.

Objective: Our study aimed to use EMA to examine the real-time associations between SCCs and daily activity participation in persons aging with stroke.

Methods: This longitudinal observational study used smartphone-based EMA for real-time assessment of individual cognitive concerns and participation in various daily activities. EMA survey items, including SCCs (concentration and learning) and participation in daily activities (location, company, current activity, and self-appraisals of performance, help needed, satisfaction, and engagement), were collected 5 times per day for 2 weeks. Multilevel models were used to analyze the data.

Results: A total of 202 individuals with mild-to-moderate chronic stroke participated in the study (n=90, 44.6% female; n=89, 44.1% Black; n=182, 90.1% ischemic stroke; mean age 59.7, SD 11.7 years). SCCs were concurrently lower when participants engaged in activities of daily living (ADL; B=−0.04, 95% CI −0.07 to −0.01; *P*=.02), instrumental ADL (B=−0.05, 95% CI −0.07 to −0.02; *P*<.001), cognitively stimulating activities (B=−0.05, 95% CI −0.08 to −0.02; *P*<.001), and social activities (B=−0.05, 95% CI −0.08 to −0.02; *P*=.002); when participants were located in a friend's home (B=−0.10, 95% CI −0.17 to −0.02; *P*=.001); and when they spent time with family members (B=−0.07, 95% CI −0.10 to −0.04; *P*<.001), friends (B=−0.05, 95% CI −0.10 to −0.01; *P*=.01), and spouse or partners (B=−0.04, 95% CI −0.07 to −0.01; *P*=.02). Conversely, SCCs were higher when participants were in the hospital (B=0.39, 95% CI 0.25 - 0.53; *P*<.001). Additionally, greater SCCs were concurrently associated with worse ratings of performance (B=−0.05, 95% CI −0.06 to −0.05; *P*<.001), satisfaction (B=−0.05, 95% CI −0.06 to −0.05; *P*<.001), and activity engagement (B=−0.05, 95% CI −0.06 to −0.04; *P*<.001).

Conclusions: EMA provides an effective means of understanding the links between poststroke cognition and participation in daily activities. Our findings suggest that ADL, instrumental ADL, cognitively demanding activities, and socially engaging activities may lessen cognitive concerns among stroke survivors, implying that clinicians should schedule these activities to help reduce poststroke cognitive issues. Conversely, interventions that enhance cognition may increase participation in these challenging activities. Tracking cognition, everyday activity involvement, and their interactions in real-world settings could ultimately help develop rehabilitation and prevention strategies for individuals at risk of dementia due to stroke.

Introduction

Stroke is the second most common cause of death and the third leading cause of disability worldwide [1,2], especially in the older population, in which stroke incidence is highest [3]. Alarmingly, stroke incidence in younger age groups (eg, <55 years) has been gradually increasing over the past few decades [4]. Although stroke mortality rates have fallen with advancements in medicine, the burden of disability and dependence on activities of daily living (ADL) after stroke remains substantial. Existing evidence has shown that the incidence of cognitive impairment in the first few weeks following a stroke exceeds 70% [5]. Although many cognitive issues in acute stroke survivors improve within weeks or months after onset [6], longitudinal studies have documented a notable cognitive decline among stroke survivors over long-term follow-up [7], suggesting the importance of investigating the long-term effect of stroke (ie, chronic stroke) and its impact.

Identifying cognitive impairments in research and clinical practice has often relied on objective assessments (eg, neuropsychological testing). In contrast, subjective cognitive concerns (SCCs), defined as whether people self-report cognitive difficulties and, if so, whether and how these problems disturb or annoy them in everyday life, are often neglected [8]. SCCs are commonly reported in people after stroke, with prevalence rates ranging from 28.6% to 90.2%, and these problems often increase over time [9]. The literature suggests that SCCs serve as early indicators of Alzheimer disease and other forms of dementia [10], which are another important source of disability in old age [11,12]. Given that stroke (acute brain tissue damage) itself is a known risk factor for subsequent dementia [13], persons after stroke, in particular, necessitate ongoing monitoring for early detection of cognitive decline. Moreover, cognitive problems prevent stroke survivors from resuming their prestroke roles or achieving independent living [14]. Therefore, monitoring subjective cognitive functioning in everyday life not only helps predict later dementia but also serves as an important indicator of stroke recovery [15].

Research has shown that time spent in passive leisure activities (eg, watching television) is negatively related to cognitive functioning in healthy older adults and increases their risk of developing cognitive impairment in subsequent years [16]. Meanwhile, participation in cognitively, physically, or socially stimulating activities is positively associated with cognitive functioning in healthy older adults and those with medical conditions [17,18]. However, these studies have primarily been conducted in laboratory or clinical settings, often assuming that cognitive characteristics are constant and stable. In fact, cognitive functioning can be influenced by daily life contexts. Furthermore, these studies exploring the link between cognitive difficulties and participation in daily activities have mostly relied on retrospective self-report questionnaires, typically collecting data at one or a few points using cross-sectional or panel designs. These methods may miss subtle changes that happen within and between days and are prone to recall bias. Therefore, it is essential to have a tool that can capture the dynamic interplay of cognition in day-to-day contexts within the study population, such as an ecological momentary assessment (EMA) often implemented via a smartphone. EMA is an intensive longitudinal data collection approach that captures an individual's daily experiences in real time to minimize recall bias in natural environments, thereby enhancing external validity [19]. Multiple studies have supported the use of EMA in stroke. For example, prior poststroke studies have used EMA to understand real-time relationships between depressed mood and daily activity participation, between somatic and mental symptoms and social interactions [20-22], and to classify poststroke latent cognitive memberships [23]. Although there are studies on these topics, no study has used EMA to identify real-time associations between SCCs and daily activity patterns in stroke survivors. Hence, this study aimed to use EMA to investigate SCCs related to daily activity participation in a sample with mild-to-moderate chronic stroke. We used EMA to evaluate SCCs and the time spent on, as well as participants' perceptions of, daily activity participation. Our first research question investigated the momentary relationships between SCCs and various factors, including activity types, locations, and interactions with other people. We hypothesized that participants would report higher SCCs when staying at home, being alone, and participating in passive leisure activities. Our second research question examined whether SCCs were momentarily associated with perceived qualities of activities. We hypothesized that SCCs would be higher during activities that participants rated as more difficult, felt less satisfied with, were less engaged in, and required more help.

Methods

Participants

Participants were recruited from a local hospital database with active enrollment from October 2018 to January 2021. The inclusion criteria were (1) mild-to-moderate stroke defined by a National Institutes of Health Stroke Scale score of 13 or less at the time of stroke onset, either hemorrhagic or ischemic stroke; (2) at least 3 months after stroke before enrollment; (3) no or mild prestroke disability; and (4) English fluency. People with premorbid neurological or psychiatric disorders, severe communication difficulties, severe apraxia, unilateral visual inattention, or limited visual acuity were excluded from this study.

Procedures

Participants completed the study protocol, which included an initial laboratory visit, 14-day EMA monitoring, and a post-EMA laboratory visit.

At the initial laboratory visit, all participants provided written informed consent, completed screening to ensure eligibility, and participated in a 20-minute tutorial on using an EMA survey mobile app [24] on either their iPhone or an iPod touch provided by our research team. Participants completed at least 1 practice

XSL•FO
RenderX

session to ensure that there were no issues using the app. They were given an EMA manual with hotlines to call should questions arise. As part of the assessment protocol, participants also completed in-laboratory measures, such as the Quality of Life in Neurological Disorders [25] and the Patient-Reported Outcome Measurement Information System [26]. Detailed information on the in-laboratory measures was published elsewhere [20].

The EMA monitoring started within 1 week of the initial visit. Participants completed 5 surveys per day for 14 consecutive days. Surveys were delivered randomly at approximately 2.5-hour intervals per day from 8 AM to 10 PM. Participants had 1 hour to complete each survey, with up to 3 reminders sent before it expired. During the first 2 days and periodically thereafter, the research team contacted participants by phone to address any technical issues or questions they might have while completing the EMA surveys at home.

After EMA monitoring, participants revisited the laboratory to uninstall the EMA app or return the device (if borrowed) and received an honorarium.

Ethical Considerations

The ethics committees of Washington University (201704024) and Northwestern University (STU00215308) approved this longitudinal observational study. All participants provided written informed consent at the initial laboratory visit. Participants received an honorarium of up to US $125 for their participation in the research.

Measures

Participants completed a validated EMA survey tailored to the unique needs of stroke survivors (refer to Bui et al [20] for detailed EMA survey questions). Each EMA survey included 23 questions, and participants took about 3 to 5 minutes to complete it. The survey was primarily composed of checkbox- or slider-format questions. At each prompt, participants answered multiple items about their daily activity participation and current levels of SCCs and other poststroke symptoms.

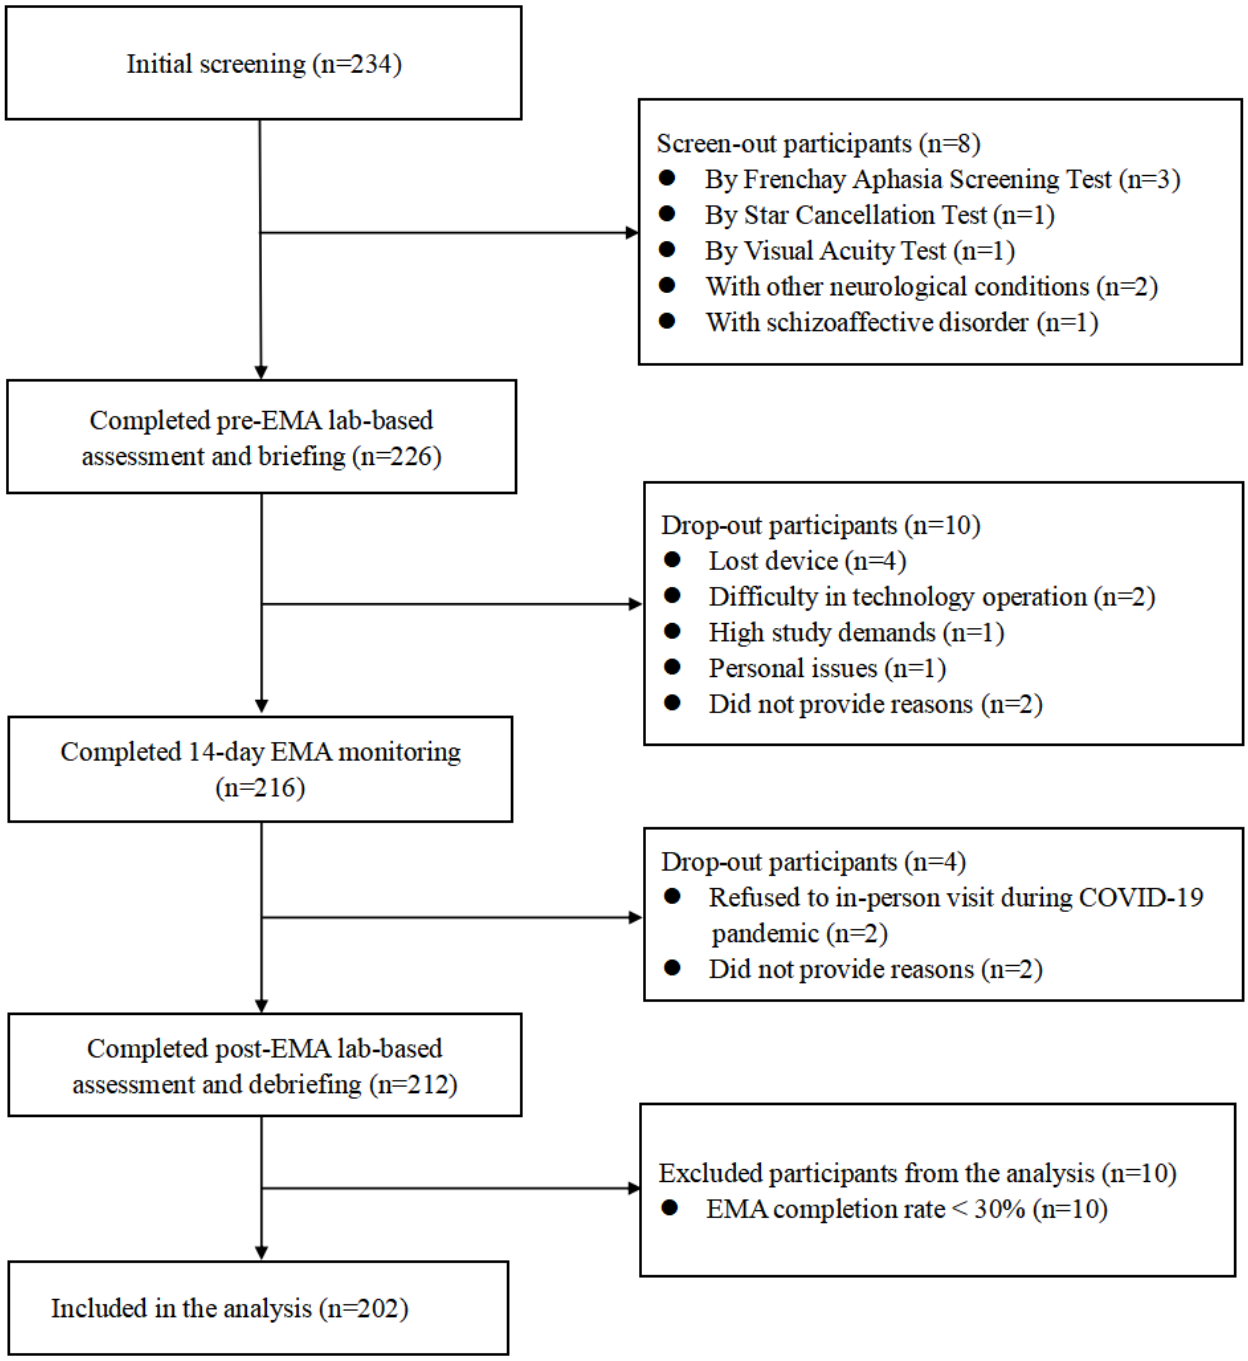
To assess participation in daily activities, participants first reported their current location (eg, home, workplace, and other) and indicated who they spent time with (eg, alone, family members, or others). The subsequent items were customized based on the participant's reported location, prompting queries about their current activities (eg, working, gardening, etc). On the basis of prior classification models [27], we categorized activities into 7 domains: physical, cognitive, social, ADL, instrumental ADL (IADL), vocational, and passive leisure activities, and further grouped them into total productive and nonproductive activities. After reporting their current activities, participants rated the activity quality in terms of the help needed, performance, satisfaction, and engagement using a 7-point scale, ranging from "no help," "not well," "not satisfied," or "not engaged" to "a lot of help," "very well," "very satisfied," or "very engaged."

To assess SCCs, participants reported their current levels using the following questions: (1) "I am having trouble concentrating" and (2) "I am having difficulty learning new tasks or instructions," with a 5-point scale ranging from "not at all" to "very much." We generated a composite score of SCCs by summing the 2 items, such that high scores indicated more cognitive concerns. These 2 items were moderately correlated (r=0.69; P<.001) [23]. Our prior research demonstrated a strong association between the EMA-measured SCCs and the Quality of Life in Neurological Disorders cognitive function (r=−0.64; P<.001) [20].

Statistical Analysis

We used descriptive statistics to examine the demographics of the study sample. Multilevel models (MLMs) examined the real-time associations between SCCs and participation in daily activities. MLMs treated data on 2 levels; EMA observations were modeled as level 1 (within-person level) nested within individuals modeled as level 2 (between-person level). All statistical tests were 2-sided, with a significance level of P<.05.

We conducted models focusing on concurrent associations, including activity type, location, the person participants were interacting with, and quality of activity as predictors of same-survey SCCs. EMA variables were centered to generate person-centered deviation scores. The centered value reflected momentary changes relative to each individual's weekly average. Centering allows the examination of within-subject and between-subject variances separately [28]. We used PROC MIXED in SAS (version 9.4; SAS Institute) to model both between-subject and within-person variances and account for autocorrelation between adjacent observations. PROC MIXED is robust in handling missing data. Thus, all data were analyzed, and random missingness was assumed [1].



Results

Participant Characteristics

Figure 1 presents the study flow diagram from enrollment to analysis. Of the 212 participants who completed the full study protocol, 10 (4.7%) were excluded because they had an EMA completion rate below 30%. The final sample consisted of 202 (95.3%) stroke survivors (n=90, 44.6% women; mean age 59.7, SD 11.7 years). We observed no significant differences in most demographic and clinical characteristics between the included and excluded participants, except that the included participants had higher global cognitive function (P=.02) and more experience with mobile device use (P=.02). Table 1 presents the details of participant characteristics. We included a total of 14,140 EMA observations for subsequent analyses.

Concurrent Relationships Between SCCs and Daily Activity Participation

Descriptive statistics on the daily activity participation, measured by EMA, were reported in our previous publication [20]. By testing the activity type from a total of 11,580 EMA observations, MLM results showed that lower SCCs were significantly associated with more time spent performing ADL (B=−0.04, 95% CI −0.07 to −0.01; *P*=.02), IADL (B=−0.05, 95% CI −0.07 to −0.02; *P*<.001), cognitively stimulating activity (B=−0.05, 95% CI −0.08 to −0.02; *P*<.001), and social activity (B=−0.05, 95% CI −0.08 to −0.02; *P*=.002) relative to passive leisure activity as the reference. We also found no significant relationships between SCCs and physical or vocational activity (Figure 2A and Table 2).

[a]EMA: ecological momentary assessment.

[b]Not applicable.

XSL•FO
RenderX

By testing the location from a total of 11,642 EMA observations, MLM results revealed that participants reported lower SCCs at the home of friends (B=−0.10, 95% CI −0.17 to −0.02; *P*=.001) but higher SCCs in the hospital, including inpatient and outpatient visits (B=0.39, 95% CI 0.25 - 0.53; *P*<.001) compared with being at home. However, the relationships between SCCs and other locations (eg, community centers and workplaces) were not robust enough to achieve significance compared with being at home (Figure 2B and Table 2).

By testing the person participants were interacting with from a total of 8860 EMA observations, MLM results indicated that participants had lower SCCs when they spent time with their family members (B=−0.07, 95% CI −0.10 to −0.04; *P*<.001), friends (B=−0.05, 95% CI −0.10 to −0.01; *P*=.01), and spouse or partners (B=−0.04, 95% CI −0.07 to −0.01; *P*=.02) when compared with being alone. We found no significant relationships between SCCs and interactions with coworkers, health care providers, and others (Figure 2C and Table 2).

Concurrent Relationships Between SCCs and Activity Qualities

By testing the activity quality from a total of 11,580 EMA observations, MLM results revealed significant associations between greater perceived performance (B=−0.05, 95% CI −0.06 to −0.05; *P*<.001), satisfaction (B=−0.05, 95% CI −0.06 to −0.05; *P*<.001), and engagement with lower SCCs (B=−0.05, 95% CI −0.06 to −0.04; *P*<.001); however, perceived help did not show a statistically significant relationship with SCCs (B=0.00, 95% CI −0.01 to 0.00; *P*=.31; Table 3).

Table . Results of multilevel models examining concurrent relationships between subjective cognitive concerns and activity quality.

Discussion

Principal Findings

This study provides the first in-the-moment examination of the relationships between SCCs and daily activity participation reported on an EMA survey in stroke survivors in naturalistic environments. With respect to our first hypothesis, the results indicated that after stroke, SCCs were not static but were experienced dynamically in daily life. Specifically, SCCs were significantly lower when performing ADL or IADL, engaging in cognitively stimulating activity, and attending social activities than when engaging in passive leisure activities among stroke survivors. Our findings align with a previous real-time assessment study by Moore et al [29], which found greater cognition and multitasking abilities were associated with less time spent in passive leisure activities among older adults living with HIV. Unexpectedly, despite existing evidence consistently indicating that cognitive impairments are linked to high levels of sedentary behavior and low levels of physical activity [30], such a relationship was not observed in this EMA study. Indeed, poststroke cognitive impairment may influence participation in physical activity [31], but the relationship is complex and may not always be direct. Other factors, such as physical limitations, psychological issues, and social support, may mediate how cognitive impairment affects physical activity participation in stroke survivors [32,33]. Further research is necessary to identify these factors as moderators or mediators and to unravel the relationship between after stroke SCCs and physical activity participation in real time.

The results revealed that SCCs were significantly lower among stroke survivors when they were at a friend's home, while higher SCCs were observed in the hospital compared with being at home. This difference may be attributed to psychological factors. As we know, people likely feel more comfortable and relaxed in the familiar surroundings of a friend's home. In contrast, an unanticipated visit to the hospital may impose additional

XSL•FO
RenderX

psychological burdens, such as stress and anxiety, leading to increased concerns of cognitive difficulties [34].

This argument can be extended to another significant finding: stroke survivors exhibited lower SCCs when spending time with family members, friends, or partners compared with when they were alone. Individuals may be more susceptible to psychological challenges when alone than when surrounded by their families and friends [35]. Other factors, such as a lack of social support and limited mobility, may further contribute to heightened SCCs in stroke survivors when they are alone [36].

It is important to recognize that the relationship between SCCs and participation in daily activities may be bidirectional. Cognitive difficulties experienced by stroke survivors can be triggered by certain activities, but these difficulties can also affect their willingness to engage in and choice of activities. For example, stroke survivors who reported higher levels of SCCs were more likely to avoid cognitively demanding activities or social interactions beyond family members and friends. Because the time-lagged relationships between SCCs and daily activity participation, such as responses from a previous EMA survey predicting responses on the current survey, have not been examined, the causal direction remains unclear. Future research could use time-lagged models to investigate these cause-and-effect relationships.

Regarding the second hypothesis, our results showed that SCCs were significantly lower when stroke survivors rated their performance, satisfaction, and engagement in daily activities as higher. It is consistent with previous research [37] indicating that cognitive impairment after stroke is closely linked to poorer performance in daily activities, suggesting that how stroke survivors rate their everyday functional limitations is closely related to their ratings of SCCs. Contrary to our hypothesis, seeking help from others was not significantly associated with SCCs. A prior study on help-seeking behaviors found that many community-dwelling stroke survivors with cognitive difficulties often hesitate to seek assistance from health care professionals. This reluctance can stem from fears of receiving a dementia diagnosis, denial of symptoms as part of “natural” aging, and limited access to care in their community [38]. These results indicate a need for screening and risk assessment of stroke survivors to prevent more severe cognitive impairments or the onset of dementia within the health care system. Future interventions should focus on ensuring that stroke survivors and their caregivers have access to support and information, as well as facilitating referrals back to specialized services if cognitive symptoms arise or persist.

Despite the contributions of this study, several limitations should be acknowledged. First, regarding our EMA survey, in-the-moment SCCs were assessed using only 2 single items. These 2 items may not provide a comprehensive measurement of cognitive functioning compared with a multi-item survey. Future studies should incorporate additional items that assess diverse cognitive domains, such as processing speed, working memory, executive functioning, and receptive and expressive language, to determine whether all types of cognitive concerns are equally significant for participation in daily activities. Furthermore, the 2 items in our study were moderately correlated, suggesting that these 2 cognitive domains may be differently associated with the daily activity predictors included in the study. Because we did not provide an option for participants to respond “not applicable” in this study, we are unable to determine whether the absence of subjective reports of cognitive difficulty reflects a lack of situational demands related to attention or learning, rather than preserved disability. This further underscores the importance of treating the association between perceived difficulties in each cognitive domain and daily activities in considerable detail to achieve a more accurate understanding of the dynamics of cognition and activity participation.

Second, two-thirds of our participants were community-dwelling individuals with neurologically mild stroke, which limits the generalizability of our results to a broader stroke population. Notably, we found that the cognitive function of participants who dropped out was significantly worse than that of participants who were included in the study, suggesting that the EMA method may not be particularly well-suited for stroke populations with more severe cognitive impairment. Similar concerns also apply to populations that lack experience with mobile devices, which significantly contributed to the dropout rate in this EMA study. Third, there may be other confounding variables affecting SCCs in stroke survivors that were not accounted for in this study, such as negative affect [21]. Future research should investigate the specific risk factors associated with developing SCCs after stroke. Additionally, while the use of EMA is a strength of this study, we only monitored participants for 14 days. It remains unclear whether these findings would hold true over a longer monitoring period.

Conclusions

The findings of this study, which used dynamic data collection methods in natural settings and involved a large sample size, support the idea that SCCs fluctuate among stroke survivors in their daily lives. Furthermore, our study highlights the importance of ongoing monitoring of cognitive concerns and daily activity functioning. This monitoring enables us to identify cognitive and functional challenges faced by individuals aging with stroke. Monitoring these factors and their dynamics in real-world contexts may ultimately help identify rehabilitation and prevention strategies for individuals at risk of dementia due to stroke.

Abstract

Background: Knee osteoarthritis (KOA) lacks disease-modifying treatment, making early identification of modifiable risk factors in asymptomatic older adults a priority. Patellar tendon stiffness (PTS) and knee extensor strength (KESt) may independently influence KOA development, yet their prognostic value in individuals free of knee symptoms is unestablished.

Objective: This study aimed to determine whether baseline extensor mechanism mechanical properties predict 2-year incident clinical KOA in community-dwelling older adults who were asymptomatic at enrollment, and to quantify the relative contribution of each parameter.

Methods: This 2-year prospective cohort study enrolled 116 community-dwelling older adults (220 knees) free of knee pain at baseline. Incident clinical KOA was diagnosed according to the American College of Rheumatology criteria. Prognostic performance was evaluated across 7 survival algorithms using 5-fold nested cross-validation with the Harrell C-index. Predictor importance was quantified using Shapley Additive Explanations (SHAP) values from the best-performing model, and absolute KOA risk was estimated across tertiles of the linear predictor score.

Results: Over 2 years, 55 (25%) knees developed incident clinical KOA. PTS and KESt were consistently selected across all cross-validation folds, whereas quadriceps muscle passive stiffness was not selected in any fold. The gradient boosted survival model achieved the highest discrimination (C-index=0.720, 95% CI 0.686-0.754), significantly exceeding chance (P<.05). SHAP analysis identified KESt as the dominant predictor (mean |SHAP| 0.314, 95% CI 0.251-0.388), with PTS as the second most important predictor (0.166, 95% CI 0.128-0.200). Knees in the highest-risk tertile showed a 24-month KOA incidence of 38.4% (28/73), which was more than twice that in the lowest-risk tertile (13/74, 17.6%).

Conclusions: PTS and KESt independently and consistently predicted 2-year incident clinical KOA in asymptomatic community-dwelling older adults. Extensor mechanism mechanical profiling may identify individuals at elevated KOA risk prior to symptom onset, although these exploratory findings require confirmation in larger cohorts before KESt and PTS can be considered for screening or preventive intervention.

Introduction

Knee osteoarthritis (KOA) is among the most prevalent musculoskeletal conditions affecting older adults worldwide, with an estimated 595 million individuals affected globally in 2020 and projections indicating a 74.9% increase by 2050 [1]. This condition is associated with substantial functional limitation and currently lacks disease-modifying pharmacological treatment [2], making early identification of modifiable prognostic markers in asymptomatic community-dwelling older adults a research priority. Among the candidate domains, biomechanical factors governing tibiofemoral load distribution are among the most modifiable determinants of KOA onset, and the extensor mechanism represents a primary target given its central role in dynamic knee joint stabilization during weight-bearing activities [3,4].

XSL•FO
RenderX

The extensor mechanism of the knee, comprising the quadriceps muscle group and the patellar tendon, functions to extend the tibiofemoral joint through coordinated muscular force transmission to the tibial tuberosity [5]. Although historically conceptualized as a simple pulley system, biomechanical evidence indicates that it operates as a mechanically complex unit in which the quadriceps musculature and patellar tendon function interdependently [3,5,6]. Three mechanical properties within this integrated system have each been independently supported by prospective evidence as contributors to KOA-related pathology: knee extensor strength (KESt), quadriceps muscle passive stiffness (QMPS), and patellar tendon stiffness (PTS).

KESt is a modifiable risk factor for KOA development. A systematic review and meta-analysis of 46,819 participants demonstrated that quadriceps weakness is a robust prospective risk factor for KOA [7], and a meta-analysis of 15 longitudinal studies found that lower KESt was associated with symptomatic progression in established KOA [8]. Reduced KESt has been associated with increased peak tibiofemoral contact forces and impaired joint stabilization during dynamic loading, which may contribute to articular cartilage degeneration [9-11]. Increased QMPS is a recognized consequence of aging arising from changes in viscoelastic tissue properties and intramuscular connective tissue deposition [12,13], and prospective evidence demonstrates that baseline QMPS is independently associated with incident clinical KOA over 12 to 24 months in community-dwelling older adults [14,15]. Although PTS generally declines with age due to structural degeneration [16], substantial interindividual variation persists even among asymptomatic older adults [17]. This interindividual variation in PTS among asymptomatic older adults may reflect subclinical differences in tendon mechanical integrity prior to symptom onset, and reduced patellar tendon elasticity has been observed in individuals with established KOA compared to asymptomatic controls [18].

Although these 3 parameters have each been examined as individual predictors in separate prospective studies, no study has simultaneously evaluated their combined predictive value, and existing approaches have relied predominantly on conventional regression methods that assume prespecified linear relationships and may not adequately characterize the nonlinear interactions likely to be present among mechanically interdependent predictors [19,20]. Unlike conventional Cox regression, which requires prespecified functional forms for each predictor, ensemble-based machine learning survival algorithms adapt to the structure of the data without assumptions about linearity or additivity and are capable of detecting complex interactions among simultaneously entered predictors. When applied within nested cross-validation frameworks with permutation-based significance testing, these methods provide discrimination estimates that are less susceptible to optimism bias than conventional regression concordance statistics [19], and Shapley Additive Explanations (SHAP) values further allow the relative contribution of each predictor to be quantified within the context of the full predictor set [21].

The purpose of this study was to determine whether baseline KESt, QMPS, and PTS, assessed in community-dwelling older adults who were asymptomatic at enrollment, predict the 2-year incidence of clinical KOA. Secondary aims were to quantify the relative prognostic contribution of each mechanical parameter through SHAP decomposition and to estimate absolute clinical KOA risk across predicted risk tertiles. We hypothesized that at least 1 of the fitted survival models would achieve a C-index of ≥0.70, indicating acceptable discrimination for the 2-year incidence of clinical KOA.

Methods

Study Design and Participants

This study used data from a 2-year prospective cohort study conducted between November 2018 and October 2019. Community-dwelling older adults aged 60 to 80 years who were able to walk 10 meters independently were recruited from local communities. Individuals were excluded if they reported hip, knee, or ankle pain at baseline, had a history of knee injury requiring medical treatment, demonstrated cognitive impairment based on the Montreal Cognitive Assessment, or had a diagnosed neurological condition. Of 225 participants (450 knees) assessed for eligibility, 142 (63%) participants (271/450, 60% knees) met the inclusion criteria. Following the exclusion of knees with missing follow-up data for clinical KOA, 49% (220/450) of knees from 52% (116/225) of participants were included in the present analysis.

A formal a priori sample size calculation was not performed, as this study used data from an existing prospective cohort. The study sample comprised 55 incident clinical KOA events, corresponding to an events-per-variable (EPV) ratio of 9.2 for the primary model. Although this was marginally below the commonly cited threshold of 10, simulation evidence demonstrates that EPV values of 5 to 10 produce acceptable parameter estimation when predictors are continuous and prespecified on theoretical grounds rather than identified through data-driven exploration [22], both of which apply to the present predictor set. Because knees were clustered within participants, we additionally quantified the effective information size. The 55 knee-level events occurred in 31% (36/116) of participants (17/36, 47% unilateral and 19/36, 53% bilateral). The within-participant correlation of the clinical KOA outcome between the 2 knees of a participant was high (intraclass correlation coefficient [ICC] 0.91), corresponding to a design effect of 1.82 and a clustering-adjusted effective EPV of 5.0, which we regarded as the lower bound for interpreting model stability.

Ethical Considerations

The study was approved by the Human Subjects Ethics Sub-committee of the Hong Kong Polytechnic University (HSEARS20180110001), and all participants provided written informed consent prior to participation in accordance with the Declaration of Helsinki.

Baseline Predictor Measurements

The primary predictor set comprised 3 extensor mechanism mechanical properties, each selected on the basis of independent prospective evidence linking it to KOA-related pathology: PTS, QMPS, and KESt [7,14,15,18]. Age, sex, and BMI were

XSL•FO
RenderX

included as covariates. Full measurement protocols, equipment specifications, and reliability data are provided in Multimedia Appendix 1.

PTS (kPa) was measured using shear-wave ultrasound elastography (Aixplorer version 4.2; Hologic Inc), with participants positioned supine and the knee flexed to 30° [23]. After 5 minutes of rest to unload tendon tension, the patellar tendon was located longitudinally using B-mode ultrasonography. Shear elastic modulus was calculated using the equation $E=3\rho c^2$, where ρ is tissue density (1000 kg/m³), and c is shear wave velocity. Three measurements were obtained and averaged. Intrarater reliability was excellent (ICC 0.98) [23].

QMPS (kPa) was defined as the unweighted mean shear modulus of the rectus femoris, vastus lateralis, and vastus medialis, each measured by shear-wave ultrasound elastography at standardized anatomical sites with the knee at 60° flexion [15]. This composite formulation was adopted to reduce the predictor count relative to the number of outcome events, thereby improving the EPV ratio. Intercorrelations among the 3 component muscles were moderate (r=0.34-0.47), supporting their aggregation into a single composite index. Intrarater reliability was excellent across all sites (ICC 0.89-0.94) [15].

KESt (Nm/kg) was assessed as isokinetic peak torque at 60°/s using an isokinetic dynamometer (Cybex Co), with participants seated and the dynamometer axis aligned with the lateral femoral epicondyle [10]. Peak torque values from the middle 3 of 5 maximal concentric contractions were averaged and normalized to body mass. All 3 mechanical predictors were measured separately on the left and right limbs, and each knee's predictor values were linked to the incident clinical KOA outcome of the corresponding knee, so that every knee contributed a self-contained set of limb-specific predictors and an outcome.

Outcome: Incident Clinical KOA

All participants were invited for in-person clinical examination between 12 and 24 months after baseline assessment, with the specific timing of each visit recorded for time-to-event analysis. Clinical examinations were performed by a single experienced physiotherapist blinded to all baseline measurements. Clinical KOA was diagnosed according to the American College of Rheumatology (ACR) clinical classification criteria [15,24,25]. Given that all participants were aged >60 years, a knee was classified as having clinical KOA if it demonstrated knee pain with an intensity of Visual Analog Scale (VAS) ≥3/10 during the examination and any 2 of the following 5 features: morning stiffness lasting <30 minutes, crepitus on active joint motion, bony tenderness on palpation, bony enlargement on inspection or palpation, or absence of palpable warmth of the synovium [15]. Knees that did not meet these criteria at the time of examination were recorded as event-free, with follow-up time defined as the time from baseline to the clinical examination visit. Pain intensity and each physical examination finding were assessed and recorded separately for the left and right knee, and the classification criteria were applied to each knee independently, so that a participant could be classified as having incident clinical KOA in 1 knee, both knees, or neither.

Machine Learning Approaches and Statistical Analysis

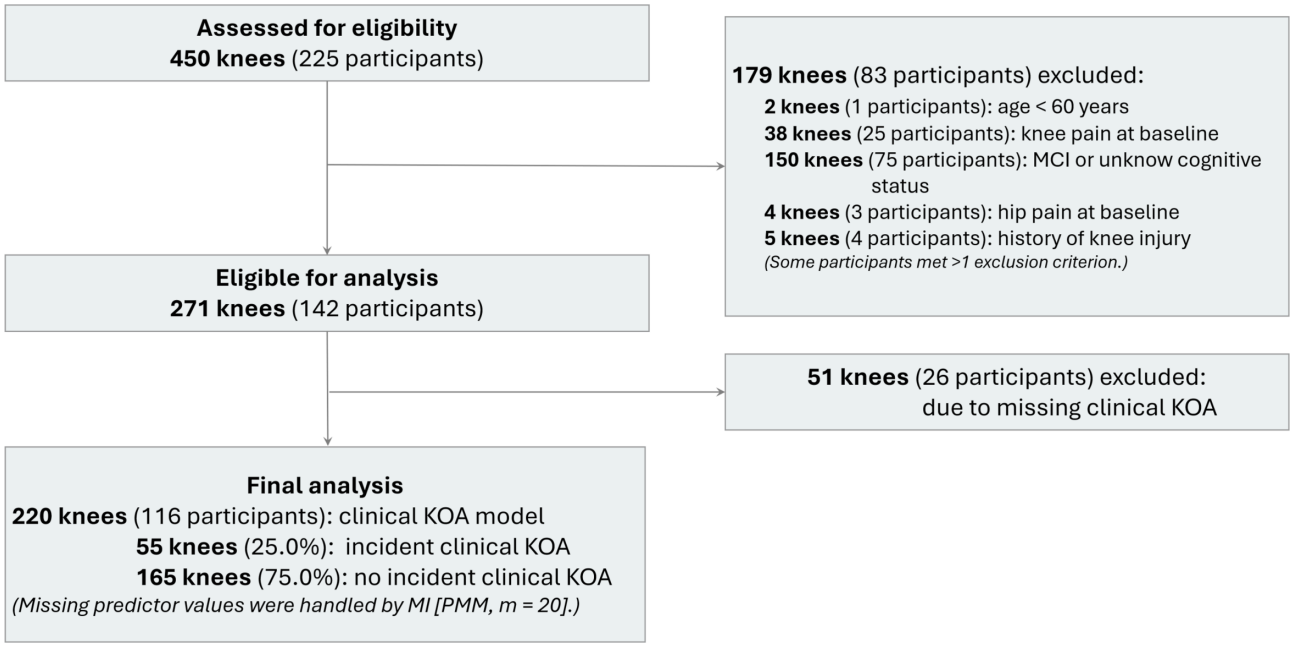
All analyses were performed using R (version 4.5.2; R Foundation for Statistical Computing). Missing predictor data (maximum 2.73% per variable) were handled using multiple imputation by chained equations (m=20 datasets, predictive mean matching), with estimates pooled using Rubin rules [26]. The primary predictor set comprised PTS, QMPS, and KESt, adjusted for age, sex, and BMI, producing an EPV ratio of 9.2, considered acceptable for prespecified predictors with strong theoretical priors [22].

Seven survival prediction algorithms were compared: cluster-robust Cox proportional hazards regression (Cox_CR) SEs as the statistical reference, accounting for within-person correlation between bilateral knees [27]; Least Absolute Shrinkage and Selection Operator (LASSO)–penalized Cox regression (LASSO_Cox) [28]; ElasticNet-penalized Cox regression (ElasticNet_Cox) [29]; random survival forest (RSF); gradient boosting survival (GBS) and componentwise LASSO GBS (LGBS) [30]; and a regression-type survival support vector machine (SurvSVM) with a radial basis function kernel [31]. All hyperparameters were optimized within each outer training fold via dedicated inner cross-validation, ensuring that no test-fold observations influenced parameter selection (Multimedia Appendix 2). Prior to hyperparameter tuning, a LASSO-penalized Cox model with 5-fold inner cross-validation (lambda.1se criterion) was applied within each outer training fold to select a parsimonious feature subset, ensuring that variable selection was entirely independent of test-fold observations.

All algorithms were evaluated using 5-fold nested cross-validation, with folds stratified at the participant level by event status to prevent data leakage from bilateral knee observations (Multimedia Appendix 3). Predictor subsets were identified within each outer fold via inner LASSO_Cox, and the selected predictors were then passed to all algorithms. Discrimination was quantified using Harrell C-index (mean across 5 folds; 95% CIs from fold-level SEs), and a participant-level permutation test (999 permutations) was used to confirm that the best-performing model exceeded chance.

Calibration and predictor importance were assessed in a participant-level held-out 20% test set. Calibration at 24 months was evaluated by comparing Kaplan-Meier–observed with model-predicted clinical KOA probabilities across 3 risk tertiles, supplemented by the inverse probability of censoring-weighted Brier score [32]. Predictor contributions were quantified using SHAP values with a Monte Carlo approximation, and directionality was confirmed from hazard ratios (HRs) estimated in a cluster-robust Cox model on the same training partition. The study sample was additionally stratified into low, intermediate, and high clinical KOA risk tertiles by linear predictor score, with 24-month Kaplan-Meier incidence estimated for each tertile. Sex-stratified C-indices were reported with bootstrap 95% CIs, and a sex-by-predictor interaction term was tested in a cluster-robust Cox model. Within-participant correlation between bilateral knees was handled consistently across all components of the analysis. Both knees of a participant were always kept together within the same partition: the nested

XSL•FO
RenderX



cross-validation folds and the final 80-20 held-out split were assigned at the participant level, so that no participant contributed knees to both the training and evaluation sets. Consequently, all machine learning algorithms, the C-index, calibration, and the inverse probability of censoring-weighted Brier score were trained and evaluated on participant-disjoint partitions, and SHAP values were computed only on the held-out test set. In the permutation test, outcome labels were permuted at the participant level so that both knees of a participant received the same permuted status, preserving the clustered data structure under the null. The Cox reference model additionally used cluster-robust SEs. As a sensitivity analysis, we repeated the modeling with each participant contributing a single observation, collapsing each participant to their more affected knee (the knee with incident clinical KOA, or, when both knees were concordant, the knee with the higher PTS). We then compared the discrimination of this participant-level model with that of the primary knee-level model on a common participant-level held-out test set and tested the difference in C-index using a bootstrap resampling procedure at the participant level.

Results

Participant Characteristics

The analytic sample comprised 220 knees from 116 participants, of whom 55 (25%) knees developed incident clinical KOA over the 2-year follow-up (Figure 1). Missing predictor data were minimal (maximum 2.73% per variable; Multimedia Appendix 4) and handled using multiple imputation. Groups did not differ significantly in age, sex, or BMI. At baseline, knees that subsequently developed clinical KOA showed significantly higher PTS (51.1 vs 40.0 kPa; *P*=.046) and lower KESt (1.14 vs 1.29 Nm/kg; *P*=.01) than knees that did not develop clinical KOA. QMPS did not differ between groups (*P*=.54; Table 1). Intercomponent correlations among the 3 quadriceps stiffness measures were moderate (Spearman *r*=0.344-0.472), supporting their aggregation into a single composite variable (Multimedia Appendix 5). Because clinical KOA is diagnosed at the level of the individual knee and the 2 knees of a participant can differ in both their mechanical properties and their outcome, each knee was treated as a separate observational unit, and incident clinical KOA was ascertained and counted per knee. The 55 incident knee-level events occurred in 36 participants, 47% (17/36) developed clinical KOA in 1 knee (unilateral) and 53% (19/36) in both knees (bilateral); within-participant correlation between paired knees was accounted for in all analyses.

Figure 1. Participant flow diagram. A total of 450 knees (225 participants) were screened for eligibility. Following application of the exclusion criteria, 60% (271/450) of knees (142/225, 63% participants) were eligible for analysis. After exclusion of knees with missing follow-up data for the clinical KOA outcome (51/450, 11% knees from 26/225, 12% participants), 49% (220/450) of knees (116/225, 52% participants) were included in the final analytic sample. Missing predictor data (maximum 2.73% per variable) were handled using multiple imputation by chained equations. KOA: knee osteoarthritis; MCI: mild cognitive impairment; MI: multiple imputation; PMM: predictive mean matching.

Table . Baseline characteristics of the analytic sample stratified by 2-year incident clinical knee osteoarthritis (KOA; N=220 knees from 116 participants)[a].

Characteristics	No KOA (n=165)	KOA (n=55)	*P* value[b]	Effect size (95% CI)[c]
Age (years), mean (SD)	65.7 (3.6)	66.0 (3.6)	.67	0.07 (−0.24 to 0.37)
Sex: female, n (%)	102 (62)	35 (64)	.94	0.01 (1.08; 0.57 to 2.04)
BMI (kg/m^2), mean (SD)	23.5 (3.2)	23.9 (3.1)	.46	0.11 (−0.19 to 0.42)
Quadriceps composite stiffness (kPa), mean (SD)	7.21 (1.77)	7.40 (2.04)	.54	0.10 (−0.20 to 0.41)
Patellar tendon stiffness (kPa), mean (SD)	40.0 (22.3)	51.1 (38.2)	.046[d]	0.41 (0.10 to 0.71)
Knee extension strength (Nm/kg), mean (SD)	1.29 (0.32)	1.14 (0.36)	.01[d]	−0.43 (−0.74 to −0.12)

[a]Both knees from each participant were included as independent observational units; 116 participants contributed 220 knees. Demographic variables reflect participant-level data, whereas mechanical variables reflect knee-level data.

[b]Between-group comparisons were performed using an independent *t* test for continuous variables and a chi-square test for categorical variables.

[c]Effect size is Cohen *d* with 95% CI for continuous variables; positive values indicate a higher mean in the KOA group. For sex, Cramer V (odds ratio; 95% CI) is reported. Standardized effect sizes with CIs are reported in preference to post hoc statistical power.

[d]*P*<.05.

Feature Selection

LASSO-penalized inner Cox regression consistently selected PTS and KESt in all 5 outer cross-validation folds (5/5 each). QMPS was not selected in any fold (0/5). In 1 fold, age and sex were additionally selected alongside the 2 mechanical predictors (Multimedia Appendix 6).

Model Discrimination

All penalized and ensemble algorithms exceeded the null model (C=0.500; Figure 2). GBS achieved the highest discrimination (C=0.720, 95% CI 0.686-0.754), followed closely by LGBS (C=0.718, 95% CI 0.683-0.752) and Cox_CR (C=0.715, 95% CI 0.679-0.750; Table 2). RSF showed comparable mean discrimination (C=0.665) but substantially greater fold-level variability (SD 0.185) than all other algorithms (Multimedia Appendix 7). SurvSVM performed below chance level (C=0.415). Both GBS and Cox_CR significantly exceeded chance-level discrimination by permutation test (*P*<.01; Multimedia Appendix 8).

XSL•FO
RenderX

Figure 2. Machine learning model performance and predictor importance for clinical knee osteoarthritis (KOA) prediction. (A) Forest plot of Harrell C-index values for 7 algorithms (5-fold nested cross-validation; n=220 knees, 55 events). Diamond points and bars represent the mean C-index and 95% CI across folds; the dashed line represents the null model (C=0.50). Gradient boosting survival (GBS) achieved the best discrimination (C=0.720, 95% CI 0.686-0.754; permutation *P*<.01). (B) Mean absolute Shapley Additive Explanations (SHAP) values for the GBS model in the held-out test set; error bars represent the bootstrap 95% CI. Knee extensor strength (KESt) was the dominant predictor (0.314, 95% CI 0.251-0.388), followed by patellar tendon stiffness (PTS), ranked second (0.166, 95% CI 0.128-0.200). (C) SHAP beeswarm plot; each point represents 1 knee, with color indicating feature value (red=high and blue=low). (D) Partial dependence plots for KESt (left) and PTS (right); shaded bands represent the 95% CI. Cox_CR: cluster-robust Cox proportional hazards regression; LGBS: LASSO gradient boosting survival; RSF: random survival forest; SurvSVM: survival support vector machine.

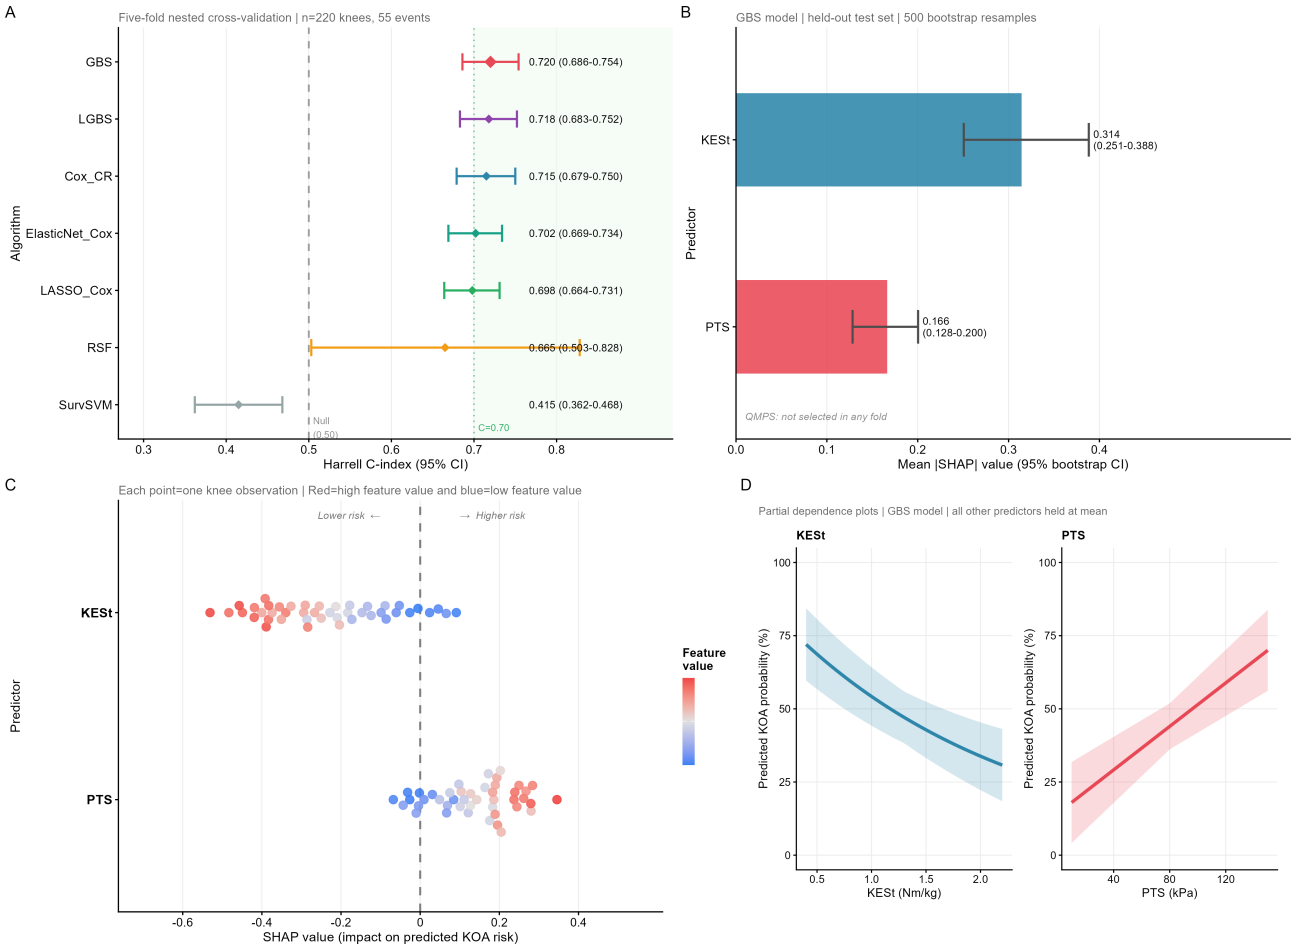

Table . Discrimination performance (Harrell C-index) of 7 survival prediction algorithms evaluated using 5-fold nested cross-validation (n=220 knees, 55 events)[a].

Algorithms	C-index, mean (SD)	95% CI
Cluster-robust Cox proportional hazards regression	0.715 (0.040)	0.679-0.750
LASSO[b]-penalized Cox regression	0.698 (0.038)	0.664-0.731
ElasticNet-penalized Cox regression	0.702 (0.037)	0.669-0.734
Random survival forest	0.665 (0.185)	0.503-0.828
Gradient boosting survival[c]	*0.720 (0.039)*	*0.686-0.754*
Componentwise LASSO gradient boosting survival	0.718 (0.040)	0.683-0.752
Survival support vector machine	0.415 (0.060)	0.362-0.468

[a]C-indices are means across 5 outer folds; 95% CI derived from fold-level SEs. Folds were stratified at the participant level by event status.

Predictor Importance and Directionality

SHAP analysis of the GBS model in the held-out test set identified KESt as the dominant predictor (mean |SHAP|=0.314, 95% CI 0.251-0.388), with higher strength consistently associated with lower clinical KOA risk across individual observations (Figure 2). PTS was the second most important contributor (mean |SHAP|=0.166, 95% CI 0.128-0.200), with higher stiffness associated with higher clinical KOA risk. Partial dependence plots confirmed monotonic dose-response relationships for both predictors in the expected directions (Figure 2). These directional findings were further confirmed by cluster-robust Cox HRs estimated on the same training partition: HR of 0.221 (95% CI 0.081-0.601; *P*=.02) for KESt and HR of 1.012 (95% CI 1.002-1.021; *P*=.049) for PTS (Table 3).

Table . Feature selection frequency, Shapley Additive Explanations (SHAP) predictor importance, and directionality for the gradient boosting survival model[a].

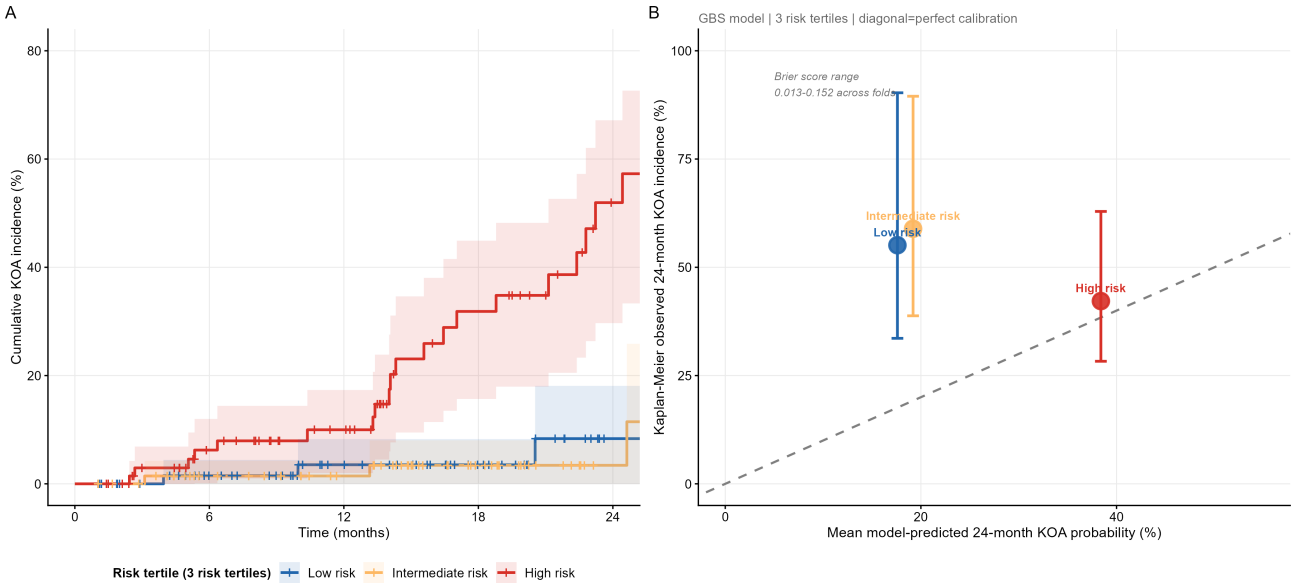
Predictors	Selection frequency	SHAP rank	Mean |SHAP| (95% CI)[b]	Hazard ratio (95% CI)[c]	Direction
Knee extension strength (Nm/kg)	5/5	1	0.314 (0.251-0.388)	0.221 (0.081-0.601)[d]	Higher to lower risk
Patellar tendon stiffness (kPa)	5/5	2	0.166 (0.128-0.200)	1.012 (1.002-1.021)[d]	Higher to higher risk
Quadriceps composite stiffness (kPa)	0/5	—[e]	—	—	Not selected

[a]Feature selection was performed via Least Absolute Shrinkage and Selection Operator–penalized Cox regression (lambda.1se) independently within each outer training fold.

[b]Mean absolute SHAP values and 95% CI were derived from 500 bootstrap resamples (200 Monte Carlo simulations).

[c]Hazard ratios and 95% CI were estimated from a cluster-robust Cox model on the same training partition.

[d]*P*<.05.



[e]Not applicable (because the predictor was not selected in any fold).

Absolute Risk Stratification and Calibration

The inverse probability of censoring-weighted Brier score at 24 months ranged from 0.013 to 0.152 across folds (Multimedia Appendix 9). Although fold-level variability in the Brier score was observed, mean model-predicted probabilities were broadly consistent with Kaplan-Meier–observed incidence across risk tertiles, indicating acceptable calibration at the group level. Stratification into low, intermediate, and high clinical KOA risk tertiles by GBS linear predictor score generated 24-month clinical KOA incidence rates of 17.6% (13/74), 19.2% (14/73), and 38.4% (28/73), respectively, with the high-risk group showing more than twice the event rate of the low-risk group (Figure 3, Multimedia Appendix 10). Model-predicted probabilities were broadly consistent with Kaplan-Meier–observed incidence across tertiles (Figure 3, Multimedia Appendix 11).

XSL•FO
RenderX

Figure 3. Absolute risk stratification and model calibration. (A) Kaplan-Meier knee osteoarthritis (KOA)–free survival curves stratified by gradient boosting survival (GBS) linear predictor risk tertile (n=220 knees, 116 participants). Low-risk tertile (n=74 knees, 47 participants, 13 events), intermediate-risk tertile (n=73 knees, 57 participants, 14 events), and high-risk tertile (n=73 knees, 48 participants, 28 events). The 24-month KOA incidence was 17.6% (13/74), 19.2% (14/73), and 38.4% (28/73) in the low-, intermediate-, and high-risk tertiles, respectively. Shaded areas represent the 95% CI. Risk tables below the panel indicate the number of knees remaining at risk at each time point. (B) Calibration plot at 24 months comparing mean model-predicted KOA probability with Kaplan-Meier–observed incidence across the 3 risk tertiles. Error bars represent 95% CI. The diagonal dashed line represents perfect calibration. The inverse probability of censoring-weighted Brier score at 24 months ranged from 0.013 to 0.152 across folds.

Sensitivity Analysis

The GBS model demonstrated consistent discrimination in male (C=0.727, 95% CI 0.564-0.835) and female (C=0.748, 95% CI 0.663-0.826) subgroups. A formal sex-by-predictor interaction term in a cluster-robust Cox model was nonsignificant (*P*=.49), indicating no meaningful effect modification by sex (Multimedia Appendix 12, Multimedia Appendix 13). In the participant-level sensitivity analysis, in which each participant contributed a single knee, discrimination on the common held-out test set was similar to that of the primary knee-level model (C=0.685 vs 0.731). The difference in C-index was not statistically significant (difference=0.046, 95% CI −0.096 to 0.162; *P*=.50). The direction of the predictor associations was preserved, with higher PTS associated with higher risk (HR 1.013; *P*=.01) and higher KESt associated with lower risk (HR 0.244; *P*=.02). These results indicate that the main findings are not an artifact of treating the 2 knees of a participant as independent observations.

Discussion

Principal Findings

In this 2-year prospective cohort study of community-dwelling older adults who were asymptomatic at enrollment, KESt and PTS were consistently identified as prognostic predictors of incident clinical KOA across all cross-validation folds, with the prespecified discrimination threshold of C-index ≥0.70 being met. To our knowledge, prospective time-to-event evidence linking higher PTS to incident clinical KOA has not previously been reported, and the present findings extend the existing literature by simultaneously quantifying the relative prognostic contributions of KESt and PTS within the same predictor set.

KESt emerged as the dominant predictor across all model interpretability metrics, with higher strength associated with lower KOA risk. This direction is consistent with prospective evidence that quadriceps weakness predicts KOA onset and progression [7,8,11] and extends those findings by quantifying the contribution of KESt within a simultaneously entered extensor mechanism predictor set. The cluster-robust Cox HR on the training partition (HR 0.221, 95% CI 0.081-0.601) was consistent in direction with previous studies [33,34]. Partial dependence analysis confirmed a monotonic dose-response relationship between KESt and predicted KOA risk, indicating a graded rather than threshold effect, which supports the inference that KESt may be a modifiable factor worth investigating as a potential target for preventive intervention in asymptomatic older adults at elevated KOA risk.

Greater baseline PTS was independently associated with a higher 2-year incidence of clinical KOA. A previous study examining PTS in participants with KOA was limited to cross-sectional designs, which cannot establish whether altered tendon mechanical properties precede or follow structural joint changes [18]. The present findings address this gap by demonstrating that PTS measured in asymptomatic older adults prior to any KOA diagnosis carries independent prognostic information over a 2-year follow-up period. From a mechanical perspective, a stiffer patellar tendon has been proposed to absorb less of the peak force produced during dynamic loading, resulting in higher tibial contact forces during locomotion [16]. Sustained elevation of tibiofemoral contact stress is a recognized contributor to articular cartilage degeneration, and patellar tendon enthesis abnormalities assessed on magnetic resonance imaging (MRI) have been shown to be associated with both knee pain and structural abnormalities in community-dwelling older adults [35], indicating that mechanical alterations at the tendon-bone

XSL•FO
RenderX

interface may contribute to the pathological process leading to clinical KOA. Structural patellar tendon abnormalities are prevalent even in asymptomatic individuals, estimated at 22% to 36% across imaging modalities and populations [36], and the present findings suggest that mechanical stiffness carries prognostic information that is not fully explained by structural abnormality alone. It should be noted that shear-wave elastography provides a measure of tissue shear modulus as an index of passive mechanical stiffness, which is distinct from direct assessment of tendon viscoelasticity, thickness, or tensile properties. Future studies incorporating multiple indices of patellar tendon mechanical behavior may more comprehensively characterize the relationship between tendon properties and KOA risk. Whether age-related changes in tendon elasticity, cumulative mechanical loading history, or physical activity levels contribute to the elevation in PTS that preceded KOA onset in the present cohort warrants investigation in future studies with longer follow-up and serial tendon assessments. In contrast, QMPS was not selected in any cross-validation fold, suggesting that passive muscle stiffness at rest may lack independent prognostic value once active force-generating capacity and tendon mechanical properties are simultaneously accounted for. This pattern indicates that the prognostic signal within the extensor mechanism is carried primarily by its active and structural components rather than by passive muscle stiffness in isolation.

The application of survival analysis with predictor importance decomposition to this prediction problem produced 3 findings of clinical relevance. First, the consistency of predictor selection across all 5 cross-validation folds indicates that PTS and KESt carry a stable prognostic signal independent of data partition. Second, SHAP-based decomposition quantified the relative contribution of each predictor without imposing prespecified functional forms, identifying KESt as contributing approximately twice the predictive weight of PTS. Partial dependence analysis confirmed that both relationships were monotonic, indicating that the associations are adequately characterized by graded, directional effects rather than nonlinear interactions. The primary value of the analytical approach in the present study lies in its capacity to simultaneously rank predictor contributions and verify functional form assumptions without requiring a priori specification. Finally, risk stratification by linear predictor score identified a high-risk tertile with a 24-month KOA incidence more than twice that of the low-risk tertile. This gradient suggests that older adults with concurrently low KESt and high PTS constitute an identifiable subgroup for whom targeted preventive strategies, including quadriceps strengthening and tendon loading programs, may warrant priority consideration, pending confirmation in prospective interventional designs.

Several limitations of this study should be acknowledged. First, clinical KOA was diagnosed according to ACR clinical classification criteria without radiographic confirmation, which precludes direct comparison with studies using Kellgren-Lawrence grading as the outcome and may have introduced misclassification at the diagnostic boundary. Second, the study was conducted in a single community-based cohort, and external validation in an independent cohort is required before the risk stratification thresholds reported here can be considered for clinical application. Third, the 12-to-24–month follow-up window may be insufficient to capture the full spectrum of KOA incidence in an asymptomatic older population, given the typically prolonged natural history of the disease. Fourth, PTS was measured at 30° knee flexion with the tendon in a partially unloaded state, which may not fully reflect the functional stiffness experienced during weight-bearing activities. Finally, the nominal EPV ratio of 9.2 was calculated from the 55 knee-level events, marginally below the conventional threshold of 10, which may have introduced instability in the penalized regression estimates, particularly in folds with fewer events. Moreover, because the 55 knee-level events were clustered within 36 participants, the effective number of independent outcome events was smaller than the nominal count (clustering-adjusted effective EPV 5.0). Although a participant-level sensitivity analysis produced discrimination that did not differ significantly from the knee-level model, this clustering reduces the effective information available for model estimation, and the findings should therefore be regarded as exploratory pending validation in larger independent cohorts. Replication in larger prospective cohorts with longer follow-up and radiographically confirmed outcomes is required to determine the generalizability of the extensor mechanism mechanical profiling approach.

Conclusions

In community-dwelling older adults free of knee symptoms at baseline, KESt and PTS were independently and consistently associated with 2-year incident clinical KOA, whereas QMPS was not retained as a prognostic predictor once KESt and PTS were simultaneously accounted for. Risk stratification based on extensor mechanism mechanical properties identified a subgroup with a 24-month KOA incidence more than twice that of the lowest-risk group, suggesting that baseline mechanical profiling of the extensor mechanism may provide clinically meaningful prognostic information prior to symptom onset. These findings support KESt and PTS as candidate targets that warrant further investigation. Given the modest sample, the clustered knee-level structure, and the reduced effective event count, these findings should be interpreted as exploratory and preliminary rather than as support for immediate use of these parameters in screening or preventive intervention. Confirmation in larger independent cohorts with radiographically confirmed outcomes is required before any clinical application.

Abstract

Background: Prior research has rarely explored the link between sleep duration trajectories and cardiovascular disease (CVD) either in cross-sectional or longitudinal data.

Objective: We aimed to analyze the relationship between sleep duration trajectories and the incidence of CVD.

Methods: Data from 5603 participants in the China Health and Retirement Longitudinal Study (CHARLS) were used in the analysis. Sleep duration was self-reported at multiple time points, and group-based trajectory modeling identified distinct patterns of total and nocturnal sleep duration over time. To investigate the link among sleep duration trajectories and CVD, Cox proportional hazards models, restricted cubic splines, and mediation analyses were used, with sensitivity analyses ensuring the results' robustness.

Results: Four sleep duration trajectories were identified, including steady high, inverted U-shaped, steady low, and U-shaped. In fully adjusted models, an inverted U-shaped sleep trajectory was associated with a 34% higher risk of hypertension compared with the steady high group (total sleep: hazard ratio [HR]=1.34, 95% CI 1.07 - 1.69; *P*=.01). Notably, the inverted U-shaped sleep trajectory showed a 110% increased stroke risk during nocturnal periods compared to the steady high group (nocturnal sleep: HR=2.10, 95% CI 1.08 - 4.05; *P*=.03). The findings remained consistent across a range of sensitivity analyses. Hypertension was identified as a partial mediator of the association between sleep instability and stroke risk.

Conclusions: The findings indicate that an inverted U-shaped sleep pattern is associated with increased cardiovascular risk, partially mediated by hypertension, highlighting sleep stability as a potential preventive target.

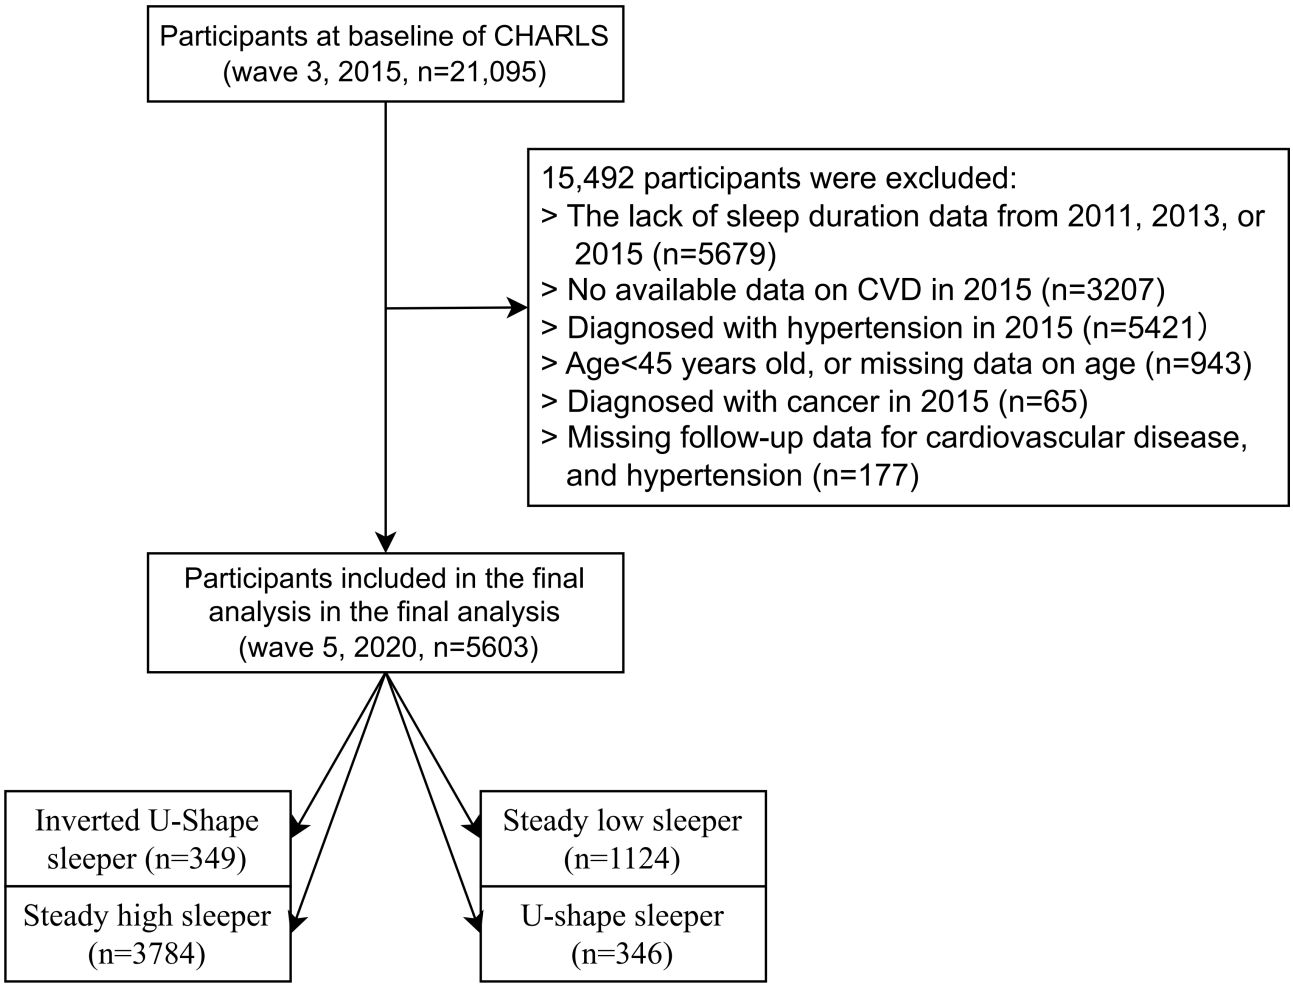
Introduction

Due to longer life expectancy and declining fertility rates, the global population aged 60 years and older is expected to rise from 12% to 22% between 2015 and 2050 [1]. China, one of the fastest-aging countries, will see the percentage of people aged >60 years grow from 12.4% in 2010 to 28% by 2040, reaching around 397 million [2]. Cardiovascular diseases (CVD) [3], including hypertension [4], stroke [5], and heart diseases [6], are particularly significant, as they represent leading causes of morbidity and mortality in older adults [7]. As the aging population increases, the burden of CVD will intensify, placing additional pressure on health care systems globally. In light of this, strategies to improve cardiovascular health and promote healthy aging are essential to reduce the impact of these diseases and enhance the quality of life for older adult individuals.

Insufficient or excessive sleep has been linked to adverse outcomes [8], including mood disorders [9], cognitive frailty [10], cancers [11], and even mortality [12]. Recent studies have shown that sleep abnormalities, including both deprivation and excessive sleep, negatively impact physiological functions and notably increase the risk of CVDs. Both short and long sleep durations are strongly linked to an elevated risk of coronary heart disease [13] and stroke [14]. Short sleep duration is

XSL•FO
RenderX

strongly associated with a higher incidence of hypertension, while the link between long sleep duration or difficulty falling asleep and hypertension remains inconclusive [15]. Although these studies explored the link between sleep duration and CVD, their conclusions were mixed. Most research relies on cross-sectional surveys and neglects the continuous development of sleep duration, offering an incomplete view of how it changes throughout life. This gap is particularly pertinent in middle-aged and older adults, where sleep patterns often change due to physiological, psychological, and social factors. Tracking these changes over time, rather than using a single measurement, is crucial for understanding their role in CVD development.



In light of these concerns, this study seeks to investigate the association between sleep duration trajectories and CVD outcomes in Chinese middle-aged and older adults (the China Health and Retirement Longitudinal Study [CHARLS]). By using a longitudinal dataset, we aim to identify distinct sleep trajectories over time and examine their potential role in the onset of CVD. This research not only contributes to the growing body of literature on sleep and health outcomes but also has important implications for public health strategies aimed at improving the quality of life and reducing the burden of CVD among the aging population.

Methods

Study Design and Participants

This nationally representative longitudinal survey, CHARLS, is designed to explore the health and economic status of Chinese people aged 45 years and older [16]. The CHARLS study's design, methods, and participant information have been extensively described in prior publications [16]. The 2011 baseline survey (Wave 1) involved 17,708 participants from over 10,000 households, with follow-up surveys conducted in 2013 (Wave 2), 2015 (Wave 3), 2018 (Wave 4), and 2020 (Wave 5). The research adhered to the STROBE (Strengthening the Reporting of Observational Studies in Epidemiology) standards for reporting observational epidemiological studies. Data from Waves 1, 2, and 3 (2011, 2013, and 2015) were used in this study to track sleep duration trajectories. The 2015 Wave 3 of the CHARLS initially assessed 21,095 participants. Participants were excluded sequentially for the following reasons: missing sleep duration data in 2011, 2013, or 2015 (n=5679); lack of CVD data in 2015 (n=3207); preexisting hypertension in 2015 (n=5421); age <45 years or missing age information (n=943); diagnosis of cancer in 2015 (n=65); and missing follow-up information on CVD or hypertension (n=177). With these exclusions, 5603 participants were included in the final longitudinal analysis, which was followed up through Wave 5 (2020) (Figure 1).

Figure 1. Flowchart of participants' selection. CVD: cardiovascular disease; CHARLS: China Health and Retirement Longitudinal Study.

Measurements of Sleep Duration

Sleep duration trajectories refer to patterns of change in an individual's total sleep duration, which includes both nighttime sleep and daytime naps, over a specific period [17]. By using longitudinal trajectories, we were able to capture long-term sleep behavior patterns, including the consistency and changes in sleep duration over multiple years, providing a more detailed characterization of sleep patterns than any single metric. Detailed data on nighttime sleep and daytime naps were obtained from the 2011, 2013, and 2015 CHARLS waves, and the total sleep duration over 24 hours was calculated for each participant at each wave. The selection of these 3 waves was intentional, as they cover all sleep assessments available before the 2015 landmark, ensuring complete observation of exposure information before follow-up starts. Moreover, latent class and longitudinal trajectory models require at least 3 repeated measurements to reliably distinguish stable, monotonic, and nonlinear patterns, meaning that using only the 2011 and 2013 waves would not provide sufficient temporal variation for meaningful trajectory identification. Surveys conducted in 2018 or 2020, which are part of the post-2015 waves, were excluded due to methodological considerations. Data on sleep duration collected after 2015 may have been influenced by intervening hypertension or cardiovascular events, leading to misclassification of exposure after the outcome and violating the required temporal order for valid conclusions. By extending the trajectory window to 2018, substantial survivor bias would be introduced, as only those who remained event-free and continued follow-up until 2018 could contribute full sleep data, resulting in a healthier, nonrepresentative sample. Focusing trajectory construction on the pre–follow-up period (2011 - 2015) offers the temporal resolution required to capture significant sleep dynamics while upholding a valid exposure-outcome framework for subsequent cardiovascular evaluations. Applying latent class mixed models (LCMM), we identified 4 distinct sleep duration trajectory groups, including inverted U-shaped sleeper, steady low sleeper, steady high sleeper, and U-shaped sleeper. Each group represents a unique sleep pattern and trend. Inverted U-shaped sleepers show an initial increase in sleep duration, followed by a peak and a gradual decrease, potentially reflecting changes in sleep patterns during different physiological or life stages in middle-aged and older adults. Steady low sleepers maintain consistently low sleep durations with minimal fluctuation, which may indicate chronic sleep deprivation, potentially linked to cognitive decline, mental health issues, and other health concerns. Steady high sleepers consistently maintain higher sleep durations, which could reflect healthy sleep habits or specific health needs, such as restorative sleep, although prolonged high sleep duration may also be associated with chronic diseases or health risks, including metabolic disorders. Finally, U-shaped sleepers exhibit a decrease in sleep duration followed by an increase, forming a U-shaped trajectory, which may reflect dynamic changes in sleep needs across different age groups or health conditions, highlighting physiological, psychological, and environmental adaptations during the aging process.

Outcome Identification

Data on cardiovascular outcomes came from self-reported physician diagnoses collected in Waves 4 (2018) and 5 (2020). In accordance with established epidemiological practice, CVD was defined strictly as the first occurrence of stroke or heart disease, and hypertension was treated as a separate end point rather than included within the CVD composite [18-20]. Participants were classified as having incident CVD if they answered "yes" to either of the following physician-diagnosis questions, "Have you ever been diagnosed by a doctor with a heart attack, angina, coronary heart disease, heart failure, or other cardiovascular problems?" or "Have you received a diagnosis of a stroke from a doctor?" [18-20]. The event date was defined as the first survey wave (2018 or 2020) at which the condition was reported. If the same condition was reported in later waves, these were treated as duplicate events, and only the earliest report was used for analysis. When concurrent events (stroke and heart disease reported in the same wave) occurred, the participant was counted as having experienced a CVD event, with the shared date assigned as the event time. Each individual could contribute a maximum of one event to the hypertension end point and one event to the cardiovascular end points. In defining CVD as a combination of stroke and heart disease, only the first diagnosis of either was acknowledged as the incident CVD event, with subsequent reports considered duplicates.

In Waves 4 (2018) and 5 (2020), data regarding hypertension were obtained through a standardized self-reported physician-diagnosis questionnaire. Instead of incorporating it into the CVD composite, hypertension was addressed as an independent end point. Participants were classified as having incident hypertension if they answered "yes" to the question, "Have you been told by a doctor that you have high blood pressure?" The initial survey wave (2018 or 2020) that recorded a physician's diagnosis of hypertension was used to define the event date. Subsequent reports were regarded as duplicates, and only the earliest one was included in the analysis. Each participant was limited to contributing one hypertension event, irrespective of their classification for stroke, heart disease, or composite CVD.

Covariates

Covariates were selected based on established literature and clinical expertise. These covariates included age, gender, marital status, education level, smoking status, alcohol consumption, hypertension, dyslipidemia, heart disease, obesity, systolic blood pressure (SBP), diastolic blood pressure (DBP), heart rate, waist circumference, waist-to-height ratio, high-density lipoprotein cholesterol, total cholesterol, hemoglobin A_{1c} (HbA_{1c}), triglycerides, low-density lipoprotein cholesterol, creatinine, blood urea nitrogen (BUN), fasting plasma glucose (FPG), BMI, and estimated glomerular filtration rate (eGFR). Hypertension was defined as a self-reported physician diagnosis, use of antihypertensive medications, and/or an average SBP of ≥140 mm Hg and/or DBP of ≥90 mm Hg [21]. Diabetes mellitus (DM) was defined as FPG of ≥126 mg/dL or HbA_{1c} level of ≥6.5%, and/or a self-reported physician diagnosis, and/or the use of glucose-lowering medications. Pre-DM was identified

XSL•FO
RenderX

by FPG levels of 100 - 125 mg/dL or HbA_{1c} level between 5.7% and 6.4%. Individuals without DM or pre-DM were classified as having normal glucose regulation [22]. Dyslipidemia was diagnosed based on a self-reported physician diagnosis, the use of lipid-lowering medications, and/or triglycerides >150 mg/dL, high-density lipoprotein cholesterol level of <40 mg/dL, low-density lipoprotein cholesterol level of >160 mg/dL, or total cholesterol level of >240 mg/dL [23]. Chronic kidney disease was defined as a self-reported physician diagnosis or an eGFR of <60 mL/min/1.73 m^2, in accordance with previous CHARLS studies [24]. Obesity was assessed by calculating BMI using the formula: weight (kg) / height^2 (m^2) [25]. Consistent with our earlier research [26,27], socioeconomic status (SES) was assessed through 4 indicators, including yearly household income, educational achievement, employment status, and medical insurance coverage. Family annual income was determined by the total household income from the prior year and divided into 2 groups, above and below the median, with the sample median set at US $2877.7 or CNY 18,130.00. Education was sorted into 3 tiers, including below high school, high school or equivalent (General Educational Development), and college or more advanced. Educational attainment was classified into 3 categories, including junior high school or below, senior high school, and college or above. Employment status was sorted into employed (covering those with paid employment, self-employment, or retired) and unemployed. Insurance coverage was divided into 2 categories, insured, which includes public or private health insurance, and uninsured.

Statistical Analyses

For continuous variables that did not conform to a normal distribution, medians and IQRs were used, and categorical variables were displayed as frequencies and percentages. The Kruskal-Wallis rank-sum test was used to compare nonnormally distributed continuous variables across the 4 groups, and the chi-square test was used for categorical variables. With the assumption that the missing data followed a random pattern, we used *multiple imputation by chained equations* (MICE) in R (R Foundation for Statistical Computing) to estimate the missing covariates. Incorporating all analytic covariates and auxiliary variables, the imputation model aimed to maximize the use of information. To achieve algorithmic stability and convergence, 5 complete datasets were generated, each undergoing 50 iterations. Predictive mean matching ("pmm") was used for continuous variables, logistic regression ("logreg") for binary variables, multinomial models for nominal categorical variables, and proportional-odds models for ordinal variables. The evaluation of convergence involved inspecting trace plots for the mean and SD of the imputed values. Each imputed dataset was analyzed with Cox proportional hazards models, and the parameter estimates were merged using Rubin rules to generate pooled coefficients and standard errors. Using the *LCMM* package in R, we applied LCMMs to study longitudinal variations in total and nighttime sleep duration. Models with different polynomial specifications (linear, quadratic, and cubic) were compared to evaluate goodness of fit, and the optimal model was determined according to the principle of Bayesian Information Criterion minimization, ensuring both statistical adequacy and practical interpretability (Table S1 and S2 in Multimedia Appendix 1). To maintain enough sample representation in each trajectory and prevent overfitting, each latent class needed to account for at least 5% of the total sample. According to these guidelines, a 4-class model provided the optimal fit, resulting in 4 distinct sleep trajectory patterns, including inverted U-shaped sleepers, steady low sleepers, steady high sleepers, and U-shaped sleepers. Using Schoenfeld residuals, the proportional hazards assumption in the Cox models was evaluated, and no significant violations were identified (all P>.05). Variance inflation factors were used to evaluate potential multicollinearity among covariates, and since all values were below 5, it indicated no serious collinearity. These diagnostic checks validated that the Cox proportional hazards models complied with crucial assumptions and were apt for the analyses. Potential confounders were pinpointed using prior epidemiological evidence and clinical relevance, encompassing demographic features, lifestyle practices, and metabolic indicators. Using Cox proportional hazards models, we investigated the relationship between sleep patterns and hypertension, as well as subsequent cardiovascular events, including stroke and heart disease. To elucidate the progressive impact of confounding, 3 hierarchical Cox proportional hazards models were fitted. Model 1 served as the crude model; Model 2 adjusted for sociodemographic and lifestyle variables (age, sex, education level, marital status, smoking, and alcohol use); and Model 3 extended the adjustment to biological variables, namely dyslipidemia, BUN, eGFR, DM, and obesity status, thereby capturing potential physiological confounding. Follow-up time from Wave 4 (2018) to Wave 5 (2020) or event occurrence served as the analytic time scale. Participants who remained free of cardiovascular events were administratively censored at their last observed follow-up. Restricted cubic spline models were applied to examine the potential nonlinear associations between sleep duration and cardiovascular outcomes. Based on established recommendations, 4 knots were set at the 5th, 35th, 65th, and 95th percentiles of the sleep-duration distribution to fit restricted cubic spline models. To enhance clinical interpretability, contrasts were determined at sleep durations of 6, 7, 9, and 10 hours. These values were selected based on both clinical relevance and the empirical distribution observed in the trajectory patterns. These values were selected a priori because they correspond to commonly used sleep duration categories in epidemiological research, with approximately 6 hours representing short sleep, 7 - 8 hours reflecting recommended sleep duration, and 9 - 10 hours representing extended sleep. Using these established thresholds allows the spline-estimated associations to be interpreted against clinically meaningful reference points without imposing additional assumptions on the functional form. An exploratory mediation analysis was conducted to see if hypertension could potentially serve as an intermediate pathway between total or nocturnal sleep trajectories and cardiovascular outcomes. Using nonparametric bootstrapping, direct and indirect effects were estimated, but the temporal structure of the data hinders causal interpretation, indicating that the findings are exploratory. For this analysis, the *mediation* package was used with 1000 iterations of simulation. To mitigate potential reverse causality and enhance the robustness of our findings, participants who experienced cardiovascular events within the first 2 years of

XSL•FO
RenderX

follow-up were excluded from the analysis. In addition, to account for uncertainty in sleep trajectory assignment, sensitivity analyses used misclassification-adjusted Cox regression models with posterior-probability weighting. Further sensitivity analyses included additional adjustments for socioeconomic status to evaluate the possible influence of leftover socioeconomic confounding. R software (version 4.4.1) facilitated all statistical analyses, with a 2-sided *P* value less than .05 considered statistically significant.

Ethical Considerations

The Biomedical Ethics Review Committee of Peking University (IRB00001052-11015) approved the study, and all participants provided written informed consent. All data used in this study were obtained from publicly available, deidentified datasets. These datasets were generated by original investigators who obtained informed consent from participants and conducted their studies in accordance with the Declaration of Helsinki and applicable institutional review board approvals. No new human participants were enrolled for this research, and no additional ethical approval was required for this secondary analysis. All data accessed are publicly available and fully anonymized prior to deposition. No personally identifiable information (such as names, addresses, contact details, or unique personal identifiers) was used or disclosed in any part of the analysis. We strictly adhered to the terms of use and data sharing policies of the original repositories. All analyses were conducted on aggregated or deidentified data, ensuring that individual privacy and confidentiality were fully maintained throughout the study. As this research involved the analysis of preexisting, deidentified data, no participants were directly involved in study procedures and no compensation was provided or required as part of this work.

Results

Baseline Characteristics of Participants and Sleep Duration Trajectories

Table 1 summarized the baseline demographic and clinical characteristics of 5603 participants, grouped by total sleep duration trajectories, including inverted U-shaped (n=349), steady low (n=1124), steady high (n=3784), and U-shaped (n=346). Figures 2A and 2B further illustrated the longitudinal trends in total and nocturnal sleep duration from 2011 to 2015, confirming 4 distinct trajectories. The overall median age was 60 (IQR 53.00 - 66.00) years, with group-specific medians ranging from 62 (IQR 52.00 - 68.00) years in the inverted U-shaped group to 61 (IQR 53.00 - 68.00) years in the U-shaped group. The cohort included 2765 (47.74%) males and 2928 (52.26%) females, with the proportion of females highest in the U-shaped group (65.90%).

Figure 2. Total sleep duration trajectories from 2011 to 2015 in Chinese middle-aged and older adults. (**A**) Total sleep duration trajectories. (**B**) Nocturnal sleep duration trajectories.

Both total sleep duration and nocturnal sleep duration differed significantly across sleep trajectory groups (*P*<.001). Participants in the inverted U-shaped sleep group exhibited the shortest median total sleep duration (4.5, IQR 3.0 - 6.0 h) and nocturnal sleep duration (4.0, IQR 3.0 - 6.0 h), whereas those in the steady high sleep group showed the longest median total sleep duration (8.0, IQR 7.0 - 9.0 h) and nocturnal sleep duration (7.0, IQR 6.0 - 8.0 h). Participants differed significantly across trajectory groups regarding age, gender, marital status, education level, smoking status, drinking status, creatinine, BUN, and obesity (all *P*<.05; Table 1). Although no significant differences were observed in estimated glomerular filtration rate (*P*=.26), DM (*P*=.05), dyslipidemia (*P*=.17), or hypertension (*P*=.11; Table 1).

Association of Sleep Duration Trajectories With New-Onset Hypertension

In the course of the follow-up, 1123 new hypertension cases were identified, making up 20% (Table 2). Differences were observed in the onset of hypertension among the sleep trajectory groups. The distribution of total sleep trajectories (Figure S1A in Multimedia Appendix 2) was 19% for steady high sleepers, 22% for steady low sleepers, 24% for inverted U-shaped sleepers, and 20% for U-shaped sleepers. Nocturnal sleep trajectories (Figure S1B in Multimedia Appendix 2) exhibited a similar pattern, with incidences of 24%, 21%, 19%, and 22% across the respective categories. For total sleep duration trajectories, compared with the steady high group (reference), participants in the inverted U-shaped group had a significantly higher risk of developing hypertension (hazard ratio [HR]=1.34, 95% CI 1.07 - 1.69; *P*=.01) in the fully adjusted model (Model 3; Table 2). The steady low and U-shaped groups showed modest but nonsignificant increases in hypertension risk HR=1.13, 95% CI 0.97 - 1.31; *P*=.11; and HR=0.98, 95% CI 0.76 - 1.26; *P*=.87, respectively; Table 2). Figure 3A illustrates the association between total sleep duration and the risk of incident hypertension. The overall association was statistically significant (for overall *P*=.04), and the test for nonlinearity also reached significance (for nonlinear *P*=.04).

For nocturnal sleep duration trajectories, similar patterns were observed. The inverted U-shaped group had a significantly elevated risk of new-onset hypertension compared to the steady-high group (HR=1.26, 95% CI 1.01 - 1.58; *P*=.04 in Model 3). No significant associations were found for the steady low (HR=1.13, 95% CI 0.97 - 1.30; *P*=.11) or U-shaped group (HR=0.97, 95% CI 0.74 - 1.26; *P*=.81). Figure 3E depicts the association between nocturnal sleep duration and hypertension risk. The overall association was statistically significant (*P* for overall=.05), whereas the test for nonlinearity was not significant (*P* for nonlinear=.24).

Association of Sleep Duration Trajectories With New-Onset CVD

Over the follow-up duration, 522 participants, which is 10.17%, developed new-onset CVD. Different sleep trajectory groups also experienced varying rates of new CVD onset. The sleep trajectory analysis (Figure S1C in Multimedia Appendix 2) showed that 8.4% of participants were classified as steady high sleepers, 11.0% as steady low sleepers, 13.0% as inverted U-shaped sleepers, and 10.0% as U-shaped sleepers. For nocturnal sleep trajectories (Figure S1D in Multimedia Appendix 2), the corresponding rates were 12%, 11%, 8.5%, and 11%, respectively. Compared to steady high sleepers (reference), those categorized as inverted U-shaped showed an increased chance of experiencing new-onset CVD. Compared to steady high sleepers, the inverted U-shaped group showed a nearly statistically significant elevated risk in the fully adjusted model, with an HR of 1.46 (95% CI 1.07 - 2.00; *P*=.02) in Model 3 (Table 3). Higher cardiovascular risk was observed in the U-shaped and steady low groups, but the associations were not statistically significant (HR=1.08 95% CI 0.76 - 1.54; *P*=.66; HR=1.22, 95% CI 0.99 - 1.50; *P*=.07; Table 3). In Figure 3B, the correlation between total sleep duration and the occurrence of new CVD is shown. The overall association was statistically significant (*P* for overall=.008), while the test for nonlinearity did not indicate evidence of a nonlinear relationship (*P* for nonlinearity=.09).

Table . Association of the sleep trajectories and new-onset cardiovascular disease.

Characteristic	N	Event, n (%)	Model 1[a]		Model 2[b]		Model 3[c]	
			HR[d] (95% CI)	*P* value	HR (95% CI)	*P* value	HR (95% CI)	*P* value
Total sleep trajectories	5603	522 (9.32)

Nocturnal sleep trajectories	5603	522 (9.32)						
Steady high sleeper	3849	329 (8.5)	Reference		Reference		Reference	
Steady low sleeper	1073	117 (11)	1.30 (1.05-1.60)	.02	1.20 (0.97-1.48)	.10	1.21 (0.98-1.50)	.08
Inverted U-shaped sleeper	386	45 (12)	1.40 (1.02-1.91)	.04	1.24 (0.90-1.70)	.18	1.30 (0.95-1.79)	.10
U-shaped sleeper	295	31 (11)	1.24 (0.85-1.79)	.26	1.11 (0.76-1.60)	.59	1.11 (0.77-1.61)	.57

[a]Model 1: crude model.

[b]Model 2: adjusted for age, gender, education level, marital status, drinking status, and smoking status.

[c]Model 3: adjusted for age, gender, education level, marital status, drinking status, smoking status, dyslipidemia (current use of lipid-lowering medications, and/or triglycerides>150 mg/dL, high-density lipoprotein cholesterol [HDL-C]<40 mg/dL, low-density lipoprotein cholesterol [LDL-C]>160 mg/dL, or total cholesterol [TC]>240 mg/dL), blood urea nitrogen, estimated glomerular filtration rate, diabetes mellitus, and obesity status.

[d]HR: hazard ratio.

[e]Participants with steady high sleep duration, which is used as the reference for comparison when reporting hazard ratios (HR) for the other sleep trajectory groups.

When evaluating nocturnal sleep duration trajectories, the overall association patterns remained consistent. Compared with steady high sleepers (reference), the steady low sleep trajectory was associated with an elevated risk of incident CVD in the fully adjusted model, although the association did not reach statistical significance (HR=1.21, 95% CI 0.98 - 1.50;

XSL•FO
RenderX

P=.08; Table 3). Similarly, individuals with an inverted U-shaped sleep trajectory showed a higher risk of new-onset CVD, but this association was marginal and not statistically significant (HR=1.30, 95% CI 0.95 - 1.79; *P*=.10). No significant association was observed for the U-shaped sleep trajectory (HR=1.11, 95% CI 0.77 - 1.61; *P*=.57; Table 3). Figure 3F depicts the association between nocturnal sleep duration and heart disease risk. The nonlinearity test did not indicate evidence of a nonlinear relationship (*P* for nonlinear=.96), whereas the overall association was highly significant (*P* for overall=.003), mirroring the pattern observed for total sleep duration.

Association of Sleep Duration Trajectories With New-Onset Stroke

In the course of the study, 100 individuals, representing 1.77% of the total, experienced a new-onset stroke. The incidence of new-onset stroke differed notably across sleep trajectory groups. For total sleep trajectories, the incidence was 1.4% among steady high sleepers, 2.5% among steady low sleepers, 2.6% among inverted U-shaped sleepers, and 2.9% among U-shaped sleepers (Figure S1E in Multimedia Appendix 2). The pattern observed in nocturnal sleep trajectories (Figure S1F in Multimedia Appendix 2) was similar, with incidences recorded at 2.8%, 2.7%, 1.4%, and 2.7%. Individuals with inverted U-shaped, steady-low, or U-shaped sleep patterns showed an increased risk of new-onset stroke compared to those with consistently high sleep durations. For total sleep duration trajectories, compared with steady high sleepers (reference), individuals in the steady low sleep trajectory exhibited a significantly higher risk of incident stroke in the fully adjusted model (HR=1.71, 95% CI: 1.07 - 2.72; *P*=.02; Table 4). In contrast, participants with an inverted U-shaped sleep trajectory showed an elevated but statistically nonsignificant risk of stroke (HR=1.85, 95% CI 0.91 - 3.79; *P*=.09). Similarly, no statistically significant association was observed for the U-shaped sleep trajectory (HR=1.77, 95% CI 0.87 - 3.60; *P*=.12; Table 4). Figure 3C illustrates the association between total sleep duration and new-onset stroke, with neither the overall association (*P* for overall=.18) nor the nonlinearity test (*P* for nonlinear=.62) reaching statistical significance.
