[d]HR: hazard ratio.

[e]Participants with steady high sleep duration, which is used as the reference for comparison when reporting hazard ratios (HR) for the other sleep trajectory groups.

For nocturnal sleep duration trajectories, the associations were more pronounced. Compared with steady high sleepers (reference), individuals in the steady low-sleep trajectory exhibited a significantly increased risk of new-onset stroke in the fully adjusted model (HR=1.83, 95% CI 1.15 - 2.91; *P*=.01; Table 4). In contrast, participants with an inverted U-shaped sleep trajectory also showed a significantly elevated risk of incident stroke (HR=2.10, 95% CI 1.08 - 4.05; *P*=.03). By comparison, although the U-shaped sleep trajectory was associated with a higher hazard ratio, the association did not reach statistical significance (HR=1.96, 95% CI 0.92 - 4.18; *P*=.08). Figure 3G illustrates the association between nocturnal sleep duration and new-onset stroke, with neither the overall association (*P* for overall=0.14) nor the nonlinearity test (*P* for nonlinear=0.84) reaching statistical significance.

Association of Sleep Duration Trajectories With New-Onset Heart Disease

Over the follow-up duration, 438 participants (7.8%) were found to have newly developed heart disease. The incidence of new-onset heart disease differed modestly across sleep trajectory groups. For total sleep trajectories (Figure S1G in Multimedia Appendix 2), the lowest incidence was observed among steady high sleepers (7.3%), followed by steady low sleepers (8.8%) and U-shaped sleepers (7.8%), whereas inverted U-shaped sleepers exhibited the highest incidence (10.0%). A similar

XSL•FO
RenderX

pattern was observed for nocturnal sleep duration trajectories (Figure S1H in Multimedia Appendix 2). The incidence of new-onset heart disease was 7.5% among steady high sleepers, increased to 8.5% among steady low sleepers, and peaked among inverted U-shaped sleepers (8.8%) before declining in the U-shaped group (7.8%). For total sleep duration trajectories, compared with steady high sleepers (reference), no statistically significant associations were observed across trajectory groups in the fully adjusted model. Specifically, the steady low sleep trajectory was associated with a modestly elevated but nonsignificant risk of heart disease (HR=1.14, 95% CI 0.90 - 1.43; *P*=.27; Table 5). Similarly, participants with an inverted U-shaped sleep trajectory showed an increased HR that did not reach statistical significance (HR=1.34, 95% CI: 0.94 - 1.90; *P*=.11). The U-shaped sleep trajectory was not associated with heart disease risk (HR=0.93, 95% CI 0.63 - 1.39; *P*=.73). Figure 3D illustrates the association between total sleep duration and heart disease risk. The overall association reached statistical significance (*P* for overall=.03); however, there was no evidence supporting a nonlinear relationship (*P* for nonlinear=.45).

Table . Association of the sleep trajectories and new-onset heart disease.

Characteristic	Total (N)	Event, n (%)	Model 1[a]		Model 2[b]		Model 3[c]

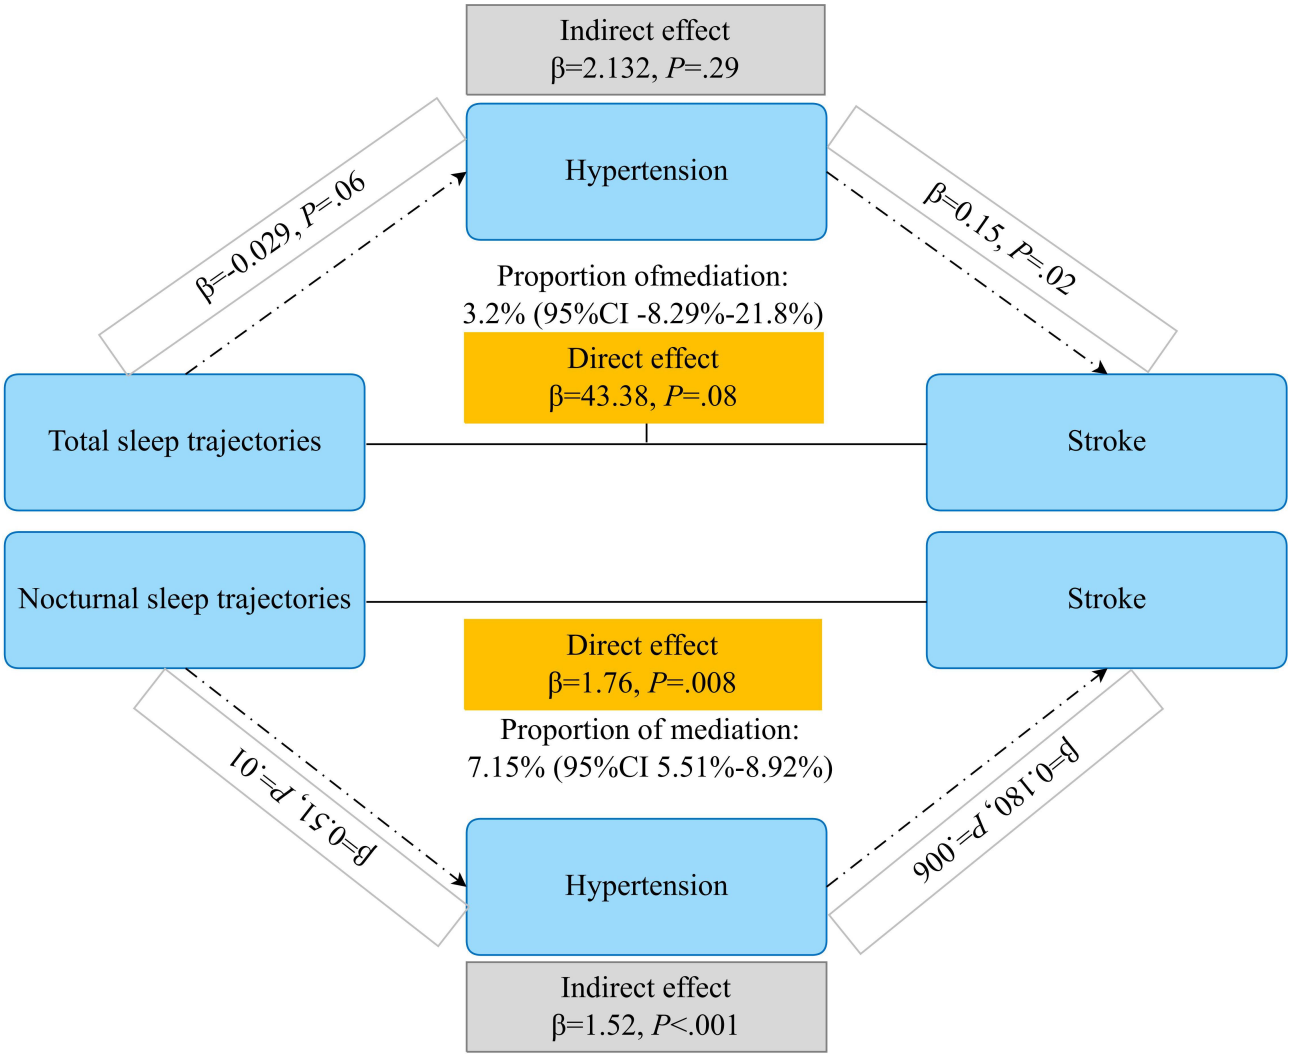
Sensitivity Analysis

In the sensitivity analysis excluding participants who developed hypertension within the first 2 years of follow-up (Table S3 in Multimedia Appendix 1), compared with steady high sleepers (reference), individuals with an inverted U-shaped sleep trajectory exhibited a significantly increased risk in the fully adjusted total sleep trajectory model (HR=1.34, 95% CI 1.06 - 1.71; *P*=.02). In contrast, compared with the steady high sleepers (reference), the association remained statistically significant in the fully adjusted nocturnal sleep trajectory model (HR=1.28, 95% CI 1.02 - 1.62; *P*=.03; Table S3 in Multimedia Appendix 1). In the sensitivity analysis excluding early CVD within the first 2 years of follow-up (Table S4 in Multimedia Appendix 1), the association between the inverted U-shaped total sleep trajectory and incident CVD was weakened and did not reach statistical significance after full adjustment (HR=1.38, 95% CI 0.93 - 2.04; *P*=.11). Excluding strokes that occurred within the first 2 years of follow-up (Table S5 in Multimedia Appendix 1), the association for total sleep trajectories was attenuated. Specifically, although individuals with an inverted U-shaped total sleep trajectory showed an elevated HR for incident stroke, the association did not reach statistical significance in the fully adjusted model (HR=2.23, 95% CI 0.90 - 5.51; *P*=.08). In contrast, for nocturnal sleep trajectories, the inverted U-shaped sleep pattern remained robustly and independently associated with an increased risk of new-onset stroke after full adjustment (HR=2.91, 95% CI 1.28 - 6.61; *P*=.01).

In misclassification-adjusted analyses using posterior-probability-weighted Cox regression (Table S6A and S6B in Multimedia Appendix 1), the overall patterns of association were largely consistent with those observed in the primary analyses. In particular, the inverted U-shaped sleep trajectory remained associated with an increased risk of adverse CVD including stroke (Total sleep trajectories-CVD- HR=1.47, 95% CI 1.07 - 2.02; *P*=.02; Nocturnal sleep trajectories-stroke-HR=1.29, 95% CI: 1.06 - 2.71, *P*=.03; Table S6B in Multimedia Appendix 1) and hypertension (Total sleep trajectories: HR=1.35, 95% CI 1.07 - 1.69; *P*=.01; Table S6A in Multimedia Appendix 1), although the strength and statistical significance of the associations varied across specific outcomes.



In sensitivity analyses with additional adjustment for SES <4 (Table S7A and S7B in Multimedia Appendix 1), the overall patterns of association between sleep trajectories and cardiometabolic outcomes were largely consistent with the primary analyses. Specifically, the inverted U-shaped pattern of total sleep maintained a significant association with a higher risk of new CVD (HR=1.58, 95% CI: 1.06 - 2.34; *P*=.02), but the link with hypertension was weakened after SES adjustment (HR=1.45, 95% CI 1.09 - 1.93; *P*=.01; Table S7A in Multimedia Appendix 1). In the same socioeconomic stratum, among nocturnal sleep trajectories, a significant association was observed between the inverted U-shaped nocturnal sleep pattern and incident stroke among participants with lower SES of <4 (HR=3.07, 95% CI 1.24 - 7.58; *P*=.01; Table S7B in Multimedia Appendix 1).

Mediator Analysis

Mediation analyses were conducted to assess whether hypertension mediated the associations between sleep duration trajectories and incident CVD, stroke, and heart disease. For total sleep duration trajectories, the indirect effect mediated through hypertension was not statistically significant (β=2.13; *P*=.30), accounting for 3.2% of the total effect (95% CI −8.29% to 21.8%). The direct effect of total sleep trajectories on stroke risk was also not statistically significant (β=43.38; *P*=.08; Figure 4). In contrast, for nocturnal sleep duration trajectories, a significant indirect effect through hypertension was observed (β=1.52; *P*<.001), with hypertension mediating 7.15% of the total association between nocturnal sleep trajectories and stroke risk (95% CI 5.51% - 8.92%; Figure 4). Notably, the direct effect of nocturnal sleep trajectories on stroke remained statistically significant after accounting for hypertension (β=1.76; *P*=.008; Figure 4). Hypertension partially mediated the association between sleep duration trajectories and stroke. For total sleep duration trajectories, neither the indirect effect through hypertension nor the direct effect on CVD reached statistical significance (indirect effect: β=0.050; *P*=.37; direct effect: β=0.029; *P*=.09), despite a modest estimated mediation proportion (8.7%; Figure S2 in Multimedia Appendix 2). Similar null findings were observed for nocturnal sleep duration trajectories, with nonsignificant indirect and direct effects on CVD. Consistent results were observed for heart disease, where neither total nor nocturnal sleep duration trajectories showed significant indirect effects mediated by hypertension, and all corresponding direct effects were also nonsignificant (Figure 3 in Multimedia Appendix 2).

Figure 4. Mediation analysis of the association between the total sleep/nocturnal sleep duration trajectories and stroke.

Discussion

Principal Findings

In this population-based study that is both longitudinal and nationally representative, researchers identified 4 distinct trajectories of total and nocturnal sleep duration. It was found that an inverted U-shaped sleep pattern was related to a greater risk of CVD, irrespective of typical risk factors. Multiple sensitivity analyses showed that these associations remained largely stable, supporting the strength of the results. We also explored the potential role of hypertension as an intermediate factor and observed preliminary evidence suggesting that hypertension may partly account for the relationship between unstable sleep trajectories and incident CVD.

This analysis highlights a clear inverted U-shaped association between sleep amount and the chance of developing hypertension. The risk of hypertension is considerably higher in individuals with an inverted U-shaped sleep duration trajectory than in those who consistently sleep for extended periods. In Model 3, the inverted U-shaped total sleep trajectory was associated with an increased risk of hypertension (HR=1.34, 95% CI 1.07 - 1.69; *P*=.01) [28]. In comparison, groups with a consistently low amount of sleep and those with a U-shaped sleep pattern did not have a significant association with the risk of hypertension. The important link identified in the inverted U-shape group is in line with past research that has related irregular or disrupted sleep patterns to an increased likelihood of hypertension. The nonlinear relationship between total sleep time and hypertension risk indicates that variability in sleep duration, rather than consistently short or long sleep, might be an important factor in the onset of hypertension. This association may be partly explained by the physiological stress induced by unstable sleep patterns, which can contribute to dysregulation of the autonomic nervous system, heightened inflammatory responses, and disruptions of circadian rhythms, all of which have been implicated in the development of hypertension [29].

With regard to the development of new-onset CVD, our findings indicate individuals with inverted U-shaped sleep duration trajectories exhibited a significantly elevated CVD risk. In the fully adjusted Model 3, the inverted U-shaped trajectory group showed an HR of 1.46 (95 %CI 1.07 - 2.00; *P*=.02) for total sleep duration, indicating a trend toward increased risk. Conversely, the U-shaped and steady low trajectory showed no significant association, likely due to limited statistical power from a smaller sample size. These results are consistent with meta-analytic data, which consistently show an irregular or insufficient relationship between sleep duration and CVD risk,

XSL•FO
RenderX

with optimal cardiovascular outcomes occurring between 7 and 8 hours of sleep per night [30]. The underlying physiological mechanisms for these associations likely involve multiple factors. Short sleep may increase stress hormone levels and inflammation, leading to endothelial dysfunction and atherosclerosis [29], while long sleep durations may be indicative of comorbid conditions such as depression or metabolic syndrome, both of which are known to be significant risk factors for CVD [30]. The study further suggests that individuals with erratic sleep patterns over the long term have a substantially higher risk of CVD, even when their sleep duration falls within the recommended range, emphasizing the role of sleep variability in cardiovascular risk.

In terms of stroke risk, there was a significant connection between the duration of sleep at night and the onset of new strokes in those with an inverted U-shaped sleep pattern, with a HR of 2.10 (95% CI 1.08 - 4.05; *P*=.03). This observation is consistent with findings from large cohort studies that have identified short sleep as a key risk factor for stroke, likely due to its impact on raising blood pressure and altering circadian rhythms [28,30]. The steady low sleep trajectory was associated with a significantly increased risk of stroke compared with the steady high sleep trajectory, both for total sleep duration (HR=1.71, 95% CI 1.07 - 2.72; *P*=.02) and nocturnal sleep duration (HR=1.83, 95% CI 1.15 - 2.91; *P*=.01). The evidence points to the possibility that chronic sleep disruption, either from insufficient sleep or prolonged sleeping, may heighten the likelihood of stroke. However, after excluding strokes occurring within the first 2 years of follow-up, the steady low sleep trajectory remained significantly associated with stroke risk, supporting the robustness of the observed association in longer-term follow-up.

No significant relationships were found between new-onset heart disease and any sleep duration trajectories, whether for overall sleep or night sleep duration. Unlike the associations seen with hypertension, CVD, and stroke, this suggests that the link between sleep duration and heart disease could differ from other cardiovascular conditions. Underlying health issues or genetic factors could potentially have a greater influence on the development of heart disease. In addition, the insignificant correlation may result from the relatively low prevalence of heart disease in our study population, highlighting the importance of conducting future research with more extensive sample sizes and prolonged follow-up durations.

Furthermore, our exploratory mediation analysis indicated that hypertension was responsible for only a slight portion of the association between nocturnal sleep patterns and stroke, comprising a modest fraction of the overall effect. The pattern suggests a potential relationship between sleep habits and stroke risk, but the temporal structure of the data does not allow for a definitive causal interpretation. No notable mediation was detected for CVD or heart disease, which suggests that the association between sleep and cardiovascular health might operate through mechanisms other than hypertension. Overall, these findings are consistent with the possibility that sleep health influences cardiovascular risk partly through its relationship with blood pressure regulation, although confirmation will require longitudinal data with more precise temporal ordering [31].

These findings are consistent with previous research linking irregular or insufficient sleep to negative cardiovascular outcomes, although the lack of significant associations for heart disease in Table 5 suggests that the effects may be specific to certain outcomes. The inverted U-shaped sleep duration trajectory consistently showed the strongest associations across outcomes, particularly for stroke, with a HR of 2.10 for nocturnal sleep. These findings are consistent with existing evidence suggesting that chronic sleep deprivation may contribute to endothelial dysfunction, oxidative stress, and inflammation, which are key mechanisms underlying cardiovascular and cerebrovascular pathogenesis. The borderline associations between the inverted U-shaped sleep trajectory and CVD and stroke may indicate potential involvement of circadian disruption or heightened sympathetic activity, whereas the nonsignificant findings for heart disease could be attributable to reduced statistical power or heterogeneity in disease pathophysiology. The absence of significant associations for the U-shaped sleep trajectory across outcomes may suggest that compensatory increases in sleep duration following periods of reduction could partially offset adverse effects. However, this hypothesis warrants further investigation in larger cohorts. The observed significant associations, especially for steady low sleepers, persisted after extensive adjustment for demographic, lifestyle, and clinical confounders, supporting the robustness of the results.

Identifying harmful trends in sleep duration has important implications for public health policies and medical practices. From the viewpoint of population health, those who regularly experience short, long, or erratic sleep durations form a high-risk group. Observing their sleep patterns over time could aid in early preventive interventions. Longitudinal data reveal that unhealthy sleep trends are associated with a heightened risk of cardiovascular conditions and death [32]. For example, a recent cohort study revealed that inconsistent sleep duration over many years significantly elevated the risk of cardiovascular problems [33]. Thus, ongoing monitoring of sleep duration and its time-related trends might contribute to risk assessment and efforts to reduce cardiovascular burden on a population scale. In a clinical context, recognizing distinct sleep-duration trajectories supports the inclusion of sleep pattern assessments in regular cardiovascular risk evaluations. Incorporating sleep-trajectory data alongside conventional risk factors (hypertension, dyslipidemia, and obesity) enables targeted interventions, including behavioral counseling on sleep hygiene, cognitive behavioral therapy for insomnia, and wearable-device monitoring, with the aim of stabilizing trajectories and mitigating subsequent cardiometabolic risk. From a mechanistic standpoint, ongoing deviations from normal sleep patterns could amplify pathophysiological processes such as sympathetic overactivity, chronic inflammation, and endothelial dysfunction, which are involved in the progression of CVD [34-36]. Further studies should integrate objective sleep-monitoring tools, such as actigraphy or polysomnography, with precision medicine approaches to enhance risk prediction and investigate if

XSL•FO
RenderX

modifying detrimental sleep patterns affects cardiovascular health.

The strengths of the current study lie in the large, nationally representative sample used for the analysis, which enhances the generalizability of the findings. Additionally, the study results remained robust across several sensitivity analyses, which further supports the reliability of the findings. The use of LCMM allowed for the clustering of individuals with similar underlying trajectories, minimizing potential misclassification and providing a more accurate representation of sleep duration patterns over time. However, several limitations must be acknowledged. First, as an observational study, the inability to establish causality is a fundamental limitation. Despite controlling for numerous potential confounders, residual confounding due to unmeasured variables cannot be ruled out, and the nonrandomized nature of the data further complicates causal inference. Although we excluded participants with prevalent CVD prior to the follow-up period and conducted a value analysis to address this concern, the observational design still precludes definitive causal conclusions. Second, the research was based on self-reported data for baseline measurements, particularly in terms of sleep duration and health outcomes, which might introduce recall bias or misclassification. The relevance of this bias is heightened among older adults, whose cognitive or memory challenges may compromise the accuracy of their self-reported information. Misreporting could result in nondifferential measurement errors, weakening the associations between sleep duration trajectories and cardiovascular outcomes, and possibly impacting the precision of trajectory classification. Nonetheless, self-reported sleep duration has been widely confirmed and applied in large-scale epidemiological studies like CHARLS, and it still serves as a practical and reliable measure for research on populations. To substantiate these findings and delve deeper into the connection between sleep patterns and cardiovascular health, future research should incorporate objective measures such as actigraphy or polysomnography. Third, although residual confounding cannot be fully ruled out, CHARLS lacks detailed dietary data, and the physical activity information has significant missing elements that could introduce bias if incorporated into the models. When interpreting the current findings, these data constraints should be taken into account. Fourth, due to the study population consisting of older adults who survived to the baseline, survivor bias might have occurred, leading to an underrepresentation of those with severe comorbidities or early death, which may have lessened the impact of the findings. A thorough examination of bias suggests that selection bias, information bias, and residual confounding together may have slightly influenced the effect estimates, underscoring the importance of careful interpretation. Fifth, the absence of cause-specific mortality records in the CHARLS dataset makes it impossible to identify whether deaths were due to cardiovascular or noncardiovascular causes. Consequently, the application of competing-risk models was not possible, possibly affecting the precision of cardiovascular event risk estimation. Finally, the sample comprised primarily middle-aged and older Chinese adults, limiting the external validity of the findings. The results may not be fully generalizable to younger populations or individuals from other countries or ethnic groups. Future research should seek to replicate these findings in more diverse populations and consider additional factors, such as sleep quality, sleep disorders, and other contextual variables, which may further refine our understanding of the relationship between sleep duration and cardiovascular health.

Conclusions

Our findings indicate that the longitudinal stability of sleep duration is an important marker of cardiovascular health. Sleep trajectories with continuous insufficiency or marked fluctuations were related to higher chances of negative cardiovascular events. In exploratory mediation analyses, hypertension accounted for a small proportion of the association between nocturnal sleep trajectories and stroke, suggesting a possible pathway through which sleep disruption may influence cerebrovascular risk. These results highlight the potential relevance of maintaining consistent sleep patterns as part of strategies to support cardiovascular health, while underscoring the need for future longitudinal research with clearer temporal ordering to clarify underlying mechanisms.

Abstract

Background: Estimated pulmonary biological age (ePBA) has emerged as a more reliable indicator for disease progression and mortality than chronological age, with chest computed tomography (CT) as a promising tool for calculating ePBA. However, the lack of models trained and validated with large-scale healthy adults hinders the generalizability of the CT-based ePBA.

Objective: This study aims to develop an aging biomarker (ePBA) from multicenter chest CTs of healthy adults using deep learning and investigate the association between age gap (ePBA - chronological age) and pulmonary function as well as all-cause mortality in patients with chronic obstructive pulmonary disease (COPD).

Methods: We used 11,187 chest CT scans from healthy adults at 3 health management centers and used multiple deep learning models. Of these, 7726 scans from institution A were used for model development. The remaining CT scans from institutions B (n=1506) and C (n=1955) served as external test datasets. To examine whether ePBA provided information beyond chronological age in patients with the disease, we investigated the association of age gap with lung function and all-cause mortality among 138 patients with COPD hospitalized at the same time period in institution A.

Results: The deep learning models demonstrated acceptable applicability for this task and exhibited a strong correlation between ePBA and chronological age. Age gap was significantly associated with forced expiratory volume in 1 second expressed as percentage of predicted values reduction (r_s=−0.18; P=.03) and an increased risk of all-cause mortality (hazard ratio: 1.16, 95% CI 1.08-1.25) in patients with COPD.

Conclusions: This study developed and validated a biomarker of aging—ePBA—with deep learning models based on chest CT. Age gap could serve as a novel clinical biomarker in patients with COPD.

KEYWORDS

estimated pulmonary biological age; chest computed tomography; chest CT; deep learning; age gap; chronic obstructive pulmonary disease

Introduction

With the acceleration in global population aging, people who have chronic respiratory diseases have increased in number, and chronic respiratory disease has become the third leading cause of death, causing substantial economic and health burdens to society. Longitudinal studies have emphasized the critical need to precisely assess pulmonary senescence [1,2], which is essential for extending health span and reducing age-related respiratory morbidity. Thus, there is an urgent necessity to

XSL•FO
RenderX

develop a biomarker of aging—estimated pulmonary biological age (ePBA)—which is applicable to large-scale populations.

Models have been developed to estimate ePBA based on genes, proteins, and cells, but their expensive and complex assays prevent clinical translation [3-6]. Imaging techniques, such as noninvasive and highly accessible diagnostic tools, are widely used across health care settings, from primary care to tertiary medical centers. Despite the common use of chest radiographs for initial respiratory assessments, their limited spatial resolution contrasts with the detailed structural and physiological insights provided by computed tomography (CT) scans. Chest CT offers a detailed assessment of changes in lung parenchyma, small airways, and pulmonary vasculature associated with declining lung function and aging [7,8]. Therefore, an ePBA assessment model based on chest CT is both highly feasible and generalizable, holding great promise for managing chronic respiratory diseases [6].

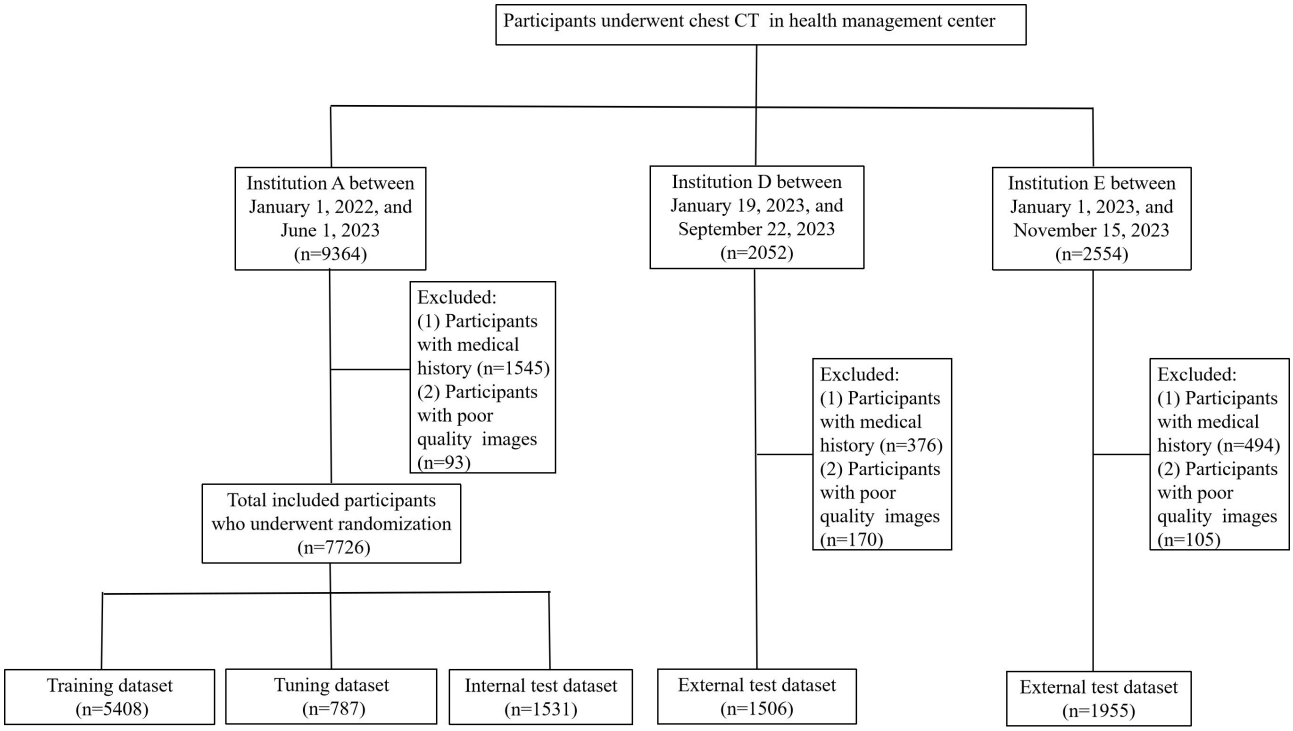
Deep learning can automatically extract features from massive training data, which is helpful for exploring the signs of aging in medical images. Although Azarfar et al [9] have explored a deep learning model for estimating biological age using chest CT, it was trained on the National Lung Screening Trial dataset, with participants having a smoking history of at least 30 pack-years and comorbidities and thus could not represent a healthy elderly population. In a previous study [10], ePBA was calculated using chest CT reconstructed bone from 2500 healthy participants, but due to the single-center nature and limited sample size in the validation dataset, the stability and generalization of the model needed to be improved. Thus, the lack of models trained and validated with large-scale healthy adults hinders the generalizability of the CT-based ePBA.

This study aimed to develop and validate ePBA using deep learning models based on chest CT scans from healthy individuals. The age gap—defined as the difference between ePBA and chronological age—was used to represent the extent of lung aging in an individual relative to a standard population. Furthermore, we examined the correlation between age gap and pulmonary function in patients with chronic obstructive pulmonary disease (COPD) and evaluated its ability to assess all-cause mortality risk in these patients, which may have potential applications for the management of patients with chronic respiratory diseases.

Methods

Participants in Model Development and Test

Participants underwent chest CT scans between January 2022 and November 2023 as periodic health check-ups in 3 health management centers (Qilu Hospital of Shandong University, Jinan [institution A]; Central Hospital Affiliated to Shandong First Medical University, Jinan [institution B]; and Shengli Oilfield Central Hospital, Dongying [institution C]), who were enrolled to develop and validate a deep learning model for calculating ePBA.



If participants underwent multiple chest CT scans during the data collection period, only the initial scan was selected. Disease registration was completed for all participants on the day of the CT examination at the 3 hospitals. The disease registration was established in accordance with the International Classification of Diseases and Related Health Problems, Tenth Revision [11,12]. Participants with disease registrations or compromised poor image quality were excluded (Figure 1).

Ethical Consideration

This retrospective and multicenter study was approved by the ethics committee of Qilu Hospital of Shandong University. No invasive operations were used or human tissue was obtained in this study, so the requirement for informed consent was waived (KYLL-202310‐027). The study was conducted in accordance with the principles of the Declaration of Helsinki. All chest CT images and clinical data were deidentified and anonymized prior to analysis to protect patient privacy. The confidentiality of participants' personal information was strictly maintained throughout the study. As this was a retrospective study, participants were not compensated.

XSL•FO

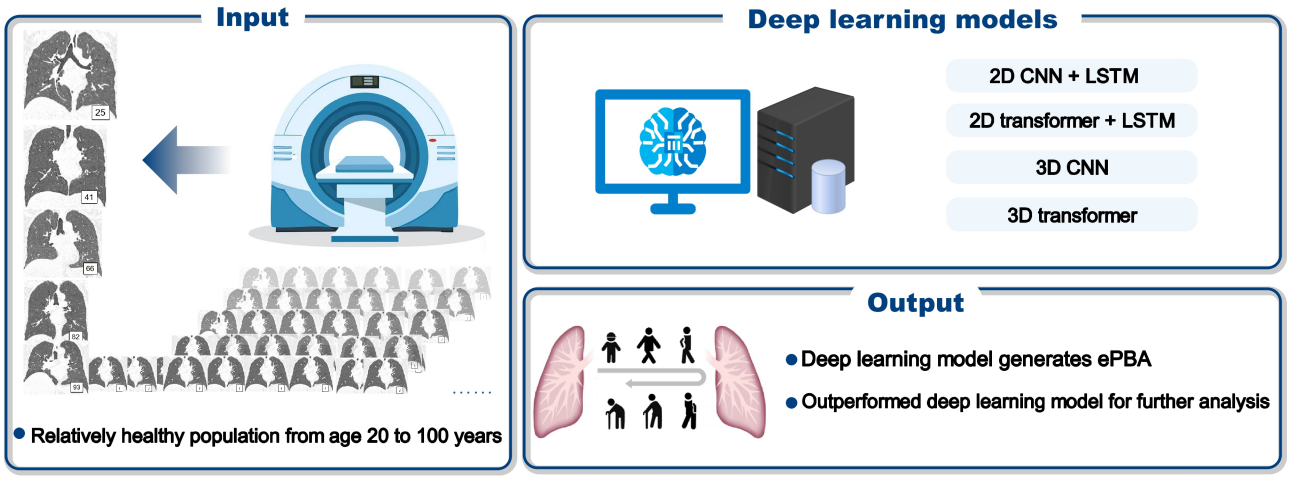
Figure 1. The flowchart of the included and excluded individuals in model development and test. CT: computed tomography.

CT Acquisition

Noncontrast CT images of healthy participants were acquired following complete inspiration. Images of the entire lung, with a slice thickness of 1 - 5 mm, were reconstructed using standard kernels. The CT scanners used were Siemens Force, SOMATOM Definition AS (both from Siemens Healthineers), Philips Incisive CT, Philips Ingenuity CT, Philips IQon Spectral CT (all from Philips Healthcare), United Imaging uCT710 (United Imaging Healthcare), GE Revolution CT, and GE Discovery CT750 HD (both from GE Healthcare). The scanning parameters are shown in Table S1 in Multimedia Appendix 1.

Ground Truth Labeling and Data Partition



Chest CT images of healthy participants were labeled using chronological age. All labeled CTs from institution A were randomly assigned in a 7:1:2 ratio into training, tuning, and internal test datasets, and age distribution consistency was preserved. The tuning dataset was dedicated to hyperparameter optimization, whereas the internal test dataset evaluated preliminary model performance. Additionally, the labeled CTs from institutions B and C were used for external test datasets.

Model Development and Test

A total of 10 deep learning models (visual geometry group [11 layers] [VGG11] [13]+long short-term memory [LSTM]; residual network (18 layers) [14]+LSTM; ConvNeXt [15]+LSTM; vision transformer [16]+LSTM; shifted windows transformer [17]+LSTM; 3D VGG11 [18]; 3D residual network (18 layers) [19]; 3D ConvNeXt [15]; 3D vision transformer [20]; 3D shifted windows transformer [21]), including 4 major categories (2D convolutional neural network [CNN]/transformer+LSTM, 3D CNN or transformer), were trained to calculate ePBA from healthy individuals (Figure 2). Further details on model training and parameter settings are available in supplementary methods in Multimedia Appendix 1. The model most suitable for this task was selected for subsequent analysis.

XSL•FO
RenderX

Figure 2. Development of deep learning estimated pulmonary biological age (ePBA) models. Deep learning–based ePBA models were developed using chest computed tomography (CT) scans from relatively healthy individuals aged 20 to 100 years with chronological age labels. CNN: convolutional neural network; LSTM: long short-term memory.

The training and tuning datasets were used to train and tune this model. Data augmentation included random horizontal flips, vertical flips, rotations, and offsets to increase the diversity of the data. The loss function used mean square error, and the optimizer used Adam. The initial learning rate was set to 10^{4}. We used a cosine annealing schedule over 500 epochs and used early stopping to prevent overfitting. Through training and tuning, we obtained an optimal model. The performance of the optimal model was evaluated on internal and external test datasets. To empirically validate the computational efficiency and performance of the 2D CNN+LSTM framework relative to 3D CNNs, we extended our ablation studies to a suite of 3D convolutional architectures. The input processing for these 3D models aligns with that of the 2D pipeline, ensuring fair comparisons across architectures.

The development process was performed using the PyTorch framework (version 1.8.1), and the hardware was an NVIDIA TITAN V GPU with 12 GB of memory.

To investigate the decision-making process of our best-performing model, we used score-weighted class activation mapping (score-CAM) [22] to visualize the discriminative regions it focused on during validation. This method represents a novel gradient-free visual interpretation technique aimed at explaining the classification decisions made by deep learning models. By highlighting important image regions in the visualizations, score-CAM reveals where the model allocates attention during the classification process. Notably, it serves as a bridge between perturbation-based and CAM-based approaches while providing intuitive and accessible insights into how the activation map weights are derived.

Application of ePBA in Patients with COPD

To evaluate the clinical applicability of the ePBA, we retrospectively enrolled patients hospitalized with COPD at institution A between January 1, 2022 and June 1, 2023. Data on demographics, pulmonary function, and medical history were collected from medical records. Dyspnea severity was assessed using the modified Medical Research Council (mMRC) scale. We also evaluated the ADO (age, dyspnea, and airflow obstruction) index [23], an abbreviated version of the BODE index (including body-mass index, airflow obstruction, dyspnea, and exercise capacity) and a simpler COPD prognostic risk index based on age, dyspnea, and airflow obstruction. Chest CT images from patients with COPD were input into the ePBA model, and the age gap (the difference between ePBA and chronological age) was subsequently calculated. Age gap above 0 indicated a higher level of aging than their healthy peers of the same chronological age, while age gap below 0 indicated a lower level of aging. The vital status was collected by reviewing medical records or through telephone calls to the patient or family. After at least 6 months of follow-up, a total of 138 patients with COPD were included in the study. The detailed inclusion and exclusion criteria are described in Figure S1 in Multimedia Appendix 1. An investigation was conducted to determine whether the age gap was related to the results of pulmonary function measurements and their risk of death.

Statistical Analysis

Categorical variables were presented as numbers and percentages. Continuous variables were summarized as mean (SD) or median and IQR, based on their distribution. Group comparisons were performed using the 2-tailed *t* test or Mann-Whitney *U* test for continuous variables and the chi-square or Fisher exact test for categorical variables, as appropriate.

The Pearson correlation coefficient (*r*), coefficient of determination (R^2), mean absolute error (MAE), mean square error, and root mean square error between the ePBA and chronological age were calculated to evaluate the regression performance of the deep learning model. The 99% CIs for these metrics were estimated using the nonparametric bootstrap method with 1000 replicates. This process involved generating 1000 independent bootstrap samples through random resampling with replacement from the original dataset, each of the same size as the original. The CIs were then derived using the percentile method, based on the 0.5th and 99.5th percentiles of the bootstrap sampling distribution.

In patients with COPD, the correlation between age gap and pulmonary function measurements was calculated. To examine the relationship between age gap and the mortality risk in

XSL•FO
RenderX

patients with COPD, Cox proportional hazards regression models were conducted with age gap used as a continuous variable and a binary variable, respectively (biologically older and younger represent age gap >0 and 0 [24], respectively). Adjustments were made for chronological age, sex, mMRC scale, smoking status, and medical history. Variance inflation factor (VIF) testing was performed to assess multicollinearity among the included variables. The proportional hazard assumption for the Cox model was checked using Schoenfeld residuals. For survival analysis, to assess the discriminatory ability of the age gap and ADO index, we performed Harrell concordance index and area under the curve, with 95% CIs yielded by 1000 bootstrap resamples. To visualize the discriminative performance of age gap, we also plotted the Kaplan-Meier curves of the biologically older and younger groups.

Statistical analyses were performed using the R software (version 3.3.3; R Foundation for Statistical Computing) and SPSS 26.0 for Windows (IBM Corp.). Statistical significance was set at $P<.05$.

Results

Demographic Characteristics of Healthy Individuals

A total of 13,970 participants with health check-ups (9364 in institution A, 2052 in institution B, and 2554 in institution C) were eligible for inclusion; 11,187 (7726 in institution A, 1506 in institution B, and 1955 in institution C) were ultimately enrolled after exclusion (Figure 1). Participants from institution A were randomly assigned to the training (n=5408, 2588 male participants), tuning (n=787, 385 male participants), and internal test datasets (n=1531, 710 male participants) in a ratio of 7:1:2. Additionally, participants from institutions B (n=1506, 814 male participants) and C (n=1955, 1310 male participants) were assigned to the external test datasets. The median ages (quartiles) of male and female participants were similar in the training, tuning, internal validation test, and the external test datasets (Table 1).

Table . Demographic characteristics of individuals.

Characteristics	Training dataset	Tuning dataset	Internal test dataset	External test dataset	
	Institution A	Institution A	Institution A	Institution B	Institution C
Total individuals	5408	787	1531	1506	1955
Male, n (%)	2588 (47.9)	385 (48.9)	710 (46.4)	814 (54.1)	1310 (67)
Female, n (%)	2820 (52.1)	402 (51.1)	821 (53.6)	692 (45.9)	645 (33)
Age (y), (min–max)					
Male	53 (20-98)	53 (22-100)	54 (23-94)	54 (20-97)	47 (21-85)
Female	53 (20-97)	53 (22-98)	54 (22-96)	54 (21-94)	47 (23-83)

Performance of Deep Learning Models for Age Estimation

All deep learning models achieved acceptable performance in this task (Table 2, Table S2-S11 in Multimedia Appendix 1). In total healthy individuals, the ePBAs derived from the VGG11+LSTM deep learning model were significantly associated with chronological ages across all datasets (training, tuning, internal test, and external test; all r >0.95, Table S2 in Multimedia Appendix 1). The external test dataset showed a strong correlation between ePBA and chronological age (r=0.97, 99% CI 0.96-0.97 in institution B, Figure 3A; r=0.98, 99% CI 0.96-0.99 in institution C, Figure 3B) and good model performance (institution B: R^2=0.93, 99% CI 0.92-0.94, MAE=4.59, 99% CI 4.34-4.83; institution C: R^2=0.93, 99% CI 0.84-0.94, MAE=3.64, 99% CI 3.47-3.81). Notably, the VGG11-LSTM model also exhibited a favorable balance between complexity and inference efficiency, containing 134.02 million parameters and achieving an average inference time of 18 ms per sample, rendering it suitable for potential clinical deployment. Thus, this model most suitable for this task was selected for subsequent analysis in patients with COPD.

Figure 3. Scatterplot between estimated pulmonary biological age (ePBA) derived from the VGG11-LSTM deep learning model and chronological age in (A) institution B and (B) institution C. (C) Score-weighted class activation mapping (score-CAM) original image class activation maps for healthy individuals. LSTM: long short-term memory; MAE: mean absolute error; VGG11: visual geometry group (11 layers).

To identify critical regions for optimizing feature localization during model training, we performed a visualization analysis using score-CAM. Figure 3C shows the score-CAM original image class activation maps of ePBA derived from VGG11-LSTM. The highlighted important image regions were located around the tracheal and bronchial vascular bundles after the visualization in healthy individuals at different age group distribution.

Application of ePBA in Patients With COPD

The ePBA of the 138 patients with COPD was significantly greater than their chronological age (ePBA: median 78.65, IQR 74.11-84.00 y vs chronological age: median 74.00, IQR 68.00-81.00 y; $P<.001$), resulting in a median age gap of median 5.43 (IQR 0.49-7.79) years, which was also significantly greater than 0 ($P<.001$). These findings indicate that these patients are in a state of accelerated aging. Table 3 provides the demographics, pulmonary function measurements, and medical history of survivors and deceased patients with COPD. As shown in Figure 4A, the age gap of deceased patients with COPD (median 6.96, IQR 3.00-11.00 y) was significantly greater than that of survivors (median 5.05, IQR –1.04 to 6.89 y; $P=.004$), and the mMRC scale score (median 4.00, IQR 3.25-4.00) was also significantly higher than that of survivors (median 3.00, IQR 2.00-4.00; $P<.001$; Table 3). There were no significant differences in other aspects.

Figure 4. (A) The distribution of age gap between survivors and deceased patients with chronic obstructive pulmonary disease (COPD); (B) comparison of the performance of age gap and ADO (age, dyspnea, and airflow obstruction) index in predicting the survival outcome of patients with COPD; (C) time-dependent area under the curve (AUC) curves for age gap and ADO index in patients with COPD; and (D) Kaplan-Meier curve of overall survival for biologically younger and older groups in patients with COPD. **P<.01.

Spearman correlation analysis showed that age gap was negatively correlated with forced expiratory volume in 1 second expressed as percentage of predicted values (FEV1%; r_s=−0.18; P=.03), while no significant correlation was observed between age gap and forced vital capacity expressed as percentage of predicted values (r_s=−0.11; P=.21) or FEV1 or forced vital capacity (r_s=−0.14; P=.09).

Before the multivariate Cox regression analysis, VIF testing was performed to assess multicollinearity among the included variables (Table S12 in Multimedia Appendix 1). As VIF values above 10 suggest significant multicollinearity, all variables demonstrated VIF values below 2, indicating the absence of severe multicollinearity. These results confirm the reliability and validity of the subsequent multivariate regression models for evaluating the independent association between age gap and mortality in patients with COPD. In the Cox regression analysis model, age gap was significantly associated with an increased risk of mortality in patients with COPD (hazard ratio [HR]: 1.12, 95% CI 1.06-1.19). Further adjustments for chronological age, sex, mMRC scale, smoking status, and medical history showed similar HR (HR: 1.16, 95% CI 1.08-1.25; Table 4). Compared with biologically younger patients, biologically older patients had a significantly higher risk of death (HR: 2.24, 95% CI 1.01-4.98), and this remained significant even after adjusting for covariates (HR: 2.78, 95% CI 1.17-6.58; Table 4). The Schoenfeld residuals test results (Table S13 in Multimedia Appendix 1) indicated that both the global test and individual covariates in the Cox proportional hazards models of this study satisfied the proportional hazards assumption (P>.05). The global Schoenfeld residuals test P values for model 1, model 2, and model 3 were .39, .75, and .42, respectively. The concordance index of age gap was 0.643 (95% CI 0.555-0.726), which was higher than the ADO index 0.556 (95% CI 0.478-0.641) in differentiating the overall survival rate of patients with COPD (Figure 4B). Age gap maintained a consistently high area under the curve value throughout the entire prediction interval (Figure 4C). The Kaplan-Meier overall survival curve demonstrated an excellent distinction in the risk of death between the younger and older biological age groups, and the survival time of the older biological age group was significantly shorter than that of the younger biological age group (P=.047; Figure 4D).

Table . Association between age gap and mortality risk in patients with chronic obstructive pulmonary disease (COPD)[a].

	Model 1[b]	P value	Model 2[c]	P value	Model 13[d]	P value
Age gap (y)	1.12 (1.06-1.19)	<.001	1.16 (1.08-1.25)	<.001	1.16 (1.08-1.25)	<.001
Age gap category						
Biologically younger	Reference		Reference		Reference	
Biologically older	2.24 (1.01-4.98)	.048	2.72 (1.16-6.35)	.02	2.78 (1.17-6.58)	.02

[a]Biologically older and younger represent age gap >0 and ≤0, respectively. All data in parentheses are 95% CI.

[c]Adjusting for chronological age, sex, BMI, and the modified Medical Research Council scale.

[d]Adjusting for covariates in model 2 plus smoking status, and medical history (hypertension, diabetes, and cerebrovascular disease).

Discussion

In this study, we developed and validated multiple deep learning models to calculate ePBA using chest CT scans from healthy individuals. Second, when applied to a COPD cohort, the derived “age gap” (ePBA—chronological age) emerged as a significant clinical biomarker, showing a negative correlation with FEV1% and proving to be a stronger predictor of all-cause mortality than the established ADO index.

In previous studies on calculating ePBA, gene-based, protein-based, and cellular marker–based ePBA calculation

XSL•FO
RenderX

models have been reported [24-26]. However, due to the high cost and complex workflow, these models were not suitable for large-scale cohort applications and were more suitable for exploring the biological mechanisms of lung aging. Liang et al [4] developed an estimation equation for lung age based on pulmonary function indicators (FEV1, FEF50%, FEF75%, and height) by the spline method (male: R^2=0.661, female: R^2=0.690). This equation might have a higher estimation error, as the coefficient of determination of this equation was lower than that of the CT-based deep learning model in this study. Furthermore, they failed to accomplish widespread clinical application due to the great difficulty in conducting pulmonary function tests in primary medical units. Among imaging tests, X-ray is often used as the first-line recommended test for chest disease. Mitsuyama et al [6] developed a biomarker of aging from chest radiography and examined the correlation between estimated age and chronological age (r=0.95). However, due to the low-density resolution of chest X-ray, chest CT is preferred for the full characterization of the aging lung in identifying signs of lung aging. The chest imaging features related to aging show vascular curvature and calcification, mediastinal lipomatosis, diaphragmatic bulge and protrusion, and musculoskeletal features, such as chest osteophyte and costal cartilage calcification [27]. Azarfar et al [9] developed an age estimation model using chest CT and deep learning and demonstrated its association with the risk of lung cancer. However, this model was trained using the National Lung Screening Trial dataset, which contains a large number of heavy smokers, and the participants have comorbidities, such as chronic lung diseases, making it difficult for this model to be generalized to patients with chronic respiratory diseases. In the study of Lu et al [10], ePBA was calculated using chest CT reconstructed bone from 2500 healthy participants, but due to the single-center nature and limited sample size in the validation dataset (n=200), the stability and generalization of the model needed to be improved. In this study, chest CT images of 11,187 healthy adults from 3 institutions were used to train the model to ensure that the model training dataset could represent a healthy population, and it was externally validated on 3461 healthy adults from 2 institutions that were included in the external test datasets, ensuring its stability and generalizability.

Importantly, we verified the application of ePBA in patients with COPD. It was observed that an increase in the ePBA-derived age gap was significantly associated with a reduction in FEV_1 % in patients with COPD. A similar negative association with lung function was also observed for phenotypic age acceleration, which was derived from phenotypic age based on chronological age and 9 clinical biomarkers as described by Wang et al [24]. After adjusting for chronological age and other covariates, the age gap remained independently associated with an elevated risk of all-cause mortality in patients with COPD. Notably, the predictive performance of age gap for mortality surpassed that of the established ADO index. Given that ePBA can be derived solely from routinely acquired chest CT images without requiring additional clinical parameters, it shows promise for improving the management of patients with chronic respiratory diseases and the implementation of targeted interventions aimed at addressing aging-related issues.

There are several limitations in this study. First, we did not compare this model with some established biological age markers (eg, epigenetic clock, DNAmGrimAge) due to the complexity and higher costs. Despite the continued refinement of epigenetic clocks over the last decade, standardized measures of organ age remain to be developed [28,29]. Second, participants were enrolled in China from a single ethnic background. The inclusion of participants with diverse ethnic, demographic, and socioeconomic backgrounds limits the generalizability of our current findings. Third, we did not construct a hybrid deep learning model based on clinical phenotype and chest CT. This was because clinical data, such as pulmonary function tests, are typically not collected during routine health check-ups, limiting their availability for model development. Finally, the COPD validation cohort has certain limitations, including its relatively small size, short follow-up, and predominance of severe cases. Although suitable for assessing mortality risk, this composition limits the direct evaluation of ePBA's ability to distinguish early pathological pulmonary aging from healthy aging. Therefore, future studies in community-based cohorts with milder disease and longer follow-up are warranted to verify the model's broader applicability.

In summary, this study constructed deep learning models to calculate the biomarker of aging—ePBA—based on chest CT images of multicenter healthy adults. The results showed that the age gap (ePBA—chronological age), representing the extent of lung aging in an individual relative to a standard population, may have potential applications for the management of patients with COPD.

Acknowledgments

We are grateful to Peng Xuewen, Zhao Weijia, Yanmin Yang, and Zhou Zhanyu for providing data from Qilu Hospital of Shandong University for this study. We are grateful to Gangming Ji for providing data from Shengli Oilfield Central Hospital for this study.

Data Availability

The study protocol and metadata are available upon request to the corresponding author. However, chest computed tomographies are not available, as these have been withheld by the hospitals that participated in this study in order to protect participant privacy. The code used to develop our model is available at [30].

Abstract

Background: The population of patients with heart failure (HF) is rapidly aging, and the prevalence of HF continues to rise among older adults. Effective HF self-care is essential for improving survival and reducing hospital readmissions, and the role of family caregivers in supporting and reinforcing these behaviors has become increasingly important. With the growing integration of digital health technologies into HF management, technology-assisted self-care is becoming more common. However, many older adults experience difficulties in adopting and effectively using digital tools, which may limit the potential benefits of digital health interventions. As both patients' and caregivers' levels of digital literacy may jointly shape HF self-care behaviors, a dyadic analytic approach is warranted to clarify their interdependent effects.

Objective: This study aimed to compare digital literacy between older patients with HF and their caregivers and to examine how digital literacy influences HF self-care behaviors within patient-caregiver dyads.

Methods: This cross-sectional study included 102 patients with HF–caregiver dyads recruited from outpatient clinics in South Korea. Digital literacy was measured using the Everyday Digital Literacy Questionnaire. HF self-care, encompassing 3 key dimensions—self-care maintenance, symptom perception, and self-care management—was assessed using the Self-Care of Heart Failure Index (version 7.2) for patients and the Caregiver Contribution to Self-Care of Heart Failure Index (version 2.0) for caregivers. Dyadic associations were analyzed using the Actor-Partner Interdependence Model with maximum likelihood estimation.

Results: Patients (age: mean 79.4, SD 9.1 years) had significantly lower digital literacy than caregivers (age: mean 59.0, SD 13.1 years). Caregivers primarily consisted of adult children (63/102, 61.8%), followed by spouses (33/102, 32.4%). The Actor-Partner Interdependence Model results revealed significant actor effects of digital literacy on symptom perception for both patients (β=0.26; *P*=.008) and caregivers (β=0.32; *P*=.002). For self-care management, a significant actor effect was observed only for patients (β=0.24; *P*=.02). No significant actor effects were found for self-care maintenance, and no partner effects reached statistical significance across any dimension.

Conclusions: Digital literacy significantly influenced individuals' own HF self-care behaviors, particularly symptom perception, but cross-partner effects were not observed within dyads. These findings suggest that digital health interventions should assess

XSL•FO
RenderX

and address patients' and caregivers' digital skills as distinct targets rather than assuming spillover effects within dyads. To optimize HF outcomes in aging populations, culturally sensitive and dyad-focused strategies that consider individual digital literacy are essential.

KEYWORDS

digital literacy; heart failure; self-care; caregiver; symptom perception

Introduction

Heart failure (HF) is a prevalent and progressive cardiovascular syndrome among older adults, affecting approximately 18.6% of adults aged 80 years and older in Korea [1]. It is driven by age-related structural and functional changes in the cardiovascular system as well as cumulative cardiac diseases across the life course [2]. Older patients with HF often present with multiple comorbidities, frailty, and functional limitations, making disease management increasingly complex [3]. As populations age globally, the burden of HF continues to rise with high readmission and mortality rates among older adults, resulting in substantial health care use and economic burden [1,2,4,5].

Effective self-care is central to slowing HF progression, preventing irreversible cardiac damage, and improving long-term outcomes [5-7]. Substantial evidence consistently demonstrates that appropriate HF self-care reduces hospital readmissions and mortality and enhances the quality of life among patients with HF [8-10]. HF self-care is theoretically grounded in situation-specific theories of HF management and conceptualized as a multidimensional process encompassing self-care maintenance, symptom perception, and self-care management. These dimensions enable patients to maintain physiological stability, detect changes in symptoms, and respond appropriately to exacerbations [6,7,11]. Particularly, symptom perception—the ability to recognize, interpret, and evaluate bodily changes—has gained increasing attention because of its strong association with lower mortality and fewer readmissions [4,12,13].

Despite its importance, effective self-care is particularly challenging for older adults with HF [3]. Cognitive decline, physical limitations, multimorbidity, and reduced self-efficacy often hinder adherence to recommended behaviors and delay timely symptom perception and management [8,12,14,15]. In the context of aging, successful self-care increasingly depends on external support, as age-related functional decline limits patients' ability to independently manage complex treatment regimens [3,14,16]. This interdependence highlights the essential role of caregivers in facilitating HF self-care among older adults [3,17]. Caregivers assist with medication management, symptom monitoring, and decision-making, compensating for cognitive or functional limitations [3,16]. Consequently, HF self-care in later life should be conceptualized as a dyadic process embedded within patient-caregiver relationships rather than as isolated individual efforts and behaviors [17-19].

As HF management increasingly incorporates digital health technologies—including mobile apps, telemonitoring systems, and wearable devices—these tools have become integral components of contemporary care, enabling remote monitoring and promoting patient-centered self-care beyond traditional clinical settings [20,21]. However, the effectiveness of digital health technologies depends largely on users' acceptance and digital literacy [22,23], particularly among older adults who often experience difficulties with technology adoption and use [24,25].

Digital literacy, defined as the ability to access, understand, evaluate, and apply digital information, is a key determinant of successful engagement with digital health interventions [22]. Older adults generally exhibit lower levels of digital literacy than younger populations, which can limit effective technology use, undermine self-care adherence, and exacerbate digital health disparities in HF care [23-25]. Because caregivers frequently assist older patients in navigating digital environments [26,27], understanding digital literacy within patient-caregiver dyads is essential for developing inclusive and sustainable HF self-care strategies [3,17].

Given the frequent and ongoing interactions between patients and caregivers in older populations, analyses focused solely on individuals are insufficient to capture the complexity of HF self-care processes [3,17,18]. A dyadic analytic framework, such as the Actor-Partner Interdependence Model (APIM), allows the simultaneous evaluation of how individual characteristics influence both one's own outcomes (actor effects) and those of one's partner (partner effects), capturing bidirectional dynamics that are often overlooked in individual-level analyses [19,28].

Importantly, patient-caregiver relationships vary substantially across cultural contexts [18,29]. While previous research in Western settings has predominantly focused on spousal caregivers [30-32], East Asian societies, influenced by Confucian values, emphasize family-centered caregiving, with adult children frequently assuming the primary caregiving role [18,29]. Despite these cultural distinctions, empirical research examining dyadic processes and the role of digital literacy in HF self-care within Asian contexts remains remarkably scarce [19]. This gap is especially salient in East Asian contexts, where family-centered caregiving and age-related digital literacy challenges frequently coexist.

Therefore, this study aimed to (1) compare digital literacy levels between older patients with HF and their caregivers and (2) examine how digital literacy influences HF self-care behaviors within patient-caregiver dyads using a dyadic analytic framework. By identifying actor and partner effects, this study seeks to inform the design of culturally sensitive, dyad-focused digital health interventions that enhance collaborative HF

XSL•FO
RenderX

self-care among older adults with HF and their caregivers in Korea and similar East Asian contexts.

Methods

Participants and Study Design

This cross-sectional study recruited 102 dyads of patients with HF and their caregivers from the outpatient clinic of a tertiary hospital in South Korea between March and September 2023. Eligible patients were adults aged 19 years or older with a confirmed diagnosis of HF. Caregivers were adults aged 19 years or older who provided unpaid care to the participating patients. Patients were excluded if they had a history of heart transplantation or left ventricular assist device implantation or had cognitive impairment that could interfere with study participation. Caregivers who were paid or formally employed by the patient or the patient's family were also excluded.

Ethical Considerations

This study was approved by the institutional review board of Yonsei University Health System (approval 4-2022-1622). All participants provided written informed consent before participation. The survey was conducted anonymously, and no personally identifiable information was collected. As compensation for participation, both patients and their caregivers received a small gift equivalent to approximately US $7.

Measurements

Digital Literacy

Digital literacy was assessed using the Everyday Digital Literacy Questionnaire (EDLQ), a 22-item instrument developed and validated for older adults in South Korea [33]. The EDLQ measures 3 domains: information and communication (9 items), content creation and management (4 items), and safety and security (9 items). Items are rated on a 5-point Likert scale ranging from 1 (strongly disagree) to 5 (strongly agree), with higher total scores indicating greater overall digital literacy. The EDLQ has demonstrated excellent internal consistency, with a Cronbach α of 0.98 at the time of development [33] and 0.96 in this study.

HF Self-Care and Caregiver Contribution to HF Self-Care

Patients' HF self-care was assessed using the Self-Care of Heart Failure Index (version 7.2), a 29-item instrument comprising 3 dimensions: self-care maintenance (11 items), symptom perception (10 items), and self-management (8 items). Items are rated on a 5-point Likert scale. Following the scoring guidelines provided by the instrument developers, raw scores of each dimension were transformed into standardized scores ranging from 0 to 100, with higher standardized scores indicating better self-care. The Self-Care of Heart Failure Index (version 7.2) was originally developed by Riegel et al [6] and has been culturally adapted and validated for use in Korea [34]. Reported internal consistency ranges from Cronbach α of 0.70 in the original version [6] to 0.71 to 0.96 in the Korean version [34]. In this study, Cronbach α values for patients' HF self-care ranged from 0.76 to 0.84 across dimensions. Additionally, the caregiver contribution to HF self-care was measured using the Caregiver Contribution to Self-Care of Heart Failure Index (version 2.0), a parallel instrument designed to assess caregivers' support for patients' HF self-care across the same 3 dimensions. Scores were standardized on a 0 to 100 scale. The Caregiver Contribution to Self-Care of Heart Failure Index (version 2.0) has demonstrated strong validity in previous studies (Cronbach α=0.90) [35]. In this study, Cronbach α values for caregiver contribution were 0.72 for maintenance, 0.85 for symptom perception, and 0.76 for self-care management.

Covariates

Dyadic mutuality was assessed using the 15-item Mutuality Scale from the Family Caregiving Inventory, which evaluates love, shared values, reciprocity, and enjoyable activities on a 5-point scale. Higher scores indicate greater perceived mutuality [36]. The scale has demonstrated strong internal consistency in previous studies (Cronbach α=0.91-0.96) [31,37] and in this study (Cronbach α=0.95). Although mutuality was assessed for both dyad members, patient and caregiver scores were highly correlated (r>0.70; P<.001). To maintain model parsimony and avoid multicollinearity within the APIMs [38], only caregiver-perceived mutuality was included as a covariate, reflecting the caregiver's central role in shaping HF self-care support and caregiving behaviors [37,39]. Caregiver relationship type (spouse vs adult children) was included to account for differences in caregiving roles and responsibilities [29,30]. Patient comorbidity burden was assessed using the age-adjusted Charlson Comorbidity Index (ACCI), which incorporates age as a weighted component in addition to comorbid conditions to better capture overall disease complexity in older adults [40]. Additionally, patients' perceived economic status and residential areas (urban vs rural) were included to capture potential socioeconomic and contextual disparities in digital literacy, health resource access, and HF self-care behaviors in older adults [22,24,25].

Data Analysis

Data analyses were conducted using SPSS Statistics (version 26.0; IBM Corp) and SPSS AMOS (version 30.0; IBM Corp). Descriptive statistics were used to summarize participant characteristics and study variables.

Preliminary Analyses and Assumptions

Before model estimation, distributional assumptions for all primary continuous variables were examined using skewness and kurtosis statistics, histogram inspection, and normal *Q-Q* plots. These diagnostic procedures were conducted to assess the suitability of maximum likelihood (ML) estimation for APIM-based structural equation models. Although several variables demonstrated mild departures from normality—common for bounded Likert-type measures in behavioral and health research—all values remained within acceptable ranges for ML estimation in structural equation modeling (|skewness|<2.0; |kurtosis|<7.0) [41-43]. No evidence of severe nonnormality or influential outliers was identified. Given these findings and the moderate sample size (102 dyads), no variable transformations were applied, and ML estimation was retained for all analyses.

XSL•FO
RenderX

Bivariate associations among key variables were examined using Pearson correlation coefficients for continuous variables. Spearman correlations were applied to assess the association involving the ordinal variables (ie, perceived economic status). A complete correlation matrix with exact sample size, correlation coefficients, and *P* values is presented in Multimedia Appendix 1.

APIM Model Specification

Dyadic relationships were analyzed using the APIM, treating dyad members as a priori distinguishable by role (patients with HF vs caregivers) [38]. Each dyad consisted of 1 patient and 1 identified primary caregiver, recruited and coded separately by role. Digital literacy was measured using the same instrument for both members, whereas HF self-care outcomes were assessed using parallel role-specific instruments (patient HF self-care vs caregiver contribution to HF self-care).

Separate APIMs were estimated for each HF self-care dimension (eg, maintenance, symptom perception, and management) using ML estimation in AMOS. In each model, four structural paths were freely estimated: (1) two actor effects (patient digital literacy predicting patient HF self-care and caregiver digital literacy predicting caregiver contribution to HF self-care) and (2) two partner effects (patient digital literacy predicting caregiver contribution to HF self-care and caregiver digital literacy predicting patient HF self-care).

Patient and caregiver digital literacy scores, specified as the primary predictors, were allowed to covary to account for interdependence within dyads. Residuals of patient HF self-care and caregiver contribution to HF self-care were also correlated to capture dyadic interdependence not explained by the predictors. Five covariates—caregiver-perceived mutuality, caregiver relationship type (spouse vs adult child), patient comorbidity burden (ACCI), patient's perceived economic status, and residential area—were specified as exogenous variables, and covariances among all exogenous variables were freely estimated. No equality constraints were imposed across patient and caregiver paths. APIMs were estimated using a structural equation modeling framework to account for dyadic interdependence. Consistent with previous APIM studies [44], global model fit indices were not reported because the model was saturated. Model evaluation focused on the magnitude, direction, and statistical significance of estimated actor and partner effects, covariance, and explained variance (R^2) for patient and caregiver outcomes. The analyses represent concurrent (cross-sectional) APIMs. No mediators were specified, and no indirect effects were estimated.

Results

Characteristics of Patients With HF and Their Caregivers

A total of 102 patient-caregiver dyads were included in the analysis. Patients with HF had a mean age of 79.4 (SD 9.1) years, and 55 (53.9%) patients were female. Caregivers were younger (age: mean 59.0, SD 13.1 years) and predominantly female (n=67, 65.7%). Most caregivers were adult children, including sons, daughters, daughters-in-law, and sons-in-law (n=63, 61.7%), followed by spouses (n=33, 32.4%). Nearly half (n=49, 48%) of the patients lived with their caregivers. Patients generally had lower educational attainment compared with caregivers, and half (n=51, 50%) of the patients resided in rural areas.

Mean mutuality score indicated moderate levels of perceived mutuality for both patients (mean 2.8, SD 0.7) and caregivers (mean 2.7, SD 0.9). Patient and caregiver mutuality were strongly correlated (r=0.70; P<.001; Multimedia Appendix 1), reflecting the interdependent nature of patient-caregiver dyads.

Regarding clinical characteristics, 55 (53.9%) patients had HF with preserved ejection fraction. The mean left ventricular ejection fraction was 52.25% (SD 12.2%). Most patients presented with mild HF symptoms, classified as New York Heart Association class I to II, accounting for 89 (87.3%) samples. Patients exhibited a substantial comorbidity burden, with a mean ACCI score of 6.4 (SD 2.2). Detailed demographic and clinical characteristics are summarized in Table 1.

[a]Patients and caregivers are members of the same dyad; therefore, values are presented for descriptive purposes only.

[b]Not applicable.

Digital Literacy and HF Self-Care Outcomes Within Dyads

Patients demonstrated significantly lower digital literacy than caregivers (mean 31.9, SD 20.6 vs mean 77.8, SD 30.8: $P<.001$). HF self-care outcomes were assessed across 3 dimensions: maintenance, symptom perception, and management. Symptom perception was the lowest-scoring dimension for both patients' HF self-care (mean 46.9, SD 16.6) and caregivers' contribution to HF self-care (mean 52.5, SD 19.7). Descriptive statistics of HF self-care outcomes across the 3 dimensions are presented in Table 2.

XSL•FO
RenderX

Table 2. Comparisons of digital literacy and heart failure (HF) self-care outcomes between patients and caregivers (N=102 dyads)[a].

Variables	Patients, mean (SD)	Caregivers, mean (SD)	*t* test (*df*)	*P* value
Digital literacy				
Total score	31.9 (20.6)	77.8 (30.8)	–12.60 (101)	<.001
Safety and security	13.5 (9.5)	33.3 (12.9)	–12.43 (101)	<.001
Information and communication	13.0 (8.1)	31.9 (12.6)	–12.98 (101)	<.001
Contents creation and management	5.4 (3.3)	12.6 (6.1)	–10.51 (101)	<.001
HF self-care				
Maintenance	62.6 (10.2)	59.0 (17.4)	2.05 (101)	.04
Symptom perception	46.6 (16.6)	52.5 (19.7)	–2.66 (101)	.009
Management	62.1 (16.1)	65.0 (18.1)	–1.39 (101)	.17

[a]Comparisons between patients and caregivers were conducted using paired *t* tests (2-tailed), as they were members of the same dyad.

Dyadic Associations Between Digital Literacy and HF Self-Care (APIM Results)

Across the 3 HF self-care dimensions, distinct patterns of association between digital literacy and self-care outcomes were observed. For HF self-care maintenance, digital literacy was not significantly associated with patient or caregiver outcomes, indicating no interpretable actor-partner structure in this dimension. In contrast, for symptom perception, significant actor effects of digital literacy were observed for both members of the dyad. Higher patient digital literacy was associated with better patient symptom perception (B=0.21; β=0.26, SE 0.08, 95% CI 0.06-0.37; *P*=.008), and higher caregiver digital literacy was associated with greater caregiver contribution to symptom perception (B=0.21; β=0.32, SE 0.07, 95% CI 0.08-0.34; *P*=.002), reflecting an actor-dominant pattern with no evidence of cross-partner effects. For self-care management, only the patient's digital literacy demonstrated a significant actor effect on patient self-care outcome (B=0.19; β=0.24, SE 0.08, 95% CI 0.03-0.35; *P*=.02), whereas no other actor or partner effects reached statistical significance for either member of the dyad. Detailed APIM results are presented in Table 3. The model accounted for approximately 22.6% of the variance in patients' symptom perception, 35.3% in caregivers' symptom perception, and 14.6% in patients' self-care management. A summary of standardized actor and partner effects across the 3 APIMs is presented in Figure 1.

Discussion

Principal Findings

To the best of our knowledge, this is the first study to examine the influence of digital literacy on HF self-care using APIM within patient-caregiver dyads. Significant actor effects of digital literacy were found for both patients and caregivers on the symptom perception dimension of HF self-care, whereas no partner effects were observed. Patients with higher digital literacy demonstrated a better ability to detect and interpret symptoms and to engage in effective self-care management. Likewise, caregivers with higher digital literacy showed greater competence in identifying HF-related changes, although their digital literacy did not significantly affect patients' overall maintenance or management behaviors. These findings highlight the independent role of digital literacy in shaping HF self-care behaviors and underscore the need for strategies that enhance digital literacy in both patients and caregivers [45].

Previous research indicates that educational attainment and access to health information are closely related to both digital literacy and HF self-care, particularly symptom perception [12,15,46]. Lower educational levels have been linked to reduced self-care autonomy and delayed recognition of symptom changes, often through the pathway of limited digital literacy [22,25]. In this study, the generally low education level of the older patients, combined with the fact that half of the participants (51/102, 50%) resided in rural areas, likely reflects a broader digital divide [22,25]. These sociocontextual factors may help explain the overall low digital literacy observed in our sample and emphasize the persistent digital disparities faced by older adults with HF [22,23,25].

In this context, caregivers with higher digital literacy demonstrated greater contributions to symptom perception,

enabling faster identification of changes in patients' health status [3,11,12,47]. However, contrary to our initial hypothesis, caregivers' digital literacy did not directly affect maintenance or management dimensions of HF self-care. These findings may also reflect the current design orientation of many digital health tools for HF, which predominantly emphasize information provision and symptom monitoring rather than sustained lifestyle modification [20,21,48,49]. Accordingly, digital literacy may facilitate symptom perception without necessarily translating into long-term behavioral change in HF self-care maintenance and management [50].

This finding may also be explained by entrenched lifestyle patterns among older adults, such as long-standing dietary and physical activity habits that are less amenable to behavioral change [8,16]. Furthermore, as most caregivers in this study were patients' adult children, their capacity to significantly alter patients' long-standing lifestyle patterns—especially regarding diet and physical activity routines—is likely limited within the context of family-centered caregiving norms in East Asian societies [18,29].

These cultural caregiving norms are particularly evident in Korea. In many East Asian societies shaped by Confucian values that prioritize filial piety, adult children frequently take primary responsibility for caregiving [18,29]. However, rapid industrialization and changing social structures have reduced opportunities for intergenerational coresidence, resulting in caregiving that is frequently provided without daily cohabitation [18,51]. In such contexts, caregivers may play more of a technical or assisting role—helping with device use or symptom monitoring—rather than engaging in continuous motivational or educational support [26,27]. This relational pattern may reduce the potential for partner effects on self-care behaviors. This finding contrasts with previous research that has emphasized caregiver support—particularly within spousal dyads—as an important determinant of adherence [9,31,32].

Finally, we adjusted for mutuality—the quality of reciprocal understanding and rapport between patient and caregiver—to isolate the effects of digital literacy [31,36]. Because mutuality is known to influence communication, decision-making, and joint self-care [31,36,37,39], future studies should explore how digital literacy and mutuality interact over time or across caregiving stages to shape dyadic engagement in digital health–based management.

Limitations

Despite the valuable insights provided by this study, several limitations should be noted. First, caregiving in South Korea often involves multiple family members rather than a single designated caregiver, which may limit the transferability of the findings. Second, the study was conducted in a single center with mixed urban and rural characteristics, and the limited sample size may affect generalizability. Third, other relevant factors, including cognitive function and depressive symptoms, were not examined and should be considered in future dyadic studies of digital health–supported self-care. Finally, the reliance on self-reported data may have introduced bias; future studies should incorporate objective measures of digital literacy, self-care behaviors, and clinical outcomes (eg, hospitalization or mortality) to better assess health impact.

Conclusions

This dyadic analysis indicates that digital literacy plays a significant role in HF self-care, particularly in enhancing symptom perception for both patients and caregivers, while cross-partner influences were not evident. The findings suggest that digital literacy interventions should engage both members of the dyad, with strategies tailored to caregiving relationships, cultural norms, and individual readiness. To bridge the gap between symptom perception and behavior change, future digital health interventions should integrate more interactive, habit-forming features beyond simple monitoring. In addition, considering older adults' ingrained habits, mutuality, and sociocultural caregiving patterns will be essential in designing effective, equitable digital self-care programs. Future longitudinal and intervention studies are needed to validate these pathways and optimize collaborative self-care in diverse populations with HF.

Acknowledgments

The authors thank the outpatient clinic staff who assisted with participant recruitment and coordination of data collection, as well as the research assistants who supported data management. The authors also appreciate the collaborative efforts of all coauthors in completing this research.

Data Availability

The datasets generated or analyzed during this study are available from the corresponding author on reasonable request.

Funding

This research was supported by the Brain Korea 21 FOUR Project through the National Research Foundation of Korea, Yonsei University College of Nursing, and a grant from the National Research Foundation of Korea funded by the Ministry of Education (grant 2340046871).

Authors' Contributions

HK conceptualized the study, developed the overall research design, and drafted the manuscript. SHC supervised the research, provided overall guidance, and managed the study process. MLC contributed to the theoretical framework and refinement of the

Abstract

Background: A higher prevalence of behavioral and psychological symptoms of dementia is associated with a greater caregiver burden and increased mortality in people with dementia. Considering the possibility of a reciprocal relationship between sleep disturbances and these symptoms, time series analyses are necessary to explore the associated temporal dynamics.

Objective: This study aimed to examine dynamic interdependencies between sleep disturbances and behavioral and psychological symptoms of dementia in older adults.

Methods: Daily interactions between sleep patterns and behavioral and psychological symptoms of dementia were analyzed over a 14-day period using a panel vector autoregressive model. Data were collected from June 2018 to June 2020 in community and institutional settings. A total of 154 older adults with dementia wore wrist actigraphy devices continuously for 2 weeks for sleep data, and caregivers recorded behavioral and psychological symptoms of dementia in a daily symptom diary.

Results: Using a panel vector autoregressive model, we analyzed data from 154 older adults living with dementia and their caregivers. The results showed unidirectional Granger causality running from the number of awakenings on the previous day to irritability (P=.03) and appetite or eating disorders (P=.04) on the following day. Conversely, some of the previous day's behavioral and psychological symptoms of dementia temporally preceded subsequent changes in sleep patterns. Specifically, delusions had a Granger-causality effect on total sleep time (P<.001), wake after sleep onset (P=.01), and the number of awakenings (P=.006), while irritability had a Granger causality effect on the number of awakenings (P=.007). Notably, bidirectional Granger causality was observed between irritability and the number of awakenings.

Conclusions: This study demonstrates that the relationship between the behavioral and psychological symptoms of dementia and sleep patterns is dynamic and forms a vicious cycle. Consequently, early intervention to alleviate symptoms is imperative, and strategies to enhance sleep quality and address sleep disturbances should be prioritized.

Introduction

Behavioral and psychological symptoms of dementia encompass a range of noncognitive disturbances [1]. The Neuropsychiatric Inventory, a scale widely used for assessing the behavioral and psychological symptoms of dementia, identifies 12 subsymptoms, including delusion, hallucination, anxiety, irritability, depression, sleep disturbances, apathy, disinhibition, changes in appetite, and agitation [1,2]. These behavioral and psychological symptoms can manifest at any stage of dementia, with their prevalence, frequency, and severity often increasing as the condition progresses [3]. Recent evidence indicates that approximately 90% of people living with dementia exhibit at least 1 behavioral and psychological symptom [4]. A higher prevalence of such symptoms is associated with a higher care burden in caregivers and increased mortality among people living with dementia [5-7]. In light of these observations, securing effective management of the behavioral and psychological symptoms of dementia is crucial to alleviating caregiver burden and improving the quality of life for those living with dementia. Among the factors contributing to behavioral and psychological symptoms of dementia, unmet physical and psychological needs have been identified as key drivers [8,9], with sleep disturbances playing a particularly important role. Individuals living with dementia commonly experience sleep disturbances [10,11], and accumulating evidence indicates that poor sleep quality is associated with behavioral and psychological symptoms of dementia, such as apathy and depression [12-14]. The existing evidence suggests that sleep patterns may correlate with the occurrence of behavioral and psychological symptoms of dementia [15-17].

Several studies have explored the relationship between sleep disturbances and the behavioral and psychological symptoms of dementia. Some studies suggest that sleep disturbances contribute to the development of such symptoms [18-20], while others claim that such symptoms may affect sleep disturbances the following day [12]. Cho et al [20] identified that sleep disturbances are a risk factor for behavioral and psychological symptoms of dementia in patients living with the condition. Nonetheless, these results have definite drawbacks because they assume a unidirectional relationship. Given the complexity of these interactions, there is a need to examine the temporal dynamics and directionality of the relationship between sleep patterns and behavioral and psychological symptoms of dementia.

Accordingly, this study used a panel vector autoregressive approach to examine day-to-day temporal dynamics between actigraphy-based sleep patterns and caregiver-recorded behavioral and psychological subsymptoms of dementia, using data collected over a 14-day period. Given the potential variability in the associations between behavioral and psychological subsymptoms of dementia and sleep patterns, we initially used a linear mixed model to account for between-participant variability. However, this approach is limited in its ability to capture dynamic changes over time and directional temporal associations. To address these limitations, we subsequently used a panel vector autoregressive model, which treats all variables as endogenous and enables the examination of reciprocal temporal interdependencies and autoregressive structures over time. This approach is well suited for exploratory analyses of complex temporal relationships without imposing predefined causal directions [21]. Accordingly, this approach allowed for an exploratory examination of day-to-day temporal dynamics between objectively measured sleep disturbances and behavioral and psychological symptoms of dementia, including 12 specific subsymptoms. By applying this framework, this study aims to provide a more nuanced understanding of the temporal interdependence between behavioral and psychological symptoms of dementia and sleep disturbances at the daily level.

Methods

Design

This study used a prospective observational design and applied a panel vector autoregressive model to explore the dynamic interdependencies between behavioral and psychological symptoms of dementia and sleep patterns.

Participants

Older adults with dementia were recruited from neurology outpatient departments of tertiary hospitals, daycare centers, and nursing homes in South Korea. The inclusion criteria for the participants were as follows: age 65 years or older, a diagnosis of dementia, a Korean Mini-Mental State Examination score less than 24 points, and the presence of behavioral and psychological symptoms of dementia at least once a week at baseline. Primary caregivers were also included if they provided the majority of care for the recruited older adults and were able to read and write in Korean. The data were collected from June 2018 to June 2020.

Procedure

Eligibility screening was conducted by trained researchers through medical record reviews and participant interviews. Two researchers visited the participants' homes or nursing homes on 2 occasions to collect data. Demographic and health data were collected during the first visit. Moreover, older adults living with dementia were instructed to wear an actigraphy device on their wrists continuously for 2 weeks, and caregivers were asked to record the behavioral and psychological symptoms of dementia in a daily diary for 2 weeks. The researchers conducted telephone follow-ups with participants and their caregivers at least 3 times during the 2-week period to monitor participation status and document any notable observations or issues. At the second visit, which was conducted 2 weeks later, the behavioral and psychological symptoms of dementia were retrieved from the diaries and actigraphy devices for data extraction and analysis.

Measurements

Demographic and Health Data

Demographic data, including age, sex, marital status, and education level, along with information on activities of daily living, Mini-Mental State Examination scores, use of sedative medication, and type of dementia diagnosis, were collected from the caregivers and participants' medical records.

XSL•FO
RenderX

Behavioral and Psychological Symptoms of Dementia

A diary consisting of checklists was developed based on the Neuropsychiatric Inventory [22], a standardized instrument for measuring 12 neuropsychiatric symptoms in people living with dementia. Caregivers were asked to record behavioral and psychological symptoms of dementia in a diary daily for 2 weeks. These symptoms were delusions, hallucinations, agitation or aggression, depression, anxiety, euphoria or elation, apathy, disinhibition, irritability, aberrant motor behavior, sleep and nighttime behavior, and appetite or eating disorders.

Sleep Patterns

Sleep patterns were objectively measured using an actigraphy device, the wGT3X-BT activity monitor (ActiGraph) [23]. Participants wore the device on their wrists for 2 weeks, and sleep data were extracted by applying the Cole-Kripke algorithm in ActiLife (version 6.13.3; Ametris) software. The following variables were derived from the daily sleep pattern data, with midnight as the reference point: total sleep time (ie, the time measured as sleep in a day), wake after sleep onset (ie, the time measured as wakefulness during sleep), the number of awakenings, and mean awakening length (ie, the average length of each awakening in minutes).

Ethical Considerations

The data collection procedures for the original study received ethics approval from the institutional review boards of Severance Hospital (4-2018-0348, 4-2019-0314, and 4-2020-0454) and Ilsan Hospital (2018-10-002-001 and 2019-08-012-001). In the original study, informed consent procedures included explicit permission for future secondary analyses of the collected data without the need for additional consent. Participants who completed the study received approximately US $38 as compensation for their participation. All data used in this study were deidentified before access by the research team. Study-related documents and electronic files were stored on a secure, password-protected computer with access limited to members of the authorized research team.

Statistical Analyses

All statistical analyses were performed using Stata (version 16.1; Stata Corp). Given the substantial individual variability in the behavioral and psychological symptoms of dementia and sleep patterns, we first applied a linear mixed model to account for between-participant differences and examine individual-level heterogeneity. We calculated the intraclass correlation coefficient (ICC) to quantify the proportion of the total variance attributable to individual differences. This coefficient indicates the extent to which the variability in a construct is explained by between-participant differences, rather than within-individual fluctuations. A higher ICC suggests that individual characteristics contribute to the observed variability in the behavioral and psychological symptoms of dementia and sleep patterns. However, as the linear mixed model has limitations in capturing bidirectional relationships, fully reflecting dynamic interactions over time, and testing causality, we further used the panel vector autoregressive model to analyze the dynamic interplay between behavioral and psychological symptoms of dementia and sleep patterns.

For the panel vector autoregressive estimation, the optimal lag length was determined as lag 1 based on the minimum modified Bayesian information criterion, modified Akaike information criterion, and modified Hannan-Quinn information criterion statistics [24] (Table S1 in Multimedia Appendix 1). To assess causality within this framework, we conducted a Granger causality test, where the null hypothesis assumed no causal relationship, and a P value <.05 indicated rejection of the null hypothesis (ie, there was a Granger causal effect). This test also allowed us to determine whether the relationship was unidirectional or bidirectional. Statistical significance was set at P<.05.

Results

Participants' General Characteristics, Behavioral and Psychological Symptoms of Dementia, and Sleep Patterns

We initially recruited 175 older adults with dementia, but 18 (10.3%) were excluded owing to refusal to wear the actigraphy device (n=10, 55.6%), hospitalization (n=6, 33.3%), death (n=1, 5.6%), and absence of a caregiver during data collection (n=1, 5.6%). We also excluded 3 (1.7%) participants with insufficient data from the actigraphy device, leaving a final sample of 154 (88%) older adults living with dementia and their caregivers.

Table S2 in Multimedia Appendix 1 shows the baseline characteristics of the participants. The mean age was 81.34 (SD 5.97) years, 93 (60.4%) were women, and most had an elementary school education or less (n=70, 49.4%). The mean activities of daily living score was 10.68 (SD 3.87), indicating difficulty in performing activities of daily living. The mean Mini-Mental State Examination score was 16.86 (SD 5.84), indicating moderate cognitive impairment. Regarding the type of dementia diagnosis, 76 (49.4%) participants were diagnosed with Alzheimer disease, 60 (39%) with Lewy body dementia, 24 (15.6%) with vascular dementia, and 34 (22.1%) with other types of dementia.

Table 1 shows the participants' behavioral and psychological symptoms of dementia and sleep patterns, with a mean of 12.85 (SD 2.40) days of data recorded per participant. Of the 2145 days on which symptoms were recorded, apathy was the most common symptom (n=293, 13.7%), followed by sleep and nighttime behavior (n=259, 12.1%), anxiety (n=238, 11.1%), irritability (n=231, 10.8%), depression (n=230, 10.7%), agitation or aggression (n=194, 9%), and delusion (n=192, 8.6%). The mean total sleep time was 458.21 (SD 253.05) minutes, with a mean of 29.37 (SD 27.47) minutes spent awake during sleep. The total number of awakenings was 12.40 (SD 10.25) per night, with each awakening lasting approximately 2.16 (SD 1.09) minutes.

Table 1. Participants' behavioral and psychological symptoms of dementia and sleep patterns (N=2145 days).

Variables	Values
Number of days of behavioral and psychological symptoms of dementia and actigraphy recordings per person, mean (SD)	12.85 (2.40)
Behavioral and psychological symptoms of dementia, n (%)	
Delusion	192 (8.6)
Hallucination	129 (5.9)
Agitation or aggression	194 (9.0)
Depression	230 (10.7)
Anxiety	238 (11.1)
Euphoria or elation	108 (4.9)
Apathy	293 (13.7)
Disinhibition	41 (1.9)
Irritability	231 (10.8)
Aberrant motor behavior	73 (3.4)
Sleep and nighttime behavior	259 (12.1)
Appetite or eating disorders	157 (7.3)
Sleep factors, mean (SD)	
Total sleep time (minutes)	458.21 (253.05)
Wake after sleep onset (minutes)	29.37 (27.47)
Number of awakenings	12.40 (10.25)
Mean awake length (minutes)	2.16 (1.09)

Linear Mixed Model Estimation Results for Total Behavioral and Psychological Symptoms of Dementia and Sleep Patterns

On the basis of the linear mixed model analysis (Table S3 in Multimedia Appendix 1), there was substantial between-participant variability in the behavioral and psychological symptoms of dementia; however, the fixed effects of sleep patterns on these symptoms were not statistically significant in this model. The ICC values suggested that approximately 49% to 50% of the total variance in the behavioral and psychological symptoms of dementia can be attributed to between-participant differences rather than within-participant fluctuations over time. The random slopes were statistically significant, indicating that the effect of the previous day's symptoms on the following day's symptoms varied between individuals.

Similarly, the total behavioral and psychological symptoms of dementia did not have a statistically significant fixed effect on sleep patterns (Table S4 in Multimedia Appendix 1). However, the ICCs ranged from 0.097 to 0.391, indicating that individual-level differences contributed moderately to the overall variance in sleep patterns, particularly for wake after sleep onset (0.339) and the number of awakenings (0.391), where the proportion of variance due to individual differences was relatively high.

Given the statistically significant random slopes, the relationship between the behavioral and psychological symptoms of dementia and sleep may be strongly influenced by individual differences. This required further analysis using a panel vector autoregressive model to capture the within-individual temporal dynamics.

Panel Vector Autoregressive Model Estimation Results for Total Behavioral and Psychological Symptoms of Dementia and Sleep Patterns

Table 2 shows the results of the panel vector autoregressive model estimation, with behavioral and psychological symptoms of dementia as the response variable. The previous day's wake after sleep onset (P=.01), the number of awakenings (P=.008), and mean awakening length (P=.008) were temporally associated with higher levels of the following day's total behavioral and psychological symptoms of dementia.

XSL•FO
RenderX

Table 2. Panel vector autoregressive model estimation results for total behavioral and psychological symptoms of dementia by sleep pattern.

Impulse variables	Response variables: total behavioral and psychological symptoms of dementia	
	β (SE)	*P* value[a]
Total sleep time	0.00089 (0.00056)	.11
Wake after sleep onset	0.00495 (0.00200)	.01
Number of awakenings	0.01580 (0.00597)	.008
Mean awakening length	0.15242 (0.05767)	.008

[a]*P* value represent the results of the Granger causality test within the panel vector autoregressive model.

Table 3 shows the results of the panel vector autoregressive model estimation using sleep patterns as the response variable. The previous day's behavioral and psychological symptoms of dementia were temporally associated with higher total sleep time (*P*<.001), greater wake after sleep onset (*P*=.003), and a higher number of awakenings (*P*=.001) on the following day.

Table 3. Panel vector autoregressive model estimation results for sleep pattern by total behavioral and psychological symptoms of dementia.

Impulse variables: total behavioral and psychological symptoms of dementia	Response variables	
	β (SE)	*P* value[a]
Total sleep time	90.49515 (25.21297)	<.001
Wake after sleep onset	4.34126 (1.47666)	.003
Number of awakenings	1.83004 (0.56304)	.001
Mean awakening length	0.00914 (0.07713)	.91

[a]*P* value represent the results of the Granger causality test within the panel vector autoregressive model.

Granger causality tests (Tables 2 and 3) were conducted to test for causality between the variables that had a statistically significant relationship. The tests revealed unidirectional Granger causality, consistent with the panel vector autoregressive model estimates.

Linear Mixed Model Estimation Results for Behavioral and Psychological Subsymptoms of Dementia and Sleep Patterns

Tables S5 and S6 in Multimedia Appendix 1 show the relationship between the 12 behavioral and psychological subsymptoms of dementia and sleep patterns as analyzed by the linear mixed model. The findings resemble those of the linear mixed model analysis of total symptoms and sleep patterns. Few of the fixed effects of sleep patterns on the behavioral and psychological subsymptoms of dementia were statistically significant, but the ICC values ranged from 0.57 to 0.83, indicating that much of the variation in the subsymptoms could be attributed to between-individual differences (Table S5 in Multimedia Appendix 1).

Similarly, the 12 behavioral and psychological subsymptoms of dementia did not exhibit a statistically significant fixed effect on sleep patterns (Table S6 in Multimedia Appendix 1). However, the ICC values, ranging from 0.099 to 0.391, suggest that individual differences account for a moderate proportion of the overall variance in sleep patterns. Notably, wake after sleep onset (ICC 0.337-0.340) and the number of awakenings (ICC 0.389-0.391) showed relatively high ICC values, indicating that a substantial portion of the variance in these sleep parameters is attributable to between-participant variability.

The high ICC values and statistically significant random slopes indicate substantial individual variability in the relationships between behavioral and psychological subsymptoms of dementia and sleep patterns. Consequently, it was necessary to use a panel vector autoregressive model to analyze these within-individual dynamic, reciprocal relationships over time.

Panel Vector Autoregressive Model Estimation Results for Behavioral and Psychological Subsymptoms of Dementia and Sleep Patterns

Tables 4-6 show the results of the panel vector autoregressive model estimation for behavioral and psychological subsymptoms of dementia as response variables. The previous day's sleep patterns were temporally associated with higher levels of some subsymptoms: irritability was temporally associated with higher total sleep time (*P*=.02), a greater number of awakenings (*P*=.03), and longer mean awakening length (*P*=.04) on the previous day, and appetite or eating disorders were temporally associated with a higher number of awakenings on the previous day (*P*=.04).

[a]*P* value represent the results of the Granger causality test within the panel vector autoregressive model.

Granger causality tests were subsequently conducted for variable pairs that demonstrated statistically significant temporal associations in the panel vector autoregressive models (Tables 5-7). The results showed unidirectional Granger causality, consistent with the panel vector autoregressive model estimation. Bidirectional Granger causality was observed only between irritability and the number of awakenings.

Discussion

Principal Findings

Using panel data and a panel vector autoregressive model, this study longitudinally analyzed the dynamic relationships between behavioral and psychological symptoms of dementia and sleep patterns among older adults with dementia. Regarding the main findings, first, the number of sleep awakenings on the previous day was temporally associated with higher levels of irritability and appetite or eating disorders on the following day. Second, some of the previous day's behavioral and psychological subsymptoms of dementia were temporally associated with subsequent changes in sleep patterns (eg, an increase in total sleep time, the number of awakenings, and mean awakening length).

A linear mixed model analysis was conducted to contextualize these findings, revealing substantial between-participant variability in both behavioral and psychological symptoms of dementia and sleep patterns. Although the fixed effects were not statistically significant, the random slopes were statistically significant, and there were moderate to high ICCs, indicating that individual differences contributed meaningfully to variability in both variables; that is, the relationships between behavioral and psychological symptoms of dementia and sleep patterns were not uniform across individuals and may involve complex, time-dependent interactions. Accordingly, a panel vector autoregressive model was implemented, revealing statistically significant temporal associations in which sleep patterns preceded changes in irritability and appetite or eating disorders. This indicates that interventions to improve sleep quality should be implemented in the early stages of sleep disturbance to alleviate the behavioral and psychological symptoms of dementia that may stem from poor sleep quality.

Importantly, our evidence implies that effectively preventing the occurrence of irritability and appetite or eating disorders in older adults with dementia requires careful and consistent monitoring and management of increases in total sleep time, the number of awakenings, and mean awakening length. Previous studies have reported that 22.6% of people with dementia have excessive daytime sleepiness and that sleep disturbances are associated with the onset of behavioral and psychological symptoms of dementia [18,19]. Furthermore, to avoid excessive total sleep time, people with dementia should engage in sufficient physical and social activity and limit daytime napping [25,26].

In particular, the number of awakenings during sleep and their duration demonstrated significant temporal associations with subsequent behavioral and psychological symptoms. These findings support other studies that have found a relationship between excessive awakenings and the occurrence of behavioral and psychological symptoms of dementia [27]. Education on sleep hygiene practices, such as maintaining consistent sleep-wake routines and optimizing the sleep environment [25], and combined nonpharmacological interventions, including physical or social activities and caregiver support interventions [28], are reportedly effective in reducing awakenings during sleep and alleviating the behavioral and psychological symptoms of dementia.

Conversely, behavioral and psychological symptoms of dementia onset were temporally associated with subsequent sleep patterns. In particular, irritability had bidirectional Granger causality with the number of awakenings, implying that poor sleep patterns may contribute to the occurrence of symptoms the next day and that the occurrence of irritability may increase the number of awakenings, their duration, and excessive total sleep time. Previous studies provide mechanistic plausibility for this reciprocal relationship, showing that increased nocturnal awakenings and sleep fragmentation can impair emotion regulation through the hyperactivation of the amygdala [29]. Notably, this bidirectional effect was specific to irritability, likely because irritability is more directly coupled with the "arousal system" than internalized symptoms such as depression. Unlike cognitive-heavy symptoms, nocturnal awakenings trigger immediate amygdala hyperreactivity and a failure in top-down

XSL•FO
RenderX

prefrontal control [30], manifesting as acute reactive irritability. This heightened physiological arousal further disrupts sleep maintenance, reinforcing a self-perpetuating reciprocal loop [31]. Clinically, these findings suggest that the relationship between behavioral and psychological symptoms of dementia and sleep can be characterized as a vicious circle, where nocturnal awakenings serve as an early warning signal of worsening irritability.

Consistent with this interpretation, previous studies in patients with Alzheimer disease have shown that on nights when patients awakened their caregivers, they exhibited more behavioral and psychological symptoms of dementia the following morning. Additionally, patients who had difficulty falling asleep displayed more behavioral and psychological symptoms of dementia at night [27]. Similarly, Kuzmik et al [12] demonstrated that higher behavioral and psychological symptoms of dementia were associated with sleep disturbances, especially prolonged sleep latency. Thus, the relationship between the behavioral and psychological symptoms of dementia and sleep patterns seems to be complex and mutually reinforcing, necessitating the integration of sleep management into dementia symptom care programs.

The behavioral and psychological symptoms of dementia represent a primary burden for caregivers of older adults with dementia [7], and sleep disturbances affect the quality of life of both the primary caregiver and the older adult with dementia, contributing to cognitive decline and difficulties with community-based care [32]. Therefore, interventions to decrease these symptoms should be initiated early in the course of the symptoms, and interventions to improve sleep quality should be promoted simultaneously. Pharmacological interventions to address the behavioral and psychological symptoms of dementia are less accessible owing to the prescription process and may have side effects; therefore, nonpharmacologic interventions are recommended, such as reminiscence and music therapy, as they can be easily implemented by caregivers [33,34]. In particular, recent reports suggest that nonpharmacological interventions are more effective when customized to reflect the characteristics and preferences of older adults with dementia, compared with standardized interventions that are applied uniformly across all [35]. This highlights the need to develop and test nonpharmacological interventions aimed at improving sleep quality and alleviating behavioral and psychological symptoms of dementia in older adults with dementia.

This study has important implications for the field. To the best of our knowledge, this is the first study to explore the relationship between the behavioral and psychological symptoms of dementia and sleep patterns through panel vector autoregressive analysis. Sleep patterns were also observed using actigraphy technology, not subjective surveys.

Limitations

This study has some limitations. First, behavioral and psychological symptoms of dementia were assessed using caregiver-recorded daily diaries, which may be vulnerable to recall bias owing to retrospective reporting. Future studies may consider ecological momentary assessment approaches using mobile apps to enable real-time symptom recording and reduce recall bias. Second, data on medications used by older adults to manage behavioral and psychological symptoms of dementia and sleep, as well as symptom-driven medication changes over time, were not available. Although the panel vector autoregressive model addresses time-invariant individual heterogeneity by modeling within-person temporal dynamics, it cannot fully adjust for unmeasured time-varying confounders, such as changes in medication use or comorbidity severity over time. Consequently, such unobserved temporal changes may have influenced both behavioral and psychological symptoms of dementia and sleep patterns and should be considered when interpreting the findings.

Third, the relatively short 14-day observation period limited the evaluation of longer lag structures and seasonal effects on sleep patterns. Future studies using longer-term longitudinal data are needed to examine extended lag dynamics and potential seasonal influences. Furthermore, the lack of observed bidirectionality in behavioral and psychological subsymptoms of dementia, other than irritability, may be due to their longer-term trajectories, which might necessitate more extended observation and larger cohorts to detect subtle daily fluctuations. Some statistically significant associations were characterized by small effect sizes, likely reflecting the chronic and progressive nature of dementia, in which abrupt day-to-day changes in behavioral and psychological symptoms of dementia and sleep are uncommon. In this context, the short observation period may have captured only subtle temporal fluctuations, and future studies with longer follow-up periods are needed to examine whether such small changes accumulate over time and become clinically meaningful.

Finally, this study relied on convenience sampling and included a relatively small sample, which may limit the generalizability of the findings. Moreover, although the overall participation rate (154/175, 88%) was relatively high for studies involving older adults with dementia, participant attrition occurred during the study period owing to reasons such as refusal to continue using the actigraphy device or hospitalization. Given that these reasons for dropout may have been more common among participants with worsening symptoms, the final analytic sample may underrepresent individuals with more severe conditions. This potential selection bias, combined with the modest sample size and wide 95% CIs for several estimates, may have reduced statistical power and increased the risk of both type I and type II errors.

Conclusions

By integrating a linear mixed model and a panel vector autoregressive model, this study provides comprehensive evidence that accounts for individual variability and examines the bidirectional relationships between behavioral and psychological symptoms of dementia and sleep disturbances. This approach enhances the robustness of our Granger causal inferences. Panel vector autoregressive analysis demonstrated that the variables had an intricate and bidirectional relationship. This suggests that addressing sleep disturbances may mitigate certain behavioral and psychological symptoms of dementia, and vice versa.

XSL•FO
RenderX

The findings imply the importance of holistic approaches to dementia care management. One potential pathway to mitigate symptoms involves detecting behavioral and psychological symptoms of dementia onset and implementing timely interventions to improve both sleep and these symptoms of dementia. Given that these findings highlight the impact of sleep patterns on behavioral and psychological symptoms of dementia, there is a critical need for interventions aimed at improving sleep quality in older adults with dementia. However, the availability of effective nonpharmacologic interventions to enhance sleep quality in older adults with dementia remains limited, highlighting the need for future research to develop and validate such interventions.

Abstract

Background: Home telemonitoring programs are increasingly used to support older adults living with chronic conditions such as heart failure (HF). While these interventions show promise for improving health outcomes and reducing care burden, their effectiveness depends largely on how patients and caregivers integrate digital technologies into everyday life and care relationships. However, relatively few studies have examined these experiences using conceptual frameworks that capture both functional and relational dimensions of care.

Objective: This study aimed to explore the experiences of older adults and their informal caregivers participating in a home telemonitoring program for HF. Drawing on the Person-Based Approach and the Person-Centered Practice frameworks, we examined how participants engaged with both the technofunctional and relational aspects of the intervention.

Methods: We conducted a qualitative study involving 34 patients, 28 informal caregivers, and 20 nurses across 3 primary care organizations in Quebec, Canada. The 6-month intervention included 4 connected devices used by patients (smartwatch, Bluetooth-enabled scale, voice-activated tablet, and a smart pill dispenser [xPill; Domedic]) and a mobile app for caregivers, complemented by remote nursing follow-up. Nurses reviewed patient data through a clinical dashboard at least once daily during weekday daytime shifts. Data were collected through semistructured interviews and field notes and analyzed using directed content analysis.

Results: Participants' experiences revealed both enabling and constraining factors across 2 key dimensions. Technofunctional engagement was shaped by digital literacy, emotional responses to the technology, alignment with daily routines, and access to technical or caregiver support. Relational aspects of care were influenced by perceived professional presence, opportunities for communication and shared decision-making, and the degree of emotional reassurance provided by remote monitoring. While many participants reported increased confidence and a sense of being supported, others experienced frustration, fatigue, or disengagement when the system disrupted routines or when feedback from clinicians was perceived as limited.

Conclusions: Engagement with home telemonitoring technologies among older adults depends not only on usability but also on the relational context in which these technologies are embedded. Combining technofunctional and relational perspectives provides a more comprehensive understanding of how telemonitoring interventions are experienced and highlights the importance of personalized support, reliable technology, and sustained clinical engagement to promote meaningful adoption.

Introduction

Overview

Heart failure (HF) remains one of the leading causes of hospitalization and mortality among older adults globally [1,2]. As health care systems grapple with the dual pressures of aging populations and rising rates of chronic illness, the demand for scalable, patient-centered models of care has become increasingly urgent. Among the most promising innovations in this space are home telemonitoring programs, which aim to support early detection of clinical deterioration, foster self-management, and reduce reliance on in-person visits or rehospitalization [3,4].

Recent evidence supports the clinical value of these interventions. A systematic review and meta-analysis of mobile health technologies for home-based cardiac rehabilitation demonstrated significant improvements in patient outcomes and engagement, suggesting the potential of these tools to enhance chronic disease management at scale [5]. However, findings across studies remain mixed. The effectiveness of home telemonitoring programs often hinges on contextual factors such as system design, user characteristics, and the broader care environment [6]. This variability underscores the importance of understanding how these technologies are experienced and navigated by those who use them in their daily lives.

Older adults, in particular, represent a user group with unique needs and vulnerabilities when it comes to digital health technologies [7,8]. Differences in digital literacy, cognitive capacity, and physical function can pose challenges to sustained engagement. Emotional responses, such as anxiety, fatigue, or frustration, may also shape how older adults relate to technology over time. Moreover, their experience is often mediated by informal caregivers, whose involvement can critically influence the adoption, maintenance, and perceived usefulness of telemonitoring interventions. Yet, despite growing interest in user-centered evaluation, relatively few studies have provided in-depth, real-world accounts of how both patients and caregivers experience home telemonitoring programs.

This study seeks to address this gap by examining the lived experiences of older adults and their informal caregivers who participated in a home telemonitoring intervention [9] for HF across 3 primary care institutions in Quebec, Canada. In this study, we use the term home telemonitoring to refer to digital systems that collect and transmit patients' physiological and self-reported health data from the home environment to clinicians for remote monitoring and follow-up.

The intervention involved 4 interconnected digital devices used by patients: a connected smartwatch, a Bluetooth-enabled scale, a voice-activated virtual assistant tablet, and a smart pill dispenser (xPill; Domedic). In addition, informal caregivers had access to the Proximity mobile app (Virtuose Technologies), which allowed them to receive alerts, monitor patient activity, and communicate with both patients and nurses. These digital tools were complemented by remote nursing follow-up, during which nurses reviewed patient data through a clinical dashboard, responded to alerts, and communicated with patients and caregivers when necessary.

Our objective was to understand how participants perceived and interacted with these technologies, how they navigated their technical and relational demands, and how the system was integrated into the routines and realities of everyday life. To achieve this goal, we draw on 2 complementary conceptual frameworks, namely, the Person-Based Approach (PBA) developed by Yardley et al [10] and the Person-Centered Practice (PCP) framework by McCance and McCormack [11]. The PBA provides a structured lens for understanding users' cognitive, emotional, and behavioral engagement with digital health tools, emphasizing the importance of contextual relevance, emotional acceptability, and iterative user-centered adaptation. The PCP framework complements this by highlighting the relational and experiential dimensions of care, such as perceived professional presence, shared decision-making, and therapeutic alliance. By analyzing user experience through these dual lenses, this study offers a more nuanced understanding of the opportunities and limitations associated with home telemonitoring for older adults with HF. In doing so, it provides actionable insights for clinicians, designers, and managers aiming to improve the effectiveness, equity, and person-centeredness of these interventions. The following section introduces each framework in more detail and outlines its relevance to this study.

Conceptual Background

The PBA Framework

To explore the techno-functional experience, we adopt the PBA to digital health intervention development [10]. The framework emphasizes the centrality of users' lived experiences and psychosocial contexts in shaping how they interact with and respond to digital health tools. It is especially well suited to evaluating complex interventions such as multidevice telemonitoring programs, where sustained engagement is contingent not only on technical usability but also on the personal significance and practical fit of the technology in everyday life. Key elements of the PBA relevant to this study include the following: contextual tailoring, emotional and cognitive response to technology, perceived relevance and burden of technology use, and autonomy, control, and iterative engagement.

The PBA stresses the importance of designing or implementing interventions in ways that reflect the diversity of users' real-life circumstances. This includes recognizing variation in cognitive functioning, literacy levels, physical capabilities, caregiving arrangements, and daily schedules. A telemonitoring system that is too rigid or uniform in its expectations may be experienced as alienating or unmanageable by users whose life

XSL•FO
RenderX

contexts do not match the assumptions embedded in the system's design.

The PBA underscores that user experience includes both affective and cognitive reactions. Feelings of reassurance, anxiety, confidence, or fatigue can influence whether and how users persist with an intervention. In the context of older adults, such responses are closely tied to familiarity with digital devices, past experiences with health care, and the presence or absence of technical or social support.

Perceived relevance and burden of technology use refers to how meaningful and manageable users perceive the intervention to be. For an older adult managing a chronic condition like HF, a telemonitoring device must clearly align with their health goals and offer value in their day-to-day life. At the same time, if the tool is perceived as cognitively demanding, repetitive, or disruptive to routines, it may generate a burden that outweighs perceived benefits, leading to frustration, disengagement, or early withdrawal.

Central to the PBA is the idea that users should feel a sense of agency when interacting with the intervention. Technologies that allow for flexibility and customization can reinforce users' self-efficacy and support their identity as active participants in care. Conversely, systems perceived as overly prescriptive or difficult to modify may reassert feelings of passivity or dependence, particularly among older individuals already accustomed to clinician-led care.

In short, by applying the PBA, we aim to capture the nuanced ways in which older adults and their informal caregivers relate to the telemonitoring devices, how they negotiate its integration into their daily lives, and how usability, meaning, and burden are interpreted differently depending on their capabilities, routines, and support networks.

The PCP Framework

Originally developed to support quality improvement and professional reflection in nursing and allied health contexts, the PCP framework offers a comprehensive model of care that integrates professional ethos, care context, clinical process, and patient outcomes. It is especially relevant for understanding how care is experienced by patients in nontraditional or hybrid contexts, such as digitally mediated care environments, where therapeutic presence, trust, and relational continuity must be maintained at a distance. While the full framework includes 4 domains, namely, prerequisites, care environment, person-centered processes, and person-centered outcomes, this study focuses on the last 2, as these most directly pertain to the interpersonal and experiential dimensions of care in a home telemonitoring model.

Person-centered processes describe how health care professionals enact person-centered values in clinical practice. They represent the core relational and therapeutic mechanisms through which patients experience empathy, partnership, and a sense of agency in their care. One such process is sympathetic presence, which refers to the professional's ability to be emotionally attuned and fully present with the patient. This presence is conveyed through attentive listening, sensitive responses, and compassionate behavior. In remote care settings, where nonverbal cues are absent, sympathetic presence must often be expressed through tone of voice, verbal phrasing, and consistent follow-up. Another key process is authentic engagement, which entails a genuine effort to understand the patient as a person, beyond their clinical profile or transmitted data. This means adapting interactions to align with each patient's preferences, values, and life context, even when mediated by digital systems.

Shared decision-making is also central to PCP. It involves actively involving patients in decisions about their care by presenting options, seeking informed consent, and ensuring mutual understanding. In the context of home telemonitoring, this process often intersects with choices around the timing and content of reminders, the frequency of follow-ups, and the interpretation of patient-reported data. Finally, person-centered care involves working with patient beliefs and values, which requires acknowledging and respecting diverse worldviews, cultural backgrounds, and personal care goals, even when these may differ from standardized clinical routines or digital system defaults.

In a home telemonitoring context, these processes are especially vulnerable to being eroded or routinized, making their presence (or absence) highly meaningful to patients and caregivers.

Person-centered outcomes represent the experiential consequences of person-centered processes and serve as key indicators for evaluating the quality of care from the patient's perspective. One such outcome is the degree of involvement in care, which reflects whether patients feel that their voice is heard and that they have meaningful input into how care is delivered. In the context of home telemonitoring, this may involve being consulted about preferred methods and times for communication or having a say in how their personal health data are used. Another important outcome is the sense of well-being generated through care interactions. This encompasses emotional comfort, reduced anxiety, and a strengthened sense of self-efficacy. Expressions of reassurance, feelings of being understood, and the perception of being genuinely "cared for" at a distance are strong indicators of success in this domain. Finally, the development of a therapeutic alliance, a relationship characterized by trust, continuity, and mutual respect, remains fundamental even in digitally mediated care. Building this alliance requires proactive engagement from clinicians, timely responses to patient inputs, and communication practices that maintain the human element of care despite the technological interface.

By foregrounding these processes and outcomes, McCance and McCormack's [11] framework helps us evaluate not just whether care is delivered, but how it is lived and interpreted by patients and informal caregivers. It provides a valuable counterbalance to the task-oriented lens of technology implementation by highlighting the relational texture of remote care.

Methods

Study Design and Setting

We adopted a qualitative study design guided by user-centered evaluation principles to explore the experiences of patients,

XSL•FO
RenderX

informal caregivers, and nurses who participated in the home telemonitoring program. This approach emphasizes understanding how end users experience and engage with technology in the context of their everyday lives and care relationships [10,12]. It prioritizes the elicitation of first-hand accounts from those directly interacting with the intervention—namely, patients and caregivers—while also incorporating nurses' perspectives to triangulate findings, enrich interpretation, and provide insight into how clinical support shaped user experiences.

Participants were recruited from 3 health care organizations in Quebec: Centre intégré de santé et de services sociaux (CISSS) Chaudière-Appalaches, CISSS Gaspésie, and CISSS Outaouais. These sites were selected by the project sponsor, the Quebec Ministry of Health and Social Services, to reflect the diversity and typical characteristics of primary care organizations across the province. Importantly, from the outset of the project, a formal governance structure was established to ensure coordination and collaboration among the 3 participating sites. Clinical managers responsible for the project in each organization worked closely together throughout its implementation, deployment, and follow-up. As such, the study was not designed to support cross-site comparisons. There was no a priori reason to expect meaningful differences in participant experiences between locations, and our analysis confirmed this assumption. Indeed, patients, informal caregivers, and nurses across sites reported broadly similar perceptions in relation to the 2 central dimensions of analysis, technofunctional use and relational care. Accordingly, findings are presented in an aggregated form.

Intervention

The home telemonitoring intervention consisted of 4 interconnected digital devices installed in the residences of older adults diagnosed with HF. All participating patients were supplied with the same digital devices. The goal was to support daily self-monitoring of symptoms, vital signs, and medication adherence, while enabling remote follow-up by nurses. Each device was preconfigured to collect specific clinical data at defined frequencies, as follows:

- Patients interacted daily with a voice-activated tablet (Samsung [13]) that administered a structured symptom questionnaire (anamnesis) focused on HF warning signs and related physiological indicators. Items included: breathing difficulty, cough, dizziness, sleep disturbances, fatigue, retrosternal pain, digestion issues, urinary and bowel elimination, and disease-related anxiety. The system also issued prompts and reminders for weight measurement and medication intake.
- A smartwatch (Biobeat [14]) was used to continuously collect biometric data, including heart rate, blood pressure, and oxygen saturation, provided the patient wore it day and night. Data were passively captured and transmitted to the nurse monitoring platform.
- Patients were asked to weigh themselves using a Bluetooth-enabled weight scale (A&D Medical [15]) daily upon waking. No specific instructions were provided regarding attire during weighing (eg, nightwear vs daytime clothing), as the objective was to integrate the measurement into patients' usual daily routines. The digital scale automatically transmitted weight data, which served as a proxy for fluid retention and clinical decompensation risk.
- A smart pill dispenser (xPill [16]) was used to issue audio-visual cues to prompt medication intake and record the date and time of each compartment opening to track adherence.

Each morning, patients received an audible alert from the voice-activated tablet signaling that it was time to complete a symptom questionnaire. They also had the option to initiate the questionnaire up to 1 hour before the scheduled alert. The questionnaire could be completed either by selecting responses directly on the tablet or by answering verbally. When responding orally, users were able to elaborate on their answers. In addition to completing the questionnaire, patients were expected to weigh themselves daily using the connected scale. The smart xPill automatically logged medication intake and allowed users to view as-needed prescriptions and detailed information about their medication regimen. The purpose of the xPill was to support medication adherence among patients and to enable nurses to monitor compliance remotely. Communication between the user and the nurse could be conducted through written messages or video calls initiated via the tablet, allowing for responsive and flexible clinical follow-up.

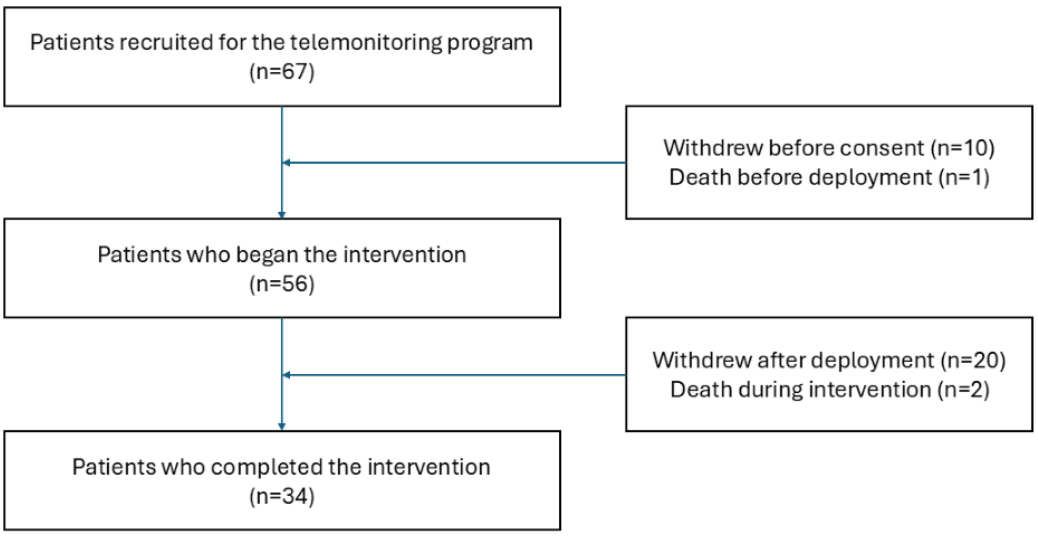
Together, these devices offered a comprehensive view of the patient's evolving health status. Data were integrated into a secure clinical dashboard monitored by nurses, who could initiate follow-up interventions when anomalies or gaps in reporting were detected. Participating nurses were required to review their assigned patients' data at least once daily during weekday daytime shifts. Although data were collected continuously (24 hours a day, 7 days a week), active monitoring occurred only during these daytime hours (8 AM to 4 PM), Monday through Friday. Outside of these hours, including evenings and weekends, patients experiencing health concerns were instructed to contact Quebec's provincial health hotline (Info-Santé 811) or seek care at the nearest emergency department. Data collected overnight during the week were reviewed by nurses the following morning, while data from the weekend were examined on Monday morning.

The home telemonitoring program was designed as a 6-month intervention for participating patients. Patients who remained enrolled for the full duration used the monitoring devices continuously during this period. However, participation length varied for some individuals because several patients withdrew from the program after deployment of the devices. As reported in the Results section, the duration of participation among those who withdrew ranged from less than 1 week to approximately 7 weeks.

Informal caregivers were also integrated into the intervention through the Proximity mobile app. The app allowed them to view automated alerts designed to support the patient's adherence to telemonitoring routines (eg, "your relative has not weighed themselves for 4 days," or "the scale's battery needs charging") and to stay informed about the patient's clinical status. Additionally, the app offered features for communicating

XSL•FO
RenderX

via text message or secure videoconferencing with the patient and the assigned nurse.



Participant Recruitment

A total of 20 nurses from the participating health care organizations were recruited by their supervisors. To participate in the project, they were required to complete an online training module on the clinical cardiac assessment of older adults [17]. This training consisted of 10 instructional videos, totaling approximately 4 hours, and concluded with a knowledge assessment.

Each nurse was responsible for identifying eligible patients from their caseload and initiating recruitment. Eligibility criteria for patients included the following: being aged 65 years or older, being francophone, having a diagnosis of HF, and currently receiving home care services related to that condition. These 4 criteria were mandatory. An additional, nonmandatory criterion was having an informal caregiver willing to participate in the study, aged 18 years or older, and possessing a smartphone or tablet with internet access.

A total of 67 patients were initially recruited into the study. Before the telemonitoring devices could be installed, however, 10 participants withdrew, while 1 patient died. For those who consented, the nurse proceeded to install the devices in the patient's home and provided basic instructions on their use. Technical support throughout the study was provided by Virtuose Technologies [18], the project's primary technology partner, alongside IT staff from each participating organization and the nurses involved in the intervention. During the intervention, 2 additional patients died, and 20 others chose to discontinue their participation. These withdrawals were observed across all participating sites. Among those who withdrew, the duration of participation varied widely, ranging from less than 1 week to more than 7 weeks. The reasons underlying early withdrawal are examined in the following section. Figure 1 summarizes patient recruitment, participation, and retention throughout the intervention.

Figure 1. Participant flowchart in the home telemonitoring program.

Recruited patients were asked to provide the name and contact information of their informal caregiver, when applicable. This information was shared with both the research team and the primary technology provider. Caregivers were then contacted by a member of the research team, who explained the study procedures and obtained their informed consent. Among the 34 patients who completed the intervention, 28 were supported by an informal caregiver who also took part in the study. Once consent was obtained, caregivers received an email from Virtuose Technologies with instructions on how to download the Proximity mobile app on their smartphone or tablet.

Lastly, as part of the onboarding process, the patient's community pharmacy was identified, and the pharmacy owner was invited to collaborate with the project to allow the prescription management system to interface with the smart xPill dispenser. Connection costs were fully covered by the company providing the smart xPill to enable seamless data integration.

Data Collection

Semistructured interviews were conducted at the end of the study with all 34 patients who completed the intervention, 16 of the 20 patients who withdrew early, 21 informal caregivers, and 20 nurses. Among informal caregivers, 13 participated in individual telephone interviews, while 8 took part in joint interviews conducted together with the patient they supported. Among the nursing staff, 18 were interviewed face-to-face, and 2 participated via telephone.

Of the 34 patients who completed the program, 32 were interviewed in person in their homes, while the remaining 2 participated via telephone. All 16 patients who withdrew early were interviewed by telephone. These interviews were analyzed alongside those of participants who completed the intervention. Although generally shorter, they provided valuable insights into barriers to sustained engagement, including emotional fatigue, technical difficulties, and misalignment with daily routines. Consequently, they were particularly informative in identifying

XSL•FO
RenderX

factors associated with disengagement and early withdrawal from the home telemonitoring program.

All interviews were conducted by a member of the research team with training in qualitative research and extensive prior experience studying digital health interventions. Conducting all interviews with the same interviewer helped ensure consistency in the interview process and familiarity with the study context. The interviewer had no prior clinical relationship with the participants.

Interview guides were developed by the research team to explore participants' experiences with the intervention while remaining closely aligned with the study's conceptual framing. Separate guides were prepared for patients, nurses, and informal caregivers to reflect their distinct roles in the program. The guides were informed by the 2 conceptual frameworks used in this study. While these frameworks helped structure the domains explored during interviews, the guides were designed to remain flexible and open-ended to allow participants to describe their experiences in their own terms and to surface issues not anticipated by the frameworks. The interview guides are provided in Multimedia Appendix 1.

No repeat interviews were conducted. However, the combination of interviews across multiple participant groups and iterative analytic discussions allowed the research team to refine and validate emerging interpretations.

The average duration of interviews varied by participant type: 45 to 60 minutes for patients who completed the program, 20 to 30 minutes for nurses, and 5 to 10 minutes for patients who withdrew early and informal caregivers. All interviews conducted in person were audio-recorded with participants' consent, except for 2 patients who declined recording. Telephone interviews were not recorded, but detailed notes were taken immediately after each interview to capture key points, striking statements, and unexpected reactions. Audio recordings were listened to in their entirety by the interviewer and the lead author to ensure familiarity with the full content of each interview.

Rather than producing full verbatim transcripts for all interviews, segments of the recordings directly relevant to the study's research objective were transcribed verbatim. These excerpts included both confirmatory and disconfirming observations related to participants' experiences with the home telemonitoring intervention. Field notes and analytic discussions among all team members were used to ensure that themes emerging outside the conceptual frameworks were not overlooked during the coding process.

Data Analysis

We conducted a directed content analysis, following the approach outlined by Hsieh and Shannon [19]. This method enabled the systematic examination of qualitative data using existing theoretical frameworks to guide the initial coding process while remaining open to insights emerging from participants' accounts. Interview notes and transcripts were first reviewed in their entirety to foster immersion in the data and develop a comprehensive understanding of participants' experiences.

A preliminary coding scheme was developed based on the study's main objective and sensitizing concepts drawn from the 2 guiding frameworks: the PBA [10] and the PCP framework [11]. The 2 frameworks were applied in a complementary manner rather than as independent analytic lenses. During coding and interpretation, particular attention was given to how participants' technofunctional experiences with the devices interacted with their relational experiences of care. For example, technical frustrations or usability challenges sometimes influenced perceptions of clinical support, whereas timely and empathetic follow-up from nurses often mitigated negative reactions to the technology. This integrative perspective helped illuminate how digital tools and relational care processes jointly shaped participants' overall experience of telemonitoring.

The interviewer also led the coding process and was therefore highly familiar with the interview material and study context. The coding process was highly iterative. Interview notes and transcripts were reviewed to identify segments relevant to the study's objective, which were then coded using sensitizing concepts derived from the 2 frameworks. Throughout the analytic process, coding decisions and emerging interpretations were discussed during regular team meetings. These discussions allowed the research team to examine the coder's analytic reasoning, question assumptions, and refine the organization of themes. Differences in interpretation were addressed through discussion until a shared understanding of the coding structure was reached.

Although the analysis was initially guided by the 2 conceptual frameworks, attention was paid to identifying experiential elements that did not fit neatly within these categories. The coding process, therefore, remained flexible and iterative, allowing the coding scheme to evolve as new insights emerged from the data.

Rigor and Reflexivity

Two strategies were used to enhance the trustworthiness of the analysis: triangulation of perspectives and collaborative interpretation. Specifically, we triangulated insights across the 3 participant groups interviewed (patients, informal caregivers, and nurses) to capture multiple perspectives on the home telemonitoring experience. Reflexivity was supported through regular analytic discussions among team members with diverse disciplinary backgrounds, including health informatics, nursing, and qualitative research.

We also drew on member-checking opportunities during follow-up meetings with clinical managers from each participating organization, during which preliminary interpretations were discussed and validated in light of their knowledge of the program's implementation and patient population.

Analytic transparency was supported by providing a detailed description of the coding procedures, explaining how the conceptual frameworks guided the analysis, and illustrating themes with representative excerpts from participants across the 3 groups interviewed. Data coding and theme development were conducted primarily by 1 member of the research team, with iterative peer debriefing sessions held with other team

XSL•FO
RenderX

members throughout the analytic process. These discussions helped challenge preliminary interpretations, ensure that coding decisions remained grounded in participants' accounts, and refine the organization of themes. Particular attention was given to identifying experiences that diverged from dominant patterns in the data, such as frustration, fatigue, or disengagement with the technology.

Although the research team was not involved in the initial design of the telemonitoring intervention, 2 authors participated in monthly meetings of the project's executive committee, and 1 author regularly attended weekly operational meetings in each participating organization. While their role in these settings was primarily observational and advisory, we acknowledge that this presence, and occasional input, may have influenced implementation dynamics or participant behavior. To mitigate this potential bias, we relied on triangulation of data sources, consensus-based interpretation, and a sustained effort to ground our analysis in participants' experiences rather than in project objectives or institutional priorities.

Ethical Considerations

This study received ethics approval from the ethics board of the CIUSSS Chaudière-Appalaches (#MP-23-2023-1037) on July 11, 2023. Ethical approval for the 2 other participating sites (CISSS Outaouais and CISSS Gaspésie) was granted through institutional agreements recognizing the lead site's ethics review. As noted above, all participants received information sheets and provided written or verbal informed consent prior to participation. Identifying information was removed from notes and transcripts, and data were stored on secure, password-protected servers. Participation in this study was voluntary and uncompensated.

As part of the informed consent process, patients were asked to identify the informal caregiver they wished to involve in the intervention. Only the caregiver explicitly authorized by the patient was granted access to the patient's health-related data via the Proximity mobile app. Patients were informed about the nature of the data shared, and participation remained entirely voluntary. For participants with limited digital literacy, additional support was provided to ensure they understood the implications of data sharing and retained autonomy in decision-making.

Results

Profile Participants

As shown in Table 1, 44% (15/34) of the patients who completed the intervention were female, with a mean age of 83 (SD 7.7) years. A total of 38% (13/34) resided in private seniors' residences, and more than half lived with a spouse or one of their children. Most participants (28/34, 82%) received active support from an informal caregiver as part of the project. In most cases, the caregiver was one of the user's children, followed by spouses and members of the extended family. In terms of perceived health status, 47% (16/34) of users described their health as fair, while the others considered it to be good or very good.

XSL•FO
RenderX

Table 1. Profile of the patients who completed the intervention (n=34).

Characteristic	Value
Female, n (%)	15 (44)
Age (years), mean (SD)	83 (7.7)
Reside in private seniors' residences, n (%)	13 (38)
Live with a spouse or relative, n (%)	21 (62)
Have an informal caregiver, n (%)	28 (82)
Perceive health status as, n (%)	
Fair	16 (47)
Good or very good	18 (53)
Perceive their level of digital literacy as, n (%)	
Low or very low	18 (53)
Average	9 (26)
High or very high	7 (21)
Use of digital devices, n (%)	
Smartwatch	34 (100)
Virtual assistant tablet	34 (100)
Bluetooth-enabled scale	31 (91)
Smart xPill dispenser	21 (62)
Perceive their autonomy level in the use of digital devices as, n (%)	
Full autonomy	27 (79)
Used with help of caregiver	4 (12)
Mainly used by caregiver	3 (9)

Regarding digital literacy, more than half of the participants reported having low or very low comfort with digital technologies. In this context, approximately 20% (7/34) were assisted by their informal caregiver in completing the symptom questionnaire (anamnesis) and logging their daily medication intake using the smart xPill dispenser. All patients used the connected smartwatch, and the vast majority also used the connected scale. However, about one-third of participants were unable to use the smart xPill, as their community pharmacy was not yet connected to the system.

Among the individuals who initially agreed to participate but ultimately did not sign the consent form, several expressed concerns about their ability to manage the technological devices during formal follow-up. Some described their health as too fragile to take on the additional demands of the project and expressed fears that participation might cause further stress or anxiety. Others felt overwhelmed after reviewing the information sheet or watching the onboarding videos, which led to doubts about their ability to manage the devices. In some cases, these concerns were discussed with informal caregivers, resulting in a mutual decision to decline participation. Overall, these early withdrawals appear to have been driven by emotional apprehension, perceived cognitive or physical limitations, and a subjective sense of unpreparedness to engage with digital health technologies.

Another group consisted of patients who withdrew after the telemonitoring devices had been installed in their homes. This group included a higher proportion of women (12/20, 60%) and had a slightly higher mean age of 84 (SD 6.9) years. As shown in Table 2, 60% (12/20) of these participants had an informal caregiver involved in the project. On average, they remained enrolled for 4.6 weeks before deciding to discontinue their participation. Compared with the 34 patients who completed the intervention, the postdeployment withdrawal group tended to be older and had lower rates of caregiver involvement.

XSL•FO
RenderX

Table 2. Demographic characteristics of patient subgroups by participation status.

Characteristic	Surviving patients who withdrew early after deployment (n=20)	Patients who completed the 6-month intervention (n=34)
Female, n (%)	12 (60)	15 (44)
Age (years), mean (SD)	84 (6.9)	83 (7.7)
With an informal caregiver, n (%)	12 (60)	28 (82)
Duration of participation (weeks), mean (SD)	4.6 (1.1)	24 (0.2)

Interviews with the 20 patients who withdrew after deployment revealed a distinct set of challenges arising from their direct experience with the system. Many reported emotional fatigue from repetitive tasks, cognitive overload due to the use of multiple devices, and frustration with technical issues such as unreliable connectivity or unintuitive interfaces. Some also found it difficult to adjust their daily routines to accommodate the system's requirements, such as scheduled prompts or weighing times, especially in the absence of regular caregiver support. Taken together, these accounts suggest that advanced age, lower digital confidence, and limited support networks were important contextual factors that contributed to early disengagement from the intervention.

As shown in Table 3, the participating nurses were predominantly women, with a mean age of 40 (SD 6.1) years. A total of 65% (13/20) held clinical nurse positions, and, on average, they had been working full-time in home care for approximately 8 years.

Table 3. Profile of the participating nurses (n=20).

Characteristic	Value
Female, n (%)	19 (95)
Age (years), mean (SD)	40 (6.1)
Job position, n (%)	
Registered nurse	7 (35)
Clinical nurse	13 (65)
Average experience in home care (years), mean (SD)	8 (2.1)
Full-time job, n (%)	20 (100)

Technofunctional Experience With Home Telemonitoring

Overview

We apply here the 4 core elements of the PBA to interpret the technofunctional experiences of patients and caregivers as they interacted with the multidevice home telemonitoring intervention. As mentioned earlier, this framework allows us to examine how participants engaged with the technologies cognitively, emotionally, and behaviorally within their daily lives. Following this thematic analysis, we present device-specific accounts to illustrate how these broader experiential patterns manifested across the 4 digital tools used in the intervention. These accounts help contextualize the variability in usability, perceived burden, and emotional response linked to each device.

Contextual Tailoring

Participants' ability to engage with the home telemonitoring program depended strongly on how well the devices aligned with their daily routines, physical capabilities, and living environments. Many participants described entering unfamiliar territory when first encountering the digital tools. Initial apprehension was common, with patients voicing fears of breaking the equipment or failing to use it correctly. As 1 patient shared, "At first, I was nervous. I didn't want to mess anything up, but the more I used it, the more confident I got" (Patient #7). These early fears diminished with hands-on practice, clear instructions, and encouragement from caregivers, demonstrating the importance of tailoring onboarding to individual learning styles and contexts.

However, integration into daily life was more difficult for participants whose routines were less predictable or socially constrained. For example, patients living in senior residences often reported difficulty aligning measurement times with scheduled meals or medication routines:

> *Sometimes I would miss the time to fill out the questionnaire or take my medication because I was still in the cafeteria. It depended on the day.* [Patient #6]

These observations highlight how routines must be considered in designing and delivering home telemonitoring interventions.

Connectivity issues compounded the challenge of learning. Several participants, particularly those living in rural settings, reported problems with Bluetooth synchronization or weak cellular signals, which led to repeated prompts or lost data. As 1 patient explained: "When it glitched, I would lose patience. I eventually figured out how to restart the system myself, but at first, I was overwhelmed" (Patient #23). These experiences

XSL•FO
RenderX

illustrate the iterative process of digital learning, where contextual barriers often dictate the pace and success of adaptation.

Emotional and Cognitive Responses to Technology

Participants expressed a wide range of emotional responses to the home telemonitoring program, ranging from reassurance and increased confidence to frustration, fatigue, and anxiety. Many felt reassured knowing their health data were monitored in real time by a clinical team, "Even if she [nurse] wasn't here, I felt like she was looking after me every day," said one patient (Patient #11). This sense of remote presence contributed to perceived security, especially for those living alone.

Others, however, experienced anxiety, irritation, or emotional fatigue. This was especially true when dealing with repetitive tasks, frequent prompts, or nighttime alerts. As 1 patient remarked:

> *It felt useless to me, because it's always the same questions… and the same answers. So, I eventually stopped responding to the robot.* [Patient #1]

A nurse confirmed these frustrations:

> *Some of my patients even mentioned being woken up repeatedly by the tablet's sound alerts, which was experienced as a source of frustration.* [Nurse #17]

When feedback loops were missing, the technology was often perceived as intrusive or indifferent, diminishing its credibility and value.

Perceived Relevance and Burden of Technology Use

Participants evaluated the usefulness of the telemonitoring system in relation to the effort required to use it, and their experiences varied substantially across the different devices. The smartwatch, which required minimal user input, was generally well received. "I liked that I didn't have to do much. But I never really knew what it was tracking or if it was working" (Patient #10). In contrast, the connected scale, though simple to use, lost value when readings were not acknowledged: "I weighed myself every morning, but it didn't seem to matter. No one ever mentioned the numbers" (Patient #5). For its part, the voice-activated tablet received mixed reviews. While some appreciated the reminders, others struggled with the interface. "It would talk to me, but I couldn't always hear it or figure out how to answer. It made me nervous" (Patient #21).

These examples suggest that bundling multiple devices under a single intervention may obscure the highly variable user experiences across technologies. Emotional and functional reactions depended not only on individual digital skills but also on how well each device fit into the participant's everyday life.

Autonomy, Control, and Iterative Engagement

Over time, some participants developed greater confidence and autonomy in using the devices, whereas others experienced persistent difficulties that led to disengagement. For some participants, learning to troubleshoot devices fostered a sense of control and accomplishment. "After a while, I knew how to fix it myself. That made me feel more in control" (Patient #17). Others, however, experienced persistent problems that eroded their confidence. "I didn't know what was wrong with the xPill, so I stopped using it. It was too stressful" (Patient #12). This divergence in experience illustrates the need for systems to support users not only during onboarding but throughout their engagement with technological devices.

Among participants who withdrew early, emotional and cognitive overload were frequent themes. "I just knew I wasn't going to be able to manage it. It's too much stress for someone like me" (Patient #20). In some cases, caregiver frustration contributed to early dropout: "My husband got frustrated with the machine after the second week. It was just easier to go back to the usual way" (Caregiver #4). These narratives point to the importance of iterative and adaptive support strategies to retain engagement over time.

Relational and Experience Aspects of Remote Care

Perceived Professional Presence at a Distance

Many participants reported that the home telemonitoring program created a sense of ongoing clinical presence, even when direct communication with nurses was limited. This theme aligns with the person-centered processes domain of the PCP framework, particularly the dimension of sympathetic presence. Many participants described feeling reassured by the knowledge that their health status was being monitored, even in the absence of direct, face-to-face contact. One patient expressed this sense of invisible support: "Even if she [nurse] wasn't here, I felt like she was looking after me every day" (Patient #11).

Nurses also made intentional efforts to convey a sense of presence despite the absence of face-to-face interactions. Several described how, without visual cues, they learned to attune more closely to patients' vocal tone and inflection. As 1 nurse noted, "You have to 'read' the patient's tone of voice… I could tell when someone wasn't doing well just by how they said hello" (Nurse #2). To maintain an empathetic connection, some nurses also relied on open-ended questions and lengthier conversations. One nurse explained, "When I didn't see their body language, I compensated by asking more open-ended questions" (Nurse #4).

These accounts illustrate that while digital devices introduce new barriers to physical proximity, person-centered care practices can still be upheld through deliberate and thoughtful communication strategies.

Shared Decision-Making and Tailored Interactions

Participants differed in the extent to which they wished to be involved in decisions related to the home telemonitoring program and their care. Shared decision-making represents a critical process within McCance and McCormack's [11] framework. Participants' experiences varied. Some felt genuinely involved when nurses contacted them to discuss their health status or device readings. One patient recounted: "She would call and ask how I felt before deciding anything. It felt personal" (Patient #5). Similarly, another participant explained how their input was acknowledged: "She asked me if it was okay to continue using the smart xPill since it was giving me trouble. I appreciated that" (Patient #9).

XSL•FO
RenderX

Others, however, preferred a more passive role and deferred entirely to clinical expertise. As 1 participant explained: "I just followed what they said. I trusted them" (Patient #13). A second participant echoed this sentiment: "I'm not the kind to ask questions. If the nurse says it's good, I go with that" (Patient #18).

These differing accounts underscore the importance of communication strategies that are responsive to individual preferences for autonomy and involvement. While some users welcomed collaborative decision-making, others derived comfort from trusting clinical judgment, highlighting the need for flexibility in how shared decision-making is operationalized in remote care settings.

Emotional Reassurance and Well-Being

For many patients and caregivers, the intervention generated a sense of reassurance by signaling that clinical professionals were overseeing the patient's condition. This theme maps onto the person-centered outcomes domain of McCance and McCormack's [11] framework, specifically the importance of emotional well-being and reassurance. Several participants expressed comfort in knowing they were being watched over, even in the absence of direct communication. One patient put it simply: "It was reassuring, knowing someone was checking in, even if we didn't talk every day" (Patient #1). Another noted: "It was nice to know someone was checking my data every day. Even if we didn't talk, I felt watched over in a good way" (Patient #8). In short, this quiet sense of presence, mediated through the smart devices, was a recurring source of comfort for many.

Informal caregivers also shared this emotional benefit. Knowing that clinical professionals were monitoring their loved ones provided peace of mind and alleviated the perceived burden of constant vigilance. As 1 caregiver explained: "I knew that if something went wrong, the nurse would see the data and call. That took a weight off my shoulders" (Caregiver #4).

Limitations of Remote Engagement

Despite these benefits, participants also recognized important limits to digitally mediated care, particularly when compared with in-person interactions. This aligns with the contextual sensitivity emphasized in McCance and McCormack's [11] framework. Some users acknowledged that the technological interface, while functional, could not replace the warmth and nuance of in-person interaction. One patient captured this sentiment: "The technology was good, but it didn't replace a nurse sitting next to you, talking face to face" (Patient #12). Nurses echoed this concern. Some reported emotional strain stemming from the lack of tangible presence and the uncertainty of whether patients felt genuinely supported. One nurse reflected: "Sometimes I wondered if they [patients] felt alone with the devices. It's not easy to know if your presence is felt" (Nurse #3).

Yet, many nurses believed that their efforts to stay in contact, personalize their communication, and respond promptly still conveyed a sense of relational continuity. One nurse recounted positive feedback from patients: "Several told me, 'It's like you're still here, even if we don't see you.' That's what we wanted" (Nurse #1).

These perspectives reinforce the idea that, while digital health technologies alter the medium of interaction, person-centered care can still be practiced and felt if thoughtfully adapted.

Discussion

Principal Results

Using the complementary lenses of the PBA and the PCP frameworks, the study findings highlight three central insights: (1) engagement with home telemonitoring technologies depends strongly on users' routines, digital confidence, and perceived burden; (2) relational support from nurses plays a critical role in shaping how patients interpret and tolerate technological challenges; and (3) informal caregivers often act as key mediators of sustained engagement with the system.

From a technofunctional perspective, findings highlight the importance of designing home telemonitoring programs that are emotionally acceptable, contextually adaptable, and responsive to user needs and constraints. Participants' engagement varied widely based on their digital literacy, cognitive capacity, comfort with wearable or interactive devices, and the fit of the system with their daily routines. While some developed confidence over time, especially when supported by informal caregivers, others experienced persistent difficulties, particularly when their routines were irregular or when onboarding was not sufficiently individualized.

Participants often reacted emotionally to the devices, reporting reassurance, frustration, or anxiety depending on their ability to interact successfully with a particular technology. Repetitive symptom questionnaires and poorly timed alerts contributed to emotional fatigue, especially when feedback was absent or unclear. These reactions were compounded when technical issues such as Bluetooth disconnections or connectivity failures disrupted user routines or sleep. In some cases, persistent problems led to disengagement or early withdrawal.

Importantly, the intervention did not impact all devices equally. The smartwatch and scale were generally well accepted due to their ease of use and alignment with daily habits. In contrast, the tablet and smart pill dispenser posed greater usability and cognitive challenges, particularly for participants with lower digital confidence or limited caregiver support. These device-specific variations underscore the need to avoid one-size-fits-all solutions and instead tailor devices to user profiles and contextual factors.

From a relational standpoint, participants often found the experience of being monitored reassuring, provided that follow-up from nurses was timely and personalized. Short, routine interactions (eg, phone calls or messages) reinforced the sense of being cared for, even at a distance. However, when follow-up was perceived as inconsistent or impersonal, patients reported feeling overlooked or abandoned. Nurses themselves reported challenges in maintaining relational presence without visual cues and in addressing technical issues beyond their clinical role.

XSL•FO
RenderX

Informal caregivers emerged as critical, if underrecognized, mediators of technology use and continuity. Their availability, digital literacy, and relationship to the patient shaped the sustainability of engagement. Caregivers often provided troubleshooting support and emotional reassurance, especially in cases in which users felt overwhelmed by the technology.

Lastly, while the PBA and PCP frameworks helped structure our analysis along technofunctional and relational dimensions, participants' experiences often spanned both domains simultaneously. In practice, engagement with the telemonitoring system emerged from the interaction between how users experienced the devices and how they experienced the care relationships surrounding those devices.

As shown in Table 4, participants' experiences with the telemonitoring intervention cannot be fully understood through a purely technological or purely relational lens. Instead, many of the themes identified in the analysis reflect the interaction between technofunctional engagement with the devices and the relational dynamics of care. For instance, the sense of reassurance reported by many patients did not stem solely from the monitoring devices themselves, but from the perception that nurses were actively reviewing the transmitted data and would intervene if necessary. Similarly, frustrations associated with repetitive tasks or technical difficulties were often amplified when feedback from the clinical team was perceived as limited or delayed. Conversely, timely communication and empathetic follow-up frequently mitigated negative reactions to the technology and encouraged sustained engagement. Taken together, these findings suggest that the effectiveness and acceptability of home telemonitoring programs depend not only on the usability of digital tools but also on the quality of relational support surrounding their use.

Table 4. Integration of technofunctional and relational dimensions of participants' experiences with home telemonitoring.

Integrated theme	PBA[a] framework (technofunctional lens)	PCP[b] framework (relational lens)	Combined insight
Reassurance through monitoring	Users interpreted device monitoring as health surveillance	Nurses' follow-up created a sense of presence	Reassurance emerged from the interaction between technology and relational care, not from the device alone
Burden of repeated tasks	Repetitive questionnaires and alerts created fatigue	Lack of feedback reduced perceived care responsiveness	Techno-functional burden was amplified when relational feedback was missing
Adaptation and confidence	Users developed autonomy through learning the devices	Supportive nurses reinforced confidence	Sustained engagement depended on both usability and relational encouragement
Disengagement and withdrawal	Technical frustration and cognitive overload	Limited caregiver support and relational reassurance	Withdrawal often resulted from combined technical and relational gaps

[a]PBA: Person-Based Approach.

[b]PCP: Person-Centered Practice.

The following section situates these findings within the broader literature on home telemonitoring and digitally mediated care.

Comparison With Prior Work

Our findings reinforce and extend prior research on home telemonitoring in aging populations, particularly along 2 key dimensions: technofunctional engagement and relational and experiential aspects of care. On the functional side, earlier studies have emphasized the importance of usability, ease of integration, and access to technical support in facilitating telehealth adoption [19,20]. This study builds on this foundation by identifying additional factors that influence sustained engagement, including emotional burden, alignment with daily routines, and users' capacity to adapt and troubleshoot technical issues—insights that closely reflect the principles of the PBA [10]. In particular, this framework highlights the importance of contextual tailoring, emotional acceptability, and perceived autonomy, all of which were evident in our participants' experiences.

Our findings also confirm prior evidence that alert fatigue, lack of personalized feedback, and the perceived irrelevance of prompts can erode motivation over time [20,21]. More broadly, the literature on older adults and digital health underscores the importance of designing interventions that are emotionally acceptable and minimally burdensome, rather than merely functionally efficient [8].

Although Feroz and Ahmad [22] did not explicitly apply the PBA, their systematic review of usability factors in secure mobile health apps aligns with many of its core tenets, including the role of emotional responses to technology, the challenges posed by unfamiliar digital environments, and the need for robust support structures. Our findings complement theirs by illustrating how these dynamics unfold in a complex, real-world home telemonitoring context involving multiple devices and interdependent roles among patients, caregivers, and nurses. In doing so, this study extends person-centered usability principles beyond app-based systems to the broader ecosystem of digitally mediated chronic care.

Turning to the relational and experiential dimensions of care, our findings align with prior research showing that digital systems can sustain a sense of connection between patients and health care professionals when supported by consistent follow-up and empathetic communication [23,24]. At the same time, few studies have examined these dynamics simultaneously from the perspectives of patients, informal caregivers, and nurses. By triangulating insights across these groups, this study highlights that the perceived quality of care relationships depends not only on the presence of user-friendly technological

XSL•FO
RenderX

devices but also on the continuity and sensitivity of communication, factors essential to maintaining therapeutic engagement at a distance.

Our results also resonate with those of Murphy et al [25], who used McCance and McCormack's [11] framework to examine older adults' experiences with integrated care. Both studies emphasize the central role of sympathetic presence, authentic engagement, and shared decision-making in shaping how care is experienced. While Murphy et al [25] focused on in-person multidisciplinary care, our findings suggest that these person-centered processes can also be preserved and meaningfully experienced within digitally mediated care contexts.

Finally, the variation observed in participants' preferences for involvement in decision-making can be interpreted through Savoli et al's [26] typology of patient self-management styles. In their study of patient portal use, Savoli et al [26] identified 3 profiles—autonomous, engaged, and reliant—based on how patients attribute responsibility for self-management and perceive the role of technology. Participants in this study who welcomed dialogue and shared decision-making resembled the engaged profile, whereas those who preferred to defer decisions to nurses reflected the reliant profile. These parallels highlight the importance of tailoring communication and support strategies to individual preferences for autonomy and relational engagement in home telemonitoring programs.

Implication for Practice

Building on these findings, several practical implications emerge for the design and implementation of home telemonitoring programs. Drawing on the principles of the PBA and PCP framework, we emphasize the importance of designing interventions that are emotionally acceptable, contextually tailored, and responsive to the lived experiences of patients and their caregivers.

First, onboarding and ongoing support must be individualized. Older adults vary widely in their levels of digital literacy, cognitive capacity, and learning preferences. Training should therefore be incremental and reinforced through scheduled follow-ups, with clear, accessible materials to help users navigate common technical challenges. Providing personalized guidance during the adaptation phase can reduce anxiety and build early confidence in system use.

Second, home telemonitoring tools must accommodate diverse daily routines. Our results highlight the friction created when device prompts conflict with users' eating habits, medication schedules, or lifestyle preferences. Data entry and alert schedules should be easily configurable by patients or caregivers to minimize disruption and support sustainable engagement. Third, relational continuity remains essential, even in digitally mediated care. Participants valued consistent, personalized interactions with nurses, and expressed distress when follow-up felt irregular or impersonal. Assigning a dedicated referent nurse or implementing minimal standards for proactive communication may help reinforce the therapeutic relationship and enhance users' sense of being seen and supported.

Fourth, regular feedback to patients is crucial for motivation. The absence of acknowledgment for submitted data diminished the perceived value of system use. Even brief, automated messages (eg, "Your data looks stable today") can reinforce engagement, provide emotional reassurance, and maintain participation over time. Fifth, interfaces should allow for user-controlled modes of interaction. While some patients appreciated detailed access to their health data, others preferred to limit their exposure to potentially anxiety-inducing information. Home telemonitoring interventions should offer flexible configurations to respect these differences and promote a sense of control.

Sixth, caregivers require tailored onboarding and communication strategies. Their ability to support patients often depended on their understanding of how the technology worked and their preferred communication channel (eg, SMS, phone, or app). Dedicated support and training for caregivers, including technical troubleshooting and role clarification, can strengthen the triad of care among patients, caregivers, and clinicians. Seventh, technical reliability is foundational, especially in rural or low-connectivity environments. Participants reported repeated frustrations linked to connectivity failures, alerts triggered by errors, and synchronization issues. Hybrid network strategies (eg, Wi-Fi and cellular backup), intuitive error messaging, and simple troubleshooting instructions are critical to sustaining trust in the system.

Eighth, integration with existing clinical workflows and community resources must be prioritized. The effectiveness of tools like the smart xPill dispenser depends on accurate and updated medication profiles, which in turn require coordination with community pharmacists. Home telemonitoring programs should not operate in isolation, but rather as part of a broader, interprofessional care ecosystem.

Finally, while many participants reported positive experiences, it is important to acknowledge that frustration, emotional fatigue, and technical difficulties were common and, for some, led to early withdrawal. These negative experiences were often exacerbated by repetitive prompts, lack of real-time feedback, or device malfunction, especially in the absence of caregiver support. For several patients, the cognitive and emotional effort required to engage with the devices outweighed the perceived benefits. These findings underscore a critical tension in distant care. Even well-designed interventions can generate unintended burdens that erode engagement over time. As such, scaling similar home telemonitoring programs without addressing these experiential barriers may exacerbate disparities in access, increase dropout rates, and strain frontline support systems. Future implementations should therefore prioritize sustained user support, adaptive personalization, and continuous feedback mechanisms to mitigate these risks.

Study Limitations

Three main limitations should be considered when interpreting the findings of this study. First, the transferability of our results is constrained by the study's geographic scope and sample size. Data were collected from 3 health care organizations located within a single Canadian province, and only 34 patients and their caregivers completed the full duration of the pilot program.

XSL•FO
RenderX

Although the participating sites were selected to represent rural, semiurban, and urban contexts, the relatively small number of participants and the contextual specificity of the intervention limit the extent to which the findings can be generalized to broader populations or settings.

At the same time, the goal of this qualitative study is not statistical generalization but analytical transferability. By providing detailed descriptions of the intervention, participant characteristics, and care context, we aim to enable readers to assess the extent to which the patterns identified in this study—such as the interplay between technological usability, caregiver support, and relational continuity with clinicians—may resonate with similar home telemonitoring initiatives in other health care environments.

The transferability of our findings to contexts outside Canada should also be interpreted with caution. The home telemonitoring program was implemented within the publicly funded Canadian health care system, where home care services, nursing roles, and digital health initiatives may be organized differently than in other countries. For instance, the involvement of home care nurses in reviewing patient data and conducting follow-up reflects organizational features that may not be present in all health systems. Nevertheless, several of the dynamics identified in this study, including the influence of digital literacy, caregiver involvement, technological burden, and the relational aspects of remote care, have been reported in home telemonitoring initiatives in other settings, suggesting that these findings may still offer useful insights for similar programs implemented in different health care contexts.

Second, the study may be subject to selection bias. Indeed, many patients agreed to participate based on a strong preexisting relationship with their home care nurse, suggesting that trust in the health care professional played a central role in motivating enrollment. Others were motivated by altruistic values such as a desire to contribute to research or "give back" to the health system. These motivations, while valuable, may have skewed the participant sample toward individuals more likely to engage with the intervention or tolerate its demands, potentially underrepresenting the perspectives of those with lower motivation, weaker support networks, or more limited digital literacy.

Third, although we used a rigorous approach to directed content analysis [19], the inherently interpretive nature of qualitative research carries the risk of subjectivity in coding and theme development. Even though coding was performed rigorously, the analytical process was inevitably shaped by our prior assumptions, research objectives, and theoretical framing. The risk of interpretive bias is especially salient given that our analysis was guided by 2 preexisting conceptual frameworks, which, while helpful in structuring the analysis, may have constrained the emergence of unexpected insights. We sought to mitigate this risk by maintaining an iterative coding process that remained open to experiential elements not fully captured by the frameworks. Divergent accounts, including frustration, disengagement, and early withdrawal from the program, were examined alongside more positive experiences to ensure that the analysis reflected the diversity of participants' perspectives.

Conclusions

Home telemonitoring programs that involve multiple digital devices can empower older adults and their caregivers, but only when they are flexibly integrated into daily routines, emotionally acceptable, and consistently supported both technically and relationally. The PBA provided a valuable framework for interpreting how users engaged with the intervention across functional, emotional, and contextual dimensions. It emphasized the importance of personalization, perceived relevance, and iterative adaptation in shaping technology use over time. Complementing this, the PCP framework helped illuminate how participants experienced presence, shared decision-making, and relational continuity, even in the absence of face-to-face contact. This framework foregrounded the relational and emotional texture of care, drawing attention to the processes through which users felt acknowledged, supported, and empowered.

By combining these 2 lenses, this study captures both the tangible functionality and the intangible relational dynamics of digitally mediated care. Together, they underscore the need for patient- and caregiver-centered design principles, sustained interpersonal engagement, and robust interprofessional coordination. Evaluating home telemonitoring interventions through both technofunctional and relational perspectives offers a fuller understanding of how such programs are lived and how they can be more effectively implemented at scale.

Acknowledgments

The authors would like to express our sincere gratitude to all the patients, informal caregivers, and nurses who generously participated in this study and shared their experiences. We also thank the Quebec Ministry of Health and Social Services for its financial support, which made this research possible. Finally, we extend our thanks to Anne-Marie Veillette for her valuable support during the conceptualization of the study.

In preparing this manuscript, the authors used ChatGPT 5.3 (OpenAI) to assist with proofreading, improving the structure of the text, and drafting the response to reviewers. All artificial intelligence (AI)–generated content was critically reviewed, edited, and approved by the authors to ensure its accuracy and compliance with ethical standards. This use of generative AI complies with JMIR Publications' guidelines on AI use in scholarly writing [27]. All authors had full access to the data and approved the initial and revised versions of this manuscript.

Data Availability

The datasets generated or analyzed during this study are available from the corresponding author on reasonable request.

Funding

This work was conducted as part of a pilot initiative sponsored and funded by the Quebec Ministry of Health and Social Services. Budget planning and financial oversight were managed by the health autorities. The budget covered device acquisition, software licensing, training, technical support, and coordination activities. Detailed financial breakdowns were not shared with the research team.

Authors' Contributions

GP contributed to conceptualization, methodology, investigation, formal analysis, project administration, and writing of the original draft, as well as review and editing of the manuscript. MPM contributed to methodology, investigation, and manuscript review and editing. PV contributed to conceptualization, funding acquisition, resources, project administration, supervision, and manuscript review and editing. AC contributed to conceptualization, methodology, and manuscript review and editing. MSH contributed to conceptualization, supervision, and manuscript review and editing. MR contributed to the investigation and manuscript review and editing.

Conflicts of Interest

AC is an Associate Editor of the *Journal of Medical Internet Research* at the time of publication.

Abstract

Background: Climate change has intensified the frequency and duration of extreme heat events worldwide, posing growing public health risks, particularly for older adults who are physiologically more susceptible to heat-related illnesses. Concurrently, alcohol consumption among older adults in the United States has risen significantly over the past 2 decades, increasing vulnerability to dehydration, cardiovascular strain, and cognitive impairment during heat exposure. Emerging evidence suggests that environmental stressors such as extreme heat may exacerbate maladaptive coping behaviors, including alcohol use; however, few studies have examined this association in aging populations. Moreover, little is known about how early-life experiences such as childhood adversity or positive parental relationships shape behavioral responses to environmental stressors later in life.

Objective: This study examines the relationship between extreme heat and alcohol consumption among older Americans, emphasizing the moderating role of early-life experiences within a life course framework.

Methods: Using data from individuals aged >50 years in the Health and Retirement Study (1996 - 2018), we analyzed the association between extreme heat exposure (>95 °F) and alcohol consumption, while examining whether early-life experiences such as parental substance abuse, law enforcement encounters, and relationships with fathers moderate this relationship.

Results: Extreme heat exposure was significantly associated with increased alcohol consumption (0.21% per additional extreme heat day, $P<.001$). A positive father-child relationship buffered this effect, while adverse early-life experiences, including law enforcement encounters (0.08%, $P<.001$) and parental substance abuse (0.05%, $P<.001$), exacerbated it.

Conclusions: Given the link between extreme heat and alcohol use in older adults, further longitudinal research and targeted interventions are needed to mitigate associated health risks. Strengthening positive childhood experiences may offer long-term protective effects by fostering resilience and healthier coping mechanisms that persist into later life.

Introduction

Background

The increasing prevalence of alcohol consumption, particularly high-risk and excessive drinking, among older adults has emerged as a growing public health concern in the United States [1-4]. Between 2001 and 2013, there was a marked rise in alcohol use patterns among US adults aged ≥65 years, characterized by a 22% increase in past-year alcohol consumption, a 65% increase in high-risk drinking, and a staggering 107% increase in alcohol use disorder diagnoses [2]. More recent data reveal that over half of adults in this age group reported alcohol consumption within the past year, with approximately 11% engaging in binge drinking within the past month [5]. These trends are particularly alarming, given the heightened susceptibility of older adults to alcohol-related health complications, owing to age-related physiological changes, coexisting chronic conditions, and potential interactions with medications—factors that collectively elevate risks for unintentional injuries, toxic reactions, and exacerbation of preexisting health conditions [6,7]. As the aging population

XSL•FO
RenderX

continues to grow, so too will the public health implications of alcohol consumption among older adults, underscoring the urgent need for risk mitigation and intervention strategies.

Extreme Heat Exposure and Alcohol Consumption

While previous research has predominantly centered on individual-level determinants of alcohol use among older adults, such as demographic characteristics, socioeconomic status, and health conditions [3-8], a growing body of literature highlights the influence of environmental factors, particularly climate-related stressors such as extreme heat. The hypothesis that climate change–induced extreme heat may exacerbate substance use disorders is gaining empirical support [9]. Scoping reviews suggest that climate change contributes to the worsening of mental health conditions, including heightened levels of anxiety, depression, and psychological distress [10], which may in turn lead to increased substance use as a maladaptive coping mechanism. Notably, empirical evidence from Shenzhen, China, the first study to investigate the relationship between extreme heat and acute excessive drinking, identified a positive correlation between heat exposure and the likelihood of engaging in heavy drinking episodes [11]. Similarly, a nationwide survey in Australia reported that 11% of respondents consumed more alcohol on extremely hot days [11]. Despite these important contributions, prior studies have not specifically targeted older adults nor used nationally representative samples, leaving critical gaps in understanding how heat exposure may influence alcohol consumption patterns in aging populations.

Several physiological and psychological mechanisms may explain the link between high temperatures and increased alcohol use. On a physiological level, alcohol can alleviate thermal discomfort by promoting vasodilation, enhancing perspiration, and facilitating heat dissipation [12,13]. Cold carbonated alcoholic beverages, such as beer, may further provide immediate relief and perceived hydration [14]. Psychologically, alcohol's mild anxiolytic and analgesic properties may offer temporary relief from heat-induced discomfort, irritability, or anxiety [15,16]. However, relying on alcohol as a coping strategy during heatwaves may pose serious health risks, exacerbating dehydration, impairing thermoregulation, and amplifying the risk of heat-related illnesses [11].

Early-Life Experiences as Moderators

Importantly, individual susceptibility to environmental stressors such as extreme heat is not uniform. Psychosocial resources and early-life experiences play a pivotal role in shaping vulnerability and resilience. The existing literature underscores that climate-related health risks are not solely determined by exposure intensity but are also mediated by underlying vulnerability factors (ie, predisposition to adverse outcomes) and resilience capacities [17]. While studies have highlighted personal socioeconomic status, education, income, and social isolation as key determinants of resilience [18], the influence of early-life experiences, both positive childhood experiences (PCEs) and adverse childhood experiences (ACEs), remains underexplored in this context.

PCEs such as parental care, emotional support, and stable family relationships foster resilience and serve as protective factors for mental health in later life [19,20]. For instance, receiving unconditional love and experiencing nurturing parenting contribute to enhanced coping skills, reducing reliance on harmful behaviors such as substance abuse [21]. Conversely, ACEs such as exposure to parental substance misuse, neglect, abuse, or encounters with law enforcement are strongly associated with heightened psychosocial vulnerability and maladaptive coping strategies, including alcohol abuse, in adulthood [22-25]. There is extensive evidence linking ACEs to increased risk of mental health challenges such as depression, psychiatric disorders, and substance misuse later in life [26-29]. Early adverse experiences may thus compound the impact of environmental stressors, amplifying health risks through entrenched behavioral and psychological pathways.

This Study

Grounded in a life course perspective, this study aims to investigate the relationship between extreme heat exposure and alcohol consumption among older adults in the United States, with a focus on how early-life experiences shape risk disparities. Leveraging over 2 decades of nationally representative data integrated with historical temperature records, we provide a comprehensive analysis of this association, addressing a critical gap in the literature. While previous research has predominantly emphasized adulthood socioeconomic and psychosocial factors, our study extends this framework by elucidating how both PCEs and ACEs moderate older adults' behavioral responses to extreme heat. This inquiry is particularly timely given the projected rise in the frequency and severity of heatwaves associated with climate change [30].

The intersection of extreme heat and alcohol consumption is a public health issue of growing urgency, as alcohol use during heatwaves may exacerbate vulnerability to acute health crises, including dehydration, hyperthermia, and heat stroke [31,32]. Older adults, already facing age-related declines in thermoregulatory capacity, are at heightened risk. By identifying how early-life experiences shape susceptibility to maladaptive coping behaviors under environmental stress, our findings offer actionable insights for designing targeted interventions and health policies aimed at mitigating alcohol-related harms in the context of climate change. To our knowledge, this is the first study to use a nationally representative dataset to explore the intersection of extreme heat exposure, substance use, and early-life experiences among older adults in the United States.

Methods

Data and Sample

As individual-level data, this research used data collected from a nationally representative sample of the Health and Retirement Study (HRS), sampling over 20,000 older adults aged ≥50 years, along with their spouses, living in the United States. Since 1992, the HRS has conducted biennial surveys. This comprehensive survey covers diverse information, including demographics, physical health, health-related behaviors, family dynamics, disabilities, housing, wealth, work history, health care

XSL•FO
RenderX

accessibility, and more [33]. This study used the 1996 to 2018 waves of the HRS.

The National Environmental Public Health Tracking Network, a Center for Disease Control and Prevention division, offers yearly county-level data concerning extreme weather incidents. This data source provides historical and projected metrics linked to temperature, heat index, heat-related ailments, and previous and predicted precipitation. To explore the relationship between heat events and the drinking behaviors of older adults, we merged the county-level data on extreme weather incidents with the individual-level data of the HRS using the participant's county of residence and the years in which the survey was conducted.

The study included participants aged ≥50 years with geographical information about their county of residence across time. The detailed sample characteristics are presented in Table 1. The average age of the sample was 68 (SD 11) years. More than half of the sample were women (57%), non-Hispanic White (64%), and coupled (61%). Approximately two-thirds of the respondents completed a high school degree or lower (76%), were unemployed or retired (73%), and owned a primary residence (74%). A total of 65% of the older adults reported good or better health, and <1% reported activity of daily living and instrumental activity of daily living with difficulty. The mean number of household members and living children was 2 (SD 1) and 3 (SD 2), respectively.

[c]IADL: instruments of activities of daily living.

Variables

The study's dependent variable was older adults' alcohol consumption behaviors measured using the natural log-transformed number of drinks consumed per week. To create the number of drinks taken per week, the study combined two questions asking how many days per week a respondent has had any alcohol to drink and how many drinks she had on the days of drinking in the previous 3 months. Responses to these questions were multiplied. The average number of alcoholic beverages consumed in a week was estimated as <1 (Table 1). The ratio of observations who had at least 1 drink per week was 5%. Among drinkers, the mean number of drinks consumed per week was estimated as 7.85 (SD 11.06).

The primary explanatory variable in the study was instances of extreme heat events taking place in the HRS respondents' county. This factor was proxied by examining the annual frequency of extreme heat days, by counting the days when the highest daily temperatures reached 95 °F, 100 °F, and 105 °F between May and September. On average, there were 17 days per year with peak temperatures of 95 °F, 7 days per year with peak temperatures of 100 °F, and 2 days per year with peak temperatures of 105 °F (Table 1).

The study considered early-life experiences as a moderator of the relationship between extreme heat days and alcohol consumption. The early-life events included paternal relational quality, police encounters, and parental substance use problems before age 18 years, all of which were included in the Leave Behind section of the HRS. Since 2006, 50% of the main survey participants have randomly been assigned to complete the Leave Behind section, and the other half was required to do so in 2008, resulting in respondents' participation in the section in 4-year intervals. The paternal relational quality before age 18 years was assessed using the question, "I had a good relationship with my father before age 18," rated on a 5-point Likert scale [34]. The mean score was 4.21 (SD 1.18), with higher values indicating better relationship quality. As the measure asked about early relational quality, the measure was also averaged across waves to have a time-invariant individual factor. The score was further standardized to have a mean of 0 (SD 1). The other early-life events associated with later-life alcohol consumption were included: "Before you were 18 years old, were you ever in trouble with the police?" "Before you were 18 years old, did either of your parent drink or use drugs so often that it caused problems in the family?" [35]. The percentage of the observations that encountered law enforcement and had parents with drinking and drug use problems was 5.28% and 16.06%, respectively. The two variables were also coded as time-invariant factors, using the mode of the responses.

The study included a comprehensive set of time-variant individual and household characteristics as covariates. These include age centered on 50 years, its squared term, marital status, self-reported health, number of activities of daily living and instrumental activities of daily living with difficulty performing, health insurance ownership, employment status, home ownership, the natural logarithm of household income and financial assets, and number of household members and living children. The study further controlled for individual and wave fixed effects. The study finally controlled for the yearly number of days experiencing intense precipitation, quantified by the annual heavy rainfall exceeding the absolute threshold of 0.01 inches. The study found that, on average, there were 8 such extreme precipitation days per year during the study period.

Empirical Models

To estimate the effect of extreme heat events on alcohol consumption behaviors, this study used individual fixed effects models. By controlling for individual fixed effects, the models were designed to capture within-individual changes in behaviors in response to changes in extreme heat events. The following is the specified model:

XSL•FO
RenderX

(1)ACiw=α0+α1EHct+α2Xiw+ii+ww+ iw

AC_{iw} denotes a respondent *i*'s alcohol consumption behaviors measured using the natural logarithm of the number of drinks consumed per week in wave *w*. Coefficients from this model can be interpreted as percentage changes in weekly alcohol consumption associated with a 1-unit increase in the number of extreme heat days in a given year. For example, a coefficient of 0.01 indicates that each additional extreme heat day is associated with a 1% increase in the number of drinks consumed per week. EH_{ct} is the measure for extreme heat events proxied for using the annual counts of days with daily maximum temperatures of 95 °F, 100 °F, and 105 °F in county *c* in year *t*. X_{iw} indicates a vector of time-variant individual and household characteristics measured in wave *w*. i_i and w_w are individual and wave fixed effects. i_i reflects all the time-invariant individual *i*'s factors such as gender, race or ethnicity, educational attainment, etc. $\in_{iw}$ is the idiosyncratic error for individual *i* in wave *w*.

The study further explores whether early-life experiences, known to be correlated with alcohol consumption and alcoholism, moderated the association between extreme heat events and alcohol consumption behaviors. The following is the individual fixed effects model after interacting the count of extreme heat days with early-life experience factors:

(2)ACiw=β0+β1EHct+β2EHctLEi+β3Xiw+ii+ww+ iw

LE_i denotes the early–life course events of respondent *i*. The early-life experiences included relational quality with a father, police encounters, and parental substance use problems before the age of 18 years. All the life course events were time invariant because the events occurred early in life. In this case, the standalone effects of life course events are absorbed in the individual effects i_i, and the combined effect therefore would be measured as $\beta_1+\beta_2$.

Ethical Considerations

This study was approved by the institutional review board (IRB) at the University of Utah (IRB Protocol #00194769). All respondents in the HRS provided informed consent prior to participation. The analyses used restricted HRS data containing county-of-residence information, which were accessed under a Restricted Data Use Agreement and analyzed in accordance with applicable data security and confidentiality requirements. No direct participant compensation was provided by the authors because this study relied on the secondary analysis of existing survey data.

Results

Extreme Heat Events on Alcohol Consumption Behaviors

Table 2 presents the estimates from individual fixed effects models where the dependent variable was the logarithm of the number of drinks per week. Regardless of the thresholds used to define extreme heat temperatures, the number of extreme heat days was positively correlated with the number of alcoholic beverages consumed per week. A 1-unit increase in the extreme heat day counts defined as the maximum temperatures of 95 °F, 100 °F, and 105 °F related to increases in the number of drinks per week by 0.21%, 0.02%, and 0.04%, respectively. Interpreting the coefficients in more meaningful units, a seasonal increase of 30 extreme heat days (rather than a single day) is associated with a 6.3% increase in weekly alcohol consumption when extreme heat is defined as temperatures ≥95 °F, a 0.6% increase when defined as ≥100 °F, and a 1.2% increase when defined as ≥105 °F.

As a sensitivity test, we restricted the sample to respondents who participated in the survey between May and September of each year and reestimated the individual fixed effects models. This procedure addresses the potential concern that the timing of drinking behavior may not align with the period during which extreme heat events are measured. As noted in the *Methods*

XSL•FO
RenderX

section, extreme heat is defined using temperature observations from May till September, whereas alcohol consumption is measured throughout the year based on the respondent's survey date. If the effect of extreme heat is short-lived and primarily influences contemporaneous or near-term drinking behavior—rather than exerting long-lasting effects over the entire year—then restricting the sample to the survey period overlapping with the heat exposure window is appropriate.

The results of this analysis are presented in Table S1 in Multimedia Appendix 1. The estimates are consistent with those from the main specification, although the significance level is reduced to $P<.05$ for models in which extreme heat days are defined as ≥95 °F and ≥100 °F. When extreme heat days are defined as ≥105 °F, the coefficient becomes statistically insignificant. Importantly, the direction and magnitude of the estimated effects remain similar, suggesting that the primary findings are not driven by the inclusion of out-of-season observations. For this reason, we retain the full analytic sample in the main analysis to preserve variation in within-person drinking behavior and maintain statistical power, while presenting the seasonal restriction as a robustness check.

Early-Life Experiences as a Moderator

From this section onward, the study used a threshold of 95 °F to define the extreme heat days. Table 3 presents the estimates from individual fixed effects models after interacting extreme heat days with early-life experiences (equation 2). All the early-life experiences appeared to moderate the association between extreme heat events and the number of drinks consumed per week. Specifically, early-life relational quality with a father could offset the adverse effect of extreme heat days on alcohol consumption (panel A in Table 3). A 30-day increase in extreme heat days is associated with approximately a 0.6% increase in weekly alcohol consumption among older adults with average levels of paternal relational quality (0.0002 × 30 days = 0.006 or 0.6%). However, for older adults whose paternal relational quality is 1 SD above the mean, this increase is effectively offset. In other words, stronger early-life relationships with fathers buffer the effect of heat exposure on later-life alcohol use. Furthermore, older adults without law enforcement encounters did not change their alcohol consumption in response to changes in extreme heat days (panel B in Table 3). In contrast, among those who experienced adverse police encounters before the age of 18 years, the same seasonal increase in extreme heat is associated with a 2.4% increase in weekly consumption (0.0008×30 days=0.024, or 2.4%). Finally, older adults who did not grow up with parents who had drinking or drug problems show no meaningful change in alcohol consumption in response to additional extreme heat. In contrast, those who did experience parental alcohol or drug problems exhibit a 1.5% increase in weekly alcohol consumption for each 30 additional extreme heat days (0.0005×30 days=0.015, or 1.5%; panel C in Table 3).

Discussion

Principal Findings

This study offers novel, population-level insights into the intersection of environmental stressors and behavioral health, specifically examining how extreme heat exposure is associated with alcohol consumption among older adults, with particular attention to the moderating role of early-life experiences. To our knowledge, this is the first analysis within the United States to explore this relationship through a life course framework,

XSL•FO
RenderX

highlighting the enduring impact of early ACEs or PCEs on later-life health behaviors.

While some studies have reported potential health benefits of light to moderate alcohol use, such as enhanced cardiovascular function and delayed cognitive decline [36,37], the deleterious consequences of excessive or binge drinking are well established. These include elevated risks of falls, cardiovascular disease, cognitive impairment, and mortality [38], risks that may be exacerbated under extreme heat conditions. Our findings demonstrate a significant association between heat exposure and increased alcohol consumption, aligning with earlier evidence from non-US contexts [39]. However, unlike prior studies, which lacked representative samples and focused on younger populations, our analysis centers on older adults, thereby filling a critical gap in understanding how environmental stress may drive maladaptive coping behaviors in aging populations.

More specifically, our findings indicate that a seasonal increase of 30 extreme heat days is associated with a 1.2% (≥105 °F) to 6.3% (≥95 °F) increase in weekly alcohol consumption. Studies have shown that alcohol consumption during heat exposure can physiologically lower core body temperature by enhancing sweating and vasodilation, which are key mechanisms of thermoregulation [13]. In addition, cold alcoholic beverages may provide immediate psychological relief and a sense of hydration, making them particularly appealing in hot weather [13]. This perceived cooling effect may encourage greater alcohol intake during high temperatures. However, given alcohol's potential to exacerbate dehydration, impair thermoregulation, and increase vulnerability to heat-related illness [11], it is not a healthy coping strategy during extreme heat. Evidence also shows that higher temperatures are associated with increased hospital visits for alcohol-related disorders [40]. This is especially salient for older adults, as even small behavioral shifts may have clinically meaningful consequences for those already vulnerable to impaired thermoregulation and hydration with aging.

Given the significant health risks associated with excessive alcohol consumption, our findings underscore the need to prioritize populations most vulnerable to both extreme heat and substance use. Targeted interventions for older adults exposed to prolonged heat should consider the compounding effect of environmental stress on health behaviors. Possible strategies include providing subsidies for home retrofitting (eg, air conditioning installation), disaster relief funds, and establishing accessible cooling centers such as community centers, public pools, and shelters. Such measures may not only alleviate heat-induced physiological stress but also reduce the likelihood of maladaptive coping mechanisms such as increased alcohol consumption.

Beyond immediate environmental interventions, this study underscores the enduring influence of early-life experiences on later-life behavioral responses to stress. Specifically, we found evidence for the protective role of PCEs, nurturing, supportive, and emotionally secure environments during early life that contribute to resilience and healthier aging trajectories. In particular, a strong paternal relationship during childhood mitigated the association between extreme heat exposure and alcohol consumption in older adulthood, suggesting that early supportive relationships may foster adaptive coping mechanisms that persist across the life course. Prior research has demonstrated that nurturing paternal relationships buffer against alcohol misuse [21] and enhance stress resilience [20]. Our findings extend this literature by suggesting that the psychological advantages conferred by early positive parenting not only shape interpersonal and emotional health but also influence behavioral responses to environmental stressors later in life. This underscores the value of policies and programs promoting positive parenting practices and mental health education aimed at fostering resilience from childhood through adulthood.

However, the nonsignificant findings for maternal relationships should not be interpreted as an absence of influence (Table S2 in Multimedia Appendix 1). This may reflect limited measurement sensitivity, recall variability, or contextual differences in how maternal warmth and caregiving were reported. Future research should use multidimensional assessments of PCEs that capture diverse caregiving roles and family contexts. Such approaches would better illuminate how early relational environments, across both paternal and maternal domains, can buffer environmental stressors and promote adaptive aging trajectories.

Conversely, the presence of ACEs, including exposure to abuse, neglect, or household dysfunction, was associated with higher alcohol consumption during extreme heat events. This pattern suggests that early-life adversity, particularly exposure to parental substance use, may contribute to enduring susceptibilities in stress regulation and coping behaviors that persist into older adulthood. This finding aligns with previous research highlighting the heightened vulnerability of individuals exposed to ACEs [41]. The influence of parental substance misuse is twofold: it both serves as a behavioral model for maladaptive coping strategies and introduces potential genetic predispositions for substance use disorders [42,43]. These factors collectively increase susceptibility to problematic drinking behaviors in response to stressors such as extreme heat. Addressing these risks necessitates a multifaceted approach—incorporating trauma-informed care, family support programs, and community-based interventions aimed at breaking the intergenerational transmission of substance abuse and fostering healthier coping mechanisms.

Additionally, our findings reveal that negative childhood interactions with law enforcement were associated with increased alcohol consumption in adulthood during heatwaves. Such early encounters often contribute to heightened stress reactivity and may normalize maladaptive coping behaviors within disadvantaged environments [29,44]. This underscores the critical need for trauma-informed policing practices and early intervention programs that mitigate the long-term psychological impacts of ACEs. Integrating trauma-awareness training for law enforcement and expanding mental health services for affected communities could serve as pivotal steps in reducing long-term health disparities.

XSL•FO
RenderX

Limitations

While this study advances the understanding of the interplay between extreme heat exposure, alcohol consumption, and early-life experiences, certain limitations warrant consideration. The use of HRS data, although robust, restricts our ability to ascertain the precise mechanisms underlying the observed associations. Future research should explore the mediating psychological or physiological pathways in more depth. Additionally, our analysis of PCEs was limited to paternal relationships, as maternal relationships did not yield statistically significant findings in relation to heat exposure and alcohol consumption (Table S2 in Multimedia Appendix 1), highlighting an avenue for further inquiry. An important caveat is that retrospective questions on early-life parental relationships were only administered to respondents who reported having a mother or father present during childhood. Individuals who lacked such parental figures did not receive these items, resulting in nonrandom missingness for that measure. Finally, the absence of detailed environmental variables (eg, home cooling resources and neighborhood infrastructure) represents a limitation, as these factors likely influence the degree of heat-related stress experienced by older adults and shape how they buffer heat-related stress. Future work could incorporate proxy information from ancillary HRS modules such as electricity spending from the Consumption and Activities Mail Survey or community facility measures from the Neighborhood and Network Data to examine potential moderating effects. Although these proxies do not directly capture older adults' adaptation to extreme heat and linking these subpopulation modules substantially reduces sample size and statistical power, incorporating such environmental factors in future studies will enrich our understanding of the multi-level determinants of health behavior under climate-related stressors.

Conclusions

This study identifies a clear association between extreme heat events and increased alcohol consumption among older adults, with early-life experiences serving as significant moderators. Positive paternal relationships appear to buffer against the adverse behavioral impacts of heat stress, while adverse experiences such as parental substance use and negative interactions with law enforcement exacerbate vulnerability. These findings emphasize the long-lasting influence of childhood environments on later-life resilience and underscore the need for integrated, trauma-informed policies and interventions. By addressing both environmental stressors and the psychosocial foundations established early in life, policymakers and practitioners can more effectively mitigate the compounding health risks facing older populations in an era of increasing climate volatility.

Abstract

Background: Medication regimen simplification has gained increasing attention as a strategy to reduce treatment burden and improve medication use. However, the overall development, knowledge structure, and emerging themes of this field have not been systematically mapped, hindering efforts to identify clear research priorities and support strategies that facilitate the translation of simplified approaches into optimized medication management.

Objective: This study aimed to examine global research trends, collaboration patterns, and research hot spots in medication regimen simplification.

Methods: A bibliometric analysis was conducted to characterize the research landscape of medication regimen simplification. Publications from the Web of Science Core Collection (January 1, 2005, to December 31, 2025) were analyzed using Microsoft Excel 365, VOSviewer, CiteSpace, and Bibliometrix in R for publication trends, countries and regions, institutions, authors, cocited references, keyword co-occurrence, clustering, and thematic evolution.

Results: A total of 468 publications were included in this bibliometric analysis. Annual publication output showed an upward trend, although fluctuations occurred across years. The United States ranked first in publication output and total citations, and Monash University was the most productive institution. Collaboration was concentrated in a limited number of country, institutional, and author clusters, with the strongest international links between North America and Europe. Cocitation and keyword analyses showed that the field evolved from a focus on HIV-related regimen optimization and medication adherence to broader themes in chronic disease management, including type 2 diabetes, heart failure, long-term care, and medication regimen complexity.

Conclusions: Research on medication regimen simplification has grown over time, but collaboration remains relatively concentrated. Current hot spots center on its use in specific disease settings and on medication complexity and adherence, whereas recent trends highlight real-world implementation. Future research should further examine the long-term impact and sustainability of simplification strategies.

(JMIR Aging 2026;9:e82274) doi:10.2196/82274

KEYWORDS

medication regimen simplification; bibliometric analysis; polypharmacy; medication adherence; medication regimen complexity

Introduction

With advances in medical care, more patients with chronic conditions such as hypertension, diabetes, and cardiovascular disease require multiple medications for long-term pharmacotherapy. However, the benefits of treatment are frequently limited by poor medication adherence, and complex drug regimens are an important contributing factor [1,2]. More complex medication regimens are associated with poorer adherence, which may compromise disease control and increase the risk of adverse outcomes [3]. Older adults, particularly those with cognitive impairment or limited health literacy, often experience difficulties with medication management, which may contribute to unintentional nonadherence, medication errors, and reduced quality of life [4-6].

Complex medication regimens in older adults, particularly those involving multiple drugs and frequent dosing, can make adherence more difficult [2]. Polypharmacy may also increase

XSL•FO
RenderX

the risk of drug-drug interactions and health care costs [7]. As a result, medication regimen simplification has become a key strategy to optimize pharmacotherapy, improve adherence, and reduce treatment burden [8,9]. Its importance is further underscored by the World Health Organization's advocacy for the rational use of medicines, ensuring that patients receive medications appropriate to their clinical needs and in correct doses for effective outcomes [10]. Similarly, a Centers for Disease Control and Prevention Grand Rounds report highlighted improved medication adherence as a key component of chronic disease management and optimal prescribing practices [11]. In clinical practice, regimen simplification may be considered as part of broader medication review and optimization processes [12].

Medication regimen simplification refers to reducing the complexity of medication use through strategies such as consolidating dosing times, reducing dosing frequency, standardizing administration routes, substituting long-acting for short-acting formulations, and using fixed-dose or other combination products when possible without altering the therapeutic goals, efficacy, or safety of treatment [8]. Importantly, medication regimen complexity is not determined solely by the number of medicines prescribed but also by dosage forms, dosing frequency, administration times, routes of administration, and additional instructions required for proper use [13-15]. Accordingly, medication regimen simplification aims to reduce the practical and cognitive burden of medication use for patients or caregivers [8]. Its application spans a wide range of clinical contexts, including polypharmacy in older adults; chronic disease management; HIV care; and other settings characterized by high regimen complexity, such as long-term care, home-based care, and multi-morbidity [16,17]. This concept is distinct from deprescribing, which primarily involves discontinuing inappropriate or unnecessary medications, whereas medication regimen simplification seeks to make an otherwise appropriate regimen easier to follow without changing its therapeutic intent [16,18]. It should also be distinguished from broader concepts such as medication optimization, medication review, rational prescribing, and adherence-enhancing interventions [19-21]. In this sense, simplification may be regarded as one component of medication optimization and one possible outcome of medication review, but it is not synonymous with either. In this study, reductions in medication regimen complexity index scores or simplification of medication administration processes were considered relevant only when they reflected a deliberate effort to simplify the medication regimen actually used by patients or caregivers [22,23].

Despite growing interest in this area, related research remains dispersed across populations, disease settings, and intervention types, and the overall intellectual structure and development of the field have not been systematically characterized. Bibliometric analysis offers a systematic and visual approach to map the structure, trends, and knowledge gaps of a research field [24,25]. This study used VOSviewer (Centre for Science and Technology Studies, Leiden University) and CiteSpace to analyze the global literature on medication regimen simplification and identify key contributors, major research themes, and emerging trends with the aim of informing future research and clinical practice.

Methods

Search Strategy and Eligibility Criteria

Publications were retrieved from the Web of Science Core Collection (WoSCC). The search was conducted on March 6, 2026, and covered the period from January 1, 2005, to December 31, 2025. All records were obtained from the Science Citation Index Expanded within WoSCC. The search was performed in the title, author keywords, and abstract fields. Only articles and reviews published in English were included. Because "medication regimen simplification" is neither a standardized indexing term nor a MeSH (Medical Subject Headings) term, the search strategy relied on a combination of free-text terms informed by related expressions reported in previous studies and by the conceptual scope of this study [8,9,26]. These terms included simplification-related expressions for regimens, medications, and therapies, as well as expressions related to reduced medication regimen complexity. The full search strategy is shown in Table 1.

XSL•FO
RenderX

Table . Summary of data source and study selection.

Item	Description
Data source	WoSCC[a]
Search date	March 6, 2026
Time span	2005-2025
Language	English
Document type	Articles and reviews
Search field	Title, author keywords, and abstract
Search strategy	TI/AK/AB = (“regimen simplification” OR “treatment simplification” OR “therapy simplification” OR “medication regimen simplification” OR “simplified regimen” OR “simplified medication regimen” OR (simplif* NEAR/3 regimen*) OR (simplif* NEAR/3 medication*) OR (simplif* NEAR/3 therap*) OR (“medication regimen complexity” NEAR/3 reduc*) OR (reduce* NEAR/3 “medication regimen complexity”))
Initial records retrieved, n	1466
Screening criteria	Records were screened by title and abstract. Publications were excluded if they did not describe medication regimen simplification as a primary focus or if any reported reduction in medication regimen complexity was not presented as an intended simplification strategy.
Final records included, n	468

[a]WoSCC: Web of Science Core Collection.

In this study, medication regimen simplification was operationally defined as strategies intended to reduce the complexity of a medication regimen while preserving its therapeutic intent. On the basis of this definition, this bibliometric analysis included publications that explicitly described such strategies as medication regimen simplification or clearly characterized them as a reduction in medication regimen complexity. Interventions such as reduced dosing frequency, consolidated administration times, long-acting formulations, and fixed-dose combinations were included only when they were presented as intended to simplify the regimen or reduce its complexity. Deprescribing was not considered equivalent to medication regimen simplification. Similarly, lower medication regimen complexity scores or simpler medication administration schedules were considered relevant only when they reflected an explicit strategy to simplify the regimen followed by patients or caregivers.

Deduplication and Screening Reliability

Two researchers independently screened the titles and abstracts of all retrieved records. Full texts of potentially eligible studies were then reviewed independently by the same 2 researchers according to the predefined inclusion and exclusion criteria. Any disagreements were resolved through discussion with a third researcher. Manual checking was performed to identify any remaining duplicate records or overlapping reports of the same study. In addition, the reference lists of included studies were screened manually to identify potentially relevant articles. Interrater agreement between the 2 researchers was assessed using the Cohen κ, which indicated a high level of agreement (κ=0.83).

Data Extraction and Collection

Bibliometric data were extracted from the included publications, including publication year, country or region, institution, author, journal, keywords, cited references, and research area information, as well as annual publication counts. Before analysis, limited manual corrections were performed to improve the consistency of country, institution, and author information. Institution names were merged when spelling variants, abbreviations, or formatting differences referred to the same organization. Country names were standardized when the WoSCC classification was evidently inconsistent. Author names were standardized only for obvious variants referring to the same individual based on publication context and affiliation information. In addition, the names of the top authors and institutions reported in the main tables were manually cross-checked against the original WoSCC records and affiliation information.

Data Processing

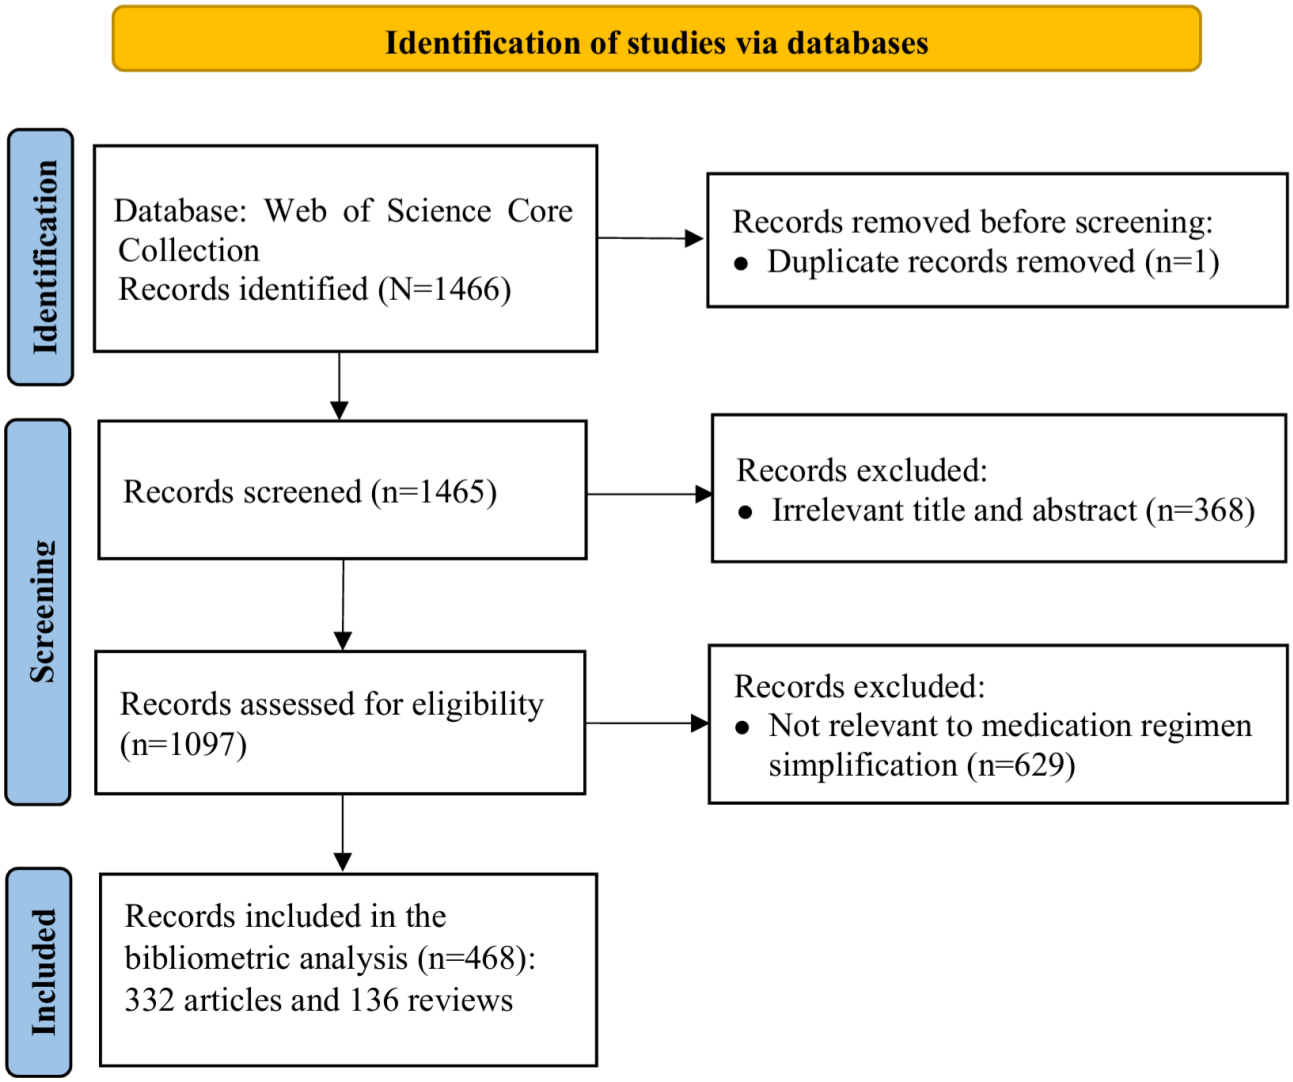
CiteSpace (version 6.4.R1 Advanced) [27] and VOSviewer (version 1.6.20) [28] were used for bibliometric visualization and network analysis. CiteSpace was used to analyze the dual-map overlay of journals, reference cocitation, keyword clustering, and burst detection. VOSviewer was used to visualize collaboration networks among countries and regions, institutions, and authors, as well as keyword co-occurrence. In addition, Bibliometrix in R (version 4.4.1; K-Synth Srl) [29] was used for supplementary visualization of countries and regions and keyword data, and Microsoft Excel 365 was used to present annual publication trends.

For network construction in VOSviewer, the following thresholds were applied: keywords with at least 3 occurrences, countries and regions with at least 5 publications, institutions

XSL•FO
RenderX

with at least 3 publications, and authors with at least 2 publications were included. These thresholds were chosen to keep the networks interpretable and reduce noise from low-frequency items [30]. In CiteSpace, the time span was set from 2005 to 2025 with 1 year per slice, and Pathfinder pruning was applied to simplify the network structure and highlight the most meaningful links. Betweenness centrality was calculated by CiteSpace using its default settings and was used to identify important nodes in the networks.

Ethical Considerations



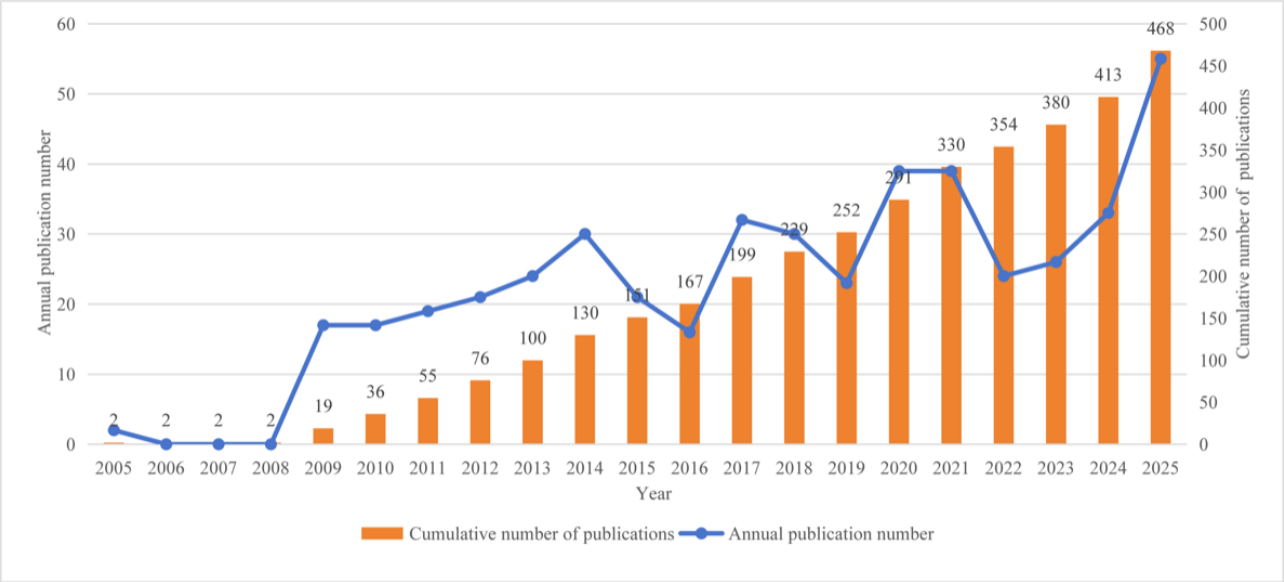
This study was based on publicly available literature and did not involve human or animal participants; thus, no ethics approval was required.

Results

Study Selection

A total of 1466 records were identified. After title and abstract screening, publications without an explicit focus on medication regimen simplification or reduction in medication regimen complexity were excluded. Ultimately, of the 1466 records, 468 (31.9%) publications were included in the final analysis. The study selection process is shown in Figure 1.

Figure 1. Flowchart of the study selection process.

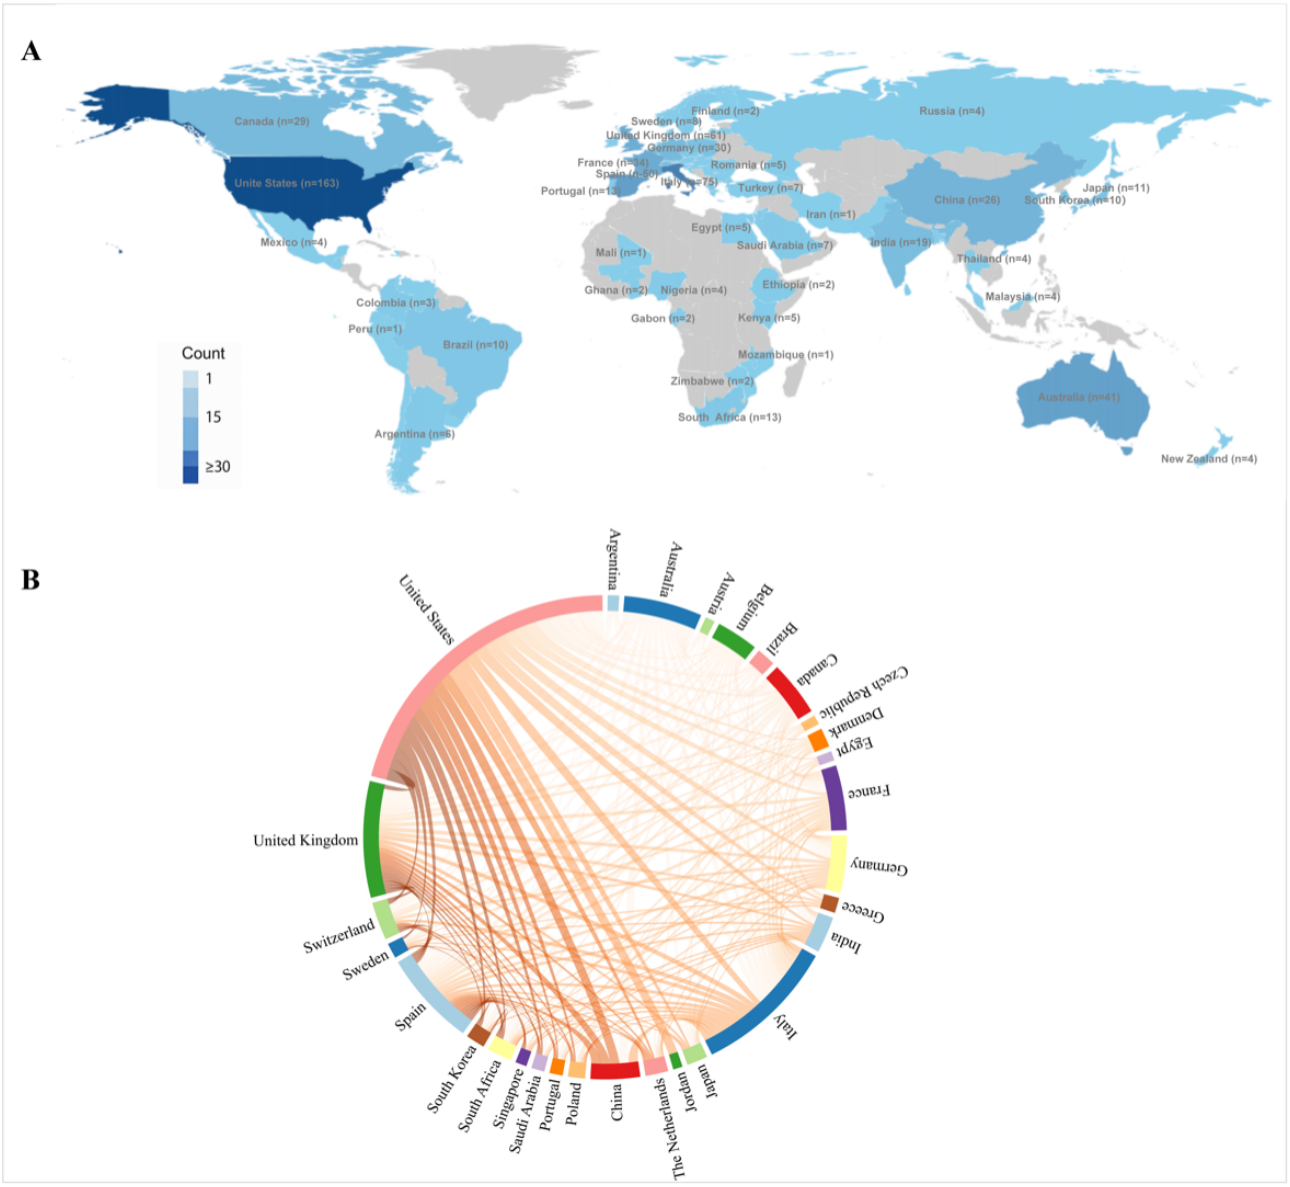


Annual Publication Statistics

Figure 2 illustrates the annual and cumulative number of publications on medication regimen simplification from 2005 to 2025. Annual publication output was low from 2005 to 2008 and then increased from 2009 onward, with fluctuations across years. The cumulative number of publications increased throughout the study period, from 2 in 2005 to 468 in 2025.

XSL•FO
RenderX

Figure 2. Annual volume of publications.



Global Contribution of Countries and Regions, Institutions, and Authors to the Field

Countries and Regions

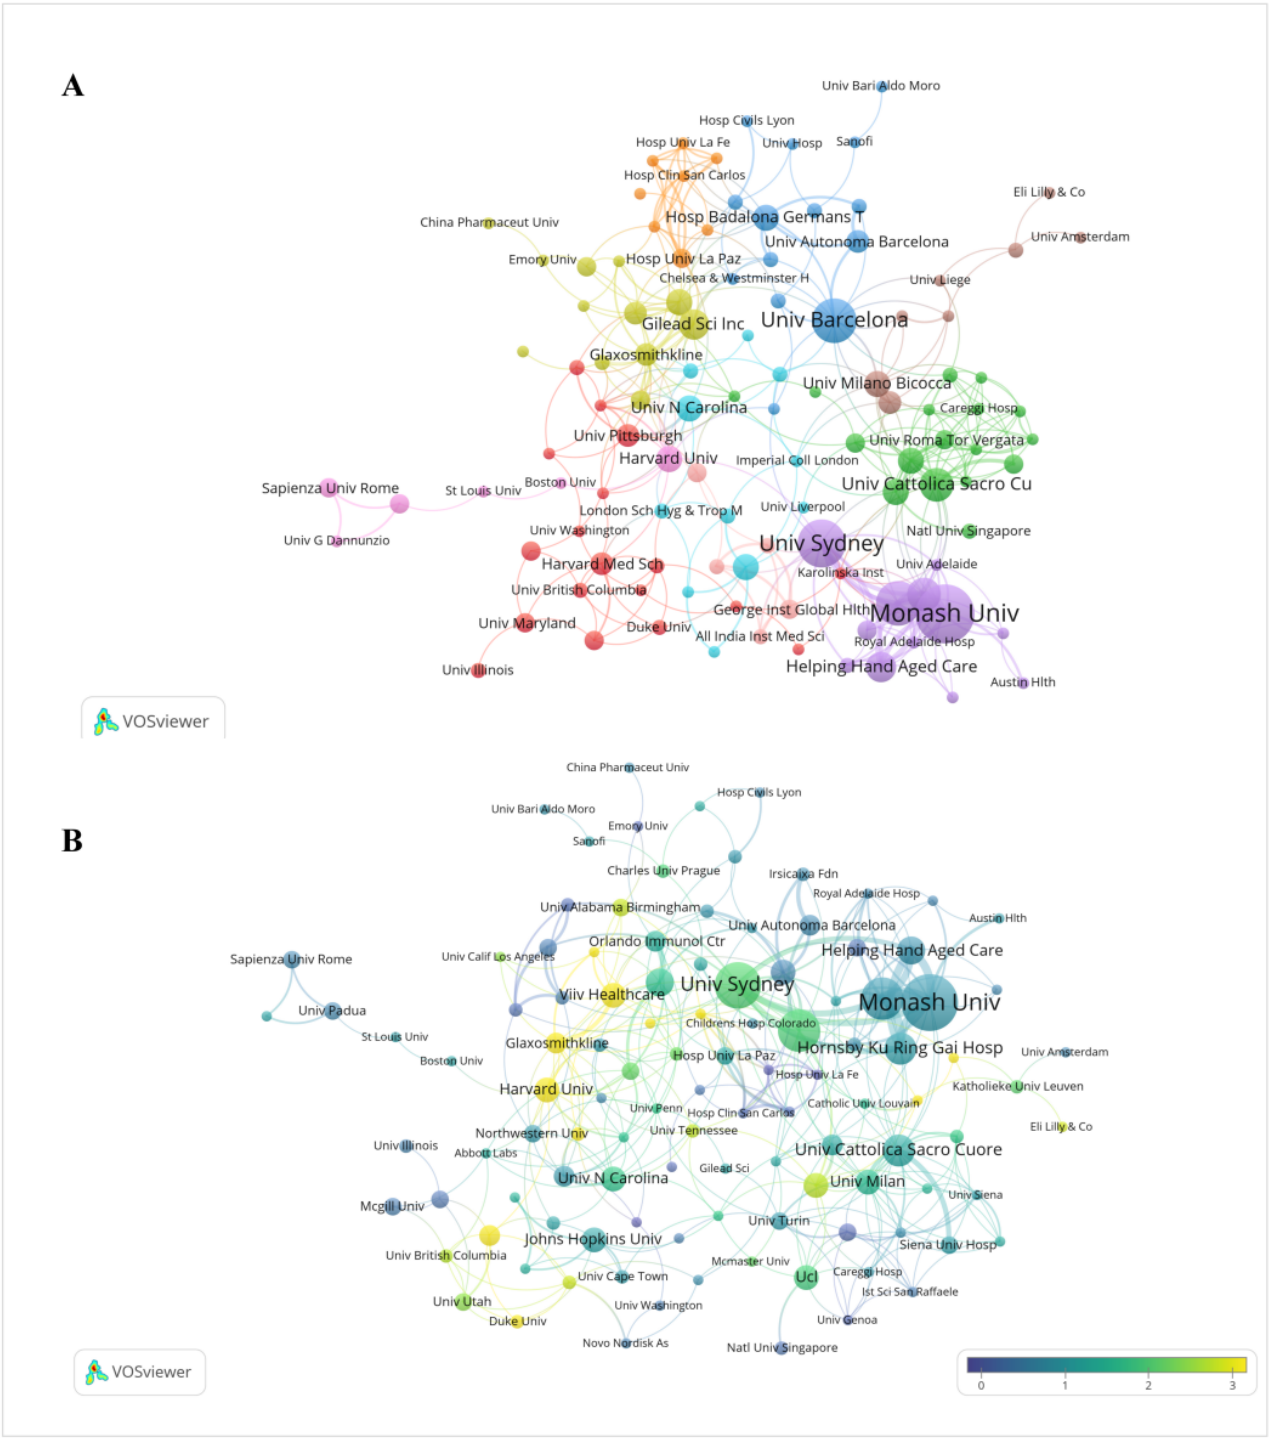
Figure 3A shows the distribution of publications on medication regimen simplification across countries and regions from 2005 to 2025. The 10 most productive countries and regions and their citation counts are listed in Multimedia Appendix 1. The United States contributed the largest number of publications (163/468, 34.8%), followed by Italy (75/468, 16.0%) and the United Kingdom (61/468, 13.0%). The United States also had the highest citation count (n=6720), followed by Italy (n=3800). Figure 3B shows the country and region collaboration network, in which the United States, the United Kingdom, Italy, Germany, China, and Australia had larger nodes and multiple links with other countries and regions. Cross-national links were most evident between North America and Europe, with additional links involving East Asia and Oceania.

XSL•FO
RenderX

Figure 3. (A) Global distribution of publications (2005-2025) and (B) networks of country cooperation. UK: United Kingdom.

Institutions

Table 2 presents the 10 institutions with the highest publication counts and total citations. A total of 2234 institutions were identified. Monash University had the highest number of publications (16/468, 3.4%), followed by the University of Sydney (13/468, 2.8%). Among the top 10 most productive institutions, 5 (50%) were from Australia, 2 (20%) were from the United States, and 2 (20%) were from Spain. The University of Sydney had the highest total citation count (n=1764), followed by Harvard University (n=1740) and the University of Barcelona (n=550). Figure 4A shows the institutional collaboration network, in which multiple clusters are visible. Figure 4B presents the overlay visualization based on average normalized citations. Harvard University, Duke University, and Vivli are located in relatively warmer areas of the network, indicating higher average normalized citations.



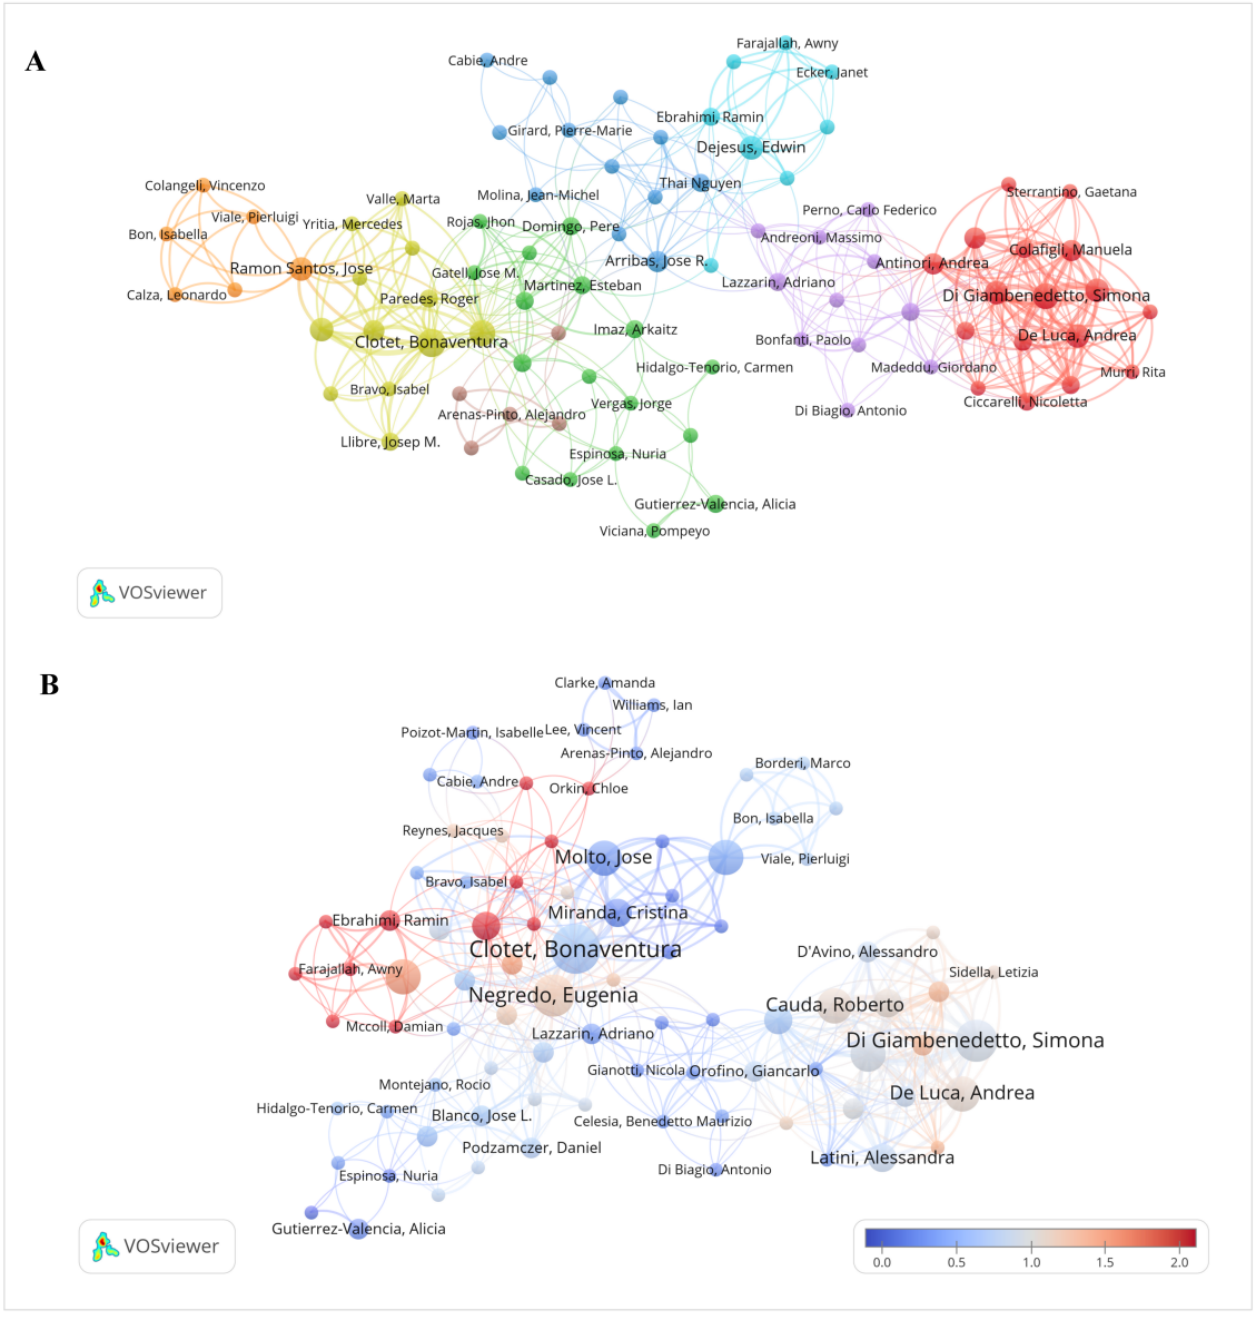
XSL•FO
RenderX

Table . Top 10 institutions by publication count and total citations.

Rank	Institution	Country	Studies (n=468), n (%)	Total citations, n
1	Monash University	Australia	16 (3.4)	333
2	University of Sydney	Australia	13 (2.8)	1764
3	University of Barcelona	Spain	12 (2.6)	550
4	University of South Australia	Australia	12 (2.6)	220
5	Hornsby Ku-ring-gai Hospital	Australia	9 (1.9)	213
6	Catholic University of the Sacred Heart	Italy	9 (1.9)	329
7	Gilead Sciences	United States	8 (1.7)	440
8	Helping Hand	Australia	8 (1.7)	149
9	Harvard University	United States	7 (1.5)	1740
10	Hospital Germans Trias i Pujol	Spain	7 (1.5)	125

XSL•FO
RenderX

Figure 4. (A) Institutional cooperation network and (B) overlay visualization of the institution network based on average normalized citations.



Authors

A total of 3109 authors contributed to the 468 publications on medication regimen simplification. Figure 5A shows the author collaboration network, in which multiple clusters are visible. Clotet, Di Giambenedetto, and De Luca are located in connected parts of the network and are linked with multiple coauthors. Figure 5B shows the overlay visualization of the author network based on average normalized citations. Warmer colors indicate higher citation impact. Clotet, Ebrahim Ramin, Farajzadeh Awny, and Di Giambenedetto are represented by relatively warmer-colored nodes. Table 3 shows author-level metrics. Bell had the highest number of publications (12/468, 2.6%), followed by Sluggett (11/468, 2.4%), and both authors had an H-index of 9. Di Giambenedetto had the highest total citation count (n=260), followed by De Luca (n=254), Bell (n=239), and Sluggett (n=237).

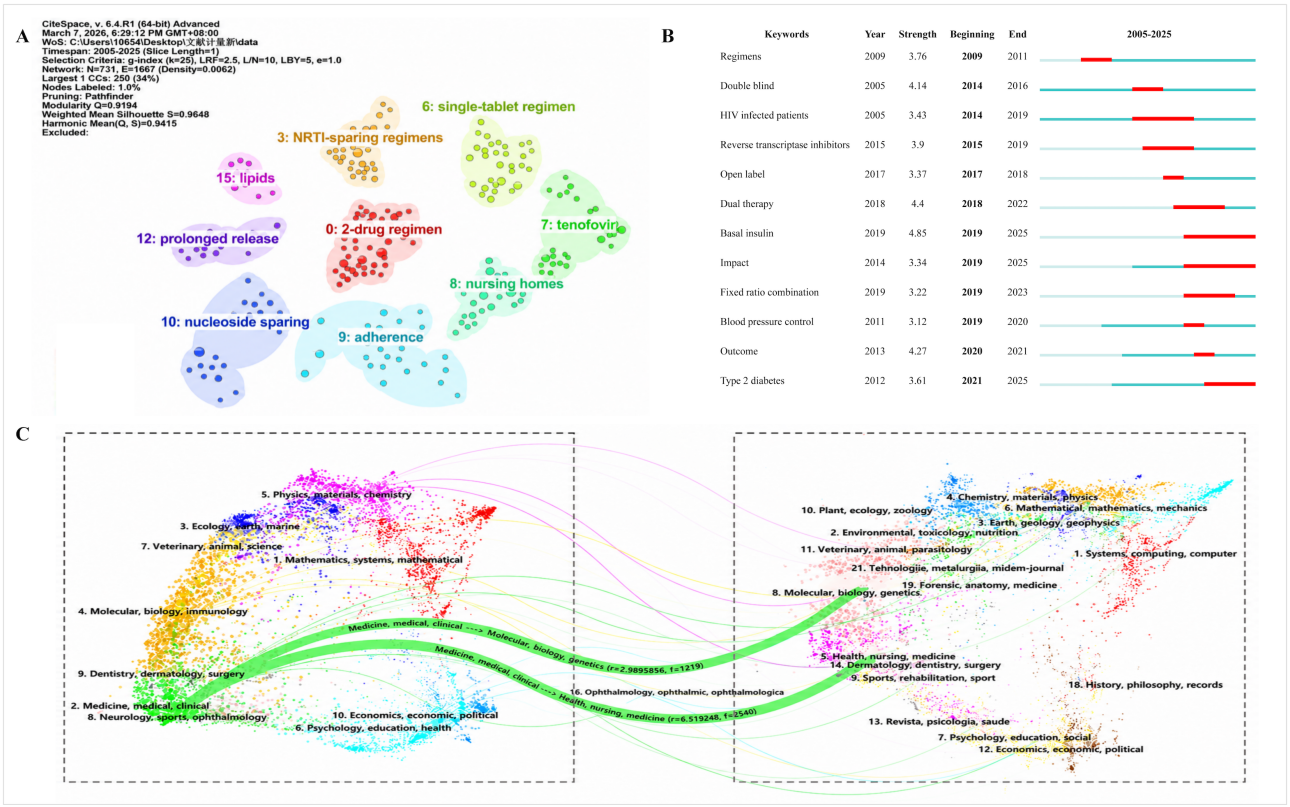
[a]H-index: Hirsch index; h publications cited at least h times each.

[b]TC: total citations.



[c]PY_start: author's first publication year in the dataset.

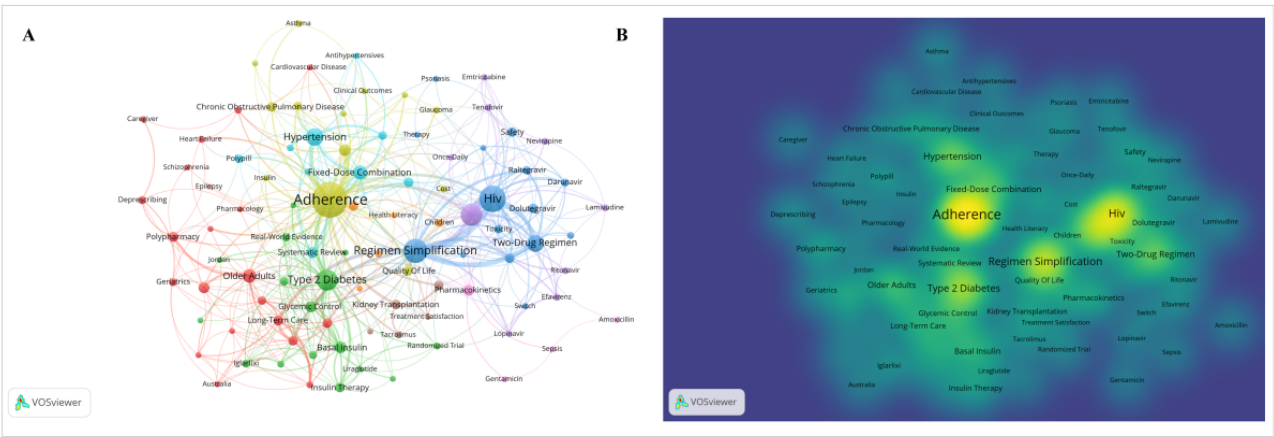
Reference Cocitation and Keyword Burst Analysis

Figure 6A shows the reference cocitation clusters. Using CiteSpace with a 1-year time slice from 2005 to 2025, the network included 731 nodes and 1667 links, with a modularity *Q* of 0.919 and a silhouette score of 0.964. The main labeled clusters included 2-drug regimen (cluster 0), nucleoside or nucleotide reverse transcriptase inhibitors–sparing regimens (cluster 3), single-tablet regimen (cluster 6), tenofovir (cluster 7), nursing homes (cluster 8), and adherence (cluster 9). Figure 6B shows the 12 keywords with the strongest citation bursts. Burst keywords occurring earlier in the study period included "regimens," "double blind," "HIV infected patients," "reverse transcriptase inhibitors," and "open label," whereas burst keywords extending into later years included "dual therapy," "basal insulin," "fixed ratio combination," "blood pressure control," "impact," and "type 2 diabetes." The burst keywords "dual therapy" and "regimens" overlapped with the regimen-related cocitation clusters in Figure 6A, including 2-drug regimen (cluster 0), nucleoside or nucleotide reverse transcriptase inhibitors–sparing regimens (cluster 3), and single-tablet regimen (cluster 6).

XSL•FO
RenderX

Figure 6. (A) Reference cocitation clusters, (B) top 12 keywords with the strongest citation bursts (2005-2025), and (C) the dual-map overlay of journals publishing studies on medication regimen simplification from 2005 to 2025 (left: citing journals; right: cited journals). NRTI: nucleoside or nucleotide reverse transcriptase inhibitors.

Changing Trends in Research Disciplines



As shown in Figure 6C, the dual-map overlay reveals the knowledge flow between disciplines in the field of medication regimen simplification. The main citation paths originated from journals in the medicine, medical, and clinical area and extended to journals in the molecular, biology, and genetics area and the health, nursing, and medicine area. The most prominent paths are shown in green.

Keyword Analysis

Keyword Co-Occurrence

Figure 7A shows the keyword co-occurrence network generated using VOSviewer. Using all keywords as the unit of analysis, and after removal of irrelevant terms, 100 keywords with at least 3 occurrences were included. The most frequent keywords were “efficacy” (n=63), “therapy” (n=61), and “adherence” (n=61; Multimedia Appendix 2). In Figure 7A, “adherence,” “HIV,” “regimen simplification,” “type 2 diabetes,” and “fixed-dose combination” are located in connected parts of the network and have multiple links with other keywords. Figure 7B shows the density visualization of keyword co-occurrence. Areas of higher density are visible around “adherence,” “HIV,” and “regimen simplification,” with additional dense areas around “type 2 diabetes” and “fixed-dose combination.”

Figure 7. (A) Keyword co-occurrence network and (B) density visualization of keyword co-occurrence.

Keyword Cluster Analysis

Figure 8A shows the keyword clustering network generated by CiteSpace. Using the log-likelihood ratio algorithm, 11 clusters were identified. The network had a modularity *Q* of 0.576 and silhouette score of 0.831. The labeled clusters were calcium channel blocker (cluster 0), antiretroviral therapy (cluster 1), type 2 diabetes (cluster 2), medication regimen complexity (cluster 3), intervention (cluster 4), intraocular pressure (cluster 5), 2-drug regimen (cluster 6), heart failure (cluster 7), mortality (cluster 8), simplification (cluster 9), and acne vulgaris (cluster 10).

Figure 8. (A) Keyword clustering map and (B) thematic evolution of keywords (2005 - 2025).

Thematic Evolution

Figure 8B shows the thematic evolution of keywords across 3 periods: 2005 to 2016, 2017 to 2021, and 2022 to 2025. From 2005 to 2016, the main keywords included “hypertension,” “adherence,” “toxicity,” “fixed-dose combination,” “antiretroviral therapy,” “nevirapine,” “medication adherence,” “polypharmacy,” “treatment,” and “safety.” From 2017 to 2021, the main keywords included “HIV,” “adherence,” “medication adherence,” “safety,” “pharmacokinetics,” “type 2 diabetes,” “hypertension,” and “long-term care.” From 2022 to 2025, the main keywords included “HIV,” “meta-analysis,” “bictegravir,” “type 2 diabetes,” “adherence,” “medication adherence,” “glucagon-like peptide-1 receptor agonists,” and “asthma.” Links between periods are shown for several keywords, including “adherence,” “medication adherence,” “HIV,” “type 2 diabetes,” and “safety.”

Discussion

Principal Findings

This study provides a bibliometric overview of research on medication regimen simplification from 2005 to 2025. The findings show increasing publication output over time, with research activity concentrated in a limited number of countries, institutions, and author groups, whereas the intellectual structure and evolving keyword patterns indicate a field centered on regimen simplification, adherence, and disease-specific applications.

At the country level, research on medication regimen simplification was dominated by a limited number of contributors. The United States ranked first in both publication output and total citations, possibly reflecting not only the size of its research community and funding environment [31,32] but also broader factors that influence bibliometric visibility, including English-language publication and database coverage. At the institutional level, Monash University and the University

XSL•FO
RenderX

of Sydney were among the leading contributors, and 50% (5/10) of the most productive institutions were from Australia. Monash University's prominent contribution may reflect both its sustained research on medication use, medication safety, healthy aging, and aged care [33] and the broader Australian policy and practice focus on polypharmacy and medication management in older adults [34,35]. Notably, several productive institutions were hospitals, aged care providers, or industry-affiliated institutions, suggesting that medication regimen simplification is often closely linked to clinical practice and service delivery. This interpretation is supported by aged care simplification studies, including the Medication Regimen Simplification Guide for Residential Aged Care and related Australian care-based research [16,36], as well as by HIV simplification studies and treatment switch trials conducted by hospital-based and industry-affiliated teams [37,38]. Meanwhile, institution-level productivity may also be influenced by organizational structures, affiliation patterns, and database indexing practices and, therefore, should be interpreted with caution. At the collaboration level, collaboration patterns were similarly concentrated. International links were most evident between North America and Europe, with additional connections involving East Asia and Oceania, whereas institutional and author networks were organized into several clusters. This pattern suggests that the field has been shaped by a limited number of active research groups and broader cross-regional and cross-institutional collaboration may be needed to expand the evidence base across different health systems and care settings.

In this study, keyword burst analysis was used to identify terms receiving rapidly increasing attention over specific periods, whereas the interpretation of broader research hot spots was based on their consistency with cocitation structure, keyword clustering, and thematic evolution. A notable feature of medication regimen simplification is its extension across multiple disease areas and care settings. The complementary analyses suggest that medication regimen simplification has developed from an initially focused literature centered largely on antiretroviral therapy, fixed-dose combinations, and treatment-related toxicity into a broader area that also encompasses chronic disease management, long-term care, and medication regimen complexity. Within this broader development, HIV remained the most consistent research direction, with persistent signals from clusters related to "2-drug regimen," "NRTI-sparing regimens," and "single-tablet regimen," together with thematic evolution results including "antiretroviral therapy," "HIV," and "bictegravir." This continuity is likely related to the long-term nature of HIV treatment and the need to reduce regimen burden while maintaining adherence and efficacy [39,40]. Beyond HIV, the field has expanded into other long-term treatment settings, particularly diabetes and cardiovascular disease [41-43], with increasing attention to "type 2 diabetes," "heart failure," "blood pressure control," "basal insulin," and "glucagon-like peptide-1 receptor agonists." However, this expansion remains uneven across disease areas. HIV, diabetes, and selected cardiovascular topics were more prominently represented in the keyword and clustering analyses, whereas depression and Alzheimer disease were present in the keywords but did not form independent clusters or clearly defined thematic pathways. It may reflect variation in dominant research priorities across disease areas, with some fields historically placing greater emphasis on efficacy or survival-oriented outcomes rather than focusing on adherence or simplification [44,45]. It may also reflect the greater difficulty evaluating regimen simplification in mental health disorders and neurodegenerative diseases, where treatment and medication management are often individualized and shaped by cognitive impairment and caregiving involvement [46,47]. Further research should examine regimen simplification more explicitly in mental health, cognitive impairment, and multi-morbidity to clarify the indications, implementation, and long-term outcomes.

A central challenge in this field is no longer whether medication regimen simplification is feasible in principle but whether it can be implemented and sustained in routine care. Existing studies have focused mainly on populations with long-term medication use and high treatment burden, particularly older adults, people receiving community care, and those in long-term care settings [23,48,49]. In these populations, implementation depends not only on the regimen itself but also on cognitive and functional status, caregiver involvement, and the level of existing medication support [8,23,50]. Furthermore, simplification may also remain a clinical and pharmaceutical balancing process. Its real-world application requires consideration of effectiveness, safety, adherence, dosage form, dosing frequency, drug interactions, and pharmacokinetic constraints [8,13]. In this sense, regimen simplification is better understood as part of comprehensive medication management than as a simple act of discontinuing or switching treatment. Additionally, system-level factors may further shape implementation. In routine practice, medication simplification strategies may be limited by unclear workflows, insufficient multidisciplinary collaboration, and poor integration into everyday care processes [51,52]. These barriers may be more prominent in long-term care and community settings, where decision-making often depends on coordination among physicians, pharmacists, nurses, and caregivers [8]. These findings suggest that the future development of this field may depend not only on identifying effective simplification strategies but also on understanding how they can be embedded, coordinated, and sustained across real-world care settings.

The wider implementation of medication regimen simplification is likely to depend on policy and system conditions that support its integration into routine care. Reimbursement and reporting requirements may facilitate this process by providing institutional support for service delivery. For example, in the United States, Medicare Part D requires sponsors to establish medication therapy management programs and incorporate them into plan benefit structures and annual reporting requirements [53]. Quality measurement is another key element to routine implementation [54]. Although existing medication-related indicators can support accountability for medication use and safety [55,56], they seldom capture whether regimens have become simpler, whether simplification recommendations have been implemented, or whether treatment burden has been reduced. Therefore, more targeted indicators of regimen complexity, implementation, and treatment burden may be

XSL•FO
RenderX

needed. Furthermore, implementation is also likely to depend on clearer professional roles and better workflow integration. In real-world practice, simplification is rarely a single prescription event but, rather, an ongoing process of assessment, decision-making, implementation, and follow-up. Clearer role allocation across physicians, pharmacists, and nurses may improve implementation [8,23,52]. In this context, the formalization of pharmacist prescribing pathways in Australia may support a more structured role for pharmacists in simplification-related care [57]. Additionally, digital support should be considered within the same implementation framework. Its value is likely to depend less on stand-alone tools than on the integration of complexity assessment, simplification prompts, and follow-up monitoring into existing workflows. Previous studies suggest that electronic decision support is more likely to be scalable when combined with routine structured medication review in long-term care [58,59]. Therefore, a more feasible approach may be to embed simplification-related functions within established care processes, including electronic health records, postdischarge medication reconciliation, and medication review in long-term care and chronic disease follow-up. Beyond reviews that focus on prescribing decisions or regimen optimization in specific patient groups [60,61], this study highlights a broader implementation-oriented perspective by linking bibliometric patterns to policy conditions for routine care.

Limitations

Several limitations should be considered when interpreting the findings. First, this analysis was restricted to English-language publications indexed in the WoSCC. Therefore, relevant studies from other databases or in other languages may not have been captured, which could affect the completeness of the research landscape reported. Second, because medication regimen simplification is not a standardized indexing term, the search strategy relied on free-text terms and an operational definition, which may have resulted in the exclusion of conceptually relevant studies using different terminology. Third, bibliometric indicators describe patterns of publication, citation, and thematic structure, and recently published articles may have been underestimated because of citation lag. In addition, despite software-assisted standardization and manual checking, residual errors in author and institutional name disambiguation may have remained. Such errors can be reduced but are difficult to eliminate completely in bibliometric datasets, particularly for common surnames and institutions with multiple name variants, which could have affected the identification of prolific authors or institutions and the collaboration network analysis.

Conclusions

This bibliometric analysis indicates a clear increase in publications on medication regimen simplification over the past 2 decades, particularly in recent years. Quantitative mapping further indicated that the literature has concentrated mainly on HIV, diabetes, and cardiovascular-related management, whereas some areas such as mental health and cognitive disorders remain comparatively underrepresented. Overall, the field is expanding, but its thematic development is still uneven. Future studies should further clarify the definition and scope of medication regimen simplification, pay more attention to underexplored diseases and care settings, and strengthen the evidence on implementation and patient-relevant outcomes. Cross-national and cross-system research will also be important for developing quality indicators, implementation pathways, and policy frameworks to support the wider use of medication regimen simplification in real-world practice.

Abstract

Background: Timely medical follow-up after a diagnosis of cognitive impairment, such as mild cognitive impairment (MCI) or dementia, is imperative for initiating appropriate medical treatment and accessing comprehensive care management and psychosocial support. However, many community-dwelling older adults who receive a positive case-finding result default on their medical follow-up appointments. This persistent challenge undermines early detection and active case-finding efforts and increases the risk of early institutionalization. Understanding the determinants is important for developing effective interventions in community-based case-finding.

Objective: This qualitative study aimed to explore the barriers and facilitators influencing medical help–seeking behavior among community-dwelling individuals in Singapore diagnosed with MCI or dementia following a positive case-finding result. The COM-B (capability, opportunity, motivation-behavior) framework of the Behavior Change Wheel (BCW) was used to systematically identify these determinants.

Methods: Using maximum variation sampling based on age, gender, ethnicity, living arrangement, relationship with caregiver, prior memory concerns, and whether participants had sought medical follow-up after their cognitive impairment diagnosis, we conducted 21 unique household semistructured interviews with 26 individuals (comprising 5 participant-caregiver dyads of MCI, 6 participants diagnosed with MCI, 1 caregiver of a participant with MCI, and 9 caregivers of participants diagnosed with dementia). These participants were a subset of individuals and caregivers recruited from a community-based study validating an artificial intelligence (AI)–based dementia case-finding tool. Interviews were audio-recorded, transcribed verbatim, and analyzed using the framework analysis method. Two authors (SRL and XX) performed inductive coding before mapping to COM-B, with subsequent discussion and review by the remaining authors. The COM-B components informed the selection of the relevant intervention functions from the BCW.

Results: Barriers to medical help–seeking behavior after cognitive impairment diagnosis included physical impairments, low health literacy to navigate the health care processes, inaccurate disease knowledge, complicated health care processes, inadequate physical infrastructure to navigate health care organizations, oversimplified cultural representation of dementia, perceived inaccuracy of the case-finding tool, and lay beliefs about seeking medical care when sick. Facilitators included adopting strategies to track medical appointments, a case-finding result letter as a cue for action, caregivers with profamily workplace policies, and valuing proactive medical disease management. Notably, social capital, (in)ability to recognize symptoms, and strong affective states triggered by the case-finding results were both barriers and enablers.

Conclusions: These findings highlight a complex interplay of individual, social, and structural determinants influencing medical help–seeking behavior following a cognitive impairment diagnosis. Rather than a linear trajectory, medical help–seeking is shaped by a dynamic interplay across the COM-B domains. Drawing on these findings, we developed a set of comprehensive and actionable recommendations grounded in the BCW intervention functions to support timely medical follow-up after a cognitive impairment diagnosis. To maximize their impact, these recommendations should be collaboratively refined and evaluated with stakeholders using the acceptability, practicability, effectiveness, affordability, side effects, and equity (APEASE) criteria.

Introduction

Background

The global prevalence of dementia is projected to increase substantially, from 57.4 million cases in 2019 to 152.8 million in 2050, primarily due to population growth and an aging population, with a greater proportion of cases occurring among women than men [1]. International bodies such as Alzheimer's Disease International [2] and the International Association of Gerontology and Geriatrics [3] have advocated for active case-finding of dementia among high-risk older adults. This involves extending beyond tertiary hospitals to proactively identify high-risk individuals through routine annual cognitive evaluations in community-dwelling older adults [3]. However, the potential benefits of these cognitive evaluations in the community are diminished when individuals do not pursue timely medical follow-up after receiving a positive case-finding result for cognitive impairment (ie, mild cognitive impairment [MCI] or dementia). Timely medical follow-up is essential, not only for initiating appropriate medical treatments (eg, cognitive enhancers), but also for accessing comprehensive care management (eg, behavioral, financial, legal, and end-of-life issues), and social support (eg, support for caregivers) [4]. Delayed follow-up can have far-reaching consequences, including compromised well-being [5,6] and increased risk of early institutionalization in long-term care facilities [7-9].

Despite these risks, little is known about the frequency of actual medical help–seeking following a diagnosis of cognitive impairment. A large national survey conducted in China between 2015 and 2018 revealed that 71.4% (1974/2766) of individuals with dementia and 97.2% (6926/7125) of individuals with MCI did not seek medical treatment [10]. In Singapore, unpublished data from a pilot case-finding study [11] by the corresponding author (TML) as part of a larger implementation project to train and implement PENSIEVE-AI, an artificial intelligence (AI) tool for early cognitive impairment detection in the community, further illustrate this challenge. Among community-dwelling older adults diagnosed with cognitive impairment and referred directly to the Singapore General Hospital (SGH) memory clinics, 20.8% (10/48) defaulted on their appointments. Of these individuals, 8 were diagnosed with MCI and 2 with dementia. These missed follow-ups occurred despite deliberate efforts to facilitate medical follow-up, including direct referrals to SGH memory clinics for individuals living near SGH, text message appointment reminders, and proactive coordination by a clinic case manager before follow-up appointments. Although these data were derived from a single, relatively well-resourced acute tertiary hospital in Singapore, they likely underestimate the extent of the default follow-up rates in the broader population. Together, these findings highlight a persistent and multifaceted challenge of timely medical follow-up after receiving a diagnosis of cognitive impairment. Addressing this gap requires a better understanding of the determinants of medical help–seeking behavior in this context.

Existing Evidence on Medical Help–Seeking Determinants

A systematic review [12] identified 5 key illness perception factors associated with delayed help-seeking among individuals with dementia and their caregivers, including cultural beliefs of caregiving duties, acceptance of diagnosis, lack of knowledge about dementia, complex health care systems (including both the positive and negative experiences from prior health care professionals and services), and perceived threat to personal independence. However, the review focused on help-seeking intentions rather than actual help-seeking behaviors. This distinction is important due to the well-established intention-action or intention-behavior gap in health behaviors [13-15]. For clarity, throughout this paper, help-seeking without the qualifier medical refers to both formal (ie, health care professionals) and informal (ie, family and friends) sources of help-seeking support. In contrast, medical help–seeking behavior refers specifically to the actual actions taken to seek and obtain care from formal health care providers, such as neurologists, psychiatrists, or general practitioners.

Building on this, a recent qualitative study [16] extended medical help–seeking intentions in individuals with dementia and identified 8 key determinants of medical help–seeking behavior among individuals with MCI. These determinants can be conceptually clustered into 3 broad categories, including psychological processes, comprising disease knowledge, perceived disease threat, symptom attribution, negative valence emotions, and reliance on cognitive strategies; socioeconomic and structural conditions, that is, financial stability and accessible health care services; and social support. However, participants in this study were recruited from a memory clinic and were already on medical follow-up. As such, the determinants influencing individuals with MCI who did not seek medical help remain underexplored, leaving an important unaddressed gap in the context of medical help–seeking following positive case-finding in the community.

Study Aim

To address these methodological and practical knowledge gaps, this qualitative study aims to explore the barriers and facilitators influencing medical help–seeking behavior among individuals diagnosed with MCI or dementia following positive community-based case-finding results in Singapore. Specifically, what are the barriers and facilitators to medical help–seeking behavior among community-dwelling individuals diagnosed with cognitive impairment following a positive case-finding result? This study forms part of a larger implementation effort involving the deployment of PENSIEVE-AI but is methodologically independent from the PENSIEVE-AI tool development study [11]. In other words, although the

XSL•FO
RenderX

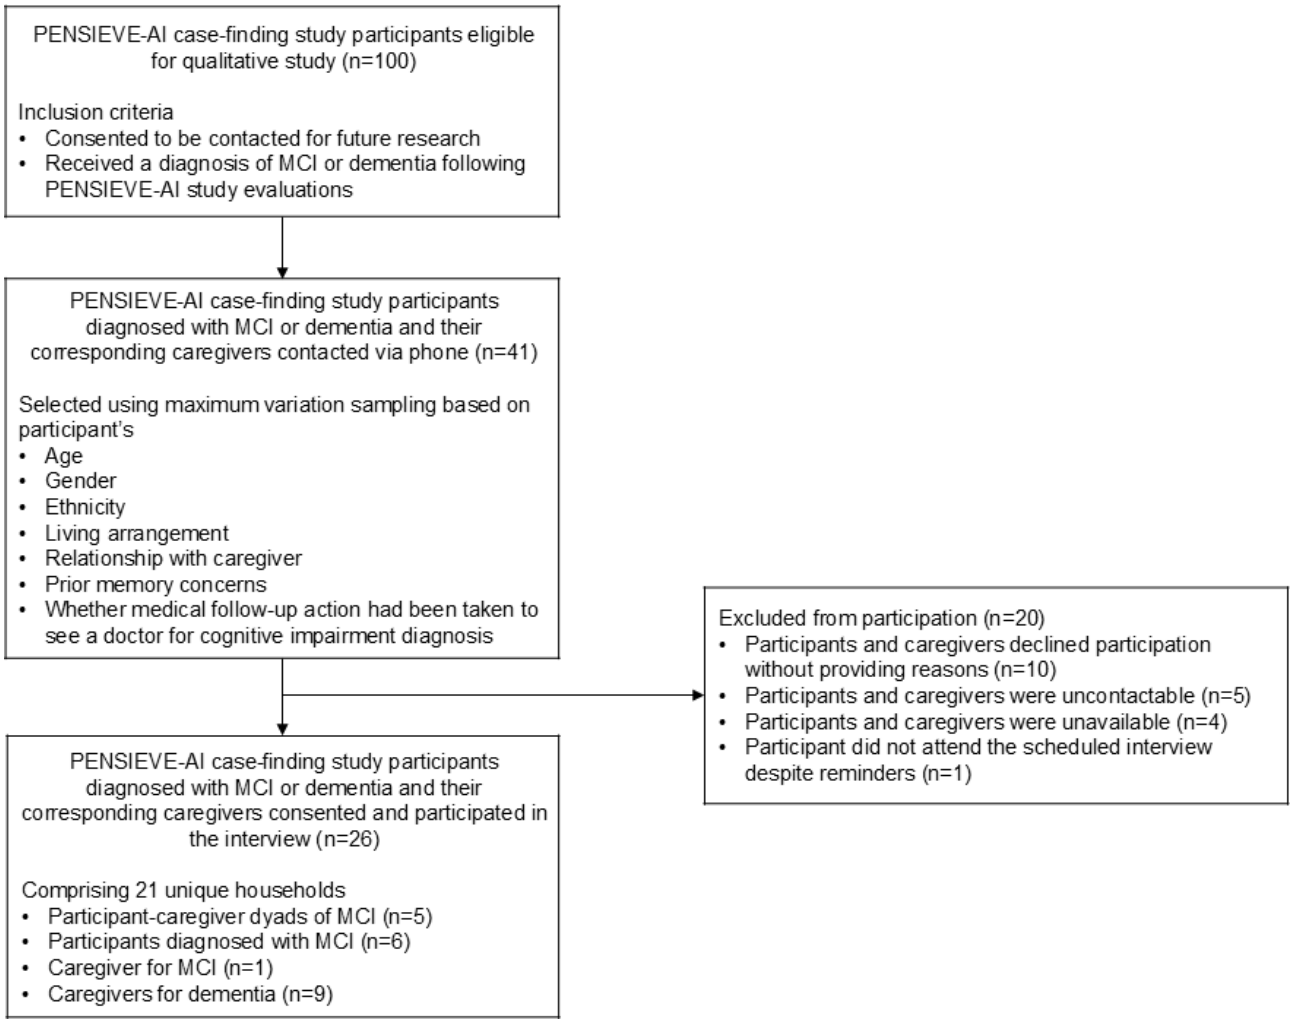
participants in this qualitative study were recruited from the PENSIEVE-AI pilot study [11], this study focuses specifically on exploring the determinants of medical help–seeking after MCI or dementia diagnosis. Given the complex, multifactorial nature of medical help–seeking behavior, a theory-informed approach was adopted to guide data collection and analysis. This approach enables the systematic identification of key determinants grounded in an established theoretical framework to inform the future development of targeted interventions and implementation strategies to improve medical help–seeking follow-up [17].

Theoretical Framework

This study applies the capability, opportunity, motivation-behavior (COM-B) framework [18,19], a widely used systematic framework for understanding behavior, designing targeted interventions, and achieving health behavior change across diverse settings, including dementia screening [20]. Within this framework, capability refers to the physical and psychological ability to perform the behavior; opportunity pertains to the physical and social environments; and motivation encompasses both automatic processes, such as emotions and impulses, and reflective processes, such as evaluation and plans [18,19]. Its utility lies not only in identifying behavioral determinants but also in linking the COM-B diagnosis with the 9 intervention functions that encircle the COM-B framework of the behavior change wheel (BCW): education, persuasion, enablement, incentivization, coercion, training, restrictions, environmental restructuring, and modeling [18,19,21]. This allows for the systematic development of tailored strategies specific to the behavioral determinants [18,19].

Methods

Study Setting



This study arose from a recent pilot case-finding study in Singapore that screened approximately 1800 community-dwelling older adults for early cognitive impairment using the PENSIEVE-AI tool [11]. Multimedia Appendix 1 outlines the steps of the PENSIEVE-AI case-finding pilot study. Community-dwelling older adults were recruited and underwent comprehensive cognitive assessments. Assessments of MCI, dementia, or normal cognition were made by 3 dementia specialists using an internationally recognized gold-standard consensus approach based on all the information from the comprehensive assessment. Community-dwelling older adults living in the SGH catchment area with positive case-finding results for MCI or dementia received direct medical appointments for follow-up at SGH memory clinics, whereas those living outside the SGH catchment area were strongly advised to seek medical attention from primary care doctors for referral to memory clinics within their home vicinity.

Study Design and Participant Selection

Forty-one eligible PENSIEVE-AI participants diagnosed with MCI or dementia and their corresponding caregivers from the pilot case-finding study [11] were contacted for the semistructured interviews over the phone. Participants who declined to participate did not preclude their caregivers from participating in the study. Interviewees were selected using maximum variation sampling to capture diverse experiences of medical help–seeking following positive case-finding. Sampling variation was based on participants' age, gender, ethnicity, living arrangement, relationship with caregiver, prior memory concerns, and whether participants had sought medical follow-up after their PENSIEVE cognitive impairment diagnosis. These characteristics were selected because they are expected to influence the cognitive impairment appraisal, access to formal and informal support for medical help–seeking, and caregiver involvement in decision-making regarding medical help–seeking. Figure 1 details the recruitment and selection process.

XSL•FO
RenderX

Figure 1. Qualitative study recruitment and selection flowchart for participants and caregivers. MCI: mild cognitive impairment.

For participants diagnosed with dementia, only their caregivers were interviewed due to practical considerations such as impaired decision-making capacity, reliance on interviewer's skill for consistent self-reports, and risk of distress during lengthy interviews. For participants diagnosed with MCI, interviews were conducted with participants alone, with participants and caregivers together, or with caregivers only, depending on participant preferences. This strategy aimed to improve interview participation rates. Interviews were conducted in either English or Mandarin Chinese. All interviews were audio recorded, anonymized, transcribed verbatim, and verified by another author (SRL or XX). Mandarin Chinese interviews were transcribed verbatim in the source language, coded in English, and only the extracts were translated into English by SRL and verified by XX. All authors are bilingual and proficient in English and Mandarin. All interviews were conducted by SRL, with XX accompanying one interview when a male participant was home alone. Interviews continued until data saturation was reached. An interview guide based on COM-B [18] was developed and used for the semistructured interviews (Multimedia Appendix 2). The COREQ (Consolidated Criteria for Reporting Qualitative Research) checklist was used as a guide for reporting our study [22]. Informed consent was taken at the start of the interview.

Data Analysis

The data were analyzed using framework analysis [23] involving the following steps: (1) familiarizing with the interviews and transcripts; (2) independent inductive coding of the transcripts (ie, open coding) using Microsoft Word's comments function and the coding macro [24] to export the codes and the associated text to Microsoft Excel; (3) grouping codes into defined facilitator and barrier categories; (4) indexing the transcripts according to the existing codes and categories; (5) charting the categories into the COM-B matrix, including quotation references; and (6) performing data interpretation.

The identified COM-B components were used to guide the selection of relevant intervention functions from the BCW. The coding, indexing, charting, and selection were performed by SRL and XX, who have respective backgrounds in psychology and sociology. The categories were developed together through discussion with TML, who has expertise in geriatric psychiatry and public health, and subsequently reviewed by the remaining authors with expertise in geriatric medicine, medicine, health services research, and public health. Disagreements in the categorization of barriers and facilitators, mapping to COM-B components, and selection of intervention functions were resolved through discussion. We maintained an audit trail of coding comments, categorization and selection decisions, and engaged in reflexive discussions throughout the analysis.

XSL•FO

Ethical Consideration

This study was approved by the SingHealth Centralized Institutional Review Board (reference number 2021/2590). Informed consent procedures for participants with cognitive impairment included a simplified capacity assessment in accordance with the Mental Capacity Act. Participants were required to demonstrate their ability to understand, retain, and use the study information to make an informed decision, and to communicate their decision to participate by paraphrasing key information, including the voluntary nature of participation and the right to withdraw at any time. The interviewer remained attentive to verbal and nonverbal cues of distress and paused interviews when necessary to ensure participants' and caregivers' well-being and to accommodate caregiving responsibilities. Participants and caregivers were reminded that they could terminate the interview at any time, and breaks were offered when needed. Data were kept confidential, with access restricted to the study team. Interview data were anonymized during transcription, with identifiable information removed and pseudonyms assigned where appropriate. Participants received Singapore $40 (US $1=1.26 Singapore Dollars) as a token of appreciation.

Results

Overview

Between May 2023 and January 2024, 26 individuals were interviewed across 21 unique households, comprising 12 households with a family member diagnosed with MCI and 9 households with a family member diagnosed with dementia. The mean interview duration was 53 minutes, ranging from 25 to 71 minutes. Of the 21 household interviews, 17 were conducted in person, and 4 by telephone. The median age group for participants with MCI was 70 - 79 years, while the median age group for the interviewed caregivers was 60 - 69 years. Most interviewees were Chinese, living with family members in a 4 - 5 room public housing apartment. Notably, 23.8% of households did not take further medical follow-up action after the positive findings from the pilot case-finding program, with 25.0% for MCI households and 22.2% for dementia households. Detailed sociodemographic characteristics of the interviewees are presented in Table 1. Five interviews were conducted in Mandarin Chinese.

[e]Denotes participants with dementia who were not interviewed.

Based on the in-depth interviews, we identified 15 determinants encompassing both facilitators and barriers of medical help–seeking behavior. These determinants were mapped onto the COM-B domains. Detailed descriptions of each determinant, along with illustrative verbatim quotes, are detailed in the sections below. Figure 2 provides an overview of these determinants as mapped onto the COM-B domains and subdomains.

Figure 2. Determinants of medical help–seeking behavior following mild cognitive impairment (MCI) or dementia diagnosis, mapped onto the capability, opportunity, motivation-behavior (COM-B) domains and subdomains. Blue-colored boxes indicate barriers; green-colored boxes indicate facilitators; and purple-colored boxes indicate determinants that are both barriers and facilitators. COM-B: capability, opportunity, motivation-behavior; MCI: mild cognitive impairment.

XSL•FO
RenderX

Capability

Physical Impairments Can Hinder Medical Follow-Up

Two types of physical impairment were identified as barriers to timely medical follow-up after cognitive impairment case-finding results. First, mobility limitations necessitated reliance on caregivers for transportation, making the decision to attend medical follow-up appointments not solely the participant's, but also contingent on the availability of social support (Extract 1).

Extract 1

> *… she can't walk very well … so most of the time my husband … will drive her. So I have to also cater to my [husband's availability too]- sometimes my husband cannot make it.* [Caregiver 8 of participant with dementia]

Second, speech and hand impairments, particularly among stroke survivors, can impede participants' ability to independently manage appointment scheduling by phone or text messages (Extract 2).

Extract 2

> *Speaking to a person sometime[s] may have a problem … (In dialect) one duck one chicken … you communicate they can't get you. Sometimes over the phone … either I cannot … Because I have (sic) stroke … now I still can talk la but the slur is still there … [When typing on the phone,] it goes to the next alpha numeral … [as] I can't type with this [disabled] hand …* [Participant 5 with MCI]

Adopting Strategies to Track Medical Appointments

A notable facilitator of psychological capability was the adoption of practical strategies to track medical appointments. To mitigate forgetfulness and minimize missed medical appointments, participants and caregivers used resourceful strategies, such as diligently recording appointment dates on physical or digital calendars (Extracts 3 and 4) and prominently displaying appointment letters in a conspicuous part of their living spaces.

Extract 3

> *… when [I have an] appointment … I must note it immediately [on the physical calendar]. If I delay, I will tend to forget …* [Participant 1 with MCI]

Extract 4

> *… when I have the [doctor's] appointment … I surely will keep it up … I will put it down [in my phone calendar] …* [Participant 2 with MCI]

Low Health Literacy to Navigate the Health Care Processes

Low health literacy, defined as the limitation in the degree to which individuals have the ability to find, understand, and use information and services to make informed health-related decisions and actions for themselves or others [25], posed a barrier to timely follow-up after case-finding of cognitive impairment. Participants and caregivers, who lacked the familiarity with, and necessary skills to navigate, the health care processes (eg, rescheduling medical appointments to follow up on cognitive impairment case-finding results) had to rely on family members living elsewhere for assistance, thereby causing further delays or defaults on their medical appointments (Extract 5).

Extract 5

> *No, I don't know [we can bring forward medical appointments]. My appointments also I don't know. My sister [who does not live with me] will do [it] for me … when she comes [by to visit us] in the evening.* [Caregiver 9 of participant with dementia]

Inaccurate Knowledge About MCI and Dementia

Three types of inaccurate knowledge about cognitive impairment were identified: (1) misperceiving symptoms as normal aging, (2) misinterpreting cognitive function improvement, and (3) misunderstanding disease progression. First, participants and caregivers' understanding of MCI and dementia was primarily based on traditional lay beliefs rather than scientific knowledge, rooted in the common misperception that the symptoms of MCI and early dementia were a normal part of aging rather than a medical condition (Extract 6). As a result, these symptoms were not considered sufficient to warrant medical attention.

Extract 6

> *Caregiver: He just said he's 85 [years old], he's just forgetful …*
>
> *Participant: I feel that I'm just being forgetful only [due to my age]* [Caregiver 7 and participant 7 with MCI]

Second, participants and their caregivers described perceived subjective improvement in participants' cognition following treatment for other health conditions, which contributed to delays or defaults in seeking medical follow-up on case-finding results (Extract 7).

Extract 7

> *It is nothing unusual for him [to have MCI] as he's over 70 years already … you will definitely have it (MCI) when you are old … it is just a matter of degree … there is no need to see a doctor for it … because he's receiving regular vitamin [B12] injection at the polyclinic, I feel that his recent memory is better, more stable … there's [an] improvement [in his memory].* [Caregiver 10 of participant with MCI]

The third inaccuracy in the lay understanding of cognitive impairment arises from a life course perspective of the disease trajectory. While participants and their caregivers recognized the value of medical care to delay disease progression, they did not anticipate the cognitive impairment progressing to the disabling state of severe dementia within the participants' remaining lifetime. They anticipated other health issues to take precedence, diminishing the perceived benefit in seeking medical treatment for cognitive impairment (Extract 8).

Extract 8

XSL•FO
RenderX

> *… so after all, she's 83. You don't know, maybe before she reached that [advanced] stage [of dementia], she has (sic) some [other] diseases.* [Caregiver 16 of participant with dementia]

(In)ability to Recognize Symptoms of MCI and Dementia

The ability to recognize the signs and symptoms of MCI and early dementia as abnormal was a key facilitator in legitimizing the need to prompt participants to seek further medical attention (Extract 9).

Extract 9

> […. I left the stove on and I went out … I may lock the door, but I will leave my key … at the gate … there were a number of times I did that … Then the other thing … was that I am not certain how to pronounce this word … I don't think it is normal. That was the trigger to seek medical attention for MCI … that was my motivation.] [Participant 1 with MCI]

Caregivers who recognized these signs used the positive case-finding result to confirm their suspicions and used the diagnosis to encourage resistant family members who disagreed about the nature of their symptoms to pursue medical follow-up. However, denial remained a barrier despite these efforts (Extract 10).

Extract 10

> *… [the PENSIEVE-AI tool result] was expected … it's just to confirm the diagnosis and then at the same time hopefully can make her wake up and acknowledge that she has this issue. But she is still in denial. Up to today she still says … it's normal aging … old folks around her age are like that so she doesn't think it's an issue.*- [Caregiver 16 of participant with dementia]

In other cases, both the participants and the caregivers failed to recognize the symptoms of cognitive impairment and dismissed them, leading to inaction, which constitutes a major barrier (Extract 11).

Extract 11

> *… there's no signs like he's getting worse off or he's getting bad … he also thinks that it's nothing wrong … it's basically more like probably because he's not occupied …* [Caregiver 6 of participant with MCI]

Opportunities

Complicated Health Care Processes

Three barriers within the health care processes impeded timely medical follow-up on cognitive impairment case-finding results. The first was variability in the referral process. Participants living near SGH received direct appointments arranged by a hospital coordinator to follow up on the case-finding results with a specialist at the SGH memory clinic (Extract 12).

Extract 12

> *This was an appointment [date] given by [the hospital]. [If the hospital did not provide an appointment date], we will not go [to see the doctor]. We will wait for the doctor, [the doctor] can message me if they have something to tell me.* [Caregiver 3 of participant with MCI]

In contrast, those living further away were advised to obtain a referral from a primary care doctor to see a memory clinic specialist by themselves. This process introduced at least 2 potential risks for appointment delays and defaults: oversight by the participants, their caregivers, or both due to other commitments (Extract 13), and potential dismissal of the referral letter by primary care doctors (Extract 14).

Extract 13

> *… I [am] also forgetful … even though I went to the polyclinic with her [recently for urine infection], I forgot to ask the doctor for a referral [to see a specialist for dementia].* [Caregiver 8 of participant with dementia]

Extract 14

> *But because the doctor is the one that told him there is no need to come … so he never see[s] that doctor again …* [Caregiver 6 of participant with MCI]

The second barrier was the perceived high cost of laboratory investigations (eg, blood tests, brain imaging; Extract 15) that deterred medical follow-up.

Extract 15

> *The issue … [for] her is [the brain imaging scan is] going to cost me a lot of money.* [Caregiver 3 of participant with MCI]

Some participants and their caregivers were reluctant to make out-of-pocket cash payments for further investigations, with some preferring to use funds from their MediSave accounts, Singapore's national medical savings scheme. The MediSave annual Singapore $300 (US $236) withdrawal limit for outpatient diagnostic and treatment imaging per person influenced decisions to medical follow-up, depending on the availability of sufficient funds in their MediSave accounts for some of these individuals (Extract 16).

Extract 16

> *As long as not using hard cash it's okay, I don't think she minds [going for a scan] if [the hospital is] able to deduct the medical expenses from the C[entral]P[rovident]F[und] MediSave … so if we can postpone her scan till the next year so that she can pay via her MediSave as currently for this year her MediSave is almost all used up.* [Caregiver 3 of participant with MCI]

The financial considerations indirectly reflected how socioeconomic constraints shaped participants' and caregivers' decisions and behaviors about medical follow-up. Finally, commonly known problems such as long waiting times for a specialist appointment, extended clinic waiting periods, and difficulty in rescheduling a specialist appointment were acutely felt by participants and caregivers (Extracts 17 and 18). Improving these processes would make follow-up appointments

XSL•FO
RenderX

for cognitive impairment less onerous and more manageable for participants and caregivers.

Extract 17

> *… The problem is I couldn't get for her [an appointment] … It is something [of a] nuisance right we have to call them and check every day … It's not so easy, that day I call[ed] so many times they pick[ed] up and then they say (sic) no, you have to call every day. Really, it's a very disturbing nuisance what. How can I call the hospital every day? You all put [her] on the waiting list and then it's better for you all that … you check your computer system and then you tell us [when there is an available slot].* [Caregiver 12 of participant with MCI]

Extract 18

> *… the appointment is as good as don't have appointment … Because we every time have to wait [for] very long … your appointment is at 2 o'clock but you're seeing the doctor at 4 plus 5. I think it's ridiculous cause sometimes I have to work, so I will [have] no choice try to bring my laptop with me and work in the hospital … All hospitals [are] the same, no matter where you go, you have to wait. Not just [the] hospital[s], [the] polyclinic[s] also have to wait [for a] very long [time].* [Caregiver 18 of participant with MCI]

Case-Finding Result Letter as a Cue for Action

In this study, all PENSIEVE-AI participants received a letter titled "Feedback on Research Participation," which conveyed their positive case-finding result (ie, MCI or dementia), informed them of upcoming follow-up appointments or provided instructions to arrange for a specialist appointment through a primary care doctor, and included lifestyle advice to mitigate further memory deterioration. This letter was intended to function as a physical cue, prompting participants and caregivers to take necessary follow-up actions based on the positive case-finding results. However, one caregiver reported not receiving the letter. Although this was an isolated case, it demonstrated the importance such letters can serve in prompting action or, conversely, how the absence of the result letter might contribute to inaction following a positive case-finding result. In another instance, a participant and caregiver mistakenly perceived the result letter solely as a referral letter intended for the polyclinic doctors, viewing their role as mere couriers responsible for delivering the letter to the polyclinic doctor without engaging with its content (Extract 19).

Extract 19

> *… they said must go to the poly[clinic], give this letter to the poly[clinic doctor] … I didn't actually read [this letter] properly … because I thought this is for [the] doctor, [so] I don't want to read, I thought it might be confidential, for [the] doctor only. Now you [are] talking [to me] then I opened up and read … [previously] I asked John to bring to the doctor la (sic). So the doctor already opened up the envelope so now I'm reading [it] to you …* [Caregiver 7 of participant with MCI (The name (John) has been replaced with a pseudonym.)]

This example illustrates that the letter's effectiveness as a cue to prompt medical help–seeking behavior depends on participants' and caregivers' engagement with its content. When unread, the result letter could lose its cue effect.

Inadequate Physical Infrastructure to Navigate Health Care Organizations

Caregivers reported that participants often avoided using escalators due to mobility concerns (Extract 20), necessitating planning routes to medical appointments that use elevators instead.

Extract 20

> *… initially, she was still okay with the escalator, stepping on the escalator that is going up. She was just afraid to step on the escalator that's coming down. But these days, she dares not step on anything that moves.* [Caregiver 21 of participant with dementia]

Elevators became essential in the commute, yet issues such as limited availability of elevators, lengthy wait times, and overcrowded elevators further hindered accessibility for participants and caregivers. For example, accessing elevators during peak travel hours when taking the train to medical appointments. These barriers, common to many older adults with mobility limitations, extend beyond cognitive impairment. Additional barriers include the lack of easily accessible ramps for wheelchairs and pushchairs, insufficient space for mobility devices on public transport, and poorly lit parking lots with unclear and difficult-to-find signage within health care facilities (Extract 21).

Extract 21

> *the roads … are not built … for easy access or handicapped people, don't talk about even dementia people, just handicapped (sic). You see a lot of these places they are steps instead of ramps and even the ramps are not built in such a way [that is] properly designed … For the purpose of wheelchair-bound people or people having difficulty in walking, even my wife have (sic) difficulty in getting down, up and down the escalator, she gets very scared … when you are a bit older, your reaction is different. Your mental reaction … and this moving escalator is very very difficult for older people … and to be very frank as a driver I find Singapore the road … signage is very bad … The [carpark] exit, their signage is so bad … the directional signs are so bad … the underground carpark, you don't know east, west, north, south … want to go to [the] medical centre, [there is] no sign.* [Caregiver 14 of participant with dementia]

Social Capital, Both an Enabler and a Barrier

Social capital, defined as the resources derived from a person's social relationships to enable a desired social action [26], functioned as both an enabler and a barrier to medical follow-up

XSL•FO
RenderX

after a cognitive impairment case-finding result. As an enabler, social capital provided direct instrumental support, such as booking or rescheduling follow-up appointments on participants' behalf (Extract 22), reminding participants of medical appointments (Extract 23), driving and accompanying them to their appointments, and providing financial aid for medical bills (Extract 24).

Extract 22

> *… my son is arranging [for his mum] to see the doctor …* [Caregiver 14 of participant with dementia]

Extract 23

> *Caregiver: I grumbled and nagged [at him to see the primary care doctor for his MCI referral letter to the specialist].*
>
> [Participant: I cannot stand it, the nagging. That's why I went eventually.] [Caregiver 7 and participant 7 with MCI]

Extract 24

> *(When asked about difficulty paying for further investigation of the case-finding of cognitive impairment result) my friend always says anytime if you need financial assistance let me know.* [Participant 5 with MCI]

Social capital also played an indirect role in facilitating timely medical follow-up among socially active participants. Social activity increased the likelihood that others with accurate knowledge about cognitive impairment would notice signs of cognitive decline and encourage medical follow-up (Extract 25).

Extract 25

> *… her friend called me … during the [Japan] trip [and informed] … that she didn't bath[e], and then personal hygiene is (sic) an issue, and then erm forgetfulness or something but then she said it's not normal … I think your mum got to get her [to go for a] check-up because she's behaving differently from before.* [Caregiver 16 of participant with dementia]

This external feedback can reinforce the positive case-finding results; together, they may be more persuasive in motivating participants and their caregivers to acknowledge cognitive decline and pursue medical follow-up. Additionally, active social engagement enables participants to vicariously experience dementia in others via witnessing the lived experiences of dementia by someone they know. This exposure may heighten their sense of personal susceptibility to the disease and the importance of early medical intervention to delay the disease progression (Extracts 26 and 27).

Extract 26

> *… my own sister in her 90s had advanced dementia. But hers was I think from … the age of 80 … my younger brother who was discovered after me, suddenly have (sic) the advanced dementia … and completely now couldn't talk … he can't recognize anybody, advanced dementia, yeah he can't control his bowel everything. Yeah so his was very fast within five years of discovering … So I don't want to follow the same route as them. In the sense that I'm aware, I can still take control of my life.* [Participant 1 with MCI]

Extract 27

> *I went to [stroke] rehab [and got to know a] man … [with] dementia … then I came to know [he was] a newspaper editor… wah very sad and pitiful when … [at] this age you have this problem … he's educated … his mind suddenly slow[ed] down … the impact [on] normal person I don't mind. But he's an editor you know, that means basically he's educated … so [you] never know, it may happen to me … the possibility [of me having dementia] is always there …* [Participant 5 of MCI]

However, social capital can be a double-edged sword. Despite its facilitative role, it may also act as a barrier. When individuals with inaccurate knowledge about cognitive impairment normalize participants' symptoms of cognitive decline as typical signs of aging (Extract 28), and when members of the participants' immediate social circle (eg, primary caregivers, noncaregiving family members, friends, neighbors) disagree on the severity of the case-finding results and the importance of seeking medical attention, such discord can lead to conflict and hinder timely medical follow-up (Extract 29).

Extract 28

> *I can't remember things and my close friend … said oh no la (sic) old age la (sic) people will get old you know, will forget, yeah, so nothing la (sic) …* [Participant 1 with MCI]

Extract 29

> *… a lot of [my] neighbours, they keep telling me your father has no memory loss, dementia. See, he still can recognize us. He can still remember us, but I guess it's because they didn't (sic) live with him. They didn't talk to him … if you look at him you will not think that he has dementia … So it's actually very different [for] a caretaker and a non-caretaker, their views will be very different … it's only when you live with them then you know that how difficult it is … [my brother who does not live with us,] it's just like the same as the outsiders. They will say that my dad is so well but it's only the outside, but inside?* [Caregiver 17 of participant with dementia]

Caregivers With Profamily Workplace Policies

Many participants required family members to accompany them to follow-up appointments, both for instrumental support with transportation to and from the hospital and to help communicate symptoms accurately to the doctors. As many of the caregivers were still working, having a profamily employer was found to be an important facilitator that enabled them to fulfill this caregiving commitment and responsibility (Extract 30).

Extract 30

XSL•FO
RenderX

> *Fortunately, my current company is quite understanding, so I just take half-day leave …* [Caregiver 17 of participant with dementia]

Oversimplified Cultural Representation of Dementia

Dementia was often portrayed in mass media as involving severe symptoms such as an inability to return home or failure to recognize family members. While such portrayals increased public awareness about the disease, they inadvertently promoted the false notion that dementia was absent unless these severe symptoms were present. This misunderstanding posed as a barrier for the participants and caregivers in recognizing the seriousness of the symptoms of MCI and early-stage dementia, as daily functioning was only minimally disrupted. As a result, participants' cognitive decline was not readily associated with dementia risk due to the mismatch with media representations. Rather than prompting timely medical help–seeking, the prevailing oversimplified cultural representation of dementia may have unintentionally justified the delays in medical follow-up (Extract 31).

Extract 31

> *… she say no la no la, I only old only la (sic) … everybody [who] get[s] old [will] get this kind of forgetfulness. See, I will never get this, not like this (referring to media portrayal of advanced dementia). So she denies.* [Caregiver 16 of participant with dementia]

Motivation

Strong Affective States Triggered by the Case-Finding Results

Participants and caregivers expressed feelings of fear, fright, hopelessness, and sadness upon learning about the case-finding results. For some, these affective states acted as catalysts for seeking medical follow-up, prompting proactive actions when sufficiently intense (Extracts 32 and 33).

Extract 32

> *… since COVID (sic) when I see my [cognitive] decline and my forgetfulness, that really frightens me … you (sic) seem so hopeless like there's no cure no nothing … I see my own decline during this COVID time and then seeing my sister's … sharp … [cognitive] decline … So that makes me worried uh scared you know … then sometimes the trouble is there is no one to point it out to you.* [Participant 1 with MCI]

Extract 33

> *Sad because I'm afraid that she can't remember me (caregiver was tearing) … I hope she won't reach that stage …* [Caregiver 8 of participant with dementia]

However, for others, these affects were more ephemeral and did not spur action toward seeking medical follow-up (Extract 34).

Extract 34

> *she was a bit moody for about one or two days then after that she's back to her old self in denial again … I think [the moodiness was due to] when she do (sic) the [case-finding of cognitive impairment] test then she realized a lot of things that she cannot remember, a lot of things she cannot recall …* [Caregiver 16 of participant with dementia]

Participants and caregivers used both emotions and moods to describe their feelings, often interchangeably, despite these being distinct constructs. Emotions, such as fear, are more concentrated, have specific sources, contain cognitive meaning, and are often short-lived, whereas moods, such as feeling bad, are relatively enduring, more diffuse, lower in intensity, lack specific sources, and have little cognitive meaning [27,28]. To capture participants' and caregivers' descriptions, we used the term affect as the generic psychological term that encompasses both emotions and moods [28].

Perceived Inaccuracy of the Case-Finding Tool

One rationale for not seeking medical attention following the positive case-finding results was rooted in the perception that the case-finding tool was biased, thus rendering the test result or diagnosis invalid. Although diagnoses in the pilot case-finding program were based on gold-standard practices (ie, consensus diagnosis by 3 specialists, including semistructured interviews, neuropsychological testing, and behavioral observations), the pilot program was embedded within a larger AI study with concurrent administration of a separate AI tool. This led to confusion among some participants and caregivers, who mistakenly assumed that the diagnosis was generated by an unvalidated AI tool still under development and testing, rather than the gold standard method for diagnosing cognitive impairment. As a result, trust in the legitimacy of the diagnosis was undermined and the need for medical follow-up was dismissed. Notwithstanding this confusion, it provided valuable insights into how perceptions of the case-finding process influence medical help–seeking behavior. Skepticism was particularly pronounced among participants with hand movement impairment due to stroke (Extract 35) and those with low technological literacy (Extract 36).

Extract 35

> *I can tell you I can easily fail [the case-finding of cognitive impairment test] … [as my mobility is] left [with] only the left hand … I think … I'm not able to pass … Because of my handicap [due to stroke] …* [Participant 5 with MCI]

Extract 36

> *She wasn't able to answer the questions because of the [case-finding tool] technology, she doesn't know how to use [the tool] … we don't know the [diagnostic] accuracy of the [case-finding] tool. But the brain scan is very accurate … which we haven't done.* [Caregiver 3 of participant with MCI]

In an extreme case, the case-finding process per se was perceived to be the direct cause of the MCI or dementia result (Extract 37).

XSL•FO
RenderX

Extract 37

> *I guess that she doesn't want to know her condition … she ever commented … the more you test, the more you see all this sickness, the better not to know that kind … Don't test, don't know, don't have.* [Caregiver 16 of participant with dementia]

Valuing Proactive Medical Disease Management

Several reasons were identified that facilitated timely medical follow-up after a positive case-finding result. These included the adage that prevention is better than cure, obtaining professional medical advice on disease management, and close monitoring of disease progression by a medical professional (Extract 38).

Extract 38

> *I don't see it as unnecessary [to see the doctor even though there is no treatment] … the specialists … at least [can] check … whether her condition deteriorates or improves or whatever … I don't see it as pointless because we're not doctors, we're not specialized, you (sic) don't even know how to evaluate the situation and her situation. So I think it would be good if the doctor in their professionalism they can actually advise her what is the condition, or at least we are prepared [for] what is going to happen. Rather than you just judge by yourself, you don't know whether it is right or wrong [and] make the wrong judgment.* [Caregiver 18 of participant with MCI]

Participants and caregivers also sought professional medical advice to support practical future planning and informed decision-making ahead of further disease deterioration. This included making a Lasting Power of Attorney to organize affairs and downsizing to a smaller apartment with dementia-friendly facilities to better accommodate the needs of the family member with dementia (Extract 39).

Extract 39

> *It is still [a] doubt or maybe [to hear from the doctor] mention by at what stage or what? … Simple things like … how? Should we downsize [our house or] relocate? And then [if we do] relocate, what kind of facilities should we look for to deal with the dementia patient? We have [a] general idea, but then we need something even more concrete [like concrete advice from the doctors] … and then which route to take or the best route to take, [what are the] possible route[s] to take. And then from there we will say, okay the route we could change later on but then at least how do we get started regarding the new route …* [Caregiver 14 of participant with dementia]

Lay Beliefs About Seeking Medical Care When Sick

The term "lay beliefs" is used here to refer to participants' and caregivers' understandings of when medical attention is needed. These beliefs may differ from clinical recommendations that promote timely and appropriate medical help–seeking for cognitive concerns. Rather than being uninformed or irrational, such beliefs are shaped by the personal, social, cultural, and economic contexts. Within this interpretive frame, several lay beliefs about medical help–seeking when sick were identified. Among participants who defaulted on their medical follow-up, there was a common belief that one should only visit the doctor when severely sick. Here, severe sickness is defined as a medical condition that markedly interferes with daily living and functional abilities (Extract 40).

Extract 40

> *For her current condition, I don't think there is a need for her to go for a brain scan … Because the doctor told me there is mild, moderate, and severe for this condition. To me, her mild condition isn't affecting her life much. But if I were to notice her condition worsens, then yes, even if have to pay cash for the [brain] scan we would go … How to differentiate mild, moderate, and severe … if for example … she went out via M[ass] R[apid] T[ransit] (train network) and can return home on her own, I think it's okay. But if she is unable to return home on her own, then I think it is problematic … and we must take action [to see the doctor].* [Caregiver 3 of participant with MCI]

Because MCI and early dementia often progress insidiously and may not noticeably disrupt daily living and functional abilities in the initial stages, some participants and caregivers perceived seeking medical attention for such conditions as unnecessary or even financially wasteful, particularly in the context of Singapore's high cost of living and the considerable out-of-pocket expenses associated with consulting a primary care doctor (Extract 41).

Extract 41

> *… I just wanted to bring her to the polyclinic for referral to [the] hospital but she is in denial … She says she doesn't [want treatment] … she's quite independent, quite stubborn, so I cannot force her to do anything … she said it's a waste of money [to see doctor] … in general. So she's kind of averse to seeing a doctor because nowadays seeing the G[eneral] P[ractitioner] is not cheap …* [Caregiver 16 of participant with dementia]

This belief was particularly salient among participants managing comorbid conditions (eg, cancer, cardiovascular diseases, and respiratory diseases), which were perceived as more severe, urgent, or life-threatening than cognitive impairment (Extracts 42 and 43).

Extract 42

> *… there is nothing worse than cancer … When people get sick, very sick or what, it's okay … What I mean is that when people die, people got cancer or what, take it easy lah. No need to worry [about the problems associated with MCI] …* [Participant 4 with MCI]

Extract 43

> *It's more of his asthma and his episodes of the asthma … it's more of his concern [than MCI] …* [Caregiver 6 of patient with MCI]

XSL•FO
RenderX

Among participants with comorbidities, disease prioritization was shaped by subjective interpretations of illness severity and financial considerations. Although these lay beliefs may diverge from clinical guidelines and recommendations advocating for early detection and intervention for cognitive impairment, they reflect a coherent lay understanding of disease severity, disease burden, and the health priorities, shaped by the lived experiences and concerns of both participants and caregivers.

Discussion

Principal Findings

This qualitative study identified 15 barriers and facilitators to medical help–seeking behavior following a diagnosis of MCI or dementia, categorized using the COM-B model. The discussion first contextualizes the findings within the existing literature, followed by integrated evidence- and practice-based recommendations.

Barriers

Our analyses on inaccurate knowledge about MCI and dementia, inability to recognize the symptoms of MCI and dementia, complicated health care processes, and low health literacy to navigate the health care processes aligned with commonly reported themes in the literature, including normalization of problems, lack of knowledge about dementia, and the complexity and inaccessibility of health care services [12,16,29,30]. Lay beliefs about seeking medical care when sick mirrored the finding of the review by Hill et al [30] on the perceived lack of benefit in medical help–seeking. Both reflect mismatches between clinical recommendations and the lay understandings that can undermine the perceived value of medical treatment, highlighting the need to increase public awareness of the benefits of timely medical intervention and care.

Strong affective states triggered by positive case-finding results were consistent with the findings of Jiao et al [16], who noted that individuals diagnosed with MCI perceived the disease as inherently threatening, characterized by negative valence emotions, such as anxiety and fear regarding disease progression. While Devoy and Simpson [29] identified fear as a barrier to medical help–seeking, our findings suggest a more nuanced, dual role, in which fear, conceptualized as a strong affective state triggered by the case-finding results, functions as both a facilitator and a barrier (eg, Extract 32). This duality reflects the multidimensional nature of fear, encompassing affective, cognitive, and psychobiological dimensions [31], with each influencing medical help–seeking behavior in different ways [32]. In the context of cancer screening, for instance, the cognitive and affective dimensions of fear facilitated cancer screening participation, while the psychobiological dimension hindered it [32].

A unique barrier identified in this study was the perceived inaccuracy of the case-finding tool. As participants were recruited from the larger case-finding pilot program using an AI tool, concerns about the tool's accuracy arose despite participants receiving diagnoses through the gold-standard consensus method. Future implementation of the PENSIEVE-AI tool [11] will need to explicitly address accuracy concerns and clarify the role of the AI tool in the cognitive impairment diagnosis process, particularly given that the consensus approach by memory specialists is not typical in routine clinical practice.

Medical help–seeking was further complicated by anosognosia in individuals with dementia and symptom fluctuation among individuals with MCI. Anosognosia, the lack of insight into one's own cognitive impairment, is a characteristic of dementia [33] that may contribute to denial and resistance to medical follow-up. This is evident in Extracts 10 and 41, where a caregiver described how her mother was in denial and misattributed cognitive symptoms to normal aging, features potentially indicative of the presenting symptoms of anosognosia. Similarly, among individuals with MCI, a clinically and neuropathologically heterogeneous group [34], the progression to dementia varies; while approximately 46% of individuals with MCI aged 65 years and older progress to dementia within 3 years [35], rising to 65% for those aged 75 years and older [36], others reported symptom improvement [37,38]. This symptom fluctuation makes early signs of cognitive impairment harder to recognize, contributing to uncertainty and delays in seeking medical help, as reflected in Extracts 7, 11, and 29.

Facilitators

Despite the identified barriers, several facilitators supported medical help–seeking behaviors. These included the ability to recognize cognitive impairment symptoms and the adoption of practical strategies to navigate symptom-related challenges, such as tracking medical appointments. Strong social capital, particularly reliance on caregivers and friends to reschedule medical appointments, provide transportation, and accompany individuals to medical appointments, facilitated medical follow-up behavior. Additionally, caregivers with profamily workplace policies and the case-finding result letter served as a physical cue to prompt medical follow-up action. For some individuals diagnosed with cognitive impairment, the strong affective states triggered by the case-finding results also prompted medical follow-up, particularly among those who valued proactive disease management through medical professional monitoring of disease progression. These facilitators align with the literature highlighting the importance of positive social support, disease knowledge, and the value of early detection in promoting medical help–seeking [16,29,30].

Our findings contrast with the paradoxical finding of Jiao et al [16] that individuals with MCI were less likely to seek medical help when using cognitive strategies. Our study found that individuals with MCI actively adopted strategies to track medical appointments, reflecting problem-solving efforts by the diagnosed individuals and their families to manage cognitive impairment symptoms. Notably, those with strong social capital and support networks were able to overcome some of the current barriers identified in this study, including physical impairments, low literacy to navigate health care processes, inadequate physical infrastructure, complicated health care processes, and lay beliefs about seeking medical care when sick. Facilitators unique to this study included caregivers with profamily workplace policies and the case-finding results letter as a cue

XSL•FO
RenderX

for action. The former strengthened social capital, while the latter is a distinctive finding in this qualitative study on determinants of medical help–seeking behavior following a cognitive impairment diagnosis via a community-based AI case-finding tool.

Integration With the Alzheimer Disease System Framework

Our findings extend the Alzheimer disease (AD) system framework of Ball et al [39] by specifying the barriers and facilitators influencing medical help–seeking behavior following a cognitive impairment diagnosis. These determinants can be situated within the AD system framework, between "health care system patient flow" and "access to support, care, and delivery," specifically following the "timely and accurate diagnosis" node [39]. Notably, current results demonstrate that the pathway from cognitive impairment case-finding or diagnosis to medical help–seeking is nonlinear. Instead, it is a process punctuated by interrelated determinants at multiple junctures, through a series of interactions between individual capacities and motivations, physical and social dynamics and opportunities, and broader structural conditions.

Although COM-B provides a systematic structure for identifying these determinants, several exhibit cross-domain interdependence. For instance, while physical impairments hindering medical follow-up are categorized under the physical capability subdomain, this barrier is closely linked to the social opportunity subdomain; many participants often relied on caregivers for transportation and company, a form of social capital that is both an enabler and a barrier. Such overlaps highlight the complexity and dynamic nature of medical help–seeking behavior following cognitive impairment case-finding results. Recognizing these interplays is essential for a nuanced understanding of medical help–seeking behavior and for designing interventions that address barriers within their broader systemic and contextual realities rather than in isolation.

Actionable Recommendations

In view of this complexity, we developed actionable recommendations by mapping BCW intervention functions onto our analytic findings. In addition to barriers, facilitators across the COM-B domains were integrated to bolster support for timely medical follow-up among individuals with cognitive impairment. Each determinant was mapped to one or more BCW intervention functions, as detailed in the matrix in Table 2. Training, coercion, and restrictions of the behavior change intervention functions were excluded; training addresses knowledge and skill gaps that are already covered by the education and enablement intervention functions, while coercion and restrictions are not suitable in this context. Further details of the recommendations are provided in Textbox 1.

Textbox 1. Actionable recommendations based on the behavior change intervention functions.

Education through promoting awareness and understanding of early cognitive impairment among the public, consumers, and health care professionals is pivotal. Educational efforts can be delivered through public outreach initiatives (eg, television programs, hospital websites, public roadshows, newsletters, informational brochures included with the case-finding result letters) with a focus on the following:

1. **Recognizing symptoms**: educating individuals about the symptoms of mild cognitive impairment (MCI) and the various stages of dementia to enable early recognition of cues and to seek timely medical help.
2. **Future planning**: highlighting the importance and value of early planning for care and decision-making for the present and the future to motivate individuals to address cognitive health.
3. **Reframing MCI and dementia as a cognitive disability**: reframing cognitive impairment, as cognitive disability as this is not different from physical disabilities. Such reframing can plausibly destigmatize cognitive impairment and rally a whole-of-society approach to improve medical help–seeking behavior. Individuals may be more likely to seek help when cognitive impairment is not perceived as a liability (ie, akin to a physical disability that requires prostheses to maintain normalcy), while immediate family and the rest of society will be more willing to step up to provide support to individuals with cognitive impairment, akin to providing a prosthetic environment for the cognitive disability.
4. **Facilitating conversations**: strategies for broaching the topic of medical help–seeking with loved ones who are resistant to medical help–seeking for their cognitive impairment (eg, expressing concern, validating feelings, addressing misconceptions, and collaboratively exploring alternatives).

Persuasion through the following strategies:

1. **Providing result letters after case-finding efforts**: the letters should be designed using psychological and behavioral science theories and principles to encourage medical follow-up. The letters should:

- Clearly explain the benefits of further follow-ups and diagnostic tests, such as brain imaging, to rule out cognitive impairments that may be treatable.
- Highlight the various subtypes of cognitive impairment, including those that may be treatable or reversible.
- Include personalized risk of dementia to increase the urgency of the desired action.
- Provide a clear, concise, and easy-to-understand description of the follow-up procedures, including the estimated cost after government subsidies, and the expected duration of each procedure.
- Highlight the benefits of early diagnosis and management of cognitive impairment, which extend beyond direct immediate health benefits, such as enabling individuals with cognitive impairment to secure a better quality of life with the necessary help and support and allowing them to plan for the future and prioritize what matters most to them even in the face of cognitive impairment.

1. **Featuring dementia specialists and community leaders on television programs and radio talk shows.**

Role modeling by showcasing interviews and testimonials from individuals who sought medical help for early cognitive impairment and are living physically, mentally, and socially active lifestyles can serve as powerful role models. These interviews should ideally incorporate the following key topics:

1. **Rationale for proactive disease management**: their reasons for taking a proactive approach to managing their condition.
2. **Support systems**: the support they received from health care professionals, caregivers, friends, and the community.
3. **Strategies to cope and live with the disease**: how they manage the strong negative emotions triggered by the case-finding results and the strategies they use to keep track of their medical appointments.

Interactive and social media platforms can be used to disseminate these videos, fostering a more proactive approach to medical care.

Enablement through:

1. **Providing information on frequently asked questions about the case-finding tool**: addressing confusion, doubts, and skepticism of the validity of the case-finding results by offering clear and accessible information on the frequently asked questions.
2. **Simplifying the referral process via direct referrals to memory clinics**: streamlining the referral process to increase follow-up rates and minimize delays by implementing direct referrals to specialized memory clinics.
3. **Formulating practice guidelines**: the practice guidelines should include simplified key points on when primary care physicians should be concerned about cognitive impairment (as opposed to normal aging) and simplified criteria on when referrals to memory clinics are considered appropriate.
4. **Deploying trained community workers/volunteers** (eg, from Active Ageing Centres and Silver Generation Office) for engagement with individuals with positive case-finding results. These community workers/volunteers can serve the dual purpose of monitoring well-being and providing educational and persuasive interventions and support, including:

- Reinforcing the importance of seeking medical help for early cognitive impairment to both individuals and caregivers.
- Supporting individuals in managing the strong negative affective states triggered by the case-finding results.
- Guiding individuals and caregivers on the strategies for tracking medical appointments.

XSL•FO
RenderX

- Coaching caregivers on managing resistant behaviors.
- Assisting with rescheduling of medical follow-up appointments if necessary.
- Accompanying individuals to the memory clinics, particularly those without immediate caregivers.
- Escalating more complex behaviors or challenges to the community health care workers (eg, community nurses).
- Linking individuals to available community programs that address the risk factors for cognitive decline (eg, programs that target physical activities, diet, and cognitive and social engagement).

Incentivization is particularly important given that financial concerns and socioeconomic constraints can deter medical help–seeking behavior. Strategies should therefore prioritize affordability and equity, including policies aimed at reducing out-of-pocket costs and addressing indirect financial burdens to improve access for individuals and families with constrained financial resources. Incentivization can be implemented in the form of:

1. **Financial incentives for medical follow-up**: providing financial incentives to individuals with positive case-finding results to encourage attending memory clinics (eg, indirect financial rewards).
2. **Increasing the withdrawal limit for national medical savings**: increasing the annual withdrawal limit of health insurance or MediSave for diagnostic testing thereby reducing out-of-pocket payment for diagnostic imaging and subsequent treatments.
3. **Subsidy for initial consultation fees**: waiving the consultation fee for the initial visit to memory clinics or providing a higher subsidy for specialist follow-ups.
4. **Providing subsidized transportation**: offering subsidized transportation to memory clinics, particularly for individuals who have physical difficulties. This should also include the accompanying caregiver and community volunteer.
5. **Profamily workplace policies** as a type of nonfinancial incentive by providing work-from-home options for caregivers, additional leave for caregiving responsibilities, increased sick leave for individuals with MCI and dementia, and emergency time off (eg, when an individual with dementia gets lost and fails to return home).

Environmental restructuring to improve accessibility, safety, and user-friendliness:

1. **Wheelchair and pushchair accessibility**: improving wheelchair and pushchair accessibility (eg, using elevators instead of escalators, and ramps instead of steps) in hospitals, public spaces, and public transport.
2. **Clear and prominent signage**: installing clear and prominent signage in public spaces, public transport, and memory clinics to aid wayfinding.
3. **Wheelchair-friendly toilets**: increasing the availability of wheelchair-friendly toilets in public spaces, near memory clinics, and at train stations.

The education behavior change intervention function addresses barriers related to psychological capability, social opportunity, and both automatic and reflective motivation. Consistent with Ball et al [39], educational content should be tailored to different audiences (ie, the general public, consumers, and health care professionals). Points 1-3 outlined in Textbox 1 apply across all audiences, whereas Point 4 targets the general public and health care professionals. Building on evidence showing improved public dementia knowledge and attitude [40], education efforts, public campaigns, and media should evolve beyond depicting individuals with severe dementia to include individuals living with MCI and early stages of dementia. In doing so, they can illustrate how individuals adapt and continue to live positively and meaningfully despite cognitive decline. This shift will enable the public to gain a more accurate understanding of early cognitive impairment, emphasizing that dementia is more than just memory loss; it also involves language difficulties, problem-solving challenges, and changes in mood and behavior. By providing a broader perspective, it can increase psychological capability and reflective motivation, thereby encouraging timely medical help–seeking behavior even in the early stages of the disease.

In tandem with education, persuasion strategies can activate both automatic and reflective motivation processes. For individuals reluctant to seek medical help after receiving positive case-finding results, carefully designed result letters may serve as a behavioral nudge, drawing on psychological and behavioral science principles, such as nudges [41-43] and loss-framed messaging that emphasizes the negative consequences of delaying medical follow-up [44]. Point 2, engaging the public through expert figures and community leaders to offer insights and perspectives on early cognitive impairment, is a powerful persuasion strategy that draws on the principle of authority to engage the public and encourage medical help–seeking behavior by deferring to the experts (eg, memory specialists) [45,46], and positioning these experts as catalysts for behavior change.

The enablement intervention function is necessary to reduce structural and procedural barriers. Our study supports simplifying the referral pathways; participants receiving direct referrals to SGH memory clinics achieved a 100% attendance rate (ie, for those living in the SGH vicinity, n=10), compared to 54.6% for those with indirect referrals to memory clinics within their home vicinity (ie, participants living outside of the SGH vicinity, n=6). The differences point to the value of simplifying the referral process to reduce cognitive load and barriers in navigating the health care system. At the organizational and policy level, establishing clear practice guidelines for referrals from primary care to memory clinics would reduce practice variations across the health care system and improve the opportunity to timely access medical care.

Finally, environmental restructuring is essential to address physical opportunity barriers, particularly for individuals living with mobility challenges. Limitations in Singapore's public transport can hinder attendance at follow-up medical

XSL•FO
RenderX

appointments, particularly during peak commuting hours when public transport is crowded and less accessible. For instance, the Singapore public buses are only able to accommodate one or 2 wheelchair users at a time [47], requiring additional wheelchair users to wait for the next available bus. Environmental restructuring and structural modifications, such as increasing wheelchair capacity on buses and improving clinic accessibility, would not only ease travel burdens but also signal a societal commitment to inclusion by proactively supporting the diverse needs of people living with cognitive and physical impairments.

Limitations and Strengths

This study has several limitations. First, the sample was drawn from participants in the PENSIEVE-AI study [11], raising the possibility of self-selection bias whereby participants may have been more inclined to follow up on their cognitive impairment. To mitigate this, we purposively included individuals who had not sought medical follow-up and expressed no intention to do so unless their symptoms became more severe (eg, difficulty returning home using a familiar route). Second, the sample lacked ethnic diversity, with limited representation from Malay and Indian minority groups relative to the Chinese majority group. Third, the long intervals between memory clinic follow-ups, typically 6-12 months, introduce uncertainty regarding continued long-term medical follow-up, particularly for individuals with MCI whose symptoms are typically less severe and may be perceived as less disruptive than those associated with dementia.

A further limitation concerns the exclusion of individuals with dementia from direct interviews. Although based on ethical and practical considerations regarding potential distress and communication challenges, this warrants critical reflection on the representation gap inherent in relying on proxy accounts. This reliance placed emphasis on caregivers' experiences and perspectives in identifying barriers and facilitators of the medical help–seeking journey following dementia diagnosis, inadvertently glossing over the affective experiences and personal autonomy of the individuals with dementia themselves. In particular, their personal decision-making in medical help–seeking, sense-making of the dementia diagnosis, and challenges in navigating health care services, as well as the interactions with caregivers and health care professionals may be underrepresented, despite being highlighted in the broader dementia literature [48-50].

Prior research emphasizes the importance of including individuals with dementia to address epistemic injustice and support person-centered approaches in research [51-56]. While caregiver accounts were sufficiently informative for understanding the barriers and facilitators to medical help–seeking in this study, we acknowledge the importance and value of including the perspectives of individuals with dementia. Future studies should adopt more inclusive and adapted approaches, such as process consent, to ethically and effectively engage individuals with dementia. Finally, evaluating the feasibility and effectiveness of our recommendations was beyond the scope of this qualitative study. Future research should apply the acceptability, practicability, effectiveness, affordability, side-effects, and equity (APEASE) criteria [19] in collaboration with stakeholders, including policymakers and community representatives (eg, patient advocates, representatives from caregiver organizations, community health care workers, or volunteers), to refine and evaluate these recommendations.

Despite these limitations, this study makes several important contributions. First, while prior research has primarily focused on medical help–seeking intentions [12,29], this study explored determinants of actual medical help–seeking behavior following a cognitive impairment diagnosis. Second, by including individuals with MCI and the caregivers of individuals with MCI or dementia who had not sought medical follow-up, we addressed a key sampling gap in earlier qualitative work [16]. This provided a more nuanced understanding of the determinants of medical help–seeking behavior, particularly among those not yet engaged in follow-up care. In doing so, this study extends the AD system framework [39] by highlighting the nonlinear processes involved in seeking medical treatment.

Conclusions

This study identified key barriers and facilitators to medical help–seeking behavior following a cognitive impairment diagnosis, demonstrating the dynamic and nonlinear processes in accessing medical treatment. Building on these findings, we developed actionable recommendations grounded in the COM-B framework and the BCW intervention functions. We advocate for a whole-of-society approach, with implications extending to policymakers, primary care providers, tertiary hospitals, and the transport and media authorities. To maximize the impact of these recommendations, ongoing collaboration with stakeholders and careful evaluation using the APEASE criteria are needed to address practical considerations and promote equity in facilitating timely medical follow-up after positive case-finding results or diagnosis.

Acknowledgments

We sincerely thank the participants and caregivers for generously sharing their experiences and insights. Their willingness to contribute and the valuable input they provided were instrumental in deepening our understanding of the research topic. We are also grateful to A/Prof Philip Yap for his insightful feedback on an earlier draft of this paper, which helped refine our work. Generative artificial intelligence tools were not used at any stage in the preparation of this manuscript.

Abstract

Background: Access to geriatric mental health (GMH) care is limited in rural areas. To meet this need, the Veterans Health Administration provides specialty tele-GMH care for aging rural veterans via regional telehealth hubs.

Objective: This study aims to create a roadmap describing key phases and determinants underlying the implementation and sustainment of tele-GMH services as part of a qualitative longitudinal evaluation of tele-GMH teams.

Methods: Semistructured interviews were conducted with clinicians from all 8 tele-GMH teams (n=25) at 3 time points across a 3-year period (October 2021-September 2024). Interview (n=46) data were summarized into key domains using a templated rapid qualitative approach, guided by the Consolidated Framework for Implementation Research (CFIR) 2.0. Further thematic analysis and team discussion elucidated the findings.

Results: We identified key activities and determinants of success in three phases: (1) preimplementation (engaging leaders, securing funding/hiring, and defining services); (2) implementation scale-up and expansion (advertising, addressing challenges, seeking feedback, refining, and growth); and (3) sustainment (maintenance). Activities within each phase were cyclical and iterative (ie, nonlinear). Barriers to implementation included unfamiliarity with local aging resources; facilitators included tailoring strategies and engaging referring clinicians.

Conclusions: Similar processes emerged across regions in the development and sustainment of tele-GMH services, allowing for the creation of a unified roadmap. Limitations including sampling bias are discussed. Further work could apply and evaluate the utility of the roadmap to guide creation of tele-GMH services in new regions to enhance access to specialty care for aging rural veterans.

(JMIR Aging 2026;9:e95286) doi:10.2196/95286

KEYWORDS

CFIR; rural health; older adults; telehealth; virtual care

Introduction

Over half (54%) of US veterans residing in rural areas are aged 65 years or older and face challenges in accessing and coordinating health care services [1]. These problems are compounded for aging rural veterans who experience complex mental health, neurocognitive, and medical needs that warrant specialized geriatric mental health (GMH) services. Access to GMH specialists is scarce, particularly in rural areas [2,3], but virtual care (ie, video/audio telehealth services and e-consultation) overcomes geographical barriers to accessing these services [4-6]. Virtual care has been demonstrated to be acceptable, feasible, and efficacious for older patients, caregivers, and referring clinicians [7-9]. However, barriers such as access to broadband internet and digital literacy attenuate the positive impact of virtual care for some rural veterans [10].

The Veterans Health Administration (VHA), the largest integrated health care system in the United States, is a leader in the provision of telehealth services [11] and in addressing barriers to care through national programs, such as a Digital

XSL•FO
RenderX

Divide Consult through which clinicians can request that veterans receive loaned video-enabled tablets with internet access [12]. The VHA also created regional telehealth centers to deliver virtual care to multiple health care systems in a VHA region. These regional telehealth centers, expanded broadly under the nomenclature of clinical resource hubs (CRHs), address gaps in VHA primary and mental health care access due to clinical staffing shortages caused by resignations, extended leave periods, difficulty hiring needed clinicians, or increasing enrollment of veterans [13,14]. CRH services, which initially focused on temporary clinical support based on requests from local VHA medical centers or clinics, have expanded to encompass specialty care such as cardiology [15], sleep medicine [16], and specialty mental health models (eg, tele-neuropsychology) that provide consultative care [17]. Other VHA programs that provide virtual care to older veterans occur as part of regular care from VHA medical centers, outpatient clinics, and geriatrics centers of excellence to rural clinics [18,19]. However, CRH-based services differ from other services in VHA in that these regional hubs have clinicians focused only on delivering virtual care and embedded support staff specifically trained to facilitate telehealth services [13].

One CRH specialty model is tele-GMH. Tele-GMH refers to the provision of pharmacological and nonpharmacological management of neurocognitive and psychiatric conditions in older adults with multiple medical conditions by one or more GMH clinicians via virtual modalities. One such tele-GMH consultation model led by a geriatric psychiatrist in a multistate rural region was the pioneering innovation that led to this evaluation [20,21]. This model of care mitigated perceived barriers impeding access to specialty geriatric psychiatry care, including geographic barriers and limited workforce [2,3], and was valued by caregivers and referring clinicians [22]. Regional needs and leadership preferences contributed to the initial development of diverse approaches to tele-GMH care, including single clinician-led services and interdisciplinary teams and models of care [23].

Best practices [24,25] and drivers of telehealth use, such as patient and clinician factors [26,27], have been identified; however, systematic examination of factors supporting implementation and growth of tele-GMH services is needed. We conducted a naturalistic prospective program evaluation (ie, systematic collection of data on the program to assess impact, acceptability, and implementation determinants) using qualitative methods guided by the Consolidated Framework for Implementation Research (CFIR) 2.0 [28]. CFIR allows for consideration of the complex setting within which care is delivered, spanning local clinics, virtual telemedicine hubs, and the larger VHA system. The objective of the evaluation was to identify barriers and facilitators of implementation and to synthesize findings across multiple sites to create an implementation roadmap to facilitate the future spread of tele-GMH services to additional VHA regions.

Methods

Study Design

This program evaluation used a qualitative longitudinal design, collecting data across different stages of development and implementation of the tele-GMH teams over a 3-year period. Interviews were conducted between February 2022 and September 2024 via convenience sampling. The initial study design was guided by CFIR 1.0 [29]; however, the study design was updated, and all analysis was conducted based on CFIR 2.0 [28]. Findings reported are based on CFIR 2.0.

Setting/Participants

We used a convenience sampling approach, focused on trying to reach all the clinicians from the 8 CRHs that provided GMH services or specialty geriatrics services between October 2021 and September 2024 to participate in one or more interviews. We invited 26 of the 27 clinicians; we were unable to invite one clinician because they left their VHA position before the invitation was sent. All clinicians served rural veterans, as identified using the rural-urban commuting area codes used by the VHA Office of Rural Health [1]. We refer to the services as tele-GMH, as the majority of clinicians and services are focused on GMH.

Measures

Led by the project director (CEG), the analysis team (MBH, ADP, and RBT) developed semistructured interview guides to be administered to clinicians at 3 time points corresponding to each service's startup (time point 1), development (time point 2), and sustainment (time point 3) stages. Interview guides are available from the first author (CEG) by request; the overarching purpose of these guides was related to the multiyear evaluation with varying data collected at each time point.

During the time point 1 interviews, clinicians were asked about factors related to the development of their service, reasons why they joined the CRH, services provided, common reasons for referral and referral sources, regularly used measures, team composition, and team collaboration. Overall, time point 1 focused on CFIR domains related to the innovation and characteristics of the inner setting.

Time point 2 interviews asked clinicians about planning and implementation of services, facilitators and barriers of implementation, service impacts on rural veterans and their caregivers, service impacts on referring clinicians and others in the health care system, outcomes to track, and reflections on the sustainment of the service. This interview guide included questions that mapped onto constructs in CFIR 1.0. Time point 2 interviews gathered information about changes to the innovation and the inner setting and the initial implementation process.

Time point 3 interviews focused on relationships with referral sources, service impacts on referring clinicians and rural veterans, barriers and facilitators to service delivery, and geriatric medicine needs [30] for rural veterans. This interview guide asked questions about any changes to innovation, the inner setting, and the implementation process.

XSL•FO
RenderX

We aimed to interview all clinicians at time point 1, then used more purposive sampling at time points 2 and 3 to ensure that perspectives were gathered from multiple disciplines and from every CRH team. This purposive approach for time points 2 and 3 allowed for gathering perspectives from every region with services while minimizing time burden on the clinicians delivering services.

Ethical Considerations

The project was reviewed by the Stanford University IRB, the IRB of record for VA Palo Alto Health Care System, and determined that this work did not meet the definition of human subjects research (review numbers: IRB-65150, IRB-70700, and IRB-73787) and program evaluation was conducted to inform VA operations. Union concurrence was obtained prior to conducting interviews. All participants provided verbal consent prior to their virtual interviews.

Procedures

In accordance with VHA policy, interview guides were sent to the unions for review and concurrence. Participants were emailed an invitation to engage in interviews approximately annually. One reminder email was sent to participants who did not respond to the first invitation. Interviews were conducted and recorded via videoconferencing technology. All interviewers were trained in qualitative interviewing by the qualitative methodologist (ADP).

Analysis

The evaluation team consisted of a geropsychologist/project director (CEG), project coordinators (CC and MFL), a qualitative analyst (MBH), a qualitative methodologist (ADP), geropsychologist (AL), a health psychologist (RBT), and a geropsychology postdoctoral fellow (LP). Interviews were conducted by 5 authors (CEG, MBH, CC, MFL, and LP). All evaluation team members participated in the analysis (see Multimedia Appendix 1 for reflexivity statements from the evaluation team). Biases were managed through discussion, weekly qualitative analysis meetings, and multiple authors reviewing narrative summaries.

Interviews were auto-transcribed using Microsoft Teams software. Team members proofread transcriptions against the audio recordings to ensure that transcripts were verbatim. Led by the project director (CEG), the team developed templates to summarize transcripts into domains (key topics of interest) that corresponded to the interview guides. Using rapid qualitative template-based analysis [31], one individual summarized each transcript, and a second individual reviewed the transcript summary; then both met to review the summary and resolve any discrepancies by consensus. Data saturation was determined through review of the transcript summaries and the written domain narratives that synthesized data across each summary. Review occurred in pairs; the full team discussed findings during twice-monthly meetings. Domain narratives with similar content were combined. This analysis focused on 8 domain summaries, including joining CRH; name of service; planning process; advertising; determinants; relationships with referral sources; services/challenges; and outcomes, sustainability, and service impacts. Two authors (CEG and MBH) used a matrix template based on CFIR 2.0 [28,32] to code the domain summaries to identify the key components of CFIR underlying our findings. These 2 authors also used the 8 domain narratives to generate the implementation roadmap. The roadmap was reviewed and refined during qualitative team meetings. The finalized implementation roadmap was reviewed with the project advisory team, which included 2 CRH geriatric psychiatrists, a CRH director, and a national leader in GMH.

The evaluation team developed materials summarizing key aspects related to the development and implementation of tele-GMH services in the CRHs, outlining steps sites may consider in the planning and implementation process. These materials were reviewed with CRH clinicians during monthly consultation meetings and were distributed to CRH clinicians via email. Minor changes (focused primarily on CRH-specific processes) were made based on feedback. This process enabled the evaluation team to engage in member checking [33] through sharing our understanding of implementation processes with the interviewees themselves.

Results

Overview

Forty-six interviews were conducted, representing perspectives from 25 clinicians across 8 CRHs. Most clinicians were geriatric psychiatrists (10/25, 40%) or geropsychologists (6/25, 24%). Other clinicians included neuropsychologists, clinical pharmacists, and a geriatrician (see Table 1). The CRH services primarily encompassed tele-GMH services, with later expansions including geriatric medicine. All models (n=23) included at least one GMH clinician and delivered synchronous telehealth services to home or clinic (see Table S1 in Multimedia Appendix 1). Teams provided services for veterans at spoke sites, including community-based outpatient clinics, smaller VHA medical centers, and video to home, including for patients receiving home-based primary care (HBPC) services. Two teams also provided telehealth services to community living centers (CLCs), VHA's nursing home equivalent.

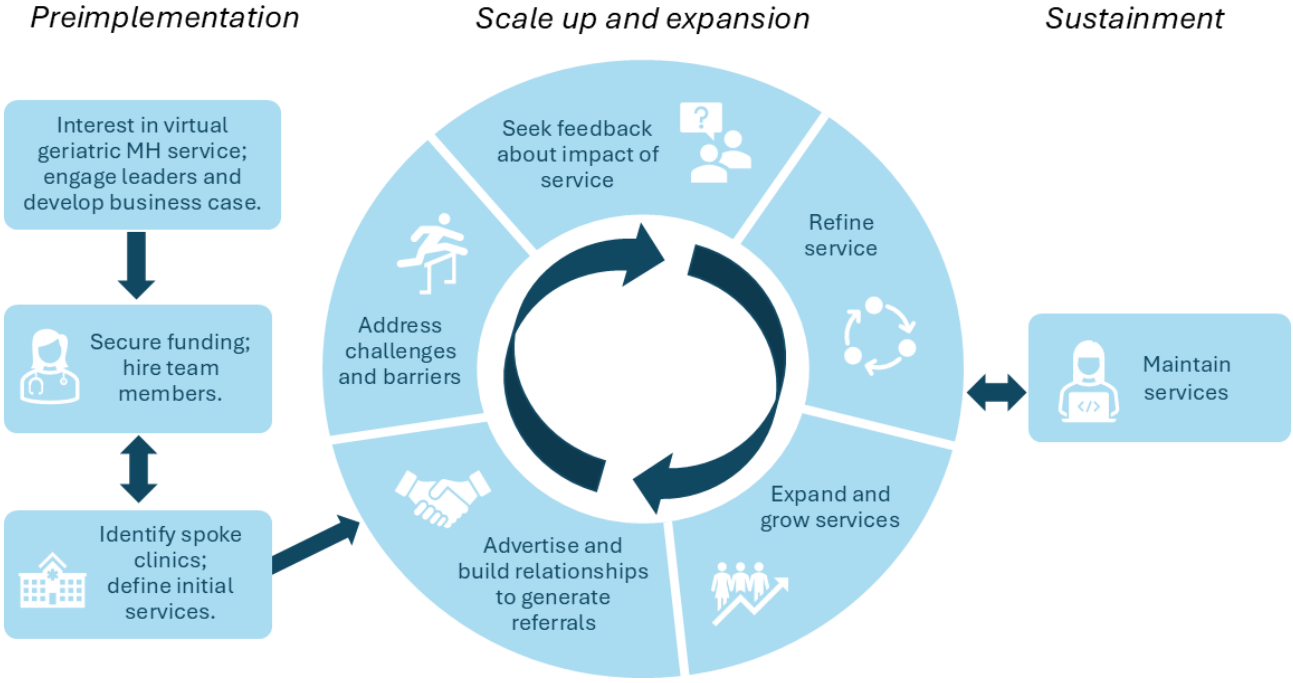
Table . Interviewee characteristics (n=25).

Characteristics	Interview phases		
	Time point 1 (n=23)	Time point 2 (n=13)	Time point 3 (n=11)
Discipline			
Geriatric psychiatrist	9 (39.1)	5 (38.5)	6 (54.5)
Geropsychologist	6 (26.1)	4 (30.8)	3 (27.3)
Neuropsychologist	4 (17.4)	1 (7.7)	0 (0)
Other clinician type[a]	4 (17.4)	3 (23.1)	2 (18.2)
Model type			
Consultative (2 regions)	8 (34.8)	3 (23.1)	4 (36.4)
Hybrid (4 regions)	10 (43.5)	7 (53.8)	5 (45.5)
Continuity (1 region)	2 (8.7)	2 (15.4)	2 (18.2)
Other model type[b] (2 regions)	3 (13.0)	1 (7.7)	0 (0)
Interview duration (minutes), mean (SD)	39.35 (0.42)	38.06 (0.42)	47.35 (0.36)
Invitation response rate[c,d], n/N (%)	23/24 (95.8)	12 (92.3)	11/12 (91.7)

[a]Other category was created to help keep data anonymized for professions with lower numbers (ie, clinical pharmacist practitioners, social workers, geriatricians).



[b]Other model types include gap coverage and tele-neuropsychology services.

[c]One interviewee completed Part 1 and Part 2 interviews at the same time point as they were transitioning to a different clinical resource hub (CRH) position; the interview duration is included in mean for Part 1 interviews.

[d]Another interviewee who was the founding clinician of tele-GMH delivered services prior to 2021 and only completed a Part 3 interview.

We identified the key steps taken to implement tele-GMH services, organized into three main phases: (1) preimplementation, (2) implementation scale-up and expansion, and (3) sustainment. As seen in Figure 1, the steps were cyclical with iterative changes over time. The following describes the steps and relevant determinants of implementation in each phase, with particular attention to the implementation of care for rural veterans.

Figure 1. Overview of roadmap for implementation of tele-geriatric mental health services. MH: mental health

XSL•FO
RenderX

Preimplementation

Defining and Adapting the Innovation

The first tele-GMH service within the CRHs focused on a consultative model encompassing assessment, treatment recommendations, and limited follow-up appointments [20]. Variations on this approach emerged to include continuity-based services and a hybridized model of consultative and continuity services (termed "hybrid model") [23]. During time point 1 interviews, we asked tele-GMH clinicians whether they had followed the originating consultative model in developing their services (guidebook available internally to VHA). Clinicians reported considering the model but making adaptations based on their own clinical experience in VHA settings to develop their service.

> *…ultimately, we decided to do more of a shared intake and offer different modalities and then also provide some follow-up. We are staffed differently which allowed for the uniqueness of being able to provide follow-up.* [ID 23, clinical pharmacist practitioner]

Others described developing their approach based on specific needs for services in their region, such as neuropsychology, continuity care for older veterans who needed care following the retirement of a local psychiatrist, or CLCs that needed psychiatry coverage. Thus, tele-GMH models can adapt to fit regional needs at start-up and to meet emergent needs over time (see Refining Service).

Building the Tele-GMH Team

Building the tele-GMH team required buy-in from and ongoing relationships with regional leadership in mental health and geriatrics to secure funding for clinical positions. In some regions, CRH leadership initiated building the tele-GMH teams, whereas in other regions, a self-identified champion (often a geriatrics or GMH clinician) advocated for establishing virtual services. Tele-GMH teams often attracted innovators with GMH expertise who were motivated to design new services. The first hires (ie, founding members of the teams) described how being involved in the design of the service gave them a sense of ownership and satisfaction in expanding access to GMH services for rural populations.

The CFIR characteristics of capability and motivation emerged as important constructs among clinicians hired into tele-GMH positions. Many described their prior VHA experience, including in settings such as HBPC, CLCs, and community-based outpatient clinics. Others who were hired from outside the VHA described their experience working in the community (eg, private practice and hospital) with older adults. Motivations included clinicians being drawn to serve the geriatric community and having the opportunity to use their training and work exclusively with older patients while addressing the national GMH clinician shortage. Many also acknowledged seeking out these positions to find a better work/life balance. One geropsychologist (ID 11) described their motivation for joining their CRH team:

> *I've always enjoyed doing things with older adults that expand services for them, so I thought that this was a nice extension of that. Also, it was a completely virtual position, so I was hopeful that would give me more life balance and that kind of thing as well… I had been in a CLC setting prior and I was ready for a change after the whole COVID year and a half where nursing homes were really just hit so hard by that. So, all of those factors combined plus it just seemed like a good, exciting opportunity to do something new with geriatrics.* [ID 11, a geropsychologist]

Others described the challenges of private practice, dealing with frequent cuts to Medicare/Medicaid reimbursement, and noting that it was "just getting harder and harder" with an influx of "corporate medicine" (ID 13, geriatric psychiatrist). Attracting clinicians into tele-GMH positions most often occurred through word of mouth from professional colleagues.

Specifying the Available Services and Identifying Initial Local Sites for Service Delivery

Prospective tele-GMH service offerings were decided at the outset by CRH leaders or the tele-GMH founding members through conversations with regional stakeholders about perceived needs and specific gaps in care pathways. Regional stakeholders included leaders in geriatrics and extended care, mental health, and primary care and their teams. Subject matter experts at sites were consulted, when possible, to avoid overlap with existing GMH services in a region. In some cases, needs assessments were conducted with the general mental health clinicians in the CRH, as they were the primary mental health clinicians for some rural clinics that experience substantial turnover of clinicians and thus would be the main referral sources for some teams. Table 2 summarizes the often-delivered services by the tele-GMH teams.

XSL•FO
RenderX

Table . Tele-geriatric mental health services. Other clinical services such as geriatrics evaluations for dementia, frailty, or multicomplexity may be delivered by geriatricians or advanced practice providers (APPs) along with other interdisciplinary team members.

Clinical functions/services	Clinicians who may deliver services[a]
Behavioral/environmental interventions to address disruptive or distress behaviors	Geropsychologist, geriatric psychiatrist, or geriatrician
Capacity evaluations[b]	Geriatrician, geriatric psychiatrist, neuropsychologist, or geropsychologist
Caregiver education related to psychiatric/neurocognitive disorders	Nurse, social worker, geropsychologist, geriatric psychiatrist, geriatrician, or advanced practice provider (APP) with geriatrics training
Cognitive assessment/neuropsychological assessment	Nurse, APP with geriatrics training, geriatrician, or geriatric psychiatrist could conduct brief cognitive assessments. Neuropsychologist or geropsychologist could conduct brief cognitive assessments or multidomain cognitive assessment batteries.
Diagnostic questions / second opinions related to neuropsychiatric presentations	Geriatric psychiatrist, geriatrician, APP with geriatrics training, neuropsychologist, or geropsychologist
Psychiatric medication recommendations and/or management	Geriatric psychiatrist, clinical pharmacist, geriatrician, or APP with geriatrics training
Psychotherapy specifically tailored for aging veterans	Geropsychologist, geriatric psychiatrist (may do brief counseling), or social worker
Psychotherapy for caregivers related to caregiver strain	Geropsychologist, geriatric psychiatrist (may do brief counseling), or social worker

[a]Clinicians from other disciplines, such as occupational therapists or speech and language pathologists, may also deliver these services.

[b]Not all teams provide this clinical service. It may depend on the specific question and state-specific rules and regulations.

A key facilitator to preimplementation was having a strong planning process, including establishing a sequence of steps and identifying key players at each local site. Telehealth coordinators played important roles in the startup as well to set up the necessary agreements for services. Delegating responsibility for each step and setting a timeline for the tasks streamlined implementation of services. Open lines of communication with other CRH clinicians who previously implemented services at a spoke site helped guide implementation. Barriers to implementation emerged when the specific processes, such as creating telehealth service agreements or identifying key points of contact, were not directly followed, which then led to delays in moving forward with service delivery.

Implementation Scale-Up and Expansion

The scale-up and expansion of the tele-GMH services was an iterative process, as represented by the cyclical phase of Figure 1. See Table 3 for examples of the CFIR constructs related to the implementation process domain.

XSL•FO
RenderX

Table . Consolidated Framework for Implementation Research (CFIR) 2.0 implementation process domain analysis. One construct (assessing context) was not used when coding the data.

Implementation process domain construct	Summary of constructs within interview data	Illustrative quote
Teaming	Collaborating intentionally on tasks with referring clinicians (eg, attending staff meetings, discussing cases) helped develop rapport and established strong working relationships.	"[I attend] all of their [CLC][a] team meetings once a week, and discuss cases with them, active ones or referrals that are coming my way and that's done for an hour every week" (ID 20, geriatric psychiatrist)
Assessing needs–innovation deliverers (ie, geriatric mental health [GMH] clinicians)	Assessing needs of innovation deliverers (GMH clinicians) guided expansion of services over time. Sometimes GMH clinicians required input from local clinicians to obtain information about local services.	GMH clinicians describe the barrier of being unfamiliar with local resources: "…we're trying to refer them for adult daycare or, even a Senior Center or something like that. And we don't know anything about what is there. I think that's an ongoing challenge when not local and don't know the local resources." (ID 20, geriatric psychiatrist)
Assessing needs–innovation recipients (ie, veterans, caregivers, and referring clinicians)	Assessing needs of innovation recipients, such as patients with cognitive and/or sensory impairments, informed implementation and service delivery including time needed to troubleshoot technology and help patients connect to telehealth appointments.	"Many of these [patients] would just get canceled or no-showed… because we are aware, we take extra effort, I have none of my consults just get canceled because I can't reach [them]. We have extra steps in place where we have someone on our team to go through the chart, just making sure we're [calling] the right person and, maybe 75% of the time, turns out we're not." (ID 8, geriatrician)
Planning	Planning the steps in implementation was evident throughout the preimplementation and early implementation stages. This included planning the desired service to deliver, initiating services at a spoke site, or advertising services.	"There's been some times where some sites seemed really eager for us to get started. And so, we'll do things out of order, and then it just kind of like backfires because then we realized, oh, we don't have all the safety contacts in place, or we didn't finalize CVT availability is going to be …" (ID 4, geriatric psychiatrist)
Tailoring strategies	Tailoring strategies occurred regarding altering the planned menu of services offered to sites, adjusting time allotted to see patients, collaborating with other clinicians on shared patients, or adjusting other aspects of implementation.	"I am starting to do more briefer therapy now… while folks are inpatient. So that has been a huge change from the start of it." (ID 7, geropsychologist)
Engaging–innovation deliverers (ie, CRH[b] clinicians)	The opportunity to build an innovative service from the ground up attracted some CRH clinicians to their roles.	What drew some GMH clinicians to their role was: "the ability to kind of build something from the ground up, kind of like building a[n] airplane while flying it in a sense and being a part of something innovative." (ID 14, social worker)
Engaging–innovation recipients (ie, veterans, caregivers, and referring clinicians)	Engaging referring clinicians and continuing to remind them of the service was a critical aspect of implementation. Advertising directly to veterans was found to be challenging due to the lack of a clear VA procedure on how to do this.	Continuing to remind referring clinicians of the service's existence and purpose is key for awareness. "If the consult service rests on its laurels and doesn't put their names out there all the time, we are private practice within the VA and they [referring clinicians] aren't going to remember us or use us if they're infrequent users of us and small outpatient CBOCs …so, we need to continue to let people know that we exist." (ID 18, geriatric psychiatrist)

XSL•FO
RenderX

Implementation process domain construct	Summary of constructs within interview data	Illustrative quote
Doing	CRH clinicians adjust clinical processes and procedures throughout implementation to optimize efficiency and workflow.	Adding a phone line for patients improved coverage and responsiveness: "We've added is a phone line where patients can call in and leave a message and then our MSAs[c] will give us the message and we can follow up… And then our nurse also created a dementia education packet that included a lot of the consistent resources that we were pulling for patients and information and educational tool." (ID 23, clinical pharmacist practitioner)
Reflecting and evaluating–implementation	GMH clinicians reflected that note templates need to be standardized across sites for better workflow. GMH clinicians also described difficulties getting homebound or rural patients to attend in-person appointments like labs or EKGs.	Challenges came from trying to schedule lab work or an electrocardiogram for homebound or rural patients who are unable to come into the facility: "Lab work is difficult. They can go to lab and lab won't come to them. And EKG [electrocardiogram], workups are difficult in [the] beginning if patient cannot go and nobody can come to them." (ID 10, geriatric psychiatrist)
Reflecting and evaluating innovation	Telehealth services have been effective for older, rural patients and are valued by patients and caregivers alike. Referrals often come from clinicians who have referred to the service previously.	"[Caregivers] love [the support group] because hearing from other caregivers about how they're surviving and that it's normal to feel overwhelmed and all, that really helps." (ID 15, geropsychologist)
Adapting	Adapting includes making modifications in response to changes that have been observed during implementation. Some sites decreased advertising efforts as the referral flow became steady and robust. Others added clinicians to the CRH GMH team or provided education.	"We did reach out to just a variety of primary care staff and it was very exhausting. It was like a press tour. It was a lot of extra work outside of work hours to do so much extra effort on top of patient care. But, I think it's valuable because we've been on cruise control for a while, like we haven't advertised for a long time, and we've had plenty of volume." (ID 8, geriatrician)

[a]CLC: community living center.

[b]CRH: clinical resource hub.

[c]MSA: medical support assistant.

Advertising and Building Relationships

Generating referrals was crucial to the scale-up process. Referrals were initially increased through advertising and marketing to VA clinicians, and ongoing referrals were maintained through care collaboration with local teams. Outreach strategies included attending local and regional leadership meetings, attending local staff meetings, connecting individually with potential referring clinicians, and initiating regular contact with local sites (see Table S2 in Multimedia Appendix 1). Several tele-GMH clinicians used marketing materials, such as flyers, with service descriptions and other necessary information for sites to place consultation requests.

Despite the many facilitative strategies used to increase referrals, inconsistency in the naming of the tele-GMH service emerged as a potential barrier. Specifically, two key contributors were identified: (1) the slightly different naming conventions for consult orders across different instances of the VHA electronic health record (EHR) in each health care system, and (2) the uncertainty expressed by some interviewees when asked directly about the name of the service. This could have implications for advertising and maintaining a referral network.

Addressing Challenges and Barriers

The challenges that arose during implementation were grouped into 4 areas, including virtual care delivery, patient-related factors, availability of local services, and logistical challenges. Virtual care delivery challenges included needing to troubleshoot technology (eg, setting up assistive devices to be compatible with the technology, connectivity, and use of video platforms) before and during visits. Tele-GMH clinicians used different strategies to help facilitate access to and use of technology, including loaning VHA internet-enabled tablets (ie, Digital Divide Consult) and connecting patients with the VHA's helpdesk to troubleshoot connecting to video visits. Telehealth clinical technicians or nurse case managers helped by conducting practice calls with patients and/or their caregivers as well.

Patient-related challenges emerged for specific populations, such as patients with cognitive impairment who do not have a caregiver present to assist with troubleshooting technology or to corroborate the patient's medical history, or when working with patients with hearing impairment who are unable to reliably hear the clinicians through telehealth. Other complications arose when the point of contact listed in the electronic health record was not involved in the patient's care. To overcome some of these challenges, tele-GMH clinicians collaborated with other

XSL•FO
RenderX

VHA teams to obtain accurate information or coordinate visits. The CFIR construct of teaming, or intentional collaboration on tasks, included having local HBPC clinicians assist patients in logging on to a tablet or phone for the tele-GMH appointment.

Additional challenges arose regarding the availability of local resources. Some rural veterans had limited access to local primary care or specialty care. This made it challenging for those veterans to obtain timely and consistent medical care, which also impacts their mental health care. One geropsychologist (ID 15) described difficulties in trying to get in touch with local clinics.

> *It's scary to me, the risks that are inherent in that [scarce resources in rural areas] and feeling so separate from it and limited in what I can do, you know, because I refer people to the patient advocate. I provide those contact numbers. I really encourage them to speak up for themselves and then they'll tell me like, 'I've called [local VHA clinic] 12 times and no one's called me back.' And you know, you just feel like your hands are tied and that's really hard for my morale and their morale.* [ID 15, a geropsychologist]

Potential solutions included working with local social workers or with the CRH nurse case managers to identify local resources.

The last challenge centered on logistics, clinical processes, and procedures. Tele-GMH clinicians described making small adjustments after they began providing services. These iterative changes, captured by the CFIR construct of doing, led to changes in patient-clinician communication (eg, adding a phone line where patients could leave messages for a medical support assistant who triages requests), workload balance among team members (eg, adjusting intake appointments), improving within-team communication (eg, developing a format for internal huddles and patient discussions), and communication with sites (eg, developing internal communication channels with each local site).

Seeking Feedback About Impact of Service

Tele-GMH clinicians described ways in which they receive feedback about the impact of their services, captured by the CFIR construct of reflecting and evaluating. Positive feedback about the service encompassed effects on veterans (acceptability of telehealth, convenience of telehealth, and positive impact on quality of life); caregivers (involvement in care and their appreciation of services); referring clinicians (assistance with patients with complex needs); and access to specialty care (see Table 4).

XSL•FO
RenderX

Table . Tele-geriatric mental health service impacts.

Theme	Definition	Illustrative quote
Increased acceptability of telehealth for older veterans	Older veterans had positive responses to telehealth technology and preferred telehealth. Referring clinicians expressed initial skepticism about telehealth being effective; however, this was overcome as the virtual team proved to be helpful.	"There's still this culture or stigma around the use of technology and older adults…I think we're seeing that, yes, there's barriers and challenges for sure. It's a unique population with unique needs, but we absolutely can make this work." (ID 6, geropsychologist)
Telehealth is convenient for older veterans	The telehealth service enables patients with age-related health conditions to avoid driving far distances by offering video-to-home appointments (VA Video Connect [VVC]) and video appointments to local clinics (Clinical Video Telehealth [CVT]).	"…saving them having to drive to places that are further away, whether they're doing VVC visits from their home, which obviously is the easiest way to do it… it's been a lot easier for them not to have to drive as far as they might otherwise." (ID 20, geriatric psychiatrist)
Caregivers are often involved in and value the services	Patients are the focus of the service; and many have stressed and overwhelmed caregivers. Caregivers benefit from direct services such as caregiver groups or brief therapy, but also from education from clinicians during the veterans' appointments.	"[Caregivers] don't feel like they can be honest about how scary [caregiving] is and how taxing and overwhelming it is because they don't want to burden other people. And they feel a sense of shame sometimes because they feel like they're supposed to just be up for it all and never complain." (ID 15, geropsychologist)
Positive effects on quality of life for veterans, particularly those with cognitive impairment	The service has resulted in patients getting high quality care managing dementia, behaviors and neuropsychiatric symptoms. This care extends to quality of life for the veterans.	"…with dementia there's no cure, but we can give them the best quality of life possible and the best time with their loved ones and caregivers, the best time with their family member with dementia that we can and, and that's the ultimate goal for us." (ID 23, clinical pharmacist practitioner)
Referring clinicians appreciate the services for patients with complex needs	This service benefits referring clinicians by reinforcing their decisions and providing additional guidance when needed. Education to direct care staff also helps them manage veterans with disruptive or challenging behaviors and conflicts with staff and other patients.	"…anticipating questions that they might not realize they might have. And I think also just trying to alleviate concerns or kind of anxieties about, you know, in particular with dementia-related behaviors to manage, just reinforcing that I'm there to provide help when needed. So, not having to worry alone." (ID 4, geriatric psychiatrist)
Services increase access to needed expertise	These services increased access to geriatrics care for highly rural patients in under-resourced areas who may otherwise "fall through the cracks" in health care systems.	"[Local clinicians] may want to refer that Veteran on to a higher level of care or to community care, and that usually delays care a lot versus having that geriatric mental health specialist or geropsychologist available. You can see that patient right away. So again, it's just really makes care a lot more accessible and efficient." (ID 1, geropsychologist)

Constructive feedback was elicited when tele-GMH clinicians connected with referring clinicians to discuss the recommendations given. During those conversations, tele-GMH clinicians learned more about situations in which the referring clinicians did not follow the recommendations. One geriatric psychiatrist (ID 20) described learning that the consultative care approach conflicted with referring clinicians' preferences.

> *I've gotten some feedback from the providers or at least in the consultation that they were really hoping for somebody to kind of take over the prescribing and be the provider for the patients going forward. I just had a consult right before this call up in [STATE] where it's a primary care doctor who is not at all comfortable prescribing the meds and was really looking for me to kind of take over that… my role hasn't changed, but maybe, we should rethink that and see what's best for it. That's probably the biggest thing.* [ID 20, a geriatric psychiatrist]

The tele-GMH team reflected on the impact of their service model on patients. For example, one clinician using a consultative care approach noted that this model allows patients to be seen within 1-2 days compared with 1-2 months. Clinicians using a hybrid model focused on stabilization or more continuity services described the challenges with longer wait times (4 - 8 wk). This latter observation led to tailoring strategies of increasing the number of intake slots and broader adaptations such as advocating to hire more clinicians to the team.

Refining Service

Refining the services largely consists of the CFIR constructs of tailoring and adapting the service delivery in response to feedback, observations, and emergent needs. One such change was to tailor the specific services offered according to the local needs. For example, a geropsychologist who initially intended

XSL•FO
RenderX

to provide behavior plans and assessments expanded their services to include brief psychotherapy (4‐5 sessions). Tele-GMH clinicians described setting aside time to intentionally collaborate on care with local clinicians through teaming strategies such as attending weekly behavioral huddle meetings in CLCs. Other adjustments focused on how the team divided up cases from the referring sites. For example, one service consisting of multiple geriatric psychiatrists learned that assigning each psychiatrist a CLC to cover was less confusing and prevented mixing of treatment styles and medication choices. Teams also described that refinement encompassed learning what expertise each discipline may bring to the team, which helped their team work more effectively together. One site found that their processes became more efficient when the newly hired nurse case manager began conducting prescreening questions prior to the patient's initial appointment.

Growth and Expansion

Growth and expansion of services encompassed adding spoke sites to be served by tele-GMH teams, offering new services (eg, caregiver groups), and hiring more clinicians. One team developed a virtual interprofessional cognitive assessment clinic in response to an emergent need within a health care system following their loss of a dementia assessment clinic after the lead clinician's retirement. For teams experiencing increasing referrals or additional sites, they met these demands by hiring additional clinicians, such as psychologists, geriatric psychiatrists, clinical pharmacists, and nurse case managers. However, moving toward interprofessional care led to logistical challenges using different disciplines (eg, how neuropsychology fits into the service, how to efficiently use a new nurse manager). A geriatric psychiatrist (ID 16) described challenges in equitably assigning workload and corresponding with referring clinicians.

> *We had to do some work because you've got three different providers covering five states, multiple different sites. And if we're all seeing one or two people here or there per week, it gets challenging for the primary providers there to know 'Who just saw my patient?' and 'Who do I reach out to?'* [ID 16, a geriatric psychiatrist]

Notably, not all teams focused on expansion. Some described stability in their workload, which led to the team decreasing advertising due to a steady stream of consultations. Others reported identifying systems-based challenges, namely serving homebound or rural patients. One geriatric psychiatrist (ID 10) described the need for a social worker to help with identifying local aging services.

> *I'm a single man army here. I don't have any social worker… I know there's [a] psychologist, but sometimes getting information about resources locally [is hard]. Again, it's not one clinic, [it's] multiple clinic[s], I go to so many, so I don't know what exactly is there.* [ID 10, a geriatric psychiatrist]

A geropsychologist (ID 15) noted the absence of geriatric medicine services as a challenge:

> *…if you're going to integrate geriatric mental health, and neuropsychology, you need the primary care in place. It's kind of crazy to be siloed as geriatric mental health when there's no geriatric physical health services in the [facility].* [ID 15, a geropsychologist]

Maintenance and Sustainment of Service

The maintenance and sustainment phase encompassed stability in the interprofessional teams and focused on collaboration with local clinicians. Other key aspects of the maintenance phase were reflections on the impact of the service on patients, caregivers, referring clinicians, and an overall increased access to geriatrics specialty care, as displayed in Table 4, and found within the CFIR construct of reflecting and evaluating.

Key facilitators to maintenance of services were positive interprofessional relationships, including mentoring new team members. One geropsychologist (ID 7) said of the founding tele-GMH team member:

> *I think that she has been a gift to me with regard to just her assistance in taking me under her wing and bringing me along with her in an already established little program that she had.* [ID 7, a geropsychologist]

Similarly, a clinical pharmacy practitioner (ID 12) felt their team nurse was "fantastic… she's been instrumental for some success" because the nurse holds multiple roles, like helping psychology with overflow work, triaging patients, and contacting veterans and facilitating connecting them with tech help. Hiring of support staff, such as a dedicated medical support assistant to assist with scheduling, was deemed to be very supportive, enabling the teams' ongoing success.

Discussion

Principal Findings

Using qualitative methods with multiple interviews conducted with tele-GMH clinicians across a 3-year period, we identified the key activities and determinants of success across three phases: (1) preimplementation, (2) implementation scale-up and expansion, and (3) sustainment of tele-GMH services for older veterans.

The preimplementation phase encompassed the crucial steps of engaging leaders, securing funding/hiring, and defining services. A key determinant of success during this phase was the use of adaptations to the tele-GMH model to meet local needs and priorities. Also important were the characteristics of the individuals involved in developing and delivering the tele-GMH services. The CFIR domains of capability (ie, expertise in GMH) and motivation to care for rural and underserved older veterans were factors that led clinicians to these CRH positions. Expanding virtual positions may be one way to address the persistent geriatrics workforce shortage and enable specialist clinicians to serve the population they trained to serve. Moreover, remote work has been found to be associated with low burnout, particularly for female health care workers [34]. Thus, expanding virtual positions may help individual clinicians while also filling the geographic need for geriatrics care in rural regions [35].

XSL•FO
RenderX

The implementation scale-up and expansion phase was cyclical and iterative, focused on building a referral network and expanding or maintaining services offered to older veterans. Key determinants in this phase included building and maintaining relationships with local clinicians, teaming (or intentional collaboration), doing (making iterative changes to processes), tailoring services for sites, and adapting services in response to feedback. This fits with findings on the importance of partnership alignment, communication, and feedback as determinants of implementing comprehensive geriatrics assessment [36]. A key determinant to both preimplementation and implementation was having the tele-GMH team embedded within CRH, which allowed the clinicians to take advantage of CRH operational knowledge to initiate services. This likely allowed the tele-GMH clinicians to focus on building relationships and designing their program while CRH staff guided them in the logistics of telehealth service delivery. This echoes previous work that identified the critical role of administrative staff in supporting virtual services [37].

Tele-GMH clinicians described periods of maintenance followed by refinement and growth in the third phase. Barriers to implementation, including patient-level factors, virtual care obstacles, and unfamiliarity with local aging resources, were addressed using refinement to processes and engaging nurse case managers, social workers, and telehealth clinical technicians. As found in our previous work with surveys of referring clinicians [22], several barriers impede the uptake of services, including lack of clarity about consultation process logistics (ie, who can place consultations and from which settings), perceptions that older veterans may not benefit from telemedicine, and not following tele-GMH clinician recommendations. Facilitators of the maintenance phase include clear messaging, teaming, relationship building within teams, and care coordination. The maintenance phase warrants future study to better understand the mechanisms underlying high-functioning remote health care teams and how these teams communicate with local VHA and community clinicians. This communication and care coordination is critical as many rural veterans use both VHA and community care [38]. Furthermore, there is a need to understand patient perspectives as they pertain to working with remote teams. A mixed methods study found unclear and overlapping health care clinician roles and limited care coordination to be barriers to the effective virtual primary care for patients with chronic diseases [39].

The growing shortage of both mental health and geriatric clinicians demands innovative and scalable solutions and programs to address the needs of older adults. This work dovetails with calls for integrated geriatric clinical service lines rather than disease-focused service lines [35]. However, due to workforce shortages [2,3] and the limited availability of geriatrics clinicians in rural areas, virtual care models must be considered. Tele-GMH has the potential to be such a program due to the adaptability of the model, sustainability of service delivery with embedded administrative support, and attraction of specialist clinicians to serve older veterans. Strengths of our study include using CFIR to identify determinants of success and barriers to implementation that can be applied in similar program development in other health care systems. Although the tele-GMH service may be adapted to care for veterans with complex needs, broader initiatives to transform health care, such as “Age Friendly Health Systems,” must be pursued to improve care for all older adults [40].

Limitations

Several limitations to this qualitative evaluation warrant consideration. First, the findings are limited to perspectives on VHA and thus may not directly apply to other health care systems. Second, we do not include quantitative outcomes or perspectives from patients or caregivers, which limits the interpretation of the acceptability of the findings and impact on service recipients. Third, our findings rely on tele-GMH clinician self-report, which may not fully capture all VHA perspectives in this report (ie, referring clinician, VHA leadership), although those perspectives have been reported elsewhere [21-23]. Fourth, we did not interview every tele-GMH clinician at each time point, potentially biasing our findings. Fifth, our findings may be biased by sampling of clinicians who chose to work in these roles in the CRH. Sixth, the rapid analytic approach fit with our team-based synthesis; however, it does not allow for the line-by-line analytic depth of traditional qualitative coding approaches.

Conclusions

Our findings provide evidence of implementation factors related to virtual GMH care, which was noted as a main weakness in the broader literature on geriatrics care models [41]. Similar processes emerged across regions in the development and sustainment of tele-GMH services, which allowed for the creation of a unified roadmap. The roadmap provides a pathway that other regions may follow to create tele-GMH services to enhance access to specialty care for aging rural veterans. Our findings underscore the role of VHA as a learning health system [42] where experts and innovators can pilot and refine new models of care.

Acknowledgments

Portions of these data were presented as posters at the American Association of Geriatric Psychiatry annual meeting in March 2023 in New Orleans, LA, United States, the Academy Health Dissemination & Implementation Conference in December 2023 in Washington, DC, and the American Association of Geriatric Psychiatry annual meeting in April 2026 in Arlington, VA, United States. Abstract

Background: Since the COVID-19 pandemic, telehealth has become a core component of modern health care, encompassing both synchronous services (real-time video or phone) and patient portals, which offer a wide range of online features to streamline care delivery, including asynchronous communication and access to medical records. Older adults often face greater barriers to these technologies, potentially widening health care access gaps.

Objective: This study examines factors influencing the adoption of patient portals and synchronous telehealth in the postpandemic era. It compares the 2 modalities and identifies distinct usage patterns across age groups to inform targeted strategies.

Methods: We analyzed data from the Health Information National Trends Survey (HINTS) Cycles 6 and 7. Outcomes over the past 12 months included (1) frequency of patient portal use (continuous), (2) use of synchronous telehealth (binary), and (3) no engagement with any telehealth services (binary). Key variables included demographics, socioeconomic status, technology familiarity, and health care behaviors. Age groups were categorized as young (18–49 years), middle-aged (50–64 years), and older adults (≥65 years). Interaction terms between age groups and other variables were included to uncover age-specific patterns. To mitigate multicollinearity arising from the interaction terms, we used penalized linear and logistic regression models using the least absolute shrinkage and selection operator (LASSO) penalty without survey weights, supplemented by bootstrapping to evaluate the stability. Using the selected variables, we then fitted survey-weighted generalized linear models to account for the complex design of the HINTS survey and more accurately represent the US population.

Results: Among 12,865 respondents, 36.1% (n=4638) were 65 years or older. Overall, 65.2% used patient portals and 38.4% used synchronous telehealth. Age alone was not a significant factor, but older adults exhibited distinct patterns. Older adults with higher care frequency were less likely to use patient portals (coefficient −0.07, 95% CI −0.10 to −0.04; P<.001). Those who completed the survey online in this age group were more likely to use patient portals (coefficient 0.32, 95% CI 0.18-0.47; P<.001) than to use a paper form. Older Black or African American patients were less likely to use patient portals (coefficient −0.30, 95% CI −0.45 to −0.16; P<.001). These age-specific patterns were identified only in patient portal use, not in synchronous telehealth use.

Conclusions: Telehealth usage among older adults differs in subtle ways from other age groups, and the factors driving adoption vary between patient portals and synchronous care. These findings underscore the need for age- and context-specific strategies to enhance the uptake of both types of services.

telehealth; eHealth; mHealth; virtual healthcare; health services for the aged

Introduction

Telehealth has emerged as a cost-effective and integral component of modern health care, offering both patient portals and synchronous care (eg, real-time video or phone consultations) to improve access to care [1]. Synchronous telehealth facilitates live communication with health care providers without the need for long-distance travel, while patient portals streamline care delivery and reduce unnecessary office visits through various features such as asynchronous communications, access to medical records, medication refills, and appointment scheduling.

XSL•FO
RenderX

As the demand for remote health care continues to grow, telehealth has expanded beyond primary care into numerous specialties, with many providers now offering both in-person and virtual care options [2]. Despite its many advantages, telehealth has also introduced new challenges, particularly in exacerbating existing disparities in health care access [3]. For instance, individuals living in areas with limited internet infrastructure have struggled to benefit from telehealth services [4,5]. Moreover, the digital divide, driven by gaps in digital literacy, has hindered telehealth adoption, especially among older adults [5,6]. Additional barriers such as limited health literacy [7] and English proficiency [8] further complicate access and use.

Although research on telehealth is expanding, critical gaps remain. The barriers to telehealth use may be intricately linked to the modality itself, with patient portal and synchronous services presenting distinct challenges and opportunities. This suggests that tailored strategies may be necessary to enhance use across different modalities. Furthermore, patterns of telehealth use may vary significantly by age group, indicating the need for age-specific approaches to promote equitable access.

Using survey data collected in the postpandemic period, this study investigates the complex relationships between 2 types of telehealth modalities (ie, patient portals and synchronous telehealth) and various patient factors, including demographic factors, socioeconomic status, medical conditions, care behaviors, and technological proficiency. For the development of effective telehealth interventions, we compare the key drivers of use across modalities. Additionally, we explore how these factors differ among age groups, particularly among older adults, testing the hypothesis that telehealth usage patterns are uniquely shaped by age-related characteristics.

Methods

Data

In this study, we used the Health Information National Trends Survey (HINTS) Cycles 6 and 7, where the surveys were conducted in 2022 and 2024, respectively [9]. These surveys include several categories of questions, such as, “Looking for Health Information, Internet and Technology Use” (in Cycle 7; referred to as “Using the Internet to Find Information” in Cycle 6), “Your Health Care,” “Telehealth,” and “You and Your Household.” Assuming no period effects, as all the survey periods were conducted postpandemic, we harmonized the 2 datasets without accounting for the survey cycles. We used only overlapping variables with necessary name and type adjustments (see Table S1 in Multimedia Appendix 1) and combined the full sample weight and 50 replicate weights following HINTS guidelines [10]. Details on data preparation are available in the GitHub repository [11].

Outcomes

To identify the use of patient portals and synchronous telehealth, we used the following survey questions: “How many times did you access your online medical record or patient portal in the last 12 months?” (AccessOnlineRecord2 in Cycle 6 and AccessOnlineRecord3 in Cycle 7) for patient portal usage, and “In the past 12 months, did you receive care from a doctor or health professional using telehealth?” (ReceiveTelehealthCare) for synchronous telehealth usage. The patient portal question captures usage frequency, with 5 response options, including 0, 1 - 2, 3 - 5, 6 - 9, and 10 or more times. Patients who selected “I do not have an online medical record or patient portal” were classified as having no use (ie, 0 times). For simplicity in implementing parametric models, this outcome was treated as continuous in the model [12], with the 5 response categories coded from 0 to 4. On the other hand, the question about synchronous telehealth focuses on the method of experience, with possible answers being no, yes by video, yes by phone call, and yes by both. For analysis, all “yes” responses were combined and treated as a binary outcome. Additionally, we created a dichotomous variable “Neither” to indicate patients who had not used any form of telehealth, meaning neither patient portals nor synchronous telehealth. We excluded those who did not answer at least one of the telehealth questions (ie, AccessOnlineRecord2/3 or ReceiveTelehealthCare) to ensure consistent analytic samples across all outcomes.

Variables

Based on existing studies [5,6,13-15], variables included demographic and socioeconomic status information (ie, age, race, ethnicity, birth sex, total number of households, and residence), tech-savviness (ie, internet use and social media use), surveys, and care behaviors (ie, frequency of care services, ability to take good care of health). The 5 age categories in the data (ie, 18 - 34 years, 35 - 49 years, 50 - 64 years, 65 - 74 years, and ≥75 years) were combined into the following 3 groups, including young (18-49 years), middle (50-64 years), and old (≥65 years). Missing values for the independent variables were imputed using multivariate imputation by chained equations (MICE) [16] without survey weights. This imputation process included all independent variables and both dependent variables (patient portal and synchronous telehealth use) and produced converged imputed values after 5 iterations. Table S1 in Multimedia Appendix 1 presents the missing rates.

Models

To examine how the 3 outcomes (ie, patient portals, synchronous, and Neither) were associated with various variables across age groups, our models incorporated interaction terms between age groups and the other variables. The 3 models used the same analytic cohort and the same set of independent variables. For the patient portal and synchronous telehealth models, use of the other telehealth modality was also added to the set of independent variables (ie, synchronous telehealth uses in the patient portal model, and vice versa). To facilitate straightforward interpretation, ordinal independent variables, in addition to the patient portal frequency outcome, were treated as continuous in the models [12].

We used a two-step approach: (1) variable selection using unweighted penalized regression models and (2) statistical inference with survey-weighted generalized linear models. As the first step, we selected variables to prevent multicollinearity and overfitting from interaction terms. This screening process was conducted solely for model specification and did not involve

XSL•FO
RenderX

the use of survey weights. We built penalized linear or logistic regression models with the least absolute shrinkage and selection operator (LASSO) penalty for each outcome [17]. We applied LASSO linear regression for the patient portal outcome and LASSO logistic regression for the synchronous telehealth and Neither outcomes. The LASSO hyperparameter, penalty magnitude (λ), was determined using 5-fold cross-validation and selected based on the penalty value that produced the smallest average error across the 5 validation sets. To assess stability, we bootstrapped 500 samples, fitted penalized linear models with LASSO, and calculated the selection frequency, 95% CIs, and *P* values for each variable based on *t* tests, defined as the mean divided by the SD [18]. Variables with a *P* value of less than .05 were selected.

In the second stage, we fitted survey-weighted generalized linear models using the selected variables to account for the complex design of the HINTS survey and ensure accurate representation of the US population [19]. We used the full sample weight to produce population-level estimates and the replicate weights to calculate the standard error and variance of those estimates. For model evaluation, adjusted R^2 (for the patient portal model) and pseudo-R^2 (for the synchronous and Neither models) were used to assess goodness of fit [20,21]. In human subject research, these values between 0.10 and 0.30 are generally considered acceptable [21,22]. We reported coefficients for linear regression, odds ratio (OR) for logistic regression, and 95% CI and *P* value for both. For inference, a positive coefficient indicates being more likely to use patient portals, while an OR over 1 indicates being more likely to use synchronous telehealth in the synchronous model or never use any form of telehealth in the Neither model. The variable significance was determined when the variable's *P* value was smaller than the significance level (.05).

All analyses were conducted using R programming (version 4.4.3; R Core Team) with the following packages: *forestplot* [23], *glmnet* [17,24], *mice* [16], and *survey* [19].

Sensitivity Analyses

We conducted sensitivity analyses under 3 different scenarios to assess potential bias arising from data cleaning. First, to assess potential bias introduced by imputation, we created 5 different imputed datasets using the same imputation method (ie, MICE) with different random seeds. Models were then built on each imputed dataset, and significant variables were compared across them. Second, since survey form type may reflect technology familiarity, we excluded this variable from the entire analysis (from imputing missing values through constructing models) and then investigated changes in the identifications of significant factors among other technology familiarity variables (ie, social media interaction and internet use). Finally, since we treated ordinal patient portal use as continuous, we applied an additional modification to confirm its reasonableness, categorizing portal use into 2 groups (<3 and ≥3 times), treating it as binary, and rerunning the entire analysis for this outcome. This new outcome type required a different regression model than the original, making the results not directly comparable in size or magnitude. Instead, we focused on whether the same variables were significant and whether their effects pointed in the same direction (positive or negative).

Ethical Considerations

This study used publicly available, deidentified HINTS data to conduct a secondary analysis. The dataset contains no personal identifiers. Because the dataset is publicly available and deidentified, this research does not constitute human subjects research as defined by federal regulations (45 CFR 46.102) and is therefore exempt from institutional ethics review. Accordingly, institutional review board review at the authors' institution was not required.

Results

Data

Excluding missing responses to either patient portal or synchronous telehealth usage, we identified 12,865 patients in this study. They were comprised of 4714 (36.6%) young-age (18-49 years), 3513 (27.3%) middle-age (50-64 years), and 4638 (36.1%) old-age (≥65 years) patients. Non-Hispanic White patients accounted for more than half (7204/12,865, 56%), followed by Hispanic (2519/12,865, 19.6%), Non-Hispanic Black or African American (1979/12,865, 15.4%), and Non-Hispanic Asian (680/12,865, 5.3%). More female patients (7739/12,865, 60.2%) participated in this survey than male (5126/12,865, 39.8%). Additionally, 37.7% of patients (4854/12,865) resided in large metropolitan areas and 22.0% (2828/12,865) in large fringe metropolitan areas, while 13.4 % lived in nonmetropolitan areas (1730/12,865). Table 1 provides an overview of the unweighted distributions by telehealth modalities, based on the imputed dataset.

Within this cohort, 8383 (65.2%) and 4942 (38.4%) used patient portals and synchronous telehealth at least once in the past 12 months, respectively. Patients who used patient portals used synchronous telehealth more, and vice versa. For example, of the 4942 patients who used synchronous telehealth, 3877 (78.5%) also used patient portals at least once. Moreover, the likelihood of using synchronous telehealth increased progressively with higher levels of patient portal use. Compared to those who never used patient portals, individuals who used it at least 10 times were significantly more likely to use synchronous telehealth, with an OR of 4.9 (See Table 2).

Table . Unweighted joint distributions of patient portal and synchronous telehealth use.

Variables	Total, n (%)	Patient portals

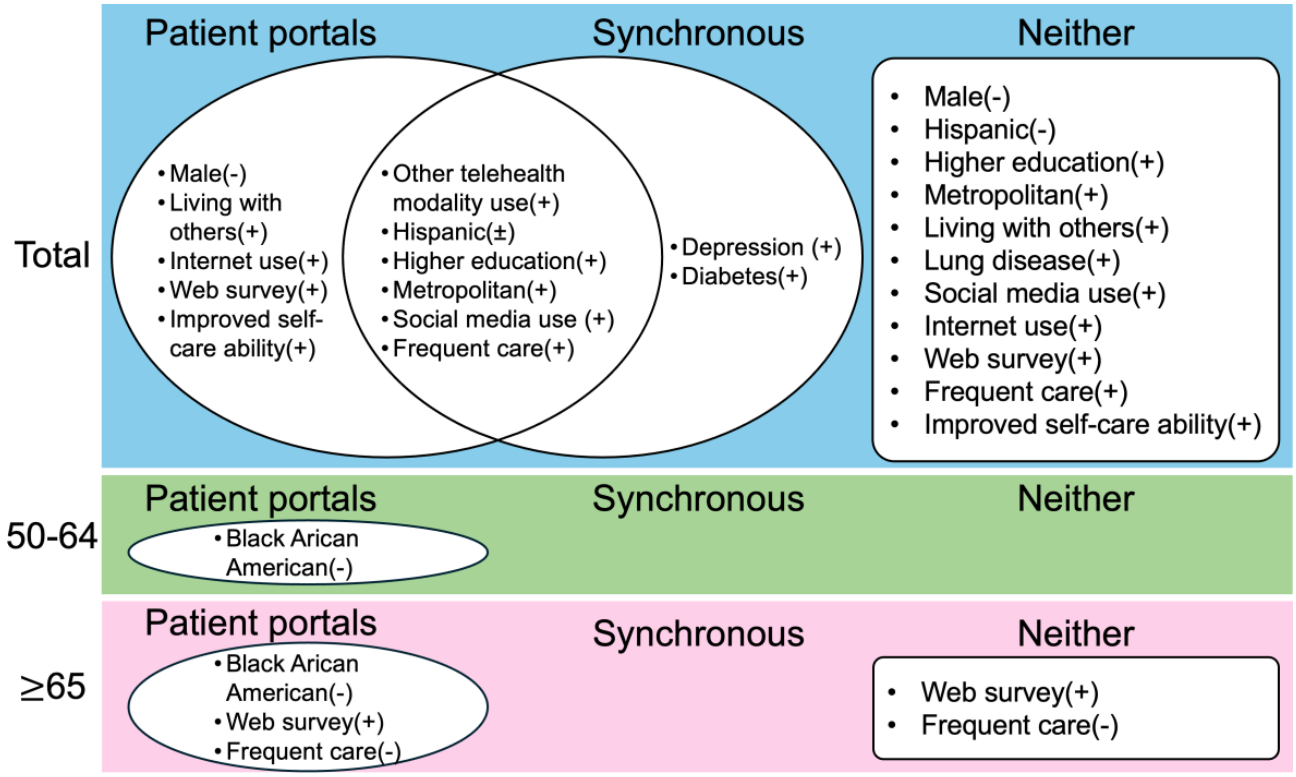
[a]Not applicable.

By age group, younger participants were more likely to use both patient portals and synchronous telehealth services (see age rows in Table 1). Among those aged 18 - 49 years (n=4714), 3375 (71.6%) participants used patient portals at least once, compared to 2377 (67.7%) in the 50 - 64 years age group (n=3513) and 2631 (56.7%) among those aged 65 years and older (n=4638). Similarly, synchronous telehealth was used by 1993 (42.3%) participants in the youngest group, 1375 (39.1%) in the middle-aged group, and 1574 (33.9%) in the oldest group. Furthermore, the mode of synchronous telehealth varied by age. Among those who used synchronous telehealth, use of phone calls only (without video) was significantly more common in the older group (672/1574, 42.7%) than in the younger group

XSL•FO
RenderX

(547/1993, 27.4%) and the middle-aged group (423/1375, 30.8%; P<.001; χ^2; see Table 3).

Table . Synchronous telehealth modes by age groups among those who used synchronous telehealth.



Variables	Total	Synchronous telehealth mode, n (%)		
		By video, n (%)	By phone call (voice only with no video), n (%)	Some by video and some by phone call, n (%)

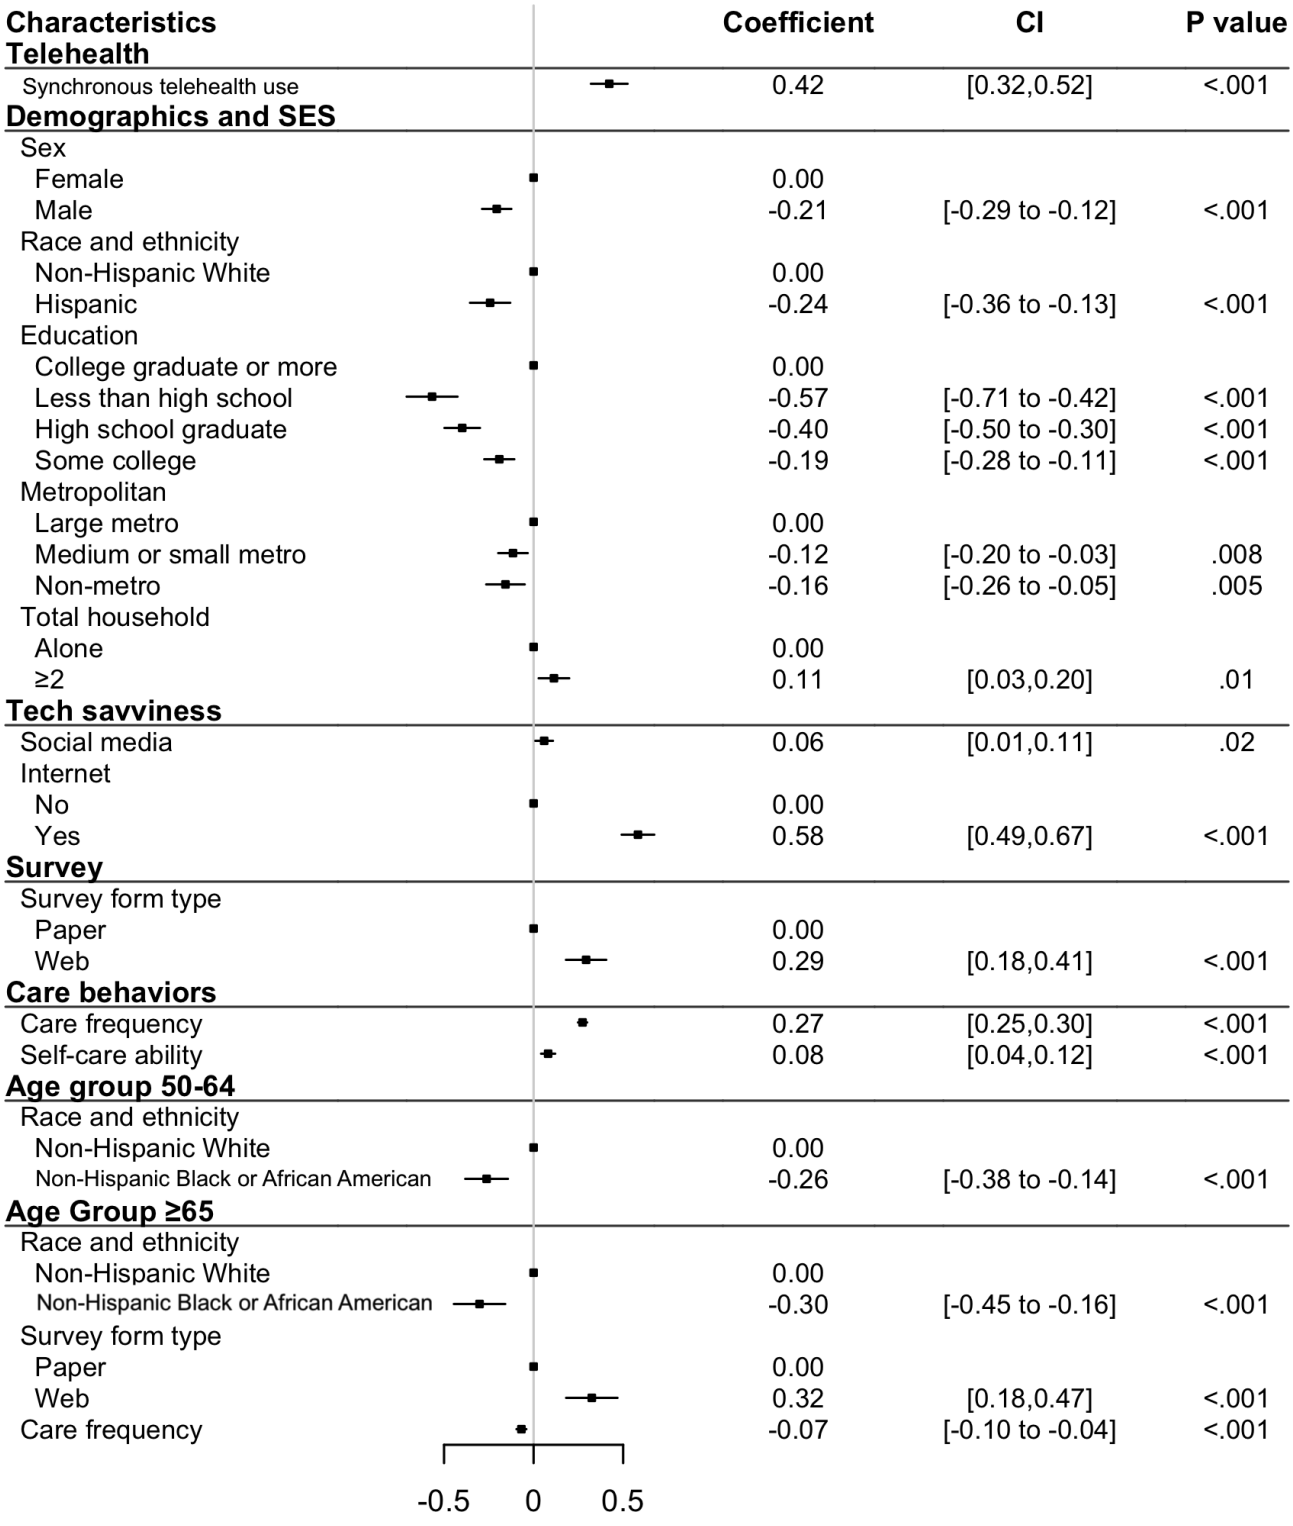
≥65	1574 (33.9)	577 (36.7)	672 (42.7)	325 (20.6)

Two-Step Approach for Variable Screening and Model Inference

Unweighted penalized regression models with bootstrapping were applied to select variables: 21 for the patient portal model, 13 for the synchronous model, and 20 for the Neither model, as shown in Tables S2-S4 in Multimedia Appendix 1. Many interaction terms were not selected because the age-specific subgroups had smaller sample sizes. Even though variables within the subgroups were consistently selected more than 480 out of 500 times, their P value was sometimes larger than .05 due to the sample sizes (eg, survey type for the middle-aged group in the patient portal model). Estimates, confidence intervals, P values, and selection frequencies for all variables are reported in Table S2-S4 in Multimedia Appendix 1.



Using the selected variables, we constructed survey-weighted generalized linear models for the 3 outcomes. The adjusted R^2 of the patient portal model was 0.31, while the pseudo-R^2 values of the synchronous telehealth model and the Neither model were 0.15 and 0.22, respectively. Based on the acceptable range of 0.10-0.30 [21,22], all models exhibited a satisfactory goodness of fit. Figure 1 presents the unique and shared significant variables identified in the models, and Figures 2-4 detail the direction and strength of associations for each model.

Figure 1. Shared and unique significant variables associated with patient portal and synchronous telehealth use, both overall and across different age groups. The figure also highlights significant variables identified in the Neither model. A plus (+) symbol indicates greater telehealth use, a minus (−) indicates less use, and a plus or minus (±) symbol denotes mixed directions of association.

Figure 4. Significant variables identified from the neither model. OR: odds ratio; SES: socioeconomic status.

Use of one type of telehealth service was positively associated with use of the other modality (coefficient 0.42, 95% CI 0.32-0.53; *P*<.001 for patient portals; OR 1.35, 95% CI 1.26-1.43; *P*<.001 for synchronous). In terms of demographics and socioeconomic status, male patients were less likely to use patient portals than female (coefficient −0.21, 95% CI −0.29 to −0.12; *P*<.001), there was no significant difference in synchronous use between male and female patients (*P*=.10; see Table S6 in Multimedia Appendix 1). Additionally, Hispanic patients showed a contrasting pattern: they were more likely to use more synchronous telehealth (OR 1.30, 95% CI 1.10-1.54; *P*=.003) but less likely to use patient portals (coefficient −0.24, 95% CI −0.36 to −0.13; *P*<.001). Furthermore, middle-aged and older non-Hispanic Black or African American patients (aged 50 years and older) were less likely to use patient portals (coefficient −0.26, 95% CI −0.38 to −0.14; *P*<.001 for 50 - 64 years; coefficient −0.30, 95% CI −0.45 to −0.16; *P*<.001 for ≥65 years).

Compared to patients in large metropolitan areas, those in medium or small metropolitan and nonmetropolitan areas were less likely to use either telehealth modality (patient portals: coefficient −0.12, 95% CI −0.20 to −0.03; *P*=.008 for medium or small metropolitan, coefficient −0.16, 95% CI −0.26 to −0.05; *P*=.005 for nonmetropolitan; synchronous: OR 0.77, 95% CI 0.64-0.93; *P*=.008 for medium or small metropolitan, OR 0.75, 95% CI 0.62-0.92; *P*=.008 for nonmetropolitan). Finally, among the demographic and socioeconomic variables, individuals living with other household members were more likely to use only patient portals (coefficient 0.11, 95% CI 0.03-0.20; *P*=.01). Those with higher educational attainment were more likely to use both services (patient portals: coefficient range [−0.57 to −0.19], 95% CI −0.71 to −0.11; *P*<.001 for all the other categories [less than high school, high school graduate, some

XSL•FO
RenderX

college]; synchronous: OR 0.80, 95% CI 0.69-0.94; *P*=.006 for high school graduate; see Figures 2 and 3).

Medical conditions played a role mainly for synchronous telehealth. Patients with depression were more likely to use synchronous telehealth services (OR 1.98, 95% CI 1.72-2.28; *P*<.001). Diabetes was associated with increased use of synchronous telehealth (OR 1.29, 95% CI 1.12-1.50; *P*=.001), and patients with lung disease were less likely to avoid telehealth altogether (OR 0.74, 95% CI 0.57-0.96; *P*=.02).

In the tech-savviness category, social media use was positively associated with telehealth use across both modalities (patient portals: coefficient 0.06, 95% CI 0.01-0.11; *P*=.02; synchronous: OR 1.37, 95% CI 1.24-1.51; *P*<.001). Moreover, those who responded using the internet were more likely to use patient portals (coefficient 0.58, 95% CI 0.49-0.67; *P*<.001). For the survey type, participants who completed web-based surveys were more likely to use patient portals than those who completed paper-based surveys (coefficient 0.29, 95% CI 0.18-0.41; *P*<.001), with this trend being even stronger among older adults (coefficient 0.32, 95% CI 0.18-0.47; *P*<.001).

Regarding care behaviors, patients who saw health care professionals more frequently were more likely to use telehealth (coefficient 0.27, 95% CI 0.25-0.30; *P*<.001 for patient portals; OR 1.24, 95% CI 1.19-1.29; *P*<.001 for synchronous). However, among older patients, this association was less pronounced for patient portals (coefficient −0.07, 95% CI −0.10 to −004; *P*<.001). Additionally, patients who reported being confident in managing their own health were more likely to use patient portals (coefficient 0.08, 95% CI 0.04-0.12; *P*<.001).

Sensitivity Analyses

Table S5-S7 in Multimedia Appendix 1 exhibit the comparisons of the significant variables across models using the imputed dataset in the main text and 5 different imputations. Most significant variables identified in the main text models remained significant. However, due to the small number of samples in the age subgroups, the interaction terms sometimes became insignificant, non-Hispanic Black or African American in the patient portal models was identified as significant 3 out of 6 instances for both the 50 - 64 years and ≥65 years age groups (see Table S6 in Multimedia Appendix 1).

As illustrated in Table S8-S10 in Multimedia Appendix 1, after excluding the form type variable, the effect of internet use became more pronounced in both the patient portal telehealth model (see Table S8 in Multimedia Appendix 1) and the Neither model (see Table S10 in Multimedia Appendix 1), where an OR closer to “0” indicates a much higher likelihood of using one or both telehealth options. For synchronous telehealth, the form type variable was not identified as significant in the original model, resulting in minimal change (see Table S9 in Multimedia Appendix 1).

Finally, the model treating patient portal use as a continuous variable largely shared significant predictors with the binary model, as shown in Table S11 in Multimedia Appendix 1. Each model, however, had a few unique significant variables: for the continuous model, nonmetro, social media use, and non-Hispanic Black or African American individuals aged 50 - 64 years; for the binary model, high blood pressure and nonmetro status among those aged 65 years or older.

Discussion

Principal Findings

Using the harmonized HINTS Cycles 6 and 7 data, including national representative patient populations, this study offers a unique examination of both patient portal and synchronous telehealth use. While both services are delivered remotely and therefore share foundational similarities, their distinct functionalities lead to divergent patterns of use. By analyzing a range of factors, including demographics, socioeconomic status, and technological proficiency, we identified several common predictors associated with the use of both modalities, as well as unique factors specific to each. Furthermore, we discovered the variations across age groups, particularly among those aged 50 - 64 years and those 65 years and older. These findings contribute to a deeper understanding of age-related differences in telehealth use and could offer insights for enhancing patient experience and promoting broader telehealth adoption.

Methodologically, our 2-step approach effectively addresses potential multicollinearity during variable selection and ensures nationally representative estimates. The bootstrapped variable selection process helps build a parsimonious set of variables while accommodating multiple interaction terms. With this reduced set of variables, the survey-weighted generalized linear models enable robust population-level statistical inference, providing both nationally representative estimates and measures of their variability.

Unique Patterns of Telehealth Use Among Older Adults

While previous research has suggested that older adults are generally less likely to use telehealth [5,6], our models did not find age itself to be a significant predictor. Instead, our findings reveal that older adults exhibit unique usage patterns that differ from the general population in several ways; some are entirely new (eg, race-related differences), some are more pronounced (eg, survey form type), and others are weaker (eg, care frequency). These nuances underscore the importance of targeted investigations into telehealth use among older adults.

As an example of an emerging pattern, our data show non-Hispanic Black or African American patients overall used patient portals at rates similar to non-Hispanic White, which contradicts findings from prior research [25,26]. However, within this race group, individuals aged 50 years and older were less likely to use patient portals in some models trained on different imputed datasets. On average, responses shifted 0.26 points toward the “no-use” end of the scale for those aged 50 - 64 years and 0.30 points for those aged 65 years and older. This suggests that the digital divide in patient portal services may not be solely age-based but could intersect with race, underscoring the possible need for multidimensional strategies to address disparities in the use.

XSL•FO
RenderX

In terms of stronger patterns in the old patient group (≥65 years), old patients who completed the web-based survey were more likely to use patient portals than the general population, with their reported usage increasing by an average of 0.32 points toward the "10 or more than 10 times" end of the scale. In the sensitivity analysis, completing a web-based survey likely reflects greater familiarity with technology. Taken together, these findings suggest that comfort with technology can significantly improve engagement with patient portal services. As such, targeted technology education initiatives for older adults could play a vital role in promoting patient portal adoption and improving health care accessibility for this population, as suggested in prior research [27].

Regarding weaker patterns observed in the old population (≥65 years), patients who frequently visited health care providers were more likely to use patient portals in the general population, but this association was weaker among older adults. For each one-point increase in visit frequency toward the "10 or more times" end of the scale, responses for patient portal use were, on average, 0.07 points lower. Patients who receive care more often are generally exposed to more educational opportunities about patient portals and have greater chances to use patient portals. However, older adults may prefer addressing all concerns during in-person visits rather than through patient portals.

Key Differences in Drivers of Patient Portals and Synchronous Telehealth

The use of patient portals and synchronous telehealth shares some common drivers, such as residing in metropolitan areas and having higher levels of education. Particularly, patients who used one type of telehealth were more likely to use the other, consistent with previous studies suggesting that telehealth experience can enhance patient satisfaction and encourage further use [28,29]. However, important differences exist between the two. Patient portal use is largely shaped by patient characteristics, whereas synchronous telehealth depends primarily on the availability of real-time care options. Patients with diabetes and those with depression were more likely to use synchronous telehealth, with odds that were 98% higher and 29% higher, respectively, compared to those without these conditions. Additionally, those with lung disease were more likely to use either type or both, as their odds of not using any form of telehealth decreased by 26%. This finding likely reflects the nature of care required. For example, psychiatric care and diabetes care can involve synchronous consultations and telemonitoring [30,31]. Chronic obstructive pulmonary disease patients may involve a wide range of services, such as telerehabilitation, health education, telemonitoring, early detection of exacerbations, psychosocial support, and smoking cessation, delivered through both modalities [32,33]. These findings highlight the potential for synchronous telehealth patients who require long-term care and frequent visits.

On the other hand, the patient portal model included more variables related to tech-savviness (ie, internet use and completion of web-based surveys) in addition to social media use, which was commonly identified as significant for both modalities. Patients who used the internet scored, on average, 0.58 points higher toward the "10 or more than 10 times" end of the scale in patient portal usage, and those who completed the HINTS online scored 0.29 points higher. This may be due to the multiple functions available in patient portals, such as sending images and secure messages, which require a certain level of technological familiarity. In contrast, synchronous telehealth can be conducted not only via video but also through phone calls, and voice-only visits demand far fewer technical skills. Additionally, a one-unit increase in patients' self-care ability toward the "very confident" end of the scale was associated with greater patient portal use, corresponding to an average increase of 0.08 points, but showed no association with synchronous telehealth use. This may be because patient portal features, such as viewing lab results or refilling prescriptions, are more directly aligned with self-management behaviors [34,35].

In terms of demographic and socioeconomic factors, prior research shows that male patients are generally less likely to use telehealth [36,37]. However, this study confirms that this pattern applies only to patient portal use, with an average decrease of 0.21 points toward the "no use" end of the scale, but not to synchronous telehealth. Additionally, patients living with household members were also more likely to use patient portals only. This pattern may be linked to the shared access features of patient portals [38]. Family members or care partners can log into the patient's account to help manage their care, which may encourage patients to engage with the portal and participate more actively in their health care. Finally, age-specific effects were identified only for patient portal use. These findings suggest that promoting patient portal adoption should be particularly tailored to individual patient characteristics.

Interestingly, Hispanic patients showed contrasting usage patterns; they were more likely to use synchronous telehealth but less likely to use patient portals. Their odds of using synchronous telehealth increased by 30%, while their responses for patient portals were, on average, 0.24 points lower toward the "no use" end of the scale. This aligns with one side of the existing literature, which remains inconclusive [39,40]. One possible explanation is that while health care providers may offer services in Spanish, patient portal platforms often lack adequate translation features, creating barriers for patients with limited English proficiency [41]. To address this, multilingual support and culturally informed design are essential for effective telehealth delivery.

Limitations

This study is based on observational, retrospective data from surveys not specifically designed for this research. As such, we were unable to explore in-depth questions, such as patient satisfaction with telehealth across both modalities and the underlying reasons for choosing patient portals and synchronous care. Furthermore, we applied survey weights to the final inference models to improve sample representativeness, but they could also be used for imputing missing values [42]. Additionally, despite the complex survey design approach, the generalizability of our findings remains limited. Survey weights adjust nonresponse based on observed characteristics, but

XSL•FO
RenderX

unobserved factors may still influence participation. Residual confounding, such as broadband connectivity and state-level telehealth policies, both known to affect remote care use, was not directly measured. For example, counties with greater broadband availability have been shown to exhibit significantly higher telehealth use [43,44], and policy variations across states continue to impact access in rural areas [45]. Therefore, future research using multilevel designs or incorporating additional factors (eg, infrastructure and policy indicators) is warranted.

Another potential limitation is endogeneity between patient portal use and health care use frequency. Individuals who have more in-person health care service encounters may receive more provider recommendations to use patient portals, leading to higher portal adoption and engagement. Such unobserved factors may simultaneously drive greater portal use [46,47]. Future analyses could apply lagged models to test temporal ordering (eg, whether prior care use predicts later portal engagement) or use instrumental variable approaches, such as broadband access or provider-level promotion, to better account for endogeneity and unobserved confounding.

While harmonizing Cycles 6 and 7, we assumed no survey period effects. However, as shown in Table S12 in Multimedia Appendix 1, the use of patient portals and synchronous telehealth varied across cycles. In Cycle 7, participants reported more frequent use of patient portals and less frequent use of synchronous telehealth compared to Cycle 6 (all P values <.001 and chi-square tests). Future research should account for these period differences.

As shown in Table 2 and suggested in existing research [5,48], we recognize that disaggregating synchronous telehealth into video and phone visits could provide valuable insights. However, splitting synchronous encounters in our dataset resulted in small cell sizes within key age strata, leading to unstable estimates and reduced statistical power. Therefore, we retained a combined synchronous category in the primary analyses while noting potential modality differences as an important direction for future research with larger samples.

Finally, in the sensitivity analysis assessing potential bias from missing data imputation, race was sometimes identified as significant and at other times not. A possible explanation is the relatively higher missing rate for races (8.6%). Obtaining more complete observations would strengthen the robustness of our findings.

Conclusions

This study identifies both shared and distinct factors significantly associated with patient portal and synchronous telehealth use, as well as age-specific use patterns. These insights contribute to a deeper understanding of how to effectively promote both modalities, particularly among aging populations. Notably, the increased use of patient portals among older adults who are more technologically adept suggests that ongoing digital education initiatives may enhance telehealth adoption in this demographic. Furthermore, targeted outreach to specific demographic groups among old patients, such as non-Hispanic Black or African American, may be necessary to address disparities in telehealth use. Collectively, these findings offer valuable guidance for optimizing telehealth implementation strategies and advancing equitable telehealth delivery.

Abstract

Background: Digital health technologies offer promising solutions for managing chronic pain and depression in older adults, yet low-income populations with limited digital literacy face substantial barriers to access. Community-based approaches that leverage existing care infrastructure may bridge this digital divide, but evidence remains limited on effective integration strategies for digitally excluded populations.

Objective: We evaluated a multimodal digital health monitoring platform for this underserved population through 6-week living lab trials with 86 low-income Korean older adults (43 intervention and 43 age- and gender-matched controls) and 25 community caregivers.

Methods: Participants were recruited offline from recipients of government-supported community care services. The platform integrated chatbot surveys, smartwatch monitoring, and motion sensors, generating personalized traffic-light alerts when health indicators deviated from individual baselines and triggering real-time caregiver notifications for persistent declines. Mobile apps for older adult users and caregivers, along with a centralized monitoring system for community center managers, were provided to the intervention group, while controls received standard community care. Pre- and posttest surveys assessed changes in pain-related functional limitations, depressive symptoms, sleep quality, and system usability through face-to-face assessments. Caregivers documented platform-triggered interventions.

Results: Following attrition due to illness (n=3) and participation burden (n=4), we analyzed 1318 days of continuous monitoring data from 35 intervention participants (mean 37.7, SD 8.8 days per participant), with 77 participants (35 intervention and 42 control) completing pre-post assessments. Distinct patterns emerged in 24-hour heart rate profiles: participants experiencing higher-than-usual pain demonstrated elevated heart rates during early morning (5-8 AM) and late evening (10-11 PM) hours compared to their low-pain days. Multilevel modeling revealed significant within-person associations between digital biomarkers and symptoms. Heart rate variability (P=.02) and moderate physical activity (P=.05) were associated with same-day pain. Heart rate variability (P=.03) and long wake episodes during sleep (P=.03) predicted next-day pain. Shorter sleep duration (P=.03) and lower sleep efficiency (P=.05) were associated with same-day depressive symptoms. A significant group-by-time interaction was observed for pain-related functional limitations (P=.03): the intervention group maintained baseline levels while the comparison group reported increased functional limitations. Depressive symptoms, sleep quality, and platform usability did not show significant changes. Community caregivers successfully conducted 37 health decline–triggered interventions during regular service hours (25 hours per week), demonstrating integration of digital monitoring with existing care workflows.

XSL•FO
RenderX

Conclusions: Integrating digital health monitoring within existing community care infrastructure may be a feasible approach to supporting vulnerable older adults. The intervention was associated with maintained pain-related functional limitations, while depressive symptoms and sleep quality showed no significant changes, possibly due to the 6-week duration. This feasibility study provides preliminary support for digital-human integration models to address health equity, though randomized controlled trials are needed to establish causal relationships and isolate active intervention components.

Introduction

The global demographic shift toward population aging has created an urgent need for innovative health care solutions [1,2]. Digital health technologies offer unprecedented opportunities for continuous monitoring and personalized care [3,4], particularly valuable for older adults managing multiple chronic conditions, including pain and depression [5,6]. However, the populations who could benefit most from these innovations—low-income older adults with limited digital literacy [7,8]—face the greatest barriers to accessing them [2,9]. This digital health divide is especially pronounced among socially isolated older adults, who experience higher rates of depression and chronic pain while lacking the support networks essential for technology adoption and health management [10,11].

Digital phenotyping—the continuous collection of behavioral and physiological data through digital devices—has shown promise in detecting and managing pain and mental health conditions in various populations [12-17]. Studies have demonstrated associations between wearable sensor data and depression symptoms, with heart rate variability (HRV), sleep patterns, and physical activity (PA) serving as reliable indicators of mental health status. Similarly, smartphone-based assessments have successfully captured daily fluctuations in pain and functional limitations among adults with chronic conditions. Recent evidence suggests that continuous monitoring can detect symptom changes before clinical deterioration, enabling timely interventions [3,18-20]. However, most digital phenotyping research has focused on younger, digitally literate populations, leaving a critical gap in understanding how these technologies might benefit older adults who face both high disease burden and significant technology barriers [5,21].

Multiple factors contribute to the digital exclusion of older adults. Age-related sensory and cognitive changes create difficulties in learning new technologies [22], while low income limits access to devices and internet connectivity [7,23,24]. Social isolation compounds these challenges, as older adults lack the informal support networks that facilitate technology learning [2]. Previous digital health interventions for older adults have shown mixed results, often failing due to high dropout rates and usability issues [25,26]. Even well-designed platforms struggle when they require direct interaction from users with limited digital skills and cognitive impairments [27,28]. These failures highlight a fundamental design flaw: most digital health solutions assume a level of digital literacy that many vulnerable older adults do not possess, perpetuating rather than addressing health inequities.

Emerging evidence suggests that community-based approaches may overcome these barriers. Studies have shown improved outcomes when digital interventions are delivered through trusted intermediaries such as nurses or trained caregivers [29-31]. Living lab methodologies, which embed technology development within users' natural environments, have demonstrated success in creating solutions that are feasible and sustainable in real-world settings [29,32]. In many countries, existing community care infrastructure already provides regular contact between formal caregivers and vulnerable older adults. These established relationships and routine visits represent an untapped opportunity for digital health delivery. By positioning caregivers as technology intermediaries rather than expecting direct use by older adults, digital health platforms could leverage existing human infrastructure to bridge the digital divide.

This study addresses this critical gap by evaluating the feasibility and preliminary effectiveness of integrating multimodal digital health monitoring within existing community care infrastructure for low-income, socially isolated older adults in South Korea. Using a 6-week living lab quasi-experimental design with an intervention and matched comparison group, we aim to answer the following three research questions: (1) Can digital biomarkers derived from continuous monitoring predict daily variations in pain and depression among older adults? (2) Does digital monitoring integrated with existing care services improve functional health outcomes compared to usual care? (3) Is it feasible to integrate digital monitoring within existing community care infrastructure without disrupting established workflows? We hypothesized that daily fluctuations in HRV, sleep quality, and PA would be associated with same-day and next-day pain and depressive symptoms (hypothesis 1 [H1]); participants receiving the integrated intervention would demonstrate improved or maintained functional health outcomes compared to those receiving usual care alone (hypothesis 2 [H2]); and community caregivers would successfully integrate platform-generated health alerts into their existing care workflows, enabling timely interventions for detected health declines without requiring additional work hours or service costs (hypothesis 3 [H3]. This quasi-experimental design would allow feasibility evaluation of an integrated digital-human care model rather than isolated digital platform effects.

XSL•FO
RenderX

Based on previous formative and pilot study [33], our approach integrates continuous digital phenotyping through smartwatches and daily chatbot surveys with existing community care services, where caregivers serve as technology intermediaries (Figure 1).

The platform's traffic-light feedback system simplifies complex health data into actionable information for both users and caregivers (Figure 2).

Figure 1. Community-mediated digital health platform architecture for vulnerable older adults. The 3-tiered service delivery system enables comprehensive health monitoring and care coordination. At the individual level, older adults in their homes interact with smartphone apps, smartwatches, and motion sensors for continuous health monitoring. When personalized algorithms detect health deterioration signals, assigned community caregivers provide targeted support through phone calls or home visits. For severe health declines or emergencies requiring coordinated response, the system escalates to the community center for comprehensive intervention. This hierarchical architecture ensures appropriate care intensity while maintaining older adults' independence in their home environment.

Methods

Overview

This study represents the culmination of a multiphase research program aimed at developing and evaluating a community-integrated digital health monitoring platform for socially vulnerable older adults. The development process began with formative research involving surveys (n=99 older adults) and focused group interviews with older adults (n=16), community caregivers (n=12), and social workers (n=3) to identify primary health concerns, understand community care workflows, and determine essential platform features. This informed the platform design, which was subsequently refined through an informal prepilot test with study staff (n=6) and a 6-week single-arm living lab pilot study (n=31) to establish feasibility and optimize functionality, which was previously reported [33].

Building on these foundational phases, this study used a 6-week quasi-experimental design with matched comparison groups to evaluate the feasibility and preliminary effectiveness of integrating digital monitoring within existing community care services. The evaluation encompassed not only the digital monitoring components but also the integration with in-person community care services and the institutional emergency alert system that enables coordinated responses from caregivers and center managers when health decline is detected. The research was conducted at a community senior welfare center in Seoul, South Korea, from October to December 2023, following formative and pilot phases that spanned the COVID-19 pandemic period (2021-2022). This iterative development approach—progressing from needs assessment through pilot testing to quasi-experimental evaluation—ensured the platform was both technically robust and contextually appropriate for the target population of low-income older adults with limited digital literacy. This iterative process was guided by a participatory, user-centered approach that engaged older adult participants, community caregivers, and welfare center administrators during and after the pandemic period. Their input informed not only platform design but also key study design decisions, including the adoption of a matched comparison rather than a randomized design, which stakeholders collectively identified as essential for ethical engagement that respects the right of choice and dignity of this vulnerable population.

Older adult participants received the Korean Government–supported Community Care Service that was provided free of charge: twice-weekly phone calls and weekly home visits from assigned caregivers, with additional follow-up services provided for acute illness episodes. Caregiver work hours are regulated at 25 hours per week under the service protocol, and poststudy caregiver surveys confirmed adherence to this standardized schedule in the intervention group without overtime work. The platform-triggered interventions in the intervention group aimed to facilitate earlier detection of health decline events; caregivers were briefly trained to use the platform to identify emerging health issues through digital alerts before these became apparent during scheduled contacts or escalated to acute episodes.

Ethical Considerations

This study was conducted in accordance with the Declaration of Helsinki and approved by the Institutional Review Boards of Korea University (approval number KUIRB-2021-0324) and Sahmyook University (approval number SYU 2022-06-003-001). Written informed consent was obtained from all individual participants included in the study prior to enrollment. Safety monitoring was conducted through community caregivers who served as technology intermediaries. Caregivers received daily health status updates via the traffic-light dashboard and responded to health deterioration alerts with phone calls or in-person visits, enabling continuous safety monitoring and timely response to detected health concerns. Privacy was protected through secure data transmission and restricted access to participant health information, with only assigned caregivers, a community center manager, and authorized research staff permitted to view individual health data.

Recruitment

Participants were identified through the Community Care service database at a municipal senior welfare facility in Seoul. Community caregivers facilitated recruitment by identifying eligible older adults from their existing caseloads and arranging initial contact with the research team.

Inclusion criteria comprised (1) age of 65 years or older, (2) living alone with low income qualifying for government-supported care services, (3) currently receiving biweekly phone calls and weekly home visits through the Community Care service, (4) possession of an Android smartphone compatible with the study application, and (5) capacity to provide informed consent. Individuals were excluded if they had cognitive impairment preventing study participation, severe sensory impairments interfering with technology use, cohabitation with others (due to motion sensor limitations), or medical conditions requiring intensive care.

The intervention group (n=43) consisted of older adults whose caregivers agreed to use the digital platform, while the comparison group (n=43) included age- (±3 years), gender-, and residential area–matched older adults whose caregivers maintained standard care practices. A total of 25 community caregivers participated as technology intermediaries for the intervention group.

Digital Health Monitoring Platform

The platform architecture integrated 3 synchronized applications: a user interface providing personalized health feedback, a caregiver dashboard for monitoring multiple recipients, and an administrative system for center managers (Figure 1). Daily health indicators were visualized using an intuitive traffic-light system (green: better than baseline, yellow: similar to baseline, red: worse than baseline), calculated from each participant's first-week average (Figure 2). Detailed technical specifications and user interface designs of the platform have been previously described in our pilot study [33]. The results from the motion sensing camera, which was integrated with experimental sessions outside the living lab, are reported separately from this study [34].

XSL•FO
RenderX

Technical components included a chatbot-enabled smartphone app for daily surveys, continuous physiological monitoring via Fitbit Sense smartwatches, and Azure Kinect motion sensors for home-based activity detection. While motion-sensing cameras were deployed as part of the platform infrastructure, their biomechanical data were analyzed in a concurrent validation study and are presented separately [34].

Physiological measures were derived from the Fitbit Sense smartwatch, a consumer-grade device. While Fitbit devices have demonstrated acceptable validity for PA, resting heart rate, and irregular heart rhythms compared to research or clinical-grade sensors [35,36], heart rate measurements during active periods and sleep staging algorithms show greater variability against polysomnography gold standards, particularly in populations with sleep disorders or arrhythmias [37,38]. Our older adult participants' high prevalence of chronic conditions may have introduced measurement noise. Thus, the use of a consumer-grade sensor in this study may have attenuated observed associations or introduced measurement error.

Intervention Protocol

Following informed consent and baseline assessment, research staff and caregivers conducted home visits to install applications and provide initial training. Participants engaged with the chatbot each morning, responding to 2 randomly selected Patient Health Questionnaire-9 (PHQ-9) items for depressive symptom screening and rating pain levels (0-10 visual analog scale [VAS]). Continuous smartwatch monitoring captured HRV, sleep patterns, and PA throughout the study period.

Community caregivers received daily updates on participants' health status through the traffic-light system displayed on their dashboard. When participants exhibited multiple red indicators (≥2 domains) for 2 or more consecutive days, caregivers were instructed to conduct follow-up interventions via phone calls or in-person visits based on severity assessment. All caregiver-initiated interventions triggered by health decline signals were systematically documented and analyzed (Figure S1 in Multimedia Appendix 2 for examples of health decline signals). Table S3 in Multimedia Appendix 2 shows the records of the community caregiver's follow-up reports after detecting health decline signals. This quasi-experimental study with both an intervention and a comparison group has been registered on ClinicalTrials.gov (NCT06270121).

Daily Digital Measures of Pain and Depression

Intervention participants completed daily assessments via the chatbot interface that was developed in our pilot study [33]. For depressive symptom screening, 2 items were randomly selected from the PHQ-9 questionnaire and presented in a yes/no format each day. Participants who responded "yes" to one or both items were coded as experiencing depressive symptoms for that day. Pain intensity was assessed using a VAS (0-10, where 0=no pain, 10=worst imaginable pain). Response rates and patterns were analyzed as engagement indicators.

Digital Biomarker Measurements

Continuous physiological monitoring via Fitbit Sense smartwatches captured 3 domains of digital biomarkers throughout the 6-week intervention period, as previously described [33]. Sleep metrics included total sleep time, sleep fragmentation index (awakening frequency divided by total sleep time), number of long wake episodes (over 5 minutes of awakening), and sleep efficiency (total sleep time divided by time in bed), calculated using validated algorithms that applied 7 correction criteria to improve actigraphy-based sleep detection accuracy [39,40].

HRV was computed every 5 minutes using the open-source "Aura-healthcare" Python package [41], generating both time-domain indicators (SD of N-N intervals and root-mean-square of successive differences) and frequency-domain measures (high-frequency/low-frequency ratio) from R-R interval data [41,42].

PA levels were quantified through daily step counts and minutes of light, moderate, and intense activity, leveraging Fitbit's validated 3-axis accelerometer algorithms [35,43,44]. These multidomain digital biomarkers provided comprehensive 24-hour physiological profiles for examining within-person associations with daily pain and depressive symptoms.

Pre- and Postsurvey Measures

Primary and secondary outcomes were assessed through structured home visits at baseline, week 3 (midintervention), and week 6 (postintervention) by trained research assistants. Caregivers also participated in brief surveys at pretest and posttest.

Pain-Related Functional Limitations

The Korean version of the Western Ontario and McMaster Universities Osteoarthritis Index (WOMAC) was administered to assess pain-related functional impairment [45,46]. WOMAC comprises 24 items evaluating 3 dimensions: pain (5 items), stiffness (2 items), and physical function (17 items). Each item is scored on a 5-point Likert scale (0-4), with higher total scores indicating greater functional limitations.

Geriatric Depression Scale Short-Form

The 15-item Geriatric Depression Scale Short-Form (GDS-SF) was used to screen for depressive symptoms [47,48]. Each item requires a yes/no response, with scores ranging from 0 to 15. Clinical cutoffs indicate normal (0-4), mild depression (5-9), and severe depression (≥10). The GDS-SF has shown high sensitivity (92%) and specificity (89%) for detecting depression in Korean older adults.

Pittsburgh Sleep Quality Index

The Pittsburgh Sleep Quality Index (PSQI) assessed subjective sleep quality over the past month [49,50]. This 19-item questionnaire evaluates 7 components: subjective sleep quality, sleep latency, sleep duration, habitual sleep efficiency, sleep disturbances, use of sleep medications, and daytime dysfunction. Global PSQI scores range from 0 to 21, with scores >5 indicating poor sleep quality. The Korean PSQI has demonstrated good internal consistency (Cronbach α=0.84) and test-retest reliability (r=0.85).

XSL•FO
RenderX

Technology Usability

System usability was measured using a simplified System Usability Scale (SUS) adapted for cognitively impaired and older adults [51]. The scale contains 10 items rated on a 5-point scale (strongly disagree to strongly agree), yielding scores from 0 to 100. Higher scores indicate better perceived usability, with scores >68 considered above average. Preintervention SUS assessed general technology use, while postintervention SUS specifically evaluated the digital health platform. To assist participants unfamiliar with digital technology, examples (smartphones and hospital kiosks) were provided during baseline assessment.

In addition to the SUS, participants were asked about the frequency of platform use and the number of functions used during the midterm assessment. At postintervention, participants provided qualitative feedback for platform improvement, which research assistants documented verbatim. Community caregivers similarly completed the SUS and reported their usage frequency and range of functions used at the postintervention assessment.

Covariates

Covariates were determined a priori based on extant literature summarizing demographic and health risk factors for daily depressive symptoms of older adults [52,53]. In addition to the baseline levels of depression, demographic and health factors linked with depression (age, sex, and chronic health conditions) were used as covariates.

Caregiver Assessments

Caregivers participated in brief surveys at pretest about their demographic and job-related information, and at posttest about their usage of the caregiver app. Poststudy surveys assessed the SUS survey, caregiver platform engagement, including working hours compliance, usage frequencies, function use, and qualitative feedback on workflow integration and user experience.

Statistical Analysis

After analyzing missing data and assessing the distributions of key variables, descriptive analyses were performed. Group comparisons between older adults with depression and without depression were conducted using *t* tests for continuous variables (eg, age, BMI, PSQI total score, daily depressive symptoms, wearable sensor assessments of HRV, sleep, and PA indicators), chi-square tests for categorical variables (eg, sex, education, income, chronic disease, and sleep disorder categories). Subsequently, bivariate correlations were explored between baseline depression and person mean variables (daily pain and depressive symptoms, and wearable sensor assessments) over 6 weeks.

Within-person associations between digital biomarkers and daily symptoms were examined using multilevel models (SAS/STAT version 9.4; SAS Institute Inc). Level 1 examined daily variations in symptoms and sensor metrics; level 2 incorporated participant characteristics. It allows for the use of participants as their own controls [54].

For pain as outcome, the model included daily depressive symptoms (binary coded: 0=no symptoms, 1=responded “yes” to at least 1 of 2 daily PHQ-9 items), sleep, HRV, and PA indices were examined as predictors of same-day and next-day pain levels. For depressive symptoms as outcome, the model included daily pain levels (VAS 0-10), sleep, HRV, and PA indices as predictors of same-day and next-day depressive symptoms using logistic multilevel models, given the binary nature of the outcome.

All level 1 predictors were person mean–centered, while level 2 covariates (age, sex, and chronic conditions) were grand mean-centered. This approach allows interpretation of estimates as within-person deviations from individual averages across the 6-week period. Bonferroni corrections were applied for multiple testing (α=.005).

The pretest and posttest results were assessed using a mixed model with time (pretest and posttest) at level 1, personal characteristics (covariates of age, gender, and chronic disease conditions) at level 2, and intervention group at level 3. All plots of results were drawn using the R software (version 4.3.1; R Foundation for Statistical Computing) ggplot2 package [55].

Power Analysis

Simulation studies demonstrate that 35 participants with >30 days of continuous monitoring yields adequate statistical power for detecting within-person effects in multilevel models [56]. For pre-post comparisons, 72 participants (32 intervention and 40 comparison) completed end point assessments, providing 80% power to detect medium effect sizes (d=0.50) in group × time interactions. Although there is no prior study to estimate effect sizes from older adult populations, this is consistent with meta-analytic evidence from human-guided digital interventions for depression in general adult populations (Hedges g=0.52-0.63) [57], which represents the closest available benchmark for digital-human integration models. Given the modest sample size, findings should be interpreted as preliminary rather than definitive evidence of intervention effectiveness.

Data Exclusion and Missing Data

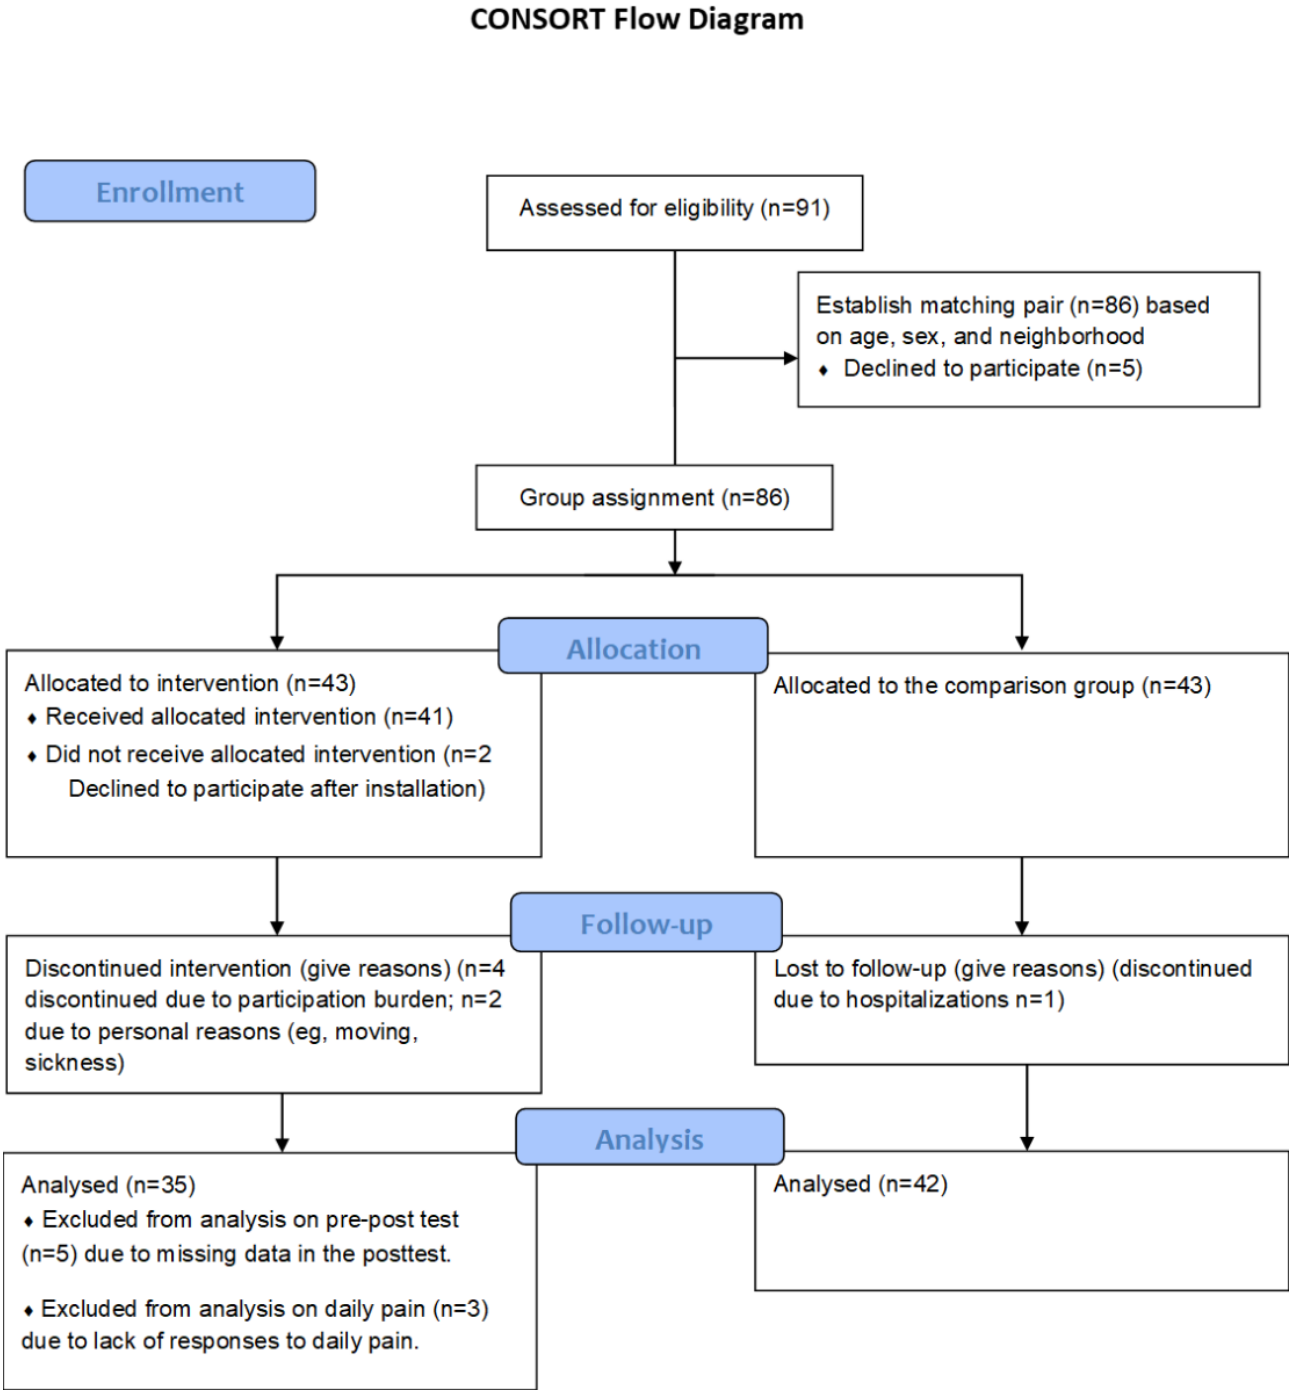
Of 86 enrolled participants, 77 provided analyzable data (35 intervention and 42 comparison), with 9 exclusions due to withdrawal (n=4 participation burden), illness (n=2), relocation (n=1), or incomplete baseline data (n=2). The intervention group generated 1318 observation days (mean 37.7, SD 8.8 days per participant) for multilevel analyses.

Missing data analyses showed missing in daily surveys (455/1318, 34.5%), HRV (356/1318, 27%), sleep monitoring (625/1218, 47.4%), and PA (126/1318, 9.6%). Missing data primarily resulted from forgetting to wear devices or charging issues, rather than technical failures or dropout. Full information maximum likelihood estimation addressed missing data, a method shown to be robust against bias with partial missingness [58].

Protocol Deviations

The trial registration (ClinicalTrials.gov NCT06270121) originally specified the Short-Form 12 health survey as the primary quality of life outcome. During implementation, we modified the primary outcome to the WOMAC to focus specifically on pain-related functional limitations, as baseline

XSL•FO
RenderX



assessments revealed that 90% (70/73) of participants experienced chronic pain, making functional outcomes more clinically relevant and responsive to our 6-week intervention than generic quality of life measures. Additionally, the PSQI was added as a secondary outcome after initial data showed that 69.2% (54/78) of participants exceeded the clinical cutoff for sleep disturbances (PSQI >5), highlighting the importance of sleep assessment in understanding the pain-mood-sleep triad in this population.

Results

Participant Characteristics

Between April and November 2023, we enrolled 78 low-income older adults living alone in Seoul, South Korea (35 intervention and 43 comparison) and 25 community caregivers. The digital health monitoring platform design and service delivery model are illustrated in Figures 1 and 2. Participant flow through the study is shown in Figure 3.

Figure 3. CONSORT (Consolidated Standards of Reporting Trials) flow diagram of participant recruitment and retention. Study enrollment occurred in October-November 2023 in Seoul, South Korea. Of 91 eligible older adults approached, 86 enrolled (43 matched pairs). The intervention group received digital health monitoring integrated with community care services; the comparison group received usual care. Attrition was primarily due to illness (n=3) or participation burden (n=4). Analysis includes 35 intervention and 42 comparison participants for pre-post outcomes, with 35 intervention participants contributing 1318 days of digital phenotyping data.

XSL•FO
RenderX

Baseline characteristics demonstrated comparable demographics and high disease burden across groups (Table 1). Mean age was 78 (SD 4.1) years, 85% (66/78) were women, and participants had limited education (mean 8.2, SD 4.7 years). Monthly income averaged KRW 900,000 (approximately US $670), confirming socioeconomic vulnerability. Participants reported an average of 4 chronic conditions, predominantly hypertension (46/78, 59%), diabetes mellitus (45/78, 58%), cataracts (43/78, 55%), and arthritis (25/78, 49%). Notably, 90% (70/78) experienced chronic pain lasting over 3 months, primarily affecting the back (50/78, 64%) and knees (39/78, 50%). Baseline assessments revealed mild depressive symptoms (mean GDS-SF score 4.3, SD 3.5), poor sleep quality (mean PSQI score 8.0, SD 3.8, exceeding the clinical cutoff of 5), and moderate pain-related functional limitations (mean WOMAC score 29.1, SD 19.0). Groups showed no significant baseline differences (all $P>.05$). Characteristics of caregivers and their platform usage were also reported in Table 2.

Table 1. Baseline characteristics of older adult participants demonstrate comparable demographics and high disease burden across groups.

Descriptive Results

We analyzed 1318 days of continuous monitoring data from 35 intervention participants (mean 37.7, SD 8.8 days per participant). Distinct patterns associated with daily pain states were revealed by 24-hour heart rate profiles (Figure 4). Participants experiencing higher-than-usual pain demonstrated elevated heart rates during early morning (5-8 AM) and late evening (10-11 PM) hours compared to their low-pain days (Figure 4A). In contrast, days with and without depressive symptoms showed similar heart rate patterns throughout the day (Figure 4B).

XSL•FO
RenderX

Figure 4. Distinct patterns associated with pain in older adults emerging in 24-hour heart rate profiles. (A) Heart rate patterns on days with higher (red) versus lower (blue) pain relative to individual average demonstrate elevated rates during early morning (5-8 AM) and late evening (10-11 PM) hours, (B) heart rate patterns on days with (red) versus without (blue) self-reported depressive symptoms show minimal variation across the day. Data represent mean (standard error of the mean) from 35 participants over 1318 observation days. Top panels show hourly averages with error bars; bottom panels display distributions as box plots with median, IQR, and outliers. BPM: beats per minute.

Correlation analyses revealed complex within-person and between-person associations among digital biomarkers and symptoms. Within-person correlations showed that daily fluctuations in sleep time (r=–0.112; P=.02) and sleep fragmentation (r=–0.114; P=.01) significantly correlated with depressive symptoms (Table S1 in Multimedia Appendix 2). Between-person correlations indicated that individuals with higher average daily pain levels had higher baseline WOMAC scores (r=0.499; P=.003), greater average daily depressive symptoms (r=0.475; P=.006), and greater baseline depressive symptoms (r=0.593; P<.001; Table S2 in Multimedia Appendix 2). Higher daily depressive symptoms are also associated with

XSL•FO
RenderX

root-mean-square of successive differences (r=0.356; P=.05), moderate PA (r=0.462; P=.02), and baseline depressive symptoms (r=0.476; P=.006).

Digital Predictors of Daily Pain and Depressive Symptoms

Multilevel modeling identified specific digital biomarkers predicting daily pain and depressive symptoms (Table 3). For pain, HRV (mean of the normal-to-normal intervals) significantly predicted both same-day pain (β=–.007, SE=0.003; P=.02) and next-day pain (β=.007, SE=0.003; P=.03). Moderate PA was associated with reduced same-day pain (β=–.601, SE=0.298; P=.047), while increased long wake episodes during sleep predicted higher next-day pain (β=.343, SE=0.151; P=.03). For depressive symptoms, participants were more likely to report symptoms on days following shorter sleep duration (odds ratio [OR] 0.998, 95% CI 0.997-1.000; P=.03) and lower sleep efficiency (OR 0.988, 95% CI 0.975-1.000; P=.05). Higher pain increased the likelihood of same-day depressive symptoms (OR 1.222, 95% CI 1.000-1.494; P=.05).

Table 3. Digital biomarkers predict daily pain and depressive symptoms in older adults. Multilevel models examine within-person associations between sensor-derived measures and self-reported symptoms over 1318 observation days from 35 participants. All predictors were person mean–centered to re-present deviations from individual baselines. Models adjusted for age, sex, and chronic conditions.

XSL•FO
RenderX

In unadjusted analyses, HRV (mean of the normal-to-normal intervals) was associated with both same-day and next-day pain (P<.05), and sleep duration was associated with next-day depressive symptoms (P<.05), providing initial support for H1. However, after Bonferroni correction for multiple testing (adjusted α=.005), none of these associations remained statistically significant. PA showed limited associations with mood outcomes across all analyses. Therefore, H1 was not supported.

Intervention Effects on Health Outcomes

The integrated intervention (digital monitoring plus enhanced caregiver support) yielded differential effects on health outcomes (Figure 5). Intervention participants maintained baseline levels of functional limitations (baseline: mean 23.1, SD 3.4 to post: mean 20.6, SD 3.5; change –2.6, 95% CI –7.8 to 2.6; P=.41), while the comparison group reported a significant increase in functional limitations (baseline: mean 21.7, SD 3.4 to post: mean 28.4, SD 3.4; change +6.7, 95% CI 2.3-11.1; P=.01). The between-group difference at postintervention was 7.8 (95% CI –16.3 to 0.6; P=.07) points, representing a potentially clinically meaningful difference that warrants confirmation in adequately powered trials (Figure 5A).

Figure 5. Changes in health outcomes over 6 weeks comparing integrated intervention with usual care. Pre-post intervention changes comparing platform users (blue) with the usual care comparison group (red). (A) Pain-related functional limitations (Western Ontario and McMaster Universities Osteoarthritis Index [WOMAC]) showed significant group × time interaction ($F_{1,72}$=5.26; ^{P}=.03), with platform users maintaining function (mean change –2.6, 95% CI –7.8 to 2.6) while the comparison group reported increased functional limitations (mean change +6.7, 95% CI 2.3 to 11.1). (B) Depressive symptoms (Geriatric Depression Scale Short-Form [GDS-SF]), (C) sleep quality (Pittsburgh Sleep Quality Index [PSQI]), and (D) system usability (System Usability Scale [SUS], platform users only) showed no significant changes. Data represent estimated marginal means (95% CI) adjusted for age, sex, and number of chronic conditions. Asterisk (*) indicates a significant interaction effect. Lower scores indicate better outcomes for WOMAC, GDS-SF, and PSQI; higher scores indicate better usability for SUS.

No significant group differences emerged for depressive symptoms (Figure 5B) or sleep quality (Figure 5C). Both groups maintained stable scores on these measures. System usability among intervention participants showed no significant changes from pre (mean 46.8, SD 20.5) to post (mean 44.9, SD 18.3) intervention (Figure 5D).

These findings partially support H2. Intervention participants demonstrated maintained functional health while the comparison group reported increased functional limitations, supporting our hypothesis for pain-related outcomes. However, the hypothesis was not supported for depressive symptoms or sleep quality, which showed no significant group differences.

Platform Engagement and Care Coordination

Despite limited baseline digital literacy, platform engagement remained robust throughout the intervention. Daily chatbot survey completion averaged 65% (863/1318), with 73%

XSL•FO
RenderX

(962/1318) compliance for heart rate monitoring, 53% (693/1318) for sleep tracking, and 90% (1192/1318) for activity monitoring. Missing data primarily resulted from device charging requirements or forgetting to wear devices rather than technical difficulties.

Table 2 presents caregiver's app usage at posttest. While maintaining the regular working hours (mean 25, SD 1.3 hours per week), community caregivers in the intervention group demonstrated strong platform engagement, with acceptable usability scores (mean SUS score 70.8, SD 16.7) and frequent daily use (16/23, 69.5% used ≥2-3 times daily). Caregivers actively used multiple functions (mean 6.0, SD 3.9), most commonly accessing voice recordings (19/23, 82.6%), step monitoring (14/23, 60.9%), and stress level tracking (13/23, 56.5%), indicating comprehensive adoption of the platform's digital monitoring features.

The platform appeared to enhance existing care services through 37 health decline–triggered interventions (Table S3 in Multimedia Appendix 1 for case reports and Figure S1 in Multimedia Appendix 1 for platform alert screenshots). When the platform detected concerning patterns (multiple red indicators for ≥2 consecutive days), caregivers conducted targeted interventions addressing: severe postprocedure pain (n=3), dizziness requiring medical attention (n=5), medication nonadherence (n=2), infections requiring hospitalization (n=1), and physical inactivity (n=26). One critical intervention identified an infected abscess requiring immediate surgical drainage, potentially preventing sepsis. All 25 community caregivers completed the study and actively responded to health alerts, demonstrating successful integration of digital monitoring with in-person care delivery.

Regarding safety, no serious adverse events were directly attributable to the platform. While 4 intervention participants withdrew citing burden and 3 participants discontinued due to unrelated illness or relocation, the 37 health decline–triggered interventions represent early detection rather than platform-induced harms.

H3 was supported. All 25 community caregivers completed the study and successfully integrated platform alerts into their workflows, conducting 37 health decline–triggered interventions. Poststudy surveys confirmed that caregivers did not exceed their contracted 25-hour work week, demonstrating that platform integration was achieved without additional work hours or service costs beyond the standardized care protocol.

Discussion

Principal Findings

This feasibility study provides preliminary evidence that integrating digital health monitoring with existing community care infrastructure may help bridge the digital divide for low-income older adults. The primary observation—that participants receiving the integrated intervention maintained functional health while the comparison group reported increased functional limitations—is consistent with potential benefits of the integrated digital-human care model, though the nonrandomized, quasi-experimental design precludes causal inference regarding which intervention components contributed to this differential pattern. The 37 health decline–triggered interventions by digital monitoring illustrate how technology may complement existing, rather than replace, human care relationships. However, it is important to note that the intervention group received caregiver interventions triggered by digital monitoring, while controls received standard care only. This fundamental confounding prevents isolation of digital platform effects from enhanced human contact. Our findings support the feasibility and preliminary effectiveness of digital-human integration but cannot establish independent clinical efficacy of the digital platform itself.

Our digital phenotyping results provide novel insights into pain and mood fluctuations among community-dwelling older adults. The distinct 24-hour heart rate patterns associated with pain—elevated rates during early morning and late evening—may reflect circadian variations in pain perception, previously observed only in controlled laboratory settings [59,60] but now demonstrated in older adults' daily living conditions. The association between HRV and both same-day and next-day pain extends previous cross-sectional findings of lower HRV in chronic pain patients [61,62], providing the first evidence that within-person HRV fluctuations may predict daily pain variations in older adults, suggesting autonomic dysregulation as an early indicator of pain exacerbation. Similarly, the relationship between sleep quality metrics and depressive symptoms aligns with established bidirectional links between sleep and mood in geriatric populations [63,64].

Regarding our hypotheses, results provided support for H2 and H3, but H1 was not supported after statistical correction. The digital phenotyping hypothesis (H1) was not supported: while HRV and sleep metrics showed initial associations with pain and depressive symptoms in unadjusted analyses, these relationships did not survive Bonferroni correction for multiple testing (adjusted α=.005). The effectiveness hypothesis (H2) received partial preliminary support: a differential pattern in functional health was observed, favoring the intervention group, but depression and sleep outcomes showed no group differences, possibly due to the short intervention duration and the confounding effects of enhanced caregiver support. The feasibility hypothesis (H3) was fully supported: caregivers successfully integrated digital monitoring into existing workflows without additional time burden, as confirmed by poststudy surveys verifying adherence to the standardized 25-hour weekly schedule. This finding is relevant for potential scalability, raising the hypothesis that integrated interventions may enhance care quality through better timing of interventions rather than requiring additional caregiver burden. This hypothesis requires confirmation through randomized designs.

Comparison With Prior Work

Previous digital health interventions for older adults have reported mixed results, with high attrition rates often limiting effectiveness [65,66]. A recent systematic review found that internet-delivered interventions for geriatric depression achieved modest effects but struggled with engagement, particularly among those with lower digital literacy [67-69]. Our approach differs fundamentally by not requiring direct technology use by

XSL•FO
RenderX

older adults themselves. This intermediary model extends traditional community health worker programs—proven effective in resource-limited settings [70-73]—by integrating digital monitoring tools with trained lay caregivers who facilitate early detection and timely intervention for mental and physical health concerns among vulnerable populations.

Our findings extend the digital phenotyping literature, which has predominantly focused on younger populations with sufficient digital literacy [4,16,74-76]. While previous studies have shown associations between PA and mood in controlled settings [77-80], our real-world data revealed more complex and weaker patterns that did not reach statistical significance. The observed trend toward a protective effect of moderate—but not intense—PA on pain aligns with recommendations for gradual, individualized exercise in older adults [81,82], though further research is needed to establish whether digital monitoring could help identify optimal activity ranges for personalized pain management [5].

Implications for Digital Health Equity

This study offers a preliminary model that, if validated through randomized trials, may be scalable for addressing digital health inequities. Rather than attempting to overcome multiple barriers simultaneously—teaching digital skills, providing devices, ensuring connectivity—our approach leverages 1 existing asset: regular contact with community caregivers. This transforms the digital literacy requirement from end users to intermediaries who typically possess better digital skills and can translate complex health data into actionable care for service-receiving older adults.

The current implementation of the developed platform in South Korea, where public community care services are well-established, suggests potential adaptability to other contexts with similar infrastructure. Many countries have comparable programs—community health worker programs operating globally [83,84]—that offer ready infrastructure for deploying digital health technologies to support aging populations.

Clinical and Policy Implications

Our findings suggest that digital health equity may require more than providing devices or training programs. Successful implementation depends on integrating technology within existing care relationships and workflows [23,70]. For clinicians, this means recognizing that digital health tools may be most effective when delivered through care teams rather than directly to patients. For policymakers, investing in community care infrastructure may paradoxically be essential for realizing the benefits of digital health investments.

The cost-effectiveness and scalability of this approach warrant future investigation. Implementation costs include (1) 1-time expenses for smartwatches (approximately US $200 per participant), smartphone app development, and server infrastructure; (2) recurring costs for device replacement, data storage, and technical support; and (3) caregiver time and wages for platform monitoring and responsive interventions. Notably, this study confirmed that these costs may be partially offset by integration with existing community care workflows—caregivers already conduct scheduled contacts, and platform monitoring required approximately 10-15 additional minutes daily per 10 assigned recipients for reviewing dashboard alerts. The critical economic question is whether early detection prevents costly downstream events. In our 6-week trial, the 37 triggered interventions included 1 case of infected abscess identified before sepsis development, suggesting substantial potential for preventing emergency department visits and hospitalizations that would far exceed platform costs. Formal cost-effectiveness analysis comparing platform-enhanced care versus usual care, incorporating quality-adjusted life years and health care use outcomes, is essential before recommending widespread implementation [85].

The below-threshold system usability scores (mean SUS score 46, SD 21.5 versus the cutoff score of 68 for acceptable usability) warrant consideration. These low scores likely reflect our target population's limited baseline digital literacy rather than platform-specific usability failures, as participants reported difficulty identifying any digital technology for reference during baseline assessment and no available internet connections at home. Nevertheless, suboptimal usability may have attenuated intervention effects by limiting engagement depth or creating frustration that offset potential benefits. In contrast, caregivers demonstrated acceptable usability scores and high engagement, with 69.5% (16/23) using the platform 2-3 times daily. Future iterations should prioritize simplified interfaces, voice-first interaction modalities, and extended onboarding support for older adults. Additionally, the low SUS scores suggest that the intermediary model—where caregivers translate platform outputs rather than expecting direct user proficiency—may be essential rather than merely convenient for this population.

Limitations

Several limitations warrant consideration. First, the quasi-experimental, nonrandomized design with unequal intervention exposure introduces fundamental confounding that limits causal inference. The intervention group received platform-triggered caregiver interventions, while the control group received standard scheduled care. This design makes it impossible to isolate the effect of the digital platform from the effect of possibly increased human contact, limiting conclusions to the feasibility and preliminary effectiveness of the integrated care model rather than independent platform efficacy. Randomization was not feasible in part because the multiphase research program spanned the COVID-19 pandemic and postpandemic periods (2021-2023), during which protecting vulnerable participants' safety and informed decision-making were prioritized. Voluntary participation through prior consultation with trusted caregivers was a prerequisite for enrollment, consistent with the participatory development process. This necessitated a matched comparison design based on caregiver and participant willingness rather than random assignment. Although the current living lab approach provides ecological validity for understanding real-world implementation within existing care systems, it was not feasible to match care services for the structured control group or require the provision of detailed reports of caregiving service types and the amount of time for each participant in both the intervention and control groups.

XSL•FO
RenderX

The nonrandomized design may have introduced additional potential selection bias, though groups were well-matched on measured characteristics. Particularly, intervention group caregivers volunteered to adopt the platform, potentially selecting for caregivers with greater technological comfort, higher motivation, or stronger relationships with their care recipients—factors that could independently affect health outcomes. The open-label nature was also unavoidable given the intervention's visibility to both participants and caregivers. Notably, both groups were drawn from older adults with established caregiver relationships who consented to face-to-face research assessments during the postpandemic period—a decision that itself reflects a degree of trust and social engagement uncommon in this population. The comparison group thus represents a relatively engaged subgroup rather than a passive usual-care population, which may partially mitigate concerns about selection bias favoring the intervention group.

Additionally, our multicomponent intervention does not allow experimental isolation of active mechanisms, and findings should not be interpreted as identifying which specific components drove the observed differential patterns. The platform integrated (1) continuous physiological monitoring via smartwatches, (2) daily chatbot surveys for symptom reporting, (3) personalized traffic-light feedback to users, (4) real-time dashboard alerts to caregivers, and (5) protocol-driven caregiver responses to health decline signals. Any or all components may have contributed to observed effects, individually or synergistically. For example, improvements could result from increased self-monitoring awareness, the supportive effect of daily chatbot interaction, enhanced caregiver responsiveness, or the earlier timing of follow-up enabled by digital alerts, or from complex interactions among these elements. Future research should use factorial designs or sequential multiple assignment randomized trials to systematically isolate component contributions and identify optimal intervention configurations for different patient subgroups.

While the multicomponent design precludes experimental isolation of active mechanisms, several observations generate testable hypotheses for future studies designed to isolate component effects. The 37 caregiver-initiated interventions were triggered by digital alerts rather than scheduled contacts, suggesting that the platform's primary mechanistic contribution may lie in the timing of care delivery—enabling earlier detection and response to health deterioration—rather than in the volume of caregiver contact. Caregivers maintained their standard 25-hour weekly schedule, further suggesting that differential outcomes may reflect improved allocation of existing care resources rather than increased service intensity. Additionally, the contrast between low older adult usability scores (mean SUS score 46, SD 21.5) and acceptable caregiver usability scores (mean SUS score 70.8, SD 16.7) suggests that intervention effects likely operated primarily through the caregiver-mediated pathway rather than through direct older adult engagement with the platform. These observations point toward caregiver-mediated early detection as a candidate mechanism, but this hypothesis requires formal testing through factorial designs that systematically vary platform components.

In addition, the 6-week intervention period represents a significant constraint. While adequate for demonstrating feasibility and detecting changes in functional limitations, this duration is insufficient for assessing depression outcomes, which meta-analytic evidence suggests require longer intervention periods [86]. Furthermore, observed effects may partly reflect novelty or Hawthorne effects that could diminish over time as participants habituate to monitoring. Long-term studies are needed to determine whether functional benefits persist, whether initially null effects on depression emerge with extended exposure, and whether engagement levels remain sustainable beyond the initial phase.

Also, missing data rates for some sensors (particularly sleep monitoring, 693/1318, 52.6%) may have limited our ability to detect associations, and nonrandom missingness cannot be excluded. Our sample of urban-dwelling Korean older adults limits generalizability to rural populations or other cultural contexts. The marginal significance of several findings after multiple testing corrections suggests the need for larger studies to confirm these associations.

Finally, our daily depression assessment—2 randomly selected binary PHQ-9 items—has limited sensitivity to mood fluctuations compared to full validated scales or ecological momentary assessment approaches with continuous response scales. This measurement constraint may have reduced our ability to detect subtle associations between digital biomarkers and mood states, potentially contributing to the null findings for depression outcomes. Future studies should use more sensitive daily mood measures, such as VASs or brief validated instruments designed for repeated administration.

Conclusions

This feasibility study provides preliminary evidence suggesting that integrating digital monitoring within existing community infrastructure may advance digital health support to low-income older adult populations. By positioning formal caregivers as technology intermediaries, vulnerable older adults were able to participate in continuous multimodal health monitoring while addressing digital literacy barriers. This approach demonstrated feasibility and raised the question of whether digital health equity may be better addressed by reimagining how, not just what, technologies are delivered within the existing community care infrastructure. Future research should use randomized controlled designs with appropriate control conditions to establish causal relationships and isolate the specific contributions of digital monitoring, enhanced feedback, and caregiver responsiveness to the observed differential patterns. Such studies will be essential for determining optimal intervention and implementation strategies across diverse settings and evaluating the long-term sustainability of this integrated care model.

Acknowledgments

We are very grateful to older adults and care service providers for their participation and the support of the staff at the Seong-buk City Senior Welfare Center.

Funding

This study was supported by a grant from the Korea Health Technology R&D Project through the Korea Health Industry Development Institute, funded by the Ministry of Health & Welfare, Republic of Korea (grant HI21C0572), the Basic Research Lab Program of the National Research Foundation of Korea funded by the Ministry of Science and ICT (RS-2025-02303227), and the Basic Science Research Program through the National Research Foundation of Korea, funded by the Ministry of Science and ICT (grant RS-2024-00348012).

Conflicts of Interest

SS and JK developed the health monitoring platform software in collaboration with M2S+ Co and hold intellectual property rights for the platform. The Ministry of Health and Welfare of the Republic of Korea, which provided funding for platform development, retains rights to use the developed platform as a public service for older adults. HYK and SYH declare no competing interests.

Abstract

Background: Sleep-dependent memory consolidation (SDMC), the process by which sleep supports the transfer of memories into long-term storage, declines with age but remains underexplored in older adults with subjective cognitive decline and mild cognitive impairment. Traditional SDMC assessments are typically conducted in lab settings, with limited evidence for feasibility to do these assessments at home for this clinical population.

Objective: To address this, we co-designed the *Sleep Memories* app, which assesses overnight memory for a previously validated 32-item word-pairs task. This pilot study first explored the feasibility and acceptability of the app, including willingness to participate. Second, we explored various demographic, clinical, and subjective sleep factors associated with task completion and SDMC performance in a memory clinic sample.

Methods: Within an 8-month period, we invited 141 older adults aged 50 years and above (mean 71.27, SD 7.51 y) from the Healthy Brain Ageing clinic, a specialist brain health and memory clinic in Sydney, to pilot the *Sleep Memories* app. Of these, 76 (mean 70.19, SD 7.75) agreed to participate. All participants underwent a full neuropsychological test battery, medical assessment, and mood assessment.

Results: Sixty-eight participants completed at least 1 test of the word-pairs task. The word-pairs task completion rate for all trials was over 50%. There was 57% (39/68) completion of both evening and morning delayed recall tests. Lower willingness to participate was associated with lower global cognitive scores, poorer sleep behavior, and clinical factors. Higher task completion was associated with greater education and greater anxiety levels. User feedback indicated that the app was well-accepted and liked, although some participants reported minor technical difficulties.

Conclusions: These findings support the feasibility of mobile app–based SDMC assessment in older adults at risk of cognitive decline and underscore the importance of considering individual characteristics (eg, subjective sleep factors, clinical characteristics, and education) when designing digital SDMC tools.

sleep-dependent memory consolidation; digital cognitive assessment; aging; cognition; sleep

Introduction

Sleep is a fundamental biological process that is essential for both physical and cognitive health [1,2]. In particular, sleep plays an important role in sleep-dependent memory consolidation (SDMC). This process involves the reactivation and replay of temporary memories during sleep, which stabilizes them into long-term storage and facilitates their transfer from the hippocampus to the neocortex [3,4]. These features are thought to support memory consolidation; however, due to methodological challenges, SDMC remains underexamined in older adults, particularly those with subjective or mild cognitive impairment (MCI). Only a few studies have explicitly investigated SDMC in these populations, albeit in small sample sizes [5-8]. These scalability barriers have limited the field's

XSL•FO
RenderX

understanding of how factors such as modifiable dementia risk factors and global cognitive impairment influence SDMC.

Several factors may account for this gap in the literature, which currently constrains research on SDMC in populations at risk of dementia. For example, traditional SDMC assessment tasks were designed for younger or cognitively intact adults. Therefore, they are not suited for older adults with cognitive impairments, jeopardizing feasibility and producing floor effects. Furthermore, SDMC tasks have typically required assessment in the sleep laboratory before and after sleep [9-11]. The laboratory environment may not reflect naturalistic sleep conditions [12], limiting both the ecological validity and scalability of SDMC assessment for research and clinical use. While this setting offers a controlled environment, the requirement to stay overnight in the laboratory deems data collection resource-intensive, costly, and a limiting factor for larger-scale studies.

Digitalization of SDMC assessments offers an opportunity to address these limitations by enabling participants to complete memory tasks remotely and in their habitual sleeping environment. However, the feasibility of transiting from the laboratory to home assessments for SDMC tasks and willingness to participate in the research need to be tested. Both feasibility and willingness to participate may be influenced by demographics, clinical, and sleep-related factors as well as barriers such as technical issues, psychological concerns, and workload demands [13]. These considerations are especially important in memory clinic settings and specialist services that assess and support individuals with cognitive concerns, where digital tools are increasingly being considered to support assessment and intervention [14,15].

Recognizing the need for feasible SDMC tasks for older people with cognitive concerns, we initially developed a 32-item word-pairs task [5] in the sleep laboratory and demonstrated its use in older adults, including those with MCI. We then co-designed a mobile app named *Sleep Memories* [12,16] that delivers the 32-item task remotely, enabling at-home unsupervised assessment of SDMC. This research tool allows participants to complete the SDMC task at their convenience in their natural sleep environment, increases accessibility for those unable to attend the laboratory, and reduces research costs by eliminating the need for in-lab supervision. In this pilot study, the primary aim was to evaluate *willingness to participate* and the *feasibility* of implementing the *Sleep Memories* app in a memory clinic setting. Secondarily, we explored various demographic, clinical, and subjective sleep-related factors that may influence both willingness to participate and feasibility of the app. Furthermore, a subset of participants was asked for *user experiences and barriers* related to using the app for assessing the *acceptability of the app* in a memory clinic setting. Next, we explored the associations of demographics, clinical, subjective sleep-related factors, modifiable dementia risk factors, and global cognitive functioning with SDMC performance. Finally, we further explored differences in characteristics between low and high SDMC performers and compared the characteristics of participants who provided user feedback with the main sample. Feasibility was defined, in accordance with prior research, as the completion rate above 50% [17] and was hypothesized to be achievable in our study. We also hypothesized that willingness to participate would depend on demographics, clinical, and subjective sleep-related factors; specifically, it would be negatively associated with higher levels of cognitive impairment and lower global cognitive functioning, as well as poorer sleep behaviors.

Methods

Participants Recruitment

Between April and December 2024, we approached all consecutive participants attending the Healthy Brain Ageing clinic at the Brain and Mind Centre, University of Sydney, for participation. This clinic is a specialist memory and cognition clinic for older adults (aged 50 y or older) with new-onset cognitive or mood concerns. As previously described [18], the exclusion criteria for the clinic were: insufficient English to complete neuropsychological assessment, Mini-Mental State Examination (MMSE) score <20 [19], current substance dependence, intellectual disability, presence of nonaffective psychiatric disorder (eg, attention-deficit/hyperactivity disorder and schizophrenia), presence of neurological disease (eg, Parkinson and epilepsy), history of head injury with loss of consciousness >30 minutes, and history of stroke. Additional exclusion criteria for this study were the absence of a mobile phone and a diagnosis of dementia. Four participants were excluded for not having a mobile phone.

Procedure

Overview

All participants underwent comprehensive and standardized neuropsychological, medical, and mood assessments conducted by a neuropsychologist, a geriatrician or neurologist, and a research psychologist, respectively. The *Sleep Memories* app was introduced to participants during their mood assessment. Those who expressed interest and provided informed consent were assisted by a researcher in installing the app on their mobile phones. Participants were also given written instructions on its use and subsequently completed memory tasks at-home in the evening and the following morning. Additionally, participants received text reminders to complete the task in the evening. Given that the sleep benefits for sleep-dependent consolidation of verbal memory are well established [3,4], and as this study was designed to assess feasibility rather than to test sleep-dependent memory effects, we did not include a control condition (eg, a wake retention interval).

Neuropsychological Assessment

A standardized battery of tests was administered by a neuropsychologist, covering a range of domains including premorbid IQ, attention, processing speed, working memory, verbal learning and memory, language, visuospatial and executive functions, and general cognitive functioning. The neuropsychological scores were adjusted for each participant's age and level of education using normative data. For this study, we reported only the premorbid IQ, as assessed by the Wechsler Test of Adult Reading [20], global cognition, as assessed by the MMSE [19], and verbal learning (trials 1 - 5) and memory

XSL•FO
RenderX

(trial 7), as assessed by the Rey Auditory Verbal Learning Test [21].

Participants who were referred to the clinic by their general practitioner for the assessment of new-onset cognitive or mood concerns were classified as either subjective cognitive decline (SCD) or MCI based on standardized criteria through a consensus meeting involving a medical specialist and 2 neuropsychologists. Participants were classified as having MCI when they scored at least 1.50 SDs below normative values for their age and education on one or more neuropsychological tests, while overall functional independence remained intact. Participants meeting criteria for MCI were further subtyped based on the domain of cognitive impairment [22]. Those with deficits primarily in the memory domain were classified as having amnestic MCI, while those with impairments in nonmemory domains (eg, language, executive function, and visuospatial skills) were classified as having nonamnestic MCI. Participants were classified as having SCD if they self-reported a persistent decline in cognitive capacity compared to a previously normal status, in the absence of objective cognitive impairment on standardized neuropsychological testing. The decline was not caused by an acute event, and was not explained by MCI, prodromal Alzheimer disease, or other psychiatric, neurological, medical, or substance-related causes [23,24].

Medical Assessment

A medical assessment was conducted by a geriatrician or a neurologist who recorded the medical history and rated the medical burden using the Cumulative Illness Rating Scale-Geriatric [25]. Each system is scored from 0 to 4, and the total score of Cumulative Illness Rating Scale-Geriatric ranges from 0 to 52, with higher scores indicating greater illness severity and comorbidity.

Mood Assessment

A research psychologist assessed lifetime and current mood and anxiety symptoms using the Mini International Neuropsychiatric Interview [26]. They also used the Cogsleep Semi-structured Interview Revised Version [27] to probe for various sleep concerns. For this study, we reported the data on bedtime, wake-up time, and frequency (days) of trouble waking up in the morning from the semistructured interview, as individual sleep patterns and morning alertness might influence willingness to participate and task completion [28]. In addition, self-reported sleep quality was assessed using the Pittsburgh Sleep Quality Index [29], with higher global scores indicating poorer sleep quality. Insomnia symptoms were assessed using the Insomnia Severity Index [30], with higher scores indicating greater severity of insomnia symptoms. For depression and anxiety symptoms, the Geriatric Depression Scale-15 [31] and Geriatric Anxiety Inventory [32] were administered, respectively, with higher scores indicating greater levels of depression and anxiety.

Sleep Memories App

Development

As previously described [12,16], the *Sleep Memories* mobile app was designed to deliver the 32-item word-pairs task via a chatbot named “Aurora.” Aurora used a low-cost internal chatbot engine that ran on the user’s device and required no Internet access. The engine was developed at Commonwealth Scientific and Industrial Research Organisation (CSIRO) and has been used extensively in other health applications [33,34] requiring ethical and safe operation. The app was co-designed by the authors and Healthy Brain Ageing researchers who provided the word-pairs task list and conducted focus groups and CSIRO software engineers who created and tested the chatbot architecture. They gathered inputs on the app’s functionality and accessibility from CSIRO staff (who tested it on their devices) [16] and older adults (4/11 were male, mean age 68.50 [SD 5.10] years; 8 had SCD and 3 had MCI) from the Healthy Brain Ageing clinic (focus group discussion) [12].

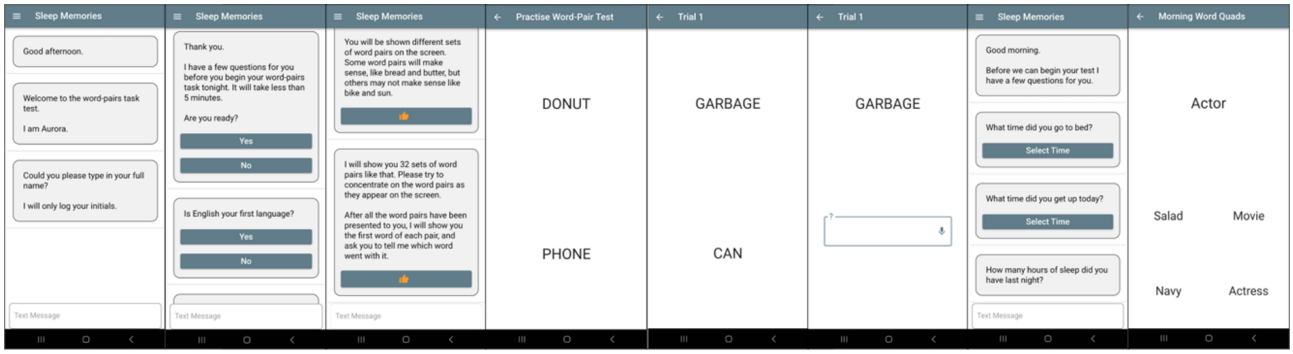
Evening Procedure

Figure 1 shows the time course and details of the app setup and completion. Upon starting the app, the chatbot collected basic demographic information, including age, gender, sleep time, and wake-up time from participants. Participants were then provided with a trial demonstration run of 3 word pairs to become familiar with the task and the app’s functionality. Participants were verbally instructed to complete the following tasks at home in a quiet, distraction-free environment and to refrain from using external aids.

XSL•FO
RenderX

Figure 1. *Sleep Memories* app task flow. The figure was modified from the past study [5].

XSL•FO
RenderX



After the demonstration, the chatbot informed participants to begin the word-pairs task within the 3-hour period preceding their reported sleep time. At the scheduled time, the participants received a notification to begin. They initially completed 4 learning trials. Each learning trial entailed a random presentation of 16 semantically related pairs (eg, syrup-maple) and 16 semantically unrelated word pairs (eg, groom-minimum). Each pair was presented for 10 seconds. At the end of each trial (ie, after all the word pairs had been presented), the participants were presented with the first word of each pair (eg, syrup) and were asked to provide the matching word (eg, maple) of each pair either by text or an audio response. The participants had 15 seconds to respond for each word pair. This was repeated for all 4 trials.

Following a 30-minute break, the participants were asked again to recall the word pairs during the evening recall test. The first word of each pair was presented for 15 seconds, and participants were asked to recall the matched word that had been paired with it. The entire evening session, excluding the break, lasted approximately 45 minutes. Participants were then able to sleep as usual.

Morning Procedure

Approximately within an hour after sleep offset, based on the wake-up time set in the app, the chatbot prompted participants to answer a few questions about their sleep and to confirm their sleep time and wake time. This was followed by two tests: (1) a morning delayed recall test whereby the first word of each pair was shown, and participants had to type or verbalize the matching word pair; and (2) a morning multiple-choice recognition test, whereby the first word of each pair was shown, along with 1 correct answer and 3 incorrect answers, and participants were asked to choose the correct matching word pair. To encourage task completion, the *Sleep Memories* app sent 4 notifications reminding participants to complete the tasks (see Figure 2 for screenshots of the *Sleep Memories* app). *Sleep Memories* logged all data on a Google Firebase service, with the server located within Australia.

Figure 2. Screenshots of the *Sleep Memories* app. (A) The Aurora chatbot introducing themselves to the participant. (B) The app probing for demographic questions, sleep time, and wake time before learning trials. (C) The app providing instructions for the word-pairs task. (D) Trial run of the word-pairs task. (E) Learning component of the word-pairs task. (F) Recall component of the word-pairs task. (G) The app requesting details of the participants' sleep before the morning tasks. (H) Multiple-choice testing component of the word pairs. The figure was modified from the past study [5].

A B C D E F G H

Participants reported their estimated sleep-onset and wake-up times when setting up the app in the evening of testing, and these were confirmed again upon waking. In addition, the app automatically recorded the timing of the encoding and recall sessions, allowing us to derive the intervals between them.

At the data analysis stage, the SDMC score (% retention) was calculated by dividing the morning delayed recall test score by the evening recall test score and then multiplying by 100 (the evening recall test measured memory retention 30 min after learning the word pairs; the morning delayed recall test assessed memory retention after a night of sleep, approximately within an hour after waking).

Follow-Up

Within 2 weeks of task completion, a subset of participants was contacted to provide feedback on their user experiences (they were selected based on availability and successful contact). Researchers conducted phone interviews using a semistructured questionnaire as a guide (see Multimedia Appendix 1). During these interviews, the researchers summarized participants' verbal responses, rather than recording or transcribing their verbatim as we did not have ethical approval for voice recording. Thus, verbatim transcription was not available. Importantly, the researchers involved in the questionnaire development and the qualitative analysis were independent of the *Sleep Memories* app development.

Feasibility and Acceptability of the *Sleep Memories* App

The feasibility of the *Sleep Memories* app was operationally defined as a completion rate of over 50% across all tasks, including evening learning trials, evening recall test, morning delayed recall test, morning multiple-choice test, and both evening recall and morning delayed recall tests [17]. This threshold was set based on prior studies of app-based cognitive assessments in older populations [35-37], reflecting the challenges of unsupervised digital cognitive assessment in older adults. It aligns with the Pragmatic-Explanatory Continuum Indicator Summary framework, which emphasizes pragmatic feasibility over idealized adherence [38]. While a scoping review of mobile-based cognitive assessments in healthy older adults reported completion rates around 60% [39], we set a slightly lower threshold of 50% as our sample included older adults with cognitive concerns who may face greater barriers to engagement with digital cognitive assessment [40].

The acceptability of the app was assessed qualitatively using a semistructured questionnaire (see Multimedia Appendix 1)

XSL•FO
RenderX

developed through a bottom-up approach based on findings from prior focus group research [12]. While the Theoretical Framework of Acceptability [41] was not used as a blueprint during the initial design phase, the questionnaire sections align with the theory. Specifically, it captured: Intervention Coherence (sections 1 and 2 on app setup, layout, and clarity of instructions), Self-efficacy (sections 3 and 4 on the SDMC task and feasibility), Affective Attitude (section 5 on subjective feelings toward the app), and Burden (any reported task demands and obstacles). Furthermore, the questionnaire was reviewed by an experienced neuropsychologist and a researcher specializing in qualitative methodologies.

Modifiable Dementia Risk Factors

The Lifestyle for Brain Health (LIBRA) index is a composite measure of 12 modifiable dementia risk factors, developed through a systematic review and expert consensus using the Delphi method [42]. The LIBRA 2 index is an updated version that incorporates additional factors, including hearing impairment, social contact, and sleep disturbances [42]. In this study, we used the validated LIBRA2 index to calculate a composite risk score by summing the available factor scores for each participant, with a theoretical range of 0 to 100. Positive weights were assigned when risk factors were present or protective factors were absent [42] (Table 1), with higher scores indicating greater dementia risk. In our sample, data were available for 13 of the 15 LIBRA2 factors, including high physical activity, sleep disturbances, high alcohol consumption, hearing impairment, kidney disease, coronary heart disease, diabetes, high cholesterol, smoking, hypertension, obesity, depression, and high cognitive activity. Data for healthy diet and low social contact were not available. Following previously published methodology [43], when less than 4 factors were missing, scores were calculated using the available factors. Four participants had 4 or more factors missing; therefore, these participants were excluded from LIBRA 2 analyses.

Table . Weights of the modifiable dementia risk factors included in Lifestyle for Brain Health (LIBRA) 2 Index[a].

Factors	Type of factors	Measurements	Weight assigned
High physical activity	Protective	At least 150 minutes of activities and at least 5 sessions of activity over 1 week	6
Sleep disturbances	Risk	PSQI[b] global score ≥5	3.3
High alcohol consumption	Risk	AUDIT-C[c] total score (≥3 for women and ≥4 for men)	3.1
Hearing impairment	Risk	Self-report (yes)	7.6
Kidney disease	Risk	Self-report (yes)	5.7
Coronary heart disease	Risk	Self-report (yes)	8.3
Diabetes	Risk	Self-report (yes)	6.8
High cholesterol	Risk	Self-report (yes)	8.2
Smoking	Risk	Self-report (current smoking)	7.9
Hypertension	Risk	Self-report (yes)	3.5
Obesity	Risk	BMI ≥30	7
Depression	Risk	GDS-15[d] total score ≥6	13
High cognitive activity	Protective	Highest tertile of CSA[e] total score	9.4
Healthy diet	Protective	—[f]	—
Low social contact	Risk	—	—

[a]Positive weights were allocated whenever the risk factors were present, or the protective factors were absent.

[b]PSQI: Pittsburgh Sleep Quality Index.

[c]AUDIT-C: Alcohol Use Disorders Identification Test.

[d]GDS-15: Geriatric Depression Scale-15.

[e]CSA: Cognitively Stimulating Activities Questionnaire.

[f]Not available.

Participant Group Definitions

We categorized participants into several groups. First, those who agreed versus those who declined to use the app. Second, those who completed all recall trials (full completers) versus those who did not complete 1 or both of the following: evening recall test and morning delayed recall test (partial completers). For additional exploratory data analysis, the median score for SDMC % retention was 92.40% (IQR 84.31-100.00). From this, we categorized participants as either low (n=18, <92.40) or high (n=18, ≥92.40) SDMC performers.

XSL•FO
RenderX

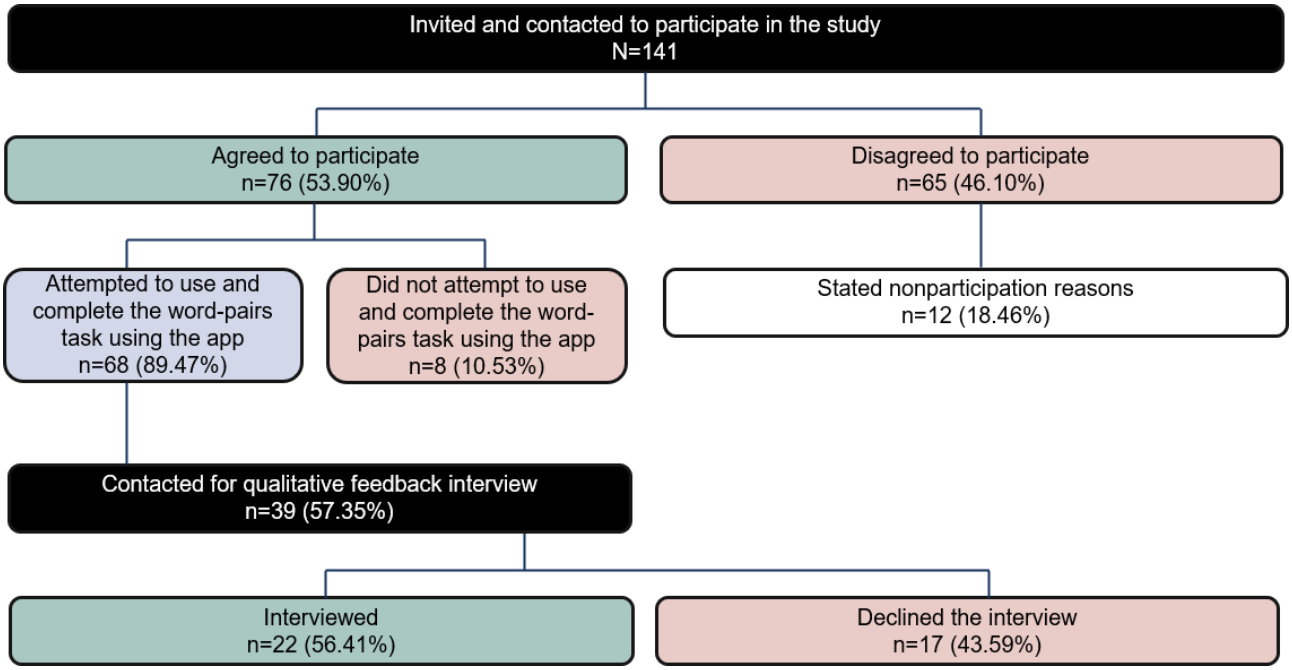
Ethical Considerations

This study was approved by the University of Sydney Human Ethics Committee (2019/HE000271) and conducted in accordance with the World Medical Association Declaration of Helsinki. All participants provided informed consent before participating and were given the option to withdraw from the study at any time. The collected data were deidentified to ensure participant privacy and confidentiality. No compensation was provided to participants.

Data Analysis

We conducted both quantitative data analysis and summarized user feedback on the *Sleep Memories* app. Quantitative data analysis was conducted using IBM SPSS Statistics (version 29) [44]. All continuous variables were inspected for normality using visual inspection (histograms), while the assumption of homogeneity of variance for these data was checked using the Levene test for equality of variances. For group comparisons, independent samples *t* tests were used for continuous variables that met assumptions of normality and homogeneity of variance. When the assumption of equal variances was violated, the Welch *t* test was applied. For nonnormally distributed variables, the nonparametric Mann-Whitney *U* test was used. Categorical variables were compared using chi-square tests. Prior to examining associations between SDMC performance and other variables (demographics, clinical factors, sleep behaviors, modifiable dementia risk factors, and global cognitive functioning), linear relationships were assessed visually using scatterplots. Following these assessments, the relationships between variables were analyzed using Pearson *r* for normally distributed variables and Spearman ρ for nonnormally distributed variables. We then compared the demographics, clinical factors, and subjective sleep-related factors between high and low SDMC performers as well as between participants who provided user feedback and those in the main sample.

Next, we summarized user feedback on the app. This analysis was based on open-ended questions at the end of each questionnaire section (see Multimedia Appendix 1), allowing participants to describe their experiences, usability, and challenges. The Likert-scale items were used only to guide discussion and provide context; no formal statistical analysis was conducted due to the small sample size (n=22), and participants' responses were optional. We reported only the descriptive summary of selected items. The data analysis was conducted in an unbiased manner, with independent coding and theme identification and development carried out by 2 researchers (CCYT and SS). Following this, a meeting was held to compare and discuss their interpretations. Any discrepancies in coding or pattern identification and development were resolved through discussion, with a third researcher, AL, facilitating consensus when needed. To ensure impartiality, CCYT and SS were blinded to participants' age, clinical diagnosis, and other personal information. Researchers identified patterns first; only then did they examine participants' age, clinical diagnosis, and task completion to assess specific difficulties completing the tasks. The summarization of user feedback was conducted based on a four-step procedure: (1) becoming familiar with the data, (2) generating initial codes, (3) clearly defining and naming them, and finally, (4) producing writing that presents a coherent narrative supported by data extracts [45].



Results

Participants and Willingness to Participate

A total of 141 consecutive clinic attendees during the data collection period were invited to participate. Of these, 54% (n=76) agreed to participate. Of those who agreed, 89% (n=68) attempted the word-pairs task using the app. A subset (n=22) was contacted for postuse feedback (see Figure 3, which details the recruitment process, including numbers who agreed or declined, task completion, and participation in interviews). Additionally, 11 participants provided explicit reasons for nonparticipation during their clinic visit, including task too lengthy (n=1), lack of time (n=2), feeling overwhelmed by the task (n=2), difficulty downloading the app (n=2), struggling with technology (n=1), inability of the phone to scan the QR code (n=1), perceived lack of memory benefits (n=1), and forgetting to bring their phone (n=1).

XSL•FO
RenderX

Figure 3. Recruitment and completion summary.

Feasibility of the *Sleep Memories* App

Of the 68 participants who attempted to use the *Sleep Memories* app to complete the word-pairs task, 68% (n=46) completed the evening recall test, 69% (n=47) completed the morning delayed recall test, and 57% (n=39) completed both tests. Out of the 46 participants who completed the evening recall test, 15% (n=7) completed only the evening recall test and not the morning delayed recall test. Similarly, of the 47 participants who completed the morning delayed recall test, 17% (n=8) completed only the morning delayed recall test and not the evening recall test.

The feasibility of the *Sleep Memories* app was assessed by examining the completion rate of the tasks: evening learning trials 1 to 4 (58/68, 85%; 57/68, 84%; 60/68, 88%; 60/68, 88%; respectively), evening recall test (46/48, 68%), morning delayed recall test (47/68, 69%), morning multiple-choice test (45/68, 66%), and both evening and morning recall tests (39/68, 57%)—all tasks had completion rates above 50% (Table 2). As described in the *Data Analysis* section, after adjusting for outliers, we computed the mean SDMC score of 92.76 (SD 13.85). In addition, the chi-square test showed no significant differences in completion rates between SCD and MCI groups (Table 3).

Table . User uptake of the *Sleep Memories* app (N=68).

Type of task	Values, n (%)[a]	95% CI
Evening learning trial 1	58 (85.29)	74.15 - 92.35
Evening learning trial 2	57 (83.82)	72.47 - 91.27
Evening learning trial 3	60 (88.24)	77.59 - 94.42
Evening learning trial 4	60 (88.24)	77.59 - 94.42
Evening recall test	46 (67.65)	55.09 - 78.20
Morning delayed recall test	47 (69.12)	56.60 - 79.46
Morning multiple-choice test	45 (66.18)	53.59 - 76.93
Completed both evening recall and morning delayed recall tests	39 (57.35)	44.80 - 69.07

[a]n (%) represents number of users completed and completion rate.

XSL•FO
RenderX

Table . User uptake of the *Sleep Memories* app in participants with subjective cognitive decline (SCD) versus mild cognitive impairment (MCI).

Type of task	χ^2 (*df*)	*P* value	ϕ
Evening learning trial 1	0.61 (1)	.44	−0.09
Evening learning trial 2	0.13 (1)	.72	−0.04
Evening learning trial 3	0.05 (1)	.82	−0.03
Evening learning trial 4	0.05 (1)	.82	−0.03
Evening recall test	2.40 (1)	.12	0.19
Morning delayed recall test	0.12 (1)	.73	−0.04
Morning multiple-choice test	0.06 (1)	.81	−0.03
Completed both evening recall and morning delayed recall tests	0.001 (1)	.98	0.004

Among those who completed both evening recall and morning delayed recall tests, on average, the interval between evening encoding and sleep onset was 98.49 (SD 56.55) minutes. In the morning, on average, the interval between wake-up time and morning delayed recall was 33.61 (SD 37.85) minutes.

Factors Influencing Willingness to Participate and Feasibility of the *Sleep Memories* App

Characteristics of Individuals Who Agreed and Disagreed to Use the Sleep Memories App

Participants who agreed to use the *Sleep Memories* app were more likely to have SCD than MCI, with higher MMSE scores, and tended to experience less difficulty waking up in the morning compared to those who declined participation (Table 4). There were no significant differences in other demographics, clinical factors, and sleep behaviors between those who agreed and those who disagreed to participate.

XSL•FO
RenderX

Table . Characteristics of participants who agreed to participate (n=76) and disagreed to participate (n=65).

Variable domains and variable	Agreed (n=76)	Disagreed (n=65)	Test statistic (*df*)	*P* value	Effect size

User Feedback and Acceptability of the *Sleep Memories* App in a Memory Clinic Setting

First, we present a brief descriptive summary of selected Likert-scale items from the Sleep Memories App Feedback Questionnaire (see Multimedia Appendix 1). Overall, 82% (18/22) of participants agreed that the app instructions were easy to understand and that the task was straightforward. A majority (20/22, 91%) indicated a preference for completing the task using the app rather than in a sleep laboratory. Additionally, 86% (19/22) reported an overall positive experience with the app. Notably, none of the participants reported needing help from their family to complete the SDMC task, while only 14% (3/22) reported needing family assistance to navigate the app.

Next, qualitative feedback from participants described age-related physical and cognitive changes that influenced their experience with the app. More specifically, 2 participants commented that the app appeared more user-friendly for individuals who are younger or more computer-literate, rather than for older users. One participant noted that being from a generation familiar with computers, but not mobile phones, made completing the task on an unfamiliar device challenging. Another suggested that improvements could be made to better accommodate individuals with vision or dexterity impairments.

Participants generally provided positive feedback, describing the app as easy to use, user-friendly, and well-designed, with some finding it fun, interesting, and convenient to complete tasks at home. One participant even shared their positive experiences with others, and another described it as one of the best apps they had ever used. Less positive feedback included feelings of nervousness or stress during testing, concerns about performance, and perceptions that the app was less suitable or engaging for older users. Given that the app is designed for cognitive testing, some level of anxiety is expected.

In addition, participants reported several technical challenges related to the functionality of the *Sleep Memories* app and the clarity of the accompanying instructions. Participants also raised concerns regarding the app's accessibility and suitability for older adults and individuals with additional needs. The most frequently mentioned issue was tasks being delivered too quickly, making it difficult to keep up. Nevertheless, they appreciated the voice input feature, making task completion easier (see Table 6 for more details).

XSL•FO
RenderX

Table . Summary of user feedback.

Patterns and comments	Participants, n
Subjective experiences	
Positive	
Easy to use, user-friendly, and straightforward	3
Well set up	1
Good layout	1
Convenient as it allowed tasks to be completed at home	1
Simple tap-based multiple-choice test	1
Interesting process	1
Shared positive experience with others	1
Best apps they had ever used	1
Less positive	
Nervous or stressed while completing the tests	3
Worried about their performance	2
Not suitable for older users	2
The app was “dry”	1
Technical challenges	
Instruction sheet provided on how to use the app was unclear	1
Needed more explanation for the morning tasks	1
Misunderstood the evening task notification as requiring immediate completion	2
Unclear wording of the second morning task (multiple-choice)	2
Unawareness that questions would automatically skip after a time limit	3
Lack of instruction on what to do if they did not know an answer	1
Confusion over morning task timing based on wake-up time	1
Delays in morning task delivery	2
Suggested the need to visually distinguish cues from response options in the multiple-choice task	2
App’s accessibility	
Tasks being delivered too quickly, making it difficult to keep up	5
Challenges using the microphone	2
Difficulty with touch functions on mobile devices due to aging	1
Needed assistance from family members to navigate the app and difficulty using it independently	1
Experienced illness during testing	2
Questioned whether individuals with dementia might become frustrated using the app	1
Voice input feature was helpful and made task completion easier	1

Predictors of SDMC Performance

There were no differences in SDMC across gender (t_{34}=−0.65, P=.52, Hedges g=0.23) and clinical diagnostic groups (t_{34}=0.55, P=.59, Hedges g=0.18). We also examined the associations between SDMC performance and several variables: demographics, clinical factors, sleep behaviors, modifiable dementia risk factors, and global cognitive functioning. We first examined these relationships using all available SDMC data points. As shown in Table 7, there was a significant and positive correlation between premorbid IQ (as measured by Wechsler Test of Adult Reading) and SDMC. Nevertheless, there were no statistically significant correlations between SDMC and other demographics, clinical factors, sleep behaviors, and modifiable dementia risk factors. Since this was an exploratory study with a small sample size, we did not correct for multiple comparisons.

Next, we conducted a sensitivity analysis to assess whether potential outliers on the evening recall task might influence the results. We excluded 3 evening recall data points that were SD 1.50 below the mean. These data points were excluded for memory consolidation-specific analyses (SDMC% retention) but retained for all other analyses. The SD 1.50 cutoff was selected as a pragmatic adaptation of common outlier detection rule [46]. Results with this exclusion are presented in Table 8, and findings were consistent both with and without the exclusion.

When comparing the characteristics of participants who provided user feedback (subsample) with those of the main sample, the subsample included a higher proportion of individuals with SCD than the main sample. Nevertheless, there was no difference between the groups in the proportion of full and partial completers. There were also no other differences between these 2 groups (Table 10).

We also reported task completion rates among participants who reported difficulty in using the app (Table 11).

Table . Task completion rates among participants reporting difficulty.

ID	Age (y)	Clinical diagnosis	Completion of 4 evening learning trials	Completion of evening test	Completion of morning test	Completion of morning multiple choice task	Notes
1	73.46	MCI[a]	Yes (all 4)	No (no score)	No (no score)	No (no score)	Experienced app malfunction and believed their data were incomplete
2	72.05	SCD[b]	No (all 4)	No (no score)	No (no score)	No (no score)	Unable to complete the task
3	70.88	SCD	Yes (all 4)	Yes	Yes	Yes	The screen went blank due to inactivity (not touching the screen)
4	76.37	SCD	Yes (all 4)	Yes	Yes	Yes	Encountered several issues with the app and could not complete the final morning task
5	73.77	MCI	Yes (all 4)	No (no score)	No (no score)	No (no score)	Thought there were 3 trials, and as a result, lost all previous results
6	70.61	SCD	Yes (all 4)	Yes	Yes	Partial (score=1)	Unable to complete the morning task
7	64.5	SCD	Yes (all 4)	Yes	Yes	Yes	Encountered an issue during the first attempt and had to clear the app data and try again

[a]MCI: mild cognitive impairment.

[b]SCD: subjective cognitive decline.

Discussion

Principal Findings

This study aimed to evaluate the willingness to engage with and the feasibility of using the *Sleep Memories* app to assess SDMC in older adults with cognitive concerns and impairments within a brain health and memory clinic setting. It is important to note that this study focused on the feasibility of a digital delivery platform for the SDMC task rather than providing objective physiological sleep metrics, such as those obtained through actigraphy or polysomnography.

Overall, the app was deemed feasible (>50% completion) as determined a priori. Notably, our study involved greater logistical demands than prior app-based cognitive studies. Sleep-dependent memory protocols require tighter scheduling around sleep periods and may involve overnight laboratory stays in unfamiliar environments, which are not always feasible for older adults with cognitive impairment. Therefore, the 57% completion rate, while modest, indicates practical feasibility for real-world implementation. Willingness to participate was higher among those with SCD than MCI, those with higher global cognitive scores, and those with less difficulty waking up in the morning. Additionally, task completion was higher among those with more years of education and higher anxiety levels.

Interestingly, while similar completion rates in the SCD and MCI groups support the app's feasibility, the higher initial refusal rate among individuals with MCI and lower cognitive scores suggests a barrier to participation. This aligns with prior

XSL•FO
RenderX

work, which showed that, relative to those with more severe cognitive impairments, individuals with SCD are often motivated to participate in research studies due to concern about cognitive decline, despite normal objective performance [47]. Future research could adopt a dyadic approach by involving a care partner to assist with technical issues at home, or potentially offering on-call technical support, helping reduce barriers for those who might otherwise decline participation.

In this study, we recorded reasons for nonparticipation from a subset of participants, which suggested that nonparticipation was influenced by a combination of perceived task burden (eg, participant perceived the word-pairs task as lengthy), technical barriers (eg, phone unable to download the app), and motivational factors (eg, participant perceived the task as lacking memory benefit). These findings are in accordance with the Unified Theory of Acceptance and Use of Technology [48], where "effort expectancy" and "facilitating conditions" correspond to the perceived task burden and technical barriers observed in this study, and "performance expectancy" reflects participants' motivation to engage with the app based on perceived cognitive benefits. Moreover, consistent with past research linking higher global cognitive functioning to greater health literacy [49], our results revealed that individuals agreeing to participate had more superior global cognition compared to those with cognitive decrements. This may be suggesting that participants with higher global cognitive functioning might be more motivated to engage in research perceived as supporting sleep and cognitive health. Difficulty with sleep also appears to affect willingness to participate in sleep-dependent memory tasks. Waking difficulties often linked to disrupted sleep or fatigue. This may reduce motivation or capacity to engage in research activities in the morning, especially those requiring structured participation such as completing tasks via a mobile app with strict timings (ie, 3 h before sleep and upon waking). Analyses of other sleep-related apps reveal similar issues. For instance, "SleepFit," which aims to enhance sleep hygiene among paramedics [50], had a substantial dropout rate of 91.40%. The authors attributed this low engagement and retention to fatigue and disrupted sleep, particularly making it difficult for users to adhere to the app's scheduled tasks.

The *Sleep Memories* app demonstrated completion rates comparable to other remote cognitive assessments in older populations. For example, a study of older adults at risk of cognitive decline and dementia (mean age 57.3, SD 5.3 y), using the smartphone-based iVitality app (featuring tests adapted from conventional neuropsychological assessments) reported completion rates of approximately 60% [36]. Similarly, an unsupervised app−based study in healthy older adults, assessing memory recall and object and scene discrimination, reported completion rates ranging from 54% to 69% [35]. Notably, the completion rate observed in this pilot study exceeded that reported for the Linus Health Core Cognitive Evaluation app in older adults (mean age 74.0, SD 6.0 y), which achieved a substantially lower rate of around 10% [37]. In this study, we found a strong initial task completion rate, particularly during the learning phase. However, the task completion rate declined during the evening recall and morning recall tests, suggesting that the completion of delayed recall tasks administered either 30 minutes later (evening recall task) or the following morning (morning delayed recall and multiple-choice tasks) may pose greater challenges in remote, unsupervised contexts. Re-engagement with the app after a delay may be influenced by contextual factors such as interruptions, competing demands, or diminished motivation to return to the task [51,52]. Notably, completion rates for all learning trials, evening, and morning tasks did not differ significantly between participants with SCD and MCI. This finding is consistent with a past study that similarly showed no significant differences in online cognitive test completion based on cognitive status [53]. Additionally, based on user feedback provided, aging—especially physical and cognitive changes—affects task completion. For instance, for some, a decline in fine motor skills appeared to hinder typing accurately on a mobile screen, especially on smaller devices. Slowed reaction times and decreased hand-eye coordination further contributed to difficulties with tasks requiring precise tapping. Additionally, reduced visual acuity common in later life [54] might also impact the ability to read small on-screen instructions and navigate through mobile apps. These sensory and motor limitations are often compounded by a general age-related unfamiliarity with digital interfaces, resulting in reduced confidence in using mobile apps. Importantly, our results showed no differences in age between full completers and partial completers, suggesting that it is not chronological age itself but the effects of aging such as changes in motor, visual, and cognitive abilities that influence task completion. Other than physical and cognitive changes due to aging, education and psychological factors also play a role in affecting the completion of app-based SDMC tasks, as we found full completers tended to have more years of education and higher anxiety levels compared to partial completers. Education fosters cognitive discipline and familiarity with structured tasks [55,56], potentially making these individuals more likely to persist through challenges. Meanwhile, elevated anxiety (when managed effectively) can enhance task vigilance, increase motivation to avoid failure, and drive individuals to complete tasks with greater urgency [57]. A similar pattern was observed when we compared the characteristics of low and high performers of SDMC tasks—high performers had more years of education and higher anxiety levels than low performers. Together, these findings suggest that education equips individuals with strategies to manage tasks, and that anxiety can provide motivation for completion and performance in SDMC tasks. When examining user feedback from full completer and partial completer groups, full completers generally reported more positive subjective experiences, noting that the app was easy to use, enjoyable, and fun. Two participants from the full completer group mentioned feeling nervous during the task, possibly due to the evaluative or confrontational nature of cognitive testing and expressed concerns about their task performance. Partial completers reported similar experiences, indicating little difference between full completers and partial completers in terms of subjective experiences. In terms of technical challenges, some full completers reported that the instructional sheet was unclear and that the task progressed too quickly. It is important to note that substantially slowing down task delivery may risk introducing ceiling effects, making the task overly easy and unnecessarily

XSL•FO
RenderX

lengthy. In contrast, partial completers provided little feedback regarding the app or technical difficulties. This lack of feedback may reflect lower motivation, earlier disengagement before issues arose, or a simple disinclination to comment. One participant in the partial completer group (diagnosed with MCI) reported needing assistance from family members to navigate the app. Although this was an isolated case, and the task had originally been designed and validated for people with MCI within the sleep laboratory [5], this observation suggests that caregiver support may be necessary to facilitate engagement with the *Sleep Memories* app among some users with greater cognitive impairment.

Having considered factors influencing willingness to participate and the feasibility of the app based on task completion, it is also important to understand those affecting SDMC performance. Notably, cognitive reserve affects SDMC performance. We observed a positive correlation between premorbid IQ and SDMC performance, which aligns with past research showing that cognitive reserve is linked to better cognitive outcomes [58]. Our findings suggest that premorbid IQ influences task performance and retention, underscoring the importance of considering cognitive reserve in remote assessments.

Given that the *Sleep Memories* app was used in an unsupervised, remote capacity, we acknowledge that contextual and behavioral factors may contribute to variability in SDMC scores. However, we found that except for premorbid IQ, none of the demographic, clinical, sleep behavior, modifiable dementia risk factors, or cognitive variables were significantly associated with overnight memory consolidation. This suggests that while such factors may introduce variability, they do not systematically account for individual differences in SDMC performance.

Research Impact

This was the first study to demonstrate the feasibility of SDMC data collection delivered unsupervised through a chatbot and mobile app. While not a replacement for laboratory studies, the *Sleep Memories* app demonstrates potential as a complementary research tool that may support more accessible and cost-effective data collection.

The comparable task completion rates between participants with SCD and those with MCI indicate that the *Sleep Memories* app and the word-pairs task can be feasibly administered across these populations. Nevertheless, as with other digital cognitive tools, unsupervised SDMC testing presents challenges related to cognitive load and user engagement. In this study, we also highlighted key factors that may facilitate the adoption of the app, which could inform the development of personalized interventions aimed at optimizing healthy brain aging in the future.

Participant feedback emphasized the value of clear, concise instructions, and well-defined expectations regarding task timing and completion. To support usability among older adults, accessible design strategies are essential, such as larger icons, high-contrast text, intuitive audio cues, and customizable interface settings. Ultimately, refining and validating remote memory tools such as the *Sleep Memories* app across global cognitive and demographic profiles will be critical for advancing equitable, scalable cognitive health monitoring in clinical and community settings.

Limitations

There are several limitations to this study. First, we did not record participants' feedback. Future qualitative studies should consider audio-recording responses and conducting formal thematic analyses of verbatim data. Nonetheless, we identified several factors that influenced participation and completion rates. Second, we did not systematically assess the digital literacy of participants, which may have influenced their ability to use the app and interpret results. Third, as widely documented in the literature, the validity of remote cognitive testing must be carefully considered, given the potential for uncontrolled distractions and external assistance. Reassuringly, the observed scores in this study were comparable to those reported in similar lab-based SDMC studies involving comparable cohorts [5]. Nonetheless, incorporating additional validity safeguards and conducting larger-scale evaluations will be important to further mitigate these limitations. Fourth, the study did not directly validate against supervised lab-based SDMC assessments. However, complete equivalence should not be expected, given differences in delivery format and response conditions, and the observed scores were comparable to those reported in similar lab-based SDMC research in older and MCI samples [5]. Finally, sleep and wake times were self-reported, and no objective measures were collected to verify these estimates. Notwithstanding these limitations, the study has strengths worth mentioning. For instance, it demonstrates high ecological validity and that recruitment and SDMC task delivery via the *Sleep Memories* app are feasible for a memory clinic setting.

Conclusions

This study demonstrated the feasibility of using the *Sleep Memories* app to assess SDMC in older adults within a memory clinic context. These findings offer valuable guidance for the development of accessible digital tools that can effectively monitor cognitive health across varying levels of impairment.

The team is currently continuing to collect SDMC data using the app from a larger sample recruited through a brain health and memory clinic setting to support ongoing refinement and larger-scale validation studies. These efforts aim to further establish the feasibility, reliability, and clinical utility of the app, the characterization of neurobiological correlates, and sensitivity to interventions and to inform scalability for community-based implementation.

Acknowledgments

The authors would like to thank all the participants for their involvement in this study, the clinical and research team of the Healthy Brain Ageing Program, University of Sydney, and the research team from Commonwealth Scientific and Industrial

Abstract

Background: Maintaining balance is essential for older adults to preserve independence and reduce fall risk. However, empirical evidence linking trunk stability with balance and gait is scarce, partly due to the lack of accessible field tests. Smartphone-based accelerometry field tests offer a promising approach to assess trunk stability outside the laboratory.

Objective: The study aimed to determine (1) the association between trunk stability and whole-body balance and gait and (2) the extent to which trunk stability and whole-body balance field tests align with laboratory-based assessments in older adults.

Methods: A total of 53 physically active older adults performed 2 trunk stability tests (ie, the lumbopelvic stability [field] and the unstable sitting posturographic [laboratory] tests), 2 whole-body balance tests (ie, the tandem stance posturographic [laboratory] and the whole-body static balance [field] tests), and 2 gait-related tests (ie, the straight-line gait and the modified Timed Up and Go [field] tests) 2 times. A Spearman correlation analysis was performed after assessing the reliability of the variables.

Results: Significant positive low-to-high correlations were found between the lumbopelvic stability and the whole-body static balance tests ($0.380 \leq r \leq 0.700$; $P<.01$). A low positive correlation ($r=0.436$; $P<.01$) was also observed between the unstable sitting posturographic test and the tandem stance posturographic test. No correlations were found between trunk stability and any gait-related test. No moderate-to-high relationships ($0.289 \leq r \leq 0.487$; $P<.05$) were found between laboratory and field tests (both for trunk stability and whole-body balance).

Conclusions: Better static lumbopelvic control during exercises like the back bridge and the bird-dog is linked to improved whole-body balance in active older adults, suggesting that these positions be included in future interventions to enhance trunk stability. Accessible smartphone-based field tests for lumbopelvic stability offer a promising approach for the standardized assessment of trunk stability. However, direct extrapolation from field tools to laboratory findings is unfeasible due to a lack of correlation. These findings highlight the potential of smartphone-based field tests to complement clinical and research assessments of balance in older adults.

Introduction

Maintaining balance and gait in older adults is crucial for functional independence and reducing fall risk [1]. Biomechanical research suggests that proper trunk neuromuscular control could play a key role in preserving motor function in this population, as it has been linked with the ability to maintain an upright posture [2], transfer loads [3], and coordinate movements during daily activities [4]. Previous studies that measured trunk stability (ie, understood as the capability to maintain or resume a relative position or trajectory of the trunk following internal or external forces) [5] in both laboratory [6] and field settings [7] support this idea, as they found reduced voluntary trunk control among older people in seated positions compared to young individuals [6], and they were able to discriminate between fallers and nonfallers [7]. More recent research has used smartphone-based accelerometry at the thoracic level to examine associations between trunk

XSL•FO
RenderX

accelerations during upright balance and functional tasks, such as the sit-to-stand task, in older adults [8-10]. While these approaches provide valuable insights into higher global postural control during standing tasks, trunk behavior is evaluated within movements in which control is distributed across multiple joints and segments. Consequently, there is a lack of empirical evidence directly linking trunk-focused stability outcomes (ie, derived from tasks designed to impose relatively high demands on lumbopelvic control) with whole-body balance and gait-related parameters in older adults. In this sense, while trunk-focused exercise programs have proven to be useful to improve balance and gait in this population [11], it remains unclear to what extent these benefits stem from enhanced trunk stability, as this capability is not typically assessed. Moreover, although correlational studies have shown positive relationships of trunk muscle strength [12-14], endurance [13], muscle thickness [15,16], and spinopelvic range of motion [12,17,18] with whole-body balance (ie, static and dynamic) [12,18], gait parameters (ie, step length, gait speed) [14,17,18], and functional capacity (ie, the time taken to complete the sit-to-stand and the Timed Up and Go tests) [12,14], correlational evidence specifically addressing trunk stability remains scarce. To the authors' knowledge, only 2 studies have linked trunk-focused stability outcomes from a seated dynamic postural control test on a force platform (in which lower-limb and arm strategies are largely constrained, making task performance predominantly dependent on trunk control) with observational-based assessments of whole-body balance and gait in older adults [19,20].

A key reason for the limited research in this field is the absence of field tests that objectively quantify trunk stability. Inertial sensors have emerged as cost-effective field-setting tools to reliably detect postural control impairments in older adults [21]. While laboratory-based force platform assessments remain the standard reference for biomechanical analysis, their limited accessibility has motivated the development of field-based alternatives. Based on this approach, our research group has developed a novel accelerometry-based field method [22] to assess trunk-focused stability outcomes during common floor-based trunk exercises (eg, bridges and bird-dogs). While this method has shown to be promising in young adults [23], its applicability and correlation with whole-body balance and gait in older adults remain unexplored. Since these exercises are used in exercise programs that aim to preserve motor function in older people [24,25], introducing an accelerometry-based assessment of trunk stability would help to establish which exercises are most closely associated with whole-body balance and gait and thus should be prioritized within training programs.

Given this scarcity of direct empirical evidence, the primary aim of this study was to explore the associations between biomechanically based trunk stability, whole-body balance, and gait outcomes in physically active older adults. This was managed by using both well-established laboratory protocols and novel inertial-sensor-based field tests: (1) trunk stability tests: the unstable sitting posturographic test (laboratory-based) [5] and the lumbopelvic stability tests (field-based) [22]; (2) whole-body balance tests: the tandem stance dynamic posturographic test (laboratory-based) [26] and the whole-body static balance test (field-based) [27]; and (3) gait-related tests: the straight-line gait [27] and the modified Timed Up and Go (field-based) [28] tests. A secondary exploratory aim was to analyze the relationships between these laboratory and field assessments to inform practitioners about their alignment. Finally, this study aimed to determine the between-session test-retest reliability (both relative and absolute) of all outcomes, to support interpretation of the correlational findings, and to guide the selection of robust and reproducible performance metrics. Based on the principle of specificity and on previous studies [23,26], it was first hypothesized that trunk stability would show moderate associations with biomechanical whole-body balance outcomes only in those tests that share task requirements. Specifically, we hypothesized that lumbopelvic stability tests would correlate with whole-body static balance tests, given the shared demand for maintaining steady positions (eg, standing, bridging, and bird-dog). Thereafter, we hypothesized that the unstable sitting posturographic test would correlate with the tandem stance posturographic test due to their common requirement to anticipate and respond to predicted disturbances. Regarding gait-related outcomes, we hypothesized that there would be no correlation with trunk stability tests, except between the unstable sitting posturographic test and the modified Timed Up and Go test, since voluntary trunk control may play a key role in standing, sitting, and turning.

Methods

Participants

In order to check the proposed hypotheses, a correlation coefficient (r) of 0.5 was expected for the sample size estimation, considering previous studies that examined the relationship between trunk stability tests and whole-body dynamic balance tests [23,26]. The software G*Power 3.1 (v3.1, University of Düsseldorf) was used with the following parameters: r=0.5; α=.006; 1–β=.8. Calculations suggested a sample size of approximately 46 participants. An additional 20% of the target sample was recruited to anticipate the loss of subjects due to the inability to implement some of the tests presented. A total of 53 volunteer participants aged 65 years or older (mean age 70.3, SD 3.8 y; 21 male participants and 32 female participants) were recruited for the study. The main sociodemographic and anthropometric characteristics and the physical activity levels of the participants are shown in Table 1. Moreover, Table S1 in Multimedia Appendix 1 shows the clinical data of the participants. Participants were asked to present a medical certificate signed by their primary care physician to guarantee that they had no contraindications to perform trunk stability, whole-body balance, and gait-related tests.

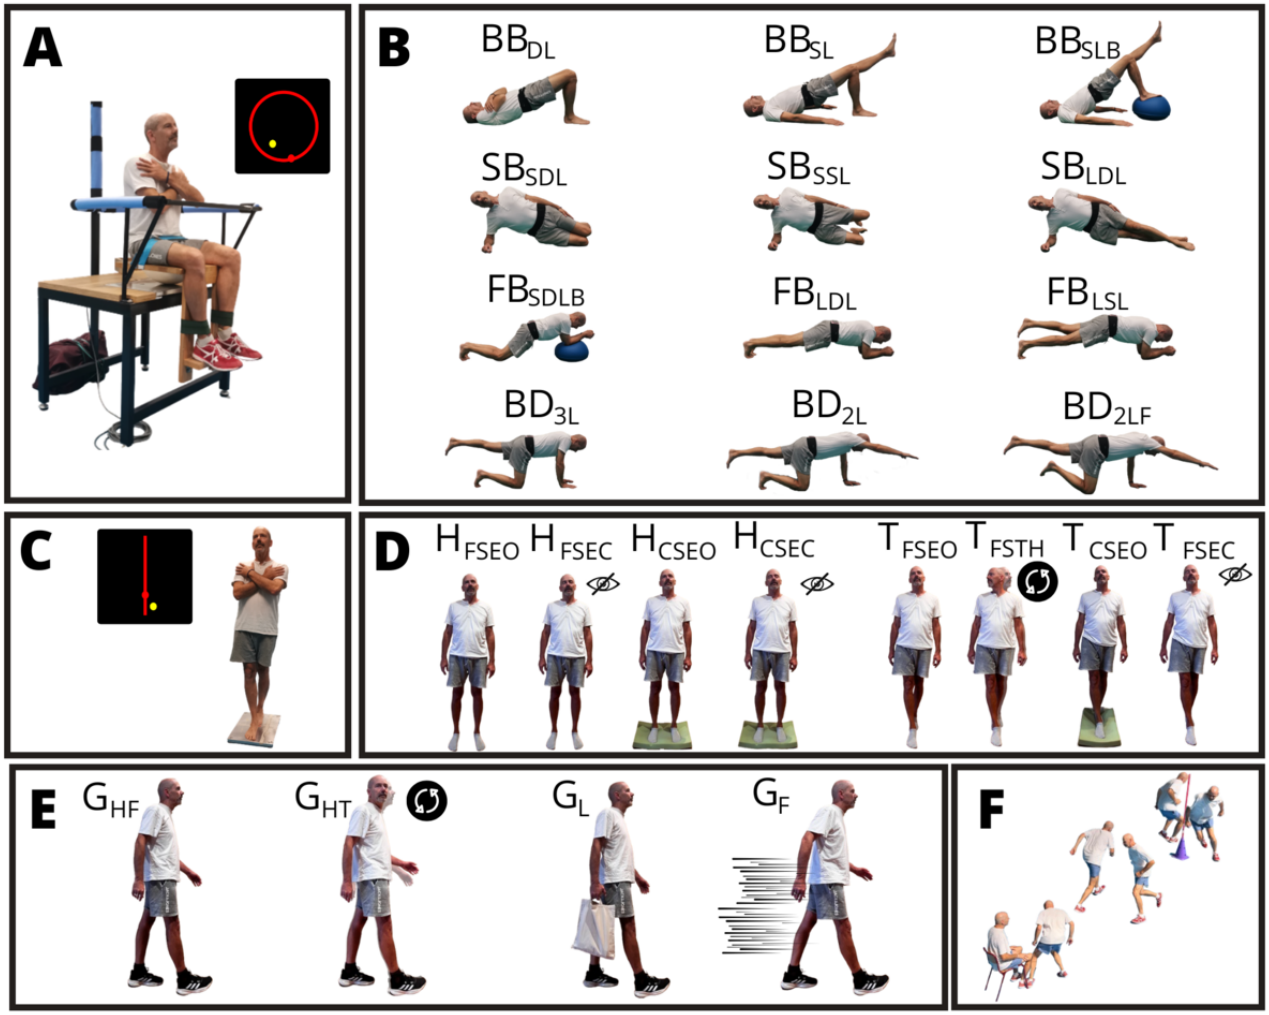
Ethical Considerations

The University Office for Research Ethics (DCD.FBM.01.23) approved this study. The study was conducted in accordance with the Declaration of Helsinki, informing the participants of the characteristics and risks of the study. Each participant provided written informed consent. Data were handled to ensure privacy and confidentiality and were accessible only to the research team. No financial compensation was provided. Written informed consent was obtained for the publication of the participant's images.

Experimental Procedure

Each participant's mass (mean 69.6, SD 10.3 kg); height (mean 1.62, SD 0.10 m); and height of the center of mass position of the head, arms, and trunk segment (estimated at 62.6% [29] of the trunk height, measured as the distance between the greater trochanter and the glenohumeral joint: 0.53, SD 0.05 m) were registered before testing. The participant's preferred leg was established as the leg that the participant would use to kick a ball. Participants carried out 2 testing sessions with a day's rest in-between, and these sessions were repeated 1 week later. The first assessment session consisted of a trunk stability assessment through lumbopelvic stability tests (using a randomized block design to avoid fatigue influence) during the back bridge, the preferred side bridge (determined by the side of the preferred leg), and the front bridge and the bird-dog positions [22]. The second assessment session consisted of trunk stability, dynamic balance, static balance, and gait-related tests (carrying out first those tests in which performance is most likely to be affected by fatigue) performed in the following order: (A) the unstable sitting posturographic test, (B) the tandem dynamic balance stance posturographic test, (C) whole-body static balance tests, (D) straight-line gait tests, and (E) the modified Timed Up and Go test. A 5 - to 7-minute warm-up was performed at the beginning of each testing session to enhance awareness of spine and pelvis alignment and to facilitate the understanding and practice of neutral spine posture. The following exercises were included in this warm-up: (1) isolated scapular retractions and

XSL•FO
RenderX



protractions; (2) isolated pelvic retroversions and anteversions; and (3) the cat-camel exercise.

Testing Protocol Description and Data Processing

Trunk Stability Tests

Lumbopelvic linear accelerations were recorded to assess the postural control challenge imposed on the participants as an index of exercise intensity during the lumbopelvic stability tests (field-based), which involved performing three 15-second back bridge, preferred side bridge, front bridge, and bird-dog positions (Figure 1B) using a novel "ad hoc" smartphone app (CoreMaker) created by our research group. A smartphone was placed with Velcro above the participant's sacrum on an elastic pelvic belt to reduce smartphone movement caused by muscle contractions similar to the protocol previously described by Heredia-Elvar et al [22]. The accelerations were recorded at 100 samples per second from a 3-axis accelerometer embedded in the smartphone (iPhone SE, 2nd generation, model MHGQ3QL/A; Apple Inc.), and it was configured using iOS version 15. Lumbopelvic stability was assessed through the mean acceleration ($m \cdot s^{-2}$) calculated as the average of the acceleration magnitude data series obtained from the 3-axis (vertical, anterior-posterior, and medial-lateral) of the smartphone accelerometer using the CoreMaker app mentioned earlier.

Figure 1. Trunk stability, whole-body balance, and gait-related tests: (A) The unstable sitting posturographic test. (B) The lumbopelvic stability tests performing 3 back bridge (back bridge with double-leg support [BB_{DL}], back bridge with single-leg support [BB_{SL}], and back bridge with single-leg support on a hemisphere ball [BB_{SLB}]), 3 preferred side bridge (side bridge with short double-leg support [SB_{SDL}], side bridge with short single-leg support [SB_{SSL}], and side bridge with long double-leg support [SB_{LDL}]), 3 front bridge (front bridge with short double-leg support and arms on hemisphere ball [FB_{SDLB}], front bridge with long double-leg support [FB_{LDL}], and front bridge with long single-leg support [FB_{LSL}]), and bird-dog (3-limb bird-dog position [BD_{3L}], 2-limb bird-dog position [BD_{2L}], and 2-limb bird-dog position with the forefoot of the supporting leg elevated [BD_{2LF}]) positions. (C) The tandem stance posturographic test. (D) The whole-body static balance tests performed with feet hip-width apart (firm surface and eyes open [H_{FSEO}], firm surface and eyes closed [H_{FSEC}], compliant surface and eyes open [H_{CSEO}], and compliant surface and eyes closed [H_{CSEC}]) and tandem (firm surface and eyes open [T_{FSEO}], firm surface and turning the head [T_{FSTH}], compliant surface and eyes open [T_{CSEO}], and firm surface and eyes closed [T_{FSEC}]) positions. (E) Straight-line gait tests (head-forward gait [G_{HF}]; head turning gait [G_{HT}]; 1-sided 10% body weight load gait [G_L]; fast gait without running [G_F]). (F) The modified Timed Up and Go test performed as fast as possible, being allowed to run. Written informed consent was obtained for the publication of the participant's images.

XSL•FO
RenderX

The unstable sitting posturographic test (laboratory-based) [5] was used to assess the participants' ability to control their trunks during a circular tracking task while sitting on an unstable seat placed on a force platform (9287CA, Kistler; Figure 1A). Real-time feedback of the participants' center of pressure displacement was displayed on a screen. Additionally, a target point (which moved in a circular trajectory) was presented to assess the participants' ability to adjust their center of pressure position to this point. A 4° inclination angle of the head, arms, and trunk center of mass (estimated at 62.6% [29] of the distance between the greater trochanter and the glenohumeral joint) was calculated to establish the movement amplitude of the target point. The participants' arms were crossed over their chest, and they performed five 70-second trials with a 60-second rest between trials. Center of pressure displacement was collected and filtered by a low-pass-Butterworth filter with a cutoff frequency of 5 Hz. The initial 10 seconds were discarded due to the nonstationarity of the signal. The mean radial error was used to quantify the trunk performance, calculated as the average of the vector distance magnitude (mm) of the center of pressure from the target point using an "ad hoc" software developed by our research group through LabView 9.0 environment (v9.0, National Instruments) [23].

Whole-Body Dynamic Balance Test

The tandem stance posturographic test (laboratory-based; Figure 1C) was used to measure the whole-body dynamic balance through an anterior-posterior tracking task (with the same characteristics as those used in the unstable sitting posturographic test but with a linear tracking task) while standing on a force platform (9286AA, Kistler) [26]. A 2° inclination angle of the whole-body center of mass (estimated at 55% [29] of each participant's height) was calculated to establish the movement amplitude of the target point. The participants performed the tandem test with their preferred lower limb placed ahead of the other limb. Their arms were crossed over their chest during both tests, and they performed each task 3 times with a 1-min rest between tasks, with a trial duration of 70 seconds. Similar to the unstable sitting posturographic test, center of pressure displacement was filtered (low-pass Butterworth filter; cutoff frequency: 5 Hz), and the initial 10 seconds were discarded [5]. Then, the mean radial error (mm) was calculated to quantify balance performance.

Whole-Body Static Balance Tests

The whole-body static balance tests (field-based) evaluated participants' postural sway through the manipulation of sensory inputs required for balance [27]. Participants wore an elastic sacroiliac belt fastened with Velcro around the lower back (around L5/S1) [27], which housed a smartphone (iPhone SE, 2nd generation, model MHGQ3QL/A). Data from the smartphone inertial sensors (accelerometer) were recorded during the tasks by the G&B smartphone app [27] at 100 samples per second. Participants were asked to stand as still as possible with their feet hip-width apart (H) and in tandem (T; Figure 1D) positions with their arms by their sides. The hip-width stance posturographic-field tests under steady-state conditions included standing on a firm surface and eyes open, on a firm surface and eyes closed, on a compliant surface and eyes open, and on a compliant surface and eyes closed. The tandem stance posturographic-field tests under steady-state conditions consisted of standing on a firm surface and eyes open, on a firm surface while turning the head, on a compliant surface and eyes open, and on a firm surface and eyes closed. The total of 8 static balance tasks (Figure 1D) were performed twice. Each trial lasted 30 seconds. The 8 tasks were performed in the order shown in Figure 1 with a rest period of 30 seconds between tasks. After a 2-min resting period, the tasks were performed again in the same order. A medium density foam mat (52 kg/m^3, 50×28×5 cm) was used as the compliant surface. The original postural stability outcome obtained from the G&B was inverse log transformed to compute the mean absolute acceleration in each balance task.

Straight-Line Gait Tests

Four gait tests in a straight line were proposed to assess walking balance (gait periodicity index) and walking speed (Figure 1E). These included head-forward gait, head turning gait, one-sided 10% body weight load gait, and fast gait without running. The gait tasks were designed to be performed at the user's preferred walking speed, except for the fast gait without running. Each task consisted of four 6-second walks. This task design allows the gait assessment to be carried out over approximately 10 m. The 4 tasks were performed in the order shown in Figure 1 with a rest period of 30 seconds between tasks, and a second set was performed in the same order after a 2-minute rest. As in the whole-body static balance tests, participants wore an elastic sacroiliac belt fastened with Velcro around the lower back (around L5/S1) [27] to house a smartphone (iPhone SE, 2nd generation, model MHGQ3QL/A). Data from the smartphone inertial sensors (accelerometer and gyroscope) were recorded by the G&B app [27] at 100 samples per second during the tasks. Specifically, a wavelet-based step-event detection algorithm and a double-pendulum gait model were used to analyze gait data by obtaining walking balance (periodicity index, %) and walking speed (m/s) outcomes through the G&B app. All straight-line gait and whole-body static balance assessments administered using the G&B smartphone app were adapted from the protocol described by Rashid et al [27], introducing additional task conditions to increase relevant task-specific postural and locomotor demands for older adults. These conditions were designed to progressively perturb balance control pathways, thereby increasing demands on segmental postural control, including the trunk.

Functional Mobility Test

The modified Timed Up and Go test consisted of standing up from a chair, moving forward 3 m, turning around a cone, returning to the chair, and sitting back down [28] (Figure 1F). Participants performed the task as fast as possible, including running if they were able, to better discriminate between participants and to avoid ceiling effects, particularly in active populations. The time (s) was recorded using a digital chronometer (HS-30W-N1V, CASIO).

If a participant failed an attempt (eg, in the lumbopelvic stability tests, a failed attempt was defined as being able to assume the required initial position but not being able to maintain proper body alignment throughout the entire trial, assuming the initial

XSL•FO
RenderX

position but discontinuing the task before completion, or not being able to assume the required initial position), the attempt was classified as invalid and repeated. Only the failed attempt was repeated, not the entire test sequence. If the participant failed again or reported being unable to safely perform the task, the trial was recorded as "not feasible," and no further attempts were requested for that specific condition. This procedure was applied consistently across all tests.

For the main analyses, we used a peak-performance criterion based on session 2 for each test condition. This approach was selected to emphasize participants' optimal task execution while limiting the impact of temporary, nonsystematic fluctuations in performance (eg, momentary attentional variation or short-term fatigue), which may occur during physically demanding tasks in older adults. Accordingly, for the lumbopelvic stability tests and for the hip-width and tandem stance posturographic-field tests, the best of the 2 recorded trials (ie, the lowest mean acceleration) was selected for further analyses. For the unstable sitting and the tandem stance dynamic posturographic laboratory tests, the average of the 2 best attempts (ie, lowest mean radial error) was used, based on 5 and 3 trials, respectively. In the straight-line gait tests, the best of the 2 recorded trials (ie, highest speed and percentage values) was used. Finally, for the modified Timed Up and Go test, participants performed 3 trials, and the best trial (ie, lowest completion time) was retained for statistical analyses.

We acknowledge that peak-performance selection can lead to an overestimation of typical functional capacity in older adults. Consequently, to evaluate the robustness and representativeness of the findings, we complemented these primary analyses with sensitivity analyses based on mean performance averaged across sessions 1 and 2. For these sensitivity analyses, performance was computed as the mean of all recorded trials within each session and then averaged across sessions. The only exception was the unstable sitting posturographic test, for which mean performance was calculated as the average of the three best attempts out of 5 trials.

Statistical Analyses

Statistical analyses were performed to address the study hypotheses and evaluate the reliability of the measurements. Data (presented as mean and SD) from those participants who carried out all the testing sessions were used for the statistical analyses. The normality of the data distribution was explored through the Shapiro-Wilk test. Since the data did not follow a normal distribution, nonparametric statistics were applied. The Wilcoxon test was performed for each test score to explore the existence of statistically significant mean differences between sessions, and the Spearman's correlation coefficient was used to analyze the relationship between the variables.

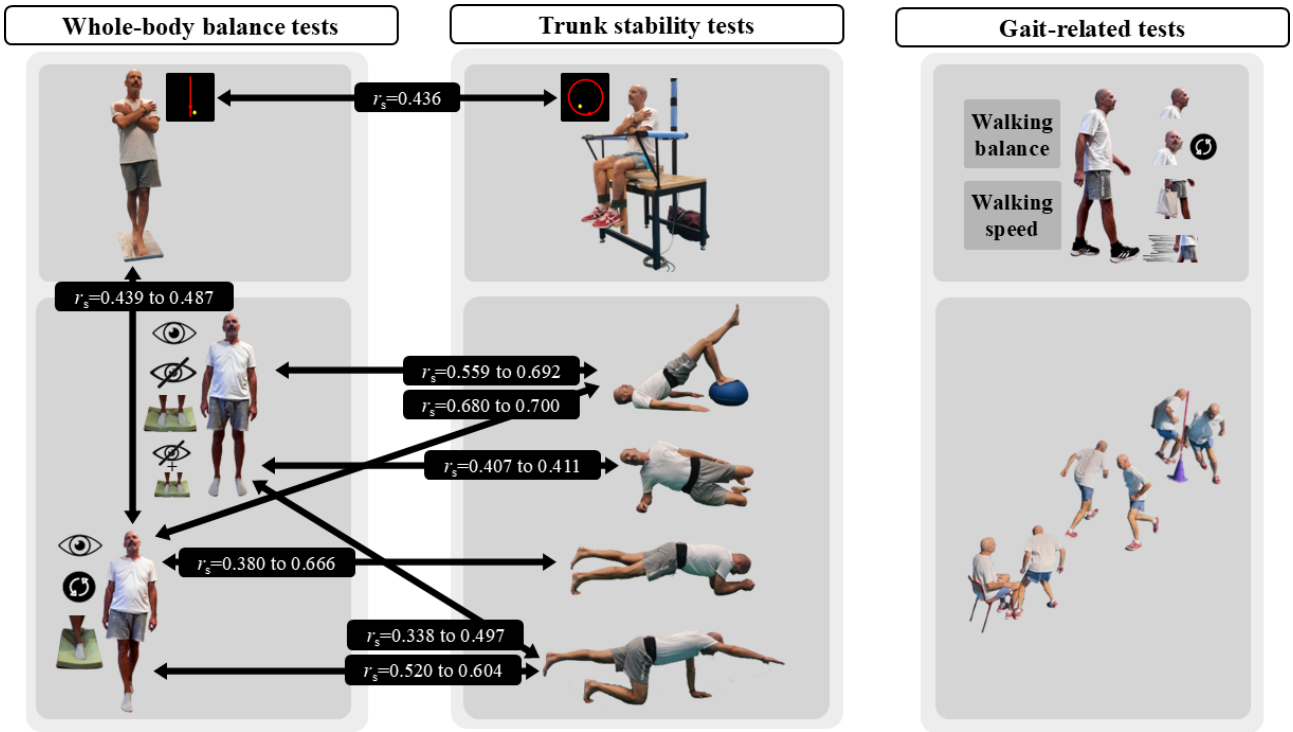
In order to avoid possible bias due to the low consistency of certain variables, typical error (TE) and intraclass correlation coefficient ($ICC_{3,1}$) were calculated (confidence limits set at 95%) to evaluate the absolute and relative test-retest reliability, respectively, and to determine which variables could be used in subsequent correlational analyses. The TE was calculated as the SD of the difference between the 2 testing sessions divided by $\sqrt{2}$. Furthermore, TE values were also expressed as percentages to facilitate data extrapolation, interpretation, and comparison with the pertinent literature. Percentage TE was calculated as the TE×100 and divided by the average of test-retest means. ICC values were interpreted according to the following criteria: poor (<0.50), moderate (0.50 - 0.75), good (0.75 - 0.90), and excellent (>0.90) [30]. Both absolute and relative reliability indexes were calculated through the spreadsheet proposed by Hopkins [31].

If some variables obtained a poor level of relative reliability [30] (ie, ICC <0.50), the Tukey outlier classification test was applied to the change between sessions. Outliers are based on the IQR (ie, [25th percentile]–1.5×IQR and [75th percentile]+1.5×IQR). The data obtained in the second assessment session for the variables that obtained a moderate-to-excellent level of relative reliability [30] (ie, ICC >0.50) were used to perform a correlation analysis (r) between them. Correlational analyses were performed with JASP 0.16.2 software (Eric-Jan Wagenmakers, Department of the Psychological Methods, University of Amsterdam, Nieuwe Achtergracht 129B). The correlation coefficient was interpreted as low (0.30 - 0.49), moderate (0.50 - 0.69), high (0.70 - 0.89), and very high (≥0.90) [32]. In order to minimize the probability of obtaining significant correlations by chance, the prespecified significance level (P<.05) was divided by the number of comparisons analyzed (Bonferroni correction).

To examine whether the observed correlations were influenced by the choice of data reduction strategy (session 2 peak-performance vs mean performance averaged across sessions 1 and 2), we conducted complementary sensitivity analyses as described in the previous section. First, we repeated the reliability analyses using mean performance across attempts within each session. Second, we repeated the correlational analyses using the average of session 1 and session 2 mean performance as a more representative estimate of typical performance and to reduce potential measurement noise. The pattern of results across these analyses was then compared with the original session 2 peak-performance analyses.

Given that the lumbopelvic stability tests represent the primary outcome of the study and that they are also the tests most affected by feasibility constraints at higher difficulty levels, an additional focused sensitivity analysis was performed to determine whether test-retest reliability metrics and the key correlations observed in the main analyses based on the session 2 peak-performance criterion were robust enough when analyses were restricted to a more homogeneous group of participants with higher physical fitness who successfully completed all 3 test levels.

Results



The reliability analyses demonstrated varying levels of test-retest reliability across the assessed variables. Trunk stability tests generally showed a moderate-to-excellent reliability (0.68≤ICC≤0.88; 12.44%≤TE≤31.54%; Table S2 in Multimedia Appendix 1) with the exception of the easiest variations of the back bridge (with double-leg support) and the preferred side bridge (with short double-leg support) and the easiest and most difficult variation of the bird-dog (3-limb position and 2-limb

XSL•FO
RenderX

position with the forefoot of the supporting leg elevated, respectively), which showed a poor level of reliability (0.19≤ICC≤0.39, 29.24%≤TE≤38.55%; Table S2 in Multimedia Appendix 1). A moderate-to-excellent level of reliability was shown regarding the reliability analyses for the whole-body balance and gait-related tests (0.51≤ICC≤0.85; 2.55%≤TE≤29.27%; Table S3 in Multimedia Appendix 1) except for the tandem on a firm surface with eyes closed static balance test, the periodicity index of the head-forward gait test, and the head turning gait test (0.37≤ICC≤0.43; 3.06%≤TE≤29.98%; Table S3 in Multimedia Appendix 1). These reliability values, particularly those for the tandem on firm surface and eyes closed static balance tests and the gait test periodicity index, were obtained after the application of the Tukey outlier classification test to address initial low reliability. The Wilcoxon test showed significant between-sessions differences for the mean radial error during the unstable sitting posturographic test and the tandem stance posturographic test, the accelerations of some lumbopelvic stability tests (side bridge with long double-leg support and 2-limb bird-dog positions), the whole-body static balance test with feet hip-width apart on firm surface and eyes open, and the walking speed during all the straight-line gait tests. These showed that there was a learning or repetition effect in these tests and therefore a significantly higher performance in these tests in session 2. For in-depth results, Table S2 in Multimedia Appendix 1 and Table S3 in Multimedia Appendix 1 show the descriptive statistics and the absolute and relative between-session reliability for trunk stability and whole-body balance, gait, and functional mobility tests, respectively.

Given the established reliability and observed learning effects, subsequent correlational analyses were performed using data from the second assessment session. These analyses explored relationships within and between different capabilities, as detailed below. Correlational analyses between the trunk stability tests (Figure 2) generally revealed no statistically significant relationships (P<.05) in the moderate-to-high range between the unstable sitting posturographic test and the lumbopelvic stability tests (Table S4 in Multimedia Appendix 1).

Figure 2. Main correlations between trunk stability tests, whole-body balance tests, and gait-related tests in physically active older adults. The bridge positions displayed represent those that showed the greatest number of correlations with the methodology used to evaluate whole-body static balance in field settings. The 2-limb bird-dog position was included because it was the only one with reliable values. The *tandem stance posturographic test* during a dynamic tracking task showed low but statistically significant correlations with the *tandem stance posturographic-field tests* under steady-state conditions, but no significant correlations with the *hip-width stance posturographic-field tests*. Overall, correlations between the *unstable sitting posturographic test* and the *lumbopelvic stability tests* were not statistically significant. The *unstable sitting* and *tandem stance posturographic tests* during a dynamic tracking task were lowly correlated. *Lumbopelvic stability tests* demonstrated low-to-high correlations with several whole-body balance tests under steady-state conditions, particularly for the back bridge and bird-dog positions. No significant associations were found between trunk stability tests and gait-related tests. Written informed consent was obtained for the publication of the participant's images.

As seen in Figure 2, broadly, no statistically significant relationships (P<.05) in the moderate-to-high range were found between the tandem stance posturographic test and the whole-body static balance tests. Focusing on some significant comparisons, whole-body static balance tests in the tandem position had a low significant relationship with the tandem stance posturographic test (0.439≤r≤0.487; P<.05; Table S5 in Multimedia Appendix 1).

Concerning the correlation analysis of the trunk stability tests with the whole-body balance performance tests, two of the four comparisons showed a significant association (Figure 2). A low significant association (r=0.436; P<.013) was found when

XSL•FO
RenderX

comparing the unstable sitting posturographic test with the tandem stance posturographic test. A range of significant associations, from low to high ($0.380 \leq r \leq 0.700$; $P<.013$; Table S6 in Multimedia Appendix 1), was observed when lumbopelvic stability tests were compared with whole-body static balance tests (Figure 2). Specifically, moderate correlations ($0.559 \leq r \leq 0.643$; $P<.013$) were found during the back bridge position with the 4 variations of the static balance tests in the hip-width position, some approaching high levels ($0.673 \leq r \leq 0.692$; $P<.013$). In addition, the most difficult back bridge (with single-leg support on a hemisphere ball) showed a high correlation with the moderate (firm surface and turning the head) and high (compliant surface and eyes open) difficulty tandem positions ($0.680 \leq r \leq 0.700$; $P<.013$). A low correlation was found with the variations in the hip-width position ($0.338 \leq r \leq 0.497$; $P<.013$) during the bird-dog position, and there was a moderate correlation with the variations in tandem position ($0.520 \leq r \leq 0.604$; $P<.013$). A low correlation was found with the low (firm surface and eyes open) and moderate (firm surface and turning the head) variations in tandem position ($0.380 \leq r \leq 0.427$; $P<.013$) during the low (with short double-leg support and arms on hemisphere ball) and moderate (with long double-leg support) variations of front bridge position. The most difficult front bridge (with long single-leg support) showed a high correlation with the most difficult tandem position (compliant surface and eyes open; $r=0.666$; $P<.013$).

Finally, no association was found between trunk stability and any gait-related test (Figure 2). The whole-body static balance tests in the hip-width position showed a consistently low association with walking speed in two of the four straight-line gait tests ($0.377 \leq r \leq 0.407$; $P<.006$) and a low-moderate inverse association with the modified Timed Up and Go test ($-0.501 \leq r \leq -0.444$; $P<.006$; Table S7 in Multimedia Appendix 1). This inverse relationship suggests that those participants with higher acceleration values (indicating worse balance control) tended to be faster in these gait-related tests. To try to understand this association better, it seems to be necessary to know the association of height (as a representation of the human inverted pendulum model) with whole-body static balance tests in the hip-width position ($0.366 \leq r \leq 0.489$; $P<.008$), with the modified Timed Up and Go test ($r=-0.527$; $P<.001$) and with the walking speed in the 1-sided 10% body weight load test and in the fast gait without running straight-line gait test ($0.451 \leq r \leq 0.503$; $P<.001$).

Sensitivity analyses of test-retest reliability based on mean performance are provided in Tables S8-S9 in Multimedia Appendix 1. Overall, reliability estimates were largely comparable to those obtained using the peak-performance approach, supporting the robustness of the measurement properties across different data reduction strategies. Sensitivity analyses of the correlational findings using mean performance and the average across both sessions revealed a consistent overall pattern of results, with the original analysis based on peak performance from session 2. Most associations between trunk stability, whole-body balance, and gait-related outcomes remained low and task-specific. However, a small number of correlations increased from nonsignificant or low to low-moderate and reached statistical significance (Figure 2 vs Figure S1 in Multimedia Appendix 1). Specifically, low but significant associations emerged between the unstable sitting posturographic test and the front bridge with long single-leg support position as well as with the 2-limb bird-dog position of the lumbopelvic stability tests. In addition, the association between the unstable sitting and the tandem stance dynamic posturographic laboratory tests increased from low to moderate, and small but significant associations were observed between these 2 latter tests and the modified Timed Up and Go test (Tables S10-S13 and Figure S1 in Multimedia Appendix 1). These changes are interpreted as the expected consequence of using more stable estimates of performance, which reduce random measurement error and day-to-day variability. Consequently, the primary findings and qualitative interpretation of the results remain unchanged, supporting predominantly low, selective, and task-dependent relationships between trunk stability, balance, and gait-related performance.

The additional focused sensitivity analysis conducted exclusively in participants who were able to successfully complete all 3 test levels yielded results consistent with the main analyses. For each lumbopelvic stability test position, analyses were restricted to the subset of participants who successfully completed all 3 difficulty levels within that test, and test-retest reliability metrics were recomputed accordingly. Although some estimates were attenuated due to a reduced between-subject variability, the overall directional pattern and structure of the findings were preserved. Variations demonstrating good-to-excellent reliability in the full sample retained comparable ICC values in the restricted subsamples, whereas variations with poorer reliability did not systematically improve (Tables S14 in Multimedia Appendix 1). Likewise, associations between trunk stability and whole-body balance were not strengthened (Tables S15 in Multimedia Appendix 1), indicating that the relationships observed in the main analyses were not driven by differences in physical capacity or task feasibility and supporting the robustness of both the reliability estimates and the observed associations.

Discussion

Principal Findings

The primary findings of this study highlight a significant association between superior lumbopelvic control during specific bridge and bird-dog exercises and enhanced whole-body static balance. Conversely, no such associations were observed between trunk stability and whole-body dynamic balance or gait-related outcomes. Importantly, consistent with existing literature [5,23], the lack of correlation between trunk stability and whole-body balance in laboratory and field tests underscores a critical point for sport science professionals and practitioners: the direct extrapolation of data obtained with the tools available in field settings to laboratory findings remains unfeasible.

Influence of Trunk Stability on Whole-Body Static Balance: Task Specificity

Our main results confirmed the first hypothesis, so maintaining a static position in floor-based lumbopelvic stability exercises was associated with the capability to maintain a static upright

XSL•FO
RenderX

posture [33]. Thus, incorporating these trunk stability exercises, which require trunk, shoulder, and leg strength to reach the posture, short-term muscle endurance, and muscle coactivation for postural control (via feedforward and/or feedback mechanisms) [34], into a workout routine may enhance whole-body static balance in older adults. However, not all stability exercises showed the same degree of association. Back bridge and bird-dog variations showed more and stronger correlations, emphasizing the role of the trunk-hip extensor (ie, some of the antigravity muscles of the posterior kinetic chain) to maintain static posture. These associations were more evident when balance was increasingly challenged by narrowing the support base through changes in foot position (tandem vs hip-width position), suggesting a greater involvement of the lumbopelvic complex. The asymmetrical tandem stance tends to induce body rotation and lateral adjustments, which may align with the demands of the single-leg back bridge and conventional bird-dog, both involving asymmetry, rotation, and multiplanar control. Conversely, frontal and lateral bridge variations showed fewer and lower correlations. The lack of relevant correlations for the side bridge variations was particularly unexpected as tandem stance tasks seem to have high frontal plane demands and previous studies have linked mediolateral balance to trunk control [34,35]. These results may be due to the fact that control during lateral bridges is heavily mediated by the physical condition of the shoulder complex [36], which could be more affected in older adults by age-related issues such as sarcopenia, tendinopathies, and arthritis [37].

While a significant positive correlation was observed between the well-established trunk stability and whole-body dynamic balance laboratory tests, our second hypothesis was partially rejected, as the strength of these correlations was unexpectedly low (r=0.436). This suggests that, although a statistical link exists, trunk stability as measured by the unstable sitting posturographic test may only have a limited practical impact on whole-body dynamic balance in physically active older adults, particularly compared to populations with greater balance deficits in which stronger associations have been reported [26]. In this sense, tandem stance performance showed stronger associations with trunk stability in people with multiple sclerosis [26] (who present neuromuscular deficits) when balance was greatly challenged by placing the weaker leg behind (r=0.540; P<.05), compared to when the stronger leg was behind (r=0.433; P<.05), suggesting a greater trunk involvement when postural demands increase. In our sample of physically active older adults, the demands in the unstable sitting posturographic test may not be as determinant for whole-body dynamic balance compared with more disabled populations. In this sense, once a minimum level of trunk stability is reached in a seated position, it no longer contributes to improving whole-body dynamic balance in tandem stance unless a greater balance challenge is imposed on this population [23]. This interpretation should be taken with caution, as higher associations were found (r>0.629; P<.05) in other samples of older adults of similar characteristics [38], suggesting that the role of trunk stability may have a different impact on whole-body dynamic balance in other scenarios.

Finally, as expected and given the lack of significant associations, maintaining static positions during bridging and bird-dog exercises seems to play a limited role in whole-body dynamic balance during voluntary weight-shifting tasks and also voluntary control during the unstable sitting posturographic test seems less relevant for whole-body static balance. The complex scenario presented in this section aligns with a previous study [39] that confirmed the involvement of task-specific cortical and subcortical pathways after analyzing the excitability of corticospinal inputs to trunk muscles during both voluntary and involuntary tasks. The study [39] also highlighted that this involvement could not be easily predicted based solely on whether the task was classified as voluntary or more “automatic” in nature. This highlights the need for personalized trunk stability assessments that take into account individual characteristics and the underlying neurophysiological mechanisms related to task demands, which may functionally impact whole-body balance in older adults.

Trunk Stability and Gait-Related Outcomes: Absence of Association

As expected, no association was observed between trunk stability and gait-related outcomes. However, the third hypothesis was partially rejected, as the anticipated correlation between the unstable sitting posturographic test and the modified Timed Up and Go test was not observed. As a previous study on physically active older adults showed [38], trunk stability does not seem to play a significant role in gait performance or even in a gait-related task, such as the Timed Up and Go test, which requires standing, sitting, and turning actions in this population. A previous study in minimally and moderately impaired people with multiple sclerosis [26] found an association with the Timed Up and Go test but not with a straight-line gait test, which is justified by the greater relevance of trunk control needed for its performance. Therefore, in populations with neuromuscular deficits, voluntary trunk control may have a more relevant role during the sit-to-stand, turn, and stand-to-sit phases of the Timed Up and Go test. Again, this interpretation should be taken with caution, as another study involving individuals with greater disability, such as those with hemiparesis following a stroke [40], found no association between an unstable sitting posturographic test and the Timed Up and Go test.

The seemingly counterintuitive inverse association between whole-body static balance (higher acceleration indicating worse control) and walking speed (straight-line gait and Timed Up and Go) might be influenced by anthropometric factors, such as participant height. Taller individuals, while potentially achieving higher walking speeds due to longer strides, often face greater challenges in maintaining static postural control due to a higher center of mass and increased pendulum-like dynamics [41]. This suggests a complex interplay wherein static balance demands differ from dynamic mobility requirements, particularly during phases like sit-to-stand, turning, and stand-to-sit in the Timed Up and Go test [42].

Discrepancy Between Field and Laboratory Assessments

The lack of correlation between tests grouped under the same capability (ie, trunk stability and whole-body balance) reinforces the notion of the multidimensional nature of postural control in older adults, as previously documented in studies involving other populations [5,23]. Therefore, sport science professionals and practitioners should be aware that the lack of correlations between the novel inertial-sensor–based field tools (CoreMaker and G&B apps) and the well-established force-platform-based assessments makes it unfeasible to extrapolate research results found through laboratory tests to the field. Despite the lack of relationship between laboratory and field tools, the technologically based trunk stability and balance assessment through field tools such as CoreMaker and G&B apps will enhance experimental studies, allowing postural control during training exercises to be assessed in larger, more representative samples, leading to more meaningful clinical findings [21]. In addition, measuring trunk stability during the exercises used for training may allow us to determine to what extent the potential benefits caused by trunk-focused exercise programs (bridges and bird-dogs [24,25]) on balance and gait may be due to an improvement in trunk stability.

Study Limitations

As with any research, it is important to highlight some limitations. A much larger sample would be desirable in the most difficult variations of bridges (Table S2 in Multimedia Appendix 1) to minimize the probability of a type II error due to undersampling. Second, our results are based on a sample of physically active older adults and of both sexes, so future studies would need to examine the relationships of these tests in more fragile populations and also potential sex differences. Although our study focused on well-established force platform and inertial sensor protocols to assess trunk stability, balance, and gait, it is important to admit that other assessment tools exist and that using different tests might have led to different results. Future studies should analyze and develop field tests to evaluate the reactive control of the trunk due to its apparent potential relationship with the mechanisms required during a fall situation in older people. Moreover, trunk-focused stability outcomes should also be analyzed during specific tests designed to quantify whole-body balance, gait, and functional mobility, particularly under conditions imposing high demands on trunk control, to better understand how performance in these tasks relates to direct measurements of trunk involvement [42,43]. Although for the accelerometry-based field tests postural control was summarized using the average of the acceleration magnitude data series obtained from the 3-axis as a proxy for performance, future studies with more focused designs should incorporate axis-specific and advanced signal analyses to further elucidate control mechanisms during the studied tasks. Although the main conclusions were robust across multiple analytical strategies and the qualitative interpretation of the results remained similar, as with any complex analytical framework, the choice of data reduction strategy may have had a modest influence on the magnitude of some associations. Importantly, the convergence of findings across these contrasting analytical strategies strengthens confidence in the robustness, task-specificity, and interpretability of the observed relationships, indicating that the primary analysis represents a conservative estimate rather than a biased one.

Conclusions

This study provides novel evidence linking lumbopelvic control in floor-based exercises (mainly back bridge and bird-dog) to whole-body static balance in physically active older adults, supporting trunk stability as a crucial factor for maintaining steady standing positions in physically active older adults. Crucially, this research highlights a notable disconnection between novel inertial sensor–based field assessments (CoreMaker and G&B apps) and traditional force platform–based laboratory protocols for trunk stability and balance. While direct extrapolation between these methods is not advisable, the accessibility of field tools like CoreMaker offers a promising avenue [21] for standardized lumbopelvic stability assessment and the monitoring of training load in broader populations. Future interventions targeting static balance in older adults should consider incorporating specific bridging and bird-dog positions [24,25] to enhance trunk control.

Abstract

Background: Individuals with locomotive syndrome (LS) have muscle weakness and reduced motor function due to musculoskeletal disorders that cause reduced mobility and physical function. In Japan, musculoskeletal disorders are the most common reason for requiring home support or nursing care, highlighting the need for preventing and ameliorating LS. Middle-aged and older adults sometimes encounter difficulty making a habit of exercise therapy (the mainstay of LS treatment).

Objective: We investigated whether digital therapeutics (DTx) can prevent or ameliorate LS in middle-aged and older adults.

Methods: We conducted a prospective, longitudinal, nonrandomized, single-group study of Japanese aged 40 years and older who were eligible for LS checkups (N=47). Each participant underwent an 8-week locomotion training intervention based on DTx supervised by medical staff. We objectively assessed the participants' subjective and objective motor abilities and motor awareness with the Timed Up and Go (TUG) test, 25-question Geriatric Locomotive Function Scale (GLFS-25), and Behavioral Regulation in Exercise Questionnaire-3 at baseline (before the DTx), an interim point (4 wk after the DTx initiation), and a final evaluation (8 wk post-DTx initiation). We compared the scores of the 3 tests at the 3 time points as dependent variables in a 3-factor ANOVA with Bonferroni correction (significance defined as 0.05/3=0.0167).

Results: No increase in amotivation to exercise or refusal to exercise was observed. Significant improvements at 8 weeks versus the baseline were observed in the TUG scores (baseline: 9.0, 95% CI 8.4 - 9.6; 8 wk: 7.5, 95% CI 7.1 - 8.0; *P*=.001) and GLFS-25 results (baseline: 18.7, 95% CI 14.5 - 22.8; 8 wk: 11.7, 95% CI 8.8 - 14.7; *P*=.004). The Behavioral Regulation in Exercise Questionnaire-3 and its subscale data did not differ significantly at any assessment time point.

Conclusions: These results indicate that an 8-week locomotive training intervention using DTx significantly improved middle-aged and older adults' TUG and GLFS-25 scores and will help prevent and ameliorate LS and establish better exercise habits among them.

Introduction

The Japanese Orthopaedic Association (JOA) proposed the concept of locomotive syndrome (LS) in 2007 [1]. The term "LS" refers to a condition in which a musculoskeletal disorder results in muscle weakness and motor weakness, leading to reduced mobility and physical function [1]. The development of LS causes a requirement for long-term care [2]. According to the 2022 Comprehensive Survey of Living Conditions in Japan, the leading cause requiring nursing care or support was musculoskeletal disorders at 26.3%, followed by falls and fractures at 13.9% and joint disorders at 10.2% [3]. The JOA recommends the early detection of a decline in motor function based on locomotive syndrome checks (LSCs), in part to prevent the requirement of assistance or care [4]. LSCs were scored as follows: 1 point (cannot put on a sock for 1 foot), 2 points (stumbles in their home), 3 points (needs a handrail to climb

XSL•FO
RenderX

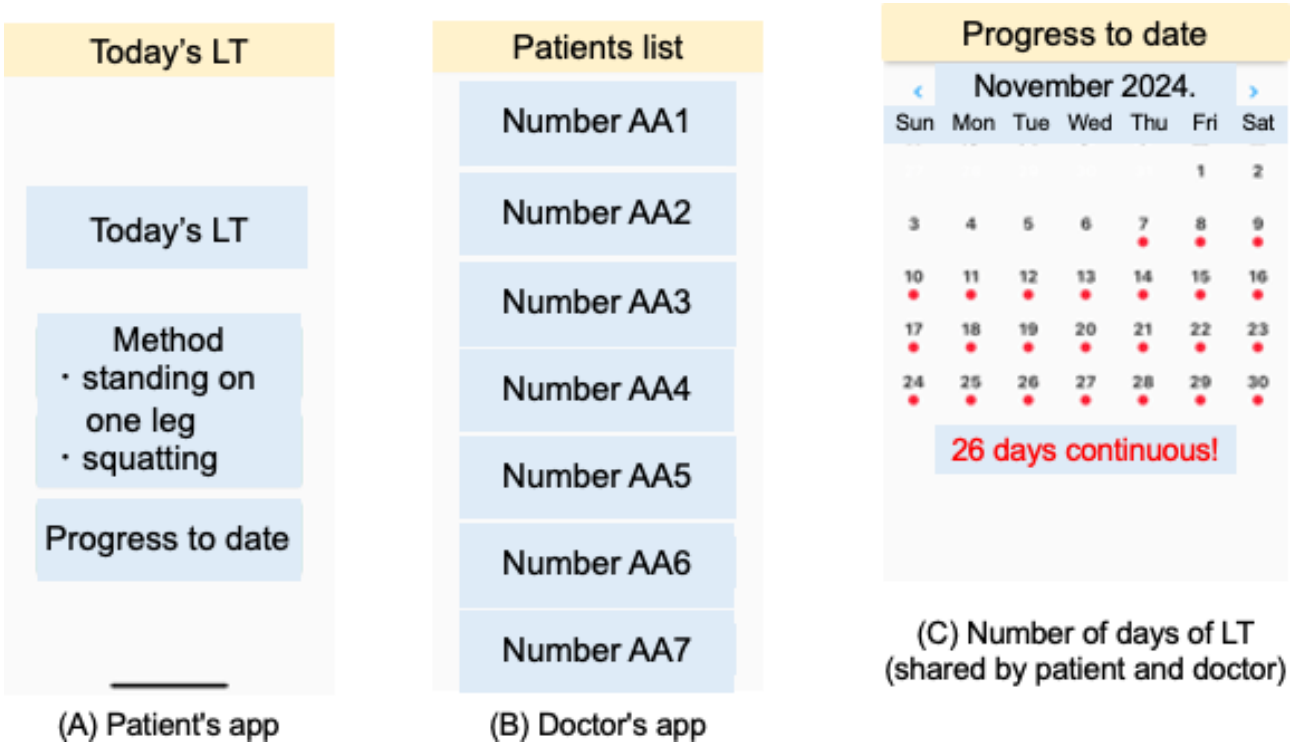
stairs), 4 points (difficulty using a vacuum cleaner at home), 5 points (difficulty carrying parcels weighing >2 kg), 6 points (difficulty walking continuously for >15 min), and 7 points (cannot cross a crosswalk with a green light) [4]. The JOA also advocates locomotion training (LT), which involves standing on 1 leg and squatting, to prevent LS and lessen existing LS [5]. Currently, the risk of developing LS is assessed based on three items: (1) a stand-up test, (2) a 2-step test, and (3) the 25-question Geriatric Locomotive Function Scale (GLFS-25) [5-7].

Exercises such as LT are effective for preventing and mitigating LS [5], but it is difficult for many middle-aged and older adults to start or continue an exercise routine. Previous studies have reported that the average adherence rate for older adults continuing a prescribed home exercise program for 6 weeks was 65% [8]. As one solution, we advocate an approach to the prevention and mitigation of LS in middle-aged and older adults who meet the criteria for LS or qualify for LSCs using IT devices.

Apart from the uses of IT in the medical field, such as electronic medical records, telemedicine, and surgical robots, the uses of mobile devices for medical procedures and support are called mobile health [9]. Digital therapeutics (DTx), defined by the Digital Therapeutics Alliance as “evidence-based therapeutic interventions driven by high-quality software programs to prevent, manage, or treat a medical disorder or disease” [10], is an area of mobile health that is receiving particular attention [11]. A variety of DTx apps have been approved by health insurance programs in some countries, including those for diabetes, hypertension self-management, and smoking cessation support [12-14]. Regarding the effects of DTx on the musculoskeletal system, the effectiveness of DTx in musculoskeletal diseases has been reported for patients with pain associated with musculoskeletal diseases and osteoarthritis [15,16]. DTx has been shown to be effective in reducing musculoskeletal pain, improving function in patients with osteoarthritis, and increasing self-management abilities. However, there have been no reports on the use of DTx intervention for LS. If DTx intervention can establish exercise habits and lead to the prevention and improvement of LS, it may lead to a reduction in the number of people in Japan who require nursing care or support due to musculoskeletal diseases. We conducted this study to determine whether this use of DTx via a smartphone app can lead to behavioral change in middle-aged and older people and prevent or ameliorate their LS.

Methods

Participants



The details of the research protocol and participant recruitment have been published [17]. The study population was 47 Japanese participants aged more than 40 years who were eligible for the LSCs. The study’s inclusion criteria were as follows: individuals aged 40 years and older who generally begin to experience a decline in lower-extremity muscle strength [18] and met any of the LSC criteria. Additional inclusion criteria were: a score of 3 points or more on the Mini-Cog. The Mini-Cog is a screening test for cognitive function assessment combining 3-word immediate recall, delayed recall, and clock drawing. A score of less than 3 points indicates suspected dementia, with reported sensitivity of 76% to 99% and specificity of 83% to 93% [19,20]. The ability to use smartphone apps and being able to provide informed consent for study participation were additional requirements. Exclusion criteria were difficulty using smartphone apps due to cognitive decline or visual or hearing impairment, withdrawal during the study period, and withdrawal during the study period due to hospitalization or accidents. The participants’ demographic information was recorded, including age, gender, musculoskeletal disorders considered potential causes of LS, and underlying conditions corresponding to LSCs.

DTx Intervention

We have created a smartphone app for middle-aged and older people who have no exercise habits and whose physical functions have declined or are suspected to be declining. The smartphone app used by the participants is a new prototype app created for this research field. We provided a smartphone equipped with a communication environment with the app already downloaded to each participant. This smartphone app has functions that support the implementation of 2 types of LT with the use of video and audio. The LT app is simple to use and is set up so that by touching the screen, a voice announcement is played, and the user can perform 2 LT programs: the 1-leg stand program and the squat program. After the completion of the day’s LT, the participant touched the screen to check the LT record on both the participant’s smartphone and his or her physician’s smartphone (Figure 1). The smartphone app automatically records the number of days of LT.

XSL•FO
RenderX

Figure 1. Screenshots of the app. (A) The app for the patients or participants has a simple design and enabled them to perform the locomotion training (LT). (B) The physician's app can check each patient's LT status based on the ID allocated to that patient. (C) The number of days of LT is reflected on the same screen for both the patient and the physician.

Participants received direct instruction on how to use the app and perform LT from their attending physician during an outpatient visit at the medical institution involved in this study. The prior instruction took an average of 10 minutes. Furthermore, after the instruction, participants were able to use the DTx without any problems. Although there were several inquiries regarding its use, participants contacted the research staff directly by phone, and all inquiries were resolved over the phone. Each participant was scheduled for the daily LT intervention for 8 weeks. A single LT session consisted of a program of standing on 1 leg for 60 seconds (or <60 s if that was the participant's best effort) plus 5 squats, performed 3 times per day, as recommended by the JOA for the prevention and improvement of LS [5]. For participants with weak legs and/or backs who would find it difficult to do the regular LT, the physician responsible for explaining the DTx advised that they stand on 1 leg while supporting their body with their hands or fingers on a desk or table, or that they sit on a chair and stand up by putting their hands on a desk or table instead of doing squats, or that they reduce the number of times they do each LT from 3 times to 1 time [21].

The advantage of this system is that healthcare providers can check the progress of their patients' LT remotely, enabling them to prepare feedback in advance and freeing up time. It also provides patients with the reassurance that they are exercising under the support of medical staff.

Study Protocol

Briefly, the participants' objective mobility was assessed using the Timed Up and Go (TUG) test score; their subjective mobility was evaluated with the GLFS-25, and the changes in exercise-related motivation were investigated based on the Behavioral Regulation in Exercise Questionnaire-3 (BREQ-3). The GLFS25 is a questionnaire that assesses physical pain and difficulties in daily life using 25 questions. Each question is rated on a scale of 0 to 4, resulting in a total score of 0 to 100 [5-7]. The self-determination theory (SDT) [22] is widely applied as a theoretical foundation for evaluating the effectiveness of behavioral change in participants. The BREQ-3 is designed based on SDT and assesses motivation for exercise with 18 questions in 6 areas: intrinsic motivation, integrative adjustment, identification adjustment, incorporative adjustment, external adjustment, and demotivation [23]. Previous studies have adopted the BREQ-3 as an indicator for evaluating behavioral change [24]. In this study, the impact of DTx on motivation for exercise and exercise spontaneity was also evaluated using the BREQ-3. The participants underwent the TUG test, GLFS-25, and BREQ-3 measurements at baseline (before the DTx intervention was started), and at 4 weeks (intermediate evaluation) and 8 weeks (final evaluation) after the start of the DTx intervention. In addition, the implementation status and compliance rate of the LT during the survey period were analyzed. This study primarily aimed to explore the efficacy, feasibility, and behavioral impact of a DTx intervention for LT. Accordingly, a single-group pre-post comparative design was adopted to efficiently evaluate within-subject changes in objective mobility, subjective mobility, and exercise-related motivation. Outcome measures and the intervention duration were set at a feasible timeframe capable of detecting clinical effects while minimizing participant burden.

Statistical Analyses

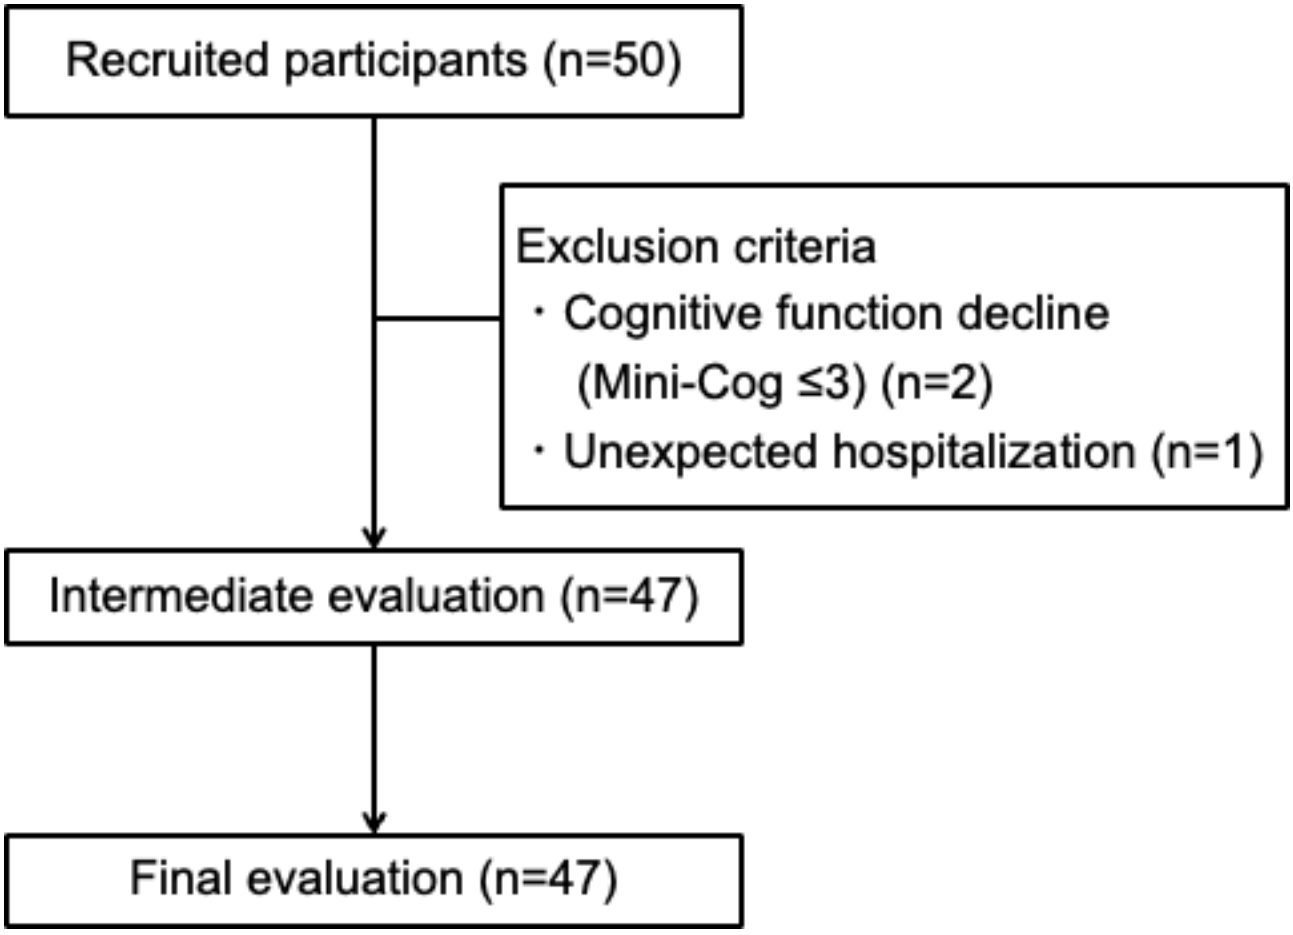
Continuous data are summarized as the mean and SD, and dichotomous or categorical data are presented as proportions. As the main study outcomes, the TUG test and GLFS-25 results

XSL•FO
RenderX

were measured at 0 weeks before the DTx intervention (baseline) and at 4 and 8 weeks after the daily DTx intervention was started. TUG and GLFS-25 data at each assessment point were compared using ANOVA. Furthermore, the Pearson correlation coefficients were calculated between the participants' baseline TUG scores and the difference in their TUG scores (Δ) after 8 weeks of DTx in each case. Similarly, the Pearson correlation coefficients were calculated for the difference between baseline and post-8 weeks DTx GLFS-25 scores. As a secondary outcome measure in this study, participants' BREQ-3 scores obtained at 3 time points were also compared using the Wilcoxon signed-rank test. The *P* values after Bonferroni correction that were <.05/3=0.0167 were considered significant. All analyses were conducted using JMP PRO 16 (SAS Institute).

The reported minimal clinically important difference (MCID) in the TUG test among patients with degenerative disc disease is 3.4 (SD 5.0) seconds [25]. Considering that finding, we set the MCID at 3.0 seconds for the present investigation. The required sample size was calculated using G*power (version 3.1.9.7; Heinrich-Heine-Universität Düsseldorf).[26]. The corresponding 2-tailed *t* test was selected, and the effect size was calculated as 0.6 based on a mean difference of 3.0 and a SD of difference of 5.0. Assuming an α-value of .05 and .80 as the power (1−β), the required estimated sample size was 24. When taking into account both the possibility that the SD is smaller than those in the previous studies and the cases of dropout, we concluded that the study had the required sample size.

Ethical Considerations



The Fukushima Medical University Ethics Review Committee provided ethical approval for this study (REC 2023 - 196). All study methods followed the relevant guidelines and regulations, and written informed consent was obtained from participants. This study was preregistered as a trial registration (University Hospital Medical Information Network Clinical Trial Registry UMIN000053922). Data was deidentified to protect participant information. Participants were not paid compensation and cooperated voluntarily.

Results

Recruitment Results Flowchart

Figure 2 illustrates the flow of participants over the course of the study. Two participants for whom cognitive function decline was observed and 1 participant who was unexpectedly hospitalized were excluded from the study. There were no dropouts after the start of the study, and all participants completed the final evaluation.

Figure 2. Flowchart of participants. Two individuals with cognitive impairment and one who was unexpectedly hospitalized were excluded from the study. After the start of the study, there were no dropouts, and 47 participants were followed up until the intermediate and final evaluations.

Participants' Characteristics

The characteristics of the 47 participants are summarized in Table 1. Most of the participants (55.3%, n=26) were aged under 65 years, and 87.2% of the participants were women. All of the participants had preserved cognitive function. The most common cause of LS in this population was knee osteoarthritis (51.1%).

Table . The participants' characteristics (N=47).

Characteristics	Value
Days of LT[a], mean (SD, 95% CI)	52.1 (5.9, 50.4 - 53.8)
Age (y), mean (SD, 95% CI)	63.5 (10.1, 60.5 - 66.5)
<65, n (%)	26 (55.3)
65 - 74, n (%)	13 (27.7)
≥75, n (%)	8 (17)

Primary Outcome Measures

TUG Test

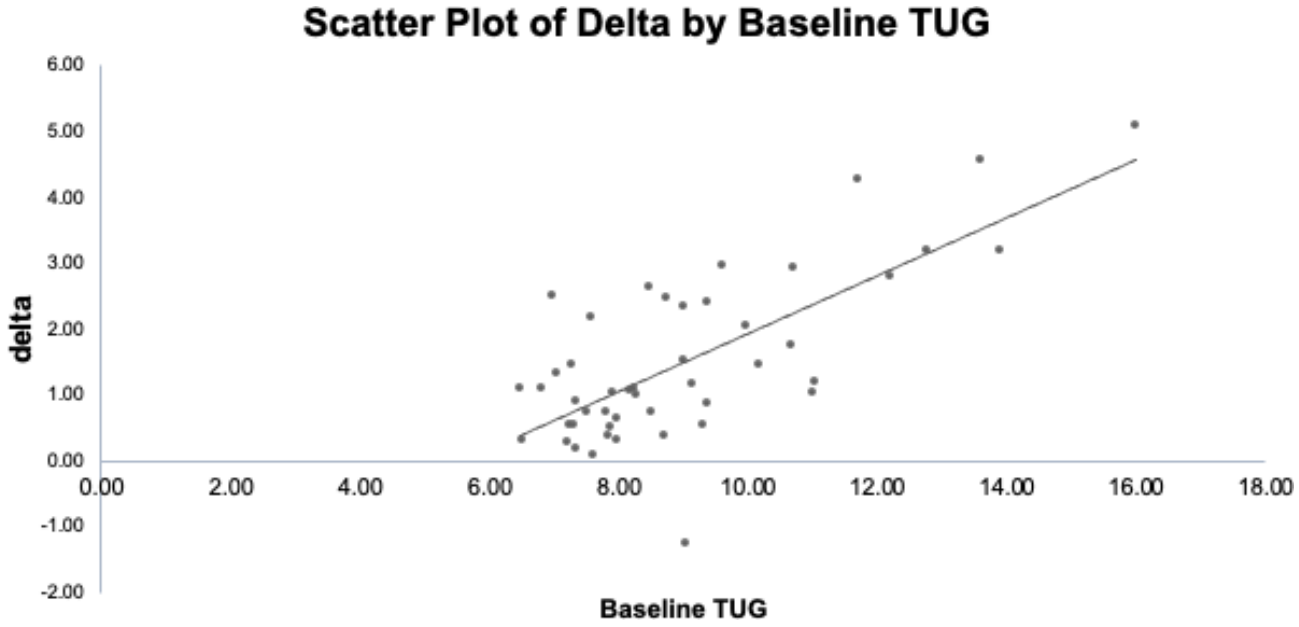
The changes in the participants' TUG scores from baseline to the end of the 8-week intervention are depicted in Table 2. Notably, with the DTx, all but 1 of the 47 participants achieved an improvement in their TUG score. The TUG score at baseline was 9.0 (95% CI 8.4 - 9.6), reduced significantly to 8.0 (95% CI 7.6 - 8.5) at 4 weeks (*P*=.01). Furthermore, compared to baseline, the TUG score significantly decreased to 7.5 (95% CI 7.1 - 8.0) at week 8 (*P*=.001).

Table . The participants' Timed Up and Go (TUG) test data at baseline, 4 weeks, and 8 weeks[a].

	TUG, mean (SD, 95% CI)	Adjusted *P* value[b]
Baseline	9.0 (2.1, 8.4 - 9.6)	—[c]
4 wk	8.0 (1.5, 7.6 - 8.5)	.01[d]
8 wk	7.5 (1.5, 7.1 - 8.0)	.001[d]

[a]The data are the mean, n (%), and ANOVA (95% CI) results.

[b]Adjusted *P* values represent comparisons with baseline.



[c]Not applicable.

[d]*P*<.05.

We next examined the correlation. The analyses revealed that the baseline TUG score was significantly positively correlated with the improvement in TUG score obtained after 8 weeks of DTx (Pearson correlation coefficient, ie, *r*=0.728; *P*<.001; Figure 3).

XSL•FO
RenderX

Figure 3. The correlation between the baseline Timed Up and Go (TUG) score and the difference in the TUG score after 8 weeks of digital therapeutics (DTx) in each participant's case. The TUG score at baseline was positively correlated with the improvement in the TUG score obtained after 8 weeks of DTx (r=0.728; P<.001).

25-Question Geriatric Locomotive Function Scale

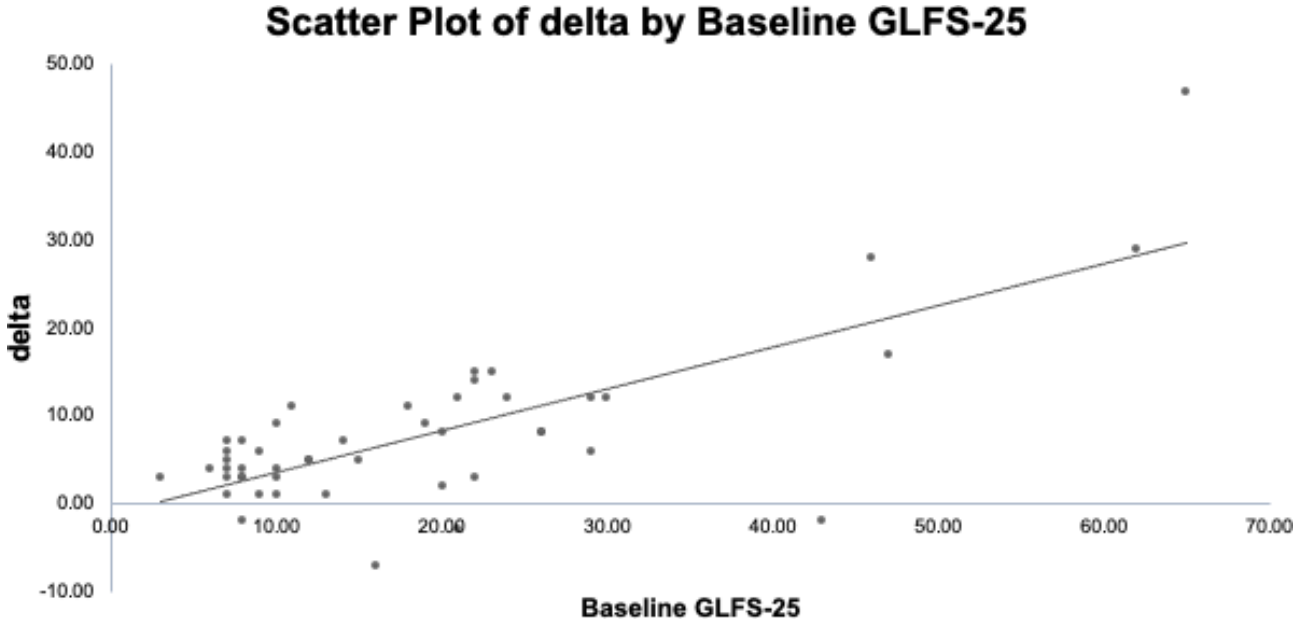
The results on this scale revealed that the GLFS-25 score improved in 43 of the 47 patients, with mean scores of 18.7 (95% CI 14.5 - 22.8) points at baseline, 12.9 (95% CI 10.4 - 15.4) points at 4 weeks, and 11.7 (95% CI 8.8 - 14.7) points at 8 weeks. The GLFS-25 at 8 weeks was significantly lower than the baseline values (P=.004; Table 3).

Table . The participants' 25-question Geriatric Locomotive Function Scale (GLFS-25) scores at baseline, 4 weeks, and 8 weeks of digital therapeutics (DTx)[a].

	GLFS-25, mean (SD, 95% CI)	Adjusted P value[b]
Baseline	18.7 (14.2, 14.5 - 22.8)	—[c]
4 wk	12.9 (8.4, 10.4 - 15.4)	.02[d]
8 wk	11.7 (10.1, 8.8 - 14.7)	.004[d]

[a]The data are the mean, n (%), and ANOVA (95% CI) results.

[b]Adjusted P values represent comparisons with baseline.



[c]Not applicable.

[d]P<.05.

When the correlation between the Δ in the GLFS-25 score from baseline to 8 weeks and the initial value was examined, a higher correlation was observed, with the participants who had higher initial GLFS-25 scores showing greater improvement at 8 weeks (r=0.749; P<.001; Figure 4).

XSL•FO
RenderX

Figure 4. The correlation between the baseline 25-question Geriatric Locomotive Function Scale (GLFS-25) score and the difference in the GLFS-25 score after 8 weeks of digital therapeutics (DTx) in each participant's case. A high correlation was observed, indicating that participants with higher initial GLFS-25 scores showed greater improvement after the 8-week intervention (r=0.749; P<.001).

Secondary Outcome Measures

BREQ-3

Our comparison of the BREQ-3 data between the baseline and end of the 8-week DTx intervention revealed no significant difference in these data (Table 4).

XSL•FO
RenderX

Table . The participants' Behavioral Regulation in Exercise Questionnaire-3 (BREQ-3) data at baseline, 4 weeks, and 8 weeks (mean and ANOVA).

Adverse Events in This Study

No adverse events such as falls occurred.

Adherence to the Study

The average LT completion rate was 93% (52.1/56 days, 95% CI 50.4 - 53.9), demonstrating high adherence to the smartphone-based DTx. Of the 47 participants, 46 continued using the app until the end of the study period, for a retention rate of 97%. Only 1 participant abandoned the app before the end of the study period.

Discussion

Principal Results

We conducted this study to determine whether the use of DTx via a smartphone app can induce behavioral change and contribute to the prevention or improvement of LS among middle-aged and older adults. To our knowledge, this is the first study assessing the efficacy of DTx for both modifying exercise behavior and managing LS. It has been reported that continued LT for a 6-month period shortened (ie, improved) participants' TUG times [23] and that practicing 1-leg standing prevents falls [27]. It was also observed that the performance of squats enhanced the muscle strength and functional capacity of older women [28]. Another study revealed that among older adults with stage 1 LS, those who underwent LT and aerobic exercise for 8 weeks showed a significant increase in grip strength from before to after the intervention compared to those who underwent aerobic exercise alone for 8 weeks [29]. Based on this evidence, we selected LT to target lower-limb strength and balance, both of which are essential for ambulation and daily functioning.

Few studies have attempted home-based LT interventions. Aoki et al [30] reported that a 3-month program with 3×/week phone calls significantly improved their study participants' physical function and health-related quality of life; they also described an 85.4% adherence rate for the program. Similarly, Ito et al [31] demonstrated the achievement of improved physical function through regular phone-based guidance in a preventive care setting. Although such prior studies demonstrated the

XSL•FO
RenderX

efficacy of home-based LT, they were highly dependent on human resources. In contrast, our findings indicate that an app-based intervention can markedly reduce this burden, providing a scalable approach to LS management.

Our participants' motor function was assessed by the TUG test, which showed a significant 1.5-second mean improvement post intervention. Although this change did not reach our study's predefined MCID of 3 seconds, the mean postintervention TUG time was 7.5 seconds, which is below the average TUG time between the ages of 40 and 59 years [32]. Furthermore, the minimum detectable change for patients with knee osteoarthritis aged 45 to 70 years has been reported to be 1.10 to 1.14 [33]. The results of this study suggest that the observed changes are clinical rather than measurement errors. Considering that the MCID of 3 seconds demonstrated in previous studies was calculated from TUG scores before and after invasive procedures such as lumbar discectomy or lumbar decompression surgery [25], the results obtained in this study through a noninvasive intervention may indicate clinically meaningful improvements related to real-world activities.

In Japan, LS corresponds to the musculoskeletal ambulation disability symptom complex (MADS), which is covered by national health insurance. A TUG time ≥11 seconds is one diagnostic criterion for MADS. Notably, all participants (7/47, 14.8%) with baseline TUG times (≥11 s) improved to below this threshold after the DTx intervention. Moreover, those with longer baseline TUG times showed greater improvement. These findings suggest that our smartphone app may have potential to improve mobility for high-risk individuals meeting the MADS criteria and eligible for outpatient rehabilitation. In this study, the sample size was designed based on the MCID of TUG, and with only 7 cases exceeding TUG 11 seconds, stratified analysis proved challenging. To optimize this intervention, future research incorporating stratified analysis with a larger sample size is required.

The results of the present DTx were further supported by significant improvements in another primary outcome, the GLFS-25. After the 8-week intervention, GLFS-25 scores were markedly reduced compared with baseline. By the end of the program, 29 of 47 (62%) participants improved by at least 1 LS stage, and 16 (34%) no longer met the diagnostic criteria for LS. Among the 10 participants initially classified as stage 3, 7 improved to stage 2, suggesting potential efficacy even in advanced cases. These findings highlight the therapeutic potential of this DTx for LS management.

The effect of DTx on individuals' exercise behavior has been assessed based on SDT [22,34]. Although our analyses of BREQ-3 results revealed no significant changes across motivational indices, some meaningful trends emerged. The number of participants reporting increased "external regulation" (a BREQ-3 subitem) remained unchanged, whereas the subitem "intrinsic motivation" and the relative autonomy index [35] tended to improve at 8 weeks compared to the baseline. These trends suggest that extended intervention may enhance participants' autonomous motivation, warranting further investigation.

In this study, all participants received an exercise program based on LT without individualization. The exercise program demonstrated a favorable continuation rate, and no increase in amotivation or external regulation was observed on the BREQ-3; consequently, the exercise intensity is considered to have been appropriate.

Limitations

This study has several limitations. It was a proof-of-concept investigation without a control group and involved a short observation period. Participants were likely to have high baseline health interest, introducing potential selection bias. Future studies should therefore use a randomized controlled design with a larger sample size, longer follow-up, and a control group receiving only verbal exercise instruction. In addition, the study intervention was a standardized LT protocol, which may not have been sufficiently tailored to the individual physical conditions and needs of each participant. The primary focus of this app's functionality was on the remote management of participants' exercise habits. However, had it been able to assess each participant's individual exercise capacity and implement more personalized exercise programs, the improvement in exercise capacity could have been greater. Further consideration is required regarding the optimization of the app's functionality in this regard. Moreover, the intervention did not produce a clear behavioral change in exercise habits. Without sustained behavioral modification, the long-term outcomes of app-based interventions may diminish. Integrating behavioral science–based strategies will be important to maintain user engagement and therapeutic efficacy. Finally, there may have been a measurement error in the evaluation of our participants' TUG times. A related measurement error of 0.22 sec has been reported [36]. The measurement error in a TUG assessment is greater in frail older adults, and the longer it takes to perform the TUG test, the greater the variability is [37].

Conclusions

The results of our analyses demonstrate that an 8-week LT intervention using DTx for middle-aged and older adults significantly improved their TUG and GLFS-25 scores. Medical staff supervised the participants' use of the smartphone DTx, and no increase in amotivation to exercise or refusal to exercise was observed. Our findings will support the prevention and amelioration of LS in middle-aged and older adults, and the establishment of better exercise habits in this population.

Acknowledgments

The authors thank all of the study participants, and we thank the staff of the Bange-Kosei General Hospital, Hanawa-Kosei General Hospital, and Minami Tohoku Fukushima Hospital for their help with participant recruitment and data acquisition.

Abstract

Background: Remote, self-administered digital assessments provide scalable approaches for monitoring cognition in older adults. Practice effects (PEs), once viewed as measurement noise, are increasingly recognized as potential markers of cognitive decline. As disease-modifying therapies for neurodegenerative conditions emerge, longitudinal digital assessments may capture subtle cognitive changes. Although the majority of PE studies have focused on memory tasks, it is critical to determine whether PEs occur in other domains. Clarifying the potential presence of PEs across multiple time points on the Food and Drug Administration–cleared Defense Automated Neurocognitive Assessment (DANA) platform remains critical for determining whether PEs can serve as a measure of cognitive decline longitudinally.

Objective: This study aimed to examine whether PEs occur and whether demographics moderate them across quarterly self-administrations of digital cognitive tasks spanning different cognitive domains in cognitively intact older adults.

Methods: Cognitively intact older adults from the Framingham Heart Study self-administered DANA tasks at baseline and every 3 months for 1 year (4 assessments: T1-T4). Tasks included Simple Reaction Time (SRT), Go/No-Go (GNG), and Code Substitution (CS). These tasks varied in complexity, from simple motor responding (SRT) to inhibitory control (GNG) and associative learning with working memory demands (CS). The primary outcome was Cognitive Efficiency, a derived measure of speed and accuracy, which are also recorded as secondary measures. PEs were quantified using linear mixed-effects models, and the change in mean score across time points was expressed in pooled SD units as Cohen *d*.

Results: A total of 717 participants completed all 4 time points (mean age 64.1, SD 9.5 years; n=469, 65.4% female participants; n=481, 67.1% college-educated). PEs were observed on all tasks, with small effects on CS (*d*=0.43) and GNG (*d*=0.32) and a below-threshold effect on SRT (*d*=0.16). Demographics influenced baseline performance: older age predicted lower baseline scores on all tasks, females scored lower on SRT and GNG, and higher education predicted better performance on all tasks. Age was the only demographic moderator of PEs, with smaller improvements on CS among participants aged 65 years or older (B=−0.39; *P*<.001).

Conclusions: Quarterly self-administered digital cognitive assessments elicited measurable PEs across processing speed, inhibitory control, and visual scanning, with stronger effects on more complex tasks. Demographics influenced baseline performance, while age moderated PEs on the most demanding task. These findings provide baseline data against which PEs in clinical populations can be compared in future work, complementing prior evidence on other cognitive instruments.

Introduction

Practice effects (PEs) refer to performance gains across repeated cognitive test administrations due to prior exposure to test materials and/or procedures [1]. Historically regarded as measurement noise, PEs are increasingly recognized as a meaningful index of learning capacity [2-4], and attenuated PEs have emerged as a candidate indicator of preclinical Alzheimer disease (AD) and prospective cognitive decline [5-8]. Failure to account for PEs can lead to misinterpretation of stable cognitive scores as preserved cognition rather than as reflecting deficits in learning capacity [9], and correcting for PEs alters rates of incident mild cognitive impairment detection [10].

PEs are mediated by test familiarity, whether with its stimuli or its procedures [2]. Stimulus-specific learning accumulates with each exposure [11], producing PEs that are largest on verbal memory tests and smallest on tests where new stimuli minimally alter task demands [12]. Alternate forms reduce but do not eliminate PEs on many tests [12,13]. The residual PEs reflect procedural familiarity with the test's instructions and response format, which generalizes across stimuli. More complex tasks plausibly offer more procedural elements to learn, although task complexity has not been formally operationalized in PE research.

Moderators of PEs include the interval between sessions and individual characteristics. Recent digital research has used high-frequency, measurement-burst, and daily ecological momentary assessment designs that produce PEs within days to weeks [14-16], whereas earlier studies of legacy paper-and-pencil tests have documented PEs across intervals ranging from months to years [17-19]. Among individual characteristics, cognitive status is the strongest moderator of PEs [5,12,20,21]. Age also moderates PEs among healthy adults, with correlations between mean age and estimated PEs ranging from −0.66 to −0.89 across reasoning, spatial, memory, and speed domains [22]. Evidence on sex and education effects has been mixed in both traditional tests [23-25] and digital studies, with some reporting no demographic moderation [26] and others identifying task-specific associations [27-29].

The Framingham Heart Study (FHS) began collecting digital, self-administered, and remote serial cognitive data in 2020 using the Defense Automated Neurocognitive Assessment (DANA) application. Subsequent studies have demonstrated DANA's feasibility and user acceptability [30,31], concurrent validity with traditional paper-and-pencil–based neuropsychological tests [32], and association with cardiovascular risk factors [33]. Although designed to minimize PE [34], Bellitti et al [27] reported modest response time (RT) PEs on 3 of 6 DANA tasks across 2 sessions spaced approximately 90 days apart in a 116-participant mixed-diagnostic sample. Whether these effects persist over additional administrations at a quarterly interval in a larger cognitively intact sample has not been established.

The primary aim of the current study was to characterize PEs across 4 quarterly assessments on 3 DANA tasks spanning a graded range of task demands (Simple Reaction Time [SRT], Go/No-Go [GNG], and Code Substitution [CS]) in a large sample of cognitively intact older adults. The secondary aim was to determine whether demographic characteristics moderate the observed PEs. The present study was not designed to test the prognostic value of PEs but rather to establish baseline PE patterns against which such questions can be evaluated in future longitudinal work. We anticipated that (1) PEs would be detectable across the 3 tasks but vary in magnitude, with more cognitively demanding tasks showing larger effects than motor-dominant tasks; and (2) older age would attenuate PE on the more demanding tasks [22], while sex and education effects would be modest given mixed prior evidence [23].

Methods

Participants

The study sample consisted of participants enrolled in the FHS, a longitudinal, population - based cohort study that began in 1948 in Framingham, Massachusetts. The FHS focuses on studying risk factors for cardiovascular disease and other major chronic diseases spanning 3 generations of participants and their descendants. Neuropsychological evaluations began in 1976 with the collection of a brief cognitive screen and progressed to a comprehensive cognitive evaluation in 1999. The FHS began enrolling participants from diverse racial and ethnic backgrounds into multiethnic cohorts (Omni cohorts) in 1990, while the generation 2 (Gen 2) and generation 3 (Gen 3) cohorts are mostly White. This study included participants from 5 subcohorts of the FHS: Gen 2, Gen 3, Omni 1, Omni 2, and New Offspring Spouse. The inclusion criteria for this study were owning a smartphone, proficiency in spoken English, and having Wi-Fi access. All participants recruited for the study were presumed to be cognitively unimpaired based on established FHS dementia surveillance protocols, which flag participants for cognitive concerns based on Mini-Mental State Examination performance (score ≤24 or decline ≥3 points between visits), self-reported or informant-reported cognitive symptoms, or clinician referral, followed by consensus dementia review by a panel with at least one neurologist and one neuropsychologist [35]. Sociodemographic data were collected in accordance with established FHS protocols [32]. Variables included self-reported age (years) at the first assessment, sex (female/male), and education (high school or less, some college, and college graduate).

A total of 1756 participants completed at least one cognitive assessment during the data collection period (July 14, 2022, to March 28, 2025) and had the opportunity to complete all 4 quarterly assessments. The primary analytic sample comprised the 717 participants who completed all 4 time points of CS; corresponding completer counts were 701 for GNG and 686 for SRT, reflecting the fixed task order in which early

XSL•FO
RenderX

discontinuation within a session resulted in retention of data for tasks completed earlier. The remaining 1039 participants completed 1 to 3 time points (partial completers) and served as the comparison sample for selection-bias analyses.

DANA Tasks

Participants were asked to complete the DANA tasks every 3 months for a year, resulting in 4 time points (baseline plus 3 additional time points). DANA tasks were delivered via the Linus Health mobile app. For each assessment interval, participants had a 42-day window to complete their assessments. Participants received automated daily notifications if tasks remained incomplete, which they had the option to mute. Research assistants provided up to 2 to 3 additional reminders per assessment window via phone, email, or text, based on participant preference.

The DANA app is a Food and Drug Administration–cleared computerized neurocognitive test battery accessible as a mobile application on iOS and Android devices. Previous work has demonstrated DANA's internal consistency and reliability [36]. Three subtests were selected for this study that collectively take approximately 5 minutes to complete. The first subtest, SRT, assesses RT by measuring latency between when a large target appears on the screen and when the participant taps the target across 40 trials. The second subtest, GNG, assesses sustained attention and impulsivity by requiring the participant to either tap or omit a response based on the color of stimuli that appear in varying locations on the screen across 30 trials. The third subtest, CS, assesses visual scanning, attention, and learning by asking the participant whether a sequence of symbol-digit pairs matches the 9 pairs shown in the key [34]. The same 9 symbol-digit pairs appeared at every administration; stimuli were not varied across the 4 time points. Task complexity is not a formally operationalized or quantified construct but rather reflects the polyfactorial demands imposed by a task, that is, the extent to which multiple cognitive domains are simultaneously engaged during task performance [27,37,38]. For reference, SRT requires only a simple motor response to a single stimulus and is therefore the least complex. GNG introduces additional inhibitory control and rule-based responding, while CS incorporates a learning component and subtle working memory demands, attributes recognized as markers of greater task complexity [37,38]. This progression is also reflected in average RT, with SRT producing the fastest responses, followed by GNG, and then CS [33].

The primary metric for DANA tasks is Cognitive Efficiency (CE), computed as percent correct divided by the mean RT for correct responses, multiplied by 60,000 to express the result in correct responses per minute units. This formulation derives from the throughput metric defined by Thorne [39], with DANA using correct-trial RTs only rather than the cumulative RTs across correct and incorrect trials in Thorne's original metric. Most neuropsychological tests prioritize either speed or accuracy, leaving the other dimension less rigorously quantified. CE integrates both into a single performance index. CE was specified as the primary outcome for all PE analyses. Where CE-based analyses revealed a significant pattern, RT (milliseconds) and accuracy (percentage of correct responses) were examined as secondary outcomes to clarify which dimension was driving the observed effect.

Analyses

Descriptive statistics are presented for the largest test sample (CS; n=717), which represents the union of all participants included in the analytic sample, with demographic characteristics summarized in Table 1. Descriptive statistics for demographic characteristics are presented as means and SDs for continuous variables and counts and percentages for categorical variables. Test descriptive statistics include means for RT, accuracy, and CE.

PEs were defined as improvements in task performance across repeated administrations and were operationalized in two ways. First, effect sizes (ie, Cohen *d*) were calculated to quantify the magnitude of observed change across time points in pooled SD units, providing a standardized comparison across tasks. Second, linear mixed-effects models (LMM) were used to test the significance of PEs and to examine potential demographic moderators. Thus, model coefficients (unstandardized B) represent the estimated average change in CE per time point, with CE specified as the primary outcome variable and time (4 assessments) as the primary predictor. For any observed demographic moderation, additional analyses were conducted examining RT and accuracy as secondary outcomes.

The main effect of time, representing PE while adjusting for age, sex, and education, was first tested using LMMs (*lme4::lmer*; R, version 4.3.1; R Foundation for Statistical Computing). Subsequent demographic models examined the influence of demographic variables at baseline and whether they moderated PE through interaction terms (time × demographic variable). To further evaluate age effects, an additional analysis dichotomized participants at 65 years of age for each DANA task. Age was modeled continuously in primary analyses; the dichotomized analysis used a conventional threshold of 65 years for older adulthood, yielding approximately balanced subgroups (55% aged 65 years or younger, 45% aged 65 years or older). Models included random intercepts for participants. Sensitivity analyses fitting random intercepts and slopes for time produced consistent fixed-effect estimates for the time term on CS and GNG, and an attenuated but directionally consistent estimate for SRT. Results from the random-intercept models are reported in the main text, and the results from the random intercepts and slopes are provided in Multimedia Appendix 1 (Tables S1 and S4).

To evaluate whether the analytic-sample restriction to participants who completed all 4 time points affected estimated PE slopes, the no-interaction main-effect-of-time model was refitted within subgroups of participants who completed 2 (n=302) or 3 (n=349) consecutive time points, separately for CS, GNG, and SRT. Results are reported in Multimedia Appendix 1 (Tables S1 and S3).

To formally test whether PE magnitude differed across tasks, a stacked LMM combining data from all 3 tasks was fit with task and time as fixed-effect predictors and a task × time interaction. Outcomes were standardized within each task by that task's pooled SD across time points, such that interaction coefficients are interpretable in standardized effect size units comparable to the Cohen *d* values reported for individual tasks. Pairwise contrasts (SRT vs CS, SRT vs GNG, GNG vs CS) were derived from the interaction model (Tables S1 and S5 in Multimedia Appendix 1).

Baseline characteristics were compared between completers (n=717) and partial completers (n=1039) to evaluate selection bias. Demographic comparisons used unadjusted 2-group tests (Welch *t* test for continuous variables and chi-square tests for categorical variables). Baseline (T1) DANA cognitive scores (CE, RT, and accuracy) on each task were compared using linear models adjusted for age, sex, and education to isolate cognition-specific differences from those driven by demographic imbalance (Tables S1 and S2 in Multimedia Appendix 1).

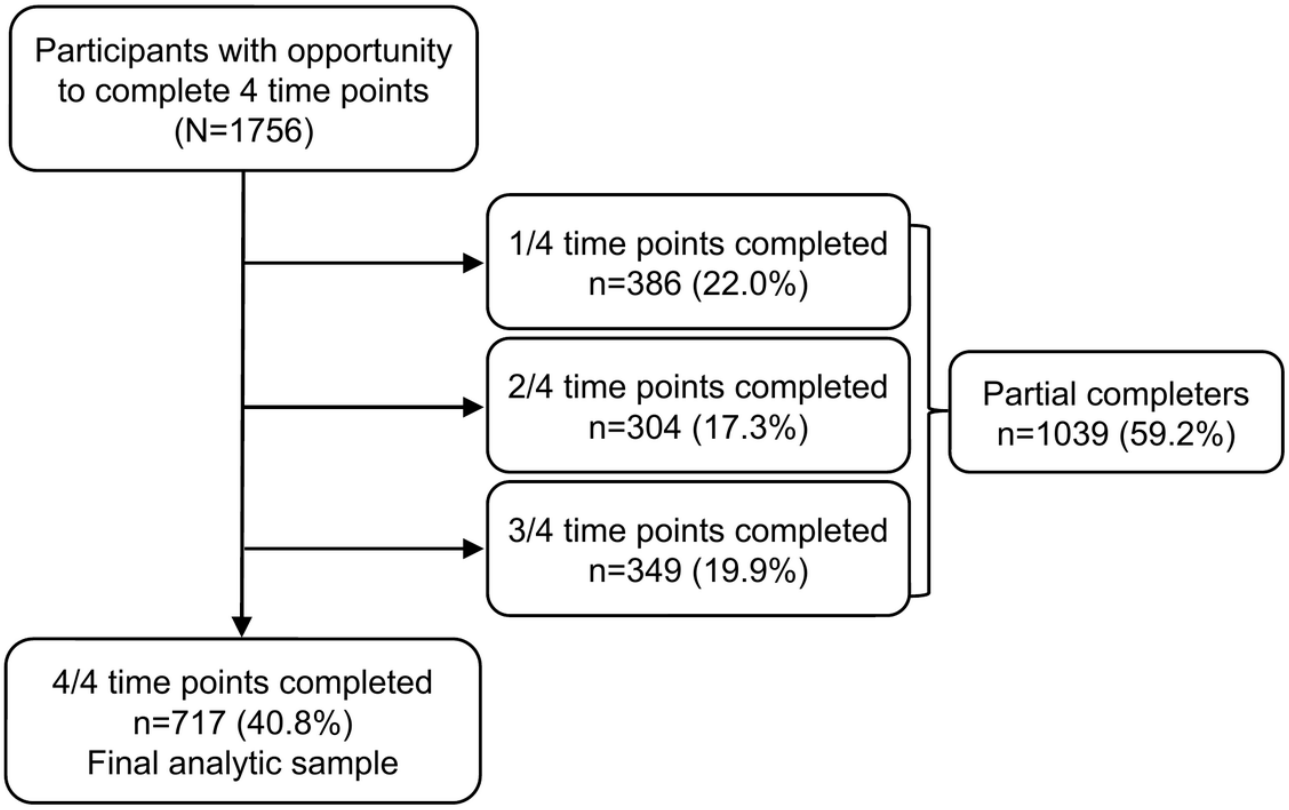
Ethical Considerations

The procedures and protocols of the FHS were approved by the institutional review board of the Boston University Medical Campus (H-40147). Written informed consent was obtained from all participants. The analyzed data did not include personal identifiers and were linked to a randomly generated identification number that cannot be used to identify participants personally. Study investigators never received or had access to identifying information. Since no identifying information was collected and no linkage file exists, there is no reasonable way to deduce participant identities from the data. The standard operating procedures used to protect the security of the data, along with other protections, are more than adequate to ensure the privacy of research participants and the confidentiality of the data. Participants were not financially compensated for participating in the study.



Results

Descriptive Characteristics

The sample comprising 717 participants (Figure 1; mean age 64.1, SD 9.5 years) was mostly White (n=669, 93.3%), female (n=469, 65.4%), and college graduates (n=481, 67.1%), primarily from the Gen 3 cohort (n=515, 71.8%, Table 1). Mean accuracy for T1 and T4 and the change in RT were as follows: for SRT, accuracy was 98.83% at T1 and 99.44% at T4, and RT decreased from 375.76 to 363.80 milliseconds; for GNG, accuracy was 96.81% at T1 and 97.36% at T4, and RT decreased from 883.46 to 843.95 milliseconds; and for CS, accuracy was 95.96% at T1 and 97.27% at T4, and RT decreased from 1941.46 to 1788.82 milliseconds (Table 2). Accuracy and RT showed an inverse relationship across tasks such that CS had the lowest accuracy and highest RT, SRT the highest accuracy and lowest RT, and GNG was intermediate on both. These descriptive trends corresponded to higher composite CE scores across assessments (Table 2).

Compared with partial completers (n=1039), the participants who completed all 4 time points were older (mean age 64.1, SD 9.5 years vs mean age 61.4, SD 10.1 years; $P<.001$), more often female (469/717, 65.4% vs 566/1039, 54.5%; $P<.001$), and more highly educated (481/717, 67.1% vs 101/1039, 9.7% college graduates; $P<.001$), with no difference in racial composition ($P=.39$; see Table S1 in Multimedia Appendix 1). After adjustment for age, sex, and education, groups did not differ in T1 CE, the primary outcome, on any task (see Tables S1 and S2 in Multimedia Appendix 1).

Figure 1. Participant selection based on adherence to the assessment schedule.

PEs

Without considering demographic influences, PEs on CE scores were observed across all subtests, reflected in significant main effects of time in the no-interaction models (Table 3). The magnitude of these PEs is shown in Figure 2, where improvements in CE from T1 to T4 were small for CS (d=0.43) and GNG (d=0.32) and below the small threshold for SRT (d=0.16). A stacked LMM with a task × time interaction confirmed that practice-effect magnitude differed across tasks, following the same ordering as the effect sizes, with all pairwise contrasts statistically significant (CS>GNG>SRT; see Tables S1 and S5 in Multimedia Appendix 1). Effect size trends in speed and accuracy indicated that changes for CS were driven by improvements in both RT and accuracy, while changes for GNG were driven almost exclusively by RT (Figure 2), reflecting baseline accuracy levels that were already at or near ceiling on GNG (mean 96.81%, SD 12.02%) and SRT (mean 98.83%, SD 6.27%). The slight decrease in cumulative effect size at T3 for SRT accuracy reflects a transient decline in performance between T2 and T3, though accuracy remained improved relative to T1 baseline. CS was the only subtest where change in accuracy reached the threshold for a small effect (d=0.21). For SRT, RT (d=0.17) and accuracy (d=0.16) contributed more evenly.

Sensitivity analyses, including those with partial completers (Tables S1 and S3 in Multimedia Appendix 1) and those fitting random intercepts and slopes for time (Tables S1 and S4 in Multimedia Appendix 1), showed no differences from the primary findings for CS or GNG; estimates for SRT were attenuated.

[d]B: unstandardized fixed-effect estimate.

Age, sex, and education models showed varied patterns of demographic-related differences in baseline performance and in their influence on PE. Older age, modeled continuously, predicted lower baseline CE scores on all tasks. The only significant age × time interaction was on CS, indicating smaller PE with increasing age. To examine categorical age effects, participants were dichotomized into younger (≤65 years; 55% of the sample) and older (>65 years) groups (Table 4). This approach confirmed what was observed in the continuous models: age-related moderation of PE occurred only for CS (B=−0.39, SE=0.10; *P*<.001). Additional analyses examining differences in speed and accuracy demonstrated that this moderation was driven by accuracy (B=0.46, 95% CI 0.09 - 0.83; *P*=.02) rather than RT (B=2.41, 95% CI −8.60 to 13.42; *P*=.67). Sex-related findings showed that at baseline, females scored lower than males on SRT and GNG, whereas no baseline sex-related differences were observed on CS. However, no significant sex × time interactions were observed, indicating that PE did not differ by sex. Education effects showed that, relative to participants with a high school degree or less, those with higher education scored better at baseline on all tasks. No significant education × time interactions were observed, indicating that PE did not vary by education.

Discussion

Principal Findings

PEs were observed across all 3 DANA tasks. The magnitude of PE increased with task complexity, likely due to the complex tasks provide greater opportunity for improvement. Among demographic variables, only age moderated performance over time, with older adults (aged 65 years or older) showing smaller PE on the CS task. This age-related moderation effect on the CS was driven primarily by accuracy rather than speed, which contrasted with the general trend of speed driving improvements in composite CE scores.

Early studies of DANA reported little evidence of PE [34,36,40], likely due to small samples, short retest intervals, preliminary practice sessions, and reliance on younger, predominantly male cohorts with high baseline performance. More recent work by Bellitti et al [27] found modest RT improvements across 2 sessions in older adults, with CS showing the largest effects and emerging as the only task differentiating cognitively intact from impaired participants. This pattern may reflect the polyfactorial nature of CS, that is, its simultaneous recruitment of multiple cognitive domains [37]. Our results are consistent with this pattern, with CS showing the largest PE, followed by GNG and then SRT in the current study. Direct comparison across studies is limited because Bellitti et al [27] did not report raw RTs and used a mixed sample of cognitively intact and impaired participants. Our larger sample revealed PE on both GNG and SRT, whereas the previous study observed no change on SRT. Prior studies have also found that CS performance relates to a broader set of abilities than SRT or GNG, with the CS task being associated with executive function, attention, processing speed, and memory [32]. Another study also found that the CS task was more strongly associated with a global measure of cognition, the Mini-Mental State Examination, than were SRT and GNG [41]. Interestingly, in a previous study, when the DANA app was administered remotely, the CS task could not be reliably completed by patients diagnosed with AD [42]. One reason could be that this task was particularly challenging to complete remotely without help for those with deteriorating cognitive abilities. Together, these findings support our description of CS as more complex than the other DANA tasks and suggest that this task might be a more sensitive task for detecting subtle impairment over time. Future longitudinal studies tracking these cohorts will be required to validate these suppositions.

Our findings also suggest that task complexity contributes to the presence of PE, but the unique contributions of speed and accuracy remain less clear. Bellitti et al [27] analyzed only speed, citing uniformly high accuracy at baseline as the reason for not examining accuracy. Our results confirm that most improvements across time were speed-driven but also indicate that the age-related moderation of PE on CS was more strongly linked to accuracy.

Speed vs Accuracy

The ability of digital assessments to measure both speed and accuracy and to combine them into composite throughput measures [39] not only creates opportunities but also introduces new analytic challenges in interpreting higher-dimensional data. Cross-sectionally, variability in RT has been more closely linked to AD than accuracy [43], and tests with a majority speed-based component tend to produce the largest PEs [44]. However, Bergman et al [44] defined speed tasks using computerized iterations of legacy measures (ie, traditional neuropsychological tests) such as Trails A (approximately 20 - 30 seconds), distinguishing them from simple reaction tasks such as SRT (approximately 3 - 4 seconds), which, in the current study, is considered the most direct measure of speed. This distinction underscores the importance of carefully translating legacy constructs into digital formats. Relative to other measures in their respective eras, both Trails A and SRT are considered prototypical indicators of processing speed. Yet their susceptibility to PE differs, as Trails A is both more complex due to its demands on visual scanning and motor coordination and is substantially longer in duration. Bergman et al [44] also administered their tasks on laptops with external mice, whereas the present study relied on smartphones. Even within modern digital platforms, operating system and hardware differences (eg, iOS vs Android) can influence response capture and timing precision, raising additional concerns about generalizability across devices [45,46]. Thus, task duration, complexity, and device type likely increase susceptibility to PE, but disentangling their relative contributions is challenging. Whereas task duration is easy to quantify, task complexity is more abstract and difficult to measure directly. More broadly, this demonstrates that although tests are operationalized precisely, they often recruit multiple domains, and the relationship between tests and cognitive constructs is fluid [47].

PE and Defining Change

This study adds to the growing literature on PE, including studies using digital cognitive assessments [20], traditional tests

XSL•FO
RenderX

across short intervals [48], and those examining cognitive trajectories alongside concurrent biomarkers or lifestyle factors [49-51]. Much of the current high-frequency cognitive testing literature emphasizes memory tasks due to their sensitivity to neuropathological changes, particularly in AD [28,29]. In contrast, this study demonstrates that digital tasks measuring other predominantly nonmemory abilities, including processing speed, sustained attention, and visual scanning, also exhibit detectable PE.

Characterizing PEs in nonmemory tasks within a large sample of cognitively intact adults provides foundational data for research examining diminished PEs as a potential indicator of cognitive decline. Documenting that PEs occur in this population establishes a baseline for evaluating whether the absence or attenuation of PEs can distinguish impaired from intact individuals across neurodegenerative conditions and neurological injuries, where small but measurable deviations from normal trajectories may have clinical significance.

The utility of PE as a potential subtle indicator of cognitive impairment depends on careful consideration of assessment parameters, as PEs vary based on testing intervals, the specific cognitive domains assessed, the types of devices used, and how performance is quantified (speed, accuracy, or composite measures). Digital cognitive assessments vary considerably not only in the types of tests and cognitive abilities they measure but also in the time intervals between assessments, ranging from intensive longitudinal or measurement burst designs with multiple assessments in one day to weekly, monthly, quarterly, or annual follow-ups. Validation in cognitively impaired groups is a natural next step before PE from these brief digital tasks can be advanced as candidate clinical indicators.

The changes in performance observed in this study were significant but small in magnitude (SRT: d=0.16, GNG: d=0.32, CS: d=0.43). Given that effect sizes are expressed in SD units, these values reflect improvements of less than half an SD across 4 time points. Conventional neuropsychological interpretation relies on a ±1.645 SD threshold to define reliable change, a widely used but arbitrary cutoff intended to detect overt dysfunction [52]. Meanwhile, contemporary perspectives emphasize that neuropathological changes emerge before overt cognitive disruption, underscoring the potential relevance of smaller within-person shifts in cognition [7]. Progress toward this more nuanced perspective is reflected in recent efforts toward a “change-on-change” approach that interprets cognitive change alongside neuropathological change [49]. The current study clarified task-specific patterns of PE on DANA in a cognitively intact sample. Future research should aim to determine thresholds of clinical significance for PE, recognizing that meaningful change may be subtle and interpreted differently if occurring concurrently with neuropathological change.

Strengths and Limitations

This study has several strengths. It represents the largest investigation of PE using the DANA platform, with participants completing 4 assessments across a 1-year period. This study contributes to the understanding of quarterly assessments, which is a relatively understudied temporal frequency situated between intensive longitudinal burst paradigms and long-interval observational studies. Another strength is the use of composite efficiency metrics that integrate both speed and accuracy, allowing both variables to contribute to the overall score.

There are also important limitations. The sample was predominantly White, female, and highly educated, which constrains generalizability. Analyses were conducted on summary scores generated by the DANA platform rather than item-level or trial-level data, which may have limited sensitivity to finer-grained practice-related changes. Also, to ensure consistency in examining PE, we only included participants who completed all 4 time points. Although sensitivity analyses of 2- and 3-time-point subsets (Tables S1 and S3, Multimedia Appendix 1) revealed statistically significant PE on CS and GNG among noncompleters, mirroring the ordinal pattern observed in the primary sample, the smaller effect magnitudes in these subsets suggest that estimates derived from the current completer sample may represent an upper bound on population-level PE among cognitively intact older adults. However, adherence to longitudinal testing is itself an important behavioral variable [53], and it remains unclear how missed or off-schedule assessments might influence the occurrence of PE. A comparison of baseline cognition between completers and partial completers showed no difference in CE after adjustment for age, sex, and education (Tables S1 and S2 in Multimedia Appendix 1). We also did not measure contextual factors such as comfort with the testing application [31] or momentary states such as arousal and distraction, which recent evidence indicates can affect cognitive performance in remote settings [54]. Finally, this study focused exclusively on cognitively intact participants without integrating biomarkers, limiting the ability to evaluate how PEs interact with underlying neuropathological changes. Future work could examine whether baseline cognitive performance moderates the magnitude of PE on these tasks.

Conclusions

This study demonstrates that PEs are detectable across multiple digital cognitive tasks, with the largest effects observed on more complex tasks. Older adults showed smaller PEs on the CS task, and this trend was driven more by accuracy than speed. These results underscore the importance of considering task demands, as well as the relative contributions of speed and accuracy, when interpreting digital cognitive data. More broadly, the findings highlight the need to move beyond legacy thresholds for reliable change, which were designed to detect overt functional decline, and toward models that evaluate incremental within-person variability embedded within contextual factors as a meaningful signal in the aging process.

Acknowledgments

The authors acknowledge the FHS participants for their dedication, as this study would not have been possible without them. The authors also thank the researchers at FHS for their efforts over the years in examining participants. The authors declare the use of generative AI to assist with editing the manuscript text and formatting tables (Claude, Anthropic).

Funding

This research was supported by the National Institute on Aging of the National Institutes of Health under award numbers U01-AG068221, R01-AG062109, R01-AG072654, U19-AG068753, R00 AG062783, and R01-AG083735. Additional support was provided under contract HHSN269201500001C and by the Alzheimer Drug Discovery Foundation.

Data Availability

Data, methods, and materials used to conduct the research in this paper, along with additional information, can be shared upon reasonable request through a formal research application to the Framingham Heart Study. Requests to access these datasets should be directed to the Framingham Heart Study [55].

Authors' Contributions

KC conceptualized the project, drafted the original manuscript, proposed an analytical plan, and created visualizations. CL conducted the formal analyses and created visualizations. CK was responsible for data curation. HD provided supervision and guidance on the analytic approach. VBK, HL, and RA contributed to funding acquisition, methodology, conceptualization, and critical review of the manuscript content. SD, AFAA, IDA-D, and KAG also provided critical review of the manuscript content. PHH provided supervision and guidance on the analytic approach. PS contributed to project conceptualization, drafting of the original manuscript, data collection, study design, analytical approach, project administration, and supervision.

Conflicts of Interest

RA is a scientific advisor for Signant Health and Novo Nordisk, which are unrelated to the work presented.

Abstract

Background: China's rapidly aging population and high burden of frailty make proactive preparation for future care increasingly urgent, yet few older adults engage in such preparation. Existing interventions often overlook the heterogeneity between prefrail and frail populations and lack precision-oriented digital strategies.

Objective: Building on a series of prior empirical studies, this study aimed to develop and pilot-test a digital intervention to support preparation for future care among community-dwelling older adults with prefrailty and frailty.

Methods: The "Yi Yang Plan," a WeChat mini-program, was developed through a rigorous multiphase process, including a scoping review, a convergent mixed methods study, and a structural equation model. These findings informed the design of a tailored, stage-specific intervention targeting the distinct needs of prefrail and frail older adults. An interdisciplinary team subsequently refined the intervention using an iterative design approach. The intervention modules comprised 4 processes: Awareness Enhancement, Care Resources, Care Decision-Making, and Care Planning. Pilot testing involved expert panel consultations and think-aloud tests. Expert characteristics, engagement, and authority coefficients were assessed, and feedback was synthesized using content analysis. Feasibility and acceptability among older adults and their family members were evaluated through task completion metrics, satisfaction surveys, think-aloud protocols, and semistructured interviews.

Results: Seven experts participated in the consultation, with an engagement coefficient of 100% and an authority coefficient of 0.88. Recommendations were synthesized into four key themes: (1) establishing mechanisms for care plan updating and review, (2) strengthening user-centered design, (3) implementing dynamic resource management and robust data security measures, and (4) enhancing integration with community care systems and policy frameworks. A total of 20 older adults and 20 family members were recruited. All participants successfully completed the assigned tasks, with a mean completion time of 20.7 (SD 5.2) minutes. Satisfaction ratings were generally favorable. The qualitative findings indicated that the intervention was perceived as useful and professionally designed, while also identifying several challenges, including variability in preparation for future care readiness and educational levels, limited interactivity, insufficient practical content, and reliance on support from adult children. Suggested improvements included enhanced personalization, additional supportive tools, improved usability, greater involvement of adult children, and stronger integration with offline services.

Conclusions: The "Yi Yang Plan" demonstrated preliminary scientific validity, feasibility, and acceptability as a multidisciplinary, collaboratively developed digital intervention to support preparation for future care among older adults with prefrailty and frailty. By translating prior empirical and theoretical findings into a differentiated, precision-oriented digital strategy, this study advances interventions beyond conventional one-size-fits-all approaches. Future iterations should focus on optimizing system architecture, user interface design, platform functionality, and implementation strategies. Further research should conduct higher-quality randomized controlled trials to evaluate the platform's effectiveness.

Introduction

In China,[1] older adults are defined as those aged 60 years and above [2]. By the end of 2024, the population of older adults in China reached approximately 310 million, accounting for 22% of the total population [3]. By 2035, older adults are expected to account for more than 30% of the population [4]. With advancing age, physiological reserve capacity progressively declines or becomes dysregulated, leading to increased vulnerability, reduced resilience to stressors, and impaired maintenance of internal homeostasis; consequently, older adults are more likely to develop frailty [5,6]. Frailty is a complex geriatric syndrome characterized by multifactorial etiologies and diverse influencing factors. Its hallmark features include reduced muscle strength, decreased endurance, and progressive physiological functional decline, which collectively increase the risks of dependency and mortality [7,8]. Evidence indicates that frailty may be associated with a 15% to 50% increase in all-cause mortality risk [9] and that for every 0.1-unit increase in the frailty index, the risk of adverse health outcomes rises by 68% [10]. Epidemiological studies suggest that the prevalence of frailty is approximately 15% among adults aged 65 years and older, increasing to 25% to 50% among those aged 80 years and above [11-13]. A systematic review further reported that the prevalence of frailty among community-dwelling older adults in China ranges from 5.9% to 17.4%, with a pooled prevalence of 10.0% [14]. The progression of frailty leads to a gradual decline in older adults' ability to live independently and may ultimately result in disability, necessitating reliance on external care and imposing substantial caregiving burdens on families and society [15]. Projections indicate that by 2050, approximately 91.4 million older adults in China will require long-term care services [16], reflecting a growing and sustained demand for formal care provision.

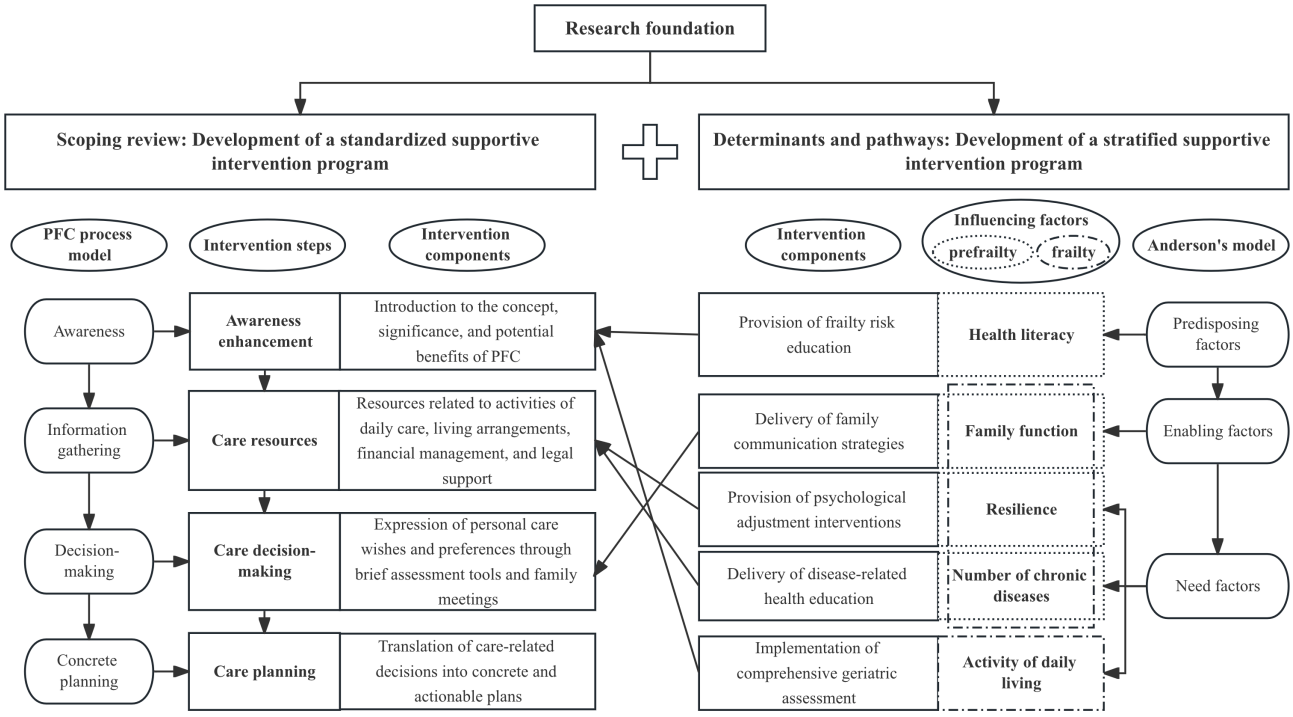
Under the influence of the cultural norm of filial piety, the traditional belief of "raising children for old-age support," and legal as well as moral regulations mandating adult children's caregiving responsibilities, older adults in China have traditionally relied predominantly on family-based care models [17,18]. However, as a result of the long-standing one-child policy, family structures have undergone profound changes, with nearly 70% of households nationwide becoming single-child families [19]. At present, the parents of the first generation of only children have entered old age, and over the next 3 decades, the number of older and oldest-old parents with a single child is expected to continue to increase. China is therefore approaching a peak period of "only-child-supported aging" [20]. Nevertheless, only children face substantial practical challenges in fulfilling eldercare responsibilities. Due to work-related pressures and obligations related to raising the next generation, they often struggle to provide adequate financial support, daily care, and emotional companionship for their aging parents [21]. In addition, with accelerating modernization and urbanization, increasing female labor force participation, and rising life expectancy among older adults, the traditional family caregiving function has been further weakened. Against this backdrop, older adults are increasingly compelled to shift from traditional family-based care models to transitional or more formalized, socially provided care arrangements [22]. This transition necessitates that older adults proactively plan for future care to mitigate potential caregiving risks. Taken together, in the face of the complex care needs associated with frailty, the traditional family care model is no longer sufficient to meet current demands. There is an urgent need for frail older adults to play a more active role by engaging in early planning, mobilizing available resources, and preparing for future care.

Preparation for future care (PFC) refers to the process of preparing for potential needs for assistance with activities of daily living resulting from functional decline due to chronic illness or health-related events in the future [23]. A substantial body of literature indicates that PFC promotes active aging [24]. Older adults who engage in more systematic planning for future care report a greater sense of control over their lives [25], higher life satisfaction [26], and lower levels of anxiety and depression [27]. Moreover, as a form of long-term risk management, PFC enables advance arrangements for future care needs, such as identifying potential caregivers, selecting care institutions, or planning for transitions in care modalities, which can substantially alleviate caregiver burden and generate benefits for caregivers as well [24]. In contrast, a lack of PFC is associated with higher risks of illness and increased financial and emotional strain [28]. Therefore, actively guiding older adults to engage in PFC is a critical component of community nursing practice in the context of population aging, with significant practical relevance and social value.

Over the past 2 decades, most interventions have focused on short-term care planning for patients at the end of life, with limited attention given to long-term care preparation among older adults [29,30]. Existing PFC interventions are predominantly delivered through face-to-face communication or group meetings and rely largely on experiential guidance, often lacking robust empirical evidence and theoretical frameworks. In addition, many studies are characterized by methodological limitations and poor scalability and feasibility for widespread implementation [31]. Consequently, developing scientifically grounded, feasible, and easily disseminated strategies to promote PFC has become a key challenge in this field. With the rapid advancement of information technology, digital nursing models have emerged as an important area of research. For example, Hoffman et al [32] developed a web-based platform that provides education, values clarification, resources, and behavioral planning for long-term care, which effectively facilitated PFC engagement among older adults and has been adopted by health care organizations. However, most existing digital PFC interventions have been developed in Western countries, particularly the United States [33]. These platforms often lack health care professional–led guidance and are not grounded in explicit theoretical frameworks, limiting their capacity to address the individualized needs of frail older adults [34].

In recent years, the Chinese government has issued a series of policy documents [35-37] emphasizing the development of nursing information networks and service platforms to deliver efficient and accessible digital nursing services to older adults in need. In light of both practical demands and policy priorities, there is an urgent need to develop a theory- and

XSL•FO
RenderX



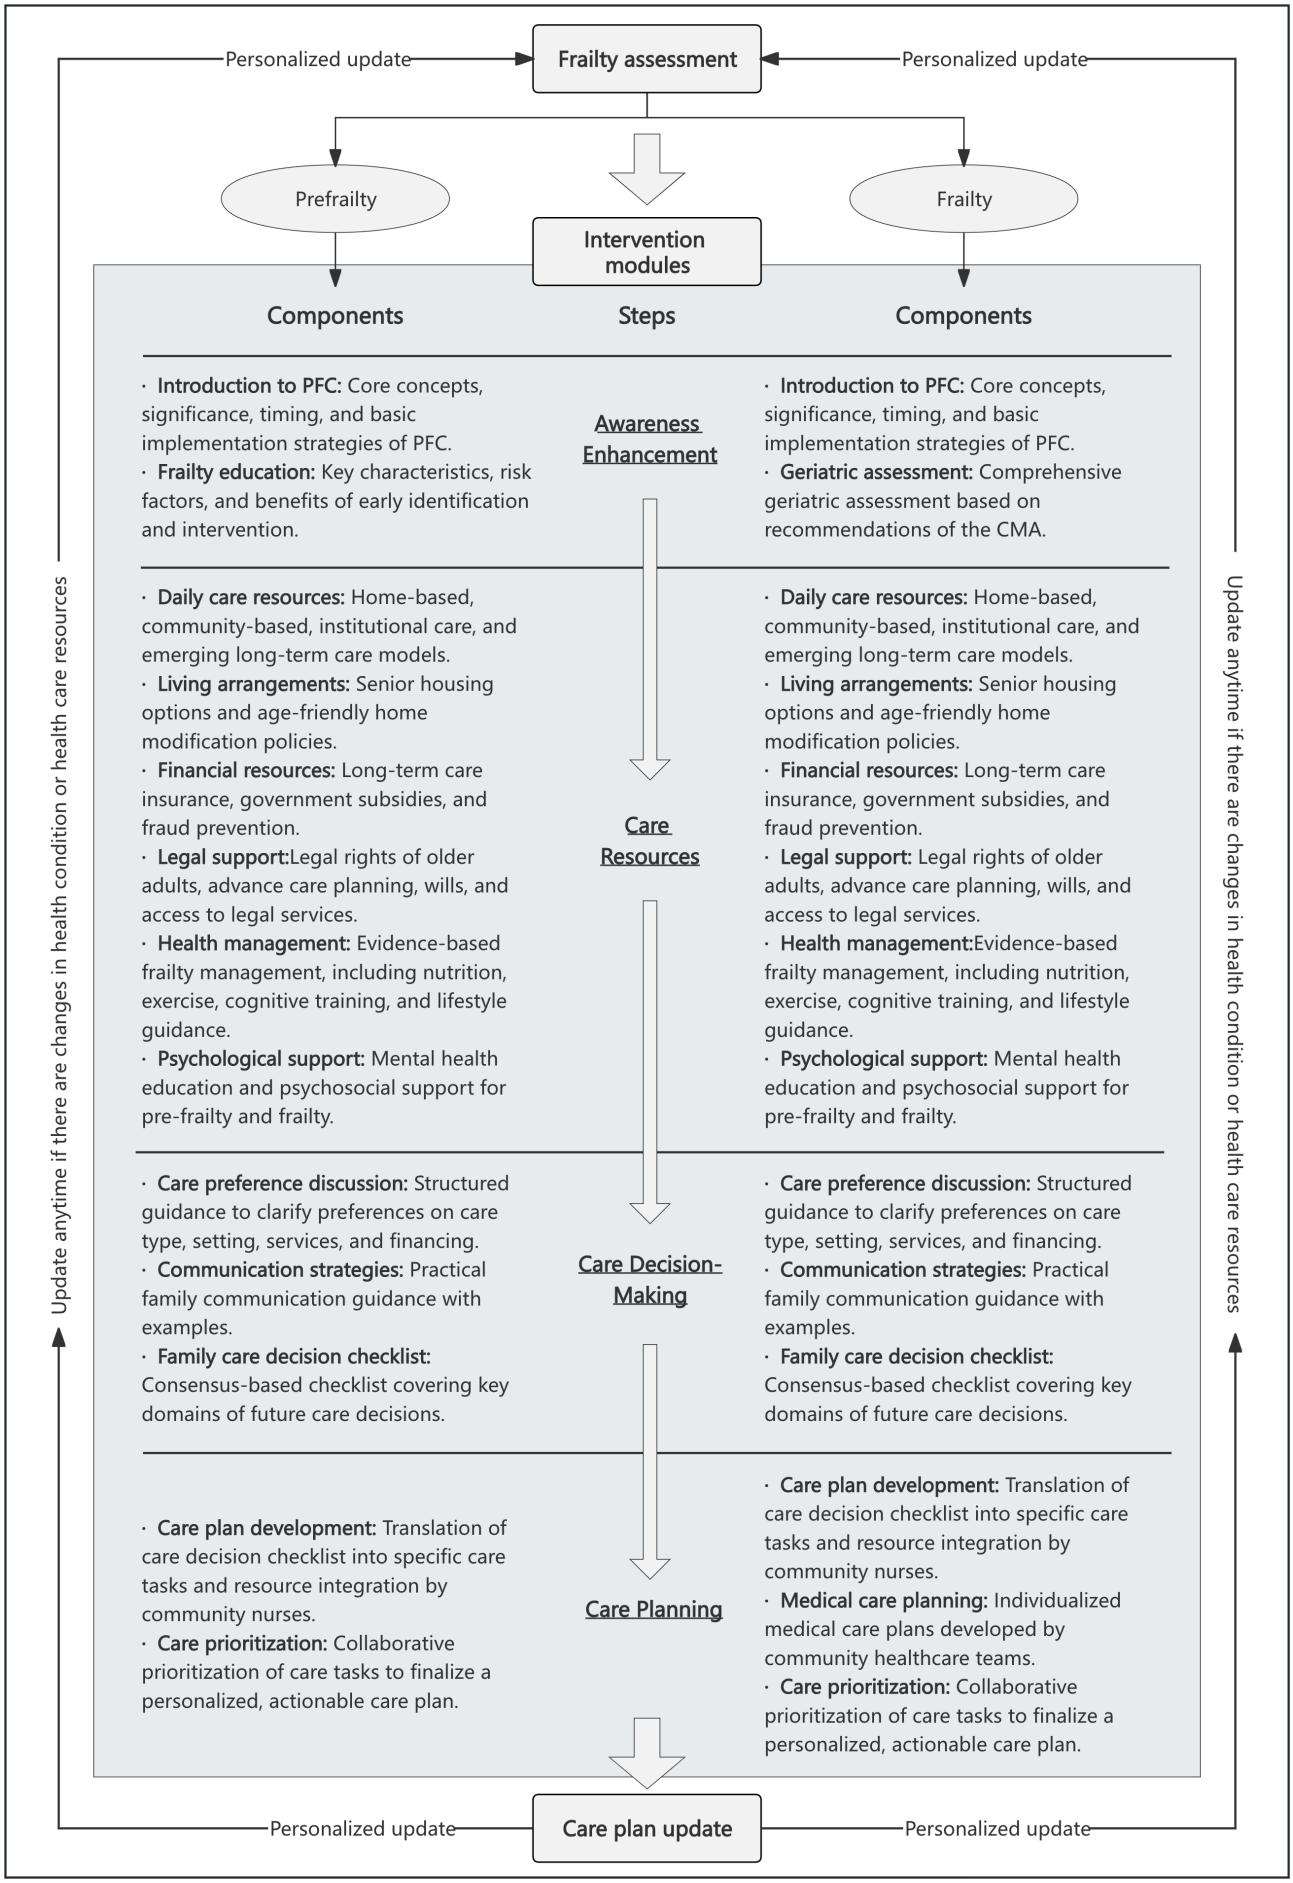
evidence-informed digital PFC intervention platform tailored to the Chinese context. Such a platform could enhance frail older adults' awareness of the importance of PFC and facilitate the implementation of practical long-term care plans, thereby optimizing the prospective allocation of aging-related resources. Therefore, the objectives of this study are twofold: (1) to develop a localized and stratified digital intervention for supporting PFC among community-dwelling older adults with prefrailty and frailty and (2) to assess the scientific validity, feasibility, and acceptability of this digital intervention using expert panel consultations and think-aloud tests. These efforts will provide a foundation for future refinements of the platform and a subsequent randomized controlled trial.

Methods

Digital Program Development: Research Foundation

To inform the development of a digital intervention for PFC among community-dwelling older adults with frailty, we conducted a series of sequential studies, including a scoping review [33], a convergent mixed methods study [38], and a structural equation model (SEM) based on triangulated findings from the mixed methods study. In brief, the scoping review identified 4 core components of PFC-supportive interventions (Awareness Enhancement, Care Resources, Care Decision-Making, and Care Planning), which are consistent with the PFC process model proposed by Sörensen et al [39]. The mixed methods study, guided by the Andersen Behavioral Model of Health Services Use, identified key determinants of PFC among prefrail and frail older adults. Furthermore, the SEM revealed that influencing pathways of PFC differ between prefrail and frail older adults, providing empirical support for a stratified intervention design (Figure 1).

Figure 1. Research foundation of digital intervention development. PFC: preparation for future care.



Based on these findings, a supportive intervention program for PFC among community-dwelling frail older adults was developed (Figure 2). The program emphasizes tailoring intervention strategies according to frailty status to enable targeted and differentiated support. Specifically, for prefrail older adults, interventions focus on frailty education, health management, psychological support, and family communication. For frail older adults, interventions focus on comprehensive geriatric assessment, health management, psychological support, and medical care planning.

Digital Program Construction

Platform Selection and Conceptualization

Based on the intervention program, the digital platform was developed as a WeChat mini-program, given that WeChat is the most widely used mobile app in China and offers high accessibility for older adults. The mini-program was named "Yi Yang Plan." In Chinese, "Yi Yang" refers to maintaining physical and mental well-being through appropriate care, reflecting the program's goal of promoting healthy and meaningful aging.

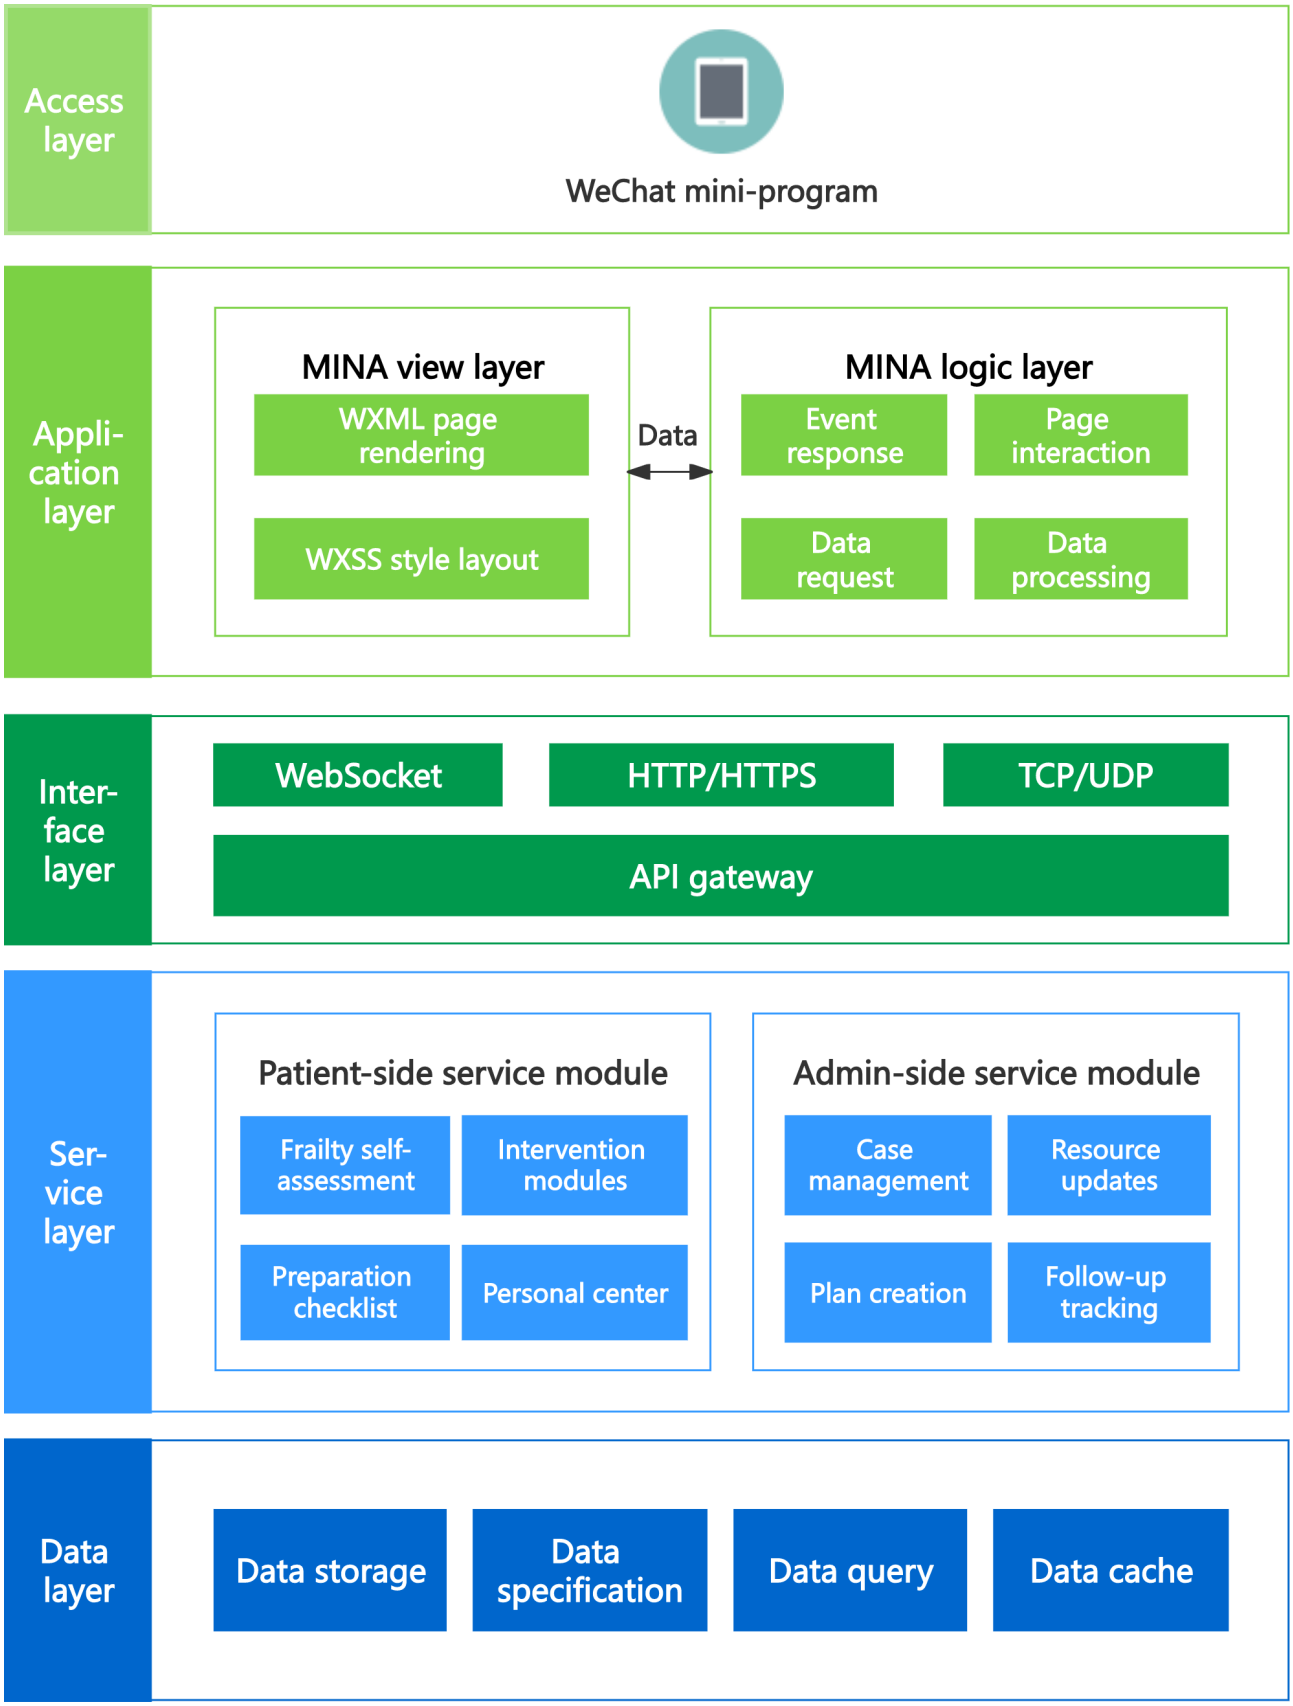
Research Team Formation

An interdisciplinary team was established, comprising 2 geriatric care experts with experience in digital health app design, 1 interface designer specializing in age-friendly design, 1 software engineer, and 1 doctoral student in nursing. The team collaboratively conducted the design, development, and refinement of the mini-program.

Interface Design and Development Process

The platform interface was designed using an iterative approach. Initially, the interface designer created preliminary prototypes based on the intervention protocol. These prototypes were reviewed by the research team on a page-by-page basis, followed by iterative revisions focusing on content clarity, navigation logic, and user experience. After multiple rounds of revisions and optimization, the finalized design was implemented by the software engineer. The interface design was developed using the Lanhu platform (version 6.0.4; Beijing Jinwei Zhiguang Information Technology Co; Multimedia Appendix 1).

Development Environment



The mini-program was developed within the official WeChat Mini Program development environment. A developer account was registered, and a unique application identification was obtained. The WeChat Developer Tools were used to support coding, debugging, and deployment, with access to standardized frameworks, components, and technical documentation. Upon completion, the software engineer uploaded and managed the program code.

System Architecture

The system adopts a front-end or back-end separated architecture. The front-end was developed using the uni-app framework with uView components, while the back-end was implemented using C#-based server-side services. Data exchange between the 2 layers is achieved through network communication protocols. The platform architecture is organized into 5 hierarchical layers: Data Layer, Service Layer, Interface Layer, Application Layer, and Access Layer. This layered architecture enhances system scalability, maintainability, and security (Figure 3).

Cognitive Load-Oriented Design

Complex content, such as financial and legal information, was simplified through multimodal presentation formats. Specifically, short videos were used to explain key concepts, text-to-speech functionality was incorporated for essential

XSL•FO
RenderX

content, and illustrative images were added to facilitate comprehension.

Digital Platform Functions

Overview

The "Yi Yang Plan" consists of 2 primary components: a community management terminal and a patient or family app terminal. The community management terminal supports case registration, list management, care plan development, resource updates, and follow-up tracking (Multimedia Appendix 2). The patient or family app terminal comprises 4 main modules: self-assessment, intervention modules, care preparation checklist, and personal center.

Self-Assessment

After account registration and binding (Multimedia Appendix 3A), users complete a frailty self-assessment (Multimedia Appendix 3B). Based on the results, users are classified as prefrail or frail, and a corresponding personalized intervention pathway is initiated (Multimedia Appendix 3C).

Intervention Modules

Guided by the PFC process model [39], the intervention is operationalized through four sequential and functionally integrated modules:

Awareness Enhancement

This module introduces the concept, importance, timing, and strategies of PFC through standardized short videos (Multimedia Appendix 4A). For prefrail users, targeted frailty education is provided, focusing on risk factors and early intervention (Multimedia Appendix 4B). For frail older adults, the module incorporates an electronic comprehensive geriatric assessment recommended by the Chinese Medical Association [40], including the Simplified Nutritional Appetite Questionnaire, SARC-F (Strength, Assistance in walking, Rise from a chair, Climb stairs, Falls), and Rapid Cognitive Screen (Multimedia Appendix 4C).

Care Resources

This module provides a structured repository of evidence-informed care resources (Multimedia Appendix 5A). Resources include daily care services, housing and home modification policies, financial planning, legal support, health management, and psychological support (Multimedia Appendix 5B-P). Information is delivered in multiple formats, including text, images, audio, and video.

Care Decision-Making

This module facilitates shared decision-making and family engagement. Structured discussion guides (Multimedia Appendix 6A) and communication strategies (Multimedia Appendix 6B) support family discussions. Users then complete a 12-domain family care decision checklist (Multimedia Appendix 7), reflecting consensus among family members (Multimedia Appendix 6C).

Care Planning

Based on the completed checklist, community nurses develop an initial care plan using the management terminal. For frail older adults, individualized medical care plans are additionally formulated. Users review, adjust, and prioritize care tasks within the mini-program, resulting in a finalized personalized care plan (Multimedia Appendix 8A-B). The system also supports ongoing plan updates (Multimedia Appendix 8C).

Care Preparation Checklist

Upon the completion of the intervention modules, the system automatically generates a comprehensive care preparation checklist integrating care plans and related resources. This checklist can be exported in PDF format for family communication or offline consultations (Multimedia Appendix 9A).

Personal Center

The Personal Center module allows users to manage their personal profiles and maintain relevant information. It also includes a "favorites" function, enabling users to save and access important resources for future reference (Multimedia Appendix 9B).

Expert Panel Consultations

Participants

A purposive sampling method was used to recruit experts from 6 fields: nursing management, community nursing, geriatric nursing, general medicine, geriatric medicine, and sociology. Experts were eligible if they met the following criteria: (1) demonstrated recognized academic expertise and authority in the treatment, care, or long-term care of community-dwelling frail older adults; (2) had experience in leading or participating in digital health-related projects; (3) held an associate senior professional title or higher; and (4) had at least 10 years of relevant professional experience.

Procedure

Prior to the consultation, all experts received the study protocol, a trial access link to the mini-program, and the meeting agenda. The consultation was conducted in a hospital conference room. At the beginning of the session, the project leader introduced the study background and objectives. With participants' informed consent, the entire session was audio-recorded. Experts were then guided through a 20-minute hands-on use of the "Yi Yang Plan" mini-program. The consultation focused on 3 key domains: scientific validity, operability, and feasibility of the intervention. During the discussion, the facilitator ensured that all questions were clearly understood and that ambiguities were resolved to accurately capture expert perspectives. Within 24 hours, audio recordings were transcribed verbatim and independently verified by 2 researchers. The transcripts were subsequently returned to the experts for member checking to confirm the accuracy and completeness of their statements.

Data Collection

Expert Characteristics

Data included gender, age, highest degree, professional title, field of expertise, and years of experience.

XSL•FO
RenderX

Expert Engagement Coefficient

Expert engagement was assessed using the response rate, reflecting the level of participation and attentiveness of experts in the consultation process. A higher response rate indicates greater engagement and contributes to the objectivity of the consultation results.

Expert Authority Coefficient

The authority coefficient was used to evaluate the credibility and expertise of the participating experts. It reflects their professional judgment and familiarity with the topic. An authority coefficient of 0.70 or above is generally considered indicative of reliable expert consultation. Detailed calculation methods are provided in Multimedia Appendix 10.

Data Analysis

Descriptive analysis was conducted to summarize expert demographics, engagement coefficients, and authority coefficients. Qualitative data from the consultation were analyzed using conventional content analysis. Transcripts were independently coded by 2 coders, followed by face-to-face discussions to modify and reconcile coding discrepancies. Data analysis was performed using MAXQDA 2024 (VERBI Software).

Think-Aloud Test

Participants

Using convenience sampling, we recruited 20 dyads consisting of community-dwelling older adults with prefrailty and frailty and their family members from a community health center in Hangzhou, China. According to Faulkner [41], 20 participants are sufficient to identify the majority of usability issues. The inclusion criteria for older adult participants were as follows: (1) aged 60 or above years; (2) self-reported as prefrail or frail based on the FRAIL (Fatigue, Resistance, Ambulation, Illness, Loss of weight) scale (1‐2 criteria indicating prefrail; ≥3 criteria indicating frail); (3) residence in the community for at least 6 months [42]; (4) ability to read, write, and understand Mandarin; and (5) ability to use a smartphone. Individuals with a clinical diagnosis history of severe psychiatric or neurological disease, such as schizophrenia or Alzheimer disease, were excluded. Each older adult was encouraged to involve 1 family member (aged ≥18 years), who was related to the patient by blood, marriage, adoption, or affinity as a significant other, and met the language and smartphone-use criteria.

Procedure

Think-aloud tests were conducted in a meeting room arranged to resemble a typical living room environment. Before each session, we prepared the necessary equipment: smartphones with the WeChat preinstalled for the participants, audio recorders, timers, and Resistance and pens for observers. We also enabled screen-recording software on the smartphones to capture on-screen interactions. Based on the core functions provided by the “Yi Yang Plan” mini-program and the typical operations required for preparing for future care, 5 core tasks were designed in consultation with a software engineering expert (Multimedia Appendix 11).

At the beginning of each session, researchers introduced the study’s purpose. Participants were informed that their verbalizations and screen operations would be recorded during the testing process, and their data were fully confidential. Participants were also informed about the think-aloud protocol and instructed to verbalize their thoughts continuously while using the mini-program. As they navigated through each feature of the mini-program, they were encouraged to speak aloud their current thoughts; any decisions they were considering; and any feelings, confusions, or difficulties they experienced. Importantly, researchers did not intervene or answer questions during the task; participants were advised beforehand that any questions or issues they raised would be addressed only after the completion of the session. If a participant became stuck or hesitant, researchers offered neutral encouragement to continue but provided no direct assistance. If certain tasks could not be completed by the participant, these were noted as uncompleted tasks in our observations.

Each test session was recorded in multiple ways. A digital audio recorder captured all spoken comments from participants, the smartphone’s screen-recording software logged the exact on-screen actions and navigation, and the timer recorded the duration of each completed task. Researchers also objectively observed and documented each participant’s spoken words and nonverbal behaviors without attempting to interpret them.

Measures

General Characteristics

For older adults, the data included age, gender, residence, education level, and prior experience with mobile health apps. For family members, the data included relationship to the older adults, age, education level, and prior experience with mobile health apps.

Platform Use Satisfaction

Platform use satisfaction was assessed using a self-developed questionnaire comprising 6 items: interface design, features and functions, ease of operation, content quality, system stability, and overall experience. Each item was rated on a 5-point Likert scale, with scores ranging from 1 (“very dissatisfied”) to 5 (“very satisfied”).

Platform User Experience Interviews

A semistructured interview guide was developed based on the technology acceptance model (TAM) [43], including three open-ended questions: (1) Do you perceive this platform as useful? (2) Do you find this platform easy to use? (3) What suggestions do you have for improving the platform?

Data Analysis

Quantitative data, including task completion time and satisfaction scores, were analyzed using descriptive statistics. Categorical variables were summarized as frequencies and percentages, and continuous variables were reported as means (SD). The qualitative data from think-aloud sessions and interviews were transcribed verbatim and analyzed within the framework of the TAM. Thematic analysis and coding were conducted with a focus on the core dimensions of perceived usefulness and perceived ease of use in order to elucidate

XSL•FO
RenderX

participants' acceptance motivations, perceived barriers, and suggestions related to their use of the "Yi Yang Plan" mini-program. Data analysis was performed using MAXQDA 2024 (VERBI Software). Data analysis was conducted in Chinese. Themes and related quotations were translated into English for report writing by the first author. Translations were reviewed by the research team, and discrepancies were resolved through discussion.

Ethical Considerations

This study followed the principles of the Declaration of Helsinki and was approved by the Ethics Research Committee of Sir Run Run Shaw Hospital Affiliated to Medical College of Zhejiang University (2024-2759-01). Before enrollment, the responsible researcher explained the possible benefits and risks of the study to each potential participant in a face-to-face conversation, and they could withdraw from the study at any time without penalty. Sufficient time was provided for individuals to consider their participation, and only those who voluntarily agreed and signed the informed consent form were included.

Results

Expert Panel Consultations

Expert Characteristics

A total of 7 experts were recruited, including 6 female experts and 1 male expert. The mean age was 52.9 SD (7.38) years, and the average year of professional experience was 30.4 (SD 10.62) years. Detailed demographic characteristics are presented in Table 1.

Table . Demographics characteristics of the experts (n=7).

No.	Age (y)	Gender	Highest degree	Professional title	Field of expertise	Years of experience
1	50	Female	Master	Chief physician	General medicine	27
2	57	Female	Master	Chief physician	Geriatrics	34
3	60	Female	Master	Professor	Geriatric nursing	41
4	45	Female	Master	Chief physician	General medicine	22
5	40	Male	PhD	Professor	Sociology	10
6	58	Female	Master	Associate chief nurse	Community nursing	39
7	60	Female	Master	Professor	Nursing management	40

Expert Engagement Coefficient

All experts actively participated in the consultation and provided constructive feedback on the digital intervention. The engagement coefficient was 100%, indicating full participation and a high level of involvement.

Expert Authority Coefficient

The calculated authority coefficient was 0.88, indicating a high level of expertise and credibility among the participating experts. Therefore, the consultation results can be considered reliable.

Expert Recommendations

Establish a Mechanism for Care Plan Updates and Reviews

Experts emphasized that future care planning is a dynamic and evolving process. Expert 3 emphasized that care plans should be adjusted according to changes in older adults' physical conditions, family structures, personal beliefs, and policy directions. Accordingly, a regular update mechanism is necessary, with experts recommending updates every 6 months. This frequency balances the need for timely adaptation without overburdening older adults or their families. Experts 6 and 7 agreed with this recommendation. Additionally, expert 1 suggested incorporating a feature that allows users to review past care plans, enabling older adults and their families to compare changes over time and understand the rationale behind adjustments. Therefore, the platform should implement a comprehensive mechanism for both updating and reviewing care plans to enhance their timeliness, continuity, and adaptability.

Strengthen User-Centered Design

Several experts highlighted the lack of user-centered design in the current platform. Expert 2 strongly recommended that the platform architecture should address the real needs of older adults, enabling users to quickly access personalized and valuable information upon opening the app. Expert 5 noted that the platform's text-heavy content is not suitable for older adults with limited digital literacy. Excessive text undermines usability, while a lack of personalized content reduces usefulness. This expert suggested using more videos, intuitive interactions, and case stories to reduce cognitive load. Expert 4, from a community practice perspective, emphasized that the platform must address practical problems faced by older adults, reinforcing the necessity of a needs-driven approach. Therefore, user experience design must go beyond functionality, aiming to create a digital environment that is friendly, inclusive, and capable of effectively conveying complex information to older adults.

Implement Dynamic Resource Management and Data Security Measures

The platform's long-term viability depends on content accuracy and technological advancement. Experts expressed concerns about static resources and limited technical support. Expert 2 highlighted that outdated resources compromise credibility and usefulness, prompting users to seek alternative information

XSL•FO
RenderX

sources. Expert 7 underscored the importance of data security, continuous technical support, and ongoing updates, noting that nursing researchers may lack the technical expertise required, necessitating interdisciplinary collaboration. This suggests that a platform lacking dynamic maintenance and professional technical support would have limited real-world effectiveness. Therefore, the platform should ensure dynamic content updates and implement strict data security measures.

Enhancing Integration With Community Care Systems and Policy Frameworks

The ultimate value of the platform lies in its ability to address real-world needs. Expert 6, a community practitioner, emphasized that the platform's value increases if it can provide actionable guidance and integrate with offline services. Expert 1 highlighted the importance of aligning the platform with national public health policies. This indicates that the platform should not function as an isolated information source; rather, it should be embedded within the existing care ecosystem, serving as a bridge between user needs and professional services. Active integration with public service systems, enabling data sharing and online appointment scheduling, would enhance accessibility and efficiency. Additionally, collaboration with community organizations and the selection of representative communities for pilot studies are recommended to evaluate effectiveness in practice.

Think-Aloud Test

Participant Characteristics

A total of 20 dyads were recruited, including 20 community-dwelling older adults and 20 family members. Among the older adults, 15 (75%) were classified as prefrail, and 13 (65%) were male participants. The mean age was 72.2 (SD 8.65) years, with 9 (45%) participants aged between 70 and 79 years. Regarding educational attainment, 8 (40%) participants had completed junior high school. Thirteen (65%) participants reported prior experience using mobile health apps. Among family members, 8 (40%) were daughters of the older adults. The mean age was 51.9 (SD 13.04) years, with 7 (35%) participants aged between 40 and 49 years. Eleven (55%) had a university-level education or higher, and 17 (85%) had prior experience using mobile health apps (Table 2).

Duration of Task Test and Satisfaction Ratings

All the set tasks were completed by the older adults and their family members. The mean total time required to complete all tasks was 20.7 (SD 5.24) minutes. Among the individual tasks, participants spent the least time on system familiarization (task 1; mean 0.8, SD 0.48 min) and the most time on exploring care resources (task 3; mean 6.9, SD 1.81 min; Table 3).

User satisfaction ratings were generally favorable across system attributes. The highest rating was observed for ease of operation, with a rate of 4.1 (SD 0.69), while content quality received the lowest rating, with a rate of 3.7 (SD 0.81), and overall experience was rated at a satisfactory level, with a rate of 3.7 (SD 0.73; Table 3).

Table . The results of the duration of task test and the satisfaction ratings.

Item	Values, mean (SD)
Duration of task test (min)	
Task 1	0.8 (0.48)
Task 2	2.9 (0.95)
Task 3	6.9 (1.81)
Task 4	6.0 (1.31)
Task 5	4.0 (1.55)
Overall	20.7 (5.24)
Satisfaction ratings	
Page design	3.8 (0.89)
Features and functions	3.8 (0.70)
Ease of operation	4.1 (0.69)
Content quality	3.7 (0.81)
System stability	3.9 (0.72)
Overall experience	3.7 (0.73)

Views on the "Yi Yang Plan" Mini-Program

Perceived Usefulness of the Mini-Program

Participants expressed mixed views about the acceptability of the "Yi Yang Plan" mini-program. Some users acknowledged the program's value. Participants noted that those with greater awareness of care planning found the content engaging and described the mini-program as professionally designed and useful. One older adult with a caregiving background strongly emphasized that such proactive planning tools are highly meaningful and necessary, highlighting that everyone will ultimately face care-related challenges. The participant stressed that the tool can help older adults recognize the importance of PFC and take preparatory actions. Some participants reported that the mini-program provided access to information and resources that had previously been difficult to obtain, which they found highly beneficial. In addition, several users also underscored that the mini-program was developed by a multidisciplinary professional team, which reinforced the credibility of its design and content:

> *As aging becomes increasingly severe ... the situation of elderly care is becoming more severe … this (mini-program) is a good tool to participate in this elderly care industry earlier.* [Male, 78 years old, high school graduate]
>
> *This mini-program provides valuable information … I think that's really good. For example, policies on age-friendly home modifications are very helpful for older adults. The way houses were renovated in the past might not suit them anymore.* [Son, 48 years old, university graduate]
>
> *I think this mini-program is very good … since it was developed by nursing professionals, and it is highly necessary.* [Female, 76 years old, high school graduate]

Nevertheless, some users adopted a cautious or reserved stance, perceiving the direct benefits of the program for older adults as limited. Certain participants demonstrated insufficient awareness of PFC and lacked the inclination to engage in proactive planning, leading them to view the mini-program as unnecessary. In contrast, others felt that they had already completed most of their preparations and therefore regarded the program as offering little additional support. This perspective underscores that older adults occupy different stages of PFC, which shapes their varying needs for the program. In addition, some pointed out that older adults with lower levels of education were unable to understand or process the information presented in the program, leaving them without the ability to use it effectively or appreciate its value:

> *A lot of older adults in rural areas can't accept the idea of actively preparing for future care … so it's pretty hard to promote and use this kind of mini-program.* [Daughter, 39 years old, high school graduate]
>
> *I've been planning for a long time. I already have information about a lot of nursing homes saved on*

XSL•FO
RenderX

> *my phone, and I've even called them to learn more.* [Female, 62 years old, university graduate]
>
> *I think there is some usefulness … (but) for older adults with low education levels, its role may not be very significant.* [Male, 63 y old, university graduate]

Perceived Usability of the Mini-Program

Many participants emphasized that the program demonstrated a high level of usability, aligning with older adults' operational habits and cognitive abilities, with logically structured, easy-to-operate, and comprehensive content. By providing a clear and accessible design, the mini-program was also perceived as enhancing older adults' confidence in using digital technologies:

> *It's just a tree structure (pointing at the screen), the operation is easy too, and it feels quite straightforward. Maybe younger people think it's not fancy enough, but for us, it's very clear.* [Male, 76 years old, middle school graduate]
>
> *The pages are very clear, and the content is quite comprehensive. For older adults like me, even if we're not super skilled with smartphones, we can still use them (with confident nodding).* [Female, 76 years old, high school graduate]

However, many older adults reported difficulties in operating and understanding complex information due to declining vision, limited education, and insufficient digital skills. For example, some noted operational barriers within the mini-program, such as unclear return or next-page buttons that required additional effort to navigate. Others highlighted barriers in page presentation, including excessively small font sizes and overly dense text, which made reading and information acquisition challenging. In addition, participants pointed out that disease-related knowledge was described as overly specialized, with numerous technical terms that hindered comprehension. Similarly, while resources such as government documents and updated laws and regulations were viewed as authoritative, they were considered too theoretical and lacking in practical applicability:

> *The return in this mini-program is a bit troublesome.* [Male, 63 years old, university graduate]
>
> *The words are so small. Even with glasses, I cannot see them.* [Female, 62 years old, university graduate]
>
> *You should explain things in simple terms, and be more concrete. Older people do not think as actively as younger ones.* [Male, 78 years old, high school graduate]

In addition, older adults indicated that when using the "Yi Yang Plan" mini-program, they preferred the participation of their adult children. This was because they were not sufficiently skilled at operating health-related digital tools, whereas younger family members were more adept at using them, leading older adults to rely on their support. In addition, some participants pointed out that PFC is a complex intergenerational family issue that requires the joint involvement of adult children in decision-making, ensuring that older adults' preferences are considered while also securing the support of their children:

> *Many older adults with low education level cannot use the mini-program and understand it. It must be the children or younger siblings who are able to process this information.* [Female, 62 years old, university graduate]
>
> *For people around my age, born in the 70 s, we can think about things like preparing for future care on our own. But for my dad's generation, it's much harder. Most of them rely on children (shake the head helplessly).* [Son, 48 years old, university graduate]

Suggestions for Improving the Mini-Program

Providing Personalized Recommendations

As highlighted in the preparation for future care process model proposed by Sörensen et al [39], older adults may be at different stages of preparation. Therefore, individualized planning processes and components should be recommended based on their current level of preparation. Although the mini-program includes an assessment function, it does not yet generate personalized resources or stage-specific recommendations from the assessment results. Hence, strengthening the function of personalized recommendations is necessary:

> *I've already thought it through, so I can make decisions directly without going through all the earlier parts. ... These resources are more like a way to fill in the gaps. I just look at what I need, and I can skip whatever I don't.* [Female, 76 years old, high school graduate]

Enhancing Supportive Tools or Assistance

Some participants suggested that many older adults with lower levels of education or limited smartphone skills showed low acceptance of using the mini-program independently. To address this, they recommended providing additional supportive measures, such as organizing offline community-based training sessions or distributing instructional videos and user manuals. These forms of assistance could help older adults better understand care preparation and use the mini-program more smoothly:

> *I think you need to organize in-person classes for those older adults with low education levels … They can't understand it just by looking (at the mini-program). You'd have to explain everything to them carefully … If they could attend in person and listen, the effect would be much better.* [Female, 62 years old, university graduate]

Improving Interaction and Content

Several participants emphasized the importance of simplifying navigation and enhancing content readability. They suggested establishing clearer logic for return and exit functions, as well as providing prompt guidance at key steps to minimize confusion. Participants also recommended increasing font size and adopting plain, accessible language to accommodate older users. In addition, they proposed breaking down lengthy passages into bullet points or lists and presenting information in a simplified format similar to PowerPoint slides, which they felt would improve clarity and ease of understanding:

XSL•FO
RenderX

> *Reduce the amount of text, and present the main points first so that they can be quickly understood … a format similar to PowerPoint would be easier for older adults to follow. In slides, you can use visual elements, extract the key content, enlarge the font, and keep the information brief.* [Daughter, 44 years old, university graduate, with work experience in IT]

Enhancing the Involvement of Adult Children

Several participants emphasized that preparation for future care is a complex issue that requires the involvement of multiple generations. Older adults often find it difficult to process the complex information contained in the mini-program and to make related decisions. As a result, they preferred that their adult children participate in the discussions and provide assistance with using the mini-program.

> *It is better for older adults to use it together with their children, and the wishes of the older adults themselves are more important.* [Male, 48 years old, university graduate]

Integrating Practical Service Resources

Some participants expressed a desire for the program to be linked with offline services to improve the feasibility of planning. For example, they recommended direct connections to local nursing homes, home care providers, domestic service agencies, and medical resources. Such integration was seen as a way to help older adults move from planning to action, although participants recognized that this would require cross-sector collaboration and long-term development:

> *It would be better if the connection to the local community could be stronger ... Which communities have connected with certain services, such as domestic services, medical services ... If you can do a good job with this connection ... the experience would definitely be better.* [Son, 48 years old, university graduate]

Discussion

Principal Findings

This study developed and pilot-tested the "Yi Yang Plan" mini-program to support PFC among community-dwelling older adults with prefrailty and frailty. The findings from expert panel consultations demonstrated the scientific rigor of the program, while think-aloud tests indicated that the mini-program was feasible to deliver and generally acceptable to users. Nevertheless, expert recommendations, usability barriers, and user-derived suggestions highlighted several areas for further refinement.

Advantages of the Digital Intervention

The "Yi Yang Plan" mini-program was developed through a rigorous, theory- and evidence-based process integrating evidence synthesis, identification of influencing factors, and multidisciplinary collaboration. A prior scoping review identified 4 key elements of PFC [33], which are consistent with the established PFC process model [39], thereby providing a strong conceptual foundation. In addition, a convergent mixed methods study identified key determinants of PFC among frail older adults, and a structural equation model based on the Andersen Behavioral Model of Health Services Use informed the development of stratified intervention pathways. This approach enabled the design of a targeted and differentiated intervention tailored to varying frailty levels. Furthermore, iterative refinement by a multidisciplinary team enhanced both usability and content quality. Collectively, this structured development process offers a replicable framework for designing digital interventions to support PFC.

Expert consultation results indicated high credibility and reliability, reflected by strong engagement and authority coefficients. Experts with substantial clinical and theoretical expertise confirmed the scientific validity of the platform and provided actionable recommendations, supporting the robustness of the development process. The findings from think-aloud testing further demonstrated good feasibility and acceptability. Participants expressed generally positive perceptions and recognized the value of the mini-program, suggesting a willingness among older adults to engage with digital health tools. These findings align with previous studies indicating that older adults perceive supportive digital interventions as useful and acceptable [32,44]. One explanation is that the platform provides accessible information and resources, thereby enhancing the awareness and understanding of PFC [45]. In addition, the involvement of health care professionals in the development process may have strengthened users' trust, as older adults tend to rely on information from credible and familiar sources [46,47].

Barriers to Digital Intervention

Despite overall positive findings, several important challenges emerged. First, heterogeneity in PFC readiness influenced user needs. Participants noted that individuals at different stages of PFC require different types of support, which is consistent with prior research [48]. This highlights the importance of tailoring intervention pathways. For individuals with low awareness, interventions should focus on early-stage awareness enhancement, whereas those with higher readiness may benefit more from decision-making and planning support.

Second, disparities in education and digital literacy posed barriers to engagement. Older adults with lower educational attainment may have limited health literacy and digital skills, which can hinder technology adoption [49-51]. Therefore, assessing digital readiness prior to intervention delivery is essential [52]. Complementary support strategies, such as printed manuals, instructional videos, and offline guidance, are necessary to improve accessibility and inclusiveness [53].

Third, although usability received the highest satisfaction ratings and all participants completed the tasks, specific usability issues were identified, including unclear navigation and suboptimal font size. Age-related declines in sensory, motor, and cognitive functions may contribute to these challenges [47,54,55]. Accordingly, future designs should simplify navigation structures, provide clearer operational logic (eg, return and exit functions), and incorporate step-by-step guidance. Established age-friendly design principles, such as larger fonts, high contrast,

XSL•FO
RenderX

concise content, and clear labeling, should be consistently applied [56].

Fourth, content quality received relatively lower ratings. While participants acknowledged the comprehensiveness of the information, they reported difficulties in understanding and applying the content. This is likely because the resource module includes policy-level and professionally complex information. Simplifying the language and incorporating patient-friendly expressions may improve comprehension [57]. Additionally, multimedia formats (eg, videos and audio) can enhance engagement and accommodate diverse learning preferences [56]. Furthermore, emerging technologies such as AI could be leveraged to deliver personalized recommendations, improve information filtering, and enhance intervention precision and scalability [58]. Importantly, participants emphasized the need for more practical, actionable resources. Strengthening partnerships with community organizations and service providers is therefore critical to ensure that digital planning can be effectively translated into real-world care arrangements.

Finally, participants highlighted the essential role of adult children in facilitating technology use and care planning. This finding is consistent with previous research showing that older adults rely heavily on family support in PFC [1,44,54]. Integrating adult children as active participants in the intervention may enhance engagement, usability, and overall effectiveness.

Optimization Strategies

Based on these findings, several optimization strategies are warranted. At the system level, a comprehensive security and privacy protection framework should be implemented, including encryption, role-based access control, data deidentification, and audit logging, to ensure the safe handling of sensitive health information. At the interface level, improvements should focus on enhancing usability and emotional engagement. This includes adopting age-friendly layouts, increasing font size and contrast, simplifying navigation, and incorporating supportive visual and narrative elements to improve the user experience. At the functional level, the platform should further strengthen personalization by integrating periodic assessments, dynamic care plan updates, resource linkage, and historical tracking functions. At the implementation level, additional support tools should be provided to users with limited digital literacy. Moreover, the formal integration of adult children and stronger collaboration with community health care providers are essential to ensure continuity between digital planning and real-world service delivery.

Limitations

This study has several limitations that should be acknowledged. First, the small sample size limits the generalizability of the findings. As a pilot study, the primary aim was to assess feasibility and acceptability rather than effectiveness. Future research should conduct adequately powered randomized controlled trials to evaluate intervention efficacy. Second, although an iterative design approach was adopted, older adults and their family members were not involved as co-designers during the early development phase. Consequently, some usability issues were only identified during pilot testing. Future studies should incorporate more principles from human factors engineering and adopt participatory design methods to better align the intervention with the needs and capabilities of end users. Third, many participants had prior experience with digital health apps, which may limit the applicability of the findings to populations with lower digital literacy. Future research should intentionally recruit individuals with lower levels of digital skills to ensure that the tool is responsive to the needs of those who require the greatest support.

Conclusion

Based on a scoping review, analysis of influencing factors, stratified path analysis, as well as a multidisciplinary collaborative development process, this study developed a digital PFC platform for community-dwelling prefrail and frail older adults. It integrates standardized core procedures, stratified precision interventions, and digital platform delivery. The pilot test showed that the “Yi Yang Plan” mini-program demonstrated initial scientific validity, usability, and feasibility. Future versions should focus on improving system architecture, user interface design, platform features, and implementation strategies. The pilot results also provide a solid foundation for further thorough evaluation through randomized controlled trials.

Acknowledgments

The authors declare the use of generative AI in the research and writing process. According to the GAIDeT taxonomy (2025), the following tasks were delegated to generative AI (GenAI) tools under full human supervision: proofreading and editing. The GenAI tool used was ChatGPT-4.5. Responsibility for the final manuscript lies entirely with the authors. GenAI tools are not listed as authors and do not bear responsibility for the final outcomes.

Abstract

Background: As smart older adult care shifts from basic information support to more continuous algorithm-driven care, concerns have grown about whether such systems support older adults' independence or weaken their sense of autonomy. Although previous research has focused mainly on technology acceptance, less is known about how algorithmic care shapes perceived autonomy and through which psychological pathways this occurs.

Objective: This study examined whether perceived algorithmic care intensity reduces older adults' perceived autonomy in community smart care settings, whether decisional substitution and perceived surveillance mediate this relationship, and whether digital literacy moderates these effects.

Methods: A 3-stage design was adopted. First, a qualitative prestudy with 15 older adults was conducted to refine the focal constructs and measures. Second, a vignette-based experiment with 233 valid participants tested the effects of algorithmic care intensity on decisional substitution, perceived surveillance, and perceived autonomy. Third, a community-based survey with 298 valid participants examined the moderated mediation model in real-world smart older adult care settings.

Results: In study 1, compared with the low-intensity condition, the high-intensity condition significantly increased decisional substitution and perceived surveillance, while reducing perceived autonomy. Indirect effects through decisional substitution (effect=−0.072, 95% CI −0.144 to −0.016) and perceived surveillance (effect=−0.084, 95% CI −0.161 to −0.019) were both significant. In study 2, perceived algorithmic care intensity positively predicted decisional substitution (β=.400, *P*<.001) and perceived surveillance (β=.440, *P*<.001), and negatively predicted perceived autonomy (β=−.356, *P*<.001). The indirect effects through decisional substitution (effect=−0.112, 95% CI −0.172 to −0.065) and perceived surveillance (effect=−0.149, 95% CI −0.215 to −0.093) were significant. Digital literacy significantly weakened the effect of algorithmic care intensity on decisional substitution (β=−.174, *P*=.002), but not on perceived surveillance (β=−.071, *P*=.18).

Conclusions: Algorithmic care may undermine older adults' perceived autonomy both directly and indirectly through decisional substitution and perceived surveillance. Digital literacy appears to be a selective rather than universal buffer. These findings extend smart older adult care research beyond technology acceptance and clarify the tension between empowerment and control in algorithmic care.

community smart eldercare; perceived algorithmic care intensity; decisional substitution; perceived surveillance; perceived autonomy

Introduction

Smart Older Adult Care and the Emerging Autonomy Question

As population aging deepens and digital technologies become increasingly embedded in community care, smart older adult care is shifting from basic information support to more continuous, algorithm-driven care [1]. Wearable devices, home sensor systems, remote health platforms, and intelligent alert tools are now widely used for fall detection, chronic disease management, risk identification, and daily support. These technologies can ease pressure on care resources, improve response efficiency, and support aging in place [2]. At the same time, as data collection, condition recognition, and automated reminders become part of older adults' daily lives, smart older adult care also raises concerns about excessive monitoring, technological dependence, privacy exposure, and weakened care relationships [2-5]. The key issue is therefore no longer only whether such technologies are usable, but whether they change how older adults experience themselves as active subjects in care [6].

XSL•FO
RenderX

Existing research has examined smart older adult care and digital health technologies mainly through technology adoption, usage intention, functional performance, and implementation barriers. Previous studies show that perceived usefulness, ease of use, digital literacy, external support, organizational resources, deployment conditions, and service fit shape older adults' acceptance and use of digital technologies [7,8]. Other studies emphasize the benefits of smart monitoring and digital care tools for health management, risk warning, and continuity of care [9,10]. Although this literature has advanced understanding of smart older adult care, its main focus remains whether older adults are willing and able to use technology. Less attention has been paid to a more psychological question: when care increasingly relies on system recommendations, automated reminders, and continuous monitoring, do older adults still feel that they are directing their own lives, or do they begin to feel managed by the system [11]?

From Technology Adoption to Psychological Mechanisms

Research grounded in self-determination theory suggests that autonomy, competence, and relatedness are central to older adults' engagement with digital health technologies. Technology is more likely to support independent living when it preserves choice, navigation, and personalized control [12]. At the same time, studies of monitoring technologies show that older adults' concerns extend beyond informational privacy to dignity, control, and the feeling of being watched [13]. Research on intelligent care systems similarly suggests that technologies designed to improve efficiency and safety may also strengthen discipline, relational distance, and external control [14]. However, these concerns are often discussed separately. Existing research has not yet provided a clear model explaining how algorithmic care may undermine older adults' perceived autonomy and through which psychological pathways this occurs. Nor has it adequately examined whether these effects vary according to older adults' digital capabilities.

This study responds to these gaps by moving the discussion of community smart older adult care beyond technology adoption and toward perceived autonomy. It examines how perceived algorithmic care intensity influences older adults' perceived autonomy through 2 parallel psychological pathways, decisional substitution and perceived surveillance, and whether digital literacy moderates these effects. Decisional substitution refers to the feeling that care arrangements, health judgments, and everyday decisions are increasingly preset, guided, or replaced by the system, whereas perceived surveillance refers to the sense that one's behavior, physical condition, and daily routines are continuously observed and recorded by the technological system. The former reflects weakened control over action and decision making, whereas the latter reflects disruption of psychological boundaries.

This Study and Its Contributions

In this study, perceived algorithmic care intensity does not refer to a single device category or fixed technical function. Rather, it captures older adults' overall perception of how deeply algorithmic systems are involved in the surrounding care environment, especially through proactive system participation, automated evaluative input, and system-shaped follow-up arrangements. On this basis, the study develops a parallel mediation framework with first-stage moderation to examine a central tension in smart older adult care—whether algorithmic care supports independent living or instead weakens older adults' agency and control in the name of safety and efficiency.

This study makes 3 main contributions. First, it extends smart older adult care research beyond technology adoption by showing how algorithmic care shapes older adults' perceived autonomy. Second, it identifies decisional substitution and perceived surveillance as 2 distinct psychological pathways through which algorithmic care affects autonomy. Third, it shows that digital literacy functions as a selective boundary condition, buffering decisional substitution more than perceived surveillance, thereby offering a more refined basis for the design of human-centered community smart older adult care.

Literature Review

Algorithmic Care and Older Adults' Perceived Autonomy

Hypothesis 1: The higher the perceived intensity of algorithmic care, the lower older adults' perceived autonomy.

According to self-determination theory, autonomy does not mean acting without external support or completing all activities independently [15]. Rather, it refers to the subjective experience that one's actions are voluntary, self-endorsed, and guided by personal choice [16,17]. In community smart older adult care, perceived autonomy refers to older adults' perceived ability to remain the primary agents of everyday care-related arrangements, daily rhythms, and responses to health and living needs while using smart care services. It therefore concerns care-related everyday autonomy within technology-supported community living, rather than formal medical autonomy over clinical treatment or legal data autonomy over personal information governance.

As people age, physical decline, chronic disease management, and increasing dependence on care can make daily life more shaped by family members, community services, and institutional arrangements [18-20]. In this context, perceived autonomy is closely linked to dignity, self-worth, life continuity, and the ability to maintain an ordinary life on one's own terms [21]. Research further suggests that positive experiences with digital health systems depend not only on functional convenience, but also on whether technology supports autonomy, competence, and social connection [12]. When systems are easy to navigate, interactive, and customizable, older adults are more likely to view them as resources for self-management rather than sources of external control [22].

However, algorithmic care creates new challenges for perceived autonomy. Unlike traditional care, it increasingly intervenes in risk detection, health assessment, anomaly alerts, behavioral reminders, and daily management [23]. In older adult care and digital monitoring settings, such technologies may improve safety and efficiency while also intensifying concerns about control, dignity, constant observation, discipline, relational distance, and external control [14]. Thus, the more strongly older adults perceive algorithmic care to shape daily care, health management, and life arrangements through system recognition,

XSL•FO
RenderX

automated judgment, and system-initiated follow-up, the more likely they are to experience reduced control and choice in the care process.

Algorithmic Care and Decisional Substitution

Hypothesis 2: The higher the perceived intensity of algorithmic care, the stronger older adults' sense of decisional substitution.

In community smart older adult care, algorithmic care deserves attention not only because it can improve efficiency, but also because it may reshape older adults' role in decision-making [11]. Decisional substitution refers to the subjective feeling that matters once requiring one's own judgment, weighing, and choice are increasingly preset, guided, or handled by an external system [24,25]. Rather than treating technology as a simple source of information support, this concept captures a psychological experience in which one's room for participation, judgment, and control is reduced [26,27]. Research on shared decision-making shows that active participation in decisions is central to maintaining agency and self-direction; when decisions are shaped mainly by external authority, procedural rules, or technical logic, individuals are more likely to shift from active decision makers to passive recipients [16].

Algorithmic care increasingly performs functions such as risk detection, anomaly alerts, health assessment, behavioral reminders, and task prioritization [28]. As such systems move from supportive tools to active participants in judgment, older adults may feel that important decisions are no longer truly made by themselves but are prestructured or partly replaced by system logic [29]. Recent studies have therefore emphasized deliberation, customization, and human-centered loops in preserving users' decision-making role [30]. Without adequate room for participation, excessive reliance on automation and monitoring may create tension between supporting care and replacing the care recipient's own judgment [31].

From this perspective, higher perceived algorithmic care intensity implies not only deeper technological involvement, but also a shift in judgmental authority. The more older adults feel that care, health management, and daily arrangements depend on system recognition, automated triggers, and programmed recommendations, the more their space for self-judgment and initiative may be reduced. As a result, they are more likely to develop a stronger sense of decisional substitution.

Algorithmic Care and Perceived Surveillance

Hypothesis 3: The higher the perceived intensity of algorithmic care, the stronger older adults' perceived surveillance.

Beyond decisional substitution, perceived surveillance represents another key pathway through which algorithmic care may shape psychological outcomes. Perceived surveillance refers to the subjective feeling that one's behavior, physical condition, and daily routines are continuously observed, recorded, and analyzed by a technological system [3,32]. Unlike ordinary information collection, it captures a situated experience in which individuals feel that their lives are being constantly seen, interpreted, and even anticipated. Previous studies suggest that in health monitoring and assisted living settings, users' concerns extend beyond data leakage to dignity, control, autonomy, and the experience of intrusive observation [4,33-35].

This logic is especially salient in community smart older adult care. Traditional care relies mainly on face-to-face observation and periodic assessment, whereas algorithmic care is typically built on continuous sensing, anomaly detection, and real-time feedback [36]. Wearable devices and home sensor systems transform physiological states, movement patterns, daily routines, and unusual behaviors into data that can be tracked, recorded, and evaluated [37]. Although such systems may improve risk warning and service response, they may also blur the boundary between supportive care and constant observation [38].

This risk arises not simply because information is collected, but because technology turns everyday life into something continuously visible, recordable, and interpretable. As monitoring devices intensify this visibility, older adults may evaluate technology not only in terms of safety, but also in terms of whether it leaves them feeling constantly seen [39]. Perceived surveillance may therefore reshape how power is experienced within the care relationship [40], especially when smart technologies become deeply embedded in care institutions and daily routines [14]. Thus, the more older adults feel that their health status, activity patterns, and daily arrangements depend on continuous data capture and automated recognition, the more likely they are to feel watched rather than merely supported [41].

The Mediating Roles of Decisional Substitution and Perceived Surveillance in Perceived Autonomy

Hypothesis 4a: Decisional substitution mediates the relationship between perceived algorithmic care intensity and older adults' perceived autonomy.

Hypothesis 4b: Perceived surveillance mediates the relationship between perceived algorithmic care intensity and older adults' perceived autonomy.

Although algorithmic care may provide timely alerts, support continuity in health management, and reduce care uncertainty, its implications extend beyond convenience and safety. As argued in previous sections, stronger algorithmic care may heighten both decisional substitution and perceived surveillance. Self-determination theory suggests that autonomy depends not on complete independence from external support, but on whether individuals feel that their actions reflect their own will and that important choices are made through understanding, participation, and endorsement [16,17]. When an external system repeatedly narrows a person's space for judgment, choice, and interpretation, perceived autonomy is likely to decline even if the system is intended to protect, assist, or optimize [3,33].

Decisional substitution is likely to reduce perceived autonomy because it weakens the sense that older adults remain active participants in directing their own lives [42]. Research on shared decision-making shows that involvement in understanding information, weighing options, and selecting outcomes is essential for maintaining agency and self-direction [43]. When key matters are preset, prioritized, or automatically triggered by an external system, individuals are more likely to move from

XSL•FO
RenderX

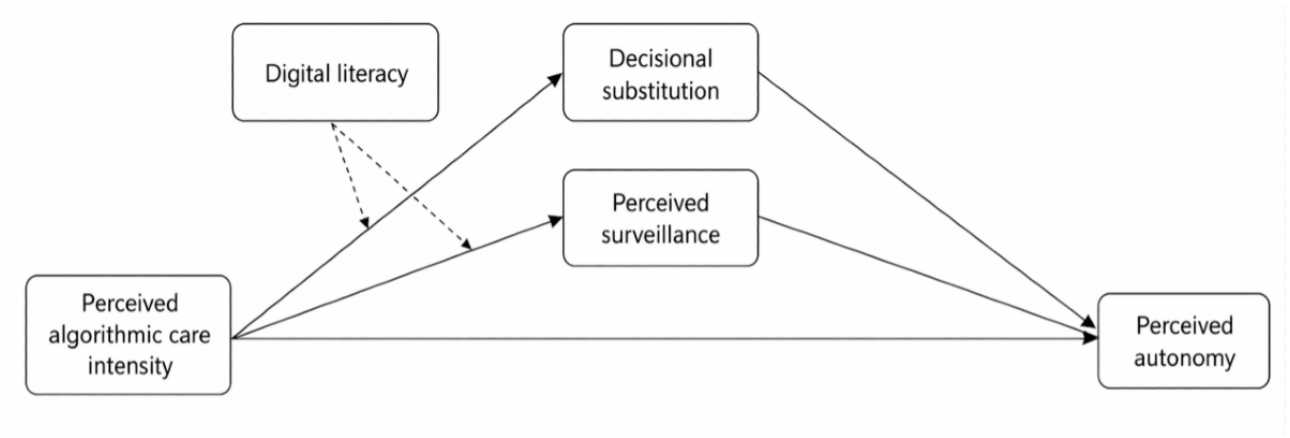
active participants to passive executors [44,45]. In community smart older adult care, this shift may emerge as older adults become accustomed to relying on system reminders, assessments, and generated priorities [46]. Over time, when the system judges first and the individual responds afterward, the experience of self-directed action is likely to weaken [29]. Related research in virtual care and long-term care similarly suggests that technology-mediated care can narrow deliberative space, which is an early sign of declining perceived autonomy [47].

Perceived surveillance is likely to reduce perceived autonomy through a different mechanism: the disruption of psychological boundaries. When bodily states, movement patterns, and daily routines are continuously observed, recorded, and analyzed, the experience is no longer simply one of information collection, but of being constantly seen and interpreted [32,33]. This ongoing visibility reshapes private space, behavioral freedom, and self-control [4]. Previous research shows that resistance to monitoring technologies often centers on privacy, intrusiveness, stigma, and the feeling of being watched [48]. When technology conflicts with users' values or everyday practices, systems intended to support independent living may instead be experienced as intrusions into personal boundaries and daily rhythms [5]. In this sense, perceived surveillance is not only a privacy concern, but also a challenge to whether one can still live freely in one's own way.

The Moderating Role of Digital Literacy and Conditional Indirect Effects

Hypothesis 5a: Digital literacy moderates the relationship between algorithmic care intensity and decisional substitution, such that this relationship is stronger for older adults with lower digital literacy than for those with higher digital literacy.

Hypothesis 5b: Digital literacy moderates the relationship between algorithmic care intensity and perceived surveillance, such that this relationship is stronger for older adults with lower digital literacy than for those with higher digital literacy.



The preceding arguments suggest that algorithmic care intensity affects perceived autonomy through decisional substitution and perceived surveillance. However, these mechanisms may not operate uniformly across individuals. Older adults differ in how well they understand digital systems, how confidently they use them, and how they interpret system outputs. Digital literacy has been widely recognized as a key factor shaping older adults' experiences with and evaluations of technology [49]. Older adults with higher digital literacy are generally better able to understand how digital systems work, interpret system outputs, and use technology with confidence, whereas lower digital literacy is associated with greater difficulty interpreting digital information and engaging with technology-based services [50,51]. Because digital literacy reflects not only tool use but also basic understanding of system operation and data processing [52], it may serve as an important boundary condition in responses to algorithmic care.

Previous research suggests that individuals with higher digital literacy are more likely to view technological systems as instrumental support rather than as substitutes for their own control, and are therefore better able to maintain a sense of agency when using them [51,53]. In smart older adult care settings, stronger algorithmic care may generate reminders, warnings, and recommended courses of action. For older adults with higher digital literacy, such interventions are more likely to be interpreted as supportive suggestions because they are better able to understand system logic and evaluate system outputs [54]. For those with lower digital literacy, however, frequent prompts and automated judgments may be experienced as a transfer of decision-making authority, thereby strengthening decisional substitution.

Digital literacy may also shape interpretations of monitoring, because older adults with stronger technical understanding may be better able to distinguish data recording from social surveillance [55]. Therefore, higher digital literacy may weaken the association between algorithmic care intensity and perceived surveillance.

The research model is illustrated in Figure 1.

Figure 1. Research model.

Methods

Overview

This study adopted a multistage design combining a qualitative prestudy, a vignette-based experiment, and a field survey of older adults in real community settings. This design was used to improve contextual validity, establish causal direction, and test the proposed model in real-world smart older adult care contexts. Previous work shows that older adults' experiences of digital health and smart care technologies are shaped by everyday contexts, especially in relation to autonomy, privacy, surveillance, and control [12,56]. Reviews of monitoring-based assisted living technologies have also noted limitations related to ecological validity, end user orientation, and weak identification of underlying mechanisms [32,48]. Accordingly, we first used semistructured interviews to refine measurement items and vignette materials, then conducted an experiment to test causal effects, and finally validated the model using a community-based survey. In the main studies, participants were recruited in participating communities by the author and the author's student research team, who also assisted with on-site study administration.

Prestudy: Semistructured Interviews and Measure Development

Before the main studies, we conducted semistructured interviews to examine whether older adults described community smart older adult care in terms such as "things are no longer decided by me," "the system makes judgments first," or "I feel watched." The goal was not to test hypotheses, but to strengthen content validity and contextual fit by incorporating older adults' own language and everyday experiences [12,56].

Using purposive sampling, we recruited 15 community residents aged 60 years or older from an older adult care community in Hangzhou, China. All participants had used or been exposed to community smart older adult care services or related devices within the past year. To increase heterogeneity, we sought variation in age, education, living arrangement, chronic disease status, and prior experience with digital technologies. Interviews followed a semistructured guide covering system involvement, perceived loss of decision control, continuous recording or observation, and perceived autonomy, comfort, control, and respect. Each interview lasted about 30-50 minutes. With consent, interviews were audio recorded and transcribed.

The transcripts were analyzed using thematic analysis. Moreover, 2 members of the research team independently reviewed the transcripts, conducted open coding, compared coding results, and resolved differences through iterative discussion until agreement was reached on higher-order themes. The resulting themes were used to revise item wording and inform the vignette materials for study 1, thereby reducing the gap between researchers' conceptual assumptions and older adults' lived experiences [57].

Study 1: Vignette-Based Experiment

Study 1 tested whether perceived algorithmic care intensity affects decisional substitution, perceived surveillance, and perceived autonomy. A vignette-based experiment was used because cross-sectional survey data cannot rule out reverse causality, and older adults' responses to monitoring and digital care technologies are strongly shaped by specific use scenarios [13,56].

Study 1 used a 1-factor, 2-level between-subjects design. The independent variable was algorithmic care intensity, manipulated as a high intensity versus low intensity scenario. In the high intensity condition, the community smart older adult care system continuously collected information about older adults' activities, routines, and health status, automatically generated reminders, risk alerts, and care suggestions, and used these outputs to shape subsequent support and care arrangements. In the low intensity condition, the system mainly provided basic recording and information display, while subsequent support and care arrangements relied primarily on discussion between the older adult and community staff. In both conditions, community staff remained present as part of the care context. The 2 vignettes were matched in length, writing style, and background context.

We recruited 255 older adults aged 60 years or older from 2 large communities in Hangzhou, China, and randomly assigned them to one of the 2 conditions. Participants first received a brief explanation of the study and provided informed consent. They were then presented with 1 vignette at random and completed manipulation check items and the main measures. The manipulation check assessed whether participants perceived the system as highly reliant on recognition, automated reminders, and programmed judgment. The main measures assessed perceived algorithmic care intensity, decisional substitution, perceived surveillance, and perceived autonomy. Age, gender, education, self-rated health, and previous experience with digital technologies were also collected as control variables.

Study 2: Community-Based Field Survey

Study 2 examined whether the proposed model holds in real community smart older adult care settings and whether digital literacy moderates the proposed mechanisms. Because older adults' evaluations of smart care technologies depend on actual environments, interaction patterns, and the extent to which technology is embedded in daily life, vignettes alone cannot demonstrate whether the model applies to real use contexts [12].

Participants were recruited through on-site distribution with researcher-assisted completion in 3 large communities, day care centers, and community health service stations in Hangzhou and Ningbo, China. These 2 cities were selected because community smart older adult care services are relatively well developed there. A total of 330 older adults participated. Eligibility criteria were (1) aged 60 years or older; (2) having used or been exposed to at least 1 type of community smart older adult care service in the past year, such as a health monitoring system, remote consultation platform, smart emergency call device, or data management platform; and (3) having basic reading ability and being able to complete the questionnaire with assistance if needed. Before the survey, researchers provided a standardized explanation of "smart older adult care services" and instructed participants to answer based on their overall experience of algorithmic involvement across

XSL•FO
RenderX

the services they had used, rather than focusing on a single device or application.

Study 2 measured the same core constructs as study 1, that is, perceived algorithmic care intensity, decisional substitution, perceived surveillance, and perceived autonomy. Digital literacy was measured as the moderator. To reduce common method bias, the questionnaire visually separated different constructs into sections and included filler items to weaken consistency responding.

We estimated a moderated mediation model to test whether digital literacy attenuates the positive effect of algorithmic care intensity on decisional substitution and perceived surveillance. Multiple regression and bias-corrected bootstrap procedures were used to estimate conditional indirect effects, and moderation was tested through interaction terms. Age, gender, and education were included as control variables in the main regression analyses.

Statistical Analysis and Measures

This study measured five core constructs: (1) perceived algorithmic care intensity [13,56], (2) decisional substitution [12,13], (3) perceived surveillance [32,48], (4) perceived autonomy [22], and (5) digital literacy [58]. Because older adults' experiences with digital health and smart care technologies are highly contextual and subjective, the items were adapted from previous studies and refined through the prestudy interviews to fit community smart older adult care settings [12,56].

All formal measures used a 7-point Likert scale, ranging from 1=strongly disagree to 7=strongly agree. Study 1 and study 2 followed the same general measurement framework, with minor wording adjustments to fit the research context. In study 1, items referred to "the community smart older adult care system described above," whereas in study 2, they referred to "the community smart older adult care services you are currently using." This approach helped maintain construct consistency while improving contextual relevance and clarity.

Perceived algorithmic care intensity measured the extent to which older adults felt that the surrounding care process relied on system recognition, automated reminders, programmed recommendations, backend judgment, and technology-shaped follow-up arrangements. The construct captured older adults' higher-order perception of how deeply algorithmic systems were embedded in the care environment, rather than any single device type, alert frequency, or task criticality [13,56].

Decisional substitution measured the extent to which older adults felt that matters requiring their own judgment and choice were instead preset, guided, or handled by the system. This measure was grounded in self-determination theory and refined with reference to research on shared decision making and user participation [12,13].

Perceived surveillance measured the subjective feeling that one's behavior, physical condition, and daily routines were continuously observed, recorded, and analyzed by the technological system. This measure was informed by research on monitoring technologies, camera-based assisted living, and digital care systems for older adults [32,48].

Perceived autonomy captured whether older adults still felt that they remained the primary agents of everyday care-related arrangements, daily routines, and responses to health and living needs in community smart older adult care. The construct focused on agency, choice, and behavioral self-direction in ordinary technology-supported care, rather than formal medical decision autonomy or legal data autonomy [22].

Digital literacy measured older adults' ability to understand, access, and use digital technologies and digital health information [58]. A shortened digital literacy scale was adopted for this purpose.

In addition to the focal constructs, study 2 collected background information on age, gender, education level, marital status, self-rated health, number of chronic conditions, living arrangement, and frequency of smart older adult care service use. Age, gender, and education were included as controls in the reported regression analyses.

Ethical Considerations

This study received ethical approval from the institutional ethics committee of the authors' affiliated university (approval 2025-HUM-021) and was conducted in accordance with the Declaration of Helsinki. Data were collected between March and June 2025 from adults aged 60 years and older, and no minors were involved. All participants provided informed consent before participation. Participation was voluntary, and all responses were collected anonymously and used solely for academic research purposes. This study was not registered in a clinical trial registry because it was not designed as a prospective clinical intervention trial. Instead, it used a 3-stage design combining a qualitative prestudy, a vignette-based experiment, and a community-based field survey.

Results

Prestudy: Semistructured Interviews and Measure Development

The qualitative prestudy confirmed that the focal constructs were meaningful and recognizable in community smart older adult care settings. A total of 15 older adults who had used or been exposed to community smart older adult care services participated in semistructured interviews. Detailed participant characteristics are reported in Multimedia Appendix 1. The interviews examined how participants understood system involvement, loss of decision control, continuous recording or observation, and perceived autonomy, comfort, control, and respect. The purpose was not to test hypotheses, but to generate empirical input for item refinement and vignette development [12,56].

The thematic analysis yielded 6 representative themes, which are summarized in Multimedia Appendix 1. Overall, participants did not evaluate smart older adult care only in terms of convenience or technological advancement. Instead, they repeatedly focused on whether algorithm-enabled involvement changed their position in the care process. Moreover, 3 patterns

XSL•FO
RenderX

were especially salient. First, participants recognized safety and convenience benefits, especially for alerts, health monitoring, chronic disease management, and reducing burdensome medical visits. Second, they became more sensitive when the system moved from information display to active judgment, reminders, and arrangement shaping, which was associated with a perceived weakening of their own decision-making role. Third, continuous monitoring was often experienced not simply as data collection, but as ongoing visibility, boundary disruption, and reduced personal control. Across these accounts, a common concern emerged, that is, whether older adults could still remain the person in charge.

These findings informed both measure refinement and vignette design. Expressions such as "many things are no longer decided by me first" informed decisional substitution items, whereas expressions such as "it feels like there are always eyes in the house" informed perceived surveillance items. Items for perceived algorithmic care intensity emphasized proactive identification, automated reminders, programmed judgments, and system-shaped care arrangements. Items for perceived autonomy focused on whether participants still felt able to decide, retain freedom of choice, and live according to their own rhythm within smart care arrangements. The high-intensity vignette emphasized continuous monitoring, automated alerts, backend analysis, and system-shaped follow-up arrangements, whereas the low-intensity vignette emphasized basic recording and information display, with subsequent support relying more on discussion between older adults and community staff.

Study 1: Results of the Vignette-Based Experiment

Overview

After the prestudy confirmed that the focal constructs fit the smart older adult care context and after the measures and vignette materials were refined, we conducted study 1 to test the effects of perceived algorithmic care intensity on decisional substitution, perceived surveillance, and perceived autonomy. A total of 255 older adults were recruited. Responses with substantial missing data on the main study variables were excluded before analysis. As a result, 233 valid responses were retained for analysis, including 115 participants in the low algorithmic care intensity group and 118 in the high algorithmic care intensity group. The final analyses were conducted on complete cases, and no statistical imputation procedure was applied. The mean age of the sample was 69.70 (SD 6.24) years, and 127 out of 233 (54.5%) participants were female. Randomization checks showed no significant between-group differences in age, number of chronic conditions, gender, education, living arrangement, or digital literacy (all *P* values>.05), suggesting that random assignment was effective and that the 2 groups were comparable.

Manipulation Check

To examine whether the experimental manipulation was successful, we first compared the 2 groups on the manipulation check scale. The results showed that the high algorithmic care intensity group reported significantly higher perceived algorithmic care intensity than the low intensity group. Specifically, the mean score was 4.79 (SD 0.95) in the high intensity condition and 4.11 (SD 0.91) in the low intensity condition, and the difference was significant (2-tailed t_{231}=5.63; Cohen *d*=0.74; *P*<.001).

Reliability, Descriptive Statistics, and Correlation Analysis

Before testing the hypotheses, we examined the internal consistency of all measures. The results showed acceptable reliability for all scales: Cronbach α was 0.753 for the manipulation check scale, 0.695 for decisional substitution, 0.716 for perceived surveillance, and 0.782 for perceived autonomy. Although the α for decisional substitution was close to the conventional threshold, it remained within an acceptable range for a brief vignette-based measure, and the scale was retained because it captured the focal construct with adequate conceptual coverage in the study 1 context.

Tables 1 and 2 present the means, SDs, reliabilities, and correlations among the variables. Perceived algorithmic care intensity was positively correlated with decisional substitution (*r*=0.27, *P*<.001) and perceived surveillance (*r*=0.25, *P*<.001), and negatively correlated with perceived autonomy (*r*=−0.22, *P*<.001). In addition, decisional substitution was negatively correlated with perceived autonomy (*r*=−0.25, *P*<.001), and perceived surveillance was also negatively correlated with perceived autonomy (*r*=−0.29, *P*<.001). Notably, decisional substitution and perceived surveillance were positively related, but the correlation was not significant (*r*=0.05, *P*=.41). This suggests that although both reflect negative psychological responses to algorithmic care, they do not fully overlap in meaning. This pattern also supports treating them as 2 parallel mediators.

Table . Descriptive statistics and reliability for study 1 variables.

Variable	Mean (SD)	Cronbach α
Perceived algorithmic care intensity	4.45 (0.99)	0.753
Decisional substitution	4.28 (0.90)	0.695
Perceived surveillance	4.11 (0.93)	0.716
Perceived autonomy	3.86 (0.99)	0.782

[a]Not applicable.

Hypothesis Testing

To test hypotheses 1-3, we used experimental condition (low algorithmic care intensity=0, high algorithmic care intensity=1) as the independent variable and compared the 2 groups on decisional substitution, perceived surveillance, and perceived autonomy. As presented in Tables 3 and 4, compared with the low intensity condition, the high algorithmic care intensity condition significantly increased decisional substitution (mean 4.43, SD 0.94 vs mean 4.13, SD 0.84; t_{231}=2.64; Cohen *d*=0.35; *P*=.009) and perceived surveillance (mean 4.27, SD 0.91 vs mean 3.95, SD 0.95, t_{231}=2.58; Cohen *d*=0.34; *P*=.01), while significantly reducing perceived autonomy (mean 3.66, SD 1.03 vs mean 4.06, SD 0.91, t_{231}=−3.17; Cohen *d*=−0.42; *P*=.002). These results support hypotheses 1-3, indicating that stronger algorithmic care increased decisional substitution and perceived surveillance while reducing perceived autonomy.

Table . Manipulation check and hypothesis testing results.

Variable	Low algorithmic care intensity, mean (SD)	High algorithmic care intensity, mean (SD)	*t* test (*df*)	Cohen *d*	*P* value	Conclusion
Perceived algorithmic care intensity (manipulation check)	4.11 (0.91)	4.79 (0.95)	5.63 (231)	0.74	<.001	Manipulation successful
Decisional substitution	4.13 (0.84)	4.43 (0.94)	2.64 (231)	0.35	.009	H2 supported
Perceived surveillance	3.95 (0.95)	4.27 (0.91)	2.58 (231)	0.34	.01	H3 supported
Perceived autonomy	4.06 (0.91)	3.66 (1.03)	−3.17 (231)	−0.42	.002	H1 supported

Table . Bootstrap results for the parallel mediation effects in study 1.

Path	Effect (95% CI)	Conclusion
Algorithmic care intensity → decisional substitution → perceived autonomy	−0.072 (−0.144 to −0.016)	H4a supported
Algorithmic care intensity → perceived surveillance → perceived autonomy	−0.084 (−0.161 to −0.019)	H4b supported
Total indirect effect	−0.156 (−0.262 to −0.066)	Significant
Direct effect	−0.247 (−0.491 to −0.006)	Still significant, partial mediation
Total effect	−0.403 (−0.650 to −0.153)	Significant

XSL•FO
RenderX

We next tested the parallel mediating roles of decisional substitution and perceived surveillance using bootstrap analysis with 5000 resamples. Experimental condition was entered as the independent variable, perceived autonomy as the dependent variable, and decisional substitution and perceived surveillance as parallel mediators. As illustrated in Tables 3 and 4, the indirect effect through decisional substitution was significant (effect=−0.072, 95% CI −0.144 to −0.016), supporting hypothesis 4a. The indirect effect through perceived surveillance was also significant (effect=−0.084, 95% CI −0.161 to −0.019), supporting hypothesis 4b. The total indirect effect was −0.156 (95% CI −0.262 to −0.066). After both mediators were included, the direct effect of algorithmic care intensity on perceived autonomy remained significant (effect=−0.247, 95% CI −0.491 to −0.006), indicating partial mediation.

Study 2: Results of the Community-Based Field Survey

Overview

Study 2 was designed to further test the applicability and robustness of the proposed model in real community smart older adult care settings and to examine the moderating role of digital literacy in the first-stage paths. Given that participants had experience with different smart older care services and devices, the findings should be interpreted as reflecting the perceived psychological consequences of algorithmic care in a heterogeneous real-world service environment rather than the effects of any single technology category.

A total of 298 valid responses were retained for analysis. Responses with substantial missing data on the focal variables were excluded before analysis. The final analyses were conducted on complete cases, and no statistical imputation procedure was applied. The mean age of the participants was 71.8 (SD 6.202) years, and 158 out of 298 (53%) participants were female. In terms of education, 221 out of 298 (74%) participants had completed high school or below, whereas 77 out of 298 (26%) participants had completed junior college or above. Although most participants had completed high school or below, the proportion with junior college education or above and the urban locations of Hangzhou and Ningbo suggest that the sample reflects older adults in relatively developed community smart care settings. This context is substantively appropriate for examining the focal mechanisms of algorithmic care, although the strength and form of these relationships may vary across regions with different levels of digital development and care infrastructure.

Measurement Model

Before hypothesis testing, we examined the descriptive statistics and correlations among the focal variables. Perceived algorithmic care intensity was positively correlated with decisional substitution and perceived surveillance, and negatively correlated with perceived autonomy. Decisional substitution and perceived surveillance were also positively related to each other and both were negatively associated with perceived autonomy.

Because study 2 relied on self-reported questionnaire data, we also assessed the potential risk of common method bias. In addition to the procedural remedies applied during questionnaire design, we conducted Harman's single factor test and compared the proposed 5-factor model with a single factor model. The results indicated that common method bias was unlikely to materially distort the measurement structure.

We next assessed the reliability and validity of the measures. All Cronbach α values exceeded the conventional threshold of 0.70, indicating strong internal consistency. Confirmatory factor analysis showed that the 5-factor measurement model fit the data well, with χ^2_{179}=353.88, comparative fit index=0.947, Tucker-Lewis index=0.938, root-mean-square error of approximation=0.057, and standardized root-mean-square residual=0.049, supporting the structural distinctiveness of perceived algorithmic care intensity, decisional substitution, perceived surveillance, perceived autonomy, and digital literacy. In addition, all standardized factor loadings exceeded 0.80, and both composite reliability and average variance extracted were above recommended thresholds, supporting convergent validity. Detailed results are reported in Table 5.

To further assess discriminant validity, we used the heterotrait-monotrait ratio (HTMT). As illustrated in Table 6, all HTMT values were below 0.85, indicating adequate discriminant validity across constructs.

Table . Measurement model results for study 2.

Constructs	Number of items	Factor loading range	CR[a]	AVE[b]	Cronbach α
Perceived algorithmic care intensity	3	0.812 - 0.895	0.919	0.791	0.920
Decisional substitution	4	0.838 - 0.877	0.919	0.740	0.918
Perceived surveillance	4	0.840 - 0.868	0.916	0.732	0.915
Perceived autonomy	4	0.852 - 0.882	0.923	0.750	0.922

Tests of Main and Mediating Effects

After confirming the measurement model, we tested the main effects and mediation effects. Consistent with the reported regression specification, age, gender, and education were included as controls in these models. As presented in Table 7, controlling for these variables, perceived algorithmic care intensity significantly and positively predicted decisional substitution (β=.400, SE 0.053; t_{293}=7.550; *P*<.001) and perceived surveillance (β=.440, SE 0.053; t_{293}=8.250; *P*<.001), and significantly and negatively predicted perceived autonomy (β=−.356, SE 0.053; t_{293}=−6.501; *P*<.001), supporting hypotheses 1-3. When decisional substitution and perceived surveillance were entered simultaneously, both negatively predicted perceived autonomy (β=−.294, SE 0.053; t_{291}=−5.533; *P*<.001; β=−.344, SE 0.055; t_{291}=−6.287; *P*<.001), whereas the direct effect of perceived algorithmic care intensity became nonsignificant (β=−.087, SE 0.055; t_{291}=−1.526; *P*=.13), indicating that the effect operated mainly through the 2 mediators. As presented in Table 8, bootstrap analysis further showed significant indirect effects through decisional substitution (effect=−0.112, 95% CI −0.172 to −0.065) and perceived surveillance (effect=−0.149, 95% CI −0.215 to −0.093). The total indirect effect was −0.261 (95% CI −0.346 to −0.189), whereas the direct effect was not significant (effect=−0.085, 95% CI −0.185 to 0.025), indicating full mediation.

Table . Regression results for main and mediating effects in study 2.

Dependent variable	Independent variable	β (SE)	*t* test (*df*)	*P* value	R^2
Decisional substitution	Perceived algorithmic care intensity	.400 (0.053)	7.550 (293)	<.001	0.193
Perceived surveillance	Perceived algorithmic care intensity	.440 (0.053)	8.250 (293)	<.001	0.217
Perceived autonomy (total effect)	Perceived algorithmic care intensity	−.356 (0.053)	−6.501 (293)	<.001	0.130
Perceived autonomy (with mediators)	Perceived algorithmic care intensity	−.087 (0.055)	−1.526 (291)	.13	0.319
Perceived autonomy (with mediators)	Decisional substitution	−.294 (0.053)	−5.533 (291)	<.001	—[a]

Table . Bootstrap results for the parallel mediation effects in study 2.

Path	Effect (95% CI)	Conclusion
Perceived algorithmic care intensity → decisional substitution → perceived autonomy	−0.112 (−0.172 to −0.065)	H4a supported
Perceived algorithmic care intensity → perceived surveillance → perceived autonomy	−0.149 (−0.215 to −0.093)	H4b supported
Total indirect effect	−0.261 (−0.346 to −0.189)	Significant
Direct effect	−0.085 (−0.185 to 0.025)	Not significant
Total effect	−0.346 (−0.446 to −0.246)	Significant

Test of the Moderating Role of Digital Literacy

After obtaining support for the main model, we further examined whether digital literacy moderated the effects of algorithmic care intensity on the 2 first-stage paths. To reduce multicollinearity, both perceived algorithmic care intensity and digital literacy were mean-centered before constructing the interaction terms. We then estimated regression models with decisional substitution and perceived surveillance as dependent variables, including the main effects, the interaction term, and the same control variables used in the main effect models, namely age, gender, and education.

As presented in Table 9, the interaction between perceived algorithmic care intensity and digital literacy was significant for decisional substitution (β=−.174, SE 0.055; t_{291}=−3.178; *P*=.002), supporting hypothesis 5a. Simple slope analysis showed that the positive effect of algorithmic care intensity on decisional substitution was strongest at low digital literacy (simple slope=0.560), moderate at the mean level (simple slope=0.398), and weakest at high digital literacy (simple slope=0.235). By contrast, the interaction between perceived algorithmic care intensity and digital literacy was not significant for perceived surveillance (β=−.071, SE 0.053; t_{291}=−1.338; *P*=.18), so hypothesis 5b was not supported. This pattern suggests that digital literacy may buffer the sense that decision making is being replaced by the system, but not sensitivity to continuous monitoring and the accumulation of digital traces.

Table . Moderating effects of digital literacy in study 2.

Dependent variable and predictor	β (SE)	*t* test (*df*)	*P* value	R^2
Decisional substitution				0.193
Perceived algorithmic care intensity	.413 (0.051)	7.763 (291)	<.001	
Digital literacy	.075 (0.054)	1.380 (291)	.17	
Algorithmic care intensity×digital literacy	−.174 (0.055)	−3.178 (291)	.002	
Perceived surveillance				0.214
Perceived algorithmic care intensity	.448 (0.051)	8.534 (291)	<.001	
Digital literacy	−.018 (0.053)	−0.339 (291)	.73	
Algorithmic care intensity×digital literacy	−.071 (0.053)	−1.338 (291)	.18	

Discussion

Principal Results

This study examined how algorithmic care shapes older adults' perceived autonomy in community smart older adult care settings. Using a qualitative prestudy, a vignette experiment, and a community-based field survey, we tested whether perceived algorithmic care intensity reduces perceived autonomy through decisional substitution and perceived surveillance, and whether digital literacy moderates these effects.

The results show that algorithmic care is not merely a neutral arrangement for improving efficiency and safety. When care relies more heavily on system recognition, automated reminders, programmed recommendations, and system-shaped follow-up arrangements, older adults are more likely to feel that decisions are no longer made by them first and that their daily lives are continuously recorded and observed. These 2 experiences, in turn, reduce perceived autonomy. This pattern was supported in both the vignette experiment and the community-based field survey.

The findings also show that decisional substitution and perceived surveillance are 2 distinct pathways. Decisional substitution reflects a perceived weakening of older adults' role in judgment and choice, whereas perceived surveillance reflects the disruption of psychological boundaries caused by continuous

XSL•FO
RenderX

observation and data recording. Digital literacy weakened the effect of algorithmic care intensity on decisional substitution, but not on perceived surveillance. This suggests that digital competence may help older adults interpret system outputs as supportive inputs rather than replacements for their own judgment, but it does not necessarily remove discomfort caused by continuous monitoring and digital traces.

Limitations

This study has several limitations. First, perceived algorithmic care intensity was examined as older adults' overall perception of algorithmic involvement in the care environment. Different technologies may produce different psychological responses. For example, passive monitoring tools may more directly trigger feelings of being watched, whereas user-initiated advisory applications may allow more decisional participation. Future research could compare passive monitoring systems, user-initiated health applications, and hybrid care platforms.

Second, the study 2 sample was drawn from Hangzhou and Ningbo, where digital infrastructure and smart older adult care implementation are relatively developed. The findings may therefore reflect older adults' experiences in urban community smart care settings. Future research could test the model in counties, rural areas, and regions with different levels of digital development and care infrastructure.

Third, this study relied mainly on self-report data. Although self-reports are appropriate for capturing subjective experiences such as autonomy, decisional substitution, and perceived surveillance, they do not provide strong behavioral evidence. Future studies could include platform usage logs, alert response records, family intervention frequency, or actual choices made after system recommendations.

Fourth, although this study combined a qualitative prestudy, an experiment, and a field survey, study 2 was still cross-sectional. It therefore could not capture the longer-term adaptation process through which older adults respond to algorithmic care. Future research could use longitudinal or staged designs to examine whether older adults gradually adapt to algorithmic care, become more dependent on it, or develop stronger resistance over time.

Comparison With Previous Work

Much of the existing smart older adult care literature has focused on technology acceptance, perceived usefulness, usage intention, and implementation barriers [7,8,56]. This work has helped explain whether older adults are willing and able to use digital technologies, but it says less about what happens psychologically after such technologies become embedded in everyday care. Previous work has argued that older adults' digital health experiences are closely tied to autonomy, competence, and relatedness rather than usefulness alone [12]. The findings of this study extend this view by showing that algorithmic care may support daily living while simultaneously weakening older adults' sense of self-direction.

This study also extends previous research on monitoring technologies. Existing studies have shown that older adults' concerns about smart monitoring often go beyond data privacy and include dignity, control, intrusiveness, and the feeling of being watched [33,48]. Research on AI in care settings has similarly noted the tension between efficient care and humane care, especially when automation increases discipline and relational distance [13]. However, these concerns are often discussed together. By distinguishing decisional substitution from perceived surveillance, this study shows that the psychological consequences of algorithmic care are multidimensional. Decisional substitution concerns whether older adults remain part of the process of deciding, whereas perceived surveillance concerns whether they feel constantly seen, recorded, and made legible to the system.

The moderating findings also refine current assumptions about digital inclusion. Policy and practice often assume that improving digital literacy will reduce older adults' difficulties with smart care technologies. Our results only partly support this view. Digital literacy reduced the likelihood that older adults experienced system outputs as replacing their own judgment, but it did not significantly reduce perceived surveillance. This suggests that some autonomy-related risks are interpretive and may be partly buffered by technological understanding, whereas others are experiential and arise from the monitoring logic of the technology itself, especially its intrusion into private boundaries, everyday rhythms, and subjective comfort [5,32].

Conclusions

This study shows that algorithmic care can reduce older adults' perceived autonomy in community smart older adult care settings by increasing decisional substitution and perceived surveillance. It also shows that digital literacy is a selective rather than universal buffer: it weakens decisional substitution but does not significantly reduce perceived surveillance. These findings move smart older adult care research beyond technology acceptance by showing how algorithmic systems can reorganize older adults' judgment, participation, and psychological boundaries in everyday care.

For smart older adult care to support rather than replace older adults, system design and service governance should preserve choice, clarify monitoring boundaries, strengthen opt-out possibilities, and keep human discussion within the care process. System prompts should rely more on suggestive than commanding logic, and care workers or family members should avoid treating algorithmic outputs as final decisions.

Acknowledgments

The authors thank the reviewers and the manuscript editor for their valuable time, constructive comments, and support during the review process.

Abstract

Background: High-resolution digital cognitive tools administered at frequent intervals enable the study of age-related cognitive change at a previously unattainable level of granularity. Computational modeling further enables the simultaneous examination of multiple aspects of cognitive performance.

Objective: The objective of this study was to examine whether repeated digital multiday learning assessments can detect age-related cognitive decline over short time frames in cognitively unimpaired older adults and to quantify age-related differences in process-based cognitive markers derived from computational modeling.

Methods: A total of 209 cognitively unimpaired older adults (mean age 73.6, SD 8.2 years; n=136, 65.1% female) from the Harvard Aging Brain Study and affiliated studies were administered the Boston Remote Assessment for Neurocognitive Health, which includes the face-name task, a paired associative learning task. Daily median response times for correct responses were used as the primary outcome. A new version of the face-name task was administered across up to 4 testing intervals over a mean of 2.8 (SD 0.4) years. Using computational modeling, we estimated longitudinal changes in peak performance, a practice-adjusted marker of an individual's best expected response time, as an indicator of age-related cognitive decline. We further examined age-related differences in peak performance, stability (within-person variability), learning within and across testing intervals, and between-interval forgetting, with embedded linear regressions for age, sex, years of education, and device type.

Results: Peak performance slowed by 0.04 seconds per year (95% credible interval 0.02-0.06; approximately 2% per year), indicating age-related cognitive decline. Higher age (+1-SD) was associated with slower peak performance (+0.19 seconds, 95% credible interval 0.12-0.26), steeper annual slowing in peak performance (+0.036 seconds per year), greater within-person variability (+0.043 seconds), reduced learning across testing intervals, and more forgetting.

Conclusions: Our findings indicate that a digital multiday learning paradigm combined with computational modeling of response times sensitively detects age-related cognitive decline over short timescales (<3 years), which are difficult to capture in conventional study designs relying on infrequent assessments. In addition, this approach identifies specific process-based cognitive markers associated with aging, including slower performance, reduced stability, and diminished learning across testing intervals.

cognitive aging; older adults; digital cognitive assessment; remote assessment; response time; computational modeling; longitudinal study; associative memory; learning; mobile health; digital biomarkers; Alzheimer disease

Introduction

Even in the absence of Alzheimer disease or other neurodegenerative disorders, older adults experience gradual cognitive decline, particularly in fluid abilities such as processing speed and episodic memory—a phenomenon commonly referred to as normative cognitive aging [1,2]. These age-related changes manifest not only in reduced task accuracy but also in decreased efficiency and stability of underlying cognitive processes. Core markers of cognitive aging include

XSL•FO
RenderX

slower and more variable performance as well as reduced capacity to learn and retain new information [3-6]. Such process-level changes can be sensitively captured using response times, which provide fine-grained, temporally resolved measures of cognitive function and allow for the assessment of the efficiency and stability of underlying cognitive processes [7], extending information beyond accuracy-based measures.

A precise characterization of cognitive aging in cognitively unimpaired older adults is essential as it provides an important reference for distinguishing age-related change from that of pathological trajectories such as Alzheimer disease. In many cognitive aging cohorts, biomarker data are unavailable, making it difficult to determine whether observed longitudinal changes may be partly attributable to early preclinical Alzheimer disease pathology [8]. As a result, it remains unclear whether age-related cognitive decline can be reliably detected over short timescales in cognitively unimpaired older adults and to what extent distinct cognitive processes—such as speed and stability of performance, as well as learning and retention—are differentially affected by age.

Addressing this question—particularly detecting gradual cognitive change over relatively short timescales—is methodologically challenging when using traditional longitudinal study designs [9-12]. These studies typically rely on infrequent, single-administration cognitive assessments administered years apart and focus on global accuracy or mean response time scores [13]. As a consequence, short-term fluctuations due to sleep, mood, or environmental factors may obscure long-term cognitive change. At the same time, repeated testing introduces substantial practice effects, which may equal or exceed true age-related decline, especially over brief follow-up intervals of only a few years [3,9,14,15]. Consequently, observed changes in test scores reflect a composite of practice-related gains, day-to-day variability, and underlying cognitive decline, limiting interpretability and reducing sensitivity to individual differences.

Recent advances in digital cognitive assessment [16,17] provide a promising avenue for addressing these challenges. Remote cognitive testing conducted repeatedly over multiple days enables the capture of cognitive processes with high temporal resolution. In parallel, computational modeling approaches applied to intensive longitudinal response time data allow practice-related gains to be separated from cognitive change and enable the decomposition of performance into theoretically meaningful process-based markers, including speed and stability of performance as well as learning rate and forgetting [14,15]. A key advantage of this approach is that change in peak performance across testing intervals can be interpreted as a practice-adjusted estimate of within-person cognitive change over time. This approach leverages the fine-grained temporal information provided by response time data to characterize the efficiency and stability of underlying cognitive processes, complementing information obtained from accuracy-based measures [7].

In the present study, we leveraged a multiday associative face-name memory task from the Boston Remote Assessment for Neurocognitive Health (BRANCH) battery [18,19] administered daily over 7 consecutive days and repeated approximately every 6 months.

Our aims were twofold: (1) to evaluate whether this paradigm detects age-related cognitive decline over short time frames in cognitively unimpaired older adults and (2) to estimate the direction and magnitude of age associations with latent process-based cognitive markers.

Methods

Participants

Participants were recruited from 3 Mass General Brigham observational cohort studies: the Harvard Aging Brain Study (2P01AG036694-11; principal investigators: RAS and KAJ), the Instrumental Activities of Daily Living study (R01AG053184 and R01AG067021; principal investigator: GAM), and the Subjective Cognitive Decline study (R01AG058825-01A; principal investigator: REA). Participants were community dwelling and required to remain cognitively unimpaired throughout the study period. Cognitive status was assessed at annual in-clinic visits and was defined based on a Clinical Dementia Rating global score of 0, a Mini-Mental State Examination score greater than 25, and a logical memory delayed recall score above education-adjusted thresholds (>4 for 8-15 years of education; >8 for ≥16 years of education). Only participants who met these criteria at every available clinical assessment during follow-up were included. The neuropsychological assessment closest to the first BRANCH testing interval was conducted, on average, 29.7 (SD 121) days before BRANCH testing. The corresponding mean time differences were 98.8 (SD 135) days for the second interval, 202.0 (SD 149) days for the third interval, and 196.0 (SD 183) days for the fourth interval. Exclusion criteria included a primary psychiatric diagnosis, unstable medical conditions, severe head trauma, and a recent history of alcohol or substance abuse.

Materials and Procedure

Digital cognitive assessment was conducted using BRANCH, a previously validated web-based platform for remote cognitive testing that includes 2 associative memory tasks and 1 processing speed task [20]. Participants completed the tests independently and remotely on a daily basis over 7 consecutive days, enabling the characterization of learning dynamics.

The present study focused on the Face-Name Test, an associative memory task, which is illustrated in Figure 1. Participants were instructed to learn 20 face-name pairs. Following a 5-minute delay, they completed two tasks: (1) *first-letter name recall* (FNLT), in which they identified the first letter of the associated name for each face; and (2) *face-name matching* (FNMT), in which they selected the correct name from 3 multiple-choice options. The primary outcome of interest in the present study was response time for correct responses, which was recorded at the item level. First, median response times for correctly answered items were calculated separately for FNLT and FNMT. These task-specific median response times were then averaged to ensure equal weighting of both tasks. Across testing days, daily response time estimates were based on an average of 28.7

XSL•FO
RenderX

(SD 10.4) correctly answered trials across both subtasks out of 40 possible trials per testing day.

Figure 1. Illustration of the face-name matching task. Although written consent for publication was obtained, the facial image has been blurred in accordance with journal policy to protect participant privacy.

Participants completed up to 4 multiday BRANCH testing intervals. Each interval used the same face-name paradigm but a different set of face-name pairs, thereby serving as an alternate-form version of the task. Alternate forms were developed according to prespecified stimulus construction rules to maintain consistency in task structure and difficulty. In an independent pilot study, the first 3 forms were administered in counterbalanced order and showed broadly comparable accuracy and modest differences in response time, with no systematic increase in response time across forms. Further details are provided in Multimedia Appendix 1. Within each interval, the same stimulus set was administered repeatedly over 7 consecutive days to characterize multiday learning. Testing intervals were designed to include 7 consecutive testing days; participants contributed an average of 6.5 (SD 1.2) testing days per interval. The second testing interval followed an average of 1.2 (SD 0.4) years after the first testing interval, the third followed an average of 2.2 (SD 0.6) years after, and the fourth followed an average of 2.8 (SD 0.4) years after.

Statistical Analysis

We used a computational phenotyping approach to model daily median response times from correct trials across repeated 7-day testing intervals administered over multiple years. No additional response time trimming or exclusion procedures were applied before calculating the daily median. Specifically, we estimated a Bayesian double-negative exponential model (BDEM) proposed by Oravecz et al [14,15]. Full model specification and estimation details are provided in Multimedia Appendix 1.

Conceptually, the model assumes that observed performance reflects several processes occurring simultaneously: short-term learning across days within a testing interval, longitudinal practice-related gains across repeated testing intervals, forgetting of prior task-related practice gains between intervals, and longer-term change in peak performance. The 2 exponential components of the model capture learning on different timescales: one models rapid learning within each 7-day testing interval, whereas the other models slower practice-related gains that accumulate across repeated testing intervals and reflect increasing task familiarity. Within each testing interval, performance is modeled as approaching an individual's peak performance. By modeling learning separately, change in peak performance over time can be interpreted as a practice-adjusted indicator of within-person cognitive change. Figure 2 provides a conceptual illustration of the model and the process-based cognitive markers derived from it.

Figure 2. Illustration of the Bayesian double-negative exponential model with 4 testing intervals for 1 synthetic participant. Data are displayed as dots. Corresponding negative exponential curves (solid lines) show model fit.

Peak performance represents an individual's estimated best expected response time within a testing interval, corresponding to the asymptote approached during short-term learning. *Change in peak performance* across testing intervals reflects longer-term, practice-adjusted within-person cognitive change and is interpreted as an indicator of cognitive aging. *Short-term learning rate* quantifies how quickly individuals approach their peak performance across repeated exposure within a 7-day testing interval. In contrast, *long-term learning rate* captures the rate of task familiarization that accumulates across repeated testing intervals and unfolds over a longer timescale than learning within an interval. In addition, the model estimates within-person variability, indexing performance inconsistency around the predicted trajectory, and forgetting between testing intervals, reflecting the loss of prior task-related practice gains.

To examine age effects and further potential associations between cognitive markers and sociodemographic variables, age, sex, and years of education were included as predictors, along with a control variable for the device used (computer or smartphone). Age and years of education were *z* standardized to facilitate comparison of their associations across the process-based cognitive markers. In the present sample, 1 SD corresponded to 8.2 years of age and 2.5 years of education. These regression parameters were embedded in the BDEM in a 1-step analysis such that all reported results represented partial regression coefficients, summarizing the effect of each predictor conditional on all others.

The model used all available median response times. Missing testing days and testing intervals contributed no likelihood term. Accordingly, the primary analysis assumed that missingness was conditionally independent of unobserved response times after accounting for the observed covariates and the longitudinal performance patterns captured by the model.

All analyses were conducted in R (version 4.4.1; R Foundation for Statistical Computing) [21]. Model fitting was performed in Stan using the *rstan* interface [22]. Convergence was assessed using standard diagnostics, and model adequacy was evaluated using posterior predictive checks [23].

Sensitivity Analysis

Several additional analyses were conducted to assess the robustness of the findings and examine the time frame over which age-related cognitive change could be detected. First, to examine whether the age-related findings persisted in the absence of elevated amyloid burden, an important marker of

XSL•FO
RenderX

preclinical Alzheimer disease, analyses were repeated in a subset of participants with available amyloid positron emission tomography, restricting analyses to those classified as amyloid beta–negative (n=167). Details on positron emission tomography image acquisition and processing are provided in Multimedia Appendix 1. Second, the analyses were repeated using 3 and 2 testing intervals to evaluate the timescale at which age-related cognitive changes can be detected within the present paradigm. Third, the analyses were repeated separately for FNLT and FNMT to examine whether observed effects were driven by one specific subtask. Fourth, to examine whether the findings were sensitive to selective attrition, we repeated the analysis in participants who completed the first 3 of the 4 testing intervals using only data from these 3 intervals. This restriction balanced completeness of follow-up against retention of a sufficiently large sample. Fifth, to examine whether the number of correct responses used to calculate the daily median response times varied systematically with age, we fitted a beta-binomial mixed-effects model to account for overdispersion in the daily accuracy data. Daily accuracy was modeled using the number of correct responses out of 40 trials per testing day, with age, testing interval, study day, sex, education, and device type as fixed effects and a random intercept for participant. Age and education were *z* standardized.

Ethical Considerations

All participants provided written informed consent prior to study participation. The study protocol was approved by the Mass General Brigham Institutional Review Board (2019P000476). Data were handled in accordance with applicable data protection regulations and were stored and analyzed in deidentified form. Participants were compensated for each attempted assessment session.

Results

Sample Characteristics

Data from 209 participants who completed up to 4 testing intervals were analyzed (mean age at study entry 73.6, SD 8.2 years; n=136, 65.1% female). Sample characteristics are summarized in Table 1. Of these participants, 62.7% (n=131) completed the second testing interval, 51.7% (n=108) completed the third, and 34.9% (n=73) completed the fourth (Figure S1 in Multimedia Appendix 1). Baseline characteristics were broadly similar between participants who completed all 4 testing intervals and those who did not, although completion status differed by cohort source (Table S1 in Multimedia Appendix 1).

Table . Demographic characteristics (N=209).

Variables	Values
Age (y), mean (SD)	73.6 (8.2)
Sex, n (%)	
Female	136 (65.1)
Male	73 (34.9)
Race, n (%)

Global CDR[b], n (%)	
0	209 (100)

[a]MMSE: Mini-Mental State Examination.

[b]CDR: Clinical Dementia Rating.

Description of Reaction Times

Correct response counts and accuracy by testing interval and study day are provided in Table S2 in Multimedia Appendix 1. To examine whether cognitive decline was observable in the raw response time data, we calculated the average response times for each participant and testing interval. Response times initially decreased substantially from the first to the second testing interval (mean 2.63, SD 0.65 seconds in the first; mean 2.47, SD 0.61 seconds in the second) before reaching a plateau in subsequent intervals (mean 2.46, SD 0.56 seconds in the third; mean 2.46, SD 0.50 seconds in the fourth). Over a mean observation period of 2.8 (SD 0.4) years, no clear age-related slowing was evident in the raw response time data.

XSL•FO
RenderX

BDEM

The observation-level R^2 was 0.87, indicating a good descriptive fit of the BDEM to the observed face-name response time data. Group-level summaries are shown in Table 2. Within the Bayesian framework, 95% credible intervals represent the range within which a parameter value lies with 95% probability, thereby reflecting the uncertainty surrounding the estimate [23]. For each cognitive marker, 2 population-level estimates are reported: the population mean across all participants and the population SD, which reflects the extent of variability in that marker.

Table . Group-level (population) estimates of Bayesian double-negative exponential model parameters.

Group-level cognitive marker	Posterior mean (SD; 95% credible interval)[a]
Peak performance (s)	2.10 (0.37; 2.05-2.15)
Change in peak performance (s/y)	0.04 (0.07; 0.02-0.06)
Forgetting between intervals (s)	1.05 (0.44; 0.99-1.10)
Short-term learning rate[b]	0.71 (0.31; 0.65-0.79)
Long-term learning rate[b]	0.64 (0.27; 0.58-0.70)
Within-person variability (s)	0.24 (0.10; 0.24-0.25)

[a]This represents the posterior mean of the group-level mean and the between-person SD.

[b]Learning rates are exponential model parameters reflecting short-term relearning within testing intervals and cumulative practice-related learning across testing intervals.

Model-estimated peak performance, derived from daily response times across the 7-day testing intervals, was 2.10 (SD 0.37) seconds on average. Peak performance slowed by 0.04 seconds per year (95% credible interval 0.02-0.06). Relative to mean peak performance, this corresponds to an average slowing of approximately 2% per year. At the beginning of a new testing interval, performance was substantially slower, as captured in the forgetting parameter: participants started, on average, 1.05 (SD 0.44) seconds slower compared to the end of the previous testing interval. Mean learning rates within (mean 0.71, SD 0.31) and across (mean 0.64, SD 0.27) testing intervals were similar. Mean within-person variability in performance was 0.24 (SD 0.10) seconds.

Results from the embedded linear regressions are shown in Table 3. Associations with age and educational attainment are reported per 1-SD increase as both variables were *z* standardized. Chronological age was associated with multiple cognitive markers. A 1-SD higher age was associated with 0.19 seconds slower peak performance. Higher age was also associated with more pronounced annual slowing in peak performance (mean 0.036 seconds per year). Older participants further showed greater within-person variability (mean 0.043 seconds), reduced benefit from prior test exposure as reflected in greater forgetting (mean 0.136 seconds), and a lower long-term learning rate (mean –0.15). Short-term learning rate was not clearly associated with age.

Additional associations were observed with sex and educational attainment. Women showed faster peak performance in the Face-Name Test than men (mean –0.177 seconds). A 1-SD increase in years of education (equivalent to 2.5 years in the present sample) was associated with faster peak performance (mean –0.052 seconds). Moreover, individuals with more years of education exhibited less pronounced slowing of peak performance over time (mean –0.017 seconds per year), indicating less cognitive aging, as well as a higher long-term learning rate (mean 0.06).

Table . Summary of results on associations between cognitive markers and person-level predictors.[a]

Cognitive marker and predictor	Results, mean (95% credible interval)
Peak performance (s)	
Age	0.19 (0.12 to 0.26)
Sex	–0.18 (–0.31 to –0.05)
Education	–0.05 (–0.11 to –0.01)
Device	0.04 (–0.07 to 0.16)
Change in peak performance (s/y)	
Age	0.04 (0.01 to 0.06)
Sex	0.00 (–0.04 to 0.05)
Education	–0.02 (–0.03 to –0.01)
Device	0.01 (–0.02 to 0.04)
Within-person variability (s)	
Age	0.04 (0.03 to 0.06)
Sex	–0.04 (–0.07 to 0.00)
Education	–0.01 (–0.02 to 0.01)
Device	0.00 (–0.04 to 0.03)
Forgetting between intervals (s)	
Age	0.14 (0.05 to 0.22)
Sex	0.10 (–0.08 to 0.29)
Education	–0.03 (–0.10 to 0.05)
Device	–0.02 (–0.18 to 0.14)
Short-term learning rate[b]	
Age	–0.08 (–0.16 to 0.00)
Sex	0.10 (–0.07 to 0.25)
Education	–0.03 (–0.10 to 0.04)
Device	0.02 (–0.13 to 0.18)
Long-term learning rate[b]	
Age	–0.15 (–0.21 to –0.09)
Sex	0.13 (–0.02 to 0.24)
Education	0.06 (0.01 to 0.11)
Device	–0.03 (–0.14 to 0.08)

[a]Age and years of education coefficients are reported per 1-SD increase. One SD corresponded to 8.2 years of age and 2.5 years of education. Reference categories were male for sex and computer (vs smartphone) for device type.

[b]Learning rates are exponential model parameters reflecting short-term relearning within testing intervals and cumulative practice-related learning across testing intervals.

Sensitivity Analyses

First, findings were replicated in the amyloid beta–negative subsample (n=167; Tables S3 and S4 in Multimedia Appendix 1), indicating that observed age-related effects are unlikely to be primarily driven by preclinical Alzheimer disease pathology. Second, analyses restricted to 2 and 3 testing intervals (Tables S5-S8 in Multimedia Appendix 1) yielded comparable group-level estimates and replicated the pattern of age and educational attainment effects observed in the full model, with aging-related slowing emerging from 3 testing intervals onward. Third, analyses conducted separately for the FNLT and FNMT (Tables S9-S12 in Multimedia Appendix 1) showed broadly similar patterns, including longitudinal slowing in peak performance and consistent associations between higher age and slower peak performance, greater within-person variability, and lower long-term learning. An age association with between-interval forgetting was observed for the FNLT but not for the FNMT. Fourth, the completer-only analysis restricted to participants who completed the first 3 testing intervals largely replicated the pattern observed in the primary analysis (Tables S13 and S14 in Multimedia Appendix 1). Peak performance

XSL•FO
RenderX

again slowed over time, and the direction and magnitude of the associations between higher age and slower peak performance, greater slowing in peak performance, greater within-person variability, more forgetting between testing intervals, and lower long-term learning were preserved. Fifth, in the beta-binomial mixed-effects model, higher age was associated with lower accuracy (odds ratio 0.72 per 1-SD increase in age, 95% CI 0.64 - 0.81; $P<.001$). Accordingly, older participants tended to contribute fewer correct trials to the calculation of the daily median response times. To examine whether the findings were robust to variation in the number of correct responses, we therefore repeated the analyses including only daily median response times based on at least 15 correct trials (Tables S15 and S16 in Multimedia Appendix 1). The resulting estimates and pattern of associations were highly similar to those observed in the primary analysis.

Discussion

Principal Results

In this study, we showed that a digital multiday learning paradigm combined with computational modeling of response times can sensitively detect age-related cognitive decline over relatively short timescales of less than 3 years in cognitively unimpaired older adults. Across repeated testing intervals, peak performance—a measure indexing cognitive performance after accounting for practice effects—declined by approximately 2% per year, with steeper declines observed at higher ages. In addition, higher age was associated with a broader process profile characterized by slower peak performance, greater within-person variability, lower long-term learning, and greater between-interval forgetting of prior task-related practice gains. These findings replicate and extend previous work addressing a long-standing methodological challenge in cognitive aging research: detecting gradual cognitive decline over brief intervals despite practice effects and day-to-day variability.

The modeling approach applied here was specifically developed to disentangle aging-related decline from other sources of within-person change but has thus far been used primarily in the context of processing speed or working memory tasks [9,14,15]. Our study extends this work in several important ways. First, we applied the model to an associative memory task, a cognitive domain particularly vulnerable to age-related decline. Second, the persistence of the age-related findings in an amyloid beta–negative subsample reduces the likelihood that they were primarily driven by preclinical Alzheimer disease pathology. All participants also remained cognitively unimpaired throughout the study period, as confirmed by repeated in-clinic neuropsychological assessments. Together, these findings strengthen the interpretation that the observed cognitive changes are related to aging rather than primarily attributable to preclinical Alzheimer disease, although contributions from other pathologies cannot be excluded. Finally, the availability of up to 4 repeated testing intervals over nearly 3 years allowed us to assess the minimum time frame over which age-related cognitive change becomes detectable. Systematic aging effects were evident with as few as 3 testing intervals, spanning a mean period of approximately 2.2 years.

A key advantage of the modeling approach is its ability to simultaneously estimate multiple latent, process-based markers of cognitive aging [15]. Chronological age was associated with a coherent pattern of changes across these markers. Older age was linked to slower peak performance, greater within-person variability, lower long-term learning, and greater forgetting of prior task-related practice gains. Notably, short-term learning within testing intervals showed no clear association with age. These findings suggest that cognitive aging in cognitively unimpaired older adults involves coordinated changes across multiple cognitive processes that would be overlooked in analyses based solely on global accuracy or mean response times.

Importantly, substantial interindividual differences in these process-based cognitive markers were not explained by chronological age alone. In particular, higher educational attainment was associated with faster peak performance, a higher long-term learning rate, and less pronounced slowing of peak performance over time, suggesting that educational attainment may be linked to greater resilience against age-related cognitive decline. These findings indicate that the applied paradigm and computational model may also be informative for studying factors that buffer age-related cognitive aging. Additionally, women showed faster peak performance than men, potentially reflecting task-specific advantages in associative face-name processing.

Comparison With Prior Work

The observed annual slowing in peak performance is consistent with prior work demonstrating gradual, small but systematic age-related cognitive slowing [3,7,24], although direct comparisons are limited due to differences in tasks, outcome measures, and study designs. In particular, our findings are consistent with the processing speed theory of cognitive aging, which posits generalized slowing as a primary mechanism of cognitive decline [2,25]. This slowing was more pronounced at older ages, aligning with trajectories of cognitive aging as described in the literature [26,27]. Greater within-person variability is consistent with prior evidence linking aging to reduced cognitive control and increased neural noise [4]. Similarly, lower long-term learning and greater forgetting of prior task-related practice gains are in line with theoretical accounts of age-related inefficiencies in encoding, consolidation, and retrieval of new information [28,29]. An interesting exception was short-term learning within testing intervals, which showed no clear association with age. This finding is notable in light of prior work suggesting that reduced multiday learning—often assessed via accuracy—is sensitive to early Alzheimer disease–related changes [19], raising the possibility that different process-based cognitive markers may show differential associations with cognitive aging vs early Alzheimer disease–related change.

The associations with educational attainment are consistent with theories of cognitive reserve and with prior evidence suggesting that life course factors shape trajectories of cognitive aging [8,30-32]. Against this background, the finding that higher educational attainment was linked not only to faster peak performance but also to less pronounced slowing over time and

XSL•FO
RenderX

better long-term learning suggests that process-based markers derived from intensive digital assessments may be useful for studying factors that buffer age-related cognitive decline. More broadly, such process-based cognitive markers are particularly relevant for prevention and intervention research as they may serve as more sensitive outcome measures in trials aimed at preserving or enhancing cognitive functioning in later life.

Limitations

Several limitations should be acknowledged. First, our sample consisted predominantly of highly educated, non-Hispanic White individuals, limiting generalizability to more diverse populations. Moreover, because BRANCH requires digital literacy and sustained adherence to repeated remote testing, its applicability to individuals with less experience using digital tools remains uncertain. Second, participants were not explicitly instructed to respond as quickly as possible; therefore, individual response strategies may have contributed to variability in response times despite item time limits and automatic progression. Third, alternate task forms were administered in a fixed sequence such that form and testing interval could not be disentangled. In the counterbalanced pilot study, the first 3 forms showed broadly comparable accuracy and modest differences in response time, with no systematic increase in response time across forms. Moreover, longitudinal slowing persisted when analyses were restricted to these first 3 forms. Nevertheless, residual alternate-form effects on response time cannot be fully separated from longitudinal change in the present longitudinal sample. Fourth, participant numbers decreased across testing intervals, raising the possibility of selective attrition. Although the main pattern of findings was preserved in the completer-only analysis, attrition associated with unobserved cognitive change or other unmeasured factors related to performance cannot be excluded. Fifth, because response times were analyzed for correct trials only and higher age was associated with lower accuracy, estimates for older participants tended to be based on fewer trials. However, older participants showed both slower response times and lower accuracy, which does not suggest a conventional speed-accuracy trade-off. Moreover, the findings were consistent across the 2 task-specific analyses and remained robust when the analysis was restricted to daily median response times based on at least 15 correct trials.

Conclusions

A digital multiday learning paradigm combined with computational modeling of response times enabled the detection of age-related cognitive decline over short time frames in cognitively unimpaired older adults. Beyond longitudinal slowing in peak performance, the approach revealed a broader pattern of aging-related differences, including slower and more variable performance, lower long-term learning, and greater forgetting of prior task-related gains. Higher educational attainment was associated with a more favorable profile across several of these markers. These findings demonstrate the potential of intensive digital assessment and computational modeling to characterize cognitive aging and support the further evaluation of process-based cognitive markers as sensitive outcomes in prevention and intervention research.

Abstract

Background: As the global aging population accelerates, mobile health (mHealth) apps have emerged as critical tools in the health management of older people. However, the promotion of mHealth apps has faced multiple obstacles, including insufficient technological adaptation to aging, digital resistance, and ageism. The impact of ageism on technology usage experiences among older adults is influenced by mechanisms such as stereotypes and biases. Notably, extant research has not adequately explored the subjective experiences of older adults in the context of mHealth app usage scenarios.

Objectives: The present study was predicated on the extended unified theory of acceptance and use of technology model and the risks of ageism model to systematically explore and understand older adults' ageism experiences in mHealth app usage. Our objectives were to provide a reference for optimizing age-friendly design and enhancing digital health management capabilities for older adults.

Methods: This qualitative study utilized an interpretive phenomenological design and was conducted between February and April 2025. Purposive sampling was employed to select older adults with experience using mHealth apps in a Shanghai community for semistructured interviews. This study used Colaizzi's phenomenological method to analyze and summarize older adults' experiences and perceptions of ageism and to extract themes.

Results: The study identified 3 core themes: (1) internalized age stereotypes, which manifest as technological uselessness and learning barriers; (2) anxiety and avoidance behaviors caused by stereotype threat; and (3) external unfair treatment (such as age-friendly design flaws and inadequate support systems), which inhibits usage. These experiences significantly impact older adults' intention to use mHealth apps.

Conclusions: Ageism profoundly affects the engagement of older adults with mHealth apps. It is advisable to execute systematic interventions to improve digital inclusion and health self-management capabilities, including strategies to challenge age stereotypes, optimize intergenerational support, refine age-friendly design, and establish strong social support networks.

Introduction

Background

The aging process of China's population is accelerating and has reached an advanced stage of development. Recent statistics indicate that by the conclusion of 2024, China's population aged 60 years and older will approximate 310 million, with those aged 65 years and older reaching around 220 million. These groups represent 22% and 15.6% of the total population, respectively [1]. As the aging process advances, the population of older internet users continues to expand. The 55th Statistical Report on China's Internet Development indicates that the population of internet users aged 60 years and above has

XSL•FO
RenderX

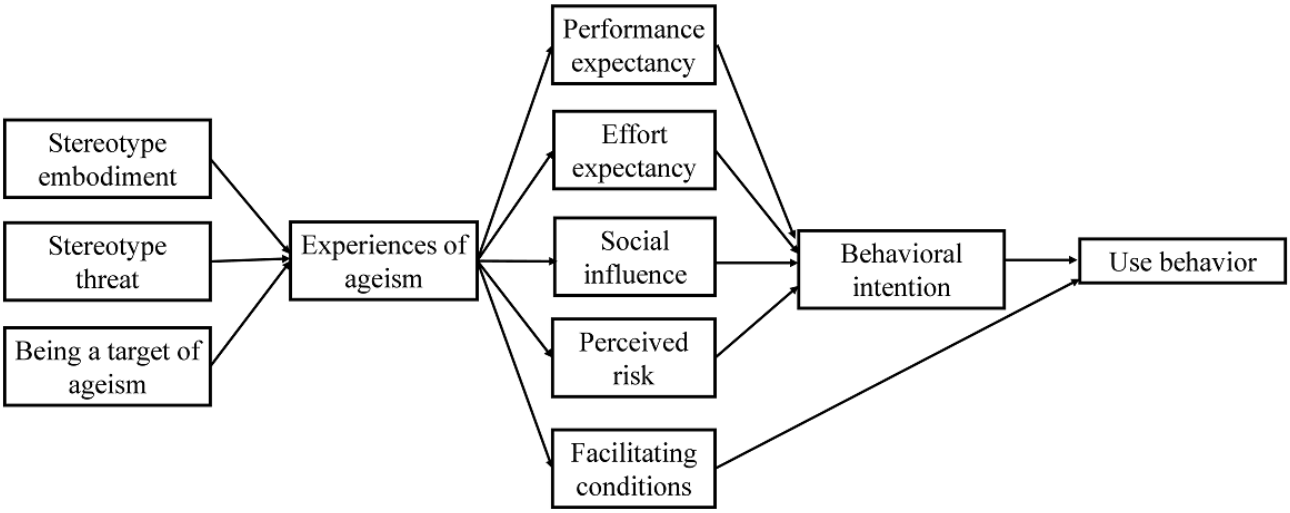
increased from 7.3 million in 2009 to 157.25 million in 2024 [2]. The internet has progressively emerged as a significant platform for older adults to obtain health information and services. Additionally, the incidence of chronic diseases in older adults has attained 75%, necessitating increasingly individualized and varied health care requirements [3]. This requires transcending conventional health care approaches to address the personalized health needs of the digital era [4]. The State Council of China has released a medium- to long-term plan (2017 - 2025) on the prevention and treatment of chronic diseases, proposing the use of information technology to promote health management [5]. Mobile health (mHealth) apps enable remote diagnostics and personalized therapies [6], particularly aiding older adults by enhancing health care access and fostering health autonomy [7]. Nevertheless, older adults exhibit low awareness and utilization rates of mobile health care [8], attributable to inadequate age-appropriate design, technological resistance, and insufficient social support [8-10]. To resolve this issue, it is necessary to improve nationwide access to digital health services. This necessitates the systematic elimination of obstacles to digital health adoption among older adults through the refinement of technical standards, optimization of service systems, and enhancement of social support.

Notably, ageism has been demonstrated to intensify the digital divide [11,12]. The World Health Organization [13] defines ageism as stereotyping, prejudice, or discrimination based on actual age [14]. This includes self-directed ageism, which refers to negative internalized beliefs about aging [15], as well as benevolent forms, such as overprotection, and hostile forms, including neglect and judgment [16,17]. Ageism impacts older adults via 3 mechanisms: internalized stereotypes, avoidance strategies, and direct discrimination experiences [18]. These mechanisms undermine the psychological well-being of older adults and exert various negative impacts on their physical and mental health [19]. Research demonstrates that ageism markedly diminishes life satisfaction among older adults, intensifies social isolation, hinders chronic disease management outcomes, and elevates the risk of depression and cognitive decline [20]. Moreover, ageism may instigate apprehension regarding operational mistakes and reduce self-efficacy by leading older adults to internalize adverse stereotypes such as “techno-phobia.” This markedly diminishes their willingness to engage with mHealth programs, thereby hindering their capacity to access health resources through mHealth apps [21]. Previous research has mostly concentrated on quantitative analyses of influencing factors [22-24]; however, it has insufficiently addressed the subjective experiences of older adults. Research on mHealth apps has identified issues such as inadequate aging [25,26], yet it seldom explores the subjective psychological effects resulting from ageism.

Objective

In order to investigate how older persons actually perceive ageism in the use of mHealth apps, this study takes an interpretive phenomenological method. It provides a reference and foundation for enhancing the age-friendly mHealth app design and creating an inclusive social support network, which will encourage older individuals’ digital integration and health management capabilities.

Theoretical Framework



In 2003, Venkatesh et al [27] proposed the unified theory of acceptance and use of technology (UTAUT) model, which posits that user behavior in adopting technology is explained by four core dimensions: performance expectation (PE), effort expectation (EE), social influence (SI), and facilitation conditions (FC). The model demonstrated an explanatory power of 70%. It has been extensively used in research examining the adoption of new technologies among older adults [28]. This study examines privacy risks in mobile health care services by including a perceived risk (PR) dimension into the UTAUT model to create an enhanced framework. That improvement has been substantiated in the domain of medical technology [29,30].

The risks of ageism model (RAM) proposed by Swift et al explains the obstacles to positive aging through 3 pathways [18]: stereotype embodiment (negative labels imposed on older people by society), stereotype threat (self-doubt caused by older people internalizing negative labels), and being a target of ageism. The RAM model’s psychosocial mechanisms are not covered by the extended UTAUT model, although it can evaluate older adults’ desire to use mHealth apps due to its five dimensions: PEs, EEs, SI, enabling factors, and PR. The RAM model focuses on the manifestation of ageism and is not directly related to technology acceptance behavior.

The extended UTAUT model, primarily utilized in quantitative research, encompasses 5 core dimensions that systematically address essential factors influencing technology acceptance behavior, thereby offering a thorough theoretical framework for examining the digital health usage behavior of older adults. This study applies qualitative research to examine the influence of ageism on older adults’ perceptions and experiences within the UTAUT dimensions, aiming to reveal underlying mechanisms that quantitative research may not address. To establish a theoretical framework, as seen in Figure 1, this study combines the 2 models and maps the 3 routes of RAM to the 5 dimensions of UTAUT. This reveals how ageism affects the mechanism of interaction between the intention to use mHealth apps and behavior through these dimensions.

Figure 1. Extended unified theory of acceptance and use of technology and risks of ageism models.

Methods

Design

We conducted face-to-face semistructured interviews from February to April 2025. This study employed a qualitative research design based on interpretive phenomenology. This approach was chosen to deeply explore the subjective experiences and psychological sentiments of older adults concerning ageism in their usage of mHealth apps from their own viewpoints. This study used Colaizzi's method to understand individuals' real experiences and experiences [31]. We followed the COREQ (Consolidated Criteria for Reporting Qualitative Research) reporting guideline to guarantee rigor and transparency.

Participant Selection

We employed purposive sampling to select older adults in a community in Shanghai based on gender, age, and mHealth app usage experience. The selection criteria for interviewees were as follows: (1) individuals aged 60 years or older, who have resided in the community for a minimum of 5 years (or at least 10 mo/y); (2) individuals with normal cognitive function, adequate physical strength to participate in the interview, and the ability to communicate in Mandarin; (3) regular use of mHealth apps for at least 3 months; and (4) voluntary consent obtained through the signing of an informed consent form. Exclusion criteria included the presence of mental illness or cognitive impairment, severe hearing or language impairment, and withdrawal from the study. We adopted the principle of maximum differentiation sampling, with sample size determined by information saturation (ie, no new themes appeared in the interview content).

Eligible interviewees were recruited through community hospital nurses. The study conducted face-to-face semistructured interviews from February to April 2025, with the interview outline designed based on the RAM and UTAUT theoretical frameworks. The research design emphasized ethical approval to ensure the protection of participants' privacy.

Ethical Considerations

This study was approved by the hospital ethics committee (RA-2021 - 465). All participants were informed that their participation was voluntary and anonymous and that no adverse consequences would result from the interview. All participants signed written informed consent forms after being informed of the study's purpose, procedures, risks, and benefits, and received guidance on mHealth apps usage as compensation. We refer to all interviewees with a number (N) and a letter to ensure their anonymity.

Setting

To facilitate comprehension among older adults regarding the study, information leaflets were handed out, and interviews were conducted in soundproof rooms to ensure privacy and minimize interference from unrelated individuals. The interviewer initially articulated the study's purpose and significance to the interviewee, ensuring that their personal information would remain confidential. Following that, after establishing trust through a 30-minute warm-up, the interviewer conducted a semistructured interview lasting 25 to 35 minutes, employing the "dual recording method" (audio recording along with written notes). The interviewer dynamically adjusted the questioning strategy and documented nonverbal cues, such as facial expressions and body language, using information saturation as the criterion for termination. The interviewer (first author) transcribed the recorded interviews verbatim within 24 hours and invited the interviewees to verify the transcripts. Data were encrypted and stored, accessible only by the project team within an ethical framework, in full compliance with the Declaration of Helsinki requirements.

Data Collection

After obtaining approval from the community hospital, we contacted the hospital staff to determine the visit time. Before inviting eligible residents to sign the informed consents, the researcher (first author) explained the study to them. After signing the informed consents, data were collected through semistructured face-to-face interviews and observations. The first author conducted individual semistructured face-to-face interviews from February to April 2025.

XSL•FO
RenderX

Following the identification of participants, researchers engaged with them to observe their daily utilization of mHealth apps, including the types of apps and their level of proficiency in usage. Using the extended UTAUT and RAM theoretical framework, we employed an interpretive phenomenological approach to develop semistructured interview outline. Following 2 rounds of Delphi expert consultation (n=5) and 3 discussions among the research team, along with practical feedback from 2 preliminary interviews (n=2), we developed a semistructured interview outline consisting of 6 theoretical dimensions: (1) EE: Which mHealth apps have you used? Can you give us a brief overview of your learning and usage experience? (2) PE: What is your attitude toward mHealth apps? Have they met your expectations? (3) SI: What is the attitude of your family, friends, or health care providers toward your usage of mHealth apps, and how does their attitude influence your usage? (4) FC and PR: What factors do you think influence your usage of mHealth apps? (5) In your opinion, what kind of mHealth app would be most suitable for you and your peers to use? (6) What kind of help would you like to receive when using mHealth apps? The research process strictly followed qualitative research standards. All interview questions were optimized for readability (Flesch-Kincaid index≤6.0) and cognitive adaptability testing to ensure that they were understandable to older interviewees.

Probing questions within the interview allowed participants to raise unexpected issues and provided flexibility to follow-up on these issues. By asking follow-up questions based on the answers to previous questions, interviewees were encouraged to freely share their experiences. The interview guide was used to ensure that all topics were covered.

Data Analysis

This study employed a systematic qualitative data analysis approach: initially, interview data was anonymized and assigned identification codes, while data collection and analysis occurred concurrently. Transcription was finalized within 24 hours post-interviews, with accuracy confirmed by a research team member and observational notes incorporated as supplementary data. The Colaizzi's method [31] was employed alongside NVivo 14.0 software to facilitate the analysis, resulting in a thematic map established through a 3-tier quality control process involving analysis by principal investigators, expert supervision, and review by the research team. Disputed content was addressed through consensus meetings to ensure the research's rigor and the interpretation's reliability.

Rigor

The content of the interview outline was determined through literature review and theoretical framework, and semistructured interviews were conducted with the target group in advance (not included in the study) to ensure that the interview outline was rigorous and easy to understand. The interviews were carried out by master's degree nursing students trained in qualitative research methodologies. To ensure the reliability of the collected data, we employed a combination of prolonged exposure, comprehensive analysis, diverse information sources, and various data collection methods, including interviews, field notes, and member checking by colleagues and participants. In the data analysis, efforts were made to incorporate the interviewees' emotions while minimizing the influence of the researchers' preconceived notions.

Results

Overview of Data and Analysis

The study achieved data saturation after conducting interviews with 12 participants, at which point no new codes emerged, leading to the termination of the interviews. A total of 12 older adults were included in the study. The total duration of the interviews was approximately 370 minutes, with the transcripts of the relevant themes totaling around 50,000 words. Table 1 presents the general information of the 12 interviewees. The analysis process is shown in Figure 2, which only showed the analysis process of Theme 3.

Figure 2. Process of thematic analysis (theme 3). EE: effort expectation; FC: facilitation condition; PE: performance expectation; PR: perceived risk; SI: social influence.

Theme 1: Stereotype Embodiment

PE: Age Labeling Weakens the Perceived Value of mHealth Apps

The internalization of age-related stereotypes caused participants to associate advanced age with a decrease in technological skills, resulting in a self-perception of "technological uselessness." The reduction in self-efficacy significantly impaired their acknowledgment of the potential health management advantages provided by mHealth apps. As N11 articulated:

> *I'm 75 years old. Why should I learn anything new? I'm getting old. These mHealth apps won't help much.*

It is worth noting that some interviewees actively use technology to compensate for age-related cognitive decline, reflecting compensatory strategies in individual behavior under the threat of stereotypes.

> *If there is something wrong with my body, I will look for answers.* [N9]
>
> *The doctor also talked about it (health-related knowledge), but we don't have very excellent recollections, so we can't remember anything. That's why we look for information online on our own.* [N10]

EE: Magnification Technology Usage Barriers Attributed to Age

Participants frequently ascribe operational challenges to the unavoidable cognitive and physical decline linked to aging, rather than to design deficiencies or insufficient guidance, thus exacerbating perceived obstacles to usage. N12 stated:

> *It's best if it's simple (in terms of operation and functions). We (elderly people) sometimes don't really understand (complex) programs.*

N11's attribution to educational background: "We have a relatively low level of education, so we don't really know how to use many of the functions, and it's quite difficult to learn," forming self-imposed barriers to technical learning. This cognitive pattern of attributing operational failures to age is essentially a concrete manifestation of implicit age stereotypes in the field of technology.

SI: Family Environment Reinforces Negative Expectations About Technology

External stereotypes are internalized as self-perceptions through significant individuals, particularly family members. Respondents reported that specific attitudes held by family members—such as the belief that "older adults are easily misled" (N10) and the idea that basic mobile phones are adequate for seniors (N8)—contributed to their negative self-perceptions about technological abilities. This indicates that the perpetuation of negative stereotypes within the social milieu substantially impedes the inclination to engage with technology.

> *My family told me not to believe what I read online because it's all scams aimed at old people, and they're worried that I'll get scammed.* [N10]
>
> *My kids said that basic phones for seniors are fine, so why do I need a smartphone?* [N8]

FC: Self-Imposed Constraints Hinder the Utilization of External Resources

Internalized stereotypes are evident in 2 specific behavioral patterns: intentional avoidance of acquiring new technologies and an overdependence on intergenerational support. The self-identification as "unlearnable" served as a significant obstacle, hindering the effective conversion of available external support resources into realized technical skills. As a result, a disconnect arose between the availability of facilitating

XSL•FO
RenderX

conditions and their actual behavioral application, thereby constraining the practical adoption of mHealth apps.

> *We're not like young people; we don't want to learn new functions; these functions are enough for us.* [N12]

> *I'm lazy. I won't learn how to use (mHealth apps) unless I have to. My kids will help us if I need it.* [N5]

Theme 2: Stereotype Threat

PE: Avoidance of Perceived Value of mHealth Apps

Internalized age stereotypes diminish older individuals' confidence in the health advantages of technology, thereby creating a cycle of self-fulfilling prophecy. N12 said,

> *I can't find the answers I want (in the software) … I like going to the hospital to visit a doctor more because I trust what they say more.*

This preference indicates a strategic avoidance of digital health information, motivated by a concern that unsuccessful attempts may reinforce the stereotype that older individuals are unable to effectively use technology. Meanwhile, N10's prudent disposition ("My mind works slowly, so I'm not very willing to try new things unless they're truly useful") illustrated the inhibition of perceived technological efficacy induced by stereotype threat, stemming from the allocation of working memory resources to anxiety.

EE: Psychological Attributions for Avoiding Technical Learning

Older adults attributed operational challenges to the inevitability of aging, creating a cognitive pattern of technical inertia. The assertions "I'm getting older and don't want to learn new things" in N7 and "I'm not familiar with it (mHealth apps) and am too lazy to learn; my son will assist me" in N4 suggest that age-related labels generate negative psychological expectations and significantly reduce the motivation to develop technological skills. This attribution corresponds with the behavioral pattern of stereotype threat characterized by low expectations and low investment, leading to additional impairment of executive processes, such as cognitive flexibility.

SI: Usage Avoidance Under Interpersonal Pressure

External stereotypes were internalized as self-restrictive ideas through intergenerational exchanges. N8 expressed that his children's belief that "the elderly are easily deceived" made him feel "afraid to look, lest my children get into trouble," while N10 stopped asking questions after encountering his children's "impatient" attitude, illustrating how adverse feedback within the familial context reinforced avoidance behavior. This social pressure may be viewed as a manifestation of "group identity threat," leading older adults to preserve interpersonal harmony by refraining from technological involvement.

PR: Safety Concerns Intensify the Crisis of Confidence

Technical risk issues combined with traditional age biases resulted in a dual barrier to trust. The primary concerns for older adults using mHealth apps were the security of personal information and the protection of property. N3's awareness of concealed charges ("they charge you after asking a few questions"), N2's apprehension and concern regarding potential fraud ("you will be scammed if you click on it"), and N12's doubt regarding the accuracy of information ("it's a mix of truth and falsehood, so it's better to go to the hospital") illustrated the spillover effect of stereotype threat; anxiety consistently undermined trust in technology, even when detached from specific contexts.

Theme 3: Being a Target of Ageism

PE: Lack of Appropriate Health Information

Systematically disregarding the cognitive traits of older adults resulted in ineffective health content. N3 indicated that "the software content (in the software) is too difficult to understand… too technical and hard to remember," while N4 complained that "the content is too technical." These perceptions indicate a failure in information design to accommodate age-related changes in cognitive processing, such as declines in working memory capacity, thereby reducing the perceived usefulness and accessibility of the information provided. N5 revealed deceptive advertising ("the recommended products claim to lower blood sugar, but there is no scientific basis for this"), which decreased trust in technology and highlighted the exploitation of older adults for profit.

EE: The Absence of Age-Friendly Design

There were considerable age-related deficiencies in interface interaction. N4 emphasized the lack of physiological adaptation, stating that "There is no version specifically designed for the elderly... the font should be enlarged." N8 emphasized the necessity for multimodal requirements, asserting that "the voice version should be directly audible." N9 criticized the "cumbersome operations and unfriendly interface," specifically highlighting the design issue of prioritizing "technology-centric" over "user-centric" in product development. The lack of age-appropriate design increased the learning burden for older adults and reduced the user experience.

SI: Disruption of Systemic Support

The intergenerational influence within families significantly impacted technology usage. N1 was designated as "specialized in buying fake medicine" and prohibited from using mHealth apps, while N4 encountered limitations due to his children's concerns regarding possible financial exploitation, demonstrating that protective measures resulted in technological deprivation.

The health care system offered minimal professional support. N10 noted, "The medical staff didn't mention it and told me to go to the hospital," whereas N1 stated, "Sometimes when I ask them, they get a little impatient."

FC: Imbalance in the Allocation of Resources

Public health education resources were insufficiently integrated into digital platforms. The lack of resources intensified the technological marginalization of older adults. Some older adults exhibited confidence in official information sources and a desire to gain knowledge.

XSL•FO
RenderX

There are no such platforms available on a regular basis, so I don't know what software is available or which software is suitable for us. Apart from what the nurses at the hospital recommend, I don't know anything else. [N8]

Because we are older and our health is not very good, we tend to have relatively limited access to information. [N9]

PR: Information Leakage and Lack of Trust

Older adults often mentioned challenges associated with breaches of personal information, excessive promotional communications, and misleading marketing practices from unregistered medical institutions.

I don't know how they got my personal information. Many "doctors" send me text messages. [N10]

They recommend products that claim to cure diabetes, but that's a scam… We also try to verify the authenticity of such information. [N8]

There are too many scams… They tried to sell me health supplements, so I just deleted the messages. [N11]

Discussion

Principal Findings

This study examined the ageism encountered by older adults in the community while using mHealth apps and the mechanisms through which it impacts them. The primary findings indicate that ageism obstructs the adoption and utilization of mHealth apps via 3 principal pathways of the RAM model: Stereotype internalization in older adults leads to the attribution of operational difficulties to aging, resulting in a self-perception of technological incompetence. This perception diminishes their acknowledgment of the benefits of mHealth and establishes a challenging learning threshold to surpass. Stereotype threat induces anxiety avoidance, characterized by fears of privacy breaches, worries regarding operational failures, and excessive protection or negative feedback from family members. These factors collectively result in the active avoidance of technology exploration and usage. External unfair treatment, evident in age-inappropriate design flaws in apps, including complex interfaces, limited information availability, and insufficient support systems, creates barriers to usage and diminishes the perceived value of these apps. Research indicates that ageism operates at various levels, including individual cognition, social interaction, and the technological environment, creating substantial barriers that impede older adults' integration into digital health.

Reconstructing Digital Health Cognition in Older Adults: A Dual-Pathway Intervention to Enhance mHealth App Usage Effectiveness

Older adults typically internalize the stereotype that "age dictates technological ability." This belief leads to attributing operational failures to age, avoiding the learning of new technologies, and concerns about inconveniencing others. Consequently, this significantly diminishes their willingness to use mHealth apps and undermines their sense of self-efficacy [32]. This cognitive pattern establishes obstacles in 3 dimensions—PE (diminished perceived health value), EE (reduced learning motivation), and FC (increased perceived learning costs)—illustrating the self-fulfilling prophecy of stereotype threat within the RAM model [33-35], thereby compromising well-being and impacting physical health [36]. Interventions should implement a dual approach to address this phenomenon. Positive narratives should be employed to highlight success stories among peers, such as in chronic disease management, underscoring that proficiency with technology is contingent upon practice rather than age, while minimizing the notion of "technological disadvantage." Meanwhile, an educational approach characterized by "low threshold+high feedback" should be adopted. This involves deconstructing essential functions, such as blood pressure monitoring and medication reminders, while offering voice navigation and immediate feedback to build successful experiences, improve self-efficacy, and encourage proactive health behaviors [37].

From Substitution to Empowerment: Developing a Novel Paradigm for Digital Health Support for Older Adults

Research indicates that benevolent ageism, characterized by overprotective family members and insufficient support from medical personnel, exacerbates older individuals' perceptions of incompetence [16]. The original intention may be to protect older adults; however, it implicitly stereotypes them as deficient in information, judgment, and technical skills, thereby diminishing their willingness to utilize mHealth apps [17,18]. This discrimination establishes a vicious cycle of "external rejection-self-rejection-behavioral withdrawal" through the "being a target of ageism" path in the RAM model and the "social influence" dimension in the UTAUT model. Studies indicate that the advice and trust that kids give notably affect older adults' willingness to adopt technology, while positive interactions between generations may improve perceptions of aging [38], Studies indicate that the advice and trust that kids give notably affect older adults' willingness to adopt technology, while positive interactions between generations may improve perceptions of aging [39]. Digital reverse mentoring should be promoted to enhance older adults' information literacy, while improving medical staff's negative perceptions of older adults [40]. The objective is to shift the support framework from "substitution" to "empowerment and accompaniment," motivating older adults to assume control over device operation, acknowledging their advancements promptly, eliminating their self-perception as "technologically disadvantaged," and enhancing their sense of worth as participants to digital health.

Eliminating Invisible Technological Barriers: A Dual-Path Approach to Aging-Friendly Design and Risk Prevention in mHealth Apps

Research indicates that only 40% of mHealth apps incorporate older adults in the design process [41], and challenges such as intricate interfaces, superfluous operations, and insufficient information availability highlight invisible ageism at the technology level. Analysis based on the UTAUT model: in the EE dimension, design deficiencies such as small font sizes and

XSL•FO
RenderX

poor-quality push notifications elevate learning costs [42]; in the PE dimension, an overabundance of technical terms and insufficient personalized guidance diminish perceived utility [43]; in the PR dimension, apprehensions regarding privacy breaches and misleading advertisements undermine usage intentions [44,45], all of which exacerbate older adults' self-perceptions of technological discrimination [41,46]. We advocate adopting a dual-faceted strategy: in terms of technology, implement age-appropriate features such as adjustable font sizes and voice navigation [47], create specialized and accessible health information [48], and engage older adults in the initial design stages to mitigate stereotypes [41]. In terms of risk prevention and control, establish data protection methods to eliminate hazardous information [49], while strengthening governmental regulation to create a trustworthy environment. By systematically optimizing design and management processes, obstacles to utilization by older adults can be efficiently reduced, consequently enhancing digital health inclusivity.

Multistakeholder Collaborative Empowerment: Constructing a Social Support System for Older Adults' Digital Health

Findings indicate that older adults frequently avoid engaging with mHealth apps due to a lack of informational resources and prevailing stereotypes (eg, "incapable of learning," "poor judgment") [50], which results in a diminished perception of resource support in the FC dimension. A multitiered support network is essential: medical institutions should incorporate mHealth guidance into health management services, and medical staff must acquire aging-friendly instructional skills to establish trust through recommendations from authoritative institutions. Research indicates that 55.5% of older internet users have encountered online risks [51], while also demonstrating significant vigilance [52]. Governments need to encourage platforms to enhance the digital environment, optimize recommendation algorithms, and implement antifraud training to bolster information discrimination capabilities. Through the combination of professional support from the medical system and social risk prevention and control, it is feasible to address older adults' demand for authoritative information while mitigating digital risks. This approach enhances the perceived benefits of mHealth apps and promotes healthy aging.

This study systematically elucidates the psychosocial mechanisms by which age discrimination affects older adults' adoption of mHealth apps, integrating and extending the UTAUT and RAM models. This study extends the application of the UTAUT model, confirming its efficacy and potential as a qualitative research framework for examining the subjective experiences of older adults. The integration of the RAM model with UTAUT elucidates the impact of ageism's psychosocial mechanisms on critical aspects of technology acceptance, providing fresh insights into the digital health barriers faced by older adults. These findings have practical implications for improving the delivery of digital health services in the communities and hospitals of Shanghai. Community health promotion activities must challenge stereotypes regarding older adults, enhancing their confidence through peer modeling and prompt feedback. Second, families and health care institutions ought to transition from "substitute operation" to "empowering accompaniment," thereby reducing psychological barriers through enhanced communication and initial guidance. Ultimately, the optimization of technology and services should be closely aligned with distinct user requirements, including interface complexity, information credibility, and the availability of continuous support.

Limitations

First, the sample size of this qualitative study is relatively small. Although small, the sample has reached theoretical saturation, meaning that adding more participants is unlikely to yield new insights. The current sample is drawn exclusively from a single community in Shanghai, which may introduce geographical and cultural biases that limit the generalizability of the findings. Second, despite using purposive sampling, selection bias may still be present, as participants who are more positive or more persistent in their usage of mHealth apps are more likely to participate. To mitigate this effect, we deliberately recruited participants who reported lower levels of mHealth apps usage. Additionally, the study was limited to older adults living in the community and did not include older adults in institutions such as nursing homes, which may have overlooked the experiences of ageism among more vulnerable groups. Therefore, future studies should include a broader population for comparative analysis to gain a more comprehensive understanding of the experiences of ageism in the use of mHealth apps among different groups.

In addition, this study used qualitative research methods, which are inherently subjective. To improve the scientific rigor of our research, we referenced qualitative research quality standards and focused on the following areas: researchers engaged in all interviews, recordings, and transcription processes to establish trust with participants, thereby enhancing credibility. Purposeful sampling was utilized to enhance the transferability of findings, accompanied by comprehensive descriptions of the sample characteristics. To ensure dependability, all interviews were audio-recorded, and comprehensive interview notes, transcripts, and research reflection journals were preserved. To ensure confirmability, 2 researchers performed independent data analyses, sought third-party consensus in cases of discrepancies, and provided organized data to research participants for verification. Although we used rigorous qualitative analysis to minimize bias, incorporating quantitative methods could provide more objective data, thereby improving the credibility and scientific rigor of the results. Future studies should adopt a mixed-method approach, combining qualitative and quantitative data to gain a more comprehensive understanding, provide objective indicators to enhance the reliability of the research results, and quantify the impact of ageism on the usage of mHealth apps. Finally, the duration of this study may limit our ability to track long-term changes in older adults' experiences of ageism. Future studies should include long-term follow-up to assess the temporal changes in ageism experiences and technology acceptance behavior, thereby providing more comprehensive insights and practical guidance for intervention design.

XSL•FO
RenderX

Conclusions

In this study, based on the extended UTAUT and RAM models, we identified 3 significant issues related to ageism in the usage of mHealth apps among older adults in the community: internalized stereotypes, benevolent ageism, and aging-friendly design flaws. We propose intervention strategies throughout 4 dimensions: psychological cognition, support systems, technological optimization, and social networks. This research is confined to a singular community sample located in Shanghai. Future studies should enhance the geographical and cultural diversity of the sample, implement longitudinal tracking and quantitative methods, and perform comprehensive research on the causal relationship between ageism and mHealth apps usage behavior to establish a foundation for creating an inclusive digital health environment.

Abstract

Background: Sarcopenia, the age-related decline in muscle mass and strength, poses a significant threat to functional independence in older adults. Despite strong evidence supporting resistance training as a preventive and therapeutic strategy, adherence to muscle-strengthening guidelines remains low. Mobile health (mHealth) technologies offer a promising avenue to bridge this gap; however, few apps are tailored to older adults or designed with their input.

Objective: This study aimed to identify key features that a muscle-strengthening exercise app should include to enhance engagement and uptake among older adults. Secondary aims were to explore perceived barriers and facilitators to app use and to inform the development of an evidence-based, co-designed mHealth intervention.

Methods: We used a qualitative co-design approach, involving 4 focus groups with 18 older adults (aged 60-83 years); each group comprised 3 to 6 older adults, stratified by experience with mHealth apps. Sessions were conducted online via Microsoft Teams and guided by a semistructured protocol informed by prior mHealth research and behavior change theory. Transcripts were analyzed using deductive thematic analysis, underpinned by the Technology Acceptance Model, focusing on perceived usefulness and perceived ease of use.

Results: A total of 4 overarching themes and 10 subthemes were identified. Theme 1, mHealth as a tool for supporting health and well-being, highlighted participants' recognition of digital tools in promoting activity and overcoming accessibility barriers. Theme 2, motivation and engagement through app features, revealed the importance of reminders, progress tracking, and feedback, although views on gamification were mixed. Theme 3, drawbacks of current mobile apps, captured concerns around complexity, poor usability, and lack of age-appropriate content, with skepticism regarding safety and evidence base. Theme 4, desired app elements and features, emphasized the need for customizable reminders, clear instructional videos, adaptable exercise options, and optional social features. Participants stressed the importance of simplicity, personalization, and relatable content to foster trust and sustained engagement.

Conclusions: Older adults are receptive to mHealth interventions for muscle-strengthening when design is user centered and grounded in their lived experiences. This study provides a framework for future app development, highlighting the need for intuitive interfaces, personalized features, and credible educational content. By aligning design with Technology Acceptance Model constructs and co-design principles, mHealth apps can better support healthy aging and sarcopenia prevention. These findings offer actionable guidance for developers and researchers aiming to enhance digital health equity and effectiveness in older populations.

Introduction

Background

Aging is a universal phenomenon, and in recent years, the global population has aged at an unprecedented rate [1]. Projections indicate that by 2050, 22% of the world's population will be aged 65 years or older [1]. Aging brings several health challenges, including increased risks of dementia and cognitive impairment, elevated blood pressure, heart disease, and diabetes mellitus [2,3]. These health issues significantly impact the ability of older adults to perform daily activities. For example, cardiovascular issues experienced in older age can lead to fatigue and shortness of breath, making everyday tasks difficult and in turn setting off a cascade of inactivity [4]. Diabetes can lead to peripheral neuropathy, vision loss, and fatigue in older adults, in turn impacting balance, fine motor tasks, driving, reading, and cooking [5]. Consequently, health and well-being have become priority areas, as reflected in the United Nations Sustainable Development Goals, particularly the goal of ensuring healthy lives and well-being for all ages [6].

One key age-related health issue is sarcopenia, which is defined as the progressive deterioration of muscle mass and strength [7,8]. This phenomenon occurs with age as type II muscle fibres and satellite cells decline, which are crucial for muscle repair [9]. Furthermore, aging causes mitochondrial dysfunction, meaning energy production in the muscle is reduced and atrophy occurs [10]. Factors such as neuromuscular decline and reduced physical activity (PA) also play a role in accelerating the onset of sarcopenia [11]. Maximum strength capacity is reached in the third decade of life, but by the time humans reach their 50s, a steady decline has already begun [12]. Reviews of skeletal muscle aging show that the trajectory and magnitude of muscle aging differ by sex, implying women may experience some aspects of functional decline earlier [13]. Indeed, it is suggested that sarcopenia has its roots in middle age [14,15]. After age 50 years, adults lose between 5% and 10% of muscle mass per decade; given muscle mass accounts for up to 60% of body mass, this loss can exert profound effects on functional independence [16]. Sarcopenia is heavily associated with several comorbidities such as diabetes, heart disease, and obesity, as well as leading to difficulties in performing activities of daily living [17].

Existing evidence points to exercise [18-22], specifically muscle-strengthening exercise, [23-25]. Kanda et al [26] demonstrated a 12-week bodyweight resistance training program undertaken twice weekly. Participants completed 2 sets of 6 exercises (targeting thighs, lower legs, buttocks, abdomen, chest, and back) for 8 repetitions (the extremities were elevated for 3 seconds and then lowered for 3 seconds), with the sets separated by 1-minute breaks. Findings demonstrated positive effects on lower limb muscle strength in a cohort of 97 participants aged 65 years or older. Muscle plasticity is well known to persist even into the ninth decade of life, as demonstrated by Wilkinson et al [27]. Despite this, guidelines for muscle-strengthening among older adults are rarely met. According to Scottish health survey data, 14% of adults aged 75 years or older complete this exercise regularly [28]. These figures are similarly reflected across the United Kingdom (17% of men and 14% of women) [29] and the United States (22% of men and 17% of women) [30].

A potential route for bridging this muscle-strengthening gap in older adults is by harnessing digital technology [31]. One particularly promising avenue is mobile health (mHealth), which incorporates mobile apps. Approximately 90% of older adults own a laptop or computer, and in the United Kingdom, approximately 70% of people aged 60 years or older own a smartphone (approximately 67% worldwide) [32]. This indicates that older adults are increasingly digitally literate [32]. mHealth can leverage features such as push notifications, daily reminders, support, and feedback [33-36]. The capability for mHealth to deliver interventions remotely is particularly beneficial for older adults, enhancing the acceptability, efficacy, and sustainability of exercise interventions within this age group [37]. The use of mHealth represents a potentially scalable, accessible delivery mechanism that can support, augment, and reinforce muscle-strengthening behaviors when appropriately designed [38]. Using mHealth as a delivery mechanism can overcome well-documented barriers to engagement in muscle-strengthening exercise among older adults, such as access to facilities, tailored guidance, and financial barriers [39]. When grounded in behavioral theory and co-designed with older adults, mHealth interventions may offer a pragmatic means of supporting self-monitoring, motivation, and adherence, which are all critical to sustained exercise engagement. Furthermore, modern cross-platform frameworks support multiple device types (eg, smartphones, tablets, personal computers, and other web-enabled platforms such as televisions). This enables access via devices that align with preferences and existing digital practices. This reduces the risk of digital exclusion, broadens reach, and helps overcome key accessibility barriers associated with device-specific mHealth apps. However, a recent scoping review concluded there was a lack of mHealth interventions focusing on muscle-strengthening for older adults, and more research is needed to refine these approaches [40]. Furthermore, there is currently no evidence-based framework to guide the design, development, and deployment of mobile technology in older adults relating to PA or exercise [41]. Without this valuable framework, mHealth interventions in older adults could encounter unintentional barriers that may impact efficacy [42]. Of more than 350,000 health-related apps on the market [43], fewer than 2000 are designed specifically for older adults [41]. Among those, few are evidence-based or involved older adults in their design and development, and given the potential of

XSL•FO
RenderX

mHealth interventions, it is prudent that further research develops a key framework to ensure future interventions are deployed effectively.

Aims and Objectives

To address these gaps, this study represents the initial phase of a broader co-design process aimed at developing an evidence-based mHealth intervention for older adults. Co-design refers to the active involvement of end users in the creation of interventions or products and is often an approach taken in mHealth development [44]. It frequently involves focus groups, interviews, and surveys [45]. The main aim of this study was to identify key features that a muscle-strengthening exercise app should contain to enhance engagement and uptake among older adults. Secondary aims were to understand limitations of existing health apps to inform the development of a more effective app for older populations that addresses these limitations and enhances engagement. This workstream was aligned with Phase 1 ("Predesign") of the co-design framework adapted from that described by Noorbergen et al [46].

Our specific research questions were:

- What do older adults perceive as positive aspects of current mobile apps?
- What do older adults perceive as barriers to current mobile apps?
- What features and considerations should a mobile app centered on exercise for older adults include?

In line with previous co-design approaches [47,48], the study conducted 4 co-design focus groups with older adults in groups of 6 to 8 participants, each lasting 40 to 80 minutes. The sessions were informed by a guided topic list that asked questions on general design preferences for an app interface as well as specific features of previous mHealth interventions and how these can be leveraged appropriately for older adults.

Methods

Overview

The study was preregistered on the Open Science Framework. Throughout the study, the COREQ (Consolidated Criteria for Reporting Qualitative Research) guidelines were adhered to [49].

Co-Design Workflow

The study used a co-design methodology. Co-design refers to "the creativity of designers and people not trained in design, working collaboratively in the design and development process"[44]. It is a process in which researchers and stakeholders work together, focusing on incorporating end-user input into the design to ensure usability, relevance, and accessibility [44,50]. Older adult participants were involved in identifying key problems in current mHealth approaches, prioritizing app features, and refining concepts through structured group discussions and visual design prompts. Participants were encouraged to critique existing app features, propose alternatives, and discuss trade-offs of competing design options, with the aim of designing a suitable app for delivering muscle-strengthening exercise. Problem framing was achieved through older adults identifying barriers to mHealth engagement, which informed feature prioritization through consensus-building discussions. Visual design prompts were used during relevant discussions to allow participants to visualize specific features, garner discussion, and collectively refine concepts in real time. The workflow comprised 5 main stages.

Stage 1: Preparatory Work and Recruitment

Initial preparatory work involved identifying the evidence-based mHealth features and behavior change techniques from previous app approaches and existing literature. Older adult participants with varying levels of experience with mHealth and general apps were recruited to offer diverse perspectives.

Stage 2: Problem Framing

In the early portion of the co-design focus group discussions, participants actively shaped the problem space by discussing physical, motivational, technological, and contextual challenges relevant to aging that prevent engagement with both apps and muscle-strengthening exercise.

Stage 3: Feature Prioritization

Participants critiqued current approaches, proposed alternative solutions, and discussed the trade-offs between usability, personalization, and engagement.

Stage 4: Concept Refinement

Participants helped to refine proposed app concepts by suggesting changes to interface layout, notifications, app messaging content, notification timing, feedback mechanisms, and exercise delivery.

Stage 5: Information Gathering and Translation

Following the data collection stages indicated above, findings were deductively thematically analyzed and used to shape a concrete app prototype. Insights were mapped directly to design requirements, ensuring the prototype reflected the priorities highlighted by participants. Furthermore, recommendations were established to guide future mHealth exercise intervention development for older adults.

Study Setting and Procedures

Demographic data including, name, age, sex, occupation, education, smartphone use per day, and self-reported digital skill level were collected from participants (Table 1). A total of 2 email reminders were sent to participants prior to the focus group sessions. Four focus group sessions were completed: 2 sessions with older adults who had experience using mHealth apps and 2 focus groups with older adults without experience using mHealth apps. Co-design focus groups were chosen as the desired data collection method because they help leverage group dynamics and offer insights into shared perspectives, encouraging open discussion, which can lead to a rich qualitative dataset [51]. Each focus group session lasted approximately 40 to 80 minutes and began with an introduction to the study's purpose and the ground rules of the session. Time was then given to allow each participant to unmute themselves and give a short introduction to the group. Four focus groups were deemed sufficient because previous systematic reviews have

XSL•FO
RenderX

shown that 4 sessions typically reach saturation when addressing well-defined topics in a structured format [52].

Table 1. Participant information.

Participant	Sex	Age (years)	Occupation	Education (ISCED[a] [53])	Smartphone use per day	Self-reported digital skill level

[a]ISCED: International Standard Classification of Education.

[b]NHS: National Health Service.

There were 2 semistructured focus group protocols, 1 for the experienced groups and 1 for the inexperienced groups (Multimedia Appendices 1 and 2). The protocol itself included 7 different topics (6 for experienced participants and 7 for inexperienced participants), and each topic comprised 2 to 4 questions. The inexperienced protocol included an additional topic on privacy and data sharing to delve deeper into participants' apprehensions regarding using mHealth technology. The topics were developed based on previous mHealth intervention features [35] and consultation of the Behavior Change Technique Taxonomy version 1 (BCTTv1) [54] to gain an understanding of perceptions of common mobile app features and behavior change techniques to take forward into the development of a muscle-strengthening app. The sessions facilitated discussions using PowerPoint (Microsoft Corp) slides with images relating to app features and design, allowing participants to visualize how the app interface may look and how specific features may function within it. This resource is provided in Multimedia Appendix 3.

Research Team and Reflexivity

All focus group discussions were designed and carried out by the lead investigator of the study (ECJB). Prior consultation with the wider research team took place to ensure all members were satisfied with the focus group structure and content. Participants in each session included some individuals who were previously known to the investigator from previous research projects, and all were made aware of the broader purpose of the study. The investigator was a novice qualitative researcher with greater expertise in quantitative methods.

Participants and Recruitment

Participants were recruited using a combination of methods. Emails were sent to control group participants of previous studies conducted by the research team who had consented to be contacted for future studies. The Men's Sheds organization, the University of the Third Age (U3A), and the LEAP project were contacted to ascertain interest. These organizations fundamentally exist for older adults and work in proximity to the target population and, as such, were seen as appropriate contacts. Further recruitment was conducted through social media advertising.

To be included, participants had to meet the following criteria (1) be English speaking, (2) community dwelling (not residing in a skilled nursing facility), (3) aged 60 years or older, (4) have access to a mobile device capable of downloading apps, and (5) have access to a device capable of accessing the Microsoft Teams software and understand how to use the platform. Participants were asked prior to recruitment whether they were experienced or inexperienced with mHealth or exercise apps.

XSL•FO
RenderX

We aimed to recruit approximately 20 older adults, as this number allowed us to have 6 to 10 participants in each focus group, which facilitates good discussion in which all participants can contribute. The final number of participants included was 18; a total of 2 participants withdrew because the study timeline did not align with their personal schedules. Of the 18 participants included, 9 had experience with mHealth or exercise apps and 9 had no experience. Inexperienced participants were included to ensure a highly inclusive and informed design process, with the view to increasing scalability.

Data Collection

Each focus group session lasted approximately 40 to 80 minutes. Initially, the ground rules of the session were outlined. Each participant was asked to provide verbal consent for the session to be recorded. Each session was recorded, and raw transcripts were produced. The lead investigator checked transcripts for accuracy, grammar, and spelling. A clean verbatim approach to transcription was selected to balance accuracy with clarity by capturing the essential meaning of participants' words while omitting unnecessary filler words, false starts, and stutters. This approach has been previously justified within focus group literature as an ideal method to ensure richness of the discussion is captured while removing excerpts that may make the transcript difficult to read [55]. Finalized transcripts were distributed to participants for member checking. All participants agreed that the transcript was an accurate depiction.

Data Analysis

All data collection and analysis were conducted by the lead investigator (ECJB) with guidance from the wider research team. Once transcribed and validated, deductive thematic analysis was undertaken to generate themes and gain an understanding of the data [56]. As part of the analysis the Technology Acceptance Model (TAM) [57] was used as the theoretical framework to guide coding and development of themes. The TAM is a widely used framework that explains how users adopt and use technology. It suggests that 2 key factors influence technology acceptance: perceived usefulness, defined as the extent to which a person believes a piece of technology will benefit them; and perceived ease of use, defined as the degree to which a person believes that using the system will be free from effort [57].

Thematic analysis followed Braun and Clarke's [56,58] 6-phase framework. To operationalize the TAM within the thematic analysis approach, participants' language was first coded inductively at the semantic level to ensure the codes remained grounded in their experiences and meaning. A deductive, theory-driven coding approach was then used, guided by the TAM and the study's research questions, by mapping the codes onto the TAM constructs. Semantic coding focused on surface-level meanings to remain close to participants' language and experiences. Codes reflecting perceived benefits, value, or relevance to participants' health were grouped under the first main construct, perceived usefulness, while codes relating to effort, complexity, navigation, and usability were grouped under the second main construct, perceived ease of use. This allowed for the development of key themes grounded in the TAM. This 2-step process ensured participants' language informed the analysis prior to interpretation and meant the TAM functioned as an organizing framework. This approach was appropriate given the aim to identify app features, barriers, and facilitators relevant to older adults. The analysis revealed positive aspects of current apps, limitations affecting mHealth uptake, and key design considerations to enhance usability. These insights directly informed the app refinement phase, ensuring alignment with older adults' preferences and needs. Finally, the report was written to present a coherent narrative linking the themes to TAM and the study aims.

Ethical Considerations

Upon expression of interest, participant information documents were shared. Participants were given the opportunity to ask any additional questions for clarity before agreeing to participate. Electronic consent forms were completed prior to the focus groups. Participants were then given details of the focus group (date and time) and emailed a meeting link along with telephone instructions on how to access the Microsoft Teams session. During the session, participants were allowed technical support from a family member or friend.

The focus groups were completed on Microsoft Teams for participant convenience; this also allowed a broader geographical sample. Participants joined the Teams session using the meeting link that had been emailed to them previously and using their own smartphone, tablet, laptop, or computer device. Each participant was asked to provide verbal consent for the session to be recorded for subsequent thematic analysis. Participants were not provided with any financial or other form of compensation for their participation. All data were treated confidentially and anonymized using participant identification numbers. Focus groups were video recorded online (with all participants' permission) to facilitate subsequent thematic analysis. Recordings and associated data were stored on password-protected computers available only to the principal investigator (ECJB).

This study was carried out in accordance with the Declaration of Helsinki and approved by the University of the West of Scotland Health and Life Sciences Academic Integrity and Ethics Committee (approval number 22512).

Results

Overview

A total of 4 main themes were identified from the analysis, with several subthemes (Table 2). These themes encompass the previous lived experience of participants with mHealth technology, areas in which participants have struggled with engagement, and key considerations to take forward to enhance usability and intervention effectiveness. Full excerpts from focus group discussions are included in Multimedia Appendix 4.

XSL•FO
RenderX

Table 2. Four main themes and the corresponding subthemes derived from thematic analysis.

Theme	Subtheme
Theme 1: mHealth[a] as a tool for supporting health and well-being	• Overcoming barriers to accessibility • Potential for educational support via mHealth
Theme 2: motivation and engagement through app features	• Progress tracking as a source of motivation • Rewards and streaks as reinforcement
Theme 3: drawbacks of current mobile apps	• Complexity and poor usability • Skepticism over effectiveness, safety, and evidence base
Theme 4: desired app elements and features	• Customizable reminders • Clear video demonstrations of muscle-strengthening exercise • Customizable exercise options and feedback • Preferences regarding social features of mHealth

[a]mHealth: mobile health.

Theme 1: mHealth as a Tool for Supporting Health and Well-Being

This theme encapsulates participants perceptions of mHealth to support health and well-being in their daily lives. Across both experienced and inexperienced users, mHealth technologies were understood to be mechanisms that help promote health behavior through increasing awareness, providing feedback, and prompting action.

Participants who were experienced with mobile technology drew upon their experiences of mHealth promoting activity via push notifications and how advanced features support them during exercise. Experienced participants highlighted that feedback mechanisms and prompts help to break long bouts of sedentary behavior and regulate activity, as one participant noted:

> *A part of my app. It tells you if you've been sat for a long time and it just basically says maybe it's time to get up and move.* [Participant 6]

These features were perceived as highly important in the context of aging, where participants noticed a steady decline in their own activity and had a desire to maintain functional independence.

Instant feedback features such as heart rate and activity summaries were described as reassuring, motivating, and a useful mechanism for tracking exercise effort and intensity with greater confidence. The theme highlights a broader understanding, primarily among experienced participants, of their own deterioration during the aging process and that mHealth interventions may encourage them to participate in exercise, which would attenuate their decline.

This first theme led to the development of the subtheme, overcoming barriers to accessibility. The subtheme broadens understanding of the challenges older adult participants have faced in relation to muscle-strengthening exercise, namely physical and financial limitations. Participants identified digital resources as a means of overcoming these barriers. One participant noted:

> *I used to go to YouTube. I've discovered fabulous 50s. For people who are over 50 and then it's just as a range of different exercises, you know, usually they're just walking included in it, and it means you can do it in the house or whatever.* [Participant 8]

Furthermore, an experienced participant reflected that an app aid accessibility by stating:

> *Rather than expecting people to have, you know, weight sets or whatever get, you know, used items that people have readily accessible round their houses.* [Participant 1]

A further subtheme identified in relation to Theme 1 was the potential for educational support via mHealth. Participants consistently emphasized the potential for mHealth technologies to provide educational support related to exercise benefits, technique, and progression. Experienced participants drew upon the self-quantifying nature of digital exercise tools, acknowledging the empowerment of personal metrics, which encouraged continued engagement. Participants highlighted the value of clear guidance to support learning at their own pace:

> *I've not got the sort of strength that I probably want to have and just want to sort of educate myself into what the next steps could be just to sort of bring myself on.* [Participant 4]

This subtheme highlights the understanding that this technology has the potential to educate older adults on muscle-strengthening exercise.

Theme 2: Motivation and Engagement Through App Features

This theme captures how mHealth features were perceived to influence motivation, routine development, and sustained engagement with exercise behavior. Participants described how features such as prompts, feedback, and reinforcement mechanisms supported adherence by fostering accountability and a sense of progress.

Participants drew upon familiar examples from fitness apps that use nudge reminders to increase engagement. Similarly, experienced participants highlighted the benefit of wearable and app technologies that use haptic nudges to prompt users to

XSL•FO
RenderX

break up sedentary time and send motivational messages to urge users to meet step goals. These features were perceived as supportive, with one participant stating:

> *That's what I like about it. I just realised I got a reminder today that I haven't done my third run of the week, so that's good.* [Participant 3]

Personalized feedback on goal progression was also viewed as central to maintaining engagement.

A subtheme generated from Theme 2 was progress tracking as a source of motivation. This subtheme identified motivators and features that engage participants, such as the ability to track their progress. Participants highlighted that tracking their own progress when working toward an activity goal and recording improvements motivated and encouraged them to continue. Inexperienced participants highlighted that progress tracking could provide reassurance and validation.

A final subtheme developed as part of Theme 2 was rewards and streaks as reinforcement. This subtheme encapsulates experienced participants' thoughts, feelings, and encounters with reward systems (ie, gamification systems). Participants expressed mixed views, highlighting a clear trade-off between motivation and engagement. For some experienced participants, rewards such as badges, medals, and streaks were described as powerful motivators for sustained engagement:

> *I got fanatical about continuing my streak.* [Participant 12]

In contrast, those who had little experience with these features viewed the prospect of gamification as childish and condescending. These participants felt that simplistic rewards such as badges undermined autonomy and preferred personalized meaningful feedback linked to functional improvement. This highlights the challenge of designing engagement features that accommodate varying levels of digital familiarity and differing motivational preferences.

Theme 3: Drawbacks of Current Mobile Apps

The third theme reinforced the key issues that older adults face when engaging with mobile apps. Across both experienced and inexperienced users, drawbacks were not described as isolated issues but as indicators that mobile apps in their current form are inadequately designed for older adults' needs and priorities. Participants highlighted a general reluctance to input personal information, reflecting broader concerns around privacy and emotional burden of mHealth. Some participants described negative experiences with continuous monitoring devices, such as sleep tracking, which were perceived to exacerbate anxiety rather support well-being:

> *I've got a problem with sleep trackers from work perspective. They induce more anxiety than they help to be perfectly honest.* [Participant 10]

These sentiments highlight broader skepticism among participants about whether app engagement would meaningfully enhance health. Mainly inexperienced participants also felt that existing apps lacked relevance for older adults. Current apps were described as cluttered and filled with unnecessary features, creating confusion and discouraging sustained use. Several participants noted that while health and fitness apps appear abundant, those targeting muscle strength while also catering to age-related needs are scarce, further highlighting the accessibility gap between older adults and app design.

A subtheme that subsequently developed was complexity and poor usability. This subtheme explored specific difficulties participants encountered when engaging with mobile apps. Experienced participants described current fitness apps as being overcomplicated and overloaded with information, which they found hard to understand. Inexperienced participants felt that even when they have attempted to use currently available apps, they found them time-consuming and burdensome. Older adults indicated that simplicity was key and expressed a preference to engage only with activities and information that were personally relevant. Interestingly, even those who self-identified as digitally competent felt that current exercise apps were complex and difficult to use effectively without becoming overloaded with information.

A further subtheme that developed was skepticism regarding effectiveness, safety, and evidence base. Participants expressed widespread skepticism regarding the effectiveness and safety of current exercise apps, particularly for older adults with musculoskeletal and chronic conditions, such as sarcopenia. Despite recognizing the importance of strength training, sometimes informed by professional health care practice (eg, nursing), some participants questioned whether current apps were evidence-based or capable of safely supporting strength improvements. Concerns were also raised about the credibility of online exercise content. As one participant noted:

> *Now I look at a lot of videos and I think these people are promoting that and it's dangerous things they are doing, you know, when they're promoting it for older folk.* [Participant 17]

These concerns contributed to hesitation around adoption and highlighted the importance of clinical credibility and age-appropriate design in future mHealth interventions.

Theme 4: Desired App Elements and Features

The final theme identified was desired app elements and features. This theme was developed in conjunction with the positive and negative aspects of current mobile apps. It synthesizes participants' perspectives on how mHealth interventions should be designed to support sustained engagement and safety among older adults. Rather than describing isolated feature requests, participants articulated broader design priorities centered on simplicity, autonomy, and relevance to older adults' needs.

Participants consistently emphasized the importance of simple interface design. Features such as clear navigation, high-contrast colors, and adjustable font sizes were described as essential for reducing cognitive load. Participants described positive experiences with apps and websites that prioritized clarity over complexity, reinforcing the need to accommodate age-related sensory decline. One participant noted:

> *Some of them are better than others, you know, and most of them are kind of intuitively simplistic. So*

XSL•FO
RenderX

probably like those, not too busy and easy to follow. Is the kind of rule of thumb. [Participant 10]

A subtheme that developed in conjunction with Theme 4 was customizable reminders. Personalization emerged as a central mechanism for supporting sustained engagement. Participants described a strong preference for control over reminder frequency and timing, highlighting the importance of aligning prompts with individual routines. The timing of notifications was encapsulated within this subtheme, with many experienced and inexperienced participants stating that a reminder in the morning to engage in exercise would suit their routine. One participant noted that it was important for this reminder to come at the start of a new week. However, counterpoints were raised, with 1 participant stating that they often find their life is busy in the morning and, as such, a reminder later in the afternoon would be beneficial because they would have more time to engage in exercise at this time of day. This subtheme highlights autonomy as a key design principle, with flexibility enabling mHealth interventions to accommodate diverse lifestyles.

A further subtheme generated was clear video demonstrations of muscle-strengthening exercise. When discussing the specific features related to enhancing usability, both experienced and inexperienced participants emphasized a need for clear video demonstrations to improve safety and effectiveness. Some participants highlighted the importance of being able to take the learning process at their own pace and felt it would be useful to have the option of pausing, fast-forwarding, and rewinding a video demonstration to ensure they could adequately perform the exercise. Furthermore, participants who had experience using similar apps for gym-based exercise recalled that being able to click on certain exercises with which they were unfamiliar and access video demonstrations helped them build confidence with the exercise. Additionally, all participants emphasized the ability to resonate with the video demonstrations, suggesting the demonstrator in current available apps is often much younger. The consensus was that if the demonstrator within the videos were an older adult, this would add a sense of realism with which users could relate.

A further subtheme developed in relation to Theme 4 was customizable exercise options and feedback. Autonomy over exercise selection and progression was viewed as essential for maintaining engagement. Participants built on this idea by highlighting that users have a range of preferences for muscle strengthening–based exercise, and allowing them to select the activity may enhance their experience. Discussion developed further to generate the idea of customization to allow users of different abilities to be signposted to exercises appropriate for them. Participants described frustration with one-size-fits-all approaches commonly experienced by older adults in gym and digital environments. A staged structure, such as tiered programs guided by front-loaded questioning, was identified to personalize exercise without requiring users to label or compare themselves to others. Participants noted that inappropriate labeling may negatively impact confidence if their own progression stalled. However, participants appreciated that their app experience would be personal to them and that their individual needs would be catered to.

A final subtheme developed in relation to Theme 4 was preferences regarding social features of mHealth. Discussion surrounded the notion of including social features within the app to allow participants to complete exercise together with family or friends. A few experienced participants underlined that they felt the option to exercise together with peers would enhance their motivation, as they often find it hard to exercise alone. Others felt social features were unnecessary, as they become competitive and distract from the initial goal of encouraging exercise. The general feeling was that having the option to engage in social aspects would be beneficial but should be secondary to encouraging the uptake of strengthening exercise. Insights gathered particularly in this theme directly informed app prototype development, ensuring older adults' identified needs were translated into design features.

Discussion

Overview

The aim of the focus groups was to determine essential features that a muscle-strengthening exercise app should include to improve engagement among older adults. This study examined the limitations of current mHealth apps that hinder effectiveness and contribute to low adoption. During deductive thematic analysis, the research questions were considered alongside the TAM framework, which helped to produce 4 interrelated themes and 10 subthemes. Participants' insights highlighted their nuanced experience of both mHealth technology and muscle-strengthening exercise. The development of these main themes helps to build on broader practical implications and recommendations for the future of muscle-strengthening app development for older adults, contributing to healthy aging.

This manuscript represents a significant contribution to the field of digital health and aging through its originality, significance, and methodological rigor. It introduces a transformative approach by applying a co-design methodology to the development of a muscle-strengthening mHealth intervention for older adults, a population historically underserved in app design. We believe this is the first study to commence co-design of a muscle-strengthening mHealth intervention for older adults. The integration of the TAM into thematic analysis offers a novel theoretical lens for interpreting older adults' engagement with digital exercise tools, advancing conceptual understanding from gerontology to digital health and beyond.

This study's significance lies in its potential to reshape how mHealth interventions are designed and deployed for older populations. By directly involving older adults with varying levels of digital literacy and app experience, the research generates actionable insights that challenge assumptions about usability, motivation, and accessibility. The findings have immediate practical implications for developers, clinicians, and policymakers seeking to address sarcopenia and promote healthy aging through scalable, evidence-based digital solutions. Methodologically, the study demonstrates exceptional rigor. The sampling strategy ensures representation across digital experience levels, and saturation is robustly evidenced. The alignment of findings with TAM constructs provides a coherent

XSL•FO
RenderX

analytical framework, and the study is transparently reported in accordance with the COREQ guidelines.

Theme 1: mHealth as a Tool for Supporting Health and Well-Being

The first theme conveyed participants' views on how mHealth technology can support daily health and well-being. Although direct experience varied across focus groups, participants generally appreciated its potential to encourage healthier behaviors and improve access to PA, particularly muscle-strengthening exercise.

Those with experience described how mHealth guided healthier behavior and increased awareness of health metrics. These findings align with nudge theory, a concept in behavioral economics suggesting that positive reinforcement and indirect suggestions can influence behavior [59]. Nudge theory has been applied in studies using mHealth to promote PA in older adults [60-62]. For example, Yamada et al [61] showed that tablet-based nudges encouraged healthier behaviors in older men. Other research has similarly demonstrated that mHealth features can be leveraged to support health and well-being in older adults. Kwan et al [63] trialed a brisk walking intervention with 33 participants using the Samsung Health app and WhatsApp, delivering programs, reminders, and rewards. The intervention enhanced moderate-to-vigorous PA uptake by 86 minutes per week post intervention, supporting consensus in the literature that mHealth promotes health behavior.

Older adults often face accessibility barriers to exercise [64], a theme echoed by participants. Research has identified extrinsic barriers such as lack of transport, supervision, or facilities, and intrinsic barriers including perceptions of being too old, fatigue, or fear of injury [65]. Numerous studies have shown that digital delivery can help reduce such barriers [66-68]. Sciammana et al [69] delivered a 24-week, 1-minute bodyweight intervention via weekly emails to 24 older adults with a mean age of 71.6 (SD 8.9) years. The findings outlined that 75% of participants completing at least half of the prescribed sessions. Extending such approaches to mHealth, with an evidence-based approach, may allow for enhanced intervention delivery methods and further increase accessibility and adherence in muscle-strengthening contexts.

A further consideration from participants was the suggestion of incorporating household items, such as filled bottles or shopping bags, into mHealth exercise interventions to overcome limited gym access. While this could provide a training stimulus [70], safety concerns arise, as equipment use increases injury risk, especially given that most older adults lack resistance training experience [71,72]. Thus, equipment-free exercises may be more appropriate for mHealth resistance programs in older adult contexts.

Participants also valued the educational potential of mHealth. They emphasized the need for simple apps providing essential information to facilitate muscle-strengthening without unnecessary features. This reflects evidence on the importance of informational support in behavior change interventions for older adults [73,74]. Concerned about age-related muscle loss, participants welcomed resistance training and mHealth initiatives but highlighted a knowledge gap that left them ill-equipped to train independently. Prior research has also identified poor understanding of resistance training's purpose and safe practice among older adults [66]. Despite guidelines recommending twice-weekly strength training [75], messaging is often vague [76]. mHealth could bridge this gap by offering educational support, such as video demonstrations, to enable safe and effective training [40].

Overall, this theme underscores mHealth as a promising avenue for promoting muscle-strengthening behavior change. Participant insights link closely to the construct of perceived usefulness, which remains a strong predictor of mHealth engagement, particularly when technology supports daily life and independence [77].

Theme 2: Motivation and Engagement Through App Features

A crucial determinant of engagement with mHealth among older adults was the presence of motivational app features. Participants consistently discussed elements such as prompts, reminders, and progress feedback, explaining how these supported the integration of health behaviors into daily routines. These features were perceived to provide structure for engaging in PA and other health-related behaviors. Specifically, prompts and reminders acted as "nudges" that encouraged consistent PA engagement and supported long-term behavior change, aligning with broader evidence identifying these functions as key to sustained mHealth use [78,79].

Participants highlighted reminder functions, typically delivered via push notifications, as behavioral cues promoting consistent app use and engagement in health behaviors. These findings correspond with literature demonstrating the effectiveness of prompts for PA promotion, particularly among older adults who benefit from external structure [80,81]. Reminders and reinforcement messages can enhance exercise adherence when they become integrated into users' routines [82,83].

Progress tracking emerged as another major motivator. Both experienced and inexperienced users described viewing their progress over time as encouraging and essential for maintaining motivation. This reflects prior work emphasizing the value of feedback and progress monitoring in behavioral interventions [84]. For instance, Geraedts et al [85] combined wearable sensors and tablet-based strength exercises, enabling participants to view improvements, which enhanced motivation. Such findings relate to the concept of self-quantification, which refers to the practice of methodically collecting, measuring, and analyzing personal data using technology [86], wherein monitoring one's data fosters engagement and motivation [87].

While mHealth interventions targeting aerobic activity benefit from automated data collection via wearables [63,88,89], muscle-strengthening interventions face greater challenges. Accurately capturing resistance or repetitions often requires manual input, increasing user burden. Nonetheless, the motivational benefits of visualizing progress may justify this effort if it enhances adherence [90].

Views on rewards and streaks were mixed. Participants familiar with such features viewed them positively, while inexperienced

XSL•FO
RenderX

users often perceived them as "condescending." Although these negative attitudes may stem from unfamiliarity [91], the literature supports the effectiveness of gamified features, particularly in step-based interventions [92-94]. It may therefore be beneficial to personalize gamification for older adults. Although studies have shown the general benefits of gamification [95-97], these features must be context-sensitive and tailored to older users. Moreover, step-based gamification relies on automated tracking, whereas applying similar approaches to strength training poses technical and usability challenges. Streak-based systems may also risk shifting focus away from meaningful engagement by becoming the main focus of the user rather than the exercise intervention at hand [98].

These findings connect closely with the TAM construct of perceived usefulness, a key predictor of intention to use. The theme encapsulates features that translate app functions into tangible benefits by motivating users to exercise or track health behaviors. When older adults perceive clear value in how an app supports their activity or progress, they are more likely to adopt and sustain its use [99]. Overall, this study highlights the importance of motivational features while urging careful, context-aware integration of gamification in mHealth design for older adults.

Theme 3: Drawbacks of Current Mobile Apps

The third theme highlighted several disadvantages older adults face that hinder uptake and sustained engagement with mHealth technology. Data from this study identified drawbacks such as poor usability, irrelevant content, and doubts regarding safety and effectiveness—issues echoed in the broader literature as key barriers to mHealth adoption among older adults [100]. Participants, particularly those inexperienced with apps, felt current designs often neglect older adults' needs. A perceived lack of personal relevance reduced engagement, consistent with research on the poor alignment between mobile app design and older users [101]. Participants also noted limited accessible options for home-based muscle-strengthening, with most apps failing to account for reduced physical capacity [102]. Moreover, distrust in tracking technologies emerged as a barrier, consistent with existing findings on digital health skepticism in this demographic [103].

Complex app interfaces were another major source of frustration. Even digitally confident participants described current exercise apps as "too advanced" or "overloaded with information." This aligns with evidence identifying cluttered design and poor navigation as key deterrents for older users [101,104]. While design guidance often focuses on elements such as button size, textual and navigational clarity remain neglected [101]. The experiences in this study reinforce the need for simplified navigation, clear signposting, and concise exercise programming to reduce user burden and flatten the learning curve—particularly for those wary of technology [105].

Participants also expressed concerns about safety and effectiveness, particularly for unsupervised, home-based exercise. Many questioned whether current or future apps could ensure correct technique and injury prevention—concerns amplified among those with chronic conditions such as osteoporosis or osteoarthritis. Experienced users further noted the risks of non–evidence-based exercise advice, contrasting such apps with the reassurance of supervised exercise. These concerns, rooted in participants' experiences, align with literature highlighting trust as a critical factor in mHealth adoption [106]. The lack of a transparent evidence base underpinning many apps remains a key limitation [107] and may particularly discourage those with long-term conditions who fear injury [108].

Participants also questioned the credibility of some exercise apps, noting that a lack of visible evidence base or endorsement from recognized organizations undermines trust [42]. The perceived absence of personalization and adaptive programming reinforced the need for tailored content and clear signposting of safe options for older adults.

Negative prior experiences and limited understanding of strength training principles led some participants to doubt apps' ability to accurately track progress. Unlike aerobic activity, which can be easily quantified via automated measures such as step counts or heart rate, tracking strength improvements often requires manual input, increasing user burden [105]. Simplifying self-reporting—for example, logging completed sets rather than repetitions or using automated sensing technologies such as accelerometers—could reduce this burden [109,110]. However, the cost of smart resistance devices poses a scalability issue [111], limiting feasibility given that mHealth interventions are intended to reduce, not increase, costs [112].

Overall, these findings correspond to the TAM constructs of perceived usefulness and perceived ease of use. Apprehension regarding safety, evidence base, and design complexity reduced participants' belief that exercise apps can effectively support health and well-being. Such perceptions lower both perceived usefulness and ease of use—key predictors of technology adoption [113]. Consequently, addressing these design and trust-related drawbacks will be essential to enhance older adults' acceptance and engagement with future mHealth interventions.

Theme 4: Desired App Elements and Features

The final theme highlights actionable recommendations for future mHealth intervention development in older adults, broadening the understanding of muscle-strengthening apps for this population. These findings help direct researchers and app developers to enhance uptake and long-term engagement with muscle-strengthening exercise and broader mHealth interventions [114].

The focus group discussions reinforced that app usability is a central priority for older adults. Participants emphasized that many existing mHealth resources do not adequately address their needs, which negatively influences uptake and sustained engagement. Clear navigation, a simplified and uncluttered interface, and high-contrast color schemes were identified as key design features that would enhance usability. Participants drew on previous negative experiences with apps featuring unnecessary functions, visually dense layouts, and small text, aligning with literature underscoring the importance of inclusive digital design [115]. Font size was also highlighted as a critical consideration; although text can be adjusted within device settings, ensuring an appropriate default size may improve

XSL•FO
RenderX

perceived ease of use, as simpler interfaces can reduce cognitive load and support engagement among older adults [116].

Participants emphasized that personalization should be a core component of the app experience. Customizable reminders were viewed as essential, with participants noting that reminder frequency and timing should align with individual routines to prevent disengagement. This reflects previous findings that excessive notifications can contribute to technology-related stress and reduced adherence among older adults [117]. As also highlighted in Theme 2, the timing and tone of prompts were considered crucial: participants generally preferred a single reminder on the morning of an exercise day, delivered in supportive and nonjudgmental language. This aligns with literature demonstrating the importance of encouraging tones in digital prompts for older adults [118]. Evidence from Wolner-Strohmeyer et al [119], who conducted a 12-week PA intervention with adults aged 60 years or older, showed that twice-weekly reminders significantly increased activity levels, further supporting the value of well-calibrated reminders. Consistent with these findings, participants suggested that one appropriately timed reminder would be sufficient. Consequently, future app development should prioritize adaptable reminder systems that can be tailored to users' daily routines to enhance engagement.

Participants expressed a preference for greater autonomy within the muscle-strengthening program, including the ability to select exercises and create personalized routines. They believed that having control over their workouts would increase enjoyment, support longer-term engagement, and allow better alignment with individual physical abilities. This aligns with evidence from previous mHealth research demonstrating that autonomy can enhance adherence. For example, Mair et al [35] reported improved adherence (67%) when participants set their own step and activity goals, while Daniels et al [120] observed a 135% adherence rate in a 5-week intervention where users selected activities and customized workouts—although this figure reflects adherence relative to self-chosen goals. However, such customization is more readily implemented in aerobic-based interventions; strength-based programs present additional challenges regarding safety and effectiveness [121]. Limited knowledge of resistance training in older adults [122] further increases the risk of unbalanced or unsafe exercise choices. Additionally, providing too many options may increase cognitive load, adding to the usability burden identified in mobile app design guidelines [101].

A key message from these discussions was the need for varied entry points in strength programs based on individual capacity. Older adults are not a homogenous group [102], and age-related conditions amplify disparities in musculoskeletal health. Sarcopenia prevalence rises from 5%-13% in adults aged 60-70 years to around 50% in those aged 80 years and older [123], with substantial declines in muscular capacity; for example, leg press 1-repetition maximum dropping from 237 kg in adults aged 60-64 years to 172 kg in those aged 80-85 years in men [124]. These findings highlight the need for structured difficulty levels within mHealth apps, enabling participants to select a starting level aligned with their ability.

Participants stressed the need for instructional clarity through clear video demonstrations of muscle-strengthening exercises. These calls were rooted in safety and confidence in the exercise materials and were an extension of the previous discussion encapsulated in Theme 3. Participants valued video demonstrations due to their accessible features (pause, rewind, and replay), emphasizing that older adults feel it is important to learn muscle-strengthening exercises at their own pace. These specific needs have been catered to in previous interventions, which have demonstrated the benefits of using video demonstrations to assist the provision of muscle-strengthening exercise for older adults [125,126]. These findings also link to the broader literature, which highlights that older adults value personalized learning and the ability to revisit material as needed [127]. A crucial consideration that emerged from discussing the provision of video demonstrations was the demand from participants that videos should be relatable, ideally carried out by an older adult with a relatable physique. Participants felt that having an older adult demonstrate the exercise would help them resonate better and reinforce that muscle-strengthening exercise is not unattainable. These findings are comparable with broader literature, which outlines how age-related promotion of exercise can help foster identification in older adults and enhance engagement [128].

Participants had mixed views on social features of apps. While some felt group-based exercise or peer support would boost their motivation to engage, other participants felt that exercise was a personal experience and did not want social exposure. These thoughts are mirrored in the literature; a previous review by Tong and Laranjo [129] highlighted that while some participants benefit from social features in mHealth activity interventions, many are concerned about direct comparisons to peers, which may become off-putting. The consensus from participants was that social features should be included but optional rather than a default requirement, thereby catering to all needs. The findings from this study link to older adult literature, which highlights that social connectedness can help boost long-term adherence to exercise programs [130]; however, imposing this in an mHealth intervention risks alienating some participants.

The fourth theme is clearly rooted in both TAM key constructs of perceived usefulness and perceived ease of use. The emphasis on simple navigation and high-contrast visuals supports perceived ease of use by reducing the physical and cognitive requirements to engage with the app. Meanwhile, personalization of reminders, exercise selection, and instructional clarity enhances participants' perceived usefulness, ensuring that the app can deliver meaningful benefits.

Strengths and Limitations

One key strength of the study is that the findings offer insight into the applicability of mHealth interventions for muscle-strengthening among older adults. The findings provide a perspective on older adults' needs, wants, thoughts, and feelings regarding engagement with mobile technology, which in turn may enhance participation. By mapping the themes to the TAM core constructs of perceived usefulness and perceived ease of use, the study offers a clear understanding of the factors

XSL•FO
RenderX

influencing mHealth uptake in older adults and presents a framework embedded within a broader co-design process. To the best of the authors' knowledge, this is the first study to outline specific design and intervention recommendations exclusively for muscle-strengthening mHealth interventions for older adults. A further strength of this study was the representation of both experienced and inexperienced older adults in engaging with mHealth technology. This helps guide future interventions to ensure they cater to all needs and maximize intervention effectiveness. Moreover, the inclusion of both males and females ensured diverse perspectives and key design considerations.

The study is not without limitations, primarily recruitment bias. The sample was recruited mainly from the central Scotland area, and the majority were well-educated. Participants' affluent backgrounds likely reduced diversity, which may limit the applicability of the framework to the broader population. Furthermore, due to participants' affluence, it is likely they had a baseline digital literacy higher than that of older adults of lower socioeconomic status [131,132].

Participants in this study may have been more likely to complete exercise, as they may have been attracted to participate in this research. This is therefore not representative of the broader older adult population, in which fewer than 2% to 20% regularly complete muscle-strengthening exercise [29,133]. The study did not formally assess participants' baseline activity levels or adherence to muscle-strengthening guidelines; therefore, it was not possible to contextualize participants' perceptions or completion of current PA guidelines. The sample may have been more health-conscious or physically active than the general older adult population. This limitation should be considered when interpreting findings, as attitudes toward mHealth and exercise may differ among the more physically inactive individuals.

Moreover, the age profile of the participants largely reflects the "young-old" older adult population [134]. The mean age of the sample was 65 years, and participants were generally healthier and potentially more digitally capable than anticipated from older age groups. This may limit the transferability of these findings to older adults living with frailty, multimorbidity, or cognitive impairment.

Practical Recommendations

In line with the principles of the co-design process [44], this study points to several key design considerations for future mHealth interventions aimed at supporting muscle-strengthening exercise in older adults. These can be distilled into five guiding recommendations (1) simplicity and clarity in interface design; (2) personalization of exercise content, reward functions, and reminders; (3) safe and relatable instructional resources, such as video demonstrations with older adult demonstrators; (4) flexible exercise customization; and (5) optional social features.

Conclusion

Overall, this study aimed to identify key features that a muscle-strengthening exercise app should include to enhance engagement and uptake among older adults and to examine the limitations of existing health apps to inform more effective design. Findings highlight both positive and negative aspects of current apps, as well as essential considerations for future development. Across 4 themes, participants recognized the potential of mHealth to support health and well-being, identified motivational features, outlined usability challenges, and proposed desired app elements. Design preferences included large font, clear navigation, personalized exercise options, customizable reminders, instructional videos, and sensitivity to age-related needs. These insights offer a user-informed framework for app refinement. In conclusion, this study provides a foundation for impactful mHealth design targeting muscle-strengthening and sarcopenia prevention in older adults, with the potential to inform future interventions and improve digital health equity.Top of Form

Abstract

Background: Spatial navigation relies on egocentric and allocentric frames of reference, with the latter critically impaired in Alzheimer disease (AD) due to hippocampal involvement. Recent evidence suggests that egocentric representations may coexist within medial temporal lobe regions; however, their relative impairment in the early stages of AD remains unclear. Virtual reality offers a promising approach to bridge this gap by assessing spatial navigation abilities and providing sensitive digital biomarkers for AD.

Objective: This study investigates spatial memory performance in individuals with amnestic mild cognitive impairment (aMCI) using a virtual reality object-location memory task that manipulated available cues during recall. An environmental boundary probed hippocampal-dependent allocentric processing, while a discrete landmark probed striatal-dependent egocentric strategies.

Methods: Eighty participants (40 individuals with aMCI and 40 healthy controls [HC]) encoded object locations in a virtual arena and recalled them using either landmark or boundary cues.

Results: Regardless of the spatial frame of reference, patients with aMCI demonstrated significantly poorer overall spatial memory than the HC group. Surprisingly, virtual egocentric error emerged as a predictor of aMCI diagnosis. No differences were observed in frame-switching, object-location binding, or across recall trials. Analysis of virtual encoding paths revealed that patients with aMCI exhibited centrifugal navigation away from the discrete landmark and toward the boundary of the arena. During recall, patients with aMCI demonstrated less effective usage of boundary and landmark cues than HC, as revealed by the distribution of response coordinates.

Conclusions: These findings indicate that, in addition to well-documented allocentric deficits, egocentric spatial memory impairments provide a complementary and potentially sensitive marker within the AD continuum. This dual impairment of spatial cognition systems may enhance our understanding of navigational difficulties in aMCI and offers insight into the nature of spatial representations in aging.

spatial navigation; dementia; mild cognitive impairment; spatial cognition; virtual reality; digital health

Introduction

Spatial navigation and memory represent cornerstone cognitive abilities that underpin our everyday functioning, playing a crucial role across the lifespan. These interconnected abilities enable self-orientation, object localization, wayfinding, and, in general, the maintenance of independence within one's surroundings. Central to these abilities is how spatial information is represented. The environment can be represented using 2 different spatial frames of reference [1,2]. The egocentric frame uses a body-dependent representation (eg, "the chair is to my right"), while the allocentric frame uses a body-independent representation (eg, "the chair is close to the north-facing wall"). Crucially, the flexible switch and use of both spatial frames of

XSL•FO
RenderX

reference sustain successful spatial navigation and memory [3-6].

Research has demonstrated that different types of cues in the environment tend to promote the use of different reference frames [7-9]. Specifically, extended environmental boundaries (such as walls) tend to promote allocentric processing, as they provide stable, viewpoint-independent reference frames. In contrast, discrete landmarks (such as a monument) often promote egocentric processing, as individuals tend to encode and recall target locations in relation to their own position relative to these salient features. Allocentric spatial memory relying on boundaries is mainly sustained by medial temporal regions, prevalently the right hippocampus and boundary cells in the subiculum and entorhinal cortex. In a virtual reality (VR) task, Lee et al [10] showed that encoding target locations close to the boundaries, compared to the center, elicited stronger theta oscillations than for target locations at the center of the environment, suggesting that the human subiculum is a key region associated with integrating boundary information into spatial memory, facilitating precise navigation and spatial recall. Conversely, egocentric spatial memory relying on landmarks is supported by the dorsal striatum and parietal cortex, with the medial prefrontal cortex serving as a critical hub for top-down modulation when both representations are similarly active [7,8,10-12].

As we age, the integrity of these spatial functions becomes increasingly significant, serving as a window into brain health. The literature indicates that spatial navigation and memory decline in normal aging, with older adults exhibiting increased use of egocentric navigation and diminished frame-switching abilities [13-15]. For instance, Schuck et al [16] manipulated geometric boundaries and local landmarks within a VR object-location (OL) memory task. Young adults demonstrated behavior patterns and medial temporal lobe activation consistent with hippocampal boundary-processing models. In contrast, older adults relied predominantly on landmark information, with their spatial learning correlating more strongly with caudate nucleus activity than hippocampal engagement, suggesting an age-related shift from a primarily hippocampal-dependent boundary-processing system to a caudate-mediated, landmark-oriented approach.

In pathological aging associated with Alzheimer disease (AD), this pattern progresses to a more severe impairment, with earlier and more marked deficits in allocentric navigation and eventual deterioration of compensatory egocentric strategies. Consistent with AD-specific neuropathological processes [17], significant allocentric deficits and frame-switching impairments have been consistently reported in AD dementia [18], even in the early stages [19]. Understanding when these deficits emerge is therefore critical for early detection. Mild cognitive impairment (MCI) has been proposed as a transitional stage from normal aging to dementia [20]. Specifically, individuals with objective impairment on memory tests, namely amnestic mild cognitive impairment (aMCI), have a heightened risk of developing AD compared to non-aMCI [21]. Consistent with this progression, individuals with aMCI not only report subjective navigational complaints but also manifest impairments in allocentric and egocentric spatial navigation, as well as in frame-switching abilities, especially from the allocentric to egocentric frame [22-25]. More recent research has begun to better reveal complex patterns of spatial impairment in this specific population. Using a VR boundary-based OL memory task, Castegnaro et al [26] found that individuals with aMCI recalled object locations less accurately than healthy controls (HC). They also exhibited increased object-binding errors, that is, difficulties in correctly associating each object with its original location, with objects frequently assigned to incorrect positions. Crucially, the distance between the recalled and encoded item locations achieved a good diagnostic classification performance (area under the curve [AUC]=0.89). However, aMCI with positive AD biomarkers performed similarly to individuals with negative AD biomarkers. The authors concluded that a possible egocentric strategy might have compensated for allocentric deficits in aMCI with AD. Nevertheless, regardless of the biomarker profile, participants with aMCI exhibited OL impairments compatible with entorhinal lesions.

Beyond allocentric deficits, there is some evidence for egocentric spatial impairments in aMCI. Studies using paradigms such as the human analog of the Morris water maze (MWM) [27] have found that individuals with aMCI plus multiple-domain impairments (aMCImd) and those with a hippocampal amnestic profile also manifested deficits in egocentric spatial memory [28,29]. In contrast, patients with focal impairment in memory (amnestic mild cognitive impairment, single-domain [aMCIsd]) were particularly impaired in allocentric spatial memory. Intriguingly, research has begun to characterize specific behavioral patterns during spatial navigation tasks. Individuals with aMCI showed responses less clustered around the target location during allocentric and egocentric conditions compared to HC and non-aMCI [27-29]. Behavioral markers during navigation tasks can reveal these underlying impairments.

Indeed, spatial behaviors tracked during a navigation task in response to specific environmental cues could express altered allocentric-hippocampal (eg, almost direct trajectory between starting and target location) and egocentric-nonhippocampal (eg, wall-hugging-centrophobic navigation, random exploration) strategies, which unveil impaired spatial navigation in AD [30]. Additionally, studies of AD risk carriers have identified distinctive navigational behaviors using VR tasks, including wall-hugging behavior when environmental boundaries were displayed and a preference for navigating closer to local landmarks to reach target locations when egocentric cues were presented [31-33].

In summary, while existing literature has demonstrated spatial navigation deficits in aMCI, significant questions remain regarding the precise nature of these impairments. Specifically, how patients with aMCI navigate when different types of spatial cues are available (environmental boundaries vs discrete landmarks) and the relative impairment in allocentric vs egocentric processing strategies remains poorly investigated.

To overcome these gaps, this study aims to exploit digital markers from the VR OL spatial memory task to evaluate boundary- and landmark-based recall strategies in aMCI compared to HC. Based on the existing literature, our study

XSL•FO
RenderX

addresses two main objectives: (1) to evaluate spatial memory performance in aMCI compared to HC. Despite some evidence suggesting possible landmark-based (egocentric) impairments, we expect a focal allocentric spatial recall (boundary-based) deficit in aMCI, which we hypothesize will predict aMCI diagnosis; (2) to investigate navigational behavioral patterns. We expect patients with aMCI to display distinct navigation strategies compared to HC, specifically wall-hugging behavior in boundary-based conditions and centripetal navigation toward discrete landmarks in landmark-based conditions.

Finally, we explore these predictions in relation to aMCI subtypes, specifically aMCIsd and aMCImd variants.

Methods

Participants

Eighty older adults were recruited for this study and divided into 40 individuals meeting the core clinical criteria for MCI [34] and 40 HC. The MCI phenotype was established [34] in the patient group (aMCIsd=10 and aMCImd=30). The presence of cognitive impairment was determined by a team of neuropsychologists (CT, CSB, and DB) and a physician (KMG), based on the patient's anamnesis, medical report, and neuropsychological diagnosis according to a screening battery. Objective cognitive impairment was determined by clinical judgment, including qualitative analysis of the participant's test performance [35], and the psychometric equivalent scores method for Italian neuropsychological tests [36]. To reduce diagnostic bias, neuropsychological tests for each participant were evaluated by a team of neuropsychologists.

Inclusion criteria for the cognitively HC group were (1) age ≥65 years, (2) absence of cognitive impairment, (3) independence in functional abilities, and (4) absence of cognitive deterioration as determined by the Italian Mini-Mental State Examination (MMSE) cut-off [37].

MCI was diagnosed according to the core clinical criteria: (1) concern about a change in cognition expressed by the participant, an informant, or a clinician; (2) cognitive impairment in one or more domains; (3) independence in functional abilities; and (4) absence of a dementia diagnosis. Additional inclusion criteria were (1) age ≥65 years and (2) absence of cognitive deterioration as determined by the MMSE cut-off [37]. aMCIsd was determined when only the memory domain (verbal and/or visuospatial) was impaired on formal neuropsychological testing, whereas aMCImd was defined when, in addition to memory (verbal and/or visuospatial), participants had an objective impairment in an additional cognitive domain.

The following exclusion criteria were applied to both HC and MCI: (1) presence of an acute stroke or transient ischemic attack in the last 6 months, (2) diagnosis of neurological (eg, multiple sclerosis and Parkinson disease) and psychiatric disorders (eg, schizophrenia) or untreated psychiatric conditions (eg, mood and anxiety disorders), (3) history of traumatic brain injury with loss of consciousness, (4) physical or functional impairments (eg, musculoskeletal disorders and limb paresis/paresthesia) that could impair the use of the VR procedure, (5) severe or uncorrected visual impairment, and (6) presence of self-reported recurrent vertigo.

To compute the sample size, we used an effect size of f=0.32 [19]. For a mixed design (2 within-participant levels and 2 between-participant levels) with a power of 0.8 and an α of .05, the total sample size was 79 (calculated using the *pwr* R package).

Participants were recruited at the Outpatient Clinic of the Department of Medicine, Neurology, and Rehabilitation, IRCCS Istituto Auxologico Italiano—Mosè Bianchi, Milan. Table 1 reports the demographic and clinical baseline characteristics of the participants included in the analyses. An extended summary table is reported in Multimedia Appendix 1.

Materials

Neuropsychological Measures

The battery we administered comprised memory, language, attention, executive function, and visuospatial domains. The full set of neuropsychological tests and descriptions is reported in Multimedia Appendix 1.

OL Spatial Memory Task

We used a VR landmark- and boundary-based spatial memory recall similar to that described by Tuena et al [38]. Participants were seated in a comfortable position at a distance of 50 cm from the computer screen. In this task, a 3dRudder and a VR-ready computer (15.6-inch MSI GF63 Thin 11UC Intel Core i7-11800H, NVIDIA GeForce RTX 3050 4 GB, 16 GB RAM, and 512 GB SSD) were used to interact with the virtual environment. The 3dRudder is a circular platform designed for use while seated in a comfortable and safe position. To operate it, the user places the feet on top of the device, which is mounted on a semispherical base. This design enables intuitive movement control by tilting the feet in the desired direction or by pushing the toes or heels to move forward or backward. The device is equipped with inertial and pressure sensors that detect the user's movements and convert them into virtual actions. The use of a

XSL•FO
RenderX

motion foot pad instead of a classic joypad is intended to recruit lower-limb motor commands instead of hand and finger motor efferent copies, which is closer to real-world navigation [39].

The structure of the spatial memory task was as follows. During the encoding phase, participants were instructed to collect 4 items at a time and encode their locations within a circular arena (with a diameter of 50 virtual meters). Critically, during encoding, both the arena boundary (wall) and a fixed intra-arena landmark (obelisk; coordinates [−10.5, 10.5]) were simultaneously visible, allowing participants to encode object locations using both cues.

Items were presented randomly, and each object was collected 4 times in a random order. The 4 objects were the same for all the participants and were presented at the same fixed coordinates (cat [−5, −14], chair [−4, 20], bike [18, 10], and carrot [5, 17]). To visualize the object, participants had to navigate to its exact location. Upon reaching it, the object disappeared, and they proceeded to find the next one. The starting position (coordinates [0, 0]) of this phase was always the center of the circular arena, facing an arbitrary north.

During the immediate recall phase, participants had to remember and navigate to the exact location where the item (cued at the bottom of the screen) had previously been collected and then press a button on the keyboard to respond. The next object was then presented. Either the wall or the obelisk was randomly removed, forcing participants to rely primarily on one type of spatial cue. In the allocentric (wall) condition, the obelisk was removed, but the visible wall remained, encouraging boundary-based spatial memory. In the egocentric (obelisk) condition, the wall became invisible, but the obelisk remained visible, encouraging landmark-based spatial memory. Fixed distal cues (ie, mountain range and clouds) remained visible in both recall conditions as orientation cues. Each object was tested twice under both egocentric and allocentric conditions, resulting in a total of 16 trials (8 trials per recall condition).

An invisible wall was implemented as a constraint during the obelisk condition to ensure comparability between the 2 recall cue conditions. Figure 1 provides an overview of the task.

Figure 1. Object-location spatial memory task structure.In the encoding phase (A), participants were asked to learn the locations of 4 consecutive objects in a circular virtual arena containing both walls (allocentric cues) and a discrete landmark (egocentric cue). Participants collected each object 4 times in random order. During the recall phase (B and C), participants were cued to navigate to previously learned object locations; however, either the obelisk (B) or the wall (C) was randomly removed, forcing reliance on egocentric or allocentric spatial recall cues, respectively. While distal orientation cues remained visible in both conditions, each object was tested twice under both cue conditions (8 trials per spatial recall cue and 16 total trials).

The recorded virtual variables were the encoding time to collect and encode the object locations; the Cartesian coordinates (x, y) of the recalled location; the Cartesian coordinates (x, y) of the paths made by participants during the encoding phase; and the error for each trial at recall, measured as the Euclidean distance (expressed in virtual Unity software meters) between the recalled position and the actual location. Details of the setup are shown in Figure S1 in Multimedia Appendix 1.

Procedure

First, participants read and signed the consent forms to participate in the study. The study was conducted across 2 sessions. In the first session, participants were administered a comprehensive neuropsychological battery (refer to "Neuropsychological Measures" subheading). In the second session, participants completed the OL spatial memory task. Before the actual task, participants were instructed by the experimenter on how to use the 3dRudder in a training virtual environment provided by the 3dRudder software. Then, the encoding phase instructions were read: "Now, you will find yourself in a circular virtual arena where your task is to collect objects and memorize their locations, as you will be asked to recall them later. You will see one object at a time, and each object will appear four times in the same position to help you remember its location more easily. To aid in memorization, you can use the obelisk, the wall, the mountain range, and the fixed clouds as reference points. You can navigate within the arena using the 3dRudder. To collect an object, move directly over it. Once collected, it will disappear, and the next object will be presented."

After this phase, the recall instructions were given: "You will be asked to place each object in the position where you originally collected it. However, either the obelisk or the wall will be randomly removed. Once you reach the location you believe is correct, press the spacebar on the keyboard to place the object and proceed to the next one. You will be asked to reposition each object multiple times, regardless of the accuracy of your previous answers." Finally, a brief debriefing on the study's aims was provided (the experimental sessions lasted approximately 1 hour and 15 minutes in total).

Data Preparation and Statistical Analyses

R (version 3.6.3; R Foundation for Statistical Computing) software was used for the analyses. The main independent variables were group (HC vs aMCI) and spatial recall cue

XSL•FO
RenderX

(egocentric vs allocentric). This resulted in a mixed between- and within-participants design.

Our study consisted of 2 sets of analyses corresponding to our 2 main research objectives: linear mixed-effects ANOVAs and generalized linear regression models (Objective 1), and binomial tests for density distributions (data points count) of Cartesian encoding and response coordinates (Objective 2).

The main dependent variable of interest for Objective 1 was the recall measure of Euclidean distance (error between encoded items' Cartesian coordinates and recalled items' Cartesian coordinates; hereafter referred to as error). In addition, to gain further insight into spatial memory performance, we assessed OL binding errors and frame-switching cost. A thorough description of the statistical methods for Objective 1 is reported in Multimedia Appendix 1. To reduce bias, we also controlled for computer expertise (refer to Table 1 and Multimedia Appendix 1 for details) in the groups and carried out analyses adjusted for potential confounding variables (eg, age, gender, and global cognition). Objective 2 details are reported in the "Data Preparation and Statistical Analyses for Navigational Behavioral Patterns" section. The significance level was set to .05 in all analyses.

Data Preparation and Statistical Analyses for Navigational Behavioral Patterns

First, we analyzed path length in the HC and aMCI groups at encoding. To quantify participants' movement within the arena, we computed the Euclidean distance between consecutive position samples (path Cartesian coordinates) for each participant. For each participant, we then computed the mean step distance (average distance traveled per time step) and the total distance (sum of all stepwise distances). Group differences in mean step distance between participants with HC and aMCI were assessed using an independent samples *t* test (with Welch correction for unequal variances). The same procedure was adopted for paths at recall. Encoding and recall path coordinates were sampled at 1 Hz (2/80 files could not be saved due to technical issues).

We also computed the Euclidean distance of each path point at encoding from the fixed landmark and the center of the arena and averaged this distance for each participant to carry out an independent samples *t* test (Welch correction for unequal variances) between the 2 groups.

Second, to analyze the spatial distribution of encoding and response patterns in the arena, we developed a systematic approach that allowed us to examine potential biases toward specific reference points in both egocentric and allocentric conditions, similar to that described by Lee et al [10]. Recall coordinates corresponded to each participant's response.

Regarding the allocentric condition data point densities (encoding paths and recall data points), we divided the circular arena (radius=25 units) into inner (radius≤12.5 units) and outer annular regions to examine biases toward the center or boundary. We calculated point densities in each region by dividing point counts by their respective areas (inner area=π x 12.5^2 and annular area=π x [25^2 – 12.5^2]). To determine whether participants showed significant deviations from the expected distribution based on relative areas (25% inner and 75% outer), we conducted binomial tests comparing observed proportions to the expected proportions. Additionally, we calculated density ratios (inner to outer) to quantify preferences toward central or peripheral regions.

For the egocentric condition densities (encoding paths and recall data points), we compared the quadrant containing the egocentric (obelisk) landmark (coordinates [−10.5, 10.5]) with the diametrically opposite quadrant. Specifically, we assessed whether participants placed objects more frequently in the upper-left quadrant (containing the obelisk) compared to the lower-right quadrant. We performed binomial tests to determine whether the proportion of points in the landmark quadrant significantly differed from 0.5 (the expected proportion under the null hypothesis of equal distribution between the 2 quadrants). We also calculated density ratios between these quadrants to quantify the strength of any spatial recall cue–based bias. In addition, we also calculated the ratio of density ratios between groups to quantify the relative strength of spatial biases across clinical populations.

Finally, before proceeding to compute data point densities for recall, we ensured that responses were unbiased to fixed object locations. We computed an intra-arena landmark attractor index, normalized by the distance of each object from the landmark. This index quantifies how much a response is shifted toward the intra-arena landmark ($[d_{target} - d_{responseLM}]/d_{target}$), where d_{target} is the Euclidean distance from the object's original location to the landmark and $d_{responseLM}$ is the distance from the participant's response to the landmark. Positive values indicate a bias toward the landmark, whereas negative values indicate a bias toward the object's true location. We also computed an arena center attractor index, normalized by the distance of each object from the arena center. This index quantifies how much a response is shifted toward the center of the arena ($[d_{target} - d_{responseC}]/d_{target}$), where d_{target} is the distance from the object's original location to the arena center, and $d_{responseC}$ is the distance from the response to the center. Negative values indicate a bias toward the center of the arena, whereas positive values indicate a bias toward the object's true location. These 2 attractor indices were analyzed separately with a linear mixed-effects model, with participants and objects as random effects and group (HC vs aMCI) as a fixed predictor.

Ethical Considerations

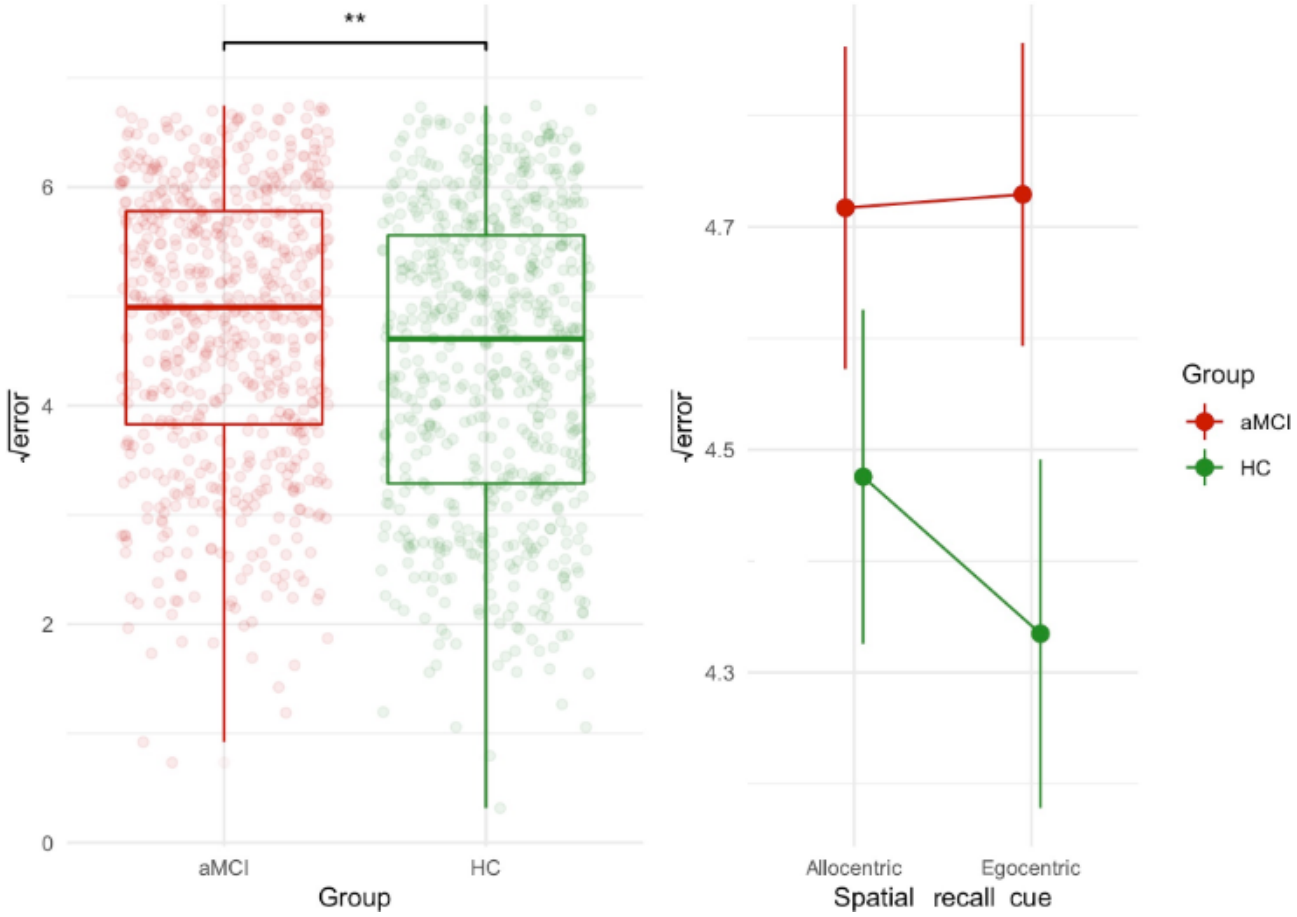
The study was conducted in accordance with the Declaration of Helsinki and approved by the Ethics Committee of Istituto Auxologico Italiano (approval no 2023_01_31_11). Written informed consent was obtained from all participants before their participation in the study. All data were de-identified prior to analysis. Participants were assigned a unique alphanumeric code, and any directly identifying information was removed and stored separately in compliance with ethical and data protection regulations.

XSL•FO
RenderX

Results

Overview

Table 1 reports the key characteristics of the 2 groups. The extended table with all the neuropsychological measures and multiple Pearson correlations in the whole sample between spatial error performance and those measures is reported in Tables S1 and S2 in Multimedia Appendix 1.



Objective 1

Differences Between aMCI and HC and Spatial Memory Recall Cues

To study group and spatial recall cue differences, we performed a linear mixed-effects ANOVA for the error metric.

We found a significant main effect of the group variable ($F_{1,77}$=8.37; *P*=.005; and *f*=0.33). Regardless of the spatial recall cue, patients with aMCI demonstrated a higher mean error of 23.9 (SD 11.3) virtual meters than HC, who showed a mean error of 21.3 (SD 11.7). We did not find a main effect of spatial recall cue (*P*=.37) or the interaction between spatial recall cue and group (*P*=.27). The significant effect of the group variable (*P*=.03) was also retained after adjusting for the covariates [26], namely age, years of education, gender (*P*=.03), retrieval time for each object, global cognition, age by time, and age by gender (*P*=.02). Figure 2 shows the results of these analyses with (A) a significant main effect of the group variable on spatial memory error, and (B) nonsignificant spatial memory performance by spatial recall cue in the groups (mean and 95% CIs), with a detailed summary of these analyses reported in Multimedia Appendix 1.

Figure 2. Group differences in the spatial memory task. aMCI: amnestic mild cognitive impairment; HC: healthy controls. ***P*<.01

Crucially, an ANOVA was conducted to explore any differences in recall time. We did not find a main effect of group (*P*=.07), spatial recall cue (*P*=.92), nor the interaction between group and spatial recall cue (*P*=.65). Results were unchanged when the model was adjusted for age, years of education, gender, and global cognition.

We also performed a polynomial linear mixed-effects model to investigate the performance across testing trials.

Concerning the error, the results of the group main effect above were replicated (*P*=.005). Crucially, we did not find any improvement or deterioration across testing trials (*P*=.40). The main effect of spatial recall cue (*P*=.37), the interaction between group and spatial recall cue (*P*=.27), the interaction between trials and group (*P*=.43), between trials and spatial recall cue (*P*=.98), and among trials, spatial recall cue, and group (*P*=.37) were not significant.

OL Memory Binding in aMCI and HC and Spatial Memory Recall Cues

To analyze the effects of group and spatial recall cues on binding errors, we performed a Poisson regression. Neither the main effect of group (*P*=.24) nor spatial recall cue type (*P*=.85) reached statistical significance. The interaction between group

XSL•FO
RenderX

and spatial recall cue type was also nonsignificant (P=.51). Results remained unchanged after adjusting for the covariates suggested by Castegnaro et al [26], namely age, education, gender, MMSE, and gender by age. Refer to Figure S2 for the binding errors in the groups. Figure S2 in Multimedia Appendix 1 shows the binding errors for the 4 objects.

Frame-Switching Cost in aMCI and HC

To analyze the effects of group (aMCI vs HC) and recall cue switching condition (ego-to-allo vs allo-to-ego vs no switch) on error, we performed a linear mixed-effects ANOVA.

We found a significant main effect of group ($F_{1,78}$=4.71; P=.03; and f=0.25). Regardless of the switching condition, HC had higher retrieval accuracy (mean 21.3, SD 6.89) compared to the aMCI group (mean 23.5, SD 6.89). The switching condition (P=.97) and the group-by-switching condition (P=.18) were not significant. We also performed a model adjusting for age, education, gender, retrieval time, MMSE, age by gender, and age by time; however, in this case, the main effect of group did not survive (P=.11). No other significant effects were found for the adjusted model. See Figure S3 in Multimedia Appendix 1 shows the unadjusted frame-switching cost results.

In addition, we performed a logistic regression analysis to explore the predictive power of the recall cue switching condition in classifying aMCI vs HC. We found that only the no-switch error (β=.12; P=.01) was positively associated with aMCI diagnosis (OR 1.13, 95% CI 1.03-1.25). The other switch predictors were not significant (ego-to-allo: P=.78 and allo-to-ego: P=.57). The association for no-switch error remained significant after adding relevant covariates (P=.04), such as age, education, gender, MMSE (β=−.4; P=.01), and age by gender. This suggests that frame switching is impaired in both conditions, as the no-switch condition was a good predictor of aMCI, whereas the other 2 conditions were not.

aMCI and HC Classification and Spatial Memory Recall Cues Performance

We investigated the predictive power of group classification of egocentric and allocentric performances using a logistic regression model.

Regarding the error, our model revealed that egocentric error was a significant predictor of group status (β=.98; P=.01), with higher error associated with aMCI diagnosis. In contrast, allocentric error did not significantly predict group membership (β=.33; P=.39). The intercept of the logistic regression was significant (β=−5.96; P=.01); when egocentric and allocentric errors were 0, there was a greater chance of being classified as HC.

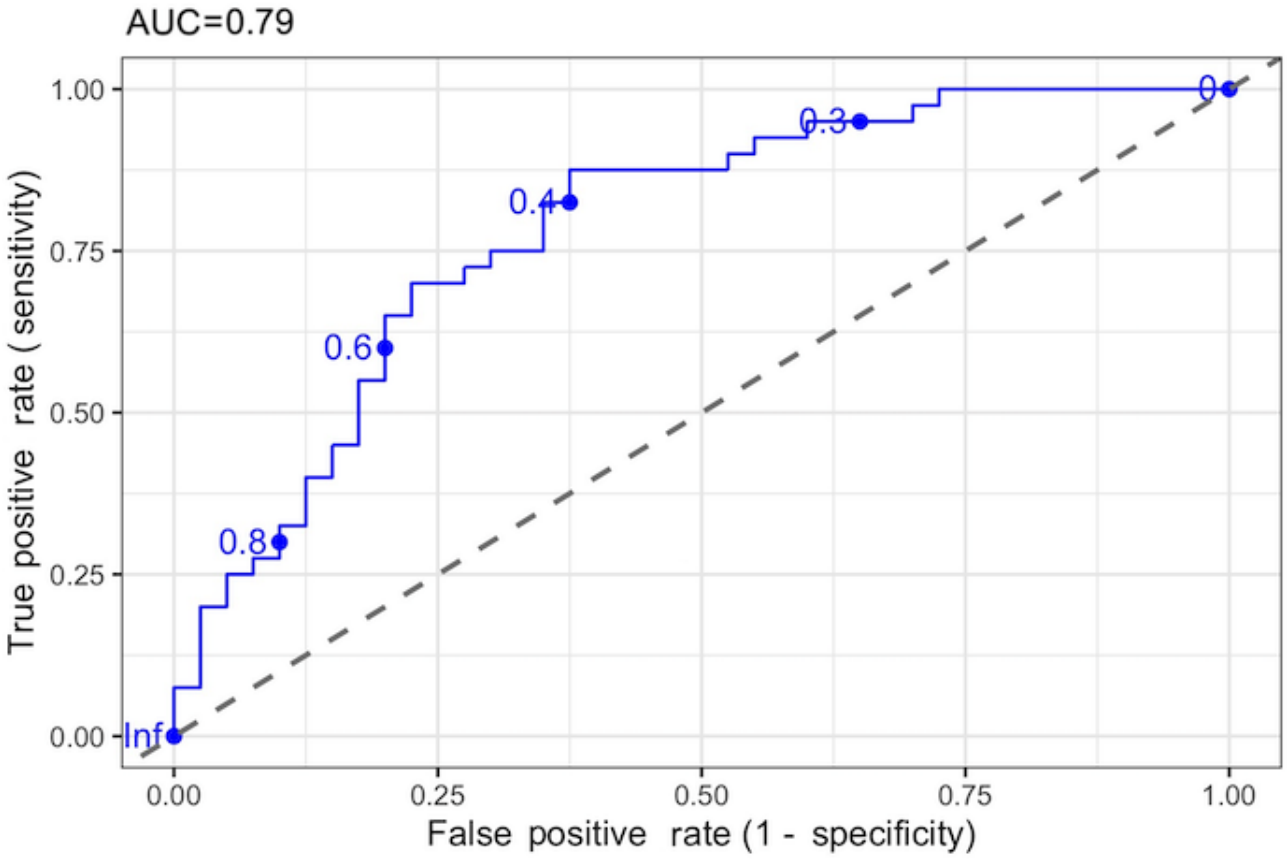
The egocentric error effect also remained significant (β=1.11; P=.03) after controlling for relevant covariates, namely age, education, gender (β_{male}=−1.65; P=.02), retrieval time, and MMSE (β=−.43; P=.01) [26]. This pattern of results suggests a selective impairment in egocentric spatial navigation in patients with aMCI compared with HCs, while allocentric spatial representations appear relatively preserved. Table 2 reports the full model results.

Table . Full model logistic regression results. Reference class: aMCI[a].

Predictor	OR[b] (95% CI)	*P* value
Egocentric error (vm)[c]	3.02 (1.20-8.96)	.03
Allocentric error (vm)	1.25 (0.51-3.15)	.60
Age (years)	1.00 (0.91-1.09)	.90
Education (years)	0.93 (0.81-1.07)	.30
Sex		
Male	0.19 (0.04-0.71)	.02
MMSE[d] (points)	0.65 (0.46-0.88)	.008
Retrieval time (s)	0.99 (0.95-1.02)	.50

[a]aMCI: amnestic mild cognitive impairment.

[b]OR: odds ratio.



[c]vm: virtual meters.

[d]MMSE: Mini-Mental State Examination.

A receiver operating characteristic curve analysis was conducted to evaluate the diagnostic performance of the full model for the classification of aMCI. The AUC was 0.79, indicating moderate discriminatory ability (Figure 3). The optimal threshold was determined using the Youden index, which maximizes the sum of sensitivity and specificity. The analysis yielded an optimal probability cutoff value of 0.43. At this threshold, the test demonstrated a sensitivity of 0.88 and a specificity of 0.63, with a global accuracy of 0.75.

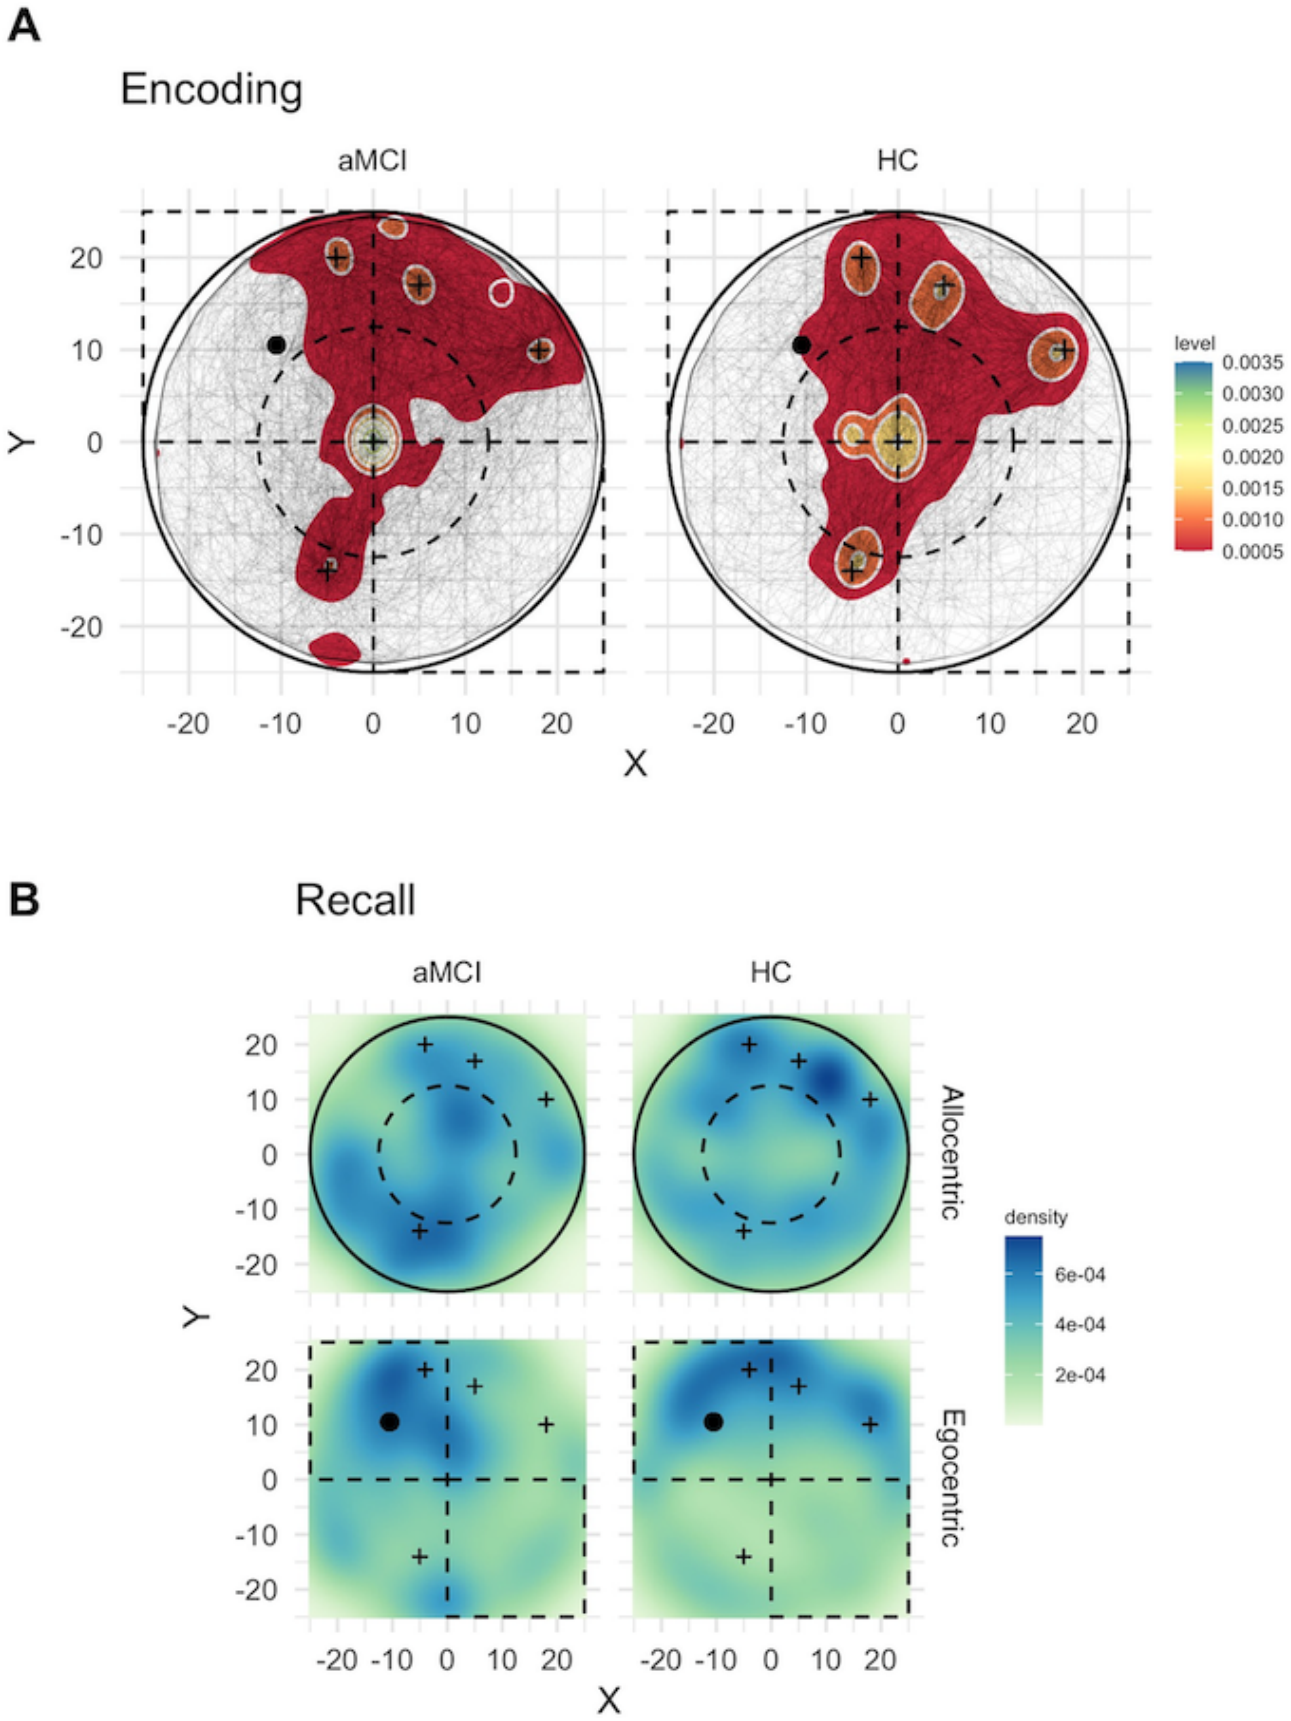
XSL•FO
RenderX

Figure 3. Receiver operating characteristic (ROC) curve of the full logistic regression model. AUC: area under the curve.

We also analyzed the cognitive measure of the model separately outside the logistic regression model. A receiver operating characteristic curve analysis was conducted to evaluate the diagnostic performance of the egocentric error measure. The AUC was 0.70, indicating moderate discriminatory ability. The optimal threshold was determined using the Youden index, which maximizes the sum of sensitivity and specificity. The analysis yielded an optimal cutoff value of 4.35. At this threshold, the test demonstrated a sensitivity of 0.80 and a specificity of 0.58. This means that egocentric error is particularly effective for ruling out aMCI, given the high sensitivity and, consequently, the low number of false negatives (ie, when egocentric error is below the cutoff, the participant is likely to be HC). Conversely, values above the cutoff may result in false-positive classifications because of the lower specificity.

Finally, MMSE showed an AUC of 0.68, indicating poor discriminatory ability. The analysis yielded an optimal cutoff value of 28.15. At this threshold, the test demonstrated a sensitivity of 0.68 and a specificity of 0.65. Consequently, the egocentric error is more accurate than MMSE for classifying healthy older adults.

Despite not being a significant predictor, we also computed a receiver operating characteristic curve analysis for the allocentric error. The AUC was 0.61, and the best cutoff was 4.87, which yielded a sensitivity of 0.5 and specificity of 0.75. This is specific to the egocentric error measure; in this case, the higher specificity is a better predictor of aMCI given the lower number of false positives, and a positive score above the cutoff may indicate aMCI.



Objective 2

Encoding Paths in aMCI and HC

We computed the patterns of encoding Cartesian (path) coordinates to explore navigation behavior in this phase. This data type allows us to explore the paths within the virtual environment during the encoding phase of the object locations. Refer to Figure 4 for the regions used in these analyses and the path density distributions in the groups at encoding. In the figure, (A) shows heat maps representing the density of encoding path points, with dark blue indicating higher concentration. Black lines represent paths taken by participants during the encoding phase, and black cross markers show object positions. The black dot represents the obelisk landmark (–10.5, 10.5), with dashed lines delineating the analyzed upper-left and lower-right quadrants; the solid circle represents the arena boundary (radius=25 units), with a dashed inner circle (radius=12.5 units) separating central and annular regions. (B) Shows heat maps of response point densities at recall, with dark blue indicating higher concentration. Black cross markers show encoding object positions. In the egocentric condition, the black dot represents the obelisk landmark (–10.5, 10.5), and in the allocentric condition, the solid circle represents the arena boundary (radius=25 units), with a dashed inner circle (radius=12.5 units) separating central and annular regions. Both cues were presented during encoding. Allocentric refers to a boundary cue presented, but no local landmark, and egocentric refers to local landmark presented, but no boundary. Legends show density levels.

XSL•FO
RenderX

Figure 4. Density distributions within the virtual environment. aMCI: amnestic mild cognitive impairment; HC: healthy control.

First, we calculated whether the groups differed in terms of path length. A *t* test showed that groups did not differ in path length (*P*=.08). Along with encoding time (refer to Table 1), this result shows that time and path do not differ quantitatively in aMCI from normal cognitive aging.

XSL•FO
RenderX

Second, a Welch 2-sample *t* test was conducted to compare the mean distance from the intra-arena landmark between participants with aMCI and HC. There was a significant difference in mean distance between the 2 groups (t_{63}=2.35; *P*=.02). Participants with aMCI (mean 19.57, SD 1.34) maintained a greater average distance from the landmark during encoding navigation compared to HC participants (mean 18.65, SD 2.05). Similarly, a Welch 2-sample *t* test was conducted to compare the mean distance from the center of the arena between participants with aMCI and HC. There was a significant difference in mean distance between the 2 groups (t_{76}=2.35; *P*=.02). Participants with aMCI (mean 15.45, SD 1.96) maintained a greater average distance from the center compared to HC participants (mean 14.45, SD 1.77). These analyses showed a tendency to navigate closer to the boundary of the arena and away from the landmark, which is replicated in the data point density analyses.

HC demonstrated significantly higher point density in the inner circle compared to patients with aMCI (36.4% vs 29.16%, binomial test *P*<.001), suggesting a centripetal pattern during the encoding phase for HC. Conversely, patients with aMCI showed significantly higher concentration in the outer ring (70.83% vs 63.6%, binomial test *P*<.001), suggesting a centrifugal bias toward the boundary during the encoding phase.

Quadrant analysis revealed that HC had significantly higher point density in the top-left quadrant (region that contained the egocentric cue [obelisk]) compared to participants with aMCI (27.75% vs 24.37%; *P*<.001), suggesting a bias toward the egocentric landmark for HC. Conversely, participants with aMCI showed a significantly higher concentration in the bottom-right quadrant (14.98% vs 13.64%; *P*<.001), suggesting a centrifugal pattern away from the egocentric cue.

Overall, the results indicate a centrifugal pattern of encoding navigation for aMCI away from the egocentric cue and toward the boundary (away from the center of the arena) and a more clustered pattern for HC toward the center of the arena and the egocentric cue.

Point Pattern Analysis and Spatial Recall Cue in HC and aMCI

We analyzed the response patterns to investigate behavioral recall differences between the groups.

First, we calculated whether the groups differed in terms of path length. Results showed that aMCI had significantly (t_{74}=3.64; *P*<.001) longer paths (mean 2.83, SD 0.89) compared to HC (mean 2.16, SD 0.74).

Second, normalized attractor index analyses for egocentric and allocentric performance showed that the HC group had a lower bias toward the landmark (β=−.21; SE=0.07; *P*=.007) and toward the center of the arena (β=−.14; SE=0.06; *P*=.02) compared to the aMCI group. This ensured that the following analyses were relatively unbiased by fixed object locations. Indeed, this result was replicated in the data point densities analyses reported in the next paragraph: aMCI recalled locations in the allocentric condition toward the center of the arena and toward the landmark during the egocentric condition.

Regarding data point densities, we started by investigating the point pattern for allocentric performance. We analyzed the spatial distribution of response points in the 2 groups by examining the density patterns relative to the structure of the circular arena. For this purpose, we divided the circular arena into an inner region (within the inner circle of radius 12.5 units, far from the wall) and an outer annular region (between the inner and outer circles, 12.5< radius ≤25 units, closer to the wall). The inner area constituted 25% of the total area, while the outer area represented 75%.

Refer to Figure 4 for the regions used in these analyses, the groups' density point distributions, and recall cue conditions.

The HC group placed 17.81% of their recall points in the inner area (57/320 points) and 82.19% in the outer area (263/320 points). This distribution significantly differed from the expected proportions based on the inner and the outer portion of the arena (binomial test; *P*=.002).

In contrast, the aMCI group placed 23.75% (76/320) of their recall points in the inner area and 76.25% (244/320) in the outer area. This distribution did not significantly differ from the expected proportions for the inner and outer sections of the arena (binomial test; *P*=.65). To account for the different sizes of the inner and outer areas, we calculated point densities (points per square unit). In the HC group, the density was 0.11 points/unit^2 in the inner area and 0.18 points/unit^2 in the outer area, yielding an inner-to-outer density ratio of 0.65.

For the aMCI group, the density (points per unit area) was 0.15 points/unit^2 in the inner area and 0.17 points/unit^2 in the outer area, resulting in an inner-to-outer density ratio of 0.93. The difference in density ratios between groups was −0.28, indicating that patients with aMCI showed a more balanced distribution of points between inner and outer areas than HC participants, who demonstrated a stronger preference for the outer area. This suggests a potential alteration in allocentric spatial memory strategies in aMCI, characterized by reduced usage of the circular boundary as a spatial reference point compared with healthy older adults.

We then inspected the egocentric performance. We examined the spatial distribution of response points across opposing arena quadrants in patients with aMCI and HC. We focused on comparing the upper left quadrant, which contained the egocentric cue (obelisk at coordinates [−10.5, 10.5]), with the diametrically opposite lower right quadrant.

In the HC group, 32.19% (103/320) of recall points were positioned in the upper left quadrant, while 17.19% (55/320) were located in the lower right quadrant. This asymmetric distribution between the 2 quadrants was statistically significant (binomial test; *P*<.001).

Similarly, the aMCI group placed 32.50% (104/320) of recall points in the upper left quadrant and 20.00% (64/320) in the lower right quadrant. This distribution also showed a significant preference for the upper left quadrant (binomial test; *P*=.003).

To account for the spatial area, point densities were calculated for each quadrant. In the HC group, the point density was 0.21

XSL•FO
RenderX

points/unit^2 in the upper left quadrant and 0.11 points/unit^2 in the lower right quadrant, yielding an upper-left–to–lower-right density ratio of 1.87.

For the aMCI group, the point density was 0.21 points/unit^2 in the upper left quadrant and 0.13 points/unit² in the lower right quadrant, resulting in a density ratio of 1.62. The difference in density ratios between groups was 0.25, indicating that HC participants showed a slightly stronger preference for the upper left quadrant compared to patients with aMCI. The absolute differences in point densities between groups were minimal in both the upper left (−0.01 points/unit^2) and lower right (−0.01 points/unit^2) quadrants, with patients with aMCI showing slightly higher densities in both regions.

Explorative Analyses in aMCIsd and aMCImd

We used robust methods to compare encoding time and spatial error differences, and robust logistic regression between aMCI phenotypes, given unequal group sizes. A comprehensive description of aMCI phenotype differences is reported in Multimedia Appendix 1. To summarize, participants with aMCIsd spent significantly more time (P=.004) in the encoding phase compared to participants in the aMCImd group. Egocentric and allocentric errors could not predict aMCIsd or aMCImd diagnosis. Regarding spatial behavior during encoding, aMCIsd showed a statistically significant centrifugal (P<.001) pattern away from the local landmark, whereas aMCImd navigated closer to the obelisk; no differences were observed between the central and annular regions of the arena. Regarding spatial behavior during recall, no differences were reported again during the boundary-recall condition between the 2 groups in the central and annular regions. The aMCImd group showed a significantly higher response density closer to the discrete landmark compared to the control region (P=.008); this pattern was not observed in aMCIsd.

Discussion

Principal Findings

In this study, we sought to profile aMCI spatial memory performance using a VR OL task that manipulated available spatial cues during recall: environmental boundaries (engaging allocentric processing) vs discrete landmarks (engaging egocentric processing). Participants were asked to collect objects and encode their locations in a virtual arena with discrete landmarks and boundaries. At retrieval, they were asked to put objects in place where they were previously collected, either using the discrete landmark or the boundary. We expected patients with aMCI to show impaired spatial memory, particularly in boundary-based recall conditions, and to exhibit distinct navigational strategies, including wall-hugging behavior and preferential use of local landmarks.

Our predictions were only partially confirmed by the study results. Concerning the first objective, we found that regardless of the spatial recall cue, patients with aMCI exhibited lower spatial memory performance than HCs; surprisingly, the egocentric error, rather than the allocentric error, was a significant predictor of aMCI diagnosis. No differences were found between aMCIsd and aMCImd. Second, we did not find deterioration in testing trials or any OL memory binding deficits in aMCI. Finally, contrary to the previous literature, we found no impairment in switching abilities (from egocentric to allocentric and from allocentric to egocentric).

Concerning our second research objective, we found a wall-hugging–like behavior in aMCI and navigation away from the discrete landmark (especially in aMCIsd) during the encoding phase.

Interestingly, patients with aMCI showed no quantitative encoding deficits (ie, comparable encoding time and path length to HCs), but differed qualitatively in their encoding strategies. Regarding the recall phase, patients with aMCI gathered the responses at the center of the environment (in both phenotypes) in the allocentric condition and toward the landmark (especially in aMCImd) during the egocentric recall cue condition. Quantitatively, the 2 groups differed in path length but not in retrieval time.

Objective 1

While Castegnaro et al [26] showed that boundary-based recall has promising discriminative performance between aMCI and HC groups, intriguingly, we also found that higher egocentric error was associated with aMCI diagnosis. First, this is in line with a recent systematic review [22] that showed both egocentric and allocentric deficits in aMCI in real-world and VR tasks, extending the traditional focus on allocentric impairments [26-29,40], including egocentric impairments across the AD continuum. Our findings are consistent with the well-established association between AD and allocentric spatial memory deficits, yet they also highlight a complementary impairment emerging along the AD continuum, especially in its early stages. Although allocentric performance did not reach significance in the logistic model, it proved useful for ruling in the condition, whereas egocentric error was more informative for ruling out an aMCI diagnosis. This pattern aligns with a recent diagnostic meta-analysis conducted by our group [41], which showed that both egocentric and allocentric measures contribute valuable diagnostic information for AD, supporting a complementary, rather than competing, approach.

Our findings on egocentric impairment also align with recent results [42-45] that have provided compelling evidence for the coexistence of boundary egocentric vectors in medial temporal structures with allocentric representations. These body-based representations can integrate head direction signals to form a map of allocentric space, aiding navigation toward significant locations within an environment. Despite the right hemisphere, and particularly the hippocampal region, being the dedicated substrate for allocentric spatial computations [7,46], the human left hippocampus supports landmark-based spatial memory by sequencing spatiotemporal navigation (eg, the sequence of body-based movements at a given location and time) in an episodic-like format [11,46]. Aligned with this, patients with aMCI with hippocampal memory deficit, compared to those with frontal memory deficit, showed a greater deficit in egocentric spatial memory [28,29]. In addition, a critical diagnostic consideration is that current MCI neuropsychological classifications do not consider the modality of memory

XSL•FO
RenderX

impairment (eg, verbal vs visuospatial aMCI), potentially masking important cognitive differences that affect spatial navigation abilities. Given the heterogeneity of MCI, caution should be adopted when designing spatial navigation and memory tasks and interpreting their results. Finally, our results confirmed that egocentric spatial memory is preserved in healthy aging and is a good metric to distinguish between aMCI and HC groups; this aligns in particular with a previous study that showed preserved landmark-based compared to boundary-based spatial memory in aging [16]. It is also worth noting that, although gender showed a significant effect as a covariate in both the ANOVAs and the logistic regression, the main results remained significant. This suggests that our findings are not biased by participants' sex. Nevertheless, future research should further investigate potential gender differences in aMCI to better elucidate possible distinctions between egocentric and allocentric processes.

Our study revealed no performance improvement or deterioration in either the aMCI or HC groups. This contradicts previous research suggesting consolidation deficits in aMCI [27-29]. The absence of deterioration, paired with similar encoding times across groups, may indicate frontal involvement in retrieval strategies rather than hippocampal consolidation deficits. This aligns with evidence highlighting dysexecutive memory impairments in aging, aMCI, and AD, as well as the critical role of executive functions in supporting spatial navigation [47-49].

Unlike findings from a previous study [26] showing performance differences during allocentric recall, we found similar OL binding performance across cue types. Our stricter age criterion (≥65 years) likely explains why aMCI and HC performed comparably, as normal aging involves associative memory binding deficits linked to hippocampal and frontal dysfunction [49-51]. However, unimpaired OL binding was also found in AD genetic risk carriers [52].

Finally, while HC demonstrated lower switching costs than aMCI overall, we observed comparable frame-switching costs between groups, contradicting previous findings [24] of differential impairments in allocentric-to-egocentric vs egocentric-to-allocentric switching. This suggests that shifting between spatial representations represents a fundamental process affected by both normal aging and AD [5,15,18,53].

Objective 2

Concerning our second objective, we confirmed that the pattern of encoding paths and responses during retrieval could be a cognitive marker of aMCI [27-29]. However, we extended previous research by demonstrating specific biases in virtual navigation according to spatial recall cues and group.

Concerning the encoding paths, we found that individuals with aMCI, at the group level, tended to explore the arena closer to the boundaries, avoiding the center of the environment. In contrast, the inverse pattern was found in HC. A similar centripetal pattern was found for the discrete landmark in aMCI, while HC tended to navigate closer to the landmark. The former finding is compatible with a thigmotaxis-like (wall-hugging) navigation behavior observed in animals in the MWM [30]. This spatial behavior has been observed in several species while exploring a novel environment and is considered a safety-seeking strategy in the early phases [54]. However, thigmotaxis could also reflect pathological spatial behavior. Indeed, rats with lesions to the hippocampus exhibit perseverative thigmotaxis and an inability to learn more successful strategies [55]. Similarly, lesions to the dorsomedial striatum lead to increased thigmotaxis due to the inability to switch from this strategy to a more efficient one [56]. Importantly, thigmotaxis has been observed in humans as an early strategy in novel environments and is associated with higher levels of fear and avoidance bias toward fear-mobilizing situations or agoraphobia [57,58]. Extensive or pathological use of egocentric behavior, such as thigmotaxis, hampers the capacity to switch between spatial navigation strategies, which is crucial to forming a gestalt-like representation of the space, also known as the cognitive map [57,59]. In line with this, research on path integration (ie, the ability to track one's current position using current self-motion cues) has provided compelling evidence that environmental cues, particularly boundaries and, to a lesser extent, discrete landmarks, can correct navigation errors [8,60,61]. The boundary-hugging bias might reflect a compensatory egocentric mechanism, possibly also driven by spatial anxiety due to disorientation, that leads individuals with aMCI to walk closer to the boundaries virtually. Complementary to this, the local landmark is not perceived as a useful affordance [39] for navigation purposes in the aMCI group. This latter pattern is particularly true for aMCIsd, which also showed longer encoding times than aMCImd, suggesting a specific deficit during the learning process. The landmark-based deficit is compatible with findings on the human analog of the MWM in the egocentric recall test [28] and path integration movements toward the landmark in individuals with genetic risk for AD [33]. In contrast, HC had higher path density in the center of the arena, hinting at an allocentric-hippocampal strategy between object locations, akin to the "direct path" observed in MWM [30]. Collectively, the results show that in addition to an allocentric navigation deficit, aMCI, especially in aMCIsd, is accompanied by an egocentric navigation deficit at encoding.

Concerning the recalled Cartesian coordinates, we found that HC effectively leverages environmental boundaries for spatial memory recall; this boundary-anchored strategy may be partially compromised in older people with aMCI, who tended to remember object locations at the center of the arena. Indeed, the human hippocampus contains boundary cells that help to encode item locations with respect to distances from a boundary and support effective recall [10]. Conversely, patients with aMCI (especially aMCImd) and HC effectively used the egocentric reference point (obelisk) when performing spatial memory recall, with a strong preference for placing objects in the quadrant containing this landmark, especially for the HC. The results were similar in both aMCI phenotypes. This is partially in line with path integration based on boundary and landmark cues in individuals at risk for AD [33]. Bierbrauer et al [33] found that the distance of the landmark to the target condition is critical for recall performance during the landmark cue condition. At the same time, for young adults with genetic risk, this is true for the boundary cue. In addition, they showed

XSL•FO
RenderX

that AD risk carriers walked toward the landmark while on the path toward the target location.

However, this finding must be interpreted considering the encoding path patterns, error performance, and group discrimination. In the former case, we demonstrated that participants with aMCI during the encoding phase tended to navigate closer to the boundary. At the same time, at recall, they remembered object locations in the center of the arena. The opposite pattern was found for HC. This hints at an allocentric spatial memory impairment that, however, is not particularly discriminative between the 2 groups.

In the latter case, the bias toward the landmark at recall, in the absence of an environmental boundary, is indicative of defective egocentric recall performance, which arises as a first step in the encoding phase, possibly due to a primary bias toward the boundary in aMCI, leading participants to navigate away from the local landmark. This behavior was not observed in HC. Consequently, while the saliency of the landmark with respect to object locations is partially preserved during the testing phase, the recall accuracy for the actual location is impaired, allowing for better discrimination between groups. Finally, both MCI phenotypes have, in addition to an allocentric, a different egocentric deficit: aMCIsd does not use the egocentric cue as an affordance at encoding, while aMCImd does at recall.

Crucially, we found that qualitative measures of navigation during encoding revealed specific deficits that were not detected by quantitative measures such as total time spent in the environment (encoding time) or path length. This underscores the importance of analyzing behavioral strategies, which may capture the distinctive spatial navigation deficits observed in aMCI and potentially in AD. Similarly, although recall time did not differ between the groups, the combination of path length and qualitative patterns of spatial memory responses indicates that participants with aMCI exhibit both quantitative and qualitative impairments in spatial navigation. This aligns with the long, and sometimes overlooked, tradition of qualitative analysis in the neuropsychology of memory [35]. Quantitative scores alone provide limited information; they should always be complemented by an examination of how patients perform a given task. Previous research in spatial navigation has demonstrated that response patterns reveal underlying spatial memory behaviors, providing valuable insights into the deficits observed in aMCI [27-29].

Limitations

Our study has some limitations that should be acknowledged. First, we lack AD biomarkers that could help to define the underlying pathology better, and we collected participants in only 1 center. Second, we used a nonimmersive VR setup, which lacks crucial bodily (eg, vestibular) information, and this could have affected spatial memory results. Future studies could overcome these limitations by using an immersive apparatus equipped with an eye-tracking system to control for visual exploration, thereby discovering innovative digital biomarkers for aMCI diagnosis in larger cohorts.

Conclusion

To conclude, our findings suggest that suspected AD pathology affects not only allocentric spatial memory in aMCI but also impairs egocentric spatial representations. The latter constitutes a complementary critical process in navigation and could represent a useful digital biomarker in the progression of AD. This dual impairment of spatial cognition provides a more comprehensive understanding of the navigational difficulties in aMCI and may offer new avenues for detection and intervention with digital health technologies.

Acknowledgments

We thank all the participants who participated in the study, as well as Sarah Todisco and Alessandra Magrelli, who supported the study during data collection.

Abstract

Background: Mild cognitive impairment (MCI) is an intermediate state between normal aging and dementia, characterized by subjective cognitive decline and objective memory impairment. Cognitive training has consistently shown short-term benefits for individuals with MCI, but evidence on the long-term effectiveness is extremely limited. Given the progressive nature of MCI and the need for sustainable strategies to delay cognitive decline, research on the long-term impact of cognitive training is necessary and timely. Mobile-based platforms offer a promising solution by enhancing accessibility and adherence, but their durability of effect over extended periods remains underexplored.

Objective: This study aimed to evaluate the long-term effects of a mobile-based cognitive training app on the cognitive function of older adults with MCI.

Methods: In total, 28 older adults with MCI used Cogthera, a mobile cognitive training app based on metamemory training. Participants completed 2 training sessions daily for 3 months, and 9 (32%) continued for an additional 12 months. Cognitive function and quality of life were assessed using the Alzheimer's Disease Assessment Scale-Cognitive Subscale 14 and EQ-5D-5L.

Results: Cognitive function improved over 15 months, as measured by Alzheimer's Disease Assessment Scale-Cognitive Subscale ($F_{2,35.56}$=7.08; P=.003). EQ-5D-5L scores increased at 3 months but did not show sustained change at 15 months ($F_{2,42.14}$=3.40; P=.04). Greater cognitive improvements were associated with younger age, higher functional status, and lower baseline cognitive function.

Conclusions: This study showed that long-term use of a mobile-based metamemory cognitive training app was associated with cognitive improvements over 15 months. Although limited by the small sample size and the absence of a control group, these findings suggest potential for mobile cognitive training as a sustainable intervention that warrants validation in larger trials.

Introduction

Background

Mild cognitive impairment (MCI) is an intermediate stage between normal aging and Alzheimer disease (AD). It has emerged as a key target for early intervention to delay AD. MCI is characterized by subjective cognitive decline along with objective memory impairment without functional impairment [1]. The prevalence of MCI is 6.7% among individuals aged between 60 and 64 years and 25.5% among those aged between 80 and 84 years [2]. In addition, approximately 10% of individuals with MCI progress to AD annually [3].

Nonpharmacological interventions, such as physical activity, social engagement, and cognitive training, are widely recommended to delay AD onset in MCI [4-7]. Cognitive training has demonstrated superior efficacy in improving cognitive function in short-term treatment [8-11]. Despite these short-term benefits, few studies have examined whether cognitive training produces sustained effects beyond 1 year because of methodological difficulties [12]. Traditional cognitive interventions also rely on in-person, paper-based sessions, which can limit accessibility and adherence [13]. Digital cognitive training based on a mobile app enables home-based, self-paced engagement and has demonstrated greater participation [14].

We have previously reported the short-term efficacy of metamemory training (MMT) [15,16]. Metamemory refers to an individual's awareness and understanding of their memory functions, including their contents and processes [17,18]. MMT is based on this concept and has been shown to be effective in teaching mnemonic strategies and improving cognitive function [19-22]. However, its long-term efficacy may need to be investigated, especially with a mobile cognitive training app.

Objectives

This study aimed to examine the long-term effects of a cognitive training app based on MMT in older adults with MCI. We hypothesized that prolonged use of the app would lead to sustained improvements in cognitive function.

Methods

Participants

Participants were recruited from 1 memory clinic. Inclusion criteria were as follows: (1) aged between 55 and 85 years; (2) diagnosed with MCI by trained psychiatrists or neurologists according to the criteria proposed by Petersen [23]; (3) ownership of a personal smartphone and no difficulties using mobile apps; (4) if taking cognitive enhancers (acetylcholinesterase inhibitors or memantine), a stable dose maintained for at least 12 weeks before randomization; (5) availability of a caregiver who spends more than 8 hours per week with the participant and agrees to assist with follow-up and clinical evaluations; (6) ability to independently make phone calls to a caregiver using a smartphone; (7) no difficulties with reading or writing in Korean; and (8) adequate vision and hearing to participate in the clinical trial. MCI diagnosis was based on the following criteria by Petersen [23]: (1) reported concerns regarding cognitive changes, (2) impairment in 1 or more cognitive domains, (3) preservation of independence in functional abilities, and (4) absence of dementia [24]. Participants underwent cognitive assessments conducted by clinical psychologists using the Clinical Dementia Rating (CDR) and the Korean version of the Consortium to Establish a Registry for Alzheimer's Disease Neuropsychological Assessment Battery (CERAD-NP). Eligibility criteria required a global CDR score of 0.5 and performance at least 1.0 SD below the mean in 1 or more memory domains of the CERAD-NP.

Exclusion criteria included the presence of serious physical illness or psychiatric disorders that could interfere with study procedures; the use of medications known to affect cognitive function (except those taken consistently for at least 3 months); and any neurological or medical conditions associated with cognitive decline other than MCI, such as stroke, central nervous system infection, head trauma, alcohol dependence, or depression. Of the 40 participants screened, 10 (25%) were excluded, 1 (3%) dropped out, and 1 (3%) experienced a stroke. Data from 28 (70%) participants were analyzed.

Ethical Considerations

This study was reviewed and approved by the institutional review board of Seoul Metropolitan Government-Seoul National University Boramae Medical Center (20-2022-48). All participants provided informed consent before participation. All collected data were deidentified and stored securely, and no personally identifiable information was accessible to the research team. Participants received KRW 200,000 (US $136) as compensation for their participation.

Intervention

Participants underwent cognitive training using Cogthera, a smartphone-based app based on MMT developed by Youn et al [16]. The structure and content of the Cogthera intervention, including its implementation of metamemory-based strategies, have been previously described in detail. The program was designed to enhance key cognitive functions, including attention, imagery, and association, which support effective memory encoding and retrieval. Attention training helped participants focus and concentrate on target information to facilitate deeper encoding. Imagery training encouraged vivid visualization to reinforce memory consolidation and retrieval. Association training promoted the integration of new information into existing semantic memory networks. Throughout the training process, Cogthera provides personalized feedback and dynamically adjusts task difficulty, enabling users to observe and evaluate their cognitive processes independently.

A 15-month single-arm longitudinal study was conducted to investigate the long-term efficacy of mobile-based cognitive training. Participants completed a 3-month cognitive training program using Cogthera, with 9 (32%) of the 28 participants continuing an additional 12 months. The training program consisted of 2 daily sessions, 7 days per week, with each session lasting approximately 15 minutes. The first session comprised 3 core cognitive exercises targeting attention, imagery, and association. The second session included 4 additional exercises, selected from 9 available options, excluding those already used

XSL•FO
RenderX

in the first session. A personalized algorithm determined daily exercise composition to optimize engagement. All participants were able to use the Cogthera program independently without external assistance. The detailed content of each exercise can be found in Multimedia Appendix 1.

Measures

Alzheimer's Disease Assessment Scale-Cognitive Subscale 14

The Alzheimer's Disease Assessment Scale-Cognitive Subscale 14 (ADAS-Cog 14) was used to assess the severity of cognitive dysfunction [25]. This measure consists of fourteen tasks: (1) word recall, (2) commands, (3) constructional praxis, (4) delayed word recall, (5) naming, (6) ideational praxis, (7) orientation, (8) word recognition, (9) maze, (10) number cancelation, (11) remembering instructions, (12) comprehension, (13) word finding difficulty, and (14) spoken language ability. The ADAS-Cog 14 subdomains were categorized into 3 cognitive domains: memory, language, and praxis [26]. The total ADAS-Cog 14 score ranges from 0 to 90 points, with higher scores indicating greater cognitive impairment, as the score reflects the number of errors made across tasks.

CERAD-NP Assessment

The CERAD-NP was administered to assess cognitive function [27,28]. This battery included the following neuropsychological tests: (1) verbal fluency, (2) Boston Naming Test, (3) Mini-Mental State Examination, (4) word list learning, (5) constructional praxis, (6) word list recall, (7) word list recognition, (8) constructional praxis recall, (9) Trail Making Test, and (10) Stroop test. The CERAD-NP total score was calculated as the sum of raw scores, with higher scores indicating better cognitive function.

CDR Scale

The CDR scale was used to stage dementia severity [29]. This scale is informed by semistructured interviews conducted with both participants and informants, covering 6 domains: memory, orientation, judgment and problem-solving, community affairs, home and hobbies, and personal care. Each domain is scored from 0 to 3, with the scores used in calculating the global CDR score and the CDR-Sum of Boxes (CDR-SB). The global CDR score is an ordinal scale ranked from 0 to 3 as follows: 0=no cognitive impairment, 0.5=questionable or MCI, 1=mild dementia, 2=moderate dementia, 3=severe dementia. The CDR-SB is a continuous measure ranging from 0 to 18, calculated by summing the individual domain scores. Higher scores on both the global CDR and CDR-SB indicate greater cognitive and functional impairment.

EQ-5D-5L Scale

The EQ-5D-5L was administered to evaluate health-related quality of life [30]. This measure consists of five dimensions: (1) mobility, (2) self-care, (3) usual activities, (4) pain and discomfort, and (5) anxiety and depression. Each dimension is rated on a 5-level scale, with response options ranging from *no problem* to *extreme problem*. Responses were converted into a single index score using a national-specific value set [31]. This value set, derived from stated preference data collected from the general population, assigns weights to each health dimension level. The index score ranges from 0 to 1, with higher scores indicating better overall health status. In contrast, a lower score on each subdimension reflects a higher level of health in that specific domain.

Data Collection

Participants who provided informed consent were screened using global CDR and CERAD-NP. During the initial visit, participants underwent cognitive function assessments using ADAS-Cog 14 and completed self-reported questionnaires, such as EQ-5D-5L. After completing these assessments, they were provided with a smartphone preinstalled with Cogthera. Follow-up data on ADAS-Cog 14 and EQ-5D-5L were collected after 3 months of using Cogthera. In addition, further assessments were conducted on 9 (32%) of the 28 participants who continued using Cogthera for 15 months. Training adherence was assessed using compliance, which was defined as the proportion of completed sessions relative to the total number of assigned sessions. The assigned frequency was 2 sessions per day, and compliance was calculated separately for the initial 3-month period and the 12-month extension.

Statistical Analysis

Linear mixed model analyses were performed to assess changes in ADAS-Cog 14 and EQ-5D-5L scores over time while accounting for both intraindividual and interindividual variations in longitudinal data. The models included time (baseline, 3 mo, and 15 mo) as a fixed factor and participant as a random effect, allowing individual variability in intercepts. To evaluate the overall effect of time, type III ANOVA was conducted.

To identify explanatory variables predicting intervention effects, the least absolute shrinkage and selection operator (LASSO) regression was used. This approach was used to identify the most relevant predictors while minimizing overfitting [32]. The outcome variable was the change in ADAS-Cog 14 at follow-up, with LASSO models including age, sex, education, CDR-SB, baseline ADAS-Cog 14 scores, and baseline EQ-5D-5L scores as predictors. All variables were standardized by centering each variable around the mean and scaling by the SD. The regularization parameter, λ, was optimized using 9-fold cross-validation to balance model complexity and predictive performance. The optimal λ value was then applied to estimate the coefficients of the selected predictors.

To contextualize cognitive changes observed in this study, descriptive data from the placebo cohort of EXPEDITION studies were used as a historical reference [33,34]. EXPEDITION and EXPEDITION-2 were multicenter, double-blind, phase 3 trials of solanezumab, including 663 patients with MCI treated with a placebo. Cognitive function was assessed using ADAS-Cog 14 at baseline and at 6 follow-up points every 3 months over 18 months. Welch *t* test (2-tailed) was conducted to compare data from this study with the EXPEDITION placebo cohort at baseline, 3 months, and 15 months, accounting for unequal variances and sample sizes.

All statistical analyses were conducted using R software (version 4.4.1; R Foundation for Statistical Computing). Statistical significance was set at $P<.05$, with all tests being 2-tailed. For

XSL•FO
RenderX

the post hoc analysis of the linear mixed model, Bonferroni-adjusted *P* values were reported. Effect sizes for the fixed time effects were also reported, with partial eta-squared (η^2_p) computed from the corresponding *F* statistics. Missing data were addressed through complete case analysis without imputation. To ensure analytic independence, all data access, monitoring, and statistical analyses were conducted exclusively by authors not affiliated with the company. Company-affiliated authors had no access to raw data and did not participate in data cleaning, analytic decisions, or interpretation of results.

Results

Demographic Characteristics

A total of 28 participants were included in the analysis (Table 1). The mean age of participants was 72.8 (SD 6.7) years, and the mean education level was 11.4 (SD 5.0) years. The sample comprised a higher proportion of female individuals (20/28, 71%) and was predominantly composed of nondrinkers (27/28, 96%) and nonsmokers (26/28, 93%). The mean CDR-SB score was 2.0 (SD 1.1), ranging from 0.5 to 4.0.

Table 1. Baseline demographic data for the participants (N=28).

Demographic characteristic	Values
Age (y), mean (SD)	72.8 (6.7)
Sex, n (%)	
Female	20 (71)
Male	8 (29)
Education (y), mean (SD)	11.4 (5.0)
Consortium to Establish a Registry for Alzheimer's Disease Neuropsychological Assessment Battery (*z* score[a]), mean (SD)	
Word list learning	–0.5 (0.9)
Word list recall	–1.6 (1.0)
Word list recognition	–1.7 (1.4)
Constructional praxis recall	–1.3 (0.9)
Clinical Dementia Rating-Sum of Boxes (score), mean (SD)	2.0 (1.1)

[a]A standardized score indicating how many SDs a value is from the mean.

Training Adherence

During the initial 3-month training period, participants completed an average of 85.3% (SD 23.6%) of assigned sessions. Among 9 (32%) of the 28 participants who continued for an additional 12 months, mean compliance during the extension period was 51.7% (SD 25.1%).

Intervention Effects of Cogthera

Linear mixed model analysis revealed a significant decrease in total ADAS-Cog 14 scores over time, indicating improved cognitive function ($F_{2,35.56}$=7.08; *P*=.003; η^2_p=0.28; Table 2). Specifically, a significant decrease in total ADAS-Cog 14 scores was observed over 15 months (Bonferroni-adjusted *P*=.001), while the change over 3 months was not significant (Bonferroni-adjusted *P*=.27; Table 3).

[a]Bonferroni-adjusted *P* values.

In the ADAS-Cog 14 subdomain analysis, praxis scores, representing executive function, showed a significant decline over time ($F_{2,39.33}$=7.11; *P*=.002; η^2_p=0.27), particularly over 15 months (Bonferroni-adjusted *P*=.001). The reduction in memory scores was marginal ($F_{2,35.83}$=2.53; *P*=.09; η^2_p=0.12), with a trend-level decrease observed at 15 months (Bonferroni-adjusted *P*=.06). The overall effect of time on language scores was not significant.

A significant change in the EQ-5D-5L index score was observed over time ($F_{2,42.14}$=3.40; *P*=.04; η^2_p=0.14), with a statistically significant increase from baseline to 3 months (Bonferroni-adjusted *P*=.03). Among the EQ-5D-5L subdimensions, mobility showed a marginal overall effect of time ($F_{2,\ 39.05}$=2.59; *P*=.09; η^2_p=0.12), with a trend-level decrease observed at 3 months (Bonferroni-adjusted *P*=.06). Detailed results for the EQ-5D-5L subdimensions are provided in Tables S1 and S2 in Multimedia Appendix 2).

Factors Associated With Intervention Effects on Cognitive Function

According to the LASSO results, CDR-SB and baseline ADAS-Cog 14 scores predicted score changes over 3 months, while age, CDR-SB, and baseline ADAS-Cog 14 scores predicted score changes over 15 months. The multiple linear regression model, which included sex, CDR-SB, and baseline ADAS-Cog 14 scores, explained a significant proportion of the variance in score changes over 3 months (R^2=0.40; adjusted R^2=0.33; *P*=.01; Table 4). Specifically, lower CDR-SB scores (β=–0.51; *P*=.02), and higher baseline ADAS-Cog 14 scores significantly predicted greater improvements (β=0.61; *P*=.01).

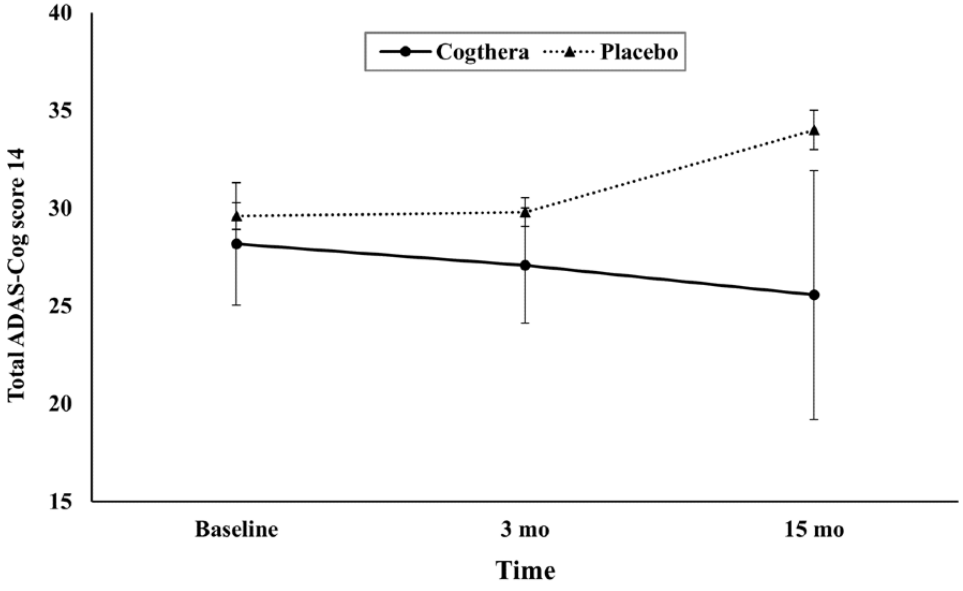
[a]Score obtained by subtracting the Alzheimer's Disease Assessment Scale-Cognitive Subscale score at 3 months from the baseline Alzheimer's Disease Assessment Scale-Cognitive Subscale score.

[b]CDR-SB: Clinical Dementia Rating-Sum of Boxes.

[c]ADAS-Cog 14: Alzheimer's Disease Assessment Scale-Cognitive Subscale.



[d]Score obtained by subtracting the Alzheimer's Disease Assessment Scale-Cognitive Subscale score at 15 months from the baseline Alzheimer's Disease Assessment Scale-Cognitive Subscale score.

The regression model, which included age, CDR-SB, and baseline ADAS-Cog 14 scores, accounted for a significant proportion of the variance in score changes observed over 15 months (R^2=0.81; adjusted R^2=0.70; *P*=.03). Specifically, younger age (β=–0.62; *P*=.02), lower CDR-SB scores (β=–1.10; *P*=.02), and higher baseline ADAS-Cog 14 scores significantly predicted greater improvements (β=1.05; *P*=.01).

Comparison With Historical Placebo Data

The mean and SD data from a previously reported placebo cohort were used for comparison at each time point. No significant differences were observed between the Cogthera group and the placebo group at baseline ($t_{29.68}$=0.89; *P*=.38; Figure 1). At 3 months, ADAS-Cog 14 scores in the Cogthera group were marginally lower than those in the placebo group ($t_{30.63}$=1.81; *P*=.08). By 15 months, the difference became statistically significant, suggesting greater cognitive improvement in the Cogthera group ($t_{8.55}$=3.01; *P*=.02).

Figure 1. Comparison of cognitive function between the Cogthera group and the historical placebo group. Error bars represent 95% CIs of the mean Alzheimer's Disease Assessment Scale-Cognitive Subscale 14 (ADAS-Cog 14) scores at each time point.

Discussion

Principal Findings

This study examined the long-term effects of a mobile-based cognitive training app in older adults with MCI. ADAS-Cog 14 scores decreased over time, and EQ-5D-5L scores increased in the early phase of training. Age, CDR-SB, and baseline ADAS-Cog 14 scores were associated with the degree of cognitive change. Although comparisons with a historical placebo cohort are limited by differences in design and sample characteristics, the observed reduction in ADAS-Cog 14 scores over 15 months suggests a pattern of cognitive change associated with long-term training use.

The primary finding of this study is the reduction in ADAS-Cog 14 total, memory, and praxis scores associated with long-term use of Cogthera. While no meaningful change was observed at 3 months, a clearer reduction emerged at 15 months. This delayed pattern may reflect the cumulative effects of training, but it could also be influenced by practice effects, familiarity with test procedures, or natural fluctuations in cognitive performance. These possibilities underscore the need for cautious interpretation, particularly in the absence of a control group. Even so, the overall pattern is consistent with previous studies, suggesting that longer training durations are more likely to yield detectable cognitive improvements [35]. Unlike other ADAS-Cog 14 subdomains, language scores did not show meaningful change. The small numerical variation observed is likely to reflect measurement variability or stabilization rather than the true effect of the intervention. This aligns with previous research indicating that language tends to remain relatively preserved in the early stage of cognitive decline compared with other ADAS-Cog 14 subdomains [36,37].

Another finding is a rise in the EQ-5D-5L index score during the first 3 months of training. This early change is consistent with previous studies reporting short-term benefits in quality of life among individuals with MCI, but the effect did not persist at 15 months in this study [38-41]. This pattern suggests that changes in perceived well-being may be limited to the initial phase of training. Such early gains may also reflect nonspecific factors, including placebo effects or heightened engagement at the beginning of training.

Predictor analyses revealed that both short- and long-term improvements in cognitive function were associated with lower baseline cognitive function and higher functional status. Participants with higher baseline ADAS-Cog 14 scores, which indicate poorer initial cognitive performance, and those with lower CDR-SB scores, which indicate less functional impairment, tended to show larger reductions over time. Previous research has reported conflicting findings regarding the relationship between baseline cognitive performance and cognitive training effectiveness [42]. Two competing hypotheses have been proposed to explain this relationship: the compensation effect and the magnification effect. The compensation effect suggests that individuals with higher baseline cognitive performance benefit less from training due to limited room for improvement. In contrast, the magnification effect proposes that they benefit more by leveraging greater cognitive efficiency and plasticity. The findings of this study align with the compensation effect, as participants with lower baseline cognitive performance showed greater training-related gains. This pattern suggests that Cogthera may have provided compensatory cognitive stimulation. Such stimulation could have helped individuals with lower baseline cognitive performance make better use of their remaining cognitive resources. CDR-SB reflects the pathological progression of cognitive and functional decline and reliably differentiates MCI from very early AD while predicting future progression [43-45]. The association between lower CDR-SB scores and greater cognitive gains may suggest that individuals with preserved daily function but greater cognitive vulnerability were more responsive to training. These observations are broadly consistent with compensatory mechanisms, while other explanations remain possible.

Younger age was associated with modestly better cognitive outcomes over the 15-month period. One possible explanation is that younger participants may engage more consistently in long-term digital interventions. Previous research has shown that they tend to complete more training sessions and demonstrate higher adherence. Such patterns of adherence may help account for the cognitive changes observed in this group [46-48].

These findings suggest that MMT delivered through a mobile app may offer a scalable and accessible approach for individuals with MCI. Mobile apps provide a practical alternative to traditional cognitive training by allowing users to engage in cognitive exercises at their convenience. As memory decline has already begun in individuals with MCI, this approach may serve as a supportive digital complement to existing strategies. A potential strength of this study is the observation that cognitive changes became more evident with prolonged use, which may help inform future work on long-term digital training. Given the lack of known adverse effects, mobile-based cognitive training could represent a feasible and well-tolerated adjunctive approach for older adults with MCI. It may be particularly useful in cases where pharmacological treatments carry a higher risk of side effects.

Limitations

Despite the observational insights provided by this study, several limitations warrant careful consideration. First, the absence of a control group limits internal validity, as it is not possible to distinguish training-related changes from those that may occur naturally over time. Without contemporaneous controls, causal inferences cannot be drawn.

Second, although 28 participants initiated the study, only 9 (32%) continued to the 15-month assessment. Because long-term participation was voluntary, those who remained may differ in motivation or engagement. However, baseline comparisons between participants who continued to 15 months and those who participated only in the initial 3-month period showed no significant differences in demographic characteristics, cognitive measures, quality of life scores, or training adherence, as presented in Table S3 in Multimedia Appendix 2. In addition, baseline-to–3-month change scores did not differ between the 2 groups, indicating that early improvement was not greater

XSL•FO
RenderX

among those who remained in the study. These findings suggest that systematic baseline differences were limited, although unmeasured factors related to motivation or persistence may still have influenced long-term retention. The small number of long-term participants also restricts the generalizability of the 15-month findings.

Finally, the overall sample size was small, constraining statistical power and limiting the ability to detect subtle effects. Future studies with larger, randomized, and more diverse samples will be essential to determine whether long-term mobile-based cognitive training produces reliable and sustained effects in individuals with MCI.

Conclusions

This study suggests that a mobile-based MMT app may offer supportive benefits for cognitive function in older adults with MCI. Although methodological limitations constrain definitive interpretation, the observed patterns indicate that mobile-based cognitive training could be a feasible and accessible approach for individuals seeking strategies to maintain cognitive health. Continued evaluation in larger, controlled studies will help determine the extent and durability of these potential effects.

Funding

This work was supported by the Technology Innovation Program (or Industrial Strategic Technology Development Program—the bioindustry technology development; grant 20018143, development and clinical application of digital therapeutic devices user experience, untact clinical cloud platforms, and real-world evidence technologies based on the brain and body of the elderly) funded by the Ministry of Trade, Industry, and Energy (South Korea).

Abstract

Background: Digital cognitive training, which involves structured, digital exercises designed to enhance cognitive functions, has shown potential benefits for older adults. While digital cognitive training has shown potential benefits for older adults, successfully incorporating it into their daily routines remains a challenge. Community readiness refers to the group's ability and capacity for a behavior change to be more effective and sustainable. In this study, readiness specifically refers to the community's preparedness to engage in and sustain digital cognitive training.

Objective: This study aimed to evaluate the feasibility of the Community Readiness Model (CRM) to identify facilitators and barriers in implementing training and applying supportive strategies to increase readiness.

Methods: This mixed methods feasibility study was conducted as part of a stepped-wedge randomized controlled trial examining the effects of digital cognitive training on functionality and cognition in older adults. Fifty-six participants were recruited from a nursing home and the community and were allocated to one of two training protocols: one group played digital leisure games for 10 hours followed by 10 hours of digital cognitive training, while the other group completed 20 hours of digital cognitive training. Readiness levels were assessed using CRM through semistructured individual interviews conducted before the intervention. Additionally, the CRM was administered to a sample of stakeholders to evaluate community-level readiness. Following the implementation of strategies aimed at enhancing readiness, as well as the delivery of the digital cognitive training, the interviews were readministered to evaluate changes in readiness levels.

Results: Before the training, participants demonstrated low levels of readiness, with a median CRM total score of 3.6 (IQR 2.2-4.6) in the 10-hour training group and 3.7 (IQR 2.7-4.3) in the 20-hour group. To address this, several strategies were implemented: dissemination of psychoeducational content via social media, distribution of cognitive exercise guides, stakeholder engagement to raise project awareness, and provision of necessary devices along with comprehensive support throughout the training. Following the implementation of these strategies and the training sessions, a significant increase in readiness was observed. Both groups achieved a median CRM total score of 6 (IQR 5-7). Participants identified key facilitators as interest in the training, noticeable cognitive improvements, team support, motivation to continue, the challenge presented by the training, and overall satisfaction. The primary barrier reported was difficulty using the technology.

XSL•FO
RenderX

Conclusions: The CRM demonstrates strong feasibility as a tool for identifying facilitators and barriers that can inform strategies to enhance readiness for digital cognitive training in older adults. The observed increase in readiness scores following the implementation of targeted strategies highlights the CRM's potential to guide the development of effective, supportive interventions. These findings emphasize the importance of addressing technological challenges while harnessing motivating factors to promote the successful adoption of digital cognitive training within this population.

healthy aging; cognitive training; internet-based interventions; behavior change; community participation

Introduction

Aging is associated with a progressive decline in several brain functions including sensory perception, attention, memory, and motor control, which is termed "age-related cognitive decline." Age-related cognitive decline is associated with a poorer quality of life, less independence, and a higher cost for the health system [1]. Therefore, investing in preventive measures to mitigate cognitive decline is necessary. Based on robust research that has elucidated the fundamental principles of brain plasticity, it is now well established that dedicated behavioral training can bring about substantial improvement in cognitive function or recovery [2-6].

Digital cognitive training has emerged as a promising intervention to enhance cognition in older adults. By engaging in these training programs, individuals can either increase their neural capacity or improve the efficiency of existing brain resources [3]. This approach generally focuses on improving general cognitive processes such as processing speed, attention, and working memory, with the premise that these improvements will transfer to real-world cognitive gains [7]. Systematic reviews and meta-analyses of digital cognitive training for older adults have concluded that these training interventions can be effective for older adults and thus should be recommended [8-11].

While the benefits associated with cognitive training for older adults are well recognized, a challenge lies in effectively implementing digital cognitive training in their lives. Previous studies that provided cognitive training to older adults were conducted under the constraints of research protocols and did not consider the resources available to the participants nor the effective behavioral and societal changes needed to ensure engagement with users. Our previous experience with clinical trials and other studies using digital cognitive training has revealed that several training-related factors affect engagement, including personal support, location, attitudes toward new learning and technology, and communication between the users [12-16].

The Community Readiness Model (CRM) is a theory-based strategic model used to assess and build community capacity to tackle social issues. The CRM allows the community's influence and knowledge to assume a central role in the application of the model, allowing researchers to meet communities where they are and on their own terms [17]. The concept of CRM revolves around the idea that starting a new program or intervention is only appropriate when the community is ready. For community interventions or programs to be successful, a community must be consistent with its awareness of the problem and its readiness for change [16,18]. The concept of community adopted in this study focuses on a community of interest defined by shared interests regardless of individuals' location or social group [19,20]. By tailoring interventions to a community's specific needs and readiness, CRM not only identifies facilitators and barriers but also promotes skill development among community members. This collaborative approach is essential for fostering sustainable change and empowering individuals to tackle the challenges they face. Engaging the community in this way ensures that solutions are relevant and supported, ultimately leading to more successful outcomes [21].

Previous applications of the CRM were effective in addressing a variety of health issues, such as health service delivery [22,23], substance use [24], childhood obesity [25], and mental health awareness [21]. On the other hand, for the design and implementation of community-based interventions, the involvement of stakeholders (eg, health promotion professionals) is important, since they can help ensure that the intervention planning is suitable given the real conditions [26,27].

Given the complexity of promoting affective engagement in digital cognitive training—an essential factor for effectively integrating such interventions into the daily routines of older adults [28]—we chose to use the CRM as a framework to support this behavior change. In the context of our study, readiness refers to the community's preparedness to adopt and support training initiatives. The CRM offers valuable insights into both behavioral factors (eg, familiarity with technological tools) and personal factors (eg, an individual's interest in participating in a specific intervention). Unlike other models, the CRM has the distinct advantage of incorporating a community-based perspective, providing a comprehensive assessment of a community's readiness. These features are critical for tailoring strategies that align with the community's current level of readiness, thereby enhancing the likelihood of implementing an effective and sustainable intervention.

We hypothesized that the CRM can be a useful and viable tool to identify barriers and facilitators in the training, which can then be used to develop strategies to increase community readiness for digital cognitive training. To examine this hypothesis, the primary objective of this study was to provide evidence for the feasibility of using the CRM to evaluate the readiness of older adults undergoing digital cognitive training and identify facilitators and barriers associated with the training. The secondary objective was to implement strategies aimed at

XSL•FO
RenderX

enhancing older adults' readiness for training and to evaluate changes in their readiness levels after completing a digital cognitive training program. To achieve the proposed objectives, we applied the CRM to a sample of older adults before and after the implementation of the training. The model was also applied to a sample of stakeholders. We used the results of the preintervention quantitative and qualitative analysis to develop and implement strategies to increase the readiness level of older adults.

Methods

Design

This mixed methods feasibility study is part of an ongoing double-blind, stepped-wedge randomized controlled trial investigating the effects of different doses (10 or 20 hours) of digital cognitive training on cognitive function and functionality in older adults. We hypothesized that participants who received 20 hours of digital cognitive training would exhibit sustained improvements in both cognitive function and functionality. All participants underwent a comprehensive initial assessment, including clinical history, as well as assessments of cognition, functionality, and symptoms of anxiety and depression. They were randomized using a hierarchical stratification by gender, age, years of education, Montreal Cognitive Assessment test score, and the Technology Activities of Daily Living Questionnaire score. They were allocated to one of two training protocols: one group played digital games for leisure for 10 hours followed by 10 hours of digital cognitive training, while the other group engaged in 20 hours of digital cognitive training. The stepped-wedge randomized controlled trial involves random and sequential crossover of groups from control to intervention until all groups are exposed to the intervention [29]. This allowed all participants to perform digital cognitive training during the study. Participants and researchers were blinded throughout the study.

Ethical Considerations

This study was conducted in accordance with the Declaration of Helsinki and was approved by the University Hospital Clementino Fraga Filho Ethics Committee (CAAE: 82713418.6.0000.5257). All participants (older adults and stakeholders) provided written informed consent prior to participation. Participant privacy was protected through data de-identification and secure data storage, with access restricted to the research team. No financial compensation or incentives were provided.

Participants and Training Conditions

Participants were recruited by advertising on social media and in a nursing home in Rio de Janeiro, or through referrals from health professionals, between April 2019 and November 2021. We invited older adults aged 60 years or above and included those who (1) provided written informed consent, (2) had normal or corrected vision and hearing, (3) had access to a computer and internet at home, and (4) were native Portuguese speakers and literate. Participants were excluded if they (1) had a diagnosis of dementia, (2) were dependent on activities of daily living, or (3) had major medical conditions that would prevent them from participating in the study.

The training platform used was BrainHQ from Posit Science, Inc, and the exercises were previously selected and aimed to improve executive functions. The exercises for cognitive training were as follows: *divided attention*, *eye for detail*, *target tracker*, *juggle factor*, and *mind-bender*. These exercises dynamically adjusted their speed and stimulus type based on participant performance. As participants improved, task difficulty systematically increased, and an algorithm maintained individual success rates around 85%. This threshold was incorporated into the design of the training program as a means of achieving an optimal balance between cognitive challenge and sustained learner engagement [4]. To enhance motivation, correct responses were rewarded with engaging visual and auditory feedback, alongside the accumulation of stars. After completing the intervention, participants received feedback provided by the BrainHQ platform on their progress in trained cognitive domains.

The leisure games condition served as a control for potential confounding factors such as computer exposure, researcher interaction, and nonspecific cognitive engagement—including attention, executive functions, and motivation—stimulated by graphics-based digital games. The leisure games were commercial online: *Bubble Poke*, *Smarty Bubbles*, *Dominoes Classic*, *Puzzle*, *Find 500 Differences*, *Find the Birds*, *Let's Clean Up*, and *Crosswords*.

In both groups, participants engaged in 15-minute sessions of 4 predetermined exercises, following the established protocol. They were encouraged to train at least twice a week. The intervention of both groups was accompanied by a video call by a research group member who explained each exercise or game in advance and supported the user by answering questions when necessary.

Stakeholders' Participation

Based on previous studies indicating that stakeholder engagement is associated with improved community readiness for facilitating change [30,31], we determined that stakeholder participation was essential for understanding community readiness and identifying potential barriers and facilitators to intervention implementation. Prior to launching the digital cognitive training program, we conducted interviews with 7 stakeholders, including 4 health professionals (a physical therapist, an occupational therapist, a physician, and a speech therapist) and 3 family members of study participants. All stakeholders had direct contact with the participants. Recruitment took place at a nursing home in Rio de Janeiro and through referrals from professionals in the field. Interviews were conducted prior to the intervention, and the CRM was applied at this stage to gather additional insights into participants' initial level of readiness.

Community Readiness Model

The CRM was applied during the initial assessment and after participants completed either 10 or 20 hours of training, through semistructured individual interviews conducted via video call. The semistructured interview had 11 questions that allowed

XSL•FO
RenderX

participants to talk about access, perceptions, expectations, and their experiences regarding the use of technological resources and digital cognitive training. The questions were developed following the criteria established in the manual proposed by Stanley [32], which assesses the community's readiness by addressing 5 key dimensions that are crucial to initiate and sustain healthy changes. These dimensions are *knowledge of the issue*, which refers to how much the community knows about the issue; *knowledge of efforts*, which refers to how much the community knows about the programs and activities of digital cognitive training; *community climate*, which reports the community's attitude toward addressing the issue; *leadership*, which indicates the leadership's attitude toward addressing the issue; and *resources*, which states how much the resources are being used or could be used to address the issue. The "leadership" dimension was not included in the interview, as the description of this dimension did not apply to the community context.

Each dimension is scored on a scale of 1 to 9, corresponding to a stage. In the initial stage of readiness, "no awareness" (1), the community lacks information about local initiatives, resulting in little awareness of the problem. As the community progresses to "denial/resistance" (2), there is resistance to acknowledging the issue due to a lack of accurate information. Community perception improves slightly in the "vague awareness" stage (3), but knowledge remains superficial. "Preplanning" (4) involves recognizing the concern more concretely, though knowledge and resources are limited. During "preparation" (5), awareness increases, and leadership supports efforts with directed resources. In "initiation" (6), most members have a basic understanding, and leadership plays a central role in planning additional initiatives. Community knowledge solidifies in the "stabilization" stage (7), and leadership ensures long-term viability with continuous resources. "Confirmation/expansion" (8) sees high community knowledge and leadership expanding initiatives, indicating lasting commitment. In the final stage, "high level of community ownership" (9), the community shows substantial knowledge, with active involvement and support from leadership, adjusting resources based on continuous evaluations. Each dimension is scored on a rating scale from 1 to 9, corresponding to these stages.

The CRM interviews were audio-recorded, transcribed, and then analyzed and scored by two independent researchers. The CRM scoring process followed the CRM handbook using anchored rating scales. After establishing a score by each researcher, a consensus was reached on the final score.

Development of Behavior Change Strategies

We implemented strategies to enhance readiness levels, drawing on each dimension of the CRM and incorporating behavior change techniques (BCTs). BCTs are commonly used to promote adherence to specific interventions [33]. The BCT taxonomy, a widely recognized framework, organizes these techniques into 16 main categories encompassing 93 distinct methods. For instance, it includes techniques such as "graded tasks," which involve starting with simple, easy-to-perform activities and progressively increasing their difficulty in a manageable way until the desired behavior is successfully achieved [34]. Strategies were informed by pretraining interviews and community feedback, with the aim of ensuring relevance and effectiveness. Implementation occurred concurrently across both groups, with no distinctions made between them.

Clinical Data and Assessments

We collected clinical and demographic variables from the participants. In addition, we assessed cognition through the application of the Montreal Cognitive Assessment [35] test; to measure functionality, we administered the Technology Activities of Daily Living Questionnaire [36]; to evaluate anxiety symptoms, we used the Geriatric Anxiety Inventory with 20 agree/disagree items [37]; and to measure the symptoms of depression, we used the 15-item version of the Geriatric Depression Scale [38].

Feasibility Outcomes

The primary results regarding the acceptability of the intervention were adapted from the study by Proctor et al [39].

- Recruitment rate: the sample size of recruited participants followed the manual's recommendation of conducting at least 6 interviews, with the possibility of more to obtain a comprehensive understanding of the community [32].
- Attendance: overall attendance rate of >60% [40].
- Attrition: retention rate of at least 75% of participants to the follow-up [40].
- Acceptability of intervention: it was assessed through the responses obtained from semistructured interviews using the CRM.

Data Analysis

The Shapiro-Wilk test was applied to determine data normality. For nonnormally distributed data, nonparametric statistics were used in the analyses. The independent sample *t* test was used to compare the two groups at baseline, the chi-square test was used to assess previous contact with a computer and gender, and the Wilcoxon test was used to verify differences of dimensions between pre- and postintervention. To identify the facilitators and barriers in the baseline and postintervention, we executed the descending hierarchical classification. This method analyzes the lexical context and generates a hierarchical scheme of word classes that are grouped into similarity classes by the chi-square test. High chi-square values characterize strong associations between word and class; we considered words with a $\chi^2_1>3.8$, corresponding to $P<.05$, for the class groupings. This analysis uses words in their reduced forms, and a minimum use of 75% of the total text segments (TS) of the original corpus is required [41]. The rate of textual segments below 75% generated by the software suggests a less homogeneous textual corpus, more dispersed concerning the analyzed content, and less representative [42]. From the TS assigned to each of the word classes revealed by the software, the data were analyzed and interpreted by the researchers to identify barriers and facilitators. The general corpus of textual analysis performed at baseline comprised 56 texts, separated into 652 TS, using 497 TS (76.2%). The postintervention analysis comprised 21 texts for the 10-hour training group, separated into 221 TS, using 172 TS (77.8%), and 20 texts for the 20-hour training group, separated into 245 TS, using 185 TS (75.5%). The data that

support the findings of this study are available on request from the corresponding author. We performed all quantitative statistical analyses using SPSS software (v. 26.0; IBM Inc) and the qualitative analysis using the IRAMUTEQ software (Université de Toulouse).

Results

Feasibility Outcomes

Recruitment Rate and Participant Characteristics

A total of 56 participants were recruited, adhering to the criteria outlined in the recruitment rate guidelines. The cohort was predominantly female, with 43 out of 56 participants (77%), and had an average age of 76.98 (SD 7.7) years and 12.77 (SD 5.03) years of education. Table 1 shows the clinical and demographic characteristics of the total sample and by group, and compares the groups concerning age, gender, education, weekly physical activity practice, number of falls in the last year, previous contact with a computer, cognition, and mood. There were no significant differences between the groups that performed 10 or 20 hours of training regarding any demographic or clinical variables.

Table 1. Participant characteristics.

	Total (n=56)	Group 10 hours training (n=31)	Group 20 hours training (n=25)	*P* value
Age (years), mean (SD)	76.98 (7.70)	77.52 (7.91)	76.32 (7.54)	.56

[b]GDS: Geriatric Depression Scale.

[c]GAI: Geriatric Anxiety Inventory.

Attrition Rate

In the group that underwent 10 hours of training, 7 participants dropped out of the study during the first 10 hours of games: 4 due to lack of interest and 3 due to health problems, resulting in an attrition rate of 22%. However, none of the participants dropped out during the 10 hours of digital cognitive training. Additionally, we missed data for another 3 participants in this group. While in the group that completed 20 hours of training, 3 participants dropped out of the study. During the first 10 hours of training, 1 participant left due to lack of interest, resulting in an attrition rate of 4%. During the next 10 hours of cognitive training, 1 participant left due to lack of interest and 1 due to health problems, resulting in an attrition rate of 8%. Furthermore, we had missing data for 2 more participants in this group. Missing data resulted from participants' unavailability for the postintervention interview despite having completed the training.

Attendance

Attendance was 100% among participants in both groups.

Community Readiness Model Score

First, we analyzed the readiness level for both groups before starting the training. Before the training, the participants had a low level of readiness both for the CRM total and for the dimensions separately, being in the "denial/resistance," "vague awareness," or "initiation" stages (Table 2).

XSL•FO
RenderX

Table 2. Readiness level at baseline.

	Group 10 hours training (n=21)		Group 20 hours training (n=20)	
	Median (IQR)	Stage of readiness	Median (IQR)	Stage of readiness
CRM[a] total	3.6 (2.2-4.6)	Vague awareness	3.7 (2.7-4.3)	Vague awareness
Knowledge of issue	2.0 (3.0-4.0)	Denial/resistance	2.0 (3.0-4.0)	Denial/resistance

Community climate	3.5 (3.0-4.0)	Vague awareness	3.5 (3.0-4.0)	Vague awareness
Resources	6.0 (3.0-7.0)	Initiation	6.0 (4.0-7.0)	Initiation

[a]CRM: Community Readiness Model.

Readiness of Stakeholders

To gain a broader understanding of the community's readiness, we also assessed the readiness of stakeholders and found it to be consistently low in all areas. The stage and readiness level for each dimension were as follows: knowledge of efforts, "initiation" (5.71); knowledge of the subject, "initiation" (5.57); community climate, "preplanning" (4.14); leadership, "vague conscience" (3.28); and resources, "vague conscience" (3.42).

Facilitators and Barriers Related to Digital Cognitive Training at Baseline

To get closer to the real needs of older adults in the face of digital cognitive training, we went beyond the quantitative analysis and performed qualitative analysis of the interviews to identify the facilitators and barriers at baseline. The content generated by the IRAMUTEQ software was categorized into specific classes and classified as either a facilitator or a barrier. Examples of quotes for each class are described in a later section.

At baseline, the facilitators were the following. (1) "Curiosity" (TS=100/599, 16.7%): refers to the curiosity to know and understand how cognitive training works and the associated benefits. (2) "Search for cognitive stimulation" (TS=103/599, 17.2%): refers to the participants' search for resources to improve cognitive abilities. (3) "Getting results" (TS=130/599, 21.7%): refers to participants' interest in training gains because they perceive cognitive difficulties. (4) "Interest in the training" (TS=193/599, 32.2%): pertains to participants' interest in training to improve brain health. The barrier was "difficulty in handling technology" (TS=73/599, 12.2%), which refers to the difficulties older adults have in using technologies that are not part of their daily lives.

Strategies Adopted

Based on these findings in the baseline with participants and stakeholders, we adopted the following targeted strategies with BCTs to increase the level of readiness in each dimension.

1. Knowledge of issue: we shared psychoeducational information through social media about the potential benefits associated with the training (BCT: information about health consequences and problem-solving).
2. Knowledge of efforts: we provided a guide explaining how each cognitive exercise works (BCT: graded tasks, social support).
3. Community climate: we contacted stakeholders and disseminated information about this project (BCT: information about health consequences).
4. Resources: we provided the hardware (computer or tablet) according to the necessity of the participant and provided full support during training and a practical guide on the use of technology (BCT: material incentive and social support [practical]).

Postintervention and Implementation of the Strategies

Subsequently, we evaluated the readiness levels of both groups following the completion of the training. The results indicated that postintervention participants advanced to the preparation, initiation, and stabilization stages (Table 3).

Table 3. Level of readiness postintervention and the application of strategies.

	Group 10 hours training (n=21)		Group 20 hours training (n=20)	
	Median (IQR)	Stage of readiness	Median (IQR)	Stage of readiness
CRM[a] total	6.0 (5.0-7.0)	Initiation	6.0 (5.0-7.0)	Initiation
Knowledge of issue	5.0 (4.0-6.5)	Preparation	5.0 (4.5-5.5)	Preparation
Knowledge of efforts	5.0 (3.5-6.0)	Preparation	5.0 (4.0-6.0)	Preparation
Community climate	5.0 (4.5-6.5)	Preparation	5.75 (4.5-7.0)	Preparation
Resources	7.0 (7.0-8.0)	Stabilization	7.25 (7.0-8.0)	Stabilization

[a]CRM: Community Readiness Model.

Subsequently, we evaluated whether the readiness levels changed postintervention. The analysis revealed statistically

XSL•FO
RenderX

significant increases in all domains of readiness postintervention in both groups, with the exception of resources in the 10-hour training group (Table 4).

[a]CRM: Community Readiness Model.

Facilitators and Barriers Related to Digital Cognitive Training Postintervention

The facilitators post intervention for the 10-hour training group were as follows.

1. Desire to keep training (TS=34/188, 18.1%): refers to participants' desire to continue training or to start other cognitive stimulation activities after the completion of the training.
2. Team support (TS=46/188, 24.5%): refers to the importance of support and encouragement offered by the research team.
3. Cognitive improvement (TS=58/188, 30.8%): refers to participants' perception of cognitive improvement after training and sharing information with the community about the benefits of training. The main barrier was "difficulty in handling technology" (50/188, 26.6%). Although the older adults used a computer during training, there were complaints regarding difficulty with access and familiarity in handling technology.

The facilitators postintervention for the 20-hour training group were as follows.

1. Cognitive improvement (TS=26/176, 14.8%): addresses the participants' perception of cognitive improvement, better performance during the training, and sharing information to the community about the benefits of training.
2. Satisfaction (TS=62/176, 35.2%): refers to the positive experience reported by participants upon completing a new activity.
3. Training challenge (TS=26/176, 14.8%): refers to the participants' motivation to overcome the challenges of training exercises. The main barrier was "difficulty in handling technology" (TS=62/176, 35.2%): this class reports the difficulty in handling technology and the participants' need for assistance from a family member during the training.

The qualitative analyses also revealed that participants continued to report difficulties in dealing with technology, even after completing the training, in both the 10-hour and 20-hour training groups. Before the training, older adults reported that they were searching for cognitive stimulation, and postintervention, both groups reported perceived cognitive improvement.

Table 5 complements these findings by providing examples of quotes for each class of facilitators and barriers, offering further insights into the personal experiences of the participants. Additionally, examples of quotes for each dimension from both groups are available in the supplementary material.

Baseline	
Facilitators	
Interest in the training (193/599, 32.2%)	*…To improve my memory. My attention, I think my attention is very bad, I can't read books.*
Curiosity (100/599, 16.7%)	*…I want to do the training because I found it interesting. I think that curiosity, we are curious to know what it is, what the result is.*
Getting results (130/599, 21.7%)	*…Because I want to work my brain to see if I don't get dementia like my mother did.*
Search for cognitive stimulation (103/599, 17.2%)	*…that's how it is, memorizing, it's the medication schedule thing, these things, I look for it, I even avoid writing it down so I don't get complacent.*
Barrier	
Difficulty in handling technology (73/599, 12.2%)	*…I have a computer, but I don't know how to deal with it very well.*
Postintervention 10 hours	
Facilitators	
Cognitive improvement (58/188, 30.8%)	*…I even noticed that there was some improvement in memory. It's... to remember things. I thought it improved a lot.*
Team support (46/188, 24.5%)	*…I want to thank the girls for their patience with us.*
Desire to keep training (34/188, 18.1%)	*…I started to think it was good, I thought it was worth it and that I want to continue if I get the chance.*
Postintervention 20 hours	
Facilitators	
Cognitive improvement (26/176, 14.8%)	*…I think it improved my mental agility because I came out of the doldrums.*
Satisfaction (62/176, 35.2%)	*…I think it was wonderful, it is fantastic to put the brains to work. I'm even recommending my mother and sister to participate.*
Training challenge (26/176, 14.8%)	*…I became so obsessed with this task that I kept doing exercises to do better, the reverse. I think I got on with that, doing my silly things, like putting some cream on the toothbrush, that was common thing, a while ago.*
Barrier	
Difficulty in handling technology (62/176, 35.2%)	*…I didn't understand a lot, I think I was doing it all wrong.*

Discussion

Our study explored the feasibility of using the CRM to identify barriers and facilitators in implementing digital cognitive training and applying strategies to increase readiness. Older adults were assessed for their initial readiness, which was low but showed significant improvement following targeted strategies and training. Key facilitators included curiosity, motivation to improve cognition, and team support. The main barrier was difficulty with technology, which remained even postintervention. Participants reported cognitive benefits and showed interest in continuing the training. We found that it was feasible to use CRM to identify facilitators and barriers in the implementation of digital cognitive training for older adults, aiming to guide support strategies to enhance readiness levels.

Although our study had a different objective, the observed increase in community readiness for digital cognitive training aligns with findings from institutional delivery services in Ethiopia. While our study addressed individual barriers and motivators, the Ethiopian study used a structured, village-based intervention with education, training, and feedback over 15 months. This highlights CRM's adaptability to different contexts and strategies [43]. Supporting this, a review study indicated that the CRM was effective in identifying stakeholders, informing them about the intervention, and enhancing community awareness of the issue [44]. Findings suggest that extended exposure to the intervention is associated with higher levels of community readiness, whereas previous research [44,45] has documented annual increases of 0.5 to 1 stage in readiness resulting from sustained intervention efforts.

We successfully recruited a target audience that exceeded the minimum required number of participants. The attrition rate was 7 out of 31 participants (22%) in the group that completed 10 hours of games, with no participants dropping out during the digital cognitive training. In the group that completed 20 hours of training, 1 out of 25 participants (4%) left during the first 10 hours. During the next 10 hours, the attrition rate was 2 out of 24 participants (8%). Attendance was high, with 100% of participants attending all 10 or 20 sessions. Attrition patterns differed between groups, with dropouts in the 10-hour group

XSL•FO
RenderX

occurring during the initial game-based activities, which may have been less stimulating than digital cognitive training. In contrast, the 20-hour group had fewer dropouts early on and remained more consistent throughout, possibly due to higher motivation or perceived benefits. External factors, such as health issues and missing data, also contributed to retention differences.

Although CRM has been used in various studies across different fields to promote behavioral changes for better health, such as preventing traumatic brain injury, reducing alcohol use, and supporting older adults, few studies have evaluated readiness before and after the intervention, as we did [23,25,26]. We found that participants had a low level of readiness before the training. However, after implementing the targeted strategies, we observed an increase in readiness, both in the overall CRM score and across its individual dimensions.

The improvement in readiness may be attributed to older adults' self-perception of benefiting from potential gains associated with training, leading to a greater awareness of the importance of brain training. A systematic review of BCT in computerized cognitive training for older adults described that feedback given by a person about behavioral outcomes can influence adherence and effectiveness of training [11]. In this study, participants received feedback from monitors who accompanied them throughout the sessions on their progress in trained cognitive domains as part of a behavior change strategy, which possibly increased their awareness of the potential benefits obtained from training. The choice to have more personalized feedback from the monitor was based on a systematic review [11] that indicated that when this feedback was provided by a computer, it tended to be less effective.

In terms of the "knowledge of the issue" dimension, participants progressed from the "vague awareness" stage at baseline to the "preparation" stage postintervention. Upon completion, they showed an improved understanding of cognitive exercise and the potential for recovering lost abilities. A qualitative study with older adults with mild cognitive impairment revealed that the computer program used in the study not only enhanced their memory and attention but also assisted in managing daily life challenges from the point of view of the participants [46]. Another study indicated that most older adult participants believed the program was beneficial for their health [47]. Motivators related to cognitive effectiveness, such as the perceived improvement in cognition and tangible evidence of that improvement, were also significant [48]. These findings suggest that as participants recognize the value of digital cognitive training and its impact on their lives, they are more motivated to engage in it.

Participants in this study also demonstrated a significant improvement in the "knowledge of the efforts" dimension. This change was observed as their initial state of "denial" or "resistance" transformed into a state of "preparation." Over time, participants expressed satisfaction with the potential benefits of cognitive training and recommended it to others, including family and community members. This is further supported by their quotes (Table 4) reflecting satisfaction following the completion of the training.

A study that applied the CRM in the context of childhood obesity prevention also reported significant behavior change by adopting strategies aimed at increasing community readiness. As participants became more aware of the issue and the benefits of healthier behaviors, they actively shared their knowledge with others in the community [49]. In line with these findings, some participants in our study expressed interest in continuing the cognitive training after the program ended, a trend also observed in previous research on cognitive training interventions [47-50]. This suggests that as participants recognize the value of training, they are more likely to seek continued engagement, further reinforcing the importance of fostering sustained motivation and readiness.

The "community climate" dimension, which refers to people's attitudes toward change—in this case, engaging in digital cognitive training—progressed from the "vague awareness" phase to the "preparation" phase. This improvement can be attributed to the BCT implemented, which kept participants informed about the objectives of cognitive training throughout the process. A Canadian study similarly found that participants who underwent digital cognitive training reported cognitive improvements that were meaningful to their daily lives [51]. Moreover, the absence of adverse effects and the reported cognitive gains likely contributed to an increased sense of self-efficacy among participants, as observed in Edwards et al [52] study on the outcomes of digital cognitive training programs.

Before the training, the "resources" dimension was already at the "initiation" stage, as access to technological devices was a prerequisite for participation. Despite a significant improvement in this dimension, participants frequently reported difficulties in handling technology both at baseline and at postintervention. This barrier, also highlighted by stakeholders during baseline assessments, reflects the digital exclusion often faced by older adults, who are less likely to use computers and the internet [53-55]. Similarly, other studies have noted limited access to devices and a lack of proficiency in using digital tools among older adults, particularly computers [54]. To address this issue, we recommend that future studies incorporate digital inclusion initiatives prior to formal training sessions. Such initiatives could help familiarize older adults with technology, build their confidence, and improve their proficiency. Evidence from recent research, such as Djabelkhir et al [56], supports this approach, showing that pretraining technology familiarization enhances participants' skills, fosters positive attitudes toward training, and boosts self-efficacy, ultimately leading to more successful digital literacy outcomes.

In our study, stakeholders showed a low level of readiness, contrasting with research that highlights strong professional support for digital cognitive programs and their role in preserving cognitive function among older adults [56]. Stakeholders in our study faced challenges in helping participants consistently integrate training into their routines, primarily due to limited familiarity with technological resources. Addressing this issue calls for collaborative efforts to enhance stakeholders' understanding of digital cognitive training and to develop strategies that effectively promote older adults' engagement with these tools.

XSL•FO
RenderX

The main facilitators identified in the baseline were related to the interest in the training, getting results, searching for cognitive stimulation, and curiosity. The facilitators identified in the postintervention analysis for the group that did 10 hours of training were related to cognitive improvement, team support, and the desire to continue training. While, for the group that completed 20 hours, the facilitators were related to cognitive improvement, satisfaction, and training challenge. Notably, the "training challenge" reported by the 20-hour group highlights the importance of programs that adapt to an individual's progress throughout the intervention [10].

In this study, participants were not compensated for their involvement, reflecting real-world conditions where individuals typically participate without financial incentives. Their voluntary engagement created a naturalistic setting, enhancing the generalizability of the findings to everyday contexts. This study has some limitations. Although we tried to diversify the sample for data collection, the criteria for participation in this study included the participant having access to a computer and the internet. As a consequence, we have a selected sample, which does not allow the generalization of these findings to populations with different characteristics. Another limitation of this study concerns the fact that we did not interview stakeholders after the participants completed the digital cognitive training, which prevented us from determining whether there were similar changes in readiness. Finally, this feasibility study was designed to establish the viability, and not to demonstrate the effectiveness of the use of CRM to increase readiness in older adults [53]. Thus, the current findings of an increase in readiness should be interpreted as exploratory and need to be confirmed.

We propose several recommendations for future research aimed at increasing readiness for digital cognitive training among older adults: (1) disseminate psychoeducational content on digital cognitive training and its associated benefits; (2) incorporate digital literacy training before cognitive training, especially for older adults who have difficulty handling technology; (3) provide feedback on training performance and the cognitive domains being trained; and (4) disseminate study findings not only at scientific events but also through mainstream media.

In conclusion, CRM is a feasible tool for identifying facilitators and barriers that can inform strategies to enhance readiness for digital cognitive training in older adults. Future studies should assess the effectiveness of applying CRM to improve readiness and examine whether higher levels of readiness are associated with greater engagement and cognitive improvements following digital cognitive training in older adults. Notably, while CRM was selected in this study due to its comprehensive framework encompassing multiple dimensions, key stakeholders, and the population of older adults, alternative models addressing behavior change may also contribute to the successful implementation of digital cognitive training programs. Therefore, further research exploring diverse theoretical frameworks is encouraged to optimize cognitive training interventions for older adults.

Acknowledgments

We are grateful to the subjects who participated in this study. The cognitive training software used in this study and all technical support were provided to us free of charge by Posit Science, Inc.

Funding

Abstract

Background: Gamified digital training may support long-term engagement in aging populations, yet randomized evidence linking behavioral effects to convergent neuroimaging outcomes remains limited.

Objective: This study tested whether a home-based digital mahjong-based cognitive engagement intervention enhanced cognition in community-dwelling older adults and explored brain changes using multimodal magnetic resonance imaging (MRI).

Methods: We conducted a single-blind, parallel-group randomized controlled trial in Taipei, Taiwan (July 2020-November 2021). Community-dwelling adults aged 55 years and older were randomized (1:1) to a 6-month digital mahjong-based intervention (two 30-minute sessions per week via an iPad app) with an incentivized walking component (Mi Band step tracking with in-game tokens) or no intervention. Primary MRI outcomes were gray matter volume, regional homogeneity (ReHo), fractional amplitude of low-frequency fluctuations (fALFF), and global brain connectivity. Secondary outcomes included cognition (Montreal Cognitive Assessment), physical activity (International Physical Activity Questionnaire), mental health (Brief Resilience Scale and Mandarin version of the Demoralization Scale), quality of life (EQ-5D with a visual analog scale), physical fitness and body composition, and blood biomarkers. Per-protocol analyses were performed. Voxel-wise imaging analyses used analysis of covariance in SPM12 with family-wise error (FWE) correction at the cluster level (P<.05). Sensitivity analyses controlling for MRI delay duration were conducted to assess robustness of findings.

Results: In total, 60 participants were enrolled (n=30, 50% per group); 96.7% (29/30) in the intervention group and 90% (27/30) in the control group completed primary assessments. Compared with controls, the intervention group showed a greater improvement in Montreal Cognitive Assessment delayed recall (between-group difference=−0.79 points, 95% CI −1.538 to −0.042; P=.04). Neuroimaging revealed increased ReHo in the right insula (FWE-corrected P<.05) and decreased gray matter volume in the left frontal pole and orbitofrontal cortex, with reduced fALFF in the left frontal pole. Changes in delayed recall were positively

XSL•FO
RenderX

associated with right insular ReHo and also showed significant associations with the right anterior cingulate gyrus (ReHo), left inferior frontal gyrus, and right paracingulate gyrus (fALFF; FWE-corrected $P<.05$ in all cases). In exploratory dose analyses, right insular ReHo correlated with total practice sessions ($r=0.48$; $P=.009$). Among physiological outcomes, the intervention group had a larger reduction in diastolic blood pressure (−3.50 mm Hg, 95% CI −6.911 to −0.091; $P=.04$), whereas the thyroid-stimulating hormone decreased but remained within the normal range. Sensitivity analyses confirmed that primary findings remained stable after controlling for MRI delay duration.

Conclusions: This 6-month home-based digital mahjong intervention improved delayed recall and increased right insular ReHo. Integrating culturally familiar cognitive challenges with lifestyle engagement may be a feasible strategy associated with salience network–related functional changes and memory performance. Future large-scale trials should use active control conditions and factorial designs to rigorously isolate component-specific mechanisms.

Introduction

Background

Declines in physical and cognitive functions are major challenges for aging populations. Although multidomain interventions can help, maintaining long-term adherence remains difficult for many older adults. The World Health Organization healthy aging framework and the US National Academy of Medicine's healthy longevity framework [1,2] indicate that effective strategies should target physical and cognitive health simultaneously rather than separately. Therefore, combining exercise with cognitive training is a recommended approach [3,4].

As neurodegenerative disorders become more prevalent, preventing functional decline is a priority [5,6]. However, purely physical or cognitive interventions often fail to maintain long-term engagement [7,8]. Previous studies have shown that multidomain interventions can promote healthy longevity; however, their benefits often diminish if participants do not continue the activities after the intervention ends [4,9]. Therefore, sustainable approaches to healthy aging must involve scientifically grounded, multifaceted strategies capable of maintaining participant engagement over the long term.

The interactive nature of digital gaming offers distinct advantages over traditional training, particularly regarding immediate feedback and user engagement. This interactivity makes digital gaming a promising tool for improving adherence in older adults [10] while also providing a feasible and relatively safe approach to support cognitive and physical activity [11]. There is recent evidence further suggesting that digital games may benefit cognitive performance and motor-related outcomes in older adults, particularly when the interventions are structured and appropriately tailored [12]. Research by Ding et al [13] and Zhang et al [14] has shown that digital versions of games such as mahjong can improve cognitive function, support mental health, and reduce cognitive decline in older adults. Mahjong, a traditional Chinese tile-based game, requires players to perform coordinated visual, mental, and cognitive tasks to achieve winning combinations. Studies indicate that both traditional and digital forms of mahjong can positively impact early-stage dementia in older adults [15].

Mechanistically, digital game training engages multiple cognitive domains, such as executive function, attention, and memory, through multitasking activities [16-18]. This process requires the brain to integrate functions across different regions to generate appropriate responses. Research has shown that, after multitasking video game training, older adults can achieve cognitive performance levels comparable to those of control participants aged 20 years [19]. Furthermore, complex game training not only improves cognitive performance in older adults but also induces significant changes in brain function and structure [20-23]. These neural changes demonstrate substantial neuroplasticity in response to targeted cognitive training, suggesting that mahjong-based game training could be an effective approach to promote brain plasticity [24]. Despite the importance of structural and functional brain markers in understanding cognitive aging, there have been few randomized controlled trials investigating the effects of digital mahjong gameplay on brain measures, cognitive function, and overall health.

We selected mahjong as the intervention for 3 reasons. First, it requires working memory, executive function, and attention, aligning with multidomain cognitive training principles [19,24]. Second, observational and experimental evidence links mahjong practice to preserved cognition [13-15]. Third, unlike laboratory tasks, mahjong is culturally familiar, which may enhance intrinsic motivation and adherence [10]. In contrast to traditional computerized cognitive training that isolates specific domains, our cognitive engagement strategy embeds training within a familiar context to improve ecological validity. We combined the core digital mahjong game with incentivized walking and gamified progression to sustain engagement. This design balances efficacy with real-world acceptability. While targeted serious games can effectively engage specific processes, our complementary approach prioritizes cultural relevance and sustainable engagement.

Objectives

In this study, we aimed to evaluate whether a 6-month digital mahjong program could improve cognitive function and be

XSL•FO
RenderX

associated with magnetic resonance imaging (MRI)–derived brain changes. We also tested whether adding a walking incentive would increase physical activity. Our study compared the intervention to a no-intervention control group across multiple domains, including MRI-derived brain measures, global and domain-relevant cognitive performance, overall health status, and blood biomarkers. We hypothesized that this integrated intervention would improve cognitive function and be associated with measurable changes in brain structure and function, reflecting the combined effects of sustained cognitive engagement and lifestyle modification.

Methods

Study Design

This was a single-blind, parallel-group randomized controlled trial registered at ClinicalTrials.gov (NCT05808426). Using a computer-generated random number sequence, we randomly assigned eligible participants in a 1:1 ratio to either an intervention group or a control group without any stratification. The control group received no intervention.

Sample Size Estimation and Participants

We performed an a priori power analysis using G*Power (version 3.1.9.7) to determine the required sample size. The sample size was calculated based on Mini-Mental State Examination data reported in a previous study examining the effects of digital game interventions on cognitive function in older adults [20] in which the intervention and control groups showed mean scores of 28.87 (SD 1.64) and 27.72 (SD 1.60), respectively. We input these values into G*Power, and the resulting effect size was approximately 0.71. Assuming a 1-tailed *t* test with an α value of .05 and power $(1 - \beta)$ of 0.8, the analysis indicated that 26 participants per group would be needed. To account for an anticipated attrition of approximately 10%, we targeted a recruitment of 30 participants in each group. Ultimately, 30 participants were enrolled in each group; by the end of the study, 96.7% (29/30) participants in the intervention group and 90% (27/30) in the control group completed the trial.

Ethical Considerations

This study was approved by the institutional review board of National Yang Ming Chiao Tung University (YM108123F). All participants provided written informed consent in accordance with the Declaration of Helsinki. Participants were informed that they could withdraw from the study at any time, and all personal data were deidentified to ensure privacy and confidentiality. At the time of study design (2019-2020), it was genuinely unknown whether the intervention was efficacious. This study was approved as a minimal-risk proof-of-concept trial. A waitlist control design was not feasible due to resource constraints and COVID-19–related delays.

Procedure

The program design, trial protocol, and intervention completion rate are provided in Multimedia Appendix 1 and Table S1 in Multimedia Appendix 2. Before starting the mahjong intervention, all participants in both groups completed baseline assessments, including questionnaires, physical examinations, blood tests, and brain MRI scans. The intervention content (the digital mahjong game and related procedures) was beta tested by the sponsoring company and piloted with a group of older adults not enrolled in the study.

This trial recruited community-dwelling adults aged 55 years and above in Taipei, Taiwan, between July 2020 and November 2021, corresponding to a 6-month intervention period for each participant. Data were collected at baseline and immediately after the intervention. Participants were enrolled via convenience sampling responding to advertisements posted in local health centers. This study was interrupted for approximately 3 months due to the COVID-19 pandemic. Participants assigned to the intervention group engaged in the digital mahjong program for the full 6-month period as planned. However, pandemic-related restrictions on physical activity caused both groups to experience a 6- to 8-month delay in undergoing postintervention brain MRI scans and other functional assessments.

Because the intervention was delivered individually and remotely, participants' start and end dates varied. For example, the first participant underwent the baseline assessment on July 28, 2020; completed the 6-month digital mahjong game intervention by January 5, 2021; and then underwent the postintervention evaluation (including the MRI scan) on September 2, 2021 (approximately 8 months after intervention completion). The last participant finished all postintervention assessments by October 13, 2021. We paused the study for 3 months during Taiwan's level 4 COVID-19 alert as restrictions prevented the delivery of Wi-Fi SIM cards. Make-up sessions were provided once restrictions eased. To mitigate potential decay of training effects due to the delay between intervention completion and postintervention MRI, we administered a 1-month "booster" retraining session to the intervention group immediately prior to the scheduled MRI assessment based on perceptual learning principles suggesting that brief refresher training can help consolidate and maintain cognitive gains.

Randomization and Blinding

Participants were not informed of their group allocation, and they had no contact with the research team during the study. The research personnel were blinded to group assignments: all participant data were labeled with anonymous codes, so investigators could not discern which intervention a given participant received. Moreover, the staff members who delivered the intervention were separate from those who conducted outcome evaluations and data analysis. The research team also ensured that participants from different groups did not interact with one another throughout the trial.

Intervention Program

The digital mahjong game was delivered via an iPad app (the Bonus Winner app), in which a single participant plays against 3 computer-controlled players, replicating the traditional game in a virtual format. The app was a commercially available platform adapted for research purposes with the developer's cooperation. The key modification for this study was the implementation of a structured difficulty progression system based on response time constraints, allowing for parametric control over cognitive load. The research team provided an

XSL•FO
RenderX

orientation to the digital mahjong platform and supplied each intervention group participant with an iPad. As part of the gamified design, participants could earn virtual bonus points through walking activity; therefore, each participant was given a Xiaomi Mi Band wristband to track their steps. A research assistant set up each participant's device by installing a SIM card for Wi-Fi connectivity, instructed participants on using the mahjong app, and monitored their gameplay progress remotely. The assistant also demonstrated how the Mi Band's recorded walking distance would be converted into in-game bonuses.

The digital mahjong game protocol (see Multimedia Appendix 1 for details) used a progressive difficulty system with real-time interactive gameplay. The game consisted of 4 levels, each with increasingly stringent response time limits:

- Level 1: 20-second response window (familiarization phase; month 1)
- Level 2: 7-second response window (standard training; months 2-6)
- Level 3: 5-second response window (advanced; optional)
- Level 4: 3-second response window (highest difficulty; optional)

To minimize ceiling effects and baseline heterogeneity, we excluded participants with regular mahjong experience (playing >3 times per year). However, we permitted basic rule familiarity to avoid the confounding load of learning game mechanics from scratch. All participants spent the first month at level 1 to ensure mastery of the digital interface before progressing. This graduated structure facilitates adaptation to increasing cognitive loads. To sustain motivation, we implemented a coin-based progression system that incentivized advancement while mitigating the frustration of losses. Comprehensive intervention details are provided in Multimedia Appendix 1.

Outcomes

The primary outcome was defined as changes in brain structure and function as measured via MRI. MRI data acquisition and image processing for structural and functional analyses were conducted using standard protocols.

All MRI scans were performed on a 3T Siemens scanner at National Yang Ming Chiao Tung University. T1-weighted anatomical images were acquired using a 3D magnetization prepared rapid gradient echo sequence with the following parameters: repetition time=3500 ms; echo time=3.5 ms; inversion time=1100 ms; flip angle=7°; field of view=256 × 256 mm^2; matrix size=256 × 256; voxel size=1.0 × 1.0 × 1.0 mm^3; 192 sagittal slices; 1 excitation. Resting-state functional MRI (fMRI) data were collected using a T2*-weighted gradient-echo echo-planar imaging sequence using the following parameters: repetition time=2500 ms; echo time=30 ms; flip angle=90°; slice thickness=3.5 mm; image matrix size=64 × 64; field of view=222 × 222 mm; 43 interleaved slices (no gap); 200 volumes (acquisition of approximately 8 minutes and 27 seconds). All raw MRI scans were reviewed by an experienced researcher to ensure no anatomical abnormalities or substantial artifacts before further processing.

To characterize intervention-related changes in the brain, we evaluated four neuroimaging metrics: (1) gray matter volume (GMV; derived from structural MRI), which reflects regional GMV differences and was used as a structural MRI marker; (2) fractional amplitude of low-frequency fluctuations (fALFF; derived from resting-state fMRI), which reflects neural activity levels and their relationship to brain metabolic rate changes [25,26]; (3) regional homogeneity (ReHo; derived from resting-state fMRI), which measures the similarity of neural activity among neighboring brain regions [27]; and (4) global brain connectivity (GBC; derived from resting-state fMRI), which measures the interconnectivity of disparate brain regions, reflecting interactions among large-scale brain networks [28].

Detailed preprocessing methods for these MRI-derived features are provided in Multimedia Appendix 1. Whole-brain voxel-wise maps for GMV, ReHo, fALFF, and GBC were generated for statistical analysis.

Secondary outcomes were assessed using validated tools across cognitive, physical, mental, and quality of life domains. Cognitive function was measured using the Montreal Cognitive Assessment (MoCA), a 30-point cognitive screening tool covering multiple domains (orientation, memory, executive and visuospatial function, language, abstraction, naming, attention, and clock drawing) [29,30]. The MoCA takes approximately 10 to 12 minutes to administer, and scores of 26 or higher are considered normal. It has strong psychometric properties and is widely used as a reliable screening instrument for dementia.

Physical activity was measured using the short form of the International Physical Activity Questionnaire (IPAQ; 7-day recall) [31,32]. This questionnaire captures physical activity across work, household, transportation, and leisure domains at 3 intensity levels. Weekly physical activity was calculated in metabolic equivalent of task (MET) minutes by summing the time spent walking (3.3 METs), in moderate-intensity activities (4.0 METs), and in vigorous-intensity activities (8.0 METs). The short form of the IPAQ has excellent content validity (content validity index=0.994) and adequate test-retest reliability (r=0.67).

Mental health was evaluated using 2 self-report scales: the Brief Resilience Scale [33] and the Demoralization Scale (Mandarin version) [34-36]. The Brief Resilience Scale is a 6-item questionnaire measuring an individual's resilience, with items rated on a 5-point Likert scale (1="strongly disagree"; 5="strongly agree"). After reverse scoring the 3 negatively worded items, responses are averaged, with higher scores indicating greater resilience. The Mandarin version of the Demoralization Scale consists of 24 items rated from 0 ("never") to 4 ("all of the time"), with a total score of 30 or higher indicating demoralization syndrome (higher scores reflect greater severity of demoralization).

Quality of life was assessed using the EQ-5D questionnaire [37,38]. This instrument evaluates 5 domains: mobility, self-care, usual activities, pain and discomfort, and anxiety and depression, each on a 3-level scale ("no problems," "some or moderate problems," and "extreme problems"). Participants also rated their overall health on the EQ-5D's visual analog scale from 0 (worst imaginable health) to 100 (best imaginable

XSL•FO
RenderX

health). The EQ-5D (including the visual analog scale) is a widely used and validated measure of general health status in older adult populations.

Additionally, we administered standard physical fitness tests, measured body composition using an InBody S10 bioimpedance analyzer, and collected blood samples for a panel of biochemical markers. Other recorded information included participants' demographic characteristics, health-related behaviors (eg, tobacco and alcohol use), and any self-reported physician-diagnosed medical conditions.

Statistical Analysis

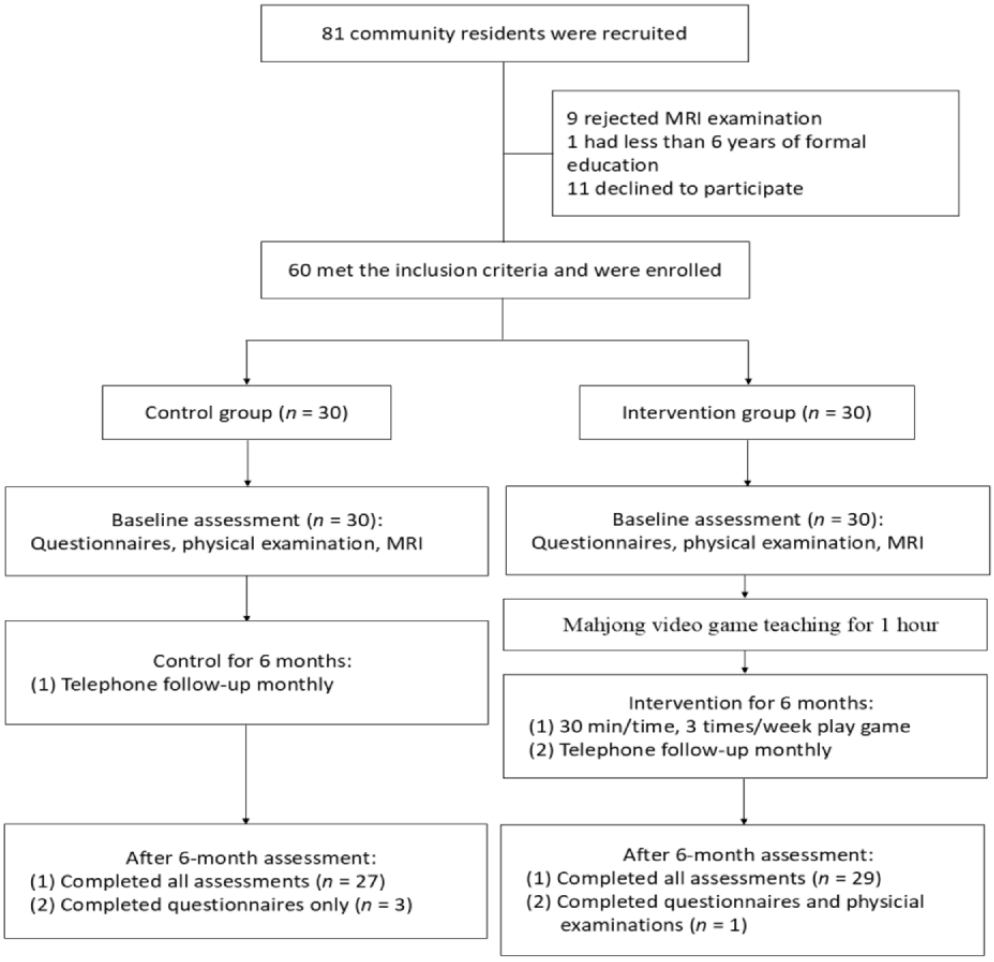
All analyses were conducted on a per-protocol basis comparing the intervention and control groups' outcomes from baseline to the postintervention time point. Continuous variables were summarized as means and SDs and compared between groups using appropriate significance tests (2-tailed Student *t* test for parametric data or Mann-Whitney *U* test for nonparametric data). Categorical variables were summarized as counts and percentages and compared using chi-square or Fisher exact tests. Statistical significance was set at a 2-sided *P* value of less than .05 (95% CIs that excluded the null value). Data were analyzed using SPSS Statistics (version 25.0; IBM Corp).

For primary outcomes derived from neuroimaging measures, we used a difference-in-differences approach to compare changes from baseline to the 6-month follow-up between groups. Specifically, after preprocessing, individual posttest-minus-pretest change maps were estimated for each MRI metric by subtracting each participant's baseline image map from the corresponding postintervention image map. These voxel-wise change maps were then entered into group-level analyses in SPM12 to test whether longitudinal changes differed between the intervention and control groups. As the dependent variables were posttest-minus-pretest change maps, baseline MRI maps were incorporated into the calculation of within-participant change rather than entered as separate covariates. We used analysis of covariance models to test for intervention effects on MRI outcomes adjusting for relevant covariates (baseline age, sex, and intracranial volume for structural measures and age and sex for functional measures). To correct for multiple voxel-wise comparisons, we applied a cluster-level family-wise error (FWE) correction at a *P* value of less than .05 using the AFNI program's 3dClustSim (version 20.3.03) with an initial voxel-wise threshold of a *P* value below .005. The minimum cluster size for significance was determined separately for each imaging metric (eg, 166 voxels for GMV, 57 voxels for ReHo, 19 voxels for fALFF, and 10 voxels for GBC).

To assess the robustness of our neuroimaging findings to variable delays between intervention completion and postintervention MRI assessment, we conducted sensitivity analyses including MRI delay duration as an additional covariate in all analysis of covariance models. This approach allowed us to evaluate whether observed brain changes were confounded by the timing of postintervention assessments. Details and results of these sensitivity analyses are provided in Multimedia Appendix 3.

To explore dose-response relationships in the intervention group, we examined whether the amount and type of mahjong practice correlated with brain changes. We first extracted the mean values from each participant's significant brain clusters (identified in the GMV, ReHo, fALFF, and GBC analyses). Then, using partial Pearson correlations (controlling for age, sex, and MRI delay duration in sensitivity analyses), we tested associations between these brain change metrics and the number of completed mahjong sessions at various difficulty levels (total sessions and sessions with 20-, 7-, 5-, and 3-second response time limits). The significance for these correlations was evaluated at a false discovery rate–corrected level of a *P* value below .05.

We also investigated whether improvements in cognitive scores were associated with neuroimaging changes. For each participant, we computed the change (baseline to posttest) in cognitive performance (eg, MoCA delayed recall) and extracted the corresponding change maps for brain outcomes. Using SPM12, we built multiple linear regression models to test the association between cognitive improvement and brain changes adjusting for age and sex (and also adjusting for baseline intracranial volume for structural MRI measures). These regression analyses did not yield any significant voxel-wise associations at the predefined threshold (cluster-level FWE $P<.05$). Further details of all statistical procedures are provided in Multimedia Appendix 1.



Results

Participants

Figure 1 shows the participant flow from initial screening and enrollment to random allocation (30 participants per group). Participant characteristics included a mean age of 64.45 (SD 5.23) years in the intervention group and 68.07 (SD 5.78) years in the control group ($P=.27$). The intervention group consisted of 34.5% (10/29) male participants, whereas the control group comprised 40.7% (11/27) male participants ($P=.78$). The groups did not differ significantly on baseline physical activity (IPAQ), physical fitness, or body composition measures, supporting comparability prior to randomization. Additional baseline demographic characteristics for each group are provided in Table S2 in Multimedia Appendix 2.

XSL•FO
RenderX

Figure 1. CONSORT (Consolidated Standards of Reporting Trials) flow diagram indicating the number of participants enrolled, the randomization process, and the study flow. MRI: magnetic resonance imaging.

Intervention Engagement

Detailed engagement metrics are provided in Table S1 in Multimedia Appendix 2. Briefly, participants in the intervention group completed a mean total of 825.2 (SD 615.0; range 289-3055) sessions over the 6-month period. All participants in intervention group (30/30, 100%) completed the familiarization phase (level 1; 20-second response window), 100% (30/30) progressed to level 2 (7-second response window), 100% (30/30) advanced to level 3 (5-second response window), and 86.7% (26/30) attempted the highest difficulty (level 4; 3-second response window). The mean number of daily steps recorded via Mi Band was 8826 (SD 3205.4; range 85.0-19,543.5). Protocol adherence (completing ≥80% of scheduled sessions) was achieved by all participants, with a mean completion rate of 94.44% (SD 6.09%; range 83.33%-100%).

Primary Outcome

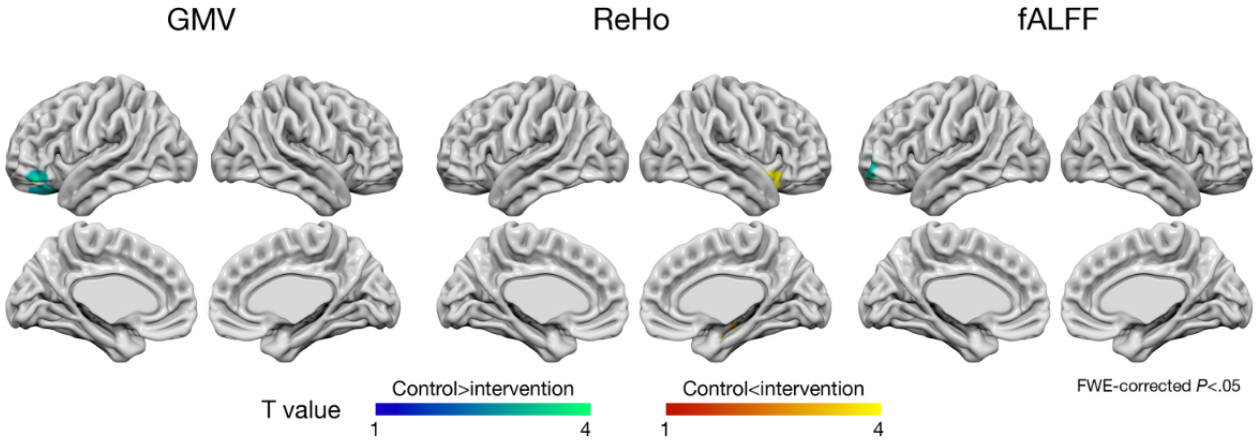
At the 6-month follow-up, the intervention group exhibited significant intervention-related changes in brain structure and function compared to controls. In voxel-wise analyses (Figure 2; Table S3 in Multimedia Appendix 2), the intervention group showed reduced GMV in the left frontal pole and left orbitofrontal cortex, as well as decreased fALFF in the left frontal pole. Conversely, ReHo in the right insula was significantly increased in the intervention group (cluster-level FWE P<.05). Notably, none of these brain changes were significantly associated with the frequency of digital mahjong gameplay during the intervention.

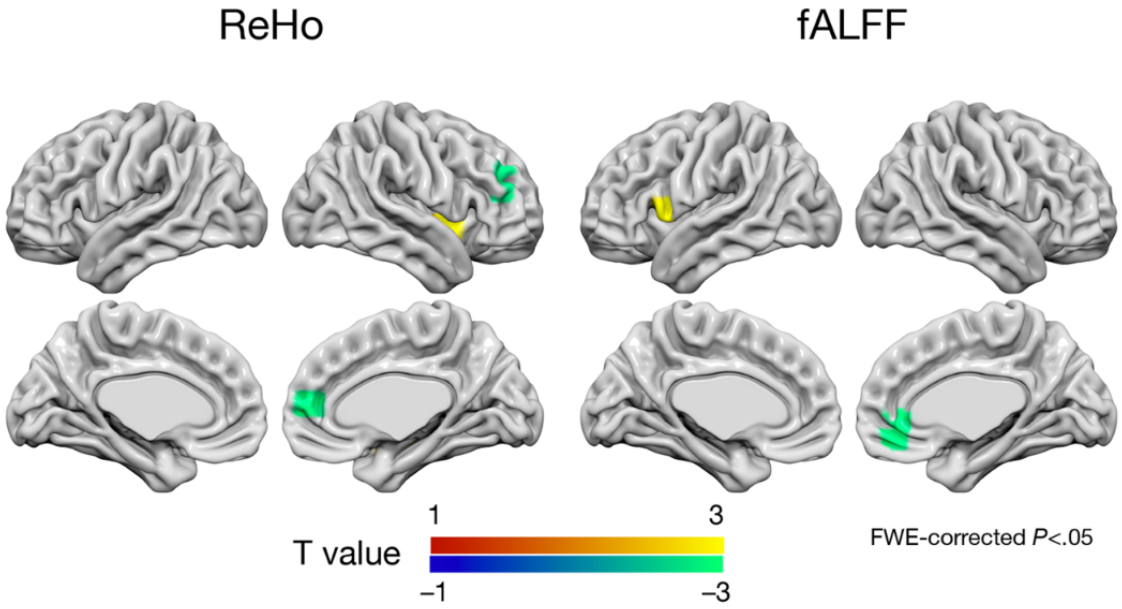
The regression analyses examining cognitive-brain relationships indicated that changes in GMV were not significantly related to improvements in cognitive performance (eg, MoCA delayed recall). In contrast, changes in MoCA delayed recall scores were significantly associated with functional connectivity changes: a greater improvement in delayed recall was associated with an increase in ReHo in the right insula and a decrease in ReHo in the right paracingulate gyrus and right frontal pole (cluster-level FWE P<.05 in all cases; Figure 3; Table S4 in Multimedia Appendix 2). Similarly, for fALFF, higher delayed recall gains were linked to increased fALFF in the left inferior frontal gyrus and decreased fALFF in the right paracingulate gyrus (FWE P<.05). Finally, intervention participants who completed more training sessions, especially those with faster response times (7- and 5-second limits), exhibited higher ReHo in the right insula. In exploratory dose analyses, right insular ReHo correlated with total practice sessions (r=0.48; P=.009; Figure 4).

XSL•FO
RenderX

Sensitivity analyses controlling for MRI delay duration confirmed the robustness of the primary findings. Detailed sensitivity analysis results are provided in Multimedia Appendix 3. Group-level results for GMV and fALFF remained consistent with those of the original analyses (Table S1 and Figure S1 in Multimedia Appendix 3). Although the ReHo activation pattern in the right insula did not survive strict cluster-level FWE correction in the adjusted model due to reduced statistical power, the effect remained visible at a relaxed threshold (uncorrected $P<.05$; cluster of >100 voxels). Importantly, the brain-behavior correlations and dose-response relationships remained significant after controlling for the delay, with peak coordinates identical to those of the original analysis (Table S2 and Figures S2 and S3 in Multimedia Appendix 3).

Figure 2. Brain measure changes between the control and intervention groups. Hot (red-yellow) regions reflect a significantly increased change in the intervention group. Cold (blue-green) regions reflect a significantly decreased change in the intervention group. fALFF: fractional amplitude of low-frequency fluctuations; FWE: family-wise error; GMV: gray matter volume; ReHo: regional homogeneity.





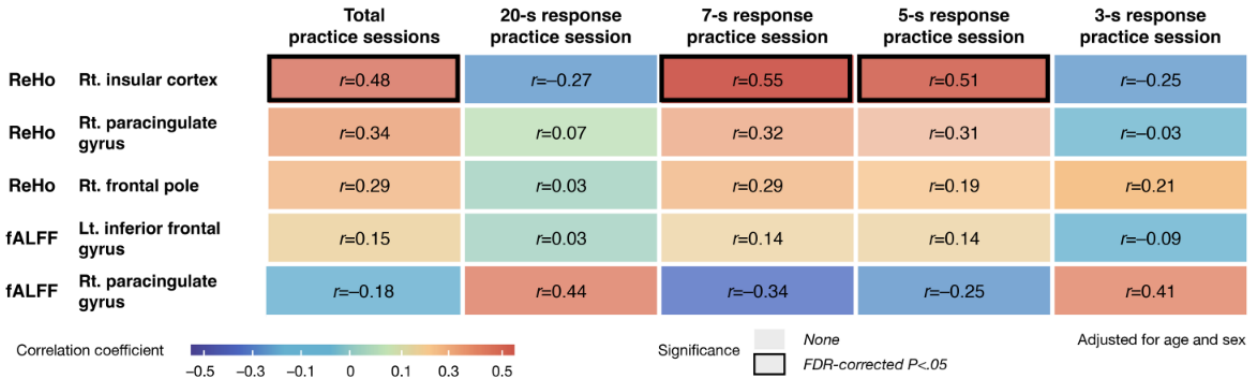


Figure 3. Associations between changes in intrinsic functional brain measures and improvements in delayed recall performance. Multiple linear regression analyses were performed to examine the associations between changes in intrinsic functional brain measures (regional homogeneity [ReHo] and fractional amplitude of low-frequency fluctuations [fALFF]) and improvements in Montreal Cognitive Assessment (MoCA) delayed recall scores. Analyses were adjusted for age and sex. Hot (red-yellow) regions reflect a significantly positive correlation with the cognition outcome. Cold (blue-green) regions reflect a significantly negative correlation with the cognition outcome. FWE: family-wise error.

XSL•FO
RenderX

Figure 4. Associations between brain signature changes and the number of mahjong training sessions completed at different response-time levels. Relationships were estimated using partial Pearson correlation analysis accounting for age and sex. Significant correlations are marked with a black box (false discovery rate [FDR]–corrected *P*<.05). fALFF: fractional amplitude of low-frequency fluctuations; Lt: left; ReHo: regional homogeneity; Rt: right.

Secondary Outcomes

Table S5 in Multimedia Appendix 2 summarizes the between-group comparisons for cognitive function, physical activity, psychological measures, quality of life, body composition, and blood biomarkers. The intervention group demonstrated a significantly greater improvement in MoCA delayed recall from baseline than the control group (between-group difference=−0.79, 95% CI −1.538 to −0.042; *P*=.04). Both groups completed identical MoCA assessments at baseline and follow-up under the same conditions. Importantly, the improvement was specific to delayed recall rather than domains more susceptible to practice effects (eg, orientation and naming), suggesting domain-relevant gains aligned with the memory demands of the intervention rather than generalized practice effects. The intervention group also reported a reduction in weekday sitting time relative to baseline, but this decrease was not significantly different from that in the control group (+71.7 minutes, 95% CI −7.8 to 141.1; *P*=.08). There were no significant between-group differences in resilience, demoralization, or quality of life outcomes.

Physical examination results showed that the intervention group had a significant reduction in diastolic blood pressure (3.50 mm Hg, 95% CI, 0.091-6.911; *P*=.04). Although the control group showed greater decreases in muscle mass measurements (right leg, left leg, total limb muscle mass, and relative appendicular skeletal muscle), these differences were not statistically significant between groups (Table S5 in Multimedia Appendix 2).

Biochemically, the intervention group showed a significant decrease in serum thyrotropin levels compared to the control group (−0.545 μIU/mL, 95% CI −1.018 to −0.072; *P*=.02). As all participants' thyrotropin level values remained within the normal range, the clinical significance of this drop is unclear. Total cholesterol levels changed slightly in the intervention group relative to controls, but there were no corresponding significant changes in high-density lipoprotein or low-density lipoprotein cholesterol.

Finally, exploratory hierarchical regression analyses (Table S6 in Multimedia Appendix 2) were conducted to investigate how the extent of engagement with the intervention related to the secondary outcomes. These analyses suggested that participants with longer average daily play time tended to have greater reductions in total cholesterol (*P*=.03) and those who frequently played with the 20-second response window tended to have higher high-density lipoprotein cholesterol (*P*=.047). Additionally, the total number of incentivized walking steps was positively correlated with thyroid-stimulating hormone levels at 7 months (*P*=.03).

Discussion

Principal Findings

Our study showed that a home-based digital mahjong-based cognitive engagement intervention significantly improved delayed recall in older adults. We also observed functional changes in the right insula, suggesting that the training involved specific brain networks. While many health interventions are effective in the short term, adherence often declines over time. Our study demonstrates that a culturally adapted digital tool can sustain engagement and improve delayed recall. Gamification has emerged as a promising approach to encourage healthy behaviors, but its long-term efficacy relative to more traditional interventions remains to be fully elucidated.

The findings from our trial indicate that the digital mahjong-based cognitive engagement intervention significantly enhanced delayed recall ability and showed accompanying changes in brain functional measures. The observed effects reflect the combined intervention package (digital mahjong, incentivized walking, and gamification) rather than any single component. In particular, the most challenging training sessions (with 7- and 5-second response time limits) showed the strongest associations with right insular ReHo. These findings align with those of previous research showing that cognitive training can enhance memory [39,40]. Our study adds exploratory neuroimaging findings to behavioral findings. Specifically, we observed increased ReHo in the right insula. The preferential engagement of this region during high-intensity (5- and

XSL•FO
RenderX

7-second) sessions may reflect increased demands on decision urgency and error monitoring. This pattern is consistent with the potential involvement of the salience network in mediating rapid switching between internal processing and external stimuli. However, because the right insular ReHo finding was attenuated in sensitivity analyses after controlling for MRI delay duration, this result should be interpreted with caution given its sensitivity to model specification.

We also noted significant GMV reduction in the frontal pole, a region critical for working memory [41,42]. Given the concurrent improvement in delayed recall performance, this decrease may be compatible with experience-related structural reorganization or enhanced neural efficiency rather than necessarily indicating maladaptive atrophy. This finding is consistent with those of recent randomized controlled trials, which similarly found no evidence of macroscopic structural growth (volume expansion) despite rigorous cognitive training. Together, these findings support the hypothesis that functional connectivity alterations (such as ReHo) may precede or accompany structural changes [43]. Behaviorally, we further noticed that participants relied heavily on in-game cues during the most challenging (7 and 5 seconds) response time sessions. This suggests that the high cognitive load necessitated external support, reinforcing the possibility that intensive cognitive engagement may be associated with changes in specific brain networks.

This trial demonstrated that a gamified cognitive engagement intervention can significantly improve cognitive performance (specifically delayed recall) in older adults, corroborating previous findings that cognitively stimulating games such as mahjong yield cognitive benefits [13,14]. Our study uniquely combined the digital game with an incentive program: participants earned virtual tokens for in-game rewards by walking, thereby motivating both cognitive engagement and physical activity. Unfortunately, the onset of the COVID-19 pandemic likely blunted the full benefits of this design. As infection concerns grew, participants became less willing to go outside, reducing their walking activity despite the token incentive. Indeed, pandemic-related restrictions and safety measures have been shown to adversely affect older adults' physical, cognitive, and mental well-being [44,45]. Although Taiwan experienced a relatively mild outbreak, these disruptions probably limited the effectiveness of our walking-based token system to simultaneously promote exercise and cognitive training.

Mahjong gameplay has also been linked to mental health benefits (eg, lower depression and better well-being), presumably through increased social interaction [46]. In our study, however, the digital format did not yield measurable gains in physical performance, psychological resilience, demoralization, or quality of life relative to controls. One explanation for the absence of these effects is a possible ceiling effect: our participants were relatively healthy at baseline, leaving little room for improvement on those measures. Moreover, both groups experienced comparable pandemic-related stress during the trial, which could have obscured subtle intervention benefits. Despite these null findings, our intervention did produce robust gains in delayed recall along with corresponding brain changes. The integrated walking incentive successfully promoted physical activity, with participants averaging 8826 (SD 3205.4) steps per day despite pandemic restrictions. This sustained activity level suggests that the gamified token economy remained effective in motivating physical movement even under constrained environmental conditions, which likely contributed to improvements in cardiovascular indicators. In fact, the intervention group showed significant reductions in diastolic blood pressure and total cholesterol, outcomes consistent with increased daily activity levels [47,48].

Unlike targeted serious games that isolate specific cognitive processes, our study prioritized ecological validity and cultural acceptability. Mahjong engages multiple domains simultaneously, mirroring real-world cognitive demands. We acknowledge the trade-off between the mechanistic precision of laboratory tasks and the implementability of lifestyle interventions. However, culturally meaningful activities such as digital mahjong often promote better long-term adherence than abstract computerized cognitive training programs. This sustained engagement may yield greater cumulative benefits over time even if the training target is less precise. Future studies should directly compare serious games with culturally adapted activities to guide recommendations for diverse populations.

Limitations

Our study has several limitations. First, the lack of an active control group limits our ability to exclude placebo effects. Participants in the intervention group received staff attention, technology, and incentives, all of which could trigger Hawthorne or expectancy effects. However, the observed gains were most evident in delayed recall, a core demand of mahjong, rather than generalized improvements. This pattern, combined with the neuroimaging correlations, suggests but does not establish intervention-specific effects. Future studies should use active controls, such as nonstrategic games or educational activities [43], to isolate the specific effects of mahjong training.

Second, COVID-19 restrictions necessitated a 6- to 8-month delay between intervention completion and MRI assessment. To mitigate potential signal decay, we administered a 1-month booster session prior to scanning and controlled for delay duration in sensitivity analyses [43]. Although these analyses confirmed the stability of brain-behavior correlations, we acknowledge that the observed neuroimaging differences may partially reflect consolidation processes or environmental factors during the hiatus rather than acute training effects alone.

Third, our intervention combined digital mahjong with incentivized walking, preventing us from isolating the specific contribution of each component. Consequently, the reported effects reflect the aggregate intervention. However, there are 2 lines of evidence suggesting that cognitive training was the primary driver of the observed neuroimaging differences. First, we found a specific dose-response relationship between mahjong practice intensity and right insular ReHo, supporting a link between cognitive training intensity and neural changes. Second, behavioral improvements were specific to delayed recall rather than physical function measures. While these findings support

XSL•FO
RenderX

the specificity of the cognitive training, we cannot rule out synergistic effects between the cognitive and physical elements.

Fourth, because the incentive (token) program was applied only to the intervention group, we could not evaluate whether control participants might also have increased their physical activity without incentives. That said, it is generally recognized that specific incentives are often required to induce meaningful behavior change in health promotion programs.

Fifth, the COVID-19 pandemic and resulting restrictions led to a temporary suspension of the trial, interrupting the link between walking and token rewards. Nevertheless, the core element of our intervention, the digital mahjong game, remained relatively resilient to pandemic disruptions. Notably, previous neuroplasticity trials have found that training gains can persist for 3 to 6 months after an intervention even if performance at follow-up is somewhat below the posttraining peak [19,49]. To help sustain the cognitive benefits in our study, we administered a 1-month "booster" retraining to the intervention group approximately 1 month before the final assessment following perceptual learning principles to reinforce memory traces [50]. Despite these efforts, the pandemic-related delays postponed our postintervention evaluations, which may have attenuated the observed effects. Therefore, our results could be underestimating the true efficacy of the intervention.

We were also concerned about this study not monitoring participants' use of the mahjong app after completion of the intervention; therefore, the sustainability of engagement, continued gameplay habits, and potential risks of excessive use could not be evaluated. Future studies should include longitudinal follow-up assessments to examine both the maintenance of intervention benefits and the promotion of appropriate, balanced use of gamified digital health apps.

Conclusions

This randomized controlled trial suggests that a digital mahjong-based cognitive engagement intervention improved delayed recall and was associated with MRI-derived functional changes (right insular ReHo) in middle-aged and older adults. We also observed secondary benefits for diastolic blood pressure and total cholesterol. These findings support the viability of integrating culturally meaningful activities into lifestyle interventions to promote healthy aging. Future large-scale trials should use active control conditions and factorial designs. Such rigor is necessary to distinguish the specific effects of cognitive training from those of physical activity and optimize these tools for routine geriatric care.

Acknowledgments

The authors would like to thank all the participants. They also would like to thank the Interdisciplinary Research Center for Healthy Longevity of National Yang Ming Chiao Tung University from the Featured Areas Research Center Program within the framework of the Higher Education Sustained Progress and Rise of Universities in Taiwan Project by the Ministry of Education in Taiwan for supporting this research. No generative artificial intelligence tools were used to generate scientific content, analyses, interpretations, or conclusions in this manuscript. All scientific content was developed and written by the named authors. Language editing was performed solely to improve clarity and readability.

Abstract

Background: Cognitive training may enhance cognition and support brain health during aging, but few trials have evaluated readily accessible chatbot-based programs with neuroimaging outcomes.

Objective: This study aimed to evaluate the effects of a chatbot-based cognitive training program on white matter microstructural organization and cognition in cognitively unimpaired older adults.

Methods: In a single-blind randomized controlled trial, 72 cognitively unimpaired older adults were assigned to chatbot-based cognitive training (30 min/day, 5 days/week for 12 weeks; n=37) or a no-intervention control (n=35). Diffusion tensor imaging at baseline and 12 weeks quantified fractional anisotropy (FA) in predefined white matter tracts, and cognition was assessed with the Cambridge Neuropsychological Test Automated Battery.

Results: Groups were comparable at baseline. After 12 weeks, the training group showed significantly less FA reduction than controls in the bilateral tapetum and right posterior thalamic radiation, surviving false discovery rate control (P<.05). The training group also improved on Paired Associates Learning (PAL), an episodic memory measure (P=.04). PAL improvement was positively associated with FA change in the right posterior thalamic radiation and right sagittal stratum (false discovery rate–adjusted P=.04 for each).

Conclusions: These findings suggest that a 12-week chatbot-based cognitive training program may support episodic memory and the relative maintenance of white matter microstructural organization in selected pathways in cognitively unimpaired older adults, consistent with a brain-maintenance framework.

Introduction

Extensive research indicates that cognitive training can mitigate age-related cognitive decline, with improvements reported across multiple domains including memory, attention, and executive functions [1-3]. Large-scale randomized controlled trials, such as the Advanced Cognitive Training for Independent and Vital Elderly (ACTIVE) trial, have demonstrated domain-specific gains in memory, processing speed, and reasoning, with benefits extending to everyday functioning over long-term follow-up [4,5]. However, many traditional interventions rely on in-person group delivery, which may be less accessible for older adults due to mobility or transportation barriers, scheduling constraints, or reluctance to participate in group-based settings. In addition, such programs often require trained facilitators, limiting scalability across communities [6]. These limitations underscore the need for accessible, scalable, home-based cognitive interventions, particularly when in-person delivery is constrained [7].

Computerized (digital) cognitive training offers a scalable alternative that can be delivered at home with fewer logistical barriers [8]. Particularly, chatbot-based cognitive training represents an evolution of mobile-delivered computerized cognitive training. By integrating conversational AI, chatbots simulate human-like interactions that provide social-cognitive stimulation, which is often lacking in passive digital platforms. This interactive nature may improve engagement and adherence—key challenges in home-based interventions for older adults—by reducing perceived technological burden and providing interactive guidance and feedback [9,10]. This is especially important for older adults living alone, where home-based assistive technologies can maintain accessibility without spatial or scheduling limitations [11,12]. Early studies suggest that chatbot interfaces reduce technological burden while supporting key adherence factors such as usability and consistent feedback [8,13].

Building on prior evidence, we developed Saemi, a chatbot-based cognitive training program delivered through KakaoTalk, a mobile messaging platform widely used in Korea [14,15]. Saemi provides structured cognitive training tasks targeting memory, attention, calculation, language, and executive function. Each daily session includes at least 2 different training modules: one consistently focused on memory and the other targeting another cognitive domain. This design emphasizes memory training as a recurring component, which is consistent with the evidence that memory decline is a key early feature of age-related cognitive changes [16-18]. By leveraging the interactive nature of chatbots, the program enhances personalization and user engagement, while its home-based format helps overcome spatial and logistical barriers, ultimately promoting sustained cognitive stimulation through accessible mobile technology.

While chatbot-based interventions represent a promising and scalable approach, their cognitive benefits and potential neurobiological correlates remain insufficiently characterized in cognitively unimpaired (CU) older adults. Relative maintenance of brain structural integrity—particularly in white matter (WM)—is considered a key mechanism supporting cognitive resilience during aging and is central to the brain maintenance framework [19-21]. WM integrity, particularly in tracts facilitating interhemispheric communication and sensory-cognitive integration, is essential for efficient neural communication and is strongly associated with memory, attention, and executive function [22-24]. Such WM microstructural changes may be sensitive to aging and experience, and may reflect plasticity-related processes over time [25-27].

Therefore, this study aimed to determine whether a 12-week chatbot-based cognitive training program could attenuate age-related decline in WM integrity and concurrently enhance cognitive performance, consistent with a brain maintenance framework. By addressing both neural mechanisms and cognitive outcomes, this work sought to evaluate the potential of a scalable, home-based intervention to support brain maintenance and cognitive resilience in aging.

Methods

Study Design

This was a prospective, single-center, rater-blind, randomized controlled trial, which was conducted from November 21, 2019, to July 13, 2020, at the Memory Disorder Clinic of Ewha Womans University Mokdong Hospital in Seoul, Republic of Korea. This study was reported in accordance with the CONSORT-EHEALTH (Consolidated Standards of Reporting Trials of Electronic and Mobile Health Applications and Online Telehealth) checklist (Multimedia Appendix 1). Patients and the public were not involved in the design, conduct, reporting, or dissemination plans of this trial.

Participants

A total of 81 CU community-dwelling individuals were recruited from the Ewha Womans University Mokdong Hospital in Seoul. All participants underwent a comprehensive neuropsychological assessment using the Seoul Neuropsychological Screening Battery, second edition (SNSB-II) [28] by trained clinical neuropsychologists. CU was defined as those aged 60 or above who scored more than –1 SD below the mean of age- and education-matched norms in tests evaluating memory, attention, language, visuospatial, and frontal executive functions in the SNSB-II. We excluded individuals with any of the following characteristics: (1) suspected or confirmed mild cognitive impairment or dementia; (2) suspected or confirmed major neurological or psychiatric illnesses, including major depressive disorders; (3) contraindications to MRI; (4) visual or hearing impairments severe enough to interfere with questionnaire response; (5) history of medications that could affect cognitive and emotional functions in the past 3 months; and (6) other major medical problems. Of the 81 participants, nine were excluded because of the withdrawal of consent before the baseline assessment. Therefore, a total of 72 participants were included in this study.

Sample Size

For the formal sample size calculation, we used the cortical thickness effect-size estimate specified in the study protocol:

XSL•FO
RenderX

an expected longitudinal cortical thickness change of 0.046 with an SD of 0.053, corresponding to a standardized effect size of Cohen *d*=0.87 [29]. The sample size calculation was based on a 2-tailed independent-samples *t* test comparing mean longitudinal change between the 2 groups. Assuming 2 parallel groups, a 2-tailed α of .05, and 90% statistical power to detect group differences, the required sample size was estimated to be 30 participants per group. To accommodate an anticipated dropout rate of approximately 20%—commonly observed in MRI-based intervention studies—we planned to enroll 36 participants per group, yielding a total target sample of 72 participants.

Ethical Considerations

Written informed consent was obtained from all participants. The study protocol was approved by the Institutional Review Board (IRB) of Ewha Womans University Mokdong Hospital (IRB number 2019-06-028). The study was conducted in accordance with the Declaration of Helsinki and relevant guidelines and regulations. Participant data were handled confidentially and deidentified for analysis in accordance with applicable institutional policies. Participants did not receive financial compensation for participation. This trial was registered with the Clinical Research Information Service (CRIS), Republic of Korea (KCT0004630).

Randomization

After the baseline assessment, 72 participants were randomly allocated in a 1:1 ratio to 2 groups: the intervention group (n=37) and the control group (n=35). A simple, computer-generated randomization sequence was created by an independent statistician who had no contact with study participants. To ensure allocation concealment, the sequence was stored in a password-protected file and revealed only after the baseline assessment was finalized. Trained research staff enrolled participants and had no access to the allocation sequence. Outcome assessors were blinded to group assignments throughout the study.

Blindness

All outcome evaluators were blinded to the group assignment of participants and were not involved in the intervention.

Intervention

All participants from both groups received 30 minutes of education about dementia prevention after undergoing the baseline assessment. Participants in the control group received education only and were instructed to continue their usual activities for 12 weeks without any additional cognitive training. This education included the definition, diagnosis, and current treatments of dementia and lifestyle modifications for dementia prevention, encompassing the importance of cognitive training, healthy foods for the brain, aerobic exercise, and stretching that could be done at home [30,31]. Beyond the study intervention, no other cointerventions were provided. To avoid confounding effects, participants continued their routine health care and agreed not to participate in any other cognitive enhancement programs throughout the trial.

All participants in the intervention group used Saemi (HAII Corporation), a chatbot-based cognitive training program delivered via a mobile messaging platform. The program provides representative brain-training tasks grouped by cognitive domains—language, memory, attention, calculation, and executive function—as illustrated in Figure 1. Participants were instructed to complete training for at least 30 minutes per day, 5 days per week, for 12 weeks. Each daily session comprised at least 2 tasks, including one consistently focused on memory and another targeting a different domain (language, visuospatial function, calculation, or executive function). Actual intervention exposure was quantified using app usage logs. Usage metrics included total training time, completed session counts, active days, and mean use time per active day. Time-based adherence rate was calculated as the percentage of the recommended minimum total training time completed according to app usage logs. The prescribed minimum dose was 30 minutes per day on 5 days per week for 12 weeks, corresponding to 30 total hours across the intervention period. Adverse events were monitored throughout the trial via participant self-reports and spontaneous reporting.

The figure shows example tasks targeting language, memory, attention, calculation, and executive function in a chat-based mobile format.

Outcome Measures

Changes in WM Microstructure

WM microstructural changes were assessed using diffusion tensor imaging (DTI). Fractional anisotropy (FA) was the principal WM metric due to its sensitivity to microstructural organization and its association with cognitive performance in aging [22,32]. Longitudinal FA changes were evaluated using predefined tract-level region-of-interest (ROI) measures extracted from tract-based spatial statistics (TBSS)–processed skeletonized diffusion maps, rather than as a single global FA average; therefore, false discovery rate (FDR) correction was applied across the predefined ROIs. Global baseline FA was used only to assess baseline comparability between groups. Additional metrics such as mean diffusivity (MD), axial diffusivity (AD), and radial diffusivity (RD) were analyzed as complementary measures to provide a broader characterization of WM changes. In line with conventional neuroimaging approaches in intervention studies, WM changes were evaluated as longitudinal alterations over the intervention period, with FA used as the principal imaging marker.

Cognitive Outcomes

Episodic memory performance was assessed using the Paired Associates Learning (PAL) task of the CANTAB [33,34]. PAL was selected because memory training was the core component of the intervention, and PAL is highly sensitive to early episodic memory decline and intervention-related improvements in CU older adults [35]. Raw scores were standardized to *z* scores based on the baseline mean and SD of the control group, with positive *z* scores reflecting better performance. PAL was the principal cognitive measure of episodic memory, reflecting its established validity as a sensitive measure of associative episodic memory.

In addition to PAL, 5 further tasks were included to assess additional cognitive domains: Delayed Matching to Sample (DMS), Rapid Visual Information Processing (RVP), Reaction Time (RTI), Spatial Working Memory (SWM), and One Touch Stockings of Cambridge (OTS). Raw scores were standardized to *z* scores as for PAL, with positive *z* scores representing better performance [36]. The models for cognitive outcomes were adjusted for age, sex, years of education, and baseline CANTAB scores; however, the reported *P* values were not corrected for multiple comparisons across cognitive outcomes.

MRI Acquisition and Processing

MRI Acquisition

All participants underwent brain MRI on the same scanner (Achieva, Philips 3.0T) using a standardized imaging protocol. The 3D T1 turbo field echo magnetic resonance images were acquired with the following imaging parameters: sagittal slice thickness=0.5 mm; no gap; repetition time (TR)=9.9 ms; echo time (TE)=4.6 ms; flip angle=8°; and a matrix size of 240×240 pixels. Fluid-attenuated inversion recovery magnetic resonance images were used to evaluate abnormal WM hyperintensities. These were assessed using the following imaging parameters: axial slice thickness=2 mm; no gap; TR=11000 ms; TE=125 ms; inversion time=2800 ms; matrix size=256×189 pixels. For TBSS, DTI were acquired using a diffusion-weighted single-shot echo-planar imaging sequence with the following parameters: TR=9.2-9.9 s; TE=91 ms; flip angle=90°; b-value=1000 s/mm^2; matrix size=128×126 pixels; 70 axial sections; slice thickness=2 mm; in-plane resolution=1.72×1.72 mm. With the baseline image without diffusion weighting (the reference volume), diffusion-weighted images were acquired from 32 different directions.

XSL•FO
RenderX

DTI Processing

DTI data were processed using the Functional Magnetic Resonance Imaging of the Brain (FMRIB) Software Library (FSL, v6.0.2). Because the JHU ICBM-DTI-81 white-matter labels atlas has been reported to contain left-right orientation and label inconsistencies in some distributed versions [37], we performed an explicit left-right orientation check after registration to standard space and verified atlas orientation before ROI masking and extraction [38,39]. Eddy current–induced distortions and head motion were corrected by affine registration of each diffusion-weighted volume to the non–diffusion-weighted (b0) image using eddy_correct (FSL), which relies on the FMRIB's Linear Image Registration Tool (FLIRT) for linear registration [40,41]. The b vectors were then rotated appropriately using the "fdt-rotate-bvecs" tool as part of FSL [38,42]. Diffusion tensors were then calculated at the level of an individual voxel to generate FA images using DTIfit, and the images of brain tissue were subsequently extracted using the Brain Extraction Tool [43] from the FSL.

The baseline and follow-up FA data of all subjects were realigned onto the standard FMRIB58_FA template provided by the FSL software using a nonlinear registration algorithm implemented in the TBSS package. To improve anatomical longitudinal alignment, we used FLIRT tools from FSL [40,41]. The registered FA images were averaged to generate a skeletonized mean FA image, which represents the main fiber tracts and the center of all tracts common to the group. A threshold of 0.2 was applied to exclude peripheral tracts where there was significant intersubject variability and/or partial volume effect due to gray matter. Each participant's aligned FA data was projected onto the mean skeleton to create a skeletonized FA map. A similar process was performed for the MD, AD, and RD. The skeletonized diffusion maps were subsequently used for atlas-based ROI extraction and ROI-level statistical analyses.

ROI Selection

Following TBSS-based preprocessing and skeletonization, ROI analyses were performed to obtain anatomically interpretable tract-level diffusion measures. ROIs were defined using the JHU ICBM-DTI-81 white-matter labels atlas (48 tracts) [44,45]. The final 17 ROIs were selected based on prior neuroanatomical and cognitive-aging literature, rather than on Shapley additive explanations (SHAP) results. As a supplementary exploratory analysis, SHAP feature-importance ranking across all 48 atlas-defined regions was examined in relation to PAL change (Figure S2 in Multimedia Appendix 2) and was not used to define the ROI set, to support confirmatory inference, or as a criterion for statistical significance [46]. The selected ROIs included the splenium of the corpus callosum, bilateral tapetum, bilateral anterior corona radiata (ACR), bilateral posterior thalamic radiation (PTR; including optic radiation), bilateral sagittal stratum (SS), bilateral cingulum (cingulate gyrus and hippocampal segments), bilateral superior longitudinal fasciculus (SLF), and bilateral uncinate fasciculus. The 17 selected ROIs and their corresponding JHU ICBM-DTI-81 atlas label numbers are provided in Table S3 in Multimedia Appendix 2. ROI-level diffusion metrics were extracted for each selected tract and used as longitudinal outcome measures.

Statistical Analyses

Statistical analyses were performed using STATA software (version 18; StataCorp). Baseline demographic and clinical characteristics were compared between groups using the chi-square test for categorical variables, independent-samples *t* tests for continuous variables, and the Mann-Whitney *U* test for nonnormally distributed variables. Baseline neuropsychological test performances were compared using analysis of covariance adjusted for age, sex, and years of education.

For cognitive outcomes, raw scores from each task were transformed into standardized *z* scores using the mean and SD of the control group at baseline; where necessary, scores were oriented such that higher *z* scores indicated better performance [47].

The main analytical approach for longitudinal changes in DTI metrics and CANTAB outcomes was a linear mixed-effects model, including fixed effects for group, visit (baseline vs follow-up), and the group-by-visit interaction, with a participant-specific random intercept to account for within-subject correlations. Models were adjusted for age, sex, years of education, and the baseline value of each outcome. Missing outcome data were handled implicitly using maximum likelihood estimation in the mixed-effects framework; inference relies on the standard missing-at-random assumption [48].

The main analysis followed the intention-to-treat (ITT) principle, including all randomized participants in the groups to which they were assigned, regardless of adherence. In addition, a supplementary per-protocol (PP) analysis included only those participants who completed the intervention and the follow-up assessment [49].

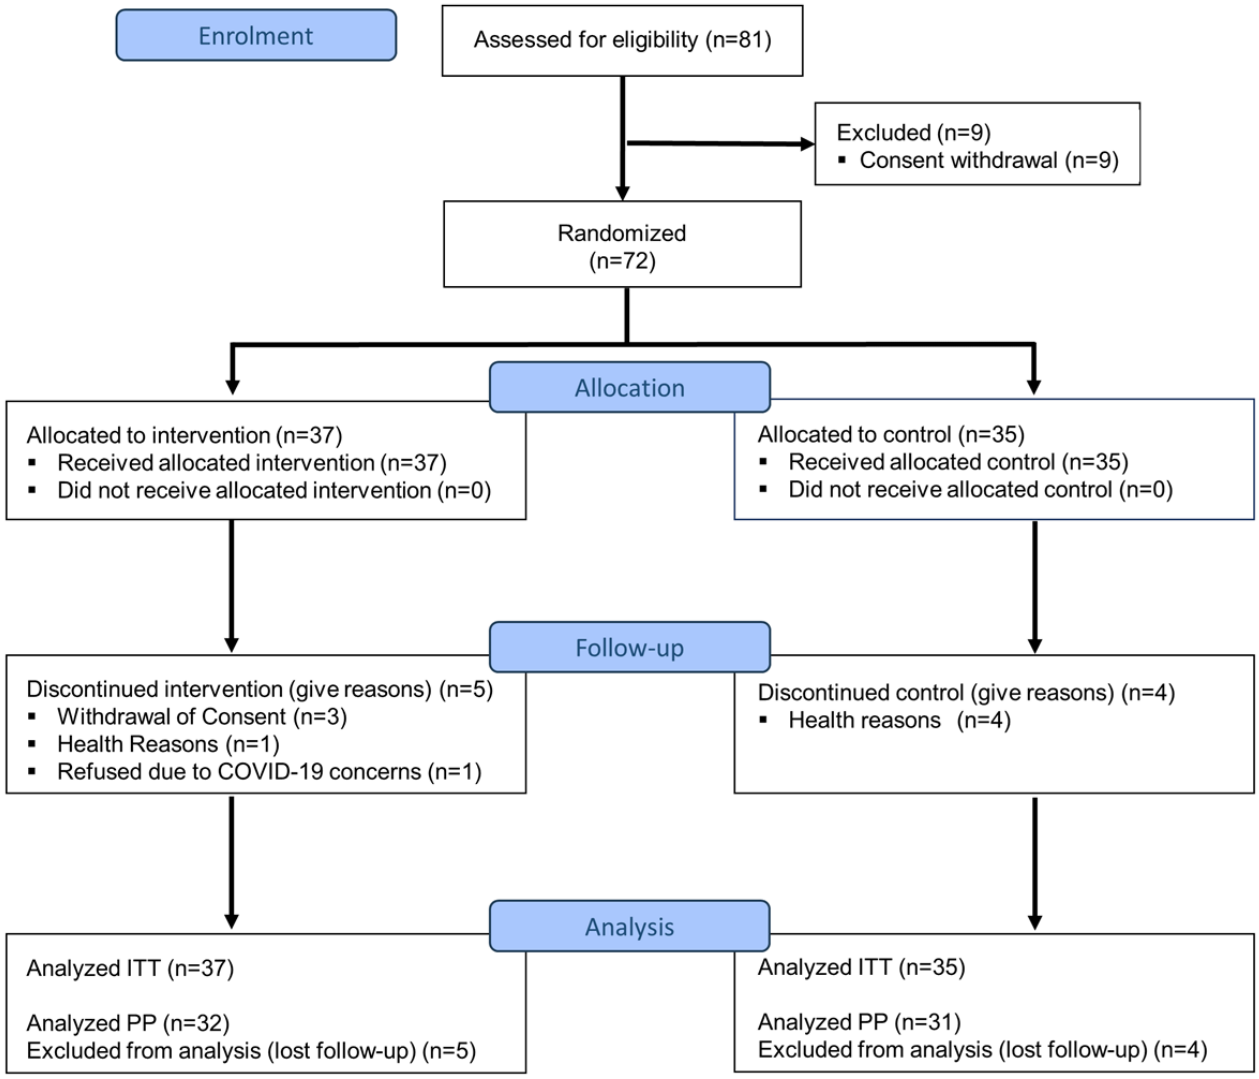
ROI diffusion metrics were analyzed using the same mixed-effects framework. To account for multiple comparisons across ROIs, FDR correction was applied, with Bonferroni-adjusted and uncorrected *P* values reported for descriptive purposes.

Associations between changes in WM microstructure (DTI metrics) and cognitive performance (CANTAB *z* scores) were examined using partial correlation analyses, adjusting for age, sex, years of education, and baseline imaging and cognitive scores. For these exploratory structure-function analyses, missing values were handled using multiple imputation by chained equations with predictive mean matching (m=20 imputations; 5 iterations) under a missing-at-random assumption, implemented in R (version 4.4.1; *mice* package) [50]. Imputed datasets were analyzed separately and combined using standard multiple-imputation pooling rules [51]. Imputation diagnostics were evaluated using density plots. *P* values were adjusted for multiple comparisons using the Benjamini-Hochberg FDR procedure.

Protocol Deviations

This trial was prospectively registered with the CRIS of the Republic of Korea (KCT0004630), with cortical thickness and

XSL•FO
RenderX



resting-state functional magnetic resonance imaging (fMRI) specified as the registered primary imaging outcomes. These modalities were acquired as planned; however, modality-specific longitudinal analyses of cortical thickness and resting-state fMRI have not yet been completed and are not included in the present report. DTI was included from the outset in the IRB-approved neuroimaging protocol but was not separately listed as an outcome in the CRIS registration. Because DTI processing and longitudinal analyses had been completed for the cohort, this study focuses on longitudinal changes in DTI-derived WM microstructure together with cognitive outcomes and should be interpreted as a focused analysis rather than as a report of the registered primary imaging outcomes. Separately, the registered protocol described a 60-minute daily cognitive training schedule, whereas the implemented intervention instructed participants to complete at least 30 minutes per day, 5 days per week for 12 weeks. This change was made before participant enrollment to reduce participant burden and improve the feasibility of sustained home-based training in older adults.

Results

Baseline Characteristics

Of the 72 participants who underwent baseline assessment, 9 (12.5%) participants withdrew from the study: 5 (13.5%) from the intervention group and 4 (11.4%) from the control group. Consequently, 63 (87.5%) participants completed the final assessment (Figure 2). No intervention-related adverse events were reported in either group. Baseline demographic characteristics, clinical variables, neuroimaging characteristics, and cognitive performance across attention, visuospatial function, memory, language, and frontal executive domains did not differ significantly between the intervention and control groups (Table 1).

Figure 2. Randomized trial flow diagram. A total of 72 cognitively unimpaired older adults aged 60 years or older were randomized into the intervention (n=37) and control (n=35) groups. During the trial, 5 participants from the intervention group and 4 from the control group withdrew from the study, and 63 participants completed the 12-week follow-up assessment. Baseline and follow-up assessments included Cambridge Neuropsychological Test Automated Battery cognitive testing and brain magnetic resonance imaging acquisition. ITT: intention-to-treat; PP: per-protocol.

[d]ICV: intracranial volume.

[e]FA: fractional anisotropy.

[f]*P* values for baseline cognitive performance (*z* scores) were obtained using analysis of covariance, adjusted for age, sex, and years of education.

Changes in WM Microstructure

At week 12, the intervention group showed significantly less reduction in FA than the control group in the right tapetum, left tapetum, and right PTR after FDR correction (*P*=.03; *P*=.03; and *P*=.04, respectively; Table 2; Figure 3). Detailed longitudinal values for each group are provided in Table S1, and within-group pre-post comparisons based on paired *t* tests are provided in Table S4 in Multimedia Appendix 2.

Regarding MD, a nominal group difference was observed in the left cingulum (cingulate gyrus; *P*=.04), but this finding did not remain significant following correction for multiple comparisons (FDR-adjusted *P*=.37; Table S5 in Multimedia Appendix 2).

In the PP analyses (participants who completed the follow-up assessment), the results were consistent with the ITT findings. Participants who adhered to the intervention protocol demonstrated less reduction in FA compared with controls at week 12 in the right tapetum (–0.03 for intervention vs –0.06 for control group; FDR-adjusted *P*=.04) and right PTR (–0.02 vs –0.03; FDR-adjusted *P*=.04; Table S6 in Multimedia Appendix 2).

Cognitive Outcomes

Episodic Memory (PAL)

In the ITT analysis, a linear mixed-effects model showed a significant between-group difference for PAL (estimated between-group difference 0.375, 95% CI 0.017 to 0.733; *P*=.04; Table 3 and Figure 4). Detailed longitudinal values for each group, including baseline, week 12, and within-group mean changes, are provided in Table S2 in Multimedia Appendix 2. A similar pattern for PAL was observed in the PP analysis (*P*=.049; Table S7 in Multimedia Appendix 2).

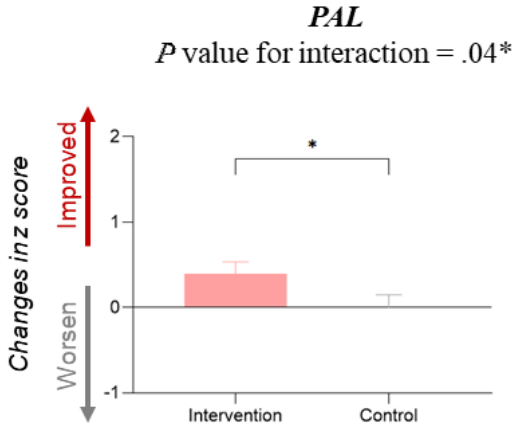

Table 3. Changes in cognitive outcomes measured by z scores after the 12-week intervention.[a]

Cognitive performance	Estimated between-group difference (95% CI)	*P* value
Memory		
Delayed Matching to Sample	0.164 (–0.421 to 0.748)	.58
Paired Associates Learning	0.375 (0.017 to 0.733)	.04
Attention		
Rapid Visual Information Processing	–0.723 (–3.006 to 1.561)	.54
Processing speed		
Reaction Time	–0.000 (–0.493 to 0.493)	>.99
Executive function		
Spatial Working Memory	–0.223 (–0.697 to 0.251)	.36
One Touch Stockings of Cambridge	0.014 (–0.464 to 0.492)	.96

[a]Adjusted for age, sex, years of education, and baseline Cambridge Neuropsychological Test Automated Battery scores. For all listed tasks, scores were transformed into *z* scores and, where necessary, oriented so that higher values indicate better cognitive performance. *P* values were not corrected for multiple comparisons across cognitive outcomes. Paired Associates Learning was the main cognitive measure of episodic memory; delayed matching to sample, Rapid Visual Information Processing, Reaction Time, Spatial Working Memory, and One Touch Stockings of Cambridge were additional cognitive outcomes.

XSL•FO
RenderX

Figure 4. Effects of the intervention on cognitive outcomes. Models were adjusted for age, sex, years of education, and baseline Cambridge Neuropsychological Test Automated Battery scores. PAL: Paired Associates Learning.

Other Cognitive Functions

No significant group × time interactions were observed for other cognitive domains including DMS (*P*=.58), RVP (*P*=.54), RTI (*P*>.99), SWM (*P*=.36), or OTS (*P*=.96; Table 3 and Figure S1 in Multimedia Appendix 2). These null results were consistent across both ITT and PP analyses. Thus, cognitive improvement was observed for PAL, whereas no detectable intervention-related changes were found in the other cognitive outcomes over the 12-week intervention period.

Structure-Function Correlations

In the ITT analysis, significant positive associations were observed between changes in FA and improvement in PAL performance in the right PTR and the right SS, and both remained significant after FDR correction (*P*=.04 for each; Table 4 and Figure 5). No other ROI demonstrated significant associations after correction for multiple comparisons. For MD, a nominal correlation was identified in the left ACR in the ITT analysis (*P*=.01), but this association did not survive FDR correction (Table S8 in Multimedia Appendix 2). In the PP analysis, nominal correlations were observed for FA in the right PTR (*P*=.03), right SS (*P*=.03), and right SLF (*P*=.03), and for MD in the right ACR (*P*=.02) and left ACR (*P*=.004); however, no additional ROI remained significant after multiple-comparison correction (Table S9 in Multimedia Appendix 2).

Intervention Use and Exploratory Dose-Response Analysis

Participants used the program for a mean of 30.73 (SD 12.84) minutes per active day and were active on a mean of 64.24 (SD 16.65) days over the 12-week intervention period, corresponding to approximately 5.35 (SD 1.39) active days per week. Participants completed a mean of 372.52 (SD 200.44) in-app training sessions. The mean total training time was 33.62 (SD 18.53) hours, and the mean time-based adherence rate was 112.1% (SD 61.8%), indicating that participants, on average, exceeded the prescribed minimum training dose of 30 total hours across 12 weeks. In unadjusted exploratory association analyses within the intervention group, the number of active days was positively correlated with PAL *z* score improvement (r=.374; P=.04), suggesting that more frequent engagement with the intervention was associated with greater memory improvement. No significant associations were observed between app-use metrics and FA changes.

Discussion

Principal Findings

This study demonstrated that a 12-week chatbot-based cognitive training intervention was associated with attenuated decline in FA within selected WM tracts and improved episodic memory in CU older adults, a pattern broadly consistent with a brain maintenance framework.

One of the major findings of this study was that DTI analysis revealed attenuated decline in FA in the intervention group compared with controls, most notably in the right PTR and the bilateral tapetum. Notably, significant group-by-time effects were observed primarily in FA, whereas complementary diffusivity metrics (MD, AD, and RD) showed largely null findings after multiple-comparison correction. FA is a composite measure influenced by fiber coherence, myelination, and axonal properties; thus, the present results are best interpreted as relative maintenance of microstructural organization rather than definitive structural restoration. Given the 12-week intervention duration and the modest effect sizes typically observed in diffusion metrics, detectable changes in MD/RD/AD may require longer follow-up and/or larger samples. These tracts are major long-range projection and commissural pathways that support interregional communication and have been implicated in cognitive aging [22,52]. While WM changes in older adults are often widespread, selective differences in projection and commissural fibers observed here are consistent with previous work suggesting activity-related modulation of myelinated pathways [53].

Projection fibers such as the PTR support posterior thalamo-cortical integration, which is relevant to visuospatial information processing and broader cognitive functions [52]. Given that PAL involves visuospatial associative binding [32,34], the observed attenuated FA decline in the right PTR may reflect relative maintenance of long-range pathways supporting visuospatial associative memory. Similarly, commissural fibers such as the tapetum showed attenuated FA decline, reinforcing their role in interhemispheric communication and integration. These commissural fibers support efficient interhemispheric information transfer, which is relevant to memory and higher-order cognition—functions that are particularly vulnerable to age-related decline [54-56].

Furthermore, the intervention group showed significant improvement in PAL performance, a task particularly sensitive to episodic memory. This domain-specific response aligns with the design of the Saemi program, in which memory training was a core, recurring element. The selective improvement in memory is consistent with previous studies reporting task-specific benefits of targeted cognitive interventions [8]. Because PAL is a visuospatial associative memory task, the observed improvement may reflect both a memory-related benefit and alignment between the intervention content and the specific cognitive demands of the task. Accordingly, these findings should not be interpreted as evidence of broad cognitive transfer across multiple domains. In contrast, no significant intervention-related changes were observed in the other cognitive outcomes, including attention, processing speed, executive function, and visuospatial recognition memory. This pattern suggests that the intervention effect on cognition was selective to episodic memory rather than generalized across all measured cognitive domains. The nonsignificant findings in the

XSL•FO
RenderX

other cognitive outcomes may reflect the memory-focused structure of the intervention, limited transfer to less directly trained domains, measurement sensitivity, the relatively short intervention duration, or limited statistical power to detect smaller effects.

These findings are more consistent with brain maintenance reflected by attenuated microstructural decline than with newly induced structural restoration. Because diffusion metrics provide an indirect index of WM microstructure and do not directly quantify myelin or synapse formation, these findings should not be interpreted as evidence of structural "restoration." Nevertheless, repeated engagement in cognitively demanding tasks has been linked to experience-dependent neuroplastic processes—including myelin-related changes and synaptic remodeling—in prior work [27,57,58], which posits that relative maintenance of brain integrity supports sustained cognitive function in older adults [21]. Although these findings are conceptually aligned with a brain-maintenance framework, the absence of longer-term follow-up assessments precludes definitive conclusions regarding the durability of this mechanism. In summary, the observed pattern is more consistent with relative maintenance of WM microstructural organization in pathways relevant to cognitive integration and memory processing, which may be related to intervention-associated improvements in episodic memory [46,53] and is conceptually aligned with a brain maintenance framework [21].

Building on the observed intervention effects on both cognitive performance and WM microstructure, we explored whether changes in these domains were interrelated. Using the imputed ITT dataset, exploratory partial correlation analyses were performed across all participants to examine whether changes in PAL performance were associated with changes in WM microstructure. Change scores were calculated as follow-up minus baseline values. Positive PAL *z* score changes indicate improvement in performance, whereas positive FA changes indicate relative preservation or increase in FA. Partial correlation analyses suggested an association between changes in episodic memory performance and WM microstructural integrity in task-relevant pathways. In addition, PAL improvement was also associated with FA change in the right SS, an associative pathway that includes major posterior cortico-cortical fibers (eg, inferior fronto-occipital and inferior longitudinal components) supporting visual information transfer and integration. Given that PAL relies on visuospatial associative binding, the concurrent PTR-SS associations may suggest that relative maintenance of posterior projection and associative pathways is related to memory-related performance during aging. However, these exploratory structure-function correlations cannot establish causal or mechanistic relationships and should be interpreted as hypothesis-generating findings that require confirmation in larger studies with longer-term follow-up. Nevertheless, this pattern is broadly consistent with the brain maintenance framework, which emphasizes relative preservation of neural structure and function in successful cognitive aging [21,22,52].

Taken together, these findings suggest a possible structure-function relationship in which improvements in episodic memory were associated with relative maintenance of white matter microstructural organization, consistent with a brain maintenance interpretation. Rather than demonstrating a definitive mechanism, our findings indicate that better episodic memory performance was associated with relatively preserved WM pathways implicated in memory-related processing. This interpretation is consistent with the integrated maintenance model, which emphasizes the contribution of both cognitive and structural resilience to successful cognitive aging [21,53,59,60].

Limitations and Future Directions

Several limitations should be acknowledged. First, the relatively small sample size may have limited the statistical power to detect smaller effect sizes and reduced the generalizability of the findings. Future studies with larger, more diverse samples are needed to confirm these results. Second, DTI-derived outcomes were not listed as outcomes in the trial registration, although DTI was included in the IRB-approved neuroimaging protocol. Therefore, these findings should be interpreted as a focused analysis rather than as the primary confirmatory findings of the registered trial. Third, although previous studies suggest that cognitive training effects can persist long-term [1,61], this study assessed only the immediate postintervention effects of a 12-week program. Therefore, the durability and longitudinal trajectory of the observed cognitive and WM changes could not be determined. In addition, without follow-up assessments beyond the intervention period, it remains unclear whether the observed WM differences reflect sustained neuroplastic change or more transient fluctuations. Longitudinal follow-up studies with repeated assessments over time are necessary to clarify the durability of these effects and the potential need for booster sessions. Fourth, potentially influential lifestyle factors such as sleep, physical activity, and social engagement were not assessed. These factors are known to affect WM integrity and may interact with cognitive training effects. Future research could consider multimodal interventions that integrate cognitive, behavioral, and lifestyle components [62]. Fifth, although the intervention emphasized memory training, likely contributing to the significant PAL improvements, no effects were observed in other cognitive domains. This domain-specific pattern suggests that the cognitive benefit was not broadly generalized across domains. Because PAL is a visuospatial associative memory task, the observed improvement may reflect both a memory-related benefit and alignment between the training content and the specific task demands. Future iterations of the program could adjust the training balance or incorporate more targeted modules to evaluate broader transfer effects. Another limitation is that the study did not include an active control condition. Accordingly, nonspecific effects such as expectancy, engagement, general mental stimulation, or digital interaction cannot be fully excluded. Therefore, the observed effects should be interpreted cautiously and should not be attributed solely to the specific cognitive-training content of the intervention. Future studies should include an active control condition matched for contact time, digital interaction, and engagement to better distinguish the specific effects of chatbot-based cognitive training from nonspecific intervention-related effects.

Nonetheless, this study demonstrated that a 12-week chatbot-based cognitive intervention was associated with

XSL•FO
RenderX

improved episodic memory and attenuated decline in WM microstructural integrity within key neural pathways. These findings provide early evidence that chatbot-based cognitive training was associated with improvements in episodic memory and attenuated decline in WM microstructural integrity, suggesting potential cognitive and neurostructural effects that warrant confirmation in larger trials.

Abstract

Background: Depression in older adults presents unique challenges in self-management. Digital tools, such as mobile health (mHealth) apps, have the potential to support this population. This study explored the facilitators and barriers to digital self-management in older adults with depression to inform the design of effective mHealth apps.

Objective: This study aims to explore the facilitators and barriers to digital self-management in older patients with depression with the aim of informing the design and development of mHealth apps for older adults.

Methods: A purposive sampling method was used to recruit 25 older patients with depression from July to September 2024. Semistructured interviews were conducted to capture real-life experiences. Directed content analysis ensured objective and accurate data interpretation, and the Capability, Opportunity, Motivation, and Behavior (COM-B) model and the Theoretical Domains Framework were applied to identify facilitators and barriers related to behavior.

Results: Six themes were identified based on the COM-B model and the Theoretical Domains Framework: perception of illness and accumulation of personal experience; dual challenges of cognitive abilities and physical limitations; integration of digital technologies and acceptance differences; social influences and access to and utilization of support resources; environmental constraints and accommodations; and intertwined influences of beliefs, emotions, and motivation. A total of 13 barriers and 11 facilitators were identified.

Conclusions: Digital self-management in older adults with depression is complex and influenced by multiple interrelated factors. Effective mHealth apps must integrate the cognitive, emotional, and social contexts of patients to provide user-friendly, personalized solutions.

Introduction

Background

With the increasing integration of information and communication technologies into health care, mobile health (mHealth) apps have become an important modality within digital health and are increasingly used to support depression management [1-3]. In parallel, self-management has gained prominence in chronic disease care as a means of enabling individuals to actively manage symptoms, improve adherence to treatment, and enhance daily functioning while reducing dependence on formal medical services [4]. Self-management emphasizes personal agency, perceived control, and the translation of therapeutic principles into daily life practices [5,6]. In the context of depression, self-management commonly includes mental health literacy, psychoeducation, medication adherence support, behavioral activation, and cognitive behavioral strategies [7]. Compared with traditional face-to-face services, digital self-management interventions offer advantages, such as improved accessibility, reduced travel burden, scalability, lower costs, and enhanced protection of privacy [8-11]. Evidence from randomized controlled trials suggests that smartphone-based interventions can reduce depressive symptoms [12] and expand access to care, particularly for

XSL•FO
RenderX

individuals who face barriers to conventional mental health services [13-16].

The growing interest in digital self-management is particularly relevant given the global burden of depression, one of the most prevalent mental health disorders worldwide and a leading cause of disability. According to the World Health Organization, more than 300 million people globally are affected by depression, and its contribution to disability-adjusted life years continues to increase [17]. Depression is particularly prevalent among older adults and not only directly leads to individual disability but also imposes a substantial economic burden on society [18,19]. Studies project that between the years 2023 and 2032, cumulative all-cause medical expenditure for patients with depression will reach US $309 million, which is 2.6 times more than that for nondepressed individuals [20]. Among individuals aged 60 years and older, global prevalence estimates range from 28.4% to 35.1%, with mortality rates reported to be as high as 9.8% [21,22]. Late-life depression is characterized by high recurrence and mortality and yet remains markedly underdiagnosed and undertreated [23,24]. Beyond its clinical impact, depression imposes considerable economic costs through reduced workforce participation, impaired productivity, increased health care utilization, and the transfer of caregiving responsibilities to family members, placing sustained strain on intergenerational care systems [22,25,26]. Despite this burden, fewer than 10% of individuals with depression worldwide receive any form of treatment, and fewer than 1% receive minimally adequate care [27]. Older adults face additional barriers, including limited service accessibility, transportation difficulties, stigma, and reduced awareness of help-seeking pathways, further increasing the risk of untreated or poorly managed depression [28-31].

Effective self-management is therefore particularly important for older adults with depression [32], although its real-world implementation remains challenging. Depression frequently coexists with multimorbidity, functional decline, and age-related cognitive and sensory changes, increasing the complexity of daily symptom management. Core depressive symptoms, such as low motivation, fatigue, and hopelessness, directly undermine the ability of individuals to initiate and maintain self-management behaviors over time [33]. Although mHealth apps provide tools for symptom monitoring, psychoeducation, and remote support, existing evidence indicates a paradoxical pattern in their use among older adults with late-life depression. Specifically, while mHealth interventions have demonstrated efficacy in controlled trials, such as reducing depressive symptoms and improving sleep quality [34], these benefits have not translated into sustained engagement or effective self-management in the real-world setting, where low uptake, rapid disengagement, and poor long-term adherence are commonly reported [35].

This discrepancy has been attributed to multiple interacting barriers, including fear of mental illness–related stigma, suboptimal user interface designs, and age-related physical and cognitive limitations [36,37]. In the real-world context, additional constraints, such as inadequate digital literacy and privacy concerns, further restrict the adoption and continued use of mHealth tools among older adults [38,39]. In addition, existing apps are rarely tailored to the specific psychosocial needs of this population and often overlook themes central to late-life depression, such as grief, loss, loneliness, and social isolation [39]. However, most studies in this field have relied predominantly on quantitative methods, focusing on the acceptance, usability, or impact on symptom outcomes of technology. Although these approaches are valuable for identifying general influencing factors, such as the digital divide and technophobia, they provide limited insight into how older adults with depression perceive, interpret, and emotionally respond to mHealth interventions in everyday life [40]. In particular, they fail to capture how depressive symptoms dynamically interact with technology use to shape both the initiation and sustained engagement in digital self-management behaviors. Without such experiential and contextual understanding, mHealth interventions risk remaining technically effective in controlled trials but poorly aligned with the needs of users in the real world, perpetuating the persistent gap between effectiveness and participation. Therefore, a qualitative approach is essential to elucidate the mechanisms through which individual, technological, and contextual factors jointly influence engagement in digital self-management among older adults with depression.

Theoretical Framework

For older adults with depression, digital self-management is not merely a matter of technology adoption but rather a complex process of modifying health behavior. Therefore, understanding this process is crucial for designing effective intervention strategies. Evidence suggests that using theoretical frameworks to identify and analyze determinants of behavior can substantially increase the likelihood of intervention effectiveness [41]. Theoretical frameworks facilitate a comprehensive understanding and interpretation of the complexity of behavior change, providing a solid foundation for effective intervention design [42]. Interventions grounded in behavioral theory models have been shown to be more effective than interventions not based on theory [43]. Therefore, incorporating theoretical frameworks is essential for understanding behavioral changes. Among various theories, the Capability, Opportunity, Motivation, and Behavior (COM-B) model and its associated Theoretical Domains Framework (TDF) have been widely used to identify behavioral facilitators and barriers, providing strong support for designing targeted interventions [44,45]. To comprehensively understand, analyze, and explain the multidimensional factors influencing the adoption and sustained use of digital self-management by older adults, this study adopted the COM-B model and the TDF as its theoretical guiding frameworks.

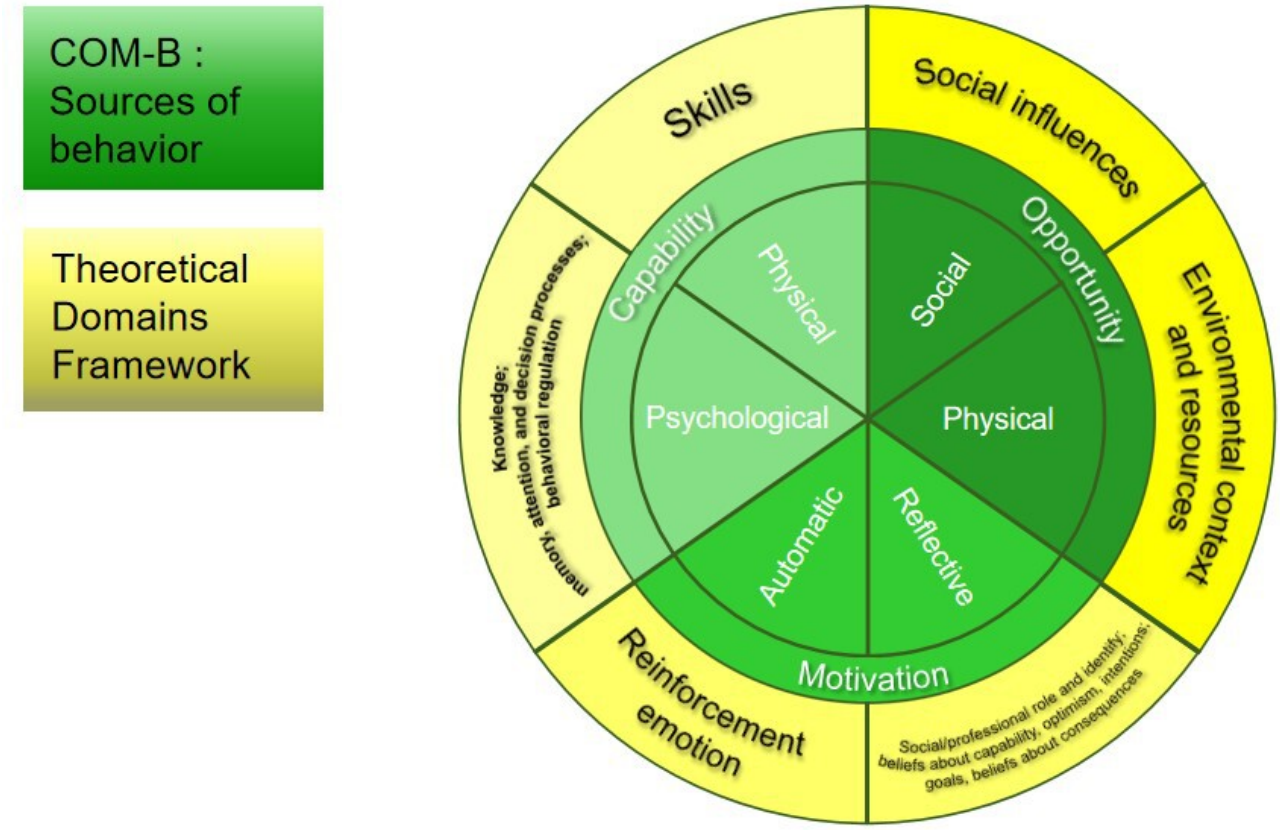
The COM-B model posits that behavior arises from the interaction of capability, opportunity (social and physical), and motivation (automatic and reflective processes) [46]. Building on this model, the TDF translates these components into 14 operational domains, including knowledge, skills, social influences, and environmental resources, offering a comprehensive and structured tool for systematically identifying and analyzing behavioral determinants [46]. Together, the COM-B model and the TDF form the core of the behavior change wheel, serving as an integrated tool for describing

XSL•FO
RenderX

behavior and designing interventions through a concise yet comprehensive analytical structure. Although the COM-B model explains behavior formation through capability, opportunity, and motivation, the TDF further elaborates on these dimensions, enabling a more comprehensive exploration of behavior change possibilities through in-depth interviews and analysis of mHealth self-management among older adults with depression [46]. Compared with other commonly used behavior change theories, the COM-B model and TDF demonstrate advantages in analyzing complex health behaviors. For example, the health belief model emphasizes the perception of disease threat and behavioral benefits by the individual but does not adequately account for social and environmental factors [47]. The theory of planned behavior primarily focuses on individual cognitive factors, such as attitudes and subjective norms, resulting in a relatively narrow perspective [48]. Although the transtheoretical model emphasizes the dynamic nature of behavior change, it lacks systematic identification and classification of specific determinants, limiting its practical applicability [49]. Consequently, the integrated COM-B model and the TDF more comprehensively capture the complex interactions between individual internal factors and external environmental influences on health behaviors, making them particularly suitable for analyzing digital self-management, which is shaped by multiple interacting factors.

In this study, the TDF was used to guide the development of the semistructured interview guide to ensure comprehensive coverage of the theoretical domains that may influence digital self-management behaviors among older adults with depression. Subsequently, qualitative analysis of interview transcripts was conducted to categorize identified barriers and facilitators into relevant TDF domains and ultimately map them onto the three core COM-B components: capability, opportunity, and motivation. This analytical process allowed for a clear and structured presentation of the findings and provided direct theoretical justification and practical guidance to develop feasible and targeted interventions based on the behavior change wheel. Currently, qualitative studies that have applied the combined TDF and COM-B model to explore digital self-management behaviors among older adults with depression in China are scarce. Therefore, this framework provides a solid theoretical foundation for understanding digital self-management behaviors in older adults with depression to inform the design of tailored, context-sensitive digital interventions suitable for Chinese patients.

This study aims (1) to systematically identify the facilitators and barriers that influence the adoption and sustained participation in mHealth interventions among older adults with depression and (2) to map these factors onto the TDF and the COM-B model to elucidate key behavioral determinants, thus informing the development of future strategies to promote the use of mHealth in this population.



Methods

Study Design

This study used a descriptive qualitative research methodology that followed the philosophical basis of naturalistic inquiry, which emphasizes the interpretation of patient experience or the presentation of events in simple language [50]. Valuable information can be gathered from understanding an individual's reactions, thoughts, facilitators, or hindrances to events [51]. To better understand the factors influencing the use of digital tools for self-management in older people with depression, it is important to explore their feelings, experiences, and perceptions related to seeking help. Data were collected through semistructured interviews with open-ended questions. The study used the COM-B model and the TDF to design the outline of the interview and to provide a framework for organizing and analyzing the data (Figure 1). The study was presented in accordance with the COREQ (Consolidated Criteria for Reporting Qualitative Research) checklist (Checklist 1 [52]).

XSL•FO
RenderX

Figure 1. Schematic diagram of the Capability, Opportunity, Motivation, and Behavior (COM-B) model and the Theoretical Domains Framework (TDF).

Study Setting and Recruitment

This study was conducted in 5-star nursing institutions and communities in Fuzhou City, Fujian Province, China. Purposive sampling was used to select interviewees, among those who met the above criteria, and the individuals most likely to provide rich information were selected. The maximum difference sampling strategy was used to account for differences in sex (male or female), age, literacy levels (ranging from primary school to college), economic situation (monthly income starting from <1000 to >5000 CNY [1 CNY=US $0.14]), and disease severity of older patients with depression (mild, moderate, or severe based on 15-item Geriatric Depression Scale scores). Additionally, to ensure diversity in digital experiences, we considered participants' smartphone ownership and their frequency of use. Based on participants' self-reported average daily usage duration during the interviews, usage frequency was categorized as low (≤1 hour/day), medium (1 - 4 hours/day), or high (≥4 hours/day). The sample size was determined based on the principle of meaning saturation (see Multimedia Appendix 1 for details). After each interview, the research team held regular meetings to review transcripts, identify emerging themes, and discuss whether new information was still being obtained. Saturation was considered achieved when 2 consecutive interviews did not yield new substantive themes related to the research questions, and additional data collection appeared redundant. The final decision on saturation was reached through consensus during these team discussions.

Inclusion and Exclusion Criteria

The inclusion criteria were as follows: (1) aged 60 years or older, (2) meeting the diagnostic criteria for depression in the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition*, (3) a 15-item Geriatric Depression Scale score of 5 or higher, (4) ability to communicate; (5) voluntary participation and provision of informed consent, and (6) no requirement for smartphone ownership or prior experience using smartphones. Including participants with heterogeneous digital skills may increase variability, whereas restricting participation to digitally experienced older adults could limit the transferability of the findings [53,54]. Older adults are not a digitally homogeneous group, and excluding those without smartphone experience may overestimate the feasibility of digital self-management and exacerbate digital inequalities [55]. Including participants with diverse levels of digital engagement allowed for a more realistic assessment of barriers and facilitators in real-world settings. The exclusion criteria were as follows: (1) serious physical illnesses preventing cooperation with the interview, (2) severe mental illnesses preventing participation in the study, and (3) illiterate individuals or those unable to understand basic written information.

Data Collection

Data were collected between July and September 2024. Information from the literature [56,57] was used for the TDF and was mapped to the components of the COM-B model to develop a semistructured interview outline. Three patients who met the inclusion criteria for preinterviews through the convenience sampling method (preinterview information was

XSL•FO
RenderX

not included in the final analysis) were selected, and consultations with relevant experts on issues that arose during the interviews allowed for modifications to the outline. The final outline of the interview was confirmed after rediscussion by the research team and is provided in Multimedia Appendix 2.

Two methods were used for data collection: (1) a demographic survey (covering age, sex, education, and economic situation) and (2) in-depth, semistructured, one-on-one face-to-face interviews. Before the interview, the researcher (ZZ) introduced herself, explained the purpose and significance of the study, outlined the necessity of on-site audio recording and the principle of confidentiality, obtained written informed consent from the interviewees, and assisted the participants in filling out the basic information form. Face-to-face interviews were conducted when the patients were free and in good condition, in a separate room without interference. The interview was conducted with open-ended questions that referred to the outline of the interview but were not restricted to the language or order of the outline. During the interview, attention was paid to recording the patient's tone of voice, expressions, movements, and other nonverbal behaviors of the patient. The interviewer also listened carefully to the patient's statements, asked questions and responded to them at the right time, and avoided the use of guiding or suggestive language. The entire interview was recorded, and the key content was noted. The interview lasted 20 to 40 minutes. After the interview, the recorded information was listened to two or three times to ensure accuracy [1], and the information was entered into Microsoft Word.

To enhance the credibility of the data analyses, participants were invited to review and validate the content after the interviews to ensure an accurate understanding and reflection of their views. Detailed records and documentation, including interview outlines, data analysis processes, and rational decision-making, were maintained to facilitate the subsequent review of the data and validate the transparency of the research process.

Data Analysis

All audio recordings were transcribed into a Word document within 24 hours of the conclusion of the interview. The verbatim transcription of the audio-recorded material was accompanied by the labeling and integration of nonverbal information such as pauses, facial expressions, and body language recorded in the field notes of the interviews. The interview data were anonymized, and the transcripts were numbered with P1, P2, P3,..., Pn codes. Other basic demographic and disease information of the study participants was recorded in a separate document from the transcribed manuscript to ensure systematic and confidential data management.

The transcribed data were analyzed using a directed content analysis approach [58,59], guided by the TDF and the COM-B model. Directed content analysis is an appropriate method when existing theory or previous research can guide initial coding and categorization, while still allowing openness to new insights. The analytical process followed 3 main stages: preparation, organization, and reporting. First, the analysis unit was defined, with meaningful sentences reflecting the experiences, perceived barriers, and facilitators of participants related to mHealth-supported self-management used as the smallest analytical units. The transcripts were then read repeatedly to achieve immersion and gain an overall understanding of the data. In the organization stage, an initial coding framework was developed deductively based on the predefined TDF domains and corresponding COM-B components (capability, opportunity, and motivation). Line-by-line coding was conducted, during which relevant text segments were coded and mapped to the corresponding TDF domains. Similar codes were subsequently grouped into subthemes, which were further organized into higher-order themes aligned with the COM-B model. Although the analytic strategy allowed for inductive coding of data that did not fit the predefined theoretical framework, all the content identified in this study could be meaningfully mapped to the TDF domains and COM-B components. Therefore, the presentation of results reflects primarily findings derived from the directed content analysis. Two co–first authors independently performed the deductive coding and mapping process using established definitions of the COM-B model [46] and the TDF [60]. Any discrepancies were resolved through team discussion to ensure analytical rigor.

Rigor

The rigor of this study was ensured through systematic steps of directed content analysis and was elaborated upon using the criteria proposed by Colorafi et al [61], specifically across the 4 dimensions of credibility, transferability, confirmability, and consistency [62]. First, to establish credibility, we used in-depth interviews and member checking: all interviews were conducted by the same researcher (ZZ) to maintain consistency in interaction, and rapport was built during interviews to encourage participants to elaborate. Furthermore, we returned key interview summaries to participants for content verification, thereby validating the accuracy of understanding. Second, to ensure transferability, we comprehensively presented the research context, participant characteristics, purposive sampling strategy, and detailed data collection and analysis procedures in the *Methods* section, providing a sufficient basis for other researchers to judge the applicability of this study's context and findings. Regarding confirmability, we implemented cross-verification among coders: initial coding and the mapping of categories to the COM-B model were independently performed by two researchers (ZZ and XL), followed by review and approval by team members not involved in the initial coding. All analytical decisions and processes were documented for reference, forming a traceable audit trail. Finally, in terms of consistency, the entire study strictly followed the established stages of directed content analysis, and consensus was reached through discussions with the research team at each key analytical junction, thus ensuring the logical coherence and methodological stability of the analytical process.

Reflexivity

In qualitative research, ensuring the rigor and quality of the study is a core responsibility of the researcher. In this context, researcher reflexivity is regarded as a crucial standard to enhance the credibility of the study [63]. Qualitative researchers use reflexivity to explain how their own subjectivity influences the

XSL•FO
RenderX

research process and to make the entire process more transparent [64]. This study was led by 2 experts in the fields of geriatric depression and mental health. All interviews were conducted by ZZ, while the primary coding and mapping analysis to the COM-B model were performed independently by ZZ and XL, with ongoing mutual feedback throughout the process. As the researcher is the primary instrument for data collection and interpretation, throughout the research process, we continuously examined the researcher's professional background (eg, in clinical psychology and geriatric health) and performance considering preexisting knowledge of digital health technologies, as well as potential assumptions and emotional responses formed during interview interactions, through team discussions, research journals, and periodic reflections. This ongoing reflection aimed to clarify the influence of the researcher's position on the study. For example, building an empathetic relationship during interviews may enhance the openness of participants to sensitive topics (such as experiences of depression), whereas the researcher's academic training may also influence the initial interpretation of "self-management" behaviors in the data. By making such reflections explicit and incorporating them into the analytical considerations, we strived to achieve a deeper understanding of the participants' experiences while enhancing the transparency of the research process and the rigor of interpretation as much as possible.

Ethical Considerations

This study received approval from the Ethics Committee of Fujian Medical University (number 2024‐87). All participants were clearly informed of the research purpose, their rights, and the principles of data confidentiality. Written or oral informed consent was obtained from each participant prior to the interviews. Audio recordings were securely stored during the research period and were uniformly destroyed upon the completion of the study. Participants had the right to withdraw unconditionally at any stage of the research without any adverse consequences. All collected data were anonymized. Participants who completed all interviews received a gift as a token of appreciation.

Results

Study Participants

Twenty-five older adult patients with depression were enrolled in this study, with an age range of 60 to 86 years (mean 76.0, SD 6.1), including 15 female patients and 10 male patients. The education levels ranged from elementary school to undergraduate degree. In terms of severity of depression, 4 cases of severe depression, 12 cases of moderate depression, and 9 cases of mild depression were identified. Regarding smartphone ownership, 22 participants owned a smartphone, whereas 3 did not. Based on the content of the interview, the frequency of smartphone usage was categorized as follows: 14 participants had medium usage frequency, 8 had low usage frequency, and 3 had high usage frequency. This distribution across multiple dimensions supports the representativeness of the sample in capturing a broad spectrum of experiences related to digital self-management among older adults with depression. The basic characteristics of the participants are detailed in Table 1. The average duration of patient interviews in this study was approximately 30 minutes.

XSL•FO

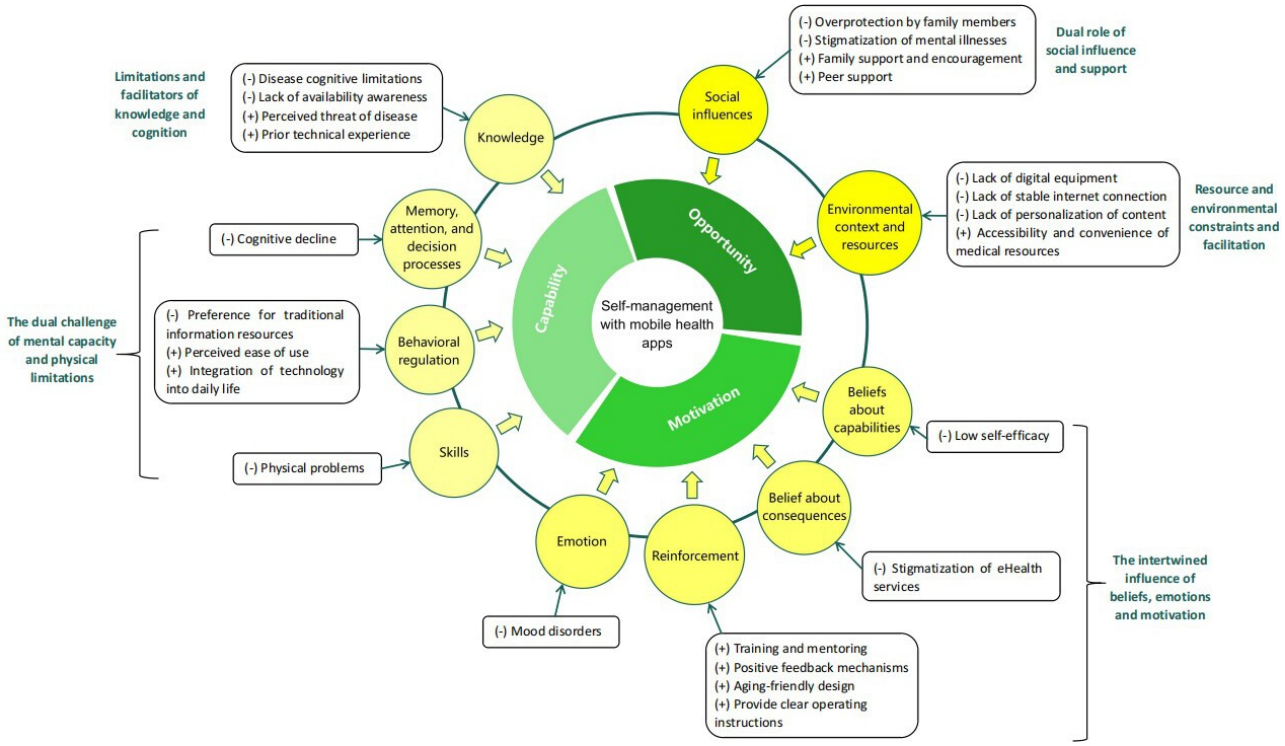
Key Themes and Related Areas



Overview

To improve theoretical clarity, the results are organized according to the COM-B model as the primary analytical hierarchy. Within each COM-B model component (capability, opportunity, motivation), relevant TDF domains and empirically derived themes are presented as subsections. Six themes were identified that were directly related to the 10 TDF domains and 3 COM-B components. The 10 TDF domains were “knowledge”; “memory, attention and decision processes”; “behavioral regulation”; “skills”; “social influences”; “environmental context and resources”; “belief about consequences”; “belief about capabilities”; “reinforcement”; and “emotion,” whereas TDF domains not identified as relevant to the use of mHealth apps to support self-management behaviors were “optimism,” “intentions,” “goals,” and “social or professional roles and identities.” These findings are

XSL•FO
RenderX

described in more detail below using the TDF and the corresponding COM-B model (Figure 2). Table 2 provides an overview of the analytical framework, summarizing the facilitators and barriers identified across the TDF domains and COM-B components for participants, whereas detailed theme descriptions and illustrative quotes are presented in Multimedia Appendix 3. The complete data analysis process, from raw interview statements to open codes and subthemes, is provided in Multimedia Appendix 4.

Figure 2. Mapping of themes to the Capability, Opportunity, Motivation, and Behavior (COM-B) model and the Theoretical Domains Framework (TDF).

XSL•FO
RenderX

Table . Facilitators and barriers to digital self-management for older patients with depression, categorized by Theoretical Domains Framework (TDF) domains and Capability, Opportunity, Motivation, and Behavior (COM-B) components.

COM-B components and TDF	Themes	Barriers (number of participants who mentioned them)	Facilitators (number of participants who mentioned them)
Capability			
Psychological capability			
Knowledge	Disease perception and personal experience building	• Cognitive limitations of the disease (n=13) • Lack of availability awareness (n=8)	• Perceived threat of disease (n=7) • Prior technical experience (n=13)
Memory, attention, and decision processes	Dual challenges of cognitive function and physical limitations	Cognitive decline (n=16)	• Not identified
Behavioral regulation	Digital technology integration and life adaptation	• Preference for traditional information resources (n=7) • Not identified	• Perceived ease of use (n=9) • Integration of technology into daily life (n=9)
Physical capability			
Skills	Dual challenges of cognitive function and physical limitations	• Restrictions on physical functioning (n=10)	• Not identified
Opportunity			
Social opportunity			
Social influences	Access to and utilization of social impact and support resources	• Overprotection by family members (n=11) • Stigmatization of mental illnesses (n=4)	• Family support and encouragement (n=14) • Peer support (n=14)
Physical opportunity			
Environmental context and resources	Resource and environmental constraints and facilitation	• Lack of digital equipment (n=3) • Lack of stable internet connection (n=2) • Lack of personalization of content (n=2)	• Accessibility and convenience of medical resources (n=10) Not identified • Not identified
Motivation			
Reflective motivation			
Belief about capabilities	The intertwined influence of beliefs, emotions, and motivation	• Low self-efficacy (n=9)	• Not identified
Belief about consequences	Intertwined influence of beliefs, emotions, and motivation	• Stigmatization of eHealth services (n=6)	• Not identified
Automatic motivation			
Reinforcement	Intertwined influence of beliefs, emotions, and motivation	• Not identified	• Training and mentoring (n=10) • Positive feedback mechanisms (n=8) • Aging-friendly design (n=8) • Providing clear operating instructions (n=2)
Emotion	Intertwined influence of beliefs, emotions, and motivation	• Mood disorders (n=11)	• Not identified

COM-B: Psychological Capability; TDF: Knowledge (Disease Perception and Personal Experience Building)

Patients' perceptions about their disease and personal experiences constitute the starting point for their involvement in digital health apps. Due to a lack of accurate understanding of emotional symptoms, some patients (n=13/25, 52%) have a hard time understanding their symptoms and fail to connect their condition with a disease that requires management. This cognitive bias directly influences their motivation to seek help.

XSL•FO
RenderX

> *I know I sometimes feel down and bored, but I don't know if this mood is depression, I don't think I can be depressed.* [P1]
>
> *Most of the time when I am in a bad mood, it is due to my back pain, sometimes my back pain is so bad that my whole body wants to die.* [P3]

This tendency to attribute depression to physical discomfort or life events diminishes their motivation to actively use self-management tools. Meanwhile, 32% (n=8/25) of the patients demonstrated a lack of awareness or skepticism regarding the value of the app itself, which further dampened their willingness to give it a try.

> *I don't know what these apps can do for me, it feels like just one more thing to worry about.* [P2]

However, when health threats become tangible, such as a noticeable decrease in physical function, patients' attitudes often shift. For instance, 28% (n=7/25) of the patients reported that concerns about diminished quality of life could translate into a strong motivation to improve, thereby making them more willing to try new technological approaches.

> *I can't move my feet right now and I'm very limited in what I can do, that's my biggest struggle and I want to learn some ways to improve my life.* [P10]

In addition, 52% (n=13/25) of patients noted that prior experience with technology served as a valuable source of confidence, effectively enhancing their acceptance of new technological tools.

> *I have no difficulty using these apps, I use a variety of software daily.* [P4]
>
> *I am quite good at operating my phone, I already have several software programs; more than enough.* [P19]

Thus, the initial willingness to use such tools is deeply rooted in how individuals perceive their own illness and the technological experience they possess. However, willingness is only the first step. When patients actually begin to use the tools, they immediately face practical challenges shaped by their own capabilities.

COM-B: Psychological Capability and Physical Capability; TDF: Memory, Attention, and Decision Processes and Skills (Dual Challenge of Cognitive Abilities and Physical Limitations)

Even with the willingness to use such tools, the cognitive and physical limitations of older patients with depression often create a "mismatch" with the functional design of apps, which constitutes a major obstacle in the adoption process. Approximately 64% (n=16/25) of patients reported that cognitive impairments, such as memory decline and attention deficits, directly challenged the basic abilities required to learn and operate new digital tools.

> *I'm a poor reader … and when I use the app, the interface is very easy to accidentally exit, I've been taught by volunteers many times before, but I still don't know how to operate it.* [P8]
>
> *The brain is not very good, looking at the screen is blurred, memory is bad, easy to forget; the cell phone is used only to make and answer calls. WeChat is not used.* [P21]

Meanwhile, 40% (n=10/25) of the patients mentioned that the physical symptoms of the disease itself, such as dizziness, visual impairment, and extreme fatigue, made seemingly simple actions like "looking at the screen" and "tapping to operate" unusually strenuous and could even exacerbate their discomfort.

> *I'm not well at the moment, I come to the nursing home to get well, and I feel that using these will increase the burden of my illness.* [P6]
>
> *I mainly look at the computer because I think the phone is too small for my eyes and it's hard to look at it, it's hard to look at it twice with my eyes.* [P23]

In contrast, several participants (n=14/25, 56%) noted that support from family members or peers helped them continue using digital tools despite physical or cognitive difficulties, as assistance with operation and emotional encouragement reduced frustration during initial attempts.

> *My eyes are blurry and my fingers aren't flexible—I almost gave up several times. But my daughter often sits down and guides me through it step by step. In those moments, my heart feels warm and I find the courage to try again.* [P25]

The above challenges that stem from the patients' own capabilities inevitably affect their perception of the convenience offered by digital tools. Although the process of operation is fraught with frustration, their attitudes toward technology integration also tend to diverge.

COM-B: Psychological Capability; TDF: Behavioral Regulation (Digital Technology Integration and Life Adaptation)

Faced with their own ability limitations, patients show a clear divergence in their responses to the integration of digital technology into health management. For instance, 36% (n=9/25) of patients noted that convenient features of apps, such as medication reminders and simple logging, effectively compensate for cognitive deficits, help establish routines, and thereby lead to positive experiences.

> *I used to forget to take my medication all the time, but now I have reminders to know when I should take my medication.* [P9]
>
> *It's easy and I'd like to have more access to it.* [P14]

Conversely, for 28% (n=7/25) of patients, these limitations reinforced their reliance on and preference for traditional methods, which they perceived as more reliable and comfortable.

> *I think it's better for older people to read books than to look at their cell phones, there is gold in books.* [P2]
>
> *I like to read newspapers, I've been reading them for more than 40 years. I'm used to it and I seldom use a cell phone.* [P6]

XSL•FO
RenderX

This variation in acceptance, rooted in individual capabilities, habits, and comfort levels, does not exist in isolation. It is profoundly shaped by the social environment in which patients live, where the attitudes of family members and peers play a crucial role.

COM-B: Social Opportunities; TDF: Social Influences (Access to and Utilization of Social Impact and Support Resources)

Patient attitudes toward and attempts to use digital health tools are deeply embedded in their social networks. Positive social influences can serve as a key factor in overcoming self-doubt about their abilities and motivating them to learn. Approximately 56% (n=14/25) of the patients mentioned that encouragement from family members and the sharing of successful experiences by peers provided important external validation and boosted their confidence.

> *My wife tried it and said it was good and kept encouraging me to try it too.* [P6]
>
> *Lao Zhuang shares his experience using the app every day and encourages us to all try it, we all have to learn from him.* [P5]

However, this social network can also become a constraint. Several participants (n=11/25, 44%) described that family overprotection not only limited their opportunities for hands-on practice but also made them increasingly doubt their own ability to use digital technologies independently, as family members frequently emphasized the difficulty of these tools.

> *My kids won't let me use it, they always tell me to leave it alone, that it's too much trouble.* [P8]
>
> *They say the techniques are too complicated and I'm sure I can't use them, but how do I know if I can use them if I haven't even tried them yet?* [P15]

Meanwhile, 16% (n=4/25) of patients mentioned that broader societal prejudices, particularly the stigma surrounding mental illness, could cause them to feel anxious and ashamed even when using health apps in private.

> *Depression is an illness that a lot of people don't understand, especially within nursing homes, they talk about you behind your back all the time.* [P12]

The power of social support or hindrance ultimately interacts with the material resources and environmental conditions that patients actually possess, jointly determining whether a technology can truly be made "usable."

COM-B: Physical Opportunity; TDF: Environmental Context and Resources (Resource and Environmental Constraints and Facilitation)

Social support can improve willingness; however, if essential material resources and a supportive environment are lacking, actual usage remains unachievable. Approximately 40% (n=10/25) of participants noted that a key advantage of digital health apps lies in their ability to reduce the time and costs associated with traditional health care access.

> *I have found that seeing a doctor through my phone and not having to run to the hospital and stand in line is a real time and money saver.* [P4]
>
> *Now that seeing a doctor and making an appointment with a doctor works on my phone, …* [P14]

However, for some patients, the inability to own a smartphone (n=3/25, 12%) or the lack of a stable internet connection (n=2/25, 8%) still constitutes a fundamental barrier that is difficult to overcome.

> *I don't have a smartphone, and these apps don't work at all.* [P2]
>
> *Mainly because of the lack of traffic, my cell phone is used to take and make calls, and I don't use the other features until I have WiFi at home.* [P24]

Even after overcoming these hardware barriers, 8% (n=2/25) of patients indicated that if the app content lacked relevance and failed to meet personalized needs, the users' motivation for continued use diminished rapidly. This reveals a gap between technological offerings and the actual needs of users.

> *It's always the same content and I don't want to use it anymore.* [P7]
>
> *There are a lot of features, but I always feel like something is missing and the advice given to me is not tailored to my individual situation, it would be great if it could be adapted to my needs.* [P15]

The interplay of limited resources and design barriers created major obstacles to sustained use. The experiences of the 3 participants without smartphones underscore that engagement in digital self-management may be constrained not only by individual willingness but also by access to basic devices and connectivity. Rather than expressing resistance, these participants described relying on family members or institutional services for health-related support, suggesting that digital self-management interventions should consider providing foundational access support and proxy-assisted pathways for those lacking personal smartphone access.

COM-B: Reflective Motivation, Automatic Motivation; TDF: Beliefs About Capability, Belief About Consequences, Reinforcement, and Emotion (The Intertwined Influence of Beliefs, Emotions, and Motivation)

The entire process of using digital health apps is continuously influenced by a complex interplay of internal beliefs, emotional states, and motivational levels of patients. Approximately 32% (n=8/25) of patients mentioned that positive user experiences, such as receiving immediate feedback and encouragement, significantly enhanced their sense of self-efficacy and willingness to continue usage.

> *Even the app is complimenting me on a job well done, which gives me confidence to keep using it.* [P13]

However, low self-efficacy and the sense of "meaninglessness" inherent in depression can fundamentally erode the internal motivation to engage with such tools.

XSL•FO
RenderX

> *I'm so old, I haven't even figured out how to use an old person's phone, how can I possibly use a smartphone.* [P2]
>
> *When I am in a bad mood, I always feel that there is no point in doing anything.* [P3]

Furthermore, 24% (n=6/25) of patients expressed deep concerns about privacy breaches and online fraud, reflecting a more profound sense of insecurity in the digital age. Such concerns may be amplified by related negative reports in society.

> *I don't dare to use it, there are too many scammers online, in case I lose all my money.* [P7]
>
> *Worried about information leakage, have to pay attention to the privacy aspect.* [P22]

Approximately 8% (n=2/25) of patients also clearly expressed that reducing the difficulty of use through aging-friendly design, clear instructions, and continuous training support is crucial for building positive beliefs and motivation.

> *Provide training, guide us how to use it a bit, how to deal with the difficulties we encounter with cell phone things. For example, I don't want this advertisement to appear, but deleting it is troublesome. Sometimes I can't do it, so I go down and ask young people to click it off.* [P16]

Discussion

Principal Findings

Guided by the COM-B model and the TDF, this qualitative study synthesized how capability, opportunity, and motivation interact to shape the engagement in digital self-management among older adults with depression. Rather than treating barriers and facilitators as isolated determinants, the combined application of the COM-B model and the TDF enabled a mechanistic understanding of why digital self-management engagement is particularly difficult to initiate and sustain in this population. The findings demonstrate that digital self-management engagement extends beyond issues of technology acceptance and is instead embedded within a complex behavioral process influenced by the perception of the disease, cognitive and functional capacity, social context, environmental resources, and depression-related emotional and motivational vulnerability. Although participants generally recognized the potential value of digital tools for mood regulation and daily management, misalignment between individual capability, contextual opportunity, and motivational readiness frequently limited meaningful and sustained engagement.

Capability: Illness Perception, Cognitive Functioning, and Functional Constraints

At the capability level, digital self-management engagement was shaped less by isolated deficits in technical knowledge and more by how participants understood depression and evaluated their own functional readiness for self-management. Many participants did not conceptualize depressive symptoms as requiring ongoing management, instead attributing emotional distress to aging or physical discomfort, which diminished the perceived relevance of digital self-management tools. This finding refines prior evidence by highlighting that deficits in the TDF "knowledge" domain are not merely informational but also involve inaccurate symptom attribution, which undermines the perceived relevance of digital self-management tools [65-69]. Cognitive decline, fatigue, and attentional limitations further reduced psychological and physical ability, amplifying the effort required to engage with digital tools. However, some participants benefited from simplified functions such as reminders or basic tracking, consistent with evidence on digital prompts facilitating self-management behaviors [70,71]. In contrast, others expressed anxiety and avoidance of digital tools, often rooted in a long-standing reliance on traditional information sources and low confidence in their ability to use technology. This pattern reflects deficits across the TDF domains of "skills" and "beliefs about capabilities" [72-76]. Importantly, our findings suggest that even age-friendly interface principles may be insufficient when depressive symptoms exacerbate cognitive load and reduce tolerance for frustration [39,77-80]. Together, these results indicate that digital self-management capability among older adults with depression should be understood as a dynamic combination of illness perception, cognitive capacity, and functional energy, rather than as a static set of skills.

Opportunity: Social Influences and Environmental Resources

Social and physical opportunity conditions substantially shaped digital self-management engagement. Consistent with existing literature, supportive involvement from family members and peers enhanced confidence and facilitated behavioral initiation [81-86]. However, this study extends prior findings by demonstrating that social support is not uniformly beneficial. Overprotective family behavior, described by participants as discouraging use or emphasizing technical difficulty, limited hands-on practice and fostered self-doubt regarding their own capabilities, thereby constraining sustained engagement. This nuance refines the TDF "social influences" domain by emphasizing that only autonomy-supportive social environments promote long-term behavioral maintenance [87-89]. With regard to the level of physical opportunity, digital self-management engagement remained constrained by limited access to devices, unstable internet connectivity, insufficient technical support, and financial burden [90-92]. Beyond individual resource limitations, participants' experiences pointed to broader structural gaps within the digital health ecosystem, which have yet to adequately accommodate the intersecting needs of aging and depression. These findings echo concerns that poorly supported digital interventions may inadvertently widen health inequities [93-95], underscoring the need for system-level adaptations rather than reliance on individual-level solutions.

Motivation: Beliefs, Emotions, and Reinforcement Mechanisms

Motivation emerged as a central mechanism linking capability and opportunity with digital self-management behavior. Core depressive features, such as apathy, emotional numbness, and reduced reward sensitivity, attenuated intrinsic motivation even when participants cognitively acknowledged potential benefits

XSL•FO
RenderX

[96]. Reflective motivation was strongly shaped by beliefs about usefulness, controllability of symptoms, and personal competence, with early negative experiences exerting a disproportionately suppressive effect on continued engagement [97,98]. This finding extends traditional technology acceptance models by highlighting how depressive symptomatology amplifies the motivational consequences of usability failure. Conversely, positive reinforcement, including structured guidance, supportive feedback, and emotionally validating design, was critical in restoring confidence and facilitating habit formation by directly targeting the TDF domains of "reinforcement" and "emotion" [99]. Importantly, motivation did not operate independently: opportunity enhancements such as initial assistance or training partially compensated for limited capability, whereas persistent opportunity barriers nullified motivation regardless of willingness. These interaction patterns help explain why single-component interventions often fail and support the use of the COM-B model as a system-level explanatory model rather than a checklist of determinants [100,101].

Taken together, these findings suggest that older adults with depression may be willing to try digital self-management tools but often face substantial barriers to maintaining engagement over time. Interventions should move beyond simply increasing access to technology and instead address the understanding of the disease, the cognitive burden, and the emotional and motivational vulnerabilities associated with depression. Guided by the COM-B model and TDF, strategies may include targeted psychoeducation to strengthen illness recognition, a simplified and personalized design to reduce cognitive load, structured onboarding and hands-on training to support early success experiences, and supportive feedback mechanisms to maintain confidence during symptom fluctuations. At the system level, embedding digital self-management support within primary care and community-based mental health services, together with basic device and connectivity support, can improve accessibility and reduce avoidable disengagement. Overall, aligning the intervention design with the lived realities of aging and depression can offer a feasible pathway to improve sustained use and long-term self-management outcomes.

Limitations

As a qualitative study using purposive sampling, this research did not aim to achieve statistical generalizability but rather sought to generate in-depth, contextually grounded insights into the facilitators and barriers shaping digital self-management among older adults with depression. The findings should be considered within the Chinese sociocultural and healthcare context, and while they may not be directly generalizable to all settings, they offer analytical insights that could be transferable to other contexts where aging, depression, and digital health intersect. Second, although this study systematically collected the perspectives and experiences of older patients with depression regarding mHealth management, it did not incorporate professional viewpoints, such as those of health care professionals. These perspectives could have provided valuable insights for the clinical implementation of intervention programs. Third, the interview duration in this study was set at 20 to 40 minutes, considering the cognitive load and attention characteristics of older adults with chronic conditions. Longer interviews could have resulted in fatigue and reduced attention, potentially affecting response quality. Although previous qualitative studies with similar older populations have generally used relatively short interview durations (approximately 15-35 minutes) [102-105], the relatively brief interview time in this study may have somewhat limited the depth and richness of the data, particularly when exploring complex experiences, behavioral factors, and decision-making processes, and may have resulted in some subtle or latent themes not being fully captured.

Conclusions

This study provides a theory-informed explanation of participation in digital self-management among older adults with depression by applying the COM-B model and the TDF as an integrated analytical lens. The findings highlight that sustained engagement depends on the alignment of capability, opportunity, and motivation rather than on technological availability or willingness. In particular, depression-related cognitive and emotional vulnerability interacts with age-related functional constraints and contextual barriers, helping to explain why engagement is difficult to maintain in real-world settings. These insights emphasize the importance of designing and implementing interventions that are feasible for older adults with depression, including supports that reduce cognitive burden, enable early success, and promote autonomy. At the policy level, strengthening community-based delivery pathways and ensuring easy access to basic digital resources may help prevent the widening of mental health disparities as digital care strategies continue to expand.

Abstract

Background: Depressive symptoms in older adults are amplified by social isolation and limited access to clinic-based mental health care. Ecological momentary assessment (EMA) enables remote self-monitoring and unobtrusively captures response times (RTs), which may serve as indicators of psychomotor and cognitive functioning.

Objective: This study investigated the use of EMA-based RT dynamics for predicting symptom change and profiling potential responders for repeated self-monitoring in late-life depression.

Methods: Forty-nine community-dwelling adults aged 65 years or older (mean age 70.7, SD 5.8 years; female: 35; male: 14) with a history of major depressive disorder received case management incorporating daily EMA. Participants provided self-reports of mood, appetite, sleep quality, and general well-being. Preassessment and postassessment included the 15-item Short Geriatric Depression Scale (GDS-15), the Center for Epidemiologic Studies Depression Scale-Revised (CESD-R), the 9-item Patient Health Questionnaire, and the Beck Anxiety Inventory. RTs were cleaned with an asymmetric IQR rule, z standardized within-person × response level, and modeled with exponential decay curves over successive EMA trials. The efficacy of EMA-adjunctive care was evaluated using pre-post comparisons of symptom scales. We then examined associations between RT-derived features and symptom change using correlational analyses. Finally, Bayesian multilevel modeling was applied to assess the clinical relevance of RT dynamics, including group differences in adaptation patterns.

Results: Older adults at risk for depression showed significant symptom reductions over the 4-week EMA-adjunctive care period across all 4 psychological scales (CESD-R: mean Δ 11.5; rank-biserial r=0.78; GDS-15: mean Δ 2.14, Cohen d=0.76), alongside high EMA adherence (>90%). In correlational analyses, descriptive EMA score metrics and raw RTs showed modest, symptom-specific associations with symptom change (ΔCESD-R: $|r|\approx0.29$; Δ9-item Patient Health Questionnaire: $|r|\approx0.32$; ΔBeck Anxiety Inventory: $|r|\approx0.35$) but were not significantly related to change in geriatric depression (ΔGDS-15: $|r|\approx0.24$). In contrast, exponential-decay model parameters derived from standardized RT were significantly associated with geriatric depressive symptom change (Δ GDS-15), with the strongest effects observed for the feeling item (eg, decay rate θ_b: $r=-0.398$, asymptote θ_c: $r=-0.321$). Bayesian multilevel modeling further indicated that EMA-adjunctive care responders showed faster RT adaptation than nonresponders (median decay-rate ratio≈4.9, 95% credible interval 1.44-14.31), whereas differences in postadaptation RT levels were smaller and uncertain (median postadaptation RT ratio≈1.25, 95% credible interval 0.95-1.58). Sensitivity analyses showed consistent decay-rate effects across alternative specifications.

Conclusions: Dynamic characteristics of EMA-based RTs emerged as a sensitive proxy for monitoring changes in depressive symptoms among older adults at risk. These findings highlight the potential use of RTs as digital biomarkers derived from brief, low-burden EMA self-monitoring, supporting the development of scalable and personalized mental health interventions for geriatric populations.

Introduction

Modern Hazards of Late-Life Depression

Population aging has brought renewed attention to late-life depression. Growth in single-person households, shrinking family networks, and weaker community ties can intensify the risk of depression in older adults, particularly in highly urbanized settings, such as South Korea [1,2]. These shifts also strain clinic-centered care models, which are often inaccessible to older adults living alone and facing mobility barriers, underscoring the need for remote, daily-life–responsive geriatric mental health strategies.

Ecological Momentary Assessment: From Monitoring to Care

Ecological momentary assessment (EMA) involves the real-time, in situ measurement of behaviors, emotions, and thoughts in everyday contexts [3,4]. By capturing experiences as they occur, EMA reduces recall bias and is well suited to symptoms that fluctuate with context [4]. Advances in mobile and sensor technologies have enabled unobtrusive, scalable EMA deployment, positioning it as a potential infrastructure for practical routine mental health support methods [5,6]. Repeated self-monitoring via EMA may also confer therapeutic benefits, particularly when combined with standard treatments [7-11]; however, effects appear heterogeneous, with reduced responsiveness among individuals with more severe baseline symptoms, highlighting the need to identify who benefits most from EMA-based approaches [12].

EMA Response Times: Linking Cognition and Depression in Older Adults

Recent EMA research has moved beyond self-reported content to "side data" such as response time (RT), which may index underlying cognitive processes. Chung et al [13] reported a nonlinear (inverted U-shaped) association between EMA RT and depression severity, suggesting that both unusually fast and slow responses may reflect dysfunction (eg, impulsivity or cognitive slowing). Hernandez [14] further showed that EMA RTs correlate with Symbol Search performance, indicating that RTs capture general processing capacity even in noncognitive EMA tasks.

EMA-derived RTs may therefore help identify individuals vulnerable to depressive symptoms. Consistent with *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition* (*DSM-5*) descriptions of major depressive disorder, which include observable psychomotor retardation [15], Hernandez et al [16] applied drift diffusion modeling to binarized EMA responses and found that RT-derived parameters (eg, drift rate and boundary separation) systematically tracked traits such as neuroticism and depressive symptoms [16]. Together, these findings position EMA RT as a candidate marker linking cognitive efficiency with affective symptomatology.

This approach may be particularly relevant in geriatric populations, where aging and depression jointly exacerbate psychomotor slowing [17-19]. Older adults with major depressive disorder (MDD) show prolonged initiation and movement times relative to controls, implicating combined executive and motor delays [17], and reviews report especially large effects for psychomotor slowing in late-life samples [20]. Depressed older adults also appear less adaptable under repeated cognitive demands: greater symptom severity has been associated with slower reaction-time learning curves and reduced improvement across training blocks, with sluggish adaptation predicting later functional decline [21,22]. Some interventions may even backfire when effort exceeds coping capacity; for instance, one randomized controlled trial reported worsening depressive symptoms following speed-of-processing training [23]. Collectively, these results motivate EMA-based RT metrics as scalable markers for monitoring cognitive-motor slowing and adaptation in late-life depression.

Challenges in Utilizing Ordinal-Scale, Noncognitive EMA RTs

Despite its potential usage, analyzing RTs from ordinal-scale EMA items presents distinct hurdles. While ordinal items, such as 5- or 7-point Likert scales, offer richer granularity than binary formats, their integration with RT data poses additional analytical considerations and requires further preprocessing steps.

One complication arises from emotional clarity. As shown in Hernandez et al [16], individuals with clearer emotional awareness due to intense emotions tend to respond more quickly to EMA questionnaires. Thus, trait-level factors, such as baseline emotional reactivity, as well as situational factors, including bereavement, acute illness, and exposure to daily stressors, may affect the RT of EMA reports. This can mask or confound the expected slowing associated with cognitive impairment, making RT a less straightforward marker when emotional clarity varies across individuals and between occasions.

A further complication lies in interface variability. Mobile EMA apps often use different visual formats (eg, sliders, buttons, or scales), which can unintentionally influence how quickly users respond. For example, a response option that is most proximal to a frequently used finger can lead to faster responses. These app-specific differences, such as user interface composition, introduce another layer of noise that must also be accounted for when analyzing ordinal-scaled EMA-based RT.

Research Purpose

In light of these issues, this study pursues the following objectives. First, we tested whether short-term EMA use (≤4 wk) alongside usual case management is associated with

XSL•FO
RenderX

symptom improvement among older adults at elevated risk for depression, evaluating EMA as a potential adjunctive intervention rather than a monitoring-only tool. Second, we examined how multiple EMA-derived features (eg, symptom ratings, response speed, and RT adaptation) relate to symptom change over time, with a focus on RT dynamics as a behavioral signature of improvement. We also introduce a scalable analytic approach that reduces key ecological confounds in RT (eg, momentary affect intensity and interface-related heterogeneity) and is broadly applicable across EMA apps and Likert-type scales. Third, we evaluated the clinical relevance of RT adaptation by using a Bayesian multilevel model to compare adaptive patterns between participants who benefited from EMA-adjunctive care and those who did not. With a modest sample size (n=50), partial pooling in a multilevel framework improves estimate stability while accommodating missing and unbalanced EMA observations [24]. Additionally, Bayesian posterior inference provides interpretable uncertainty for group differences in adaptation parameters, thereby quantifying the evidence for between-group differences in adaptive patterns [24-26]. This research ultimately supports the objective, remote stratification of individuals who are most likely to benefit from EMA-enabled care.

Methods

Eligibility Criteria

Participants eligible for this study were aged 65 years or older, regardless of gender, and had expressed their willingness to participate through recruitment notices posted at the community-based Suwon Geriatric Mental Health and Welfare Center in Gyeonggi-do, Republic of Korea. Individuals who met the following eligibility criteria were included: (1) participants must have had a prior diagnosis of depressive disorder by a psychiatrist, with no change in medication for the last 3 months and without symptom aggravation; (2) absence of medical or neurological disorders such as dementia, stroke, or Parkinson disease that may affect the research; and (3) current recipients of case management services at the Suwon Geriatric Mental Health and Welfare Center.

Ethical Considerations

All participants who met these criteria provided written informed consent prior to enrollment and completed demographic information and preassessment questionnaires. Those who completed these surveys were then given detailed guidance and support for installing and using the app, with additional assistance provided to those less familiar with digital tools. Given the specific population's limited experience with digital devices, only individuals who demonstrated the ability to follow the mobile app (BIG4+) usage guidelines independently were enrolled. Participation was entirely voluntary, and participants were free to withdraw at any time without any disadvantage. All procedures were approved by the Public Institutional Bioethics Committee designated by the Ministry of Health and Welfare of the Korean Government (MOHW; P01-202405-01-019) and were supported by Digital Medic Inc. Written informed consent was obtained from all participants. Participant privacy was protected by analyzing all data in deidentified form and restricting access to authorized research staff only. Electronic data were stored in password-protected encrypted files, and physical records were kept in locked storage. Participants received KRW 100,000 (approximately US $67.50) for completing the full study protocol. For early withdrawal, compensation was provided on a prorated basis according to the week of completion.

Research Design

The study used an observational, single-arm design. Participants were community-dwelling older adults enrolled through the Suwon Geriatric Mental Health and Welfare Center.

Case management was provided throughout the study, consisting of 1 monthly home visit and 1 to 2 interim telephone contacts, during which case managers monitored participants' daily living conditions and mental health status. In addition to this standard case management, participants were asked to use the Big4+ mobile app as an adjunctive care tool over a 4-week period. The Big4+ app, developed specifically for research purposes, was available on both Android (AOS) and iOS platforms and collected daily self-reports on mood, appetite, sleep quality, and overall well-being using a 7-point Likert scale (1=minimum to 7=maximum).

Each participant visited the center twice: once prior to initiating app usage (baseline assessment, V1) and once at the end of the 4-week period (postassessment, V2). During both visits, participants completed a battery of self-report questionnaires administered in paper format by case managers, with each session lasting approximately 30 minutes.

Standardized psychological scales administered to participants included the Korean version of the Center for Epidemiologic Studies Depression Scale-Revised (CESD-R) [27-29], the Korean version of the 15-item Short Geriatric Depression Scale (GDS-15) [30,31], the 9-item Patient Health Questionnaire-9 (PHQ-9) [32,33], and the Beck Anxiety Inventory (BAI) [34,35].

Data Preprocessing

Handling RT Outliers

To the best of our knowledge, there is no established gold standard for identifying outliers in RTs associated with noncognitive and ordinal EMA items. Furthermore, the population of this study (older adults at high risk for depression) was highly specific, making it necessary to define acceptable RTs empirically based on the distribution within the dataset. We adopted the IQR rule, where the IQR is calculated as the difference between the third quartile and the first quartile. Outlier boundaries were defined as specific multiples of the IQR from Q1 and Q3. Given that RT distributions were heavily right-skewed, we applied asymmetric boundaries across the dataset: a lower bound of $Q1 - 0.5 \times IQR$ and an upper bound of $Q3 + 1.5 \times IQR$. These boundaries were calculated separately for each EMA item (feeling, appetite, feeling of sleep, and general evaluation). Trials with RTs falling outside these bounds were excluded from the analysis. The details of the predefined outlier thresholds and the decision-making process are provided in Section I in Multimedia Appendix 1.

XSL•FO
RenderX

Standardization of RTs

EMA RTs are noisy and can be confounded by momentary affect (eg, faster responses during more intense or clearly defined states) and device or app characteristics [16]. To improve comparability, we standardized RTs within individuals and response options, expressing each latency relative to that participant's typical speed at a given Likert level.

For individual *i*, response option *j* (1-7), and trial *k*, standardized RT (Z-RT) was as follows:

$$Zijk=RTijk-\overline{RT}ij\sigma ij,$$

where RT_{ij} and σ_{ij} are the mean and SD of RT for participant *i* at option *j*. This z-transformation reduces between-context and between-person variability, supporting more reliable downstream analyses.

Extracting EMA-Based Digital Features

Descriptive features were extracted from 4 weeks of EMA data collected from each participant. For each EMA item, we computed the mean, SD, minimum, maximum, and interquartile values (25th, 50th, and 75th percentiles) of the reported scores to characterize overall mood patterns throughout the study period. In addition, identical descriptive statistics of EMA-based RTs were derived as indicators of cognitive processing speed and consistency.

Beyond overall response latency, we quantified how participants adapted to repeated EMA self-reflection over time. Such "practice effects" (ie, progressive reductions in RT with repeated exposure) are widely documented in cognitive tasks and are relevant to EMA given evidence that even noncognitive RTs reflect cognitive traits [16]. Although practice effects are often modeled with power-law decay [36], exponential decay may better capture adaptation in older adults, who typically show slower motor and cognitive adjustment [37,38]. Accordingly, we fit an exponential decay curve to each participant's longitudinal RT series (both raw RT and standardized RT):

$$ft=\theta a\cdot\exp-\theta b\cdot t+\theta c,$$

where *t* indexes time or trials. Parameters were estimated via nonlinear least squares (Levenberg-Marquardt; scipy.optimize.curve_fit; max 10,000 iterations). The parameter θ_a (amplitude) captures the initial elevation in RT above the asymptote (ie, $f(0)–\theta_c$), reflecting the potential magnitude of improvement across repeated trials. The parameter θ_b (decay rate) indexes the speed of adaptation, indicating how rapidly an individual becomes accustomed to repeated self-monitoring. The parameter θ_c (asymptote or postadaptation RT) represents the asymptotic minimum RT, interpreted as the stabilized latency after maximal adaptation within the observation window. The model was fit to both raw and standardized RTs, with parameter bounds set to match the scale and range of each outcome.

In this stage, exponential decay parameters were estimated separately for each participant (ie, without partial pooling) to serve as person-level features that can be computed in naturalistic settings where no external reference data are available. This individual-fit approach also facilitates a fair comparison with other EMA-derived features (eg, self-report scores and RT descriptives), which were likewise calculated at the individual level without borrowing strength from group-level information. Technical details regarding the fitting of the exponential-decay model are provided in Section II in Multimedia Appendix 1.

Defining Symptom Improvement

A key step prior to the analyses was to select an appropriate metric for symptom change. Although treatment response is often operationalized using simple change scores (post-pre), this approach has been criticized for its dependence on baseline severity and the resulting negative correlation with baseline values [39-41]. Percentage change scores adjust for baseline differences and are widely used in other clinical domains [42,43] but can be difficult to interpret and may reduce statistical power due to skewed distributions [40,41]. Regression-based alternatives (eg, analysis of covariance or residualized change) can control for baseline levels yet may yield biased estimates when baseline severity is related to treatment effects, which is common in observational settings [40,41]. Given these considerations and prior methodological work supporting the robustness of simple change scores in nonrandomized contexts [40,44,45], we used simple change score Δ(post-pre) as the primary symptom improvement outcome.

Responder Classification (Minimally Detectable Change Criteria)

Participants were classified as "responders" or "nonresponders" to EMA-adjunctive care based on minimally detectable change (MDC) thresholds derived from the GDS-15. A recent meta-analysis by González-Domínguez et al [46], which included 5876 older adults across 21 studies (mean age 76 y), reported that a score reduction of 3.81 points on the GDS-15 corresponds to the MDC threshold, defined as the level of change with only a 5% probability of being attributable to measurement error (95% CI 3.59-4.04) [47]. Based on these findings, an MDC threshold of –3.81 points was applied, reducing the arbitrariness of classification and accounting for measurement error.

Analysis

Explorative Effects of EMA-Based Self-Monitoring

Explorative analysis was conducted to assess the benefits of EMA-adjunctive care in older populations. Given the single-arm design, the effectiveness of EMA-based self-monitoring in geriatric depression was assessed by comparing symptom scores collected at baseline (V1) and postintervention (V2) using paired statistical tests. The choice of test was determined based on the normality of the difference scores, as assessed by the Shapiro-Wilk test. When the assumption of normality was satisfied, a paired-samples *t* test was applied. In cases where the normality assumption was violated, the nonparametric Wilcoxon signed-rank test was used instead. All paired tests in this analysis were 1-tailed.

Association Between EMA-Derived Features and Symptom Improvement

We examined whether EMA-derived features, particularly RT dynamics, track symptom improvement using correlational

XSL•FO
RenderX

analyses. We computed Spearman correlations between EMA-derived features and Δ on the GDS-15 and assessed specificity using parallel analyses for the CESD-R, PHQ-9, and BAI.

Clinical Relevance of EMA Trajectories for Symptom Improvement

To examine the clinical relevance of EMA-based RT dynamics, we fitted a moderated Bayesian multilevel exponential-decay model to test whether adaptive patterns of EMA-based RTs differed by the MDC group. The model equation is demonstrated as a fully randomized model. For detailed model specifications and rationales, see Section III in Multimedia Appendix 1.

Observation Model

For each observation n=1, ..., N_{obs},

$$RTn \sim LogNormal(\eta n, \sigma log) \Leftrightarrow log(RTn) \sim N(\eta n, \sigma log2),$$

we assumed each observation follows a log-normal distribution, ensuring positive predictions and accommodating the right-skew typical in RT data.

Mean Structure (RT Adaptation)

Expected log-RT followed a subject-specific exponential decay over normalized time $t \in [0, 1]$:

$$\eta n = \theta ai \cdot \exp(-\theta bi \cdot t + \theta ci,r),$$

where *i* indexes subjects and $r \in 1, ..., R$ indexes response options (Likert-7 scale).

Multilevel Effects and MDC Moderation

Amplitude and decay rate were modeled on the log scale (log-linked) for positive constraints and allowed to vary by subject, with MDC group moderation:

$$\log(\theta a) = \beta 0a + \beta 1a \cdot g(i) + \sigma a \cdot z(a)i, z(a)i \sim N(0,1)$$
$$\log(\theta b) = \beta 0b + \beta 1b \cdot g(i) + \sigma b \cdot z(b)i, z(b)i \sim N(0,1)$$

Baseline log-RT or postadaptation RT ((,)) was decomposed into group, subject, and response-option components:

$$\theta c(i,r) = (\beta 0c + \beta 1c \cdot g(i)) \text{ Group-Moderated Baseline} + uc(i) \text{ Subject Intercept} + \alpha c(r) \text{ Option Main Effect} + c(i,r) \text{ Cell Residual}$$

with $uc(i) \sim N(0, \sigma subj2)$, $c(i,r) \sim N(0, \sigma cell2)$, and $\sum r=1R \alpha c(r)=0$ for identifiability. The decomposition of baseline log-RT or postadaptation RT aligns with the framework advocating for the within-person and within-response option standardization of RTs. By explicitly modeling these components, the model accounts for response-option biases in observed latency while simultaneously partitioning subject-specific baseline variance.

Priors and Inference

We used weakly informative priors $\beta 0* \sim N(\mu emp, 32)$, $\beta 1* \sim N(0,32)$, $\alpha c(r) \sim N(0,12)$, σ_a, σ_b, σ_{subj}, $\sigma_{cell} \sim HalfNormal(1.5)$, and $\sigma_{log} \sim HalfNormal(1)$. Models were fit in PyMC using NUTS (4 chains; 1000 warm-up + 1000 draws per chain; target acceptance = 0.95) [48].

To determine the appropriate degree of hierarchical structure in EMA-based RT trajectories, we compared a set of nested Bayesian exponential-decay models that differed only in their random-effects specification. Specifically, we evaluated (1) a nonhierarchical model with fixed parameters across participants, (2) partially hierarchical variants allowing subject-level variation in selected parameters (eg, random θ_b only; random θ_a and θ_b; random θ_b and θcir), and (3) a full hierarchical model with subject-level variation in key components. Models were compared using Pareto-smoothed importance sampling leave-one-out cross-validation (PSIS-LOO), summarizing out-of-sample predictive performance via the expected log pointwise predictive density leave-one-out cross-validation (ELPD-LOO). To isolate the contribution of random effects, MDC-group moderation terms were omitted during this model-structure comparison. Based on the best-performing random-effects structure (selected model; random θ_b and θ_c, with θ_a fixed across subjects), we then tested clinical relevance by extending the selected model to include MDC group moderation, allowing these parameters to vary systematically between responders and nonresponders.

Group differences were quantified using Bayesian posterior summaries rather than frequentist hypothesis tests. For log-linked parameters (eg, θ_a, θ_b), effects were expressed as responder to nonresponder multiplicative ratios exp (β1); for baseline parameters on the log-RT scale (eg, θ_c), group effects were additive on the log scale and additionally converted to RT ratios via exponentiation. We report the posterior median of the responder-to-nonresponder ratio, computed draw-by-draw from the posterior samples, along with the 95% credible interval (CrI) for this ratio. A ratio of 1 indicates no difference between the groups on the original scale; ratios greater than 1 indicate larger parameter values in responders (eg, a ratio of 1.30 corresponds to ~30% higher values), whereas ratios less than 1 indicate smaller values in responders relative to nonresponders. The 95% CrI represents the range containing 95% of the posterior probability for the quantity (given the specified model and priors). We also report the posterior probability of an increase, $P(\text{Ratio}_{\text{Responder/Nonresponder}} > 1|\text{data})$, which quantifies the evidence that responders have larger parameter values than nonresponders.

Models were fit separately for each EMA item and additionally for an averaged RT outcome across items; for the averaged outcome, continuous scores were discretized into 7 bins to align with the response-option structure used in item-level models. Finally, we conducted sensitivity analyses by refitting the model under alternative weakly informative priors (Student *t*) and a more complex plausible random-effects specification and verified that key group effect conclusions were robust across these reasonable modeling choices.

Results

Participants

A total of 50 older adults aged 65 years or older were recruited for the study (mean age 70.6, SD 5.8 y), of whom 72% (n=35) were female. Among the participants, 49 had a documented history of MDD, and 1 had a history of bipolar disorder. To ensure consistency and avoid confounding effects arising from the natural mood fluctuations associated with bipolar disorder, only participants with MDD were included in all statistical

XSL•FO

analyses (n=49). Baseline psychological assessments indicated clinically elevated symptoms across multiple domains. Preassessment scores were as follows: GDS-15 mean=9.37 (SD 4.42), CESD-R mean=33.94 (SD 18.24), PHQ-9 mean=13.04 (SD 7.40), and BAI mean=22.76 (SD 16.46). Following the study period, scores were as follows: GDS-15 mean=7.22 (SD 4.44), CESD-R mean=22.65 (SD 16.15), PHQ-9 mean=8.59 (SD 6.30), and BAI mean=13.31 (SD 11.52). All participants successfully installed and used the BIG4+ app over the 4-week period, with a mean compliance rate above 93%. All descriptive details are summarized in Table 1.

EMA-Adjunctive Care and Short-Term Symptom Improvement in at-Risk Older Adults

To evaluate the benefit of EMA-based self-monitoring, preassessment and postassessment scores were compared across 4 psychological scales (GDS-15, CESD-R, PHQ-9, BAI). The results indicated that CESD-R, PHQ-9, and BAI scores violated the assumption of normality (*P* values =.01, .01, and .01, respectively), while the GDS-15 difference scores did not (*P*=.33). Consequently, Wilcoxon signed-rank tests were applied to the CESD-R, PHQ-9, and BAI, and a paired-samples *t* test was used for the GDS-15 (Table 2).

All 4 measures showed statistically significant improvements following the intervention. CESD-R scores decreased by a mean of 11.50 points (SD 15.8; SE 2.26; *W*=1045.00; *P*<.001), with a rank biserial correlation of 0.78. PHQ-9 scores decreased by a mean of 4.50 points (SD 6.9; SE 1.00; *W*=947.00; *P*<.001), with an effect size of 0.75. BAI scores were reduced by 9.00 points (SD 11.7; SE 1.67; *W*=940.00; *P*<.001), with a rank biserial correlation of 0.82. GDS-15 scores showed a significant reduction of 2.14 points (SD 2.8; SE 0.40; t_{48}= 5.30; *P*<.001), corresponding to a Cohen *d* of 0.76.

Table . Paired tests of psychological assessment scores between preintervention (V1) and postintervention (V2).

Associations Between EMA-Derived Features and Symptom Improvement

Linear relationships between EMA-derived features and changes in depressive and anxiety symptoms were examined using correlational analyses. A full table of correlational analyses is presented in Multimedia Appendix 2.

Descriptive statistics of EMA scores showed generally small-to-modest associations with mental health change scores (Table 3), with no significant correlations for ΔGDS-15 across items. Significant associations emerged for other outcomes, suggesting item-specific links with symptom change: ΔCESD-R was correlated with the minimum of appetite (*r*=0.294; *P*=.04) and general evaluation (*r*=0.29; *P*=.04). ΔPHQ-9 was correlated with the median of feeling (*r*=0.291; *P*=.04), mean (*r*=0.325; *P*=.02), and minimum of appetite rating (*r*=0.291; *P*=.04), and the minimum of general evaluation (*r*=0.286; *P*=.046). For anxiety, ΔBAI was associated only with the minimum sleep quality rating (*r*=0.335; *P*=.02).

[d]CESD-R: Center for Epidemiologic Studies Depression Scale-Revised.

[e]PHQ-9: 9-item Patient Health Questionnaire.

[f]BAI: Beck Anxiety Inventory.

Descriptive statistics of raw EMA RTs showed limited associations with symptom change (Table 3). No RT features were significantly correlated with ΔGDS-15, ΔCESD-R, or ΔPHQ-9. The only significant RT associations were observed for anxiety change (ΔBAI), where mean (r=–0.301; P=.04) and maximum (r=–0.35; P=.01) of appetite RT were negatively correlated with ΔBAI, underscoring the challenge of using noisy, naturalistic raw RT descriptives to track depressive symptom change in at-risk older adults.

In contrast, exponential-decay parameters derived from Z-RT (within subject×response-option standardization) showed clearer associative patterns (Table 4). For the feeling item, both the decay rate and asymptote were significantly associated with ΔGDS-15 (θ_b: r=–0.398; P=.005, θ_c: r=–0.321; P=.03), representing the strongest ΔGDS-15 correlations among the RT-derived features and exceeding those observed for EMA score descriptives. Feeling-item parameters also showed significant associations with other outcomes: ΔCESD-R was related to model fit and dynamics (R^2: r=0.358; P=.01, θ_b: r=–0.302; P=.04, θ_c: r=–0.305; P=.04), while ΔBAI was associated only with goodness-of-fit (R^2: r=0.33; P=.02). Notably, no significant associations were observed for decay parameters fitted to appetite, sleep quality, or general evaluation across change scores (all P>.05), and no Z-RT decay features were significantly related to ΔPHQ-9.

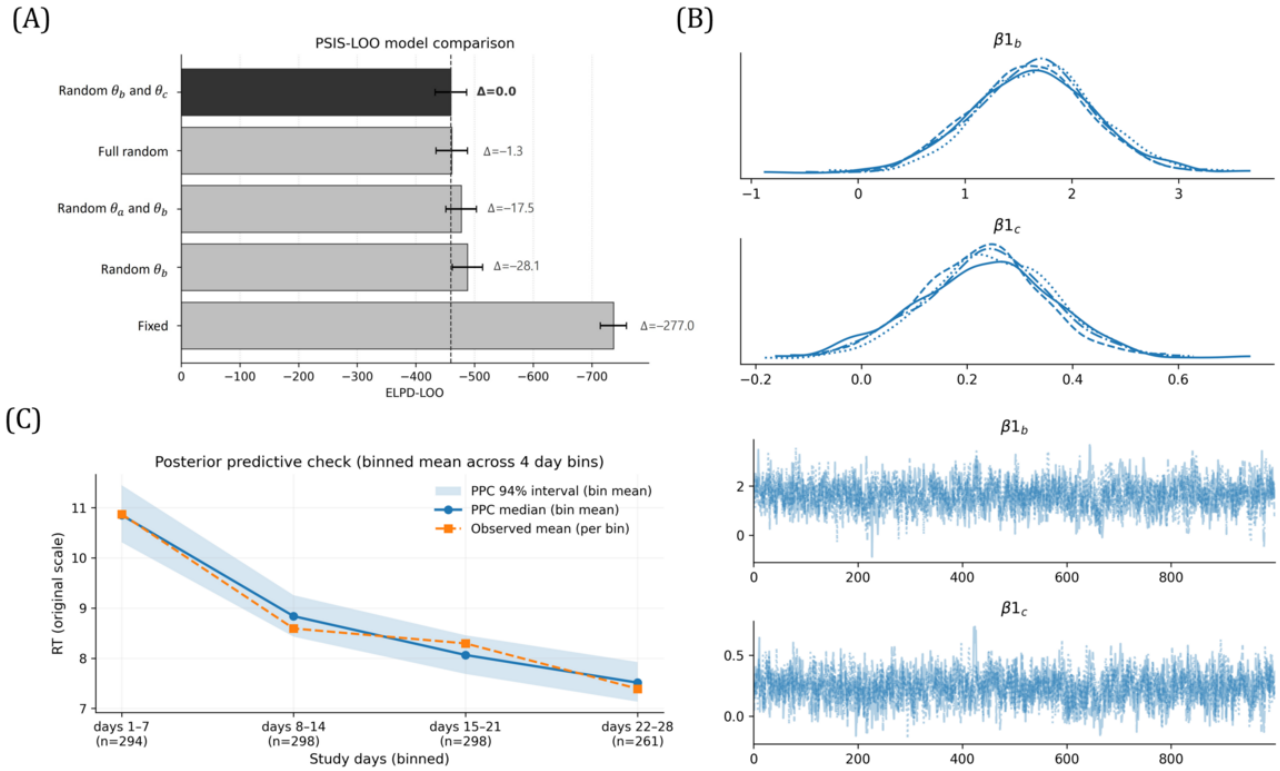
Group Differences in RT Trajectories by EMA-Adjunctive Care Response

Bayesian Multilevel Modeling



We next evaluated the clinical relevance of EMA-based RT trajectories in relation to depressive symptom improvement during EMA-adjunctive care. Responder-status moderation was tested via the posterior distribution of the group term (β1) in a Bayesian multilevel exponential-decay model, where responders were defined as participants whose GDS-15 change exceeded the MDC threshold (ΔGDS-15≤–3.81). Because prior correlational analyses indicated that only RT dynamic parameters from the feeling item were reliably associated with ΔGDS-15, the following results focus on models fit to feeling-item RT (including model selection, adequacy checks, and group effects). Group differences are summarized using posterior estimates, responder-to-nonresponder parameter ratios, and posterior probabilities of increase.

Model Selection (Random-Effects Structure)

PSIS-LOO model comparison favored a partial hierarchical exponential-decay model with subject-level random effects on the decay rate (θ_b) and postadaptation RT (θ_c) (Figure 1A; ELPD-LOO=−459.7). A full random-effects model performed similarly (ΔELPD-LOO=1.3) but showed higher effective complexity (ploo: 112.2 >109.5), indicating limited predictive benefit from additionally allowing subject-specific variability in amplitude (θ_a). Models with reduced or no random effects showed substantially poorer predictive performance, supporting the need to model between-person heterogeneity in RT adaptation. Accordingly, the model with random decay rate (θ_b) and postadaptation RT (θ_c) was selected for subsequent analyses.

XSL•FO

Figure 1. Model selection and diagnostic summary. (A) Pareto-smoothed importance sampling leave-one-out (PSIS-LOO) expected log predictive density (ELPD) by random-effects structure (higher is better). (B) Markov chain Monte Carlo (MCMC) trace plots for responder-status moderation terms (β1) on key parameters (θ_b and θ_c). (C) Binned posterior predictive check comparing observed response time (RT) summaries with posterior predictive medians and 94% intervals. PPC: posterior predictive check.

Model Adequacy and Diagnostics

Building on the selected random-effects structure (random θ_b and θ_c), adding responder-status moderation produced a small but consistent gain in out-of-sample predictive performance relative to the nonmoderated model (ELPD-LOO: −457.2 vs −459.7; SE≈26.6 - 26.7). Although the absolute improvement was modest, it suggests that responder status explains some systematic variation in RT trajectories beyond subject-to-subject heterogeneity. LOO influence diagnostics were stable (99.7% of observations with Pareto k≤0.7), indicating that the model's predictive evaluation was not driven by a small set of highly influential observations and that PSIS-LOO approximations were reliable. Markov chain Monte Carlo diagnostics further supported reliable posterior inference. Trace plots showed good mixing with no visible chain separation (Figure 1B), and convergence metrics (R≈1.00–1.01 with generally high ESS) indicated that posterior summaries are numerically stable and unlikely to reflect sampling pathologies. Finally, posterior predictive checks demonstrated that the model captures the key empirical pattern of interest, simulated trajectories reproducing the overall decay trend, and binned observed means closely tracked posterior predictive check medians while remaining largely within the 94% predictive intervals on the original RT scale (Figure 1C). Together, these checks suggest that the moderated model provides an adequate and generalizable description of RT dynamics in this sample, supporting the downstream interpretation of responder-nonresponder differences in adaptation parameters.

Responder Versus Nonresponder Differences in RT Adaptation

Responders exhibited markedly faster RT adaptation for the feeling item than nonresponders (Table 5). The responder-to-nonresponder ratio for the decay rate was substantially greater than 1 (median θ_b ratio=4.86, 95% CrI 1.44-14.31; P (increase)=.99), indicating a steeper decline (4.86 times faster adaptation) in RT over repeated EMA administrations. Responders also exhibited higher postadaptation RT level than nonresponders (median exp (θ_c) ratio=1.25), indicating 1.25 times slower response after repeated administrations. However, group differences in the postadaptation RT level were more uncertain (95% CrI 0.95-1.58; P (increase)=.95), suggesting at most modest separation in late-phase baseline latency.

Group-averaged trajectories were consistent with the posterior estimates, showing a steeper RT decline among responders (Figure 2A). Differences in the postadaptation RT level became more apparent when model-implied trajectories were extrapolated to 100 days beyond the observed study window (shaded region in Figure 2A). Subject-specific estimates supported the group-level findings (Figure 2B). Although posterior estimates varied within each group, such that some responders exhibited slower adaptation or lower baseline RT (and vice versa), individual trajectories generally followed the overall group trend. Consistent with this, rank plots of participant-level parameters showed responders tending to

XSL•FO
RenderX

appear toward higher values of the decay rate and postadaptation RT level, indicating generally larger estimated values.

Table . Group moderation effects across EMA domains[a].

Quantity and EMA[b] item	Posterior median (IQR; width; 95% CrI[c])	Posterior *P* (increase)

RenderX

Figure 2. Responder-status (minimally detectable change [MDC]) moderation results for the feeling item. (A) Model-implied response time (RT) trajectories by group (posterior median with 95% credible interval [CrI]). The shaded region shows an illustrative extrapolation of the fitted trajectories up to 100 days. (B) Participant-level estimates for key parameters (θ_b and θ_c) by group. (C) Sensitivity analysis of group-effect ratios across alternative model specifications.

Item-Specific Moderation Across EMA Domains

Additionally, moderation effects were examined across individual EMA items and an averaged RT outcome. Evidence for group separation was strongest for the feeling item, which showed the largest and most certain decay-rate difference (θ_b ratio=4.86, 95% CrI 1.44-14.31; *P*=.99). Other items and the averaged outcome showed smaller, less certain decay-rate ratios with CrIs generally overlapping 1. A similar pattern was shown for the postadaptation RT level, the feeling item again showed the largest (but still uncertain) group ratio (exp (θc) ratio=1.25, 95% CrI 0.95-1.58), whereas the remaining items showed minimal differences with intervals spanning 1.

Sensitivity Analyses

Group-effect conclusions for the feeling item were robust across plausible alternative specifications, including a full

XSL•FO
RenderX

random-effects model and a Student *t* likelihood or alternative priors (Figure 2C). The responder-to-nonresponder decay-rate ratio remained consistently around 5 (~4.8), with 95% CrIs entirely above 1 across specifications, indicating a stable group difference in RT adaptation speed. By contrast, the postadaptation RT ratio remained modest (~1.3), and its CrIs overlapped 1 in all specifications, suggesting that late-phase RT differences are small and uncertain in this dataset.

Discussion

Summary of Results

This study provides preliminary evidence for the feasibility and potential efficacy of EMA-based self-monitoring in reducing psychological symptoms among older adults at elevated risk. Across 4 validated scales (CESD-R, PHQ-9, BAI, and GDS-15), participants showed statistically significant symptom reductions over the 4-week period, with medium-to-large effect sizes. These findings align with prior work suggesting that EMA-related benefits may be enhanced when used as an adjunct to treatment as usual, and they extend that evidence to a geriatric context. The high adherence to the EMA mobile app (>90%) further indicates that EMA-based self-monitoring is feasible and acceptable in older adults, including those with limited familiarity with mobile technologies, supporting its promise as a scalable adjunct to depression care in late life.

Correlational analyses also indicated that EMA-derived features can predict variation in symptom change, but with important limitations. Descriptive statistics of EMA scores and raw EMA RTs showed symptom-specific associations across measures, yet they were not significantly related to changes in the geriatric depression scale (ΔGDS-15), suggesting reduced sensitivity for tracking geriatric depressive symptom change using simple descriptives alone. In contrast, features derived from exponential-decay parameters fitted to standardized response times (Z-RT) showed consistent associations with depressive symptom change (ΔGDS-15 and ΔCESD-R). In particular, faster adaptation (higher decay rate), higher postadaptation RT level (asymptote/baseline), and better fit quality for the emotionally salient feeling item are associated with greater symptom improvement, suggesting that RT dynamics during EMA engagement may reflect clinically meaningful change during EMA-adjunctive care.

These patterns were further corroborated by the Bayesian multilevel modeling results. Compared with nonresponders, responders to EMA-adjunctive care exhibited markedly faster adaptation (higher decay rate) and modestly higher postadaptation RT levels. This suggests that potential responders show a distinct trajectory characterized by more rapid accommodation to repeated self-reflection, although the underlying mechanism cannot be determined from the current design (ie, whether EMA-adjunctive care enhances self-monitoring efficiency, or whether individuals with greater baseline capacity for such adaptation are more likely to benefit). Evidence for between-group differences in the postadaptation RT level was comparatively uncertain, and the direction (ie, slightly higher baseline RT in responders) may appear counterintuitive if faster responding is assumed to reflect greater efficiency. One plausible interpretation is that faster late-phase responding among nonresponders could reflect a tendency toward more superficial or less attentive responding rather than more efficient self-reflection, but this remains speculative and warrants direct validation. Additionally, sensitivity analyses across plausible alternative specifications yielded the same qualitative conclusions, supporting the robustness of the central group-difference inference. Collectively, these results highlight the potential clinical use of behavioral signatures embedded in EMA responding, particularly RT adaptation dynamics, for tracking depressive symptom improvement in older adults.

Interestingly, consistent with the correlational findings, group contrasts were strongest when the model was fitted to the feeling item among the 4 EMA domains examined. Moreover, although prior work suggests that averaging RT across multiple EMA items can increase measurement reliability [14,16], group differences in adaptive patterns were larger when using the feeling item alone. This finding suggests that EMA response dynamics may be item-specific rather than purely reflecting a global response-speed trait, raising the possibility that different symptom domains could exhibit distinct behavioral signatures in EMA trajectories.

Clinical Implications

These findings suggest that EMA-adjunctive care may be both feasible and clinically beneficial for older adults at risk of depression. Digital mental health interventions (DMHIs) are often considered difficult to implement in late-life populations because limited familiarity with digital tools can reduce sustained engagement. In contrast, adherence in this study remained high (on average >90%), indicating strong real-world acceptability. The EMA protocol used here, brief daily reporting on four items, appeared manageable even for participants who might be expected to show reduced willingness or capacity for sustained participation due to depressive burden. To support sustained engagement in real-world deployment, the intended implementation can incorporate an explicit feedback loop, such as clinician-facing dashboards, periodic review during EMA engagements, or automated triggers that prompt timely outreach when a missing response is detected. Importantly, symptom reductions observed across validated scales indicate that EMA use in this context may confer benefits beyond feasibility, supporting EMA-adjunctive care as a promising component of geriatric depression management.

A second implication concerns the objective monitoring of symptom change. Remote psychiatric care still relies heavily on self-reported symptoms, ranging from retrospective standardized questionnaires to daily EMA ratings, both of which remain vulnerable to recall bias and other reporting distortions (eg, mood-congruent evaluation, self-reflective bias). EMA-derived RT metrics are not fully “passive” because they require active responding; however, they provide a comparatively objective behavioral signal that reflects underlying cognitive and psychomotor processes and is less directly shaped by deliberative self-presentation or response framing. The observed association between RT adaptation dynamics and clinically meaningful symptom improvement, therefore, supports RT trajectories as a complementary marker

XSL•FO
RenderX

for tracking depressive symptom variation in naturalistic settings, potentially improving reliability when subjective reports are noisy or inconsistent.

Moreover, EMA-RT adaptation features may help make digital mental health interventions more actionable and personalized. As noted in the *Introduction* section, the effects of ecological momentary interventions are heterogeneous and depend on individual characteristics. Consequently, a practical barrier to scaling digital care is identifying early on who will benefit from a given protocol and who will require additional support. Our results suggest that RT adaptation patterns within an initial monitoring window (approximately 1 month) may provide an early indicator of EMA responsiveness. Such early stratification could guide stepped-care decisions (eg, prompting intensified clinician contact, alternative interventions, or safety monitoring for likely non-responders) while allowing responders to continue with lower-intensity, self-guided support, thereby supporting more efficient allocation of constrained clinical resources and optimizing just-in-time adaptive intervention approaches. We also note that this early stratification window may be shortened through systematic investigation of the optimal decision period. Specifically, building on the observed faster adaptation among responders, future work could quantify within-person day-to-day EMA-RT gradients (or slopes over rolling windows) and evaluate candidate "decision days" (eg, 7, 10, 14, or 21 days) to determine an earlier, reliable point for stepped-care decisions.

Finally, the item-specific links observed between EMA domains and symptom changes suggest a pathway to broaden EMA monitoring beyond depression. Because psychiatric symptoms frequently co-occur, identifying domain-specific behavioral signatures (eg, the feeling-depression linkage observed here) may enable EMA to track multiple symptom dimensions simultaneously, supporting more nuanced, individualized monitoring and intervention planning.

Limitations

First, regarding the observed effectiveness of the EMA-based self-monitoring, although significant reductions in depressive and anxiety symptoms were detected across multiple validated scales, the absence of a control group precludes definitive causal attribution. Participants were not randomized, and potential concurrent treatments, such as case management, pharmacotherapy, or psychotherapy, were not systematically recorded or controlled, introducing possible confounding influences. Additionally, postintervention assessments were conducted only once at the 4-week mark without follow-up measurements to evaluate the durability of treatment effects. As such, the long-term efficacy and sustainability of EMA-based self-monitoring in older adults with depression remain undetermined.

While several EMA-derived features were shown to be associated with symptom variation, some unexpected patterns emerged in the relationship between self-reported EMA scores and symptom change. Specifically, positive correlations were observed between mood-related EMA scores and symptom change in both depression and anxiety domains. These findings suggest that higher EMA ratings during the intervention period were paradoxically linked to less clinical improvement. One possible interpretation is that individuals with persistent depressive symptoms may have reduced self-reflective precision, leading to inflated or undifferentiated positive reports. Alternatively, healthier participants may have demonstrated more nuanced and accurate self-monitoring. However, this hypothesis requires further empirical validation.

Additionally, given the modest sample size (n<50), the correlational analyses were likely underpowered to detect small associations between symptom-change scores and EMA-derived features; thus, null or weak correlations should be interpreted cautiously. Larger cohorts will be needed to more precisely estimate small effects and confirm the robustness and generalizability of the observed associations, particularly those involving the exponential-decay parameters.

Finally, in examining dynamic EMA response trajectories, the most distinctive group-level differences between responders and non-responders emerged in the fitted parameters of the feeling item, whereas appetite, sleep quality, and general evaluation items yielded less pronounced contrasts. This discrepancy may reflect the unique psychological salience of the feeling item, which directly targets the immediate emotional state, in contrast to the more somatically anchored or abstract content of the other items. Alternatively, the fixed order of EMA item presentation, wherein the feeling item was always administered first, may have contributed to its stronger predictive utility. It is plausible that the first item elicits more cognitive effort or reflects the initiation speed of self-reflective responses, thus capturing more variance in related cognitive functioning. This potential order effect should be systematically examined in future studies to better delineate what EMA-based response latencies truly index in ecological settings.

Conclusions

This study demonstrates the feasibility of using EMA-based self-monitoring as both an adjunctive care and a behavioral phenotyping tool in older adults with a high risk of depression.

The implications for digital health care are manifold. First, the integration of response-time dynamics into mobile health platforms offers a nonobtrusive means of tracking cognitive and emotional engagement, even in populations with limited digital literacy. The method's compatibility with brief, low-frequency EMA schedules (eg, daily reports, about a month) makes it especially suitable for aging individuals, who may be less tolerant of intensive digital protocols. Second, the use of within-subject standardization and curve-fitting models supports individualized tracking, allowing for the detection of meaningful intra-individual changes. This has significant implications for the early identification of symptom relapse, monitoring of treatment responsiveness, and tailored interventions based on dynamic behavioral signatures.

In sum, the introduced EMA-based modeling offers a novel, sensitive, and pragmatic approach for advancing mental health care in aging populations. Future work should aim to validate these findings in randomized controlled settings, investigate the mechanistic underpinnings of RT adaptations, and explore broader applications in digital psychiatry and geriatric care.

Abstract

Background: Against the backdrop of global population aging, the development of low-burden and widely acceptable interventions to support emotional health in older adults has become a critical research priority. Virtual reality (VR) has been increasingly applied in medical rehabilitation and psychological interventions due to its immersive and interactive features. However, its potential as a form of digital therapy that integrates cultural content and artistic design remains underexplored, particularly with respect to the mechanisms through which such experiences facilitate emotional regulation in older populations. Empirical studies combining subjective emotional outcomes with objective physiological indicators are especially scarce.

Objective: This study aimed to examine the emotional regulation effects of an artistic cultural heritage–based VR experience among older adults and to explore its underlying mechanisms by integrating subjective psychological assessments with objective physiological responses.

Methods: A mixed methods experimental design was adopted using the United Nations Educational, Scientific and Cultural Organization Historic Centre of Macao as the study context. Two VR conditions were developed for comparison: (1) an artistic cultural heritage VR environment and (2) a conventional photorealistic replica VR environment. A total of 49 participants aged 60 years and older were recruited. During the VR experience, electrodermal activity (EDA) was continuously recorded to capture emotional arousal. Physiological data were triangulated with pre- and postintervention psychological questionnaires assessing emotional states, as well as semistructured interviews.

Results: Compared with the realistic replication VR condition, the cultural heritage VR condition was associated with significantly higher positive affect and lower negative affect (P<.05). At the physiological level, a significant between-group difference was observed in mean normal-to-normal interval (P=.01; Cohen d=0.91), whereas no significant differences were found in EDA measures (all P>.05). EDA results showed notable interindividual variability but did not demonstrate consistent group-level effects. These findings suggest that emotional changes may be more prominently reflected in subjective experience than in physiological arousal.

Conclusions: By integrating subjective and physiological measures, this study provides preliminary empirical evidence that cultural heritage VR is associated with improved emotional outcomes in older adults. The findings propose a conceptual interpretative pathway linking digital cultural experience, emotional engagement, and psychological well-being, while highlighting the importance of individual variability in physiological responses. This study contributes to the development of content- and experience-oriented approaches in digital therapeutics and provides an evidence-based framework for emotion-supportive design in digital heritage and aging-related contexts.

Introduction

The World Health Organization [1] projects that the global population aged 60 years and older will reach 2.1 billion by 2050. Mental health conditions such as depression and anxiety are expected to exert an increasingly significant impact on quality of life in later adulthood [2]. As population aging accelerates worldwide, enhancing emotional well-being and life satisfaction among older adults has become a central concern across public health, psychology, and design-related disciplines [3]. Declines in physical capacity and social participation increase vulnerability to loneliness, depression, and anxiety in

XSL•FO
RenderX

later life, which in turn affect daily functioning and overall physical and mental health [2,4].

Traditional approaches to emotional regulation in older adults—such as art therapy, group activities, and cultural visits—are often constrained by mobility limitations, health conditions, or external disruptions such as pandemics [5,6]. In response, digitally mediated therapeutic interventions have emerged as a promising alternative [7]. Identifying effective digital strategies to stimulate positive emotions and psychological resilience in older populations has thus become a key focus of interdisciplinary research [8]. In this context, virtual reality (VR), owing to its immersive, controllable, and spatially representational properties [9], offers new opportunities to enhance emotional experiences among older adults [10-12].

Presence, commonly defined as the subjective sensation of "being there" within a mediated environment, represents a central psychological construct in VR research. A strong sense of presence can enhance users' emotional engagement, attentional focus, and cognitive involvement in virtual environments. Previous studies have demonstrated that higher levels of presence are associated with stronger affective responses and more pronounced physiological reactions during immersive experiences. In particular, presence has been identified as an important psychological pathway through which immersive VR environments influence emotional and behavioral outcomes [13,14]. For example, the National Arts Council of Singapore, in collaboration with the National Gallery Singapore, has provided 1-hour virtual heritage art tours for older adults [15]. Although these programs have been widely welcomed and in high demand, empirical evaluations of their emotional impact remain limited.

Existing studies have demonstrated that VR-based interventions can alleviate depressive and anxiety symptoms and improve overall psychological well-being among older adults [16-18]. However, most prior research has focused on natural environments, cognitive training, or reminiscence-based content, with relatively little attention paid to immersive experiences that incorporate cultural depth and artistic expression [19-21]. Evidence suggests that older users—including individuals with dementia—prefer VR content related to travel, nature, art, social interaction, or familiar environments [22,23].

Unlike conventional cultural reproduction, cultural heritage–based VR emphasizes aesthetic transformation and contextual storytelling. It integrates historical spaces, cultural narratives, and artistic expression into immersive virtual experiences, rather than merely replicating physical environments. Such experiences may strengthen cultural identity and emotional immersion while eliciting deeper affective engagement. Despite this potential, heritage-based VR as a form of digital therapy remains underexplored at the intersection of VR research and aging studies.

Another limitation of this research lies in its heavy reliance on self-report measures, such as questionnaires and interviews, when examining the emotional effects of VR-based cultural experiences [8,24]. Objective physiological indicators are rarely incorporated. Electrodermal activity (EDA), a sensitive measure of autonomic nervous system activity, provides real-time information on emotional arousal and attentional engagement during immersive experiences [25]. Wearable physiological sensors have become an increasingly reliable method for collecting autonomic nervous system signals in naturalistic and experimental contexts [26]. When combined with self-report measures, EDA can reduce biases associated with retrospection and offer a dynamic representation of emotional fluctuations over time. Recent findings highlight the particular sensitivity of EDA responses to emotional arousal and presence in VR environments, underscoring its methodological value for emotional health research [27]. Incorporating EDA into VR-based cultural experience studies therefore represents an important methodological advancement.

To address these gaps, this study selected the Historic Centre of Macao as the experimental context, with a focus on the Ruins of St. Paul's and its surrounding urban spaces. Prior research suggests that historical heritage settings can foster meaning, identity, and subjective well-being among older adults [28,29]. As a United Nations Educational, Scientific and Cultural Organization World Heritage site, Macao embodies distinctive historical narratives and artistic symbolism. The virtual environments were modeled according to real spatial proportions and architectural characteristics to recreate the physical form, spatial scale, and ambient qualities of the historic district. Building on this foundation, an "artistic cultural experience" design approach was introduced, embedding cultural information through aesthetic and interactive elements.

Through heritage-oriented VR experiences, VR was positioned not merely as a tool for spatial replication, but as a medium for artistic translation and emotional regulation [30]. From the perspective of digital cultural heritage and art experience research, artistic interpretation can intensify emotional engagement and perceived meaning, enabling virtual environments to function as affective and interpretive media rather than purely technical simulations [31,32]. By integrating EDA with subjective assessments, this study further explores the relationship between virtual cultural-artistic experiences and physiological emotional responses.

The contributions of this study are 3-fold. First, it advances VR content design from literal replication toward artistic reinterpretation, encouraging emotional resonance and identity engagement among older participants. Second, it combines EDA with subjective measures to examine whether a coordinated pathway exists linking experience, emotional arousal, and emotional health. Third, by using the Historic Centre of Macao as a case study, it explores the social value of cultural heritage digitization in health promotion contexts. This interdisciplinary approach provides both a novel empirical pathway and a model for integrating design research, environmental psychology, and aging studies. Theoretically, it elucidates how design-led content and physiological feedback jointly shape emotional mechanisms in later life. Practically, it offers a replicable framework for digital cultural experiences applicable to cultural institutions, community care settings, and urban cultural policy.

Based on the theoretical framework and the identified research gaps, this study aims to examine whether cultural heritage VR experiences can enhance emotional health among older adults

XSL•FO
RenderX

and to explore the emotional mechanisms associated with such experiences. Specifically, this study addresses 3 core research questions (RQs): (RQ1) whether cultural heritage VR is more effective than realistic replication VR in improving emotional health among older adults, (RQ2) whether cultural heritage VR elicits stronger electrodermal responses reflecting emotional arousal, and (RQ3) whether individual psychological traits including emotion regulation difficulty and psychological resilience are associated with subjective emotional states and depression levels before and after VR intervention. Accordingly, 3 hypotheses (H1-H3) were formulated corresponding to these RQs (Table 1).

Table . Correspondence between research hypotheses (H) and research questions (RQs).

Research hypotheses	Corresponding RQs
H1. Older adults who experience cultural heritage VR[a] will exhibit higher levels of emotional health than those in the realistic replication VR condition.	RQ1. Can digital therapeutics based on cultural heritage VR significantly improve emotional health in older adults?
H2. Cultural heritage VR experiences will elicit stronger electrodermal responses, reflecting greater emotional arousal.	RQ2. Does cultural heritage VR induce significantly higher electrodermal activity, indicating stronger arousal, compared with the control condition?
H3. Individual psychological traits such as difficulty in emotion regulation and psychological resilience are significantly correlated with emotional states (PA[b]/NA[c]) before and after VR intervention.	RQ3. Do individual psychological traits such as emotion regulation ability and psychological resilience influence the intervention effect of VR cultural heritage experience on the emotional health of older people?

[a]VR: virtual reality.

[b]PA: positive affect.

[c]NA: negative affect.

Methods

Ethical Considerations

Older adult participants were recruited through local community committees and care institutions for older people in Zhuhai and Foshan, Guangdong Province. All participants met the study inclusion criteria and participated on a voluntary basis. Ethics approval for this study was granted by the Academic Committee of the School of Innovative Design, City University of Macao (approval Ref 2025 09291315). Written informed consent was obtained from all participants prior to study initiation. Participants' capacity to provide informed consent was independently assessed by a licensed clinical psychologist who was not involved in the study, in order to ensure adequate comprehension and voluntary participation. All collected data were anonymized. Data handling and storage complied with the Organic Law on the Protection of Personal Data and Guarantee of Digital Rights (Law 3/2018, enacted on December 5, 2018). The study was conducted in accordance with good research practice standards and the principles of the Declaration of Helsinki.

Participants

The sample size was estimated based on effect sizes reported in previous studies examining the impact of VR interventions on physiological outcomes, including heart rate variability (HRV) and EDA. Prior studies have demonstrated that VR-based interventions can significantly modulate autonomic and physiological responses, suggesting moderate to large effects [33,34]. Based on these estimates, a minimum of 30 participants per group was required to achieve 80% statistical power at a significance level of .05.

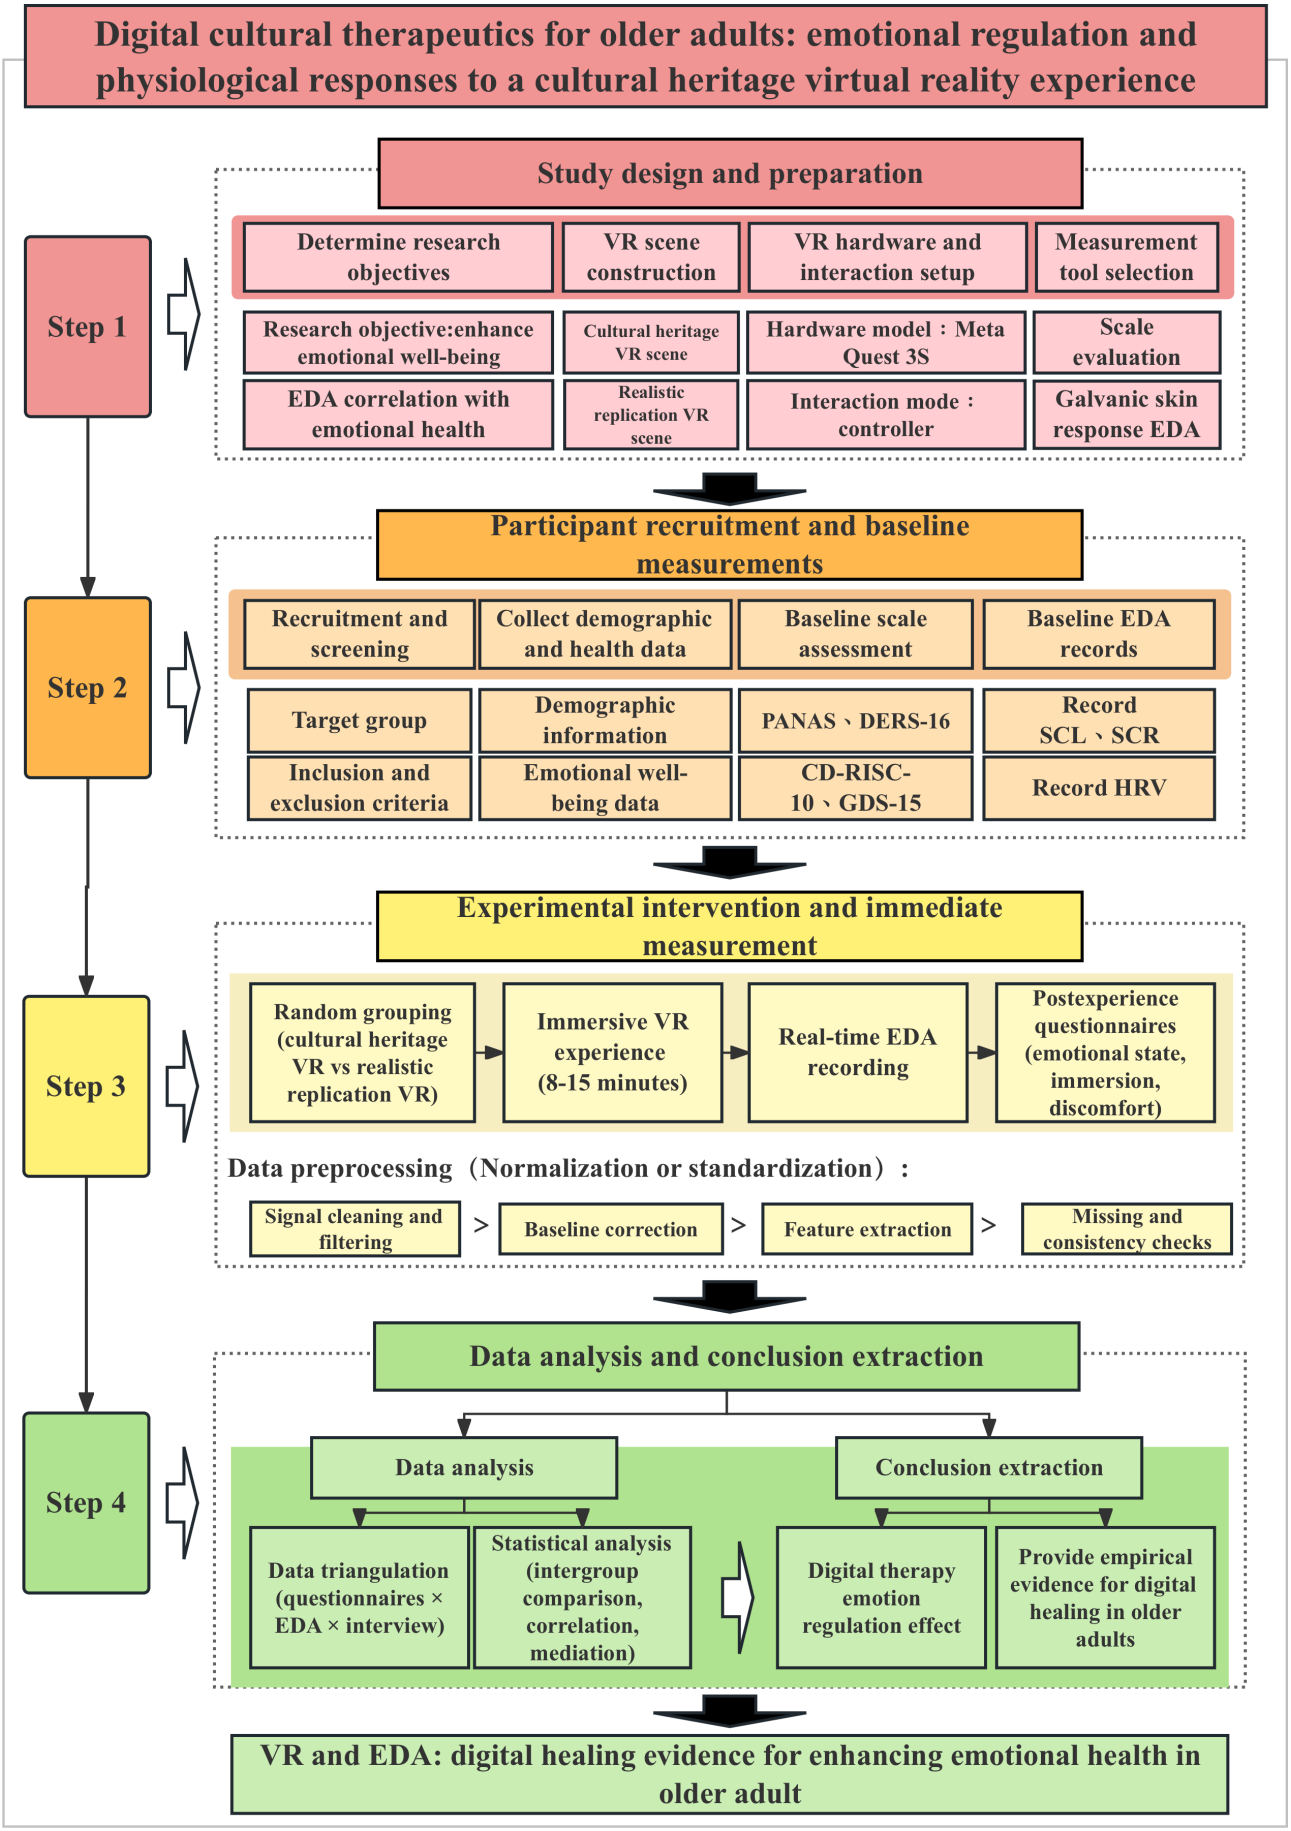
To further account for potential attrition during the VR intervention and follow-up assessments, an anticipated dropout rate of approximately 18% was incorporated, based on prior research involving older adults in VR settings [35]. Accordingly, the target sample size was increased, resulting in a final sample of 49 older adults; the study aimed to recruit at least 30 participants per group. A final sample of 49 older adults was included in the analysis.

Participants were eligible for inclusion if they met the following criteria: (1) aged 60 years or older and able to complete the experimental procedures independently or with assistance; (2) able to understand the study procedures and provide written informed consent, with additional auditory or visual explanations provided when necessary; (3) no uncontrolled cardiovascular disease or epilepsy (participants with stable conditions were included only after clinical approval); and (4) no severe cognitive impairment. Cognitive status was screened using the Mini-Mental State Examination, with a cutoff score of ≥24 indicating eligibility.

Exclusion criteria were (1) a history of severe motion sickness, recent ear surgery, or dermatological conditions that could interfere with EDA electrode attachment; and (2) recent use of medications known to strongly affect autonomic nervous system activity. When medication use could not be avoided, it was recorded and treated as a covariate in subsequent analyses.

This randomized experiment had a total duration of 3 months and concluded on November 30, 2025. Participant recruitment was conducted between September and November 2025. The baseline assessment took place on September 1, 2025, and the final assessment was completed on November 30, 2025.

Research Materials



Overview

The study used VR equipment, standardized psychometric questionnaires, and multimodal physiological recording devices to establish an integrated assessment framework combining subjective and objective measures (Figure 1).

VR Scene Materials

This study adopted a mixed methods design that combined subjective self-report measures with objective physiological signals to examine the effects of cultural heritage–based VR experiences on emotional health in older adults.

The VR environment was developed based on the Historic Centre of Macao, a United Nations Educational, Scientific and Cultural Organization World Heritage Site, selected due to its rich cultural significance and well-preserved architectural heritage. The inclusion criteria for the VR environment were (1) cultural and historical relevance, (2) visual richness and environmental complexity, and (3) the potential to evoke emotional and cognitive engagement. These criteria were informed by prior research suggesting that immersive and meaningful environments can enhance user engagement and modulate emotional and physiological responses in VR settings [36,37].

The experimental framework comprised 2 parallel VR conditions: a cultural heritage VR scene and a realistic replica VR scene. Both conditions were modeled on the same landmarks—the Ruins of St. Paul's (A01) and St. Dominic's Church (A02)—to ensure consistency in spatial content across conditions (Figure 2).

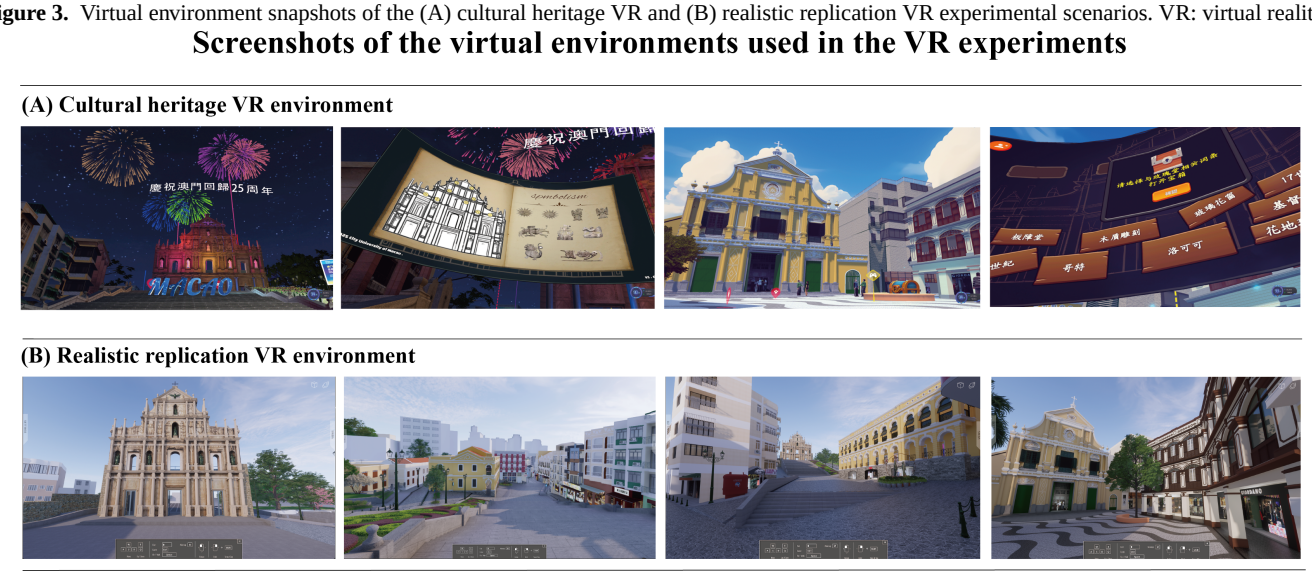

Figure 2. Study area.

Participants were randomly assigned to either the cultural heritage VR group or the realistic replica VR group. Prior to the experiment, participants were blinded to their group allocation. The cultural heritage VR scenes incorporated creative enhancements, including visual aesthetic augmentation, soundscape design, light interactive elements, gamified tasks, and embedded cultural information. These features were intended to increase immersion, cultural engagement, and the elicitation of positive emotional responses among older participants. In contrast, the realistic replica VR scenes served as the control condition and were designed to provide a neutral, realistic replication reproduction of the same spaces. These scenes included no background music, no gamified interactions, and no cultural prompts. Visual presentation, auditory input, and interactivity were deliberately kept minimal to control for artistic and experiential factors. Representative snapshots of the virtual environments used in the study are presented in Figure 3.

XSL•FO
RenderX

Figure 3. Virtual environment snapshots of the (A) cultural heritage VR and (B) realistic replication VR experimental scenarios. VR: virtual reality.

Equipment and Technical Setup

The experimental setup comprised immersive VR hardware and physiological signal acquisition devices. VR experiences were delivered using a head-mounted display (Meta Quest 3/3S), which offers 4K-level resolution, a refresh rate of 90 - 120 Hz, and 6 degrees of freedom tracking, ensuring stable and highly immersive visual performance. All VR content was developed by the research team led by PW at the School of Innovative Design, City University of Macau.

To ensure comparability across experimental conditions, the cultural heritage VR and realistic replica VR scenes were matched in spatial structure, viewpoint trajectories, and lighting parameters. The only differences between conditions concerned the presence or absence of artistic enhancements. Specifically, the cultural heritage VR condition incorporated environmental music, narrative voice prompts, cultural knowledge pop-ups, light interactive tasks, and gamified feedback, whereas these elements were deliberately excluded from the realistic replica condition.

Physiological data were collected using the EryLife S2 multimodal sensing device (Wecare Medical Co), which enables synchronized recording of EDA and HRV signals [38]. The sampling frequency for EDA was set at 4 Hz. Given that EDA signals primarily consist of slow-varying tonic and phasic components, relatively low sampling rates have been shown to be sufficient for capturing meaningful skin conductance responses [39]. Photoplethysmography signals were collected at 100 Hz for HRV analysis. This sampling rate is consistent with previous studies demonstrating that ≥100 Hz provides adequate temporal resolution for reliable interbeat interval detection and HRV estimation, in line with established HRV measurement principles [40]. EDA was measured using medical-grade dry electrodes attached to the inner side of the nondominant wrist, ensuring signal stability and wearing comfort for older participants. HRV data were obtained via a photoplethysmography sensor, providing complementary information on sympathetic and parasympathetic nervous system activity.

Psychological Measures

To systematically assess baseline emotional health prior to the VR intervention, psychological questionnaires were categorized into three functional domains:

1. Emotional state indicators: Positive and Negative Affect Schedule (PANAS),
2. Emotional burden indicators: Geriatric Depression Scale-15 and University of California, Los Angeles Loneliness Scale-8, and
3. Regulatory trait indicators: Difficulties in Emotion Regulation Scale-16 and Connor-Davidson Resilience Scale-10.

This classification facilitated the distinction between short-term emotional changes (state variables) and relatively stable emotional characteristics (trait variables) in subsequent analyses and supported the examination of potential mechanisms underlying VR intervention effects across different psychological dimensions.

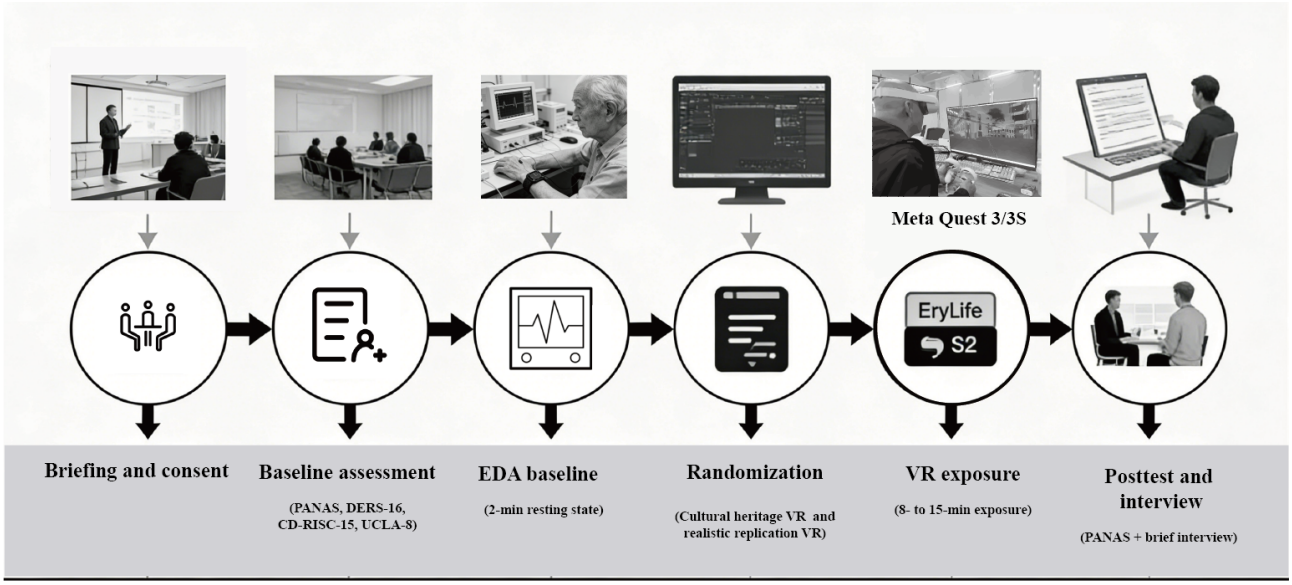
The 20-Item Positive and Negative Affect Schedule [41] was used to assess changes in positive affect (PA) and negative affect (NA) before and after the VR experience. The 16-Item Difficulties in Emotion Regulation Scale (DERS-16) [42] measured individual differences in emotion regulation difficulties, allowing exploration of how regulatory capacity may moderate VR-related emotional benefits. The 10-Item Connor-Davidson Resilience Scale (CD-RISC-10) [43] was administered to evaluate psychological resilience and its potential influence on emotional improvement. The 15-Item Geriatric Depression Scale (GDS-15) [44] served as a screening tool for depressive symptoms in older adults and was used to control for baseline emotional burden. The short version of the University of California, Los Angeles Loneliness Scale [45] assessed perceived social loneliness, enabling further examination of whether immersive VR experiences could alleviate loneliness-related emotional distress.

In addition, demographic variables (eg, living arrangements) and behavioral information (eg, prior exposure to VR) were collected via questionnaire.

XSL•FO
RenderX

All psychological scales used in this study are well-established instruments with demonstrated validity in prior research. To assess internal consistency within the current sample, reliability analyses were conducted by the research team using Cronbach α coefficients in SPSS (IBM Corp). The results indicated satisfactory internal consistency across all measures, with Cronbach α values exceeding the recommended threshold of 0.70.

Experimental Procedure



Overview of the Procedure

Upon arrival at the laboratory, all participants received a standardized explanation of the study procedures and provided written informed consent. Participants then completed baseline psychological assessments, including PANAS, DERS-16, CD-RISC-10, GDS-15, and 8-Item University of California, Los Angeles Loneliness Scale (UCLA-8), to establish initial emotional states, emotional burden, and regulatory and resilience-related traits.

Following the questionnaire assessment, participants underwent a 2-minute resting-state EDA recording in a quiet environment with constant lighting conditions. This baseline recording was used to obtain individual skin conductance level (SCL) and SCR measures. After baseline data collection, participants were randomly assigned by computer algorithm to either the cultural heritage VR group or the realistic replica VR control group.

Participants then engaged in an immersive VR experience lasting approximately 8 - 15 minutes using the Meta Quest 3/3S head-mounted display. During the VR session, EDA and heart rate activity were continuously recorded using the EryLife S2 Watch device. Immediately after the VR experience, participants completed the postintervention PANAS assessment and, when appropriate, participated in a brief semistructured interview to supplement subjective experience data (Figure 4).

Figure 4. Experimental procedure (illustrative example). CD-RISC-15: 15-Item Geriatric Depression Scale; DERS-16: 16-Item Difficulties in Emotion Regulation Scale; PANAS: Positive and Negative Affect Schedule; UCLA-8: 8-Item University of California, Los Angeles Loneliness Scale; VR: virtual reality.

EDA Signal Preprocessing and Feature Extraction

EDA data were continuously collected during the VR experience using the EryLife S2 device and processed through a multistage standardized pipeline. First, the raw signals underwent automated artifact detection and low-pass filtering to remove motion-related noise and signal distortions caused by poor electrode contact. Second, baseline correction was performed using each participant's resting-state SCL, ensuring comparability across individuals. Subsequently, key EDA features were extracted from the cleaned signals, including SCR frequency, peak amplitude, temporal characteristics, and area under the curve. Finally, *z* score normalization and percentage transformation were applied to optimize data distribution properties and to provide a robust basis for subsequent statistical analyses.

RQs and Analytical Strategy

To address the RQs, a controlled experimental design was implemented. Specifically, RQ1 was examined by comparing emotional health outcomes between the cultural heritage VR condition and the realistic replication VR condition using self-report measures. RQ2 was investigated by analyzing physiological emotional responses based on EDA signals recorded during the VR experience. RQ3 was explored by examining the relationships between subjective emotional responses and physiological indicators, with the aim of identifying potential mechanisms underlying emotional health improvements associated with VR exposure.

Data Processing and Analysis

A multilevel analytical strategy integrating quantitative and qualitative approaches was used to examine the effects of artistic VR experiences on emotional health in older adults and to explore their underlying physiological mechanisms. First, statistical analyses were conducted on questionnaire data,

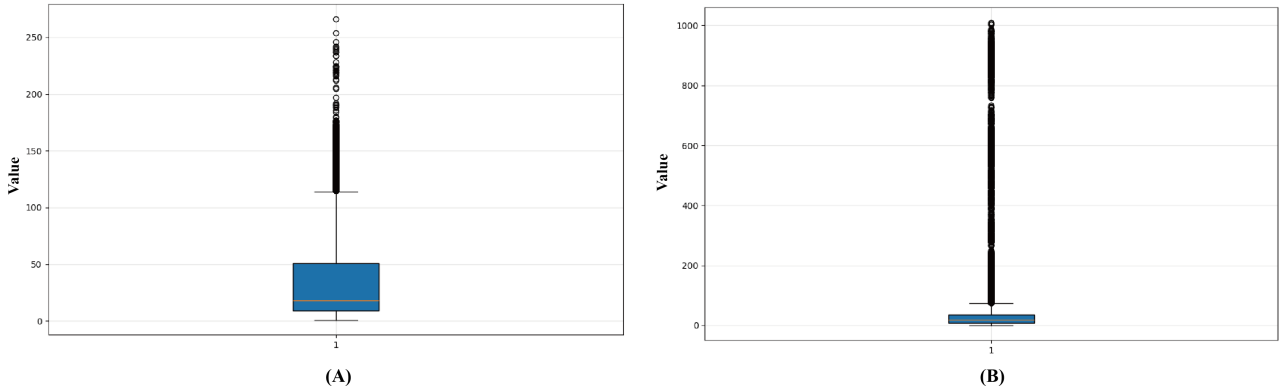
XSL•FO
RenderX

including PANAS, DERS-16, CD-RISC-10, GDS-15, and the 8-Item University of California, Los Angeles Loneliness Scale. Second, to mitigate potential interpretive bias associated with reliance on a single physiological indicator, EDA and HRV signals were jointly analyzed. This multimodal autonomic assessment enabled evaluation of VR-related emotional arousal across multiple dimensions of autonomic nervous system activity. Physiological measures were aggregated at the individual level prior to statistical testing to enhance the robustness and interpretability of the results. Finally, a data triangulation approach was applied to integrate findings from self-report measures, physiological indicators, and semistructured interviews, providing a comprehensive assessment of emotional responses to the VR experience.

To examine changes in emotional states associated with VR exposure, repeated-measures analysis of variance (RM-ANOVA) was conducted on PANAS PA and NA scores, with time (pre- vs postintervention) treated as the within-subject factor and group (cultural heritage VR vs realistic replication VR) as the between-subject factor. Because the within-subject factor consisted of only 2 levels, the assumption of sphericity for RM-ANOVA was inherently satisfied.

Results

Physiological Responses



Overview

To objectively compare autonomic nervous system responses under different VR conditions in older adults, between-group analyses were conducted using HRV and EDA indicators. For all measures, change scores (Δ=post–pre) were calculated at the individual level and used for statistical comparisons between groups. Continuous variables were expressed as mean (SD). Descriptive analyses were first performed to examine the distributional characteristics of the physiological data. Boxplots were used to visualize the median, IQR, and dispersion of each indicator. Subsequently, nonparametric Mann-Whitney *U* tests were applied to both HRV and EDA measures to assess between-group differences.

EDA Result

Descriptive analyses revealed clear differences in the distributional properties of EDA between the cultural heritage VR and realistic replica VR conditions. Examination of the boxplots (Figure 5) allowed further differentiation of the sources of these distributional differences.

Figure 5. Distributional characteristics of electrodermal activity under different VR conditions: (A) cultural heritage VR and (B) realistic replication VR. VR: virtual reality.

Under the cultural heritage VR condition, the EDA box (representing the IQR, ie, the middle 50% of observations) was relatively compact, with the median located at a low level (approximately 25), indicating that baseline SCRs were clustered within a narrow range for most participants. However, the upper tail of the distribution was markedly extended and accompanied by several high-value outliers. This pattern indicates that a small subset of participants exhibited SCRs substantially higher than the group norm, thereby considerably increasing overall dispersion.

In the realistic replica VR condition, the EDA box was similarly concentrated in a low-value range, with a relatively low median, suggesting generally stable and homogeneous physiological responses across participants. Although a few high-value outliers were also observed, their number and influence on the overall distribution were limited, resulting in a lower degree of dispersion compared with the cultural heritage VR condition.

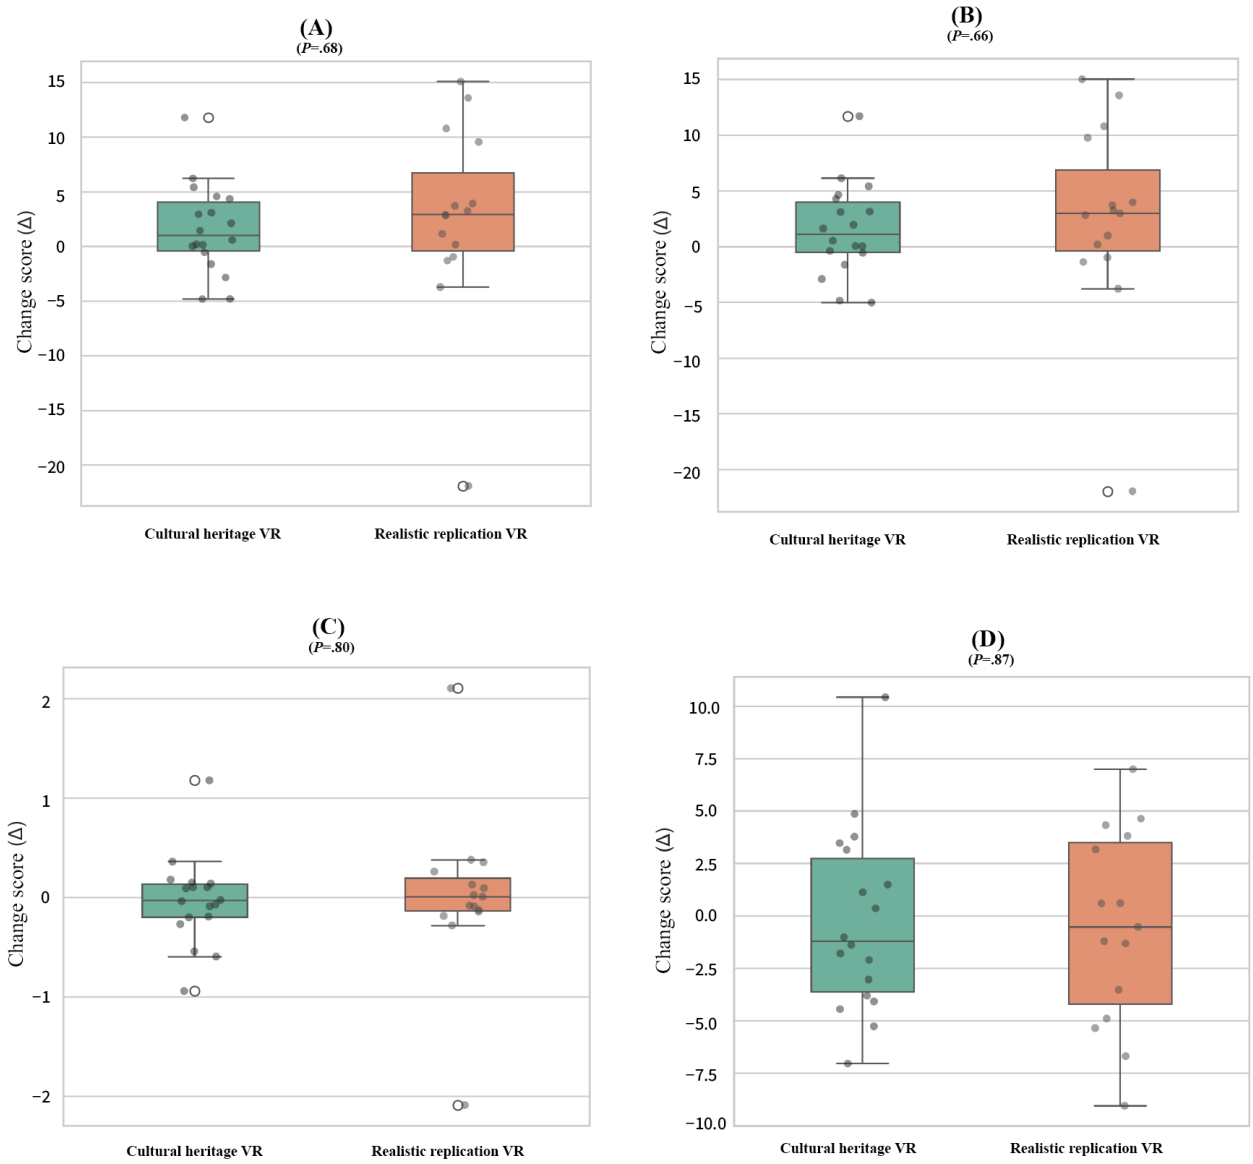
Overall, the primary differences between the 2 VR conditions lay in distributional dispersion and upper-tail structure rather than in a pronounced shift in central tendency. These findings suggest that cultural heritage VR experiences are more likely to elicit pronounced interindividual variability in autonomic responses, whereas realistic replica VR experiences are associated with more uniform and stable EDA response patterns.

The between-group comparisons of EDA indicators are presented in Table 2. No statistically significant differences were observed between the 2 VR conditions across all EDA measures, including mean EDA (P=.68; Cohen d=−0.16), SCL (P=.66; Cohen d=−0.16), SCR amplitude (P=.80; Cohen d=−0.09), and SCR peak rate (P=.87; Cohen d=0.06). All effect sizes were small ($|d|$<0.20), indicating limited practical differences in EDA responses between the 2 conditions.

XSL•FO
RenderX

Table . Group comparisons of electrodermal activity (EDA) indicators.

Signal source and feature	Cultural heritage VR[a] (n=25), mean (SD)	Realistic replication VR (n=24), mean (SD)	*P* value	Cohen *d*
EDA				
Mean EDA	1.58 (4.09)	2.61 (8.75)	.68	−0.16
SCL[b]	1.52 (4.12)	2.61 (8.77)	.66	−0.16
SCR[c] amplitude	−0.04 (0.44)	0.02 (0.81)	.80	−0.09
SCR peak rate	−0.29 (4.33)	−0.56 (4.67)	.87	0.06



[a]VR: virtual reality.

[b]SCL: skin conductance level.

[c]SCR: skin conductance response.

Distributional analyses (Figure 6) further showed substantial overlap in medians and IQRs across groups, with no clear separation between conditions. Although several indicators exhibited occasional extreme values, these variations were primarily observed at the individual level and did not translate into consistent group-level effects.

Figure 6. Changes in EDA indicators across VR conditions. (A) Mean EDA, (B) SCL, (C) SCR amplitude, and (D) SCR peak rate. EDA: electrodermal activity; HRV: heart rate variability; SCL: skin conductance level; SCR: skin conductance response; VR: virtual reality.

XSL•FO
RenderX

From a physiological perspective, SCL reflects tonic sympathetic arousal, whereas SCR-related measures (amplitude and peak rate) capture phasic, event-related responses. These findings suggest that, under the present experimental conditions, EDA indicators did not demonstrate consistent group-level differentiation, potentially reflecting high interindividual variability and the complex nature of emotional arousal in immersive environments.

HRV Result

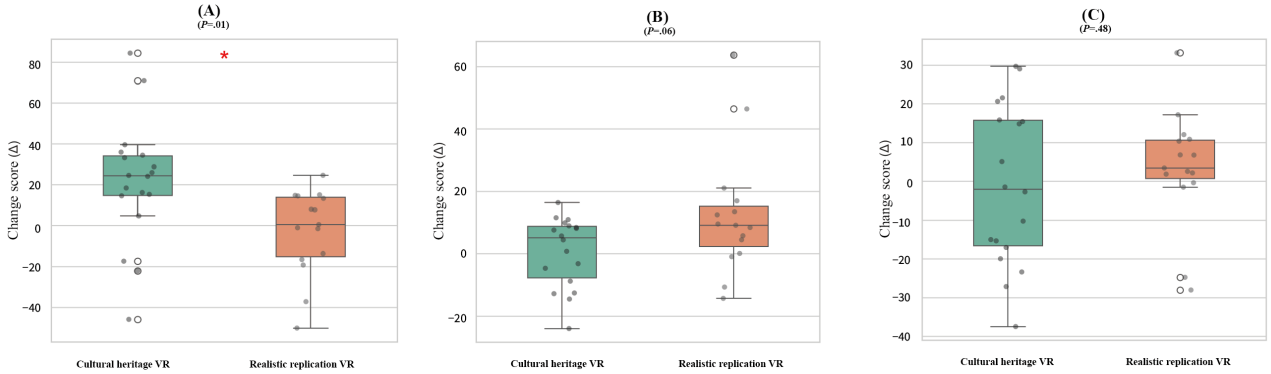
The between-group comparisons of HRV indicators are presented in Table 3. The results showed that a significant difference was observed for the mean HRV-derived value between the 2 VR conditions (*P*=.01; Cohen *d*=0.91), with higher change scores in the cultural heritage VR group (mean 21.48, SD 30.39) compared to the realistic replication VR group (mean −2.69, SD 21.03).

Table . Group comparisons of heart rate variability (HRV) indicators.

Signal source and feature	Cultural heritage VR[a] (n=25), mean (SD)	Realistic replication VR (n=24), mean (SD)	*P* value	Cohen *d*
HRV				
Mean NN[b] interval	21.48 (30.39)	−2.69 (21.03)	.01	0.91
SDNN[c]	0.71 (11.26)	12.40 (20.00)	.06	−0.74
RMSSD[d]	−0.96 (20.70)	3.52 (14.89)	.48	−0.24

[a]VR: virtual reality.

[b]NN: normal-to-normal.



[c]SDNN: standard deviation of NN.

[d]RMSSD: root-mean-square of successive difference.

In contrast, conventional time-domain HRV indices, including the standard deviation of NN intervals (SDNN) and the root-mean-square of successive differences (RMSSD), did not show statistically significant differences between groups. Although SDNN exhibited a numerical difference (*P*=.06; Cohen *d*=−0.74), it did not reach statistical significance. Similarly, no significant difference was found for RMSSD (*P*=.48; Cohen *d*=−0.24).

Distributional analyses (Figure 7) indicated that the mean normal-to-normal (NN) interval (mean RR interval) tended to be higher under the cultural heritage VR condition, whereas substantial overlap was observed between groups for SDNN and RMSSD. Overall, the between-group difference was primarily reflected in the mean NN interval, while no consistent pattern was observed across standard time-domain HRV measures.

Figure 7. Changes in heart rate variability indicators across VR conditions. (A) Mean NN interval, (B) SDNN, and (C) RMSSD. NN: normal-to-normal; RMSSD: root-mean-square of successive differences; SDNN: standard deviation of NN; VR: virtual reality.

From a physiological perspective, RMSSD is generally considered to reflect parasympathetic activity, whereas SDNN represents overall HRV. However, as these conventional indices did not show significant differences, the physiological interpretation of the observed group difference should be approached with caution. The findings suggest that the effects of different VR conditions on autonomic regulation may be limited or influenced by substantial interindividual variability.

Subjective Emotional Outcomes and Psychological Measures

Baseline Sample Characteristics and Between-Group Comparability

To ensure comparability between the cultural heritage VR group and the realistic replica VR group prior to intervention, chi-square tests were conducted on participants' demographic and health-related background variables. A total of 12 indicators were examined, including sex, age group, educational attainment, marital status, living arrangement, occupational

XSL•FO
RenderX

background, economic status, visual and auditory conditions, sleep quality, experience with smart devices, and prior exposure to VR or digital therapeutic applications (Table 4).

No statistically significant differences were observed between the 2 groups for any of the variables examined (χ^2 tests; all P>.05). These results indicate a high degree of baseline equivalence between groups in terms of sociodemographic structure, health status, and technology-related experience, thereby minimizing potential confounding effects attributable to sample composition and providing a reliable baseline for subsequent analyses of emotional and physiological outcomes.

Between-Group Differences in Baseline Psychological Traits

Prior to the VR intervention, 2-tailed independent-samples *t* test were performed to compare baseline psychological trait measures between groups, including emotion regulation difficulties (DERS-16), psychological resilience (CD-RISC-10), and depressive symptoms (GDS-15). No significant between-group differences were detected for emotion regulation difficulties (t_{47}=−1.08; *P*=.29), psychological resilience ($t_{25.538}$=1.869; *P*=.07), or depressive symptoms ($t_{31.212}$=−0.688; *P*=.49; Table 5). These findings further confirm baseline homogeneity between the 2 groups at the psychological trait level, establishing an appropriate foundation for evaluating VR-induced emotional changes.

Table . Results of 2-tailed independent-samples *t* tests.

Variable	Group		*t* test (*df*)	*P* value
	Cultural heritage VR[a] experience (n=25), mean (SD)	Realistic replication VR experience (n=24), mean (SD)		
Emotion regulation difficulties	39.00 (8.48)	41.67 (8.81)	−1.08 (47)	.29

[a]VR: virtual reality.

Effects of VR Intervention on PA and NA

To examine the effects of VR exposure on emotional state, RM-ANOVA was conducted on PANAS PA and NA scores, with time (pre- vs postintervention) as the within-subject factor and group (cultural heritage VR vs realistic replica VR) as the between-subject factor.

Descriptive statistics are presented in Table 6. At baseline, PA and NA scores were comparable between the 2 groups. Following the intervention, PA increased and NA decreased in both groups, with more pronounced changes observed in the cultural heritage VR group.

For PA, RM-ANOVA revealed a significant main effect of time ($F_{1,47}$=211.20; *P*<.001; η^2=0.818), indicating an overall increase following VR exposure. A significant main effect of group ($F_{1,47}$=5.67; *P*=.02; η^2=0.108) and a significant time×group interaction ($F_{1,47}$=12.47; *P*=.001; η^2=0.210) were also observed (Table 7).

XSL•FO
RenderX

Table . Descriptive statistics of positive affect (PA) and negative affect (NA) scores before and after the virtual reality (VR) intervention.

Measure and time	Cultural heritage VR experience (n=25), mean (SD)	Realistic replication VR experience (n=24), mean (SD)
PA		
Preintervention	30.96 (1.54)	30.79 (2.86)
Postintervention	43.48 (4.36)	38.42 (7.34)
NA		
Preintervention	19.00 (2.24)	21.38 (6.44)
Postintervention	10.32 (1.11)	17.46 (6.98)

Table . Repeated-measures ANOVA results.

Measure and effect	Type III sum of squares	*df*	Mean square	*F* test (*df*=1, 47)	*P* value	Effect size (η^2)
PA[a]						
Time	2484.619	1	2484.619	211.196	<.001	0.818
Group	167.573	1	167.573	5.674	.02	0.108
Time×group	146.7	1	146.7	12.47	.001	0.210
NA[b]						
Time	971.486	1	971.486	118.709	<.001	0.716
Group	554.103	1	554.103	14.151	<.001	0.231
Time×group	138.914	1	138.914	16.974	<.001	0.265

[a]PA: positive affect.

[b]NA: negative affect.

For NA, a similar pattern was observed. RM-ANOVA showed a significant main effect of time ($F_{1,47}$=118.71; P<.001; η^2=0.716), along with significant main effects of group ($F_{1,47}$=14.15; P<.001; η^2=0.231) and a significant time× group interaction ($F_{1,47}$=16.97; P<.001; η^2=0.265; Table 7).

Simple effects analyses (Tables 8 and 9) revealed a consistent pattern of significant time effects and differential group effects over time. At baseline, no significant between-group differences were observed in either PA or NA. Following the intervention, PA increased significantly in both the cultural heritage VR experience group and the realistic replication VR experience group; however, the increase was significantly greater in the cultural heritage VR group, resulting in higher postintervention PA compared with the control condition. Conversely, NA decreased significantly in both groups across time, with a significantly larger reduction observed in the cultural heritage VR group, which also exhibited significantly lower postintervention NA relative to the realistic replication VR group.

Table . Within-group simple effects analysis of positive affect (PA) and negative affect (NA) across time points[a].

Measure and group	Comparison	Mean difference (SE)	*P* value

Associations Between Psychological Traits and Emotional Changes

To further explore individual differences in emotional responses to VR, Pearson correlation analyses were conducted to examine associations among emotion regulation difficulties, psychological resilience, depressive symptoms, and emotional state before and after the intervention (Table 10).

XSL•FO
RenderX

Table . Pearson correlation analysis between emotion regulation difficulty, depression, and emotional indicators before and after the intervention.

[a]PA: positive affect.

[b]NA: negative affect.

[c]Not available.

Emotion regulation difficulties were significantly negatively correlated with psychological resilience (r=−0.530; P<.01) and positively correlated with depressive symptoms (r=0.526; P<.01). In addition, higher emotion regulation difficulties were associated with lower PA and higher NA both before and after the VR experience, indicating greater emotional burden among individuals with poorer regulation capacity.

Psychological resilience showed the opposite pattern, exhibiting significant positive correlations with PA and significant negative correlations with NA and depressive symptoms. These findings suggest that resilience may serve a buffering and facilitative role in VR-based emotional interventions.

Convergence Between Subjective Emotional Outcomes and EDA Responses

Comparative analysis of subjective emotional changes and EDA responses revealed consistent patterns across modalities. Relative to the realistic replica VR condition, participants exposed to cultural heritage VR exhibited higher and more sustained levels of skin conductance during the experience, alongside larger increases in PA and more pronounced reductions in NA on self-report measures.

This convergence between subjective emotional outcomes and autonomic physiological responses indicates coherent emotion-related effects across measurement modalities under different VR content conditions, providing an empirical basis for subsequent multimodal interpretations of VR-induced emotional regulation effects.

Discussion

Convergence of Subjective and Physiological Evidence and the Emotional Regulation Potential of Cultural Heritage VR

This study provides an exploratory evaluation of the role of cultural heritage VR in promoting emotional health among older adults by integrating subjective emotional measures with physiological indicators. The findings indicate that, compared with the visually neutral realistic replication VR condition, cultural heritage VR was associated with higher PA and lower NA. At the physiological level, only the mean NN interval showed a statistically significant between-group difference. In contrast, no significant differences were observed in EDA measures (all P>.05). However, EDA measures showed

XSL•FO
RenderX

substantial interindividual variability in their distribution patterns. It should be noted that the mean NN interval reflects overall cardiac cycle length rather than conventional HRV variability indices.

From the perspective of emotional arousal theory, changes in EDA are widely regarded as sensitive indicators of sympathetic nervous system activation and are closely linked to emotional engagement and attentional resource allocation [39,46,47]. The cultural heritage VR condition in this study incorporated enhanced visual aesthetics, soundscape design, narrative cues, and light interactive elements. These features may have facilitated affective engagement and sustained attention among older participants. However, this potential emotional arousal did not translate into stable group-level differences in EDA measures. Instead, it was reflected as variability at the individual level. Notably, although the physiological findings were limited, subjective emotional improvements showed a clearer pattern of differentiation between the 2 conditions. The discrepancy between subjective emotional improvement and physiological responses suggests a potential dissociation between perceived experience and autonomic activation.

This dissociation may be explained by several mechanisms. First, EDA primarily reflects sympathetic arousal. It may be less sensitive to changes in emotional valence when arousal levels remain moderate. In this study, the cultural heritage VR condition appeared to enhance PA without inducing strong physiological arousal, resulting in limited differentiation in EDA responses at the group level. Second, emotional engagement in VR environments may operate through cognitive-affective pathways, such as meaning-making and narrative immersion, which are more strongly reflected in subjective reports than in autonomic activation. Third, substantial interindividual variability in EDA responses may have obscured potential group-level effects. This variability may be particularly pronounced in older populations, where physiological responsiveness differs considerably.

Comparison With Previous Research: Cultural Heritage VR, Digital Therapeutics, and Emotional Health in Older Adults

Previous studies have widely reported that VR-based interventions can improve negative emotional states, enhance subjective well-being, and increase psychological engagement among older adults. These applications have primarily focused on rehabilitation training, cognitive stimulation, and social participation [11,48,49]. In such studies, emotional improvements are often attributed to immersion, novelty, and heightened attentional engagement afforded by VR technology [50,51].

However, much of the existing literature conceptualizes VR primarily as a technological medium, with limited systematic discussion of how artistic expression and cultural meaning embedded in virtual content contribute to emotional regulation [38]. In contrast, this study explicitly distinguishes between cultural heritage VR and realistic replica VR. Empirical evidence demonstrates that different types of virtual content do not elicit equivalent emotional responses. Emotional changes in older participants were not driven solely by VR technology itself but were more strongly influenced by artistic expression, cultural narrative structures, and experiential guidance embedded within the virtual environment. This finding extends existing VR intervention research by highlighting the emotional consequences of content differentiation.

Recent studies have begun incorporating music, narrative, or aesthetic elements into VR interventions and have reported positive outcomes at the subjective level. Nonetheless, most rely heavily on self-report measures and lack objective physiological validation [52-54]. By synchronously collecting EDA data, this study provides a complementary perspective to the existing literature. However, in contrast to prior studies reporting significant physiological changes, no significant between-group differences were observed in EDA indicators in this study. This discrepancy may be attributable to differences in experimental design and stimulus characteristics. Prior studies reporting significant physiological changes often used high-intensity or event-based stimuli, whereas this study used a more continuous and immersive experiential paradigm. Such differences may lead to distinct patterns of autonomic activation. Continuous experiences may elicit more subtle and distributed physiological responses. These responses may not be readily captured by conventional EDA metrics. This finding suggests that the emotional effects of VR interventions may not necessarily be accompanied by pronounced increases in physiological arousal, but may instead be more prominently reflected through subjective experiential pathways.

Nevertheless, distributional patterns indicate that a subset of participants in the cultural heritage VR condition exhibited relatively higher physiological responses, suggesting a greater potential for emotional activation at the individual level. Accordingly, the emotional effects of VR interventions appear to be partially individual-dependent, with physiological manifestations likely influenced by multiple factors, including individual differences and the degree of engagement with the virtual environment. These results support a shift in digital therapeutics research from a technology-centered effectiveness perspective toward a content- and experience-driven explanatory framework.

Mechanistic Pathways and Design Implications: A Conceptual Framework for Digital Therapeutics

Based on the integrated analysis of subjective emotional assessments and EDA data, this study proposes a conceptual pathway to explain the emotional effects of cultural heritage VR. The pathway emphasizes that culturally meaningful artistic experiences are associated with elevated emotional arousal, which in turn corresponds to changes in emotional states among older adults. It should be noted that this pathway is interpretative and hypothesis-generating rather than a fully validated causal model.

At the experiential level, cultural heritage VR may foster sustained emotional engagement and meaning construction through aesthetic visual language, soundscape design, narrative cues, and light interactive tasks. These features transform virtual environments from purely observable spaces into culturally situated emotional contexts, providing conditions conducive to

XSL•FO
RenderX

emotional activation. At the physiological level, higher levels of affective engagement and sustained attentional states may be reflected in autonomic activation, as indicated by electrodermal responses in a subset of individuals. However, this effect does not manifest as a consistent difference at the group level. This pattern suggests that emotional processing in VR may involve partially independent pathways for subjective experience and physiological activation. Affective engagement and meaning construction may enhance perceived emotional states. However, their translation into measurable autonomic responses may depend on factors such as stimulus intensity, individual sensitivity, and attentional dynamics. Unlike stress-induced or high-intensity stimulation responses, the observed EDA changes are more consistent with moderate, regulatable emotional arousal and co-occur with increased PA and reduced NA. This suggests that physiological arousal elicited by cultural heritage VR is more indicative of emotional participation and meaning experience rather than nonspecific sensory stimulation.

From the perspective of digital therapeutics and design practice, this conceptual pathway carries important implications. The findings underscore that content design in VR interventions is not ancillary but may constitute a primary condition for emotional effects to emerge. Moreover, incorporating physiological measures such as EDA into experience evaluation frameworks can address limitations inherent in exclusive reliance on self-report data and provide a more objective, verifiable basis for emotional health assessment in older adults. Future studies may further refine this pathway by introducing psychological constructs such as immersion and presence to test mediating mechanisms with greater precision. This pathway further suggests that emotional effects may depend on the dynamic coupling among contextual meaning, affective engagement, and physiological responses, rather than being driven by stimulus intensity alone.

Limitations and Future Research Directions

Despite its systematic design and methodological integration, this study has several limitations that warrant further investigation. First, the sample size was relatively modest, and participants were recruited from community settings within a limited geographic region. This may introduce homogeneity in cultural background and technology acceptance, thereby constraining the generalizability of the findings. Future research should incorporate multiregional and cross-cultural samples to assess the broader applicability of cultural heritage VR–based emotional interventions.

Second, the study primarily examined the immediate or short-term emotional effects of a single VR exposure. Long-term outcomes and the stability of emotional benefits remain unclear and should be explored through longitudinal designs with follow-up assessments. Third, although EDA was used as a sensitive indicator of emotional arousal, it cannot fully capture the complexity of autonomic nervous system responses. Future work may integrate additional physiological measures, such as electroencephalography or eye-tracking, to construct a more comprehensive multimodal analytical framework.

Furthermore, while the study emphasizes the emotional value of artistic design in cultural heritage VR, the experimental conditions incorporated multiple experiential elements simultaneously. The cultural heritage VR environment included background music, narrative voice prompts, interactive tasks, and cultural information pop-ups, whereas the photorealistic VR condition provided a comparatively minimal stimulus environment. As a result, the observed emotional differences may not be attributable solely to the cultural heritage content itself. Additional factors such as auditory stimulation, increased interactivity, task engagement, or novelty effects may also have contributed to the observed outcomes. This study therefore cannot fully disentangle the independent and interactive effects of these design components. Future research should adopt more controlled experimental paradigms—such as factorial or modular designs—in which specific elements (eg, auditory cues, interaction levels, narrative guidance, or cultural storytelling) are systematically manipulated in order to clarify their relative contributions to emotional responses.

In addition, this study did not directly assess immersion or sense of presence. Future research could incorporate validated presence scales or structural equation modeling approaches to more precisely examine the mediating role of emotional arousal within this process. Overall, this study provides preliminary but robust empirical support for the application of artistic VR in promoting emotional health among older adults. It also offers a methodological and theoretical foundation for future research at the intersection of design studies, environmental psychology, and digital therapeutics.

Conclusions

This study aimed to examine the effects of cultural heritage–based VR on emotional health in older adults, in comparison with a realistic replication VR condition. In addition, the study explored the relationships between subjective emotional responses, physiological indicators (HRV and EDA), and individual psychological characteristics.

The findings indicate that, compared with the realistic replication VR condition, cultural heritage VR significantly enhanced PA and reduced NA. These results support the hypothesis that culturally meaningful and artistically enriched VR environments can more effectively promote emotional well-being in older adults.

At the physiological level, a significant between-group difference was observed only for the mean NN interval, whereas no statistically significant differences were found in EDA measures. Furthermore, physiological indicators did not demonstrate fully consistent relationships with subjective emotional changes, suggesting that physiological responses to VR may be more variable and influenced by individual differences.

In addition, emotion regulation–related traits and psychological resilience were found to be associated with emotional outcomes, highlighting the importance of individual psychological characteristics in shaping responses to VR interventions. These findings provide preliminary support for a conceptual pathway

XSL•FO
RenderX

linking immersive experience to emotional health, although the underlying mechanisms require further empirical investigation.

This study contributes to the field in 3 main ways. First, it provides empirical evidence supporting the emotional benefits of cultural heritage VR as a potential digital intervention for older adults. Second, it demonstrates the value of integrating subjective measures with physiological indicators to achieve a more comprehensive assessment of emotional responses. Third, it offers a preliminary framework for understanding the mechanisms underlying VR-induced emotional change.

From a practical perspective, the findings inform the design of culturally meaningful and emotion-oriented VR applications for aging populations. Future research should examine the long-term effects of such interventions in larger and more diverse samples and further explore the generalizability of artistic VR approaches across different cultural contexts.

Acknowledgments

The authors thank the research team led by PW at City University of Macau for their support in conducting this study. The authors are also grateful to all older adults who participated in this research and to their families for their time, cooperation, and valuable contributions. The authors further acknowledge the China National Arts Fund for supporting the cultural heritage artistic creation project that provided the visual materials and creative foundation for the cultural heritage virtual reality environment used in this study. Special thanks are extended to Zhang Yangyang, Lu Yao, Dong Yuxuan, and Liu Gaolu for their contributions to the creation and development of the cultural heritage virtual reality materials. The authors used ChatGPT (OpenAI, GPT-5.5) to assist with language editing, grammar refinement, and manuscript organization. All scientific content, data analysis, interpretation of results, and final manuscript revisions were performed and verified by the authors.

Funding

The authors declared no financial support was received for this work.

Data Availability

The datasets generated and analyzed during this study are not publicly available because they contain potentially identifiable participant information. Deidentified data may be available from the corresponding author upon reasonable request and subject to institutional ethics approval requirements.

Abstract

Background: Demoralization negatively affects the quality of life, especially in people with mental disorders.

Objective: This study aims to assess demoralization in a cohort of community-dwelling older adults, to identify groups of individuals who share similar characteristics in terms of mental health conditions and the severity of demoralization domains, and to investigate the different characteristics across these groups.

Methods: Participants were enrolled in 3 centers as part of the cross-sectional MentDis_ICF65+ study and were assessed using the Demoralization Scale and the Composite International Diagnostic Interview at baseline. A cluster analysis was conducted using the partitioning around medoids algorithm with Gower's distance to classify individuals based on demoralization severity and the diagnosis of mental health disorders, allocating individuals to a distinct number of patterns by examining their similarities across these variables.

Results: Among the final sample of 1369 participants, 3 clusters were identified: the "low psychopathology" cluster, with very few mental health diagnoses; the "affective" cluster, characterized by affective disorders (100% of participants); and the "anxiety" cluster, characterized by anxiety disorders (100% of participants). Men were prevalent in the "low psychopathology" cluster (n=635, 59.1%; P<.001), while women were more prevalent in the "affective" cluster (n=133, 72.3%; P<.001) and the "anxiety" cluster (n=79, 71.8%; P<.001). The "affective" cluster had the highest mean scores for disheartenment (17.1, SD 6.7; P<.001), dysphoria (12.1, SD 3.5; P<.001), and loss of meaning (11.8, SD 4.9; P<.001) but the lowest for sense of failure (17.4, SD 3.2; P<.001).

Conclusions: The identification of different clusters of demoralization and mental health disorders in community-dwelling older adults, as well as sex-based differences, highlights the need for tailored mental health interventions in this vulnerable population.

demoralization; depression; anxiety; cluster; older

Introduction

Demoralization was conceptualized more than 40 years ago as a state of existential distress denoting a persistent failure to cope with stress and occurs in patients with severe physical or mental illnesses, specifically those that threaten life or the integrity of being [1]. Subsequently, it has been described as a syndrome characterized by loss of purpose and meaning, a state of persistent feeling of subjective incompetence and existential distress, hopelessness, and helplessness, and an inability to cope

XSL•FO
RenderX

and solve problems [2-4]. As a construct, demoralization only partly overlaps with depression, with demoralized individuals not experiencing the lack of motivation typical of major depression, but rather an uncertainty in the appropriate course of action that results in an inability to cope with external sources of distress [5-7].

Demoralization has been extensively investigated in patients with medical comorbidities, including, but not limited to, those with cardiac, dermatological, and oncological conditions [8-10], as well as mental disorders. Additionally, demoralization has been shown to be associated with suicidal ideation, poorer quality of life, and worse outcomes in both mental and somatic disorders [7,11,12]. It has also been established that the prevalence of mental health diagnoses increases with demoralization [13,14] and that demoralization might play a role in the development or exacerbation of mental health conditions, such as anxiety disorders or depression [15].

In the older population, demoralization syndrome has not been examined in detail, apart from a few authors, such as Ramm et al [16], who found a higher prevalence of demoralization in people aged ≥65 years compared to younger people, as well as an increase in older adulthood (65-74 y, 75-84 y, and 85 yrs and older, 50% prevalence).

Since previous studies among the older individuals with mental disorders, especially depression, showed that they had a worse quality of life and higher levels of disability compared to their peers without a mental health diagnosis [17], it is imperative to understand the impact of demoralization in the aging population [18].

By using cluster analysis, or clustering, a machine learning technique that can automatically identify natural groupings in data by decomposing heterogeneous data [19], the impact of demoralization and mental health disorders in the older population could be examined in a proper way. While predictive modeling is used to predict the already-existing class, clustering algorithms play a key role when the classes are unknown, and the instances have to be classified into [20]. Cluster analysis offers a better understanding of the heterogeneity that exists in patient characteristics in clinical populations [21]. This method has already been applied to identify subtypes of medical patients suffering from demoralization. For instance, Rafanelli et al [22], by studying 1560 medically ill patients, found that 373 had demoralization, and 4 clusters were identified: in 3 out of 4 clusters, demoralization was comorbid with a mental health diagnosis (either major depression, anxiety, and somatoform disorders); in one cluster, it was not associated with any mental health condition (110/373, 29.5% of the sample). Cluster analysis has also been successfully applied to a large mental health registry to describe subgroups of patients in order to program resource allocations [23].

The aims of this study were to assess demoralization in a cohort of community-dwelling older adults and to identify whether groups of individuals cluster together by sharing similar characteristics in terms of demoralization scores as well as domains and mental health disorders. A secondary aim was to investigate clinical and sociodemographic differences across those groups.

Methods

Design

We examined data from the European project Mental Disorders in the Elderly (MentDis_ICF65+), a multicenter study aimed at investigating mental disorders in the community-dwelling older population, including incidence, prevalence, and correlations with the intensity of symptoms, levels of engagement in activities, participation, and use of services [24,25].

The study was conducted in 6 countries (Germany, Great Britain, Israel, Italy, Spain, and Switzerland) and included 3142 participants aged between 65 and 84 years of age. The exclusion criteria were severe cognitive impairment and insufficient proficiency in the corresponding language. It consisted of a community survey administered at baseline, with a follow-up at 12 months. The survey aimed to collect 12-month and 1-month prevalence and comorbidity of mental disorders, as well as information on the prior course of the disorders, quality of life, health care use, help-seeking behavior, impairments, and participation in community life.

Only 3 centers (ie, Ferrara, Geneva, and Hamburg) out of the 6 centers examined the construct of demoralization in addition to the standard protocol and were, therefore, included in the present analysis.

Measures

All participants in the 6 centers underwent individual clinical interviews, along with the completion of psychometric instruments. Additionally, aspects such as quality of life, health care use, help-seeking behavior, impairments, and participation in community life were assessed.

Mental health was assessed using the Composite International Diagnostic Interview for the Elderly (CIDI65+) [26], a version of the Composite International Diagnostic Interview (CIDI) specifically adapted to the needs and abilities of the older individuals. The CIDI65+ test-retest reliability has been examined and was considered satisfactory [26]. This interview assessed the 1-month and 12-month prevalence of somatic morbidity, somatoform disorders, anxiety disorders, obsessive-compulsive disorders, affective disorders, psychotic symptoms, substance abuse, adjustment and stress-related disorders, and cognitive impairment. For the purpose of this investigation, only the 1-month prevalence was considered.

The assessment of physical health included a checklist of primary medical conditions (such as cardiovascular disease, cancer, and musculoskeletal disease) self-reported by the participants, as well as a survey on the use of medications and access to health care facilities. Demographic and socioeconomic data were also gathered as part of the standard assessment.

The Demoralization Scale (DS), developed by Kissane et al [27], is a 24-item self-report tool measuring demoralization syndrome through a 5-point Likert scale (“never”=0; “all the time”=4) in 4 domains: disheartenment, loss of meaning or purpose, dysphoria, and sense of failure. The disheartenment domain includes feelings of discouragement and isolation, the

XSL•FO
RenderX

loss of meaning domain pertains to the loss of role, purpose, and sense of worth in life; the dysphoria domain encompasses emotions of distress and regret; and the sense of failure domain assesses the levels of accomplishment experienced by the individual [27]. The overall demoralization score (DS-Total) is calculated by summing item scores, ranging from 0 to 96. A total score equal to or exceeding 30 is indicative of a demoralized status, according to the criteria established by Kissane et al [27]. The DS has previously demonstrated robust levels of validity and reliability in several populations, such as patients with cancer [28], medically ill patients [5], and patients with nonpsychotic affective disorders [29].

Statistical Analysis

Descriptive statistics were computed for all study variables. Individuals were classified as demoralized in a categorical variable, according to Kissane [27].

In this study, we applied a cluster analysis method to allocate individuals to a distinct number of patterns by investigating individuals' similarities regarding variables that described several aspects of demoralization and the presence or absence of mental health disorders. Cluster analysis is an exploratory method for identifying groups of objects that share common characteristics. Generally, the groups are built such that objects belonging to the same groups share a similar response pattern on the observed variables, while such patterns are as different as possible between objects in different groups [30].

Eight variables were used as classifiers, namely (1) four continuous variables aimed at describing the severity of demoralization, that is, four domains of the DS as identified by Grassi et al [8]: disheartenment, sense of failure, dysphoria, and loss of meaning and purpose; (2) four binary variables aimed at identifying the presence or absence of mental health disorders: anxiety disorders (phobic disorder, panic attack, panic disorder, generalized anxiety disorder (GAD), obsessive-compulsive disorder), affective disorders, and nonaffective psychosis (major depressive disorder, dysthymic disorder with or without hierarchy, double depression, bipolar 1, bipolar 2, psychosis), alcohol dependence or abuse disorder, and somatoform pain disorder. Individuals with missing information regarding mental health diagnoses (5/1479) or demoralization (105/1479) were excluded from the cluster analysis.

Raw scores on demoralization domains were standardized to z-scale scores based on their mean and SD in the full sample pooled across centers to prevent variables with larger numerical ranges from dominating the clustering procedure [31]. Since the data contained both continuous and categorical variables, Gower's similarity measure was used to generate the matrix of similarities [32]. In computing the similarity measure, the same weight was assigned to each variable, and binary variables were treated as nominal variables. Based on this matrix, individuals were clustered by the partitioning around medoids (PAM) algorithm [33]. For a given number of groups, PAM allocates individuals so that the dissimilarity to the medoid is minimized within groups. We used several criteria to select the optimal number of clusters over 2‐7 cluster solutions. First, we constructed a total within sum of squares (WSS) plot and used the so-called elbow method to identify the optimal number of clusters so that adding another cluster would not improve the total WSS. Second, we computed the silhouette and identified the number of clusters for which the average silhouette width was maximized. Similarly, we employed the GAP statistics and found the solution cluster that maximized the statistics. Finally, we computed the average distance to cluster centroid to determine which solutions had the lowest value [33]. After identifying the optimal number of clusters, cluster-wise stability was assessed using bootstrap resampling with Jaccard similarity. The Jaccard index, computed as the mean over the Jaccard similarities between the original and the bootstrapped clusters, was used to evaluate the stability of a cluster. An index approaching 1 indicates a stable cluster, while lower values suggest instability [34]. The number of resampling was set to 1000.

Finally, we used t-distributed stochastic neighbor embedding (t-SNE) to visualize them. t-SNE is a nonlinear dimensionality reduction technique that allows the visualization of high-dimensional datasets in a lower-dimensional space. Data can, therefore, be represented as a scatter plot, where points that were close in the original space remain close, and points that were far away in the original space remain out to be far away [35]. The t-SNE representation was used only for visualization purposes, and not as evidence of separability.

After identifying the groups, we assessed the characteristics of the clusters by comparing the variables used for clustering (eg, the 4 subscales of the DS and the presence or absence of mental health disorders).

Furthermore, we assessed the characteristics of the clusters by comparing the external variables (eg, those not used for clustering, including sociodemographic variables such as sex, age, marital status, household, number of school years, working status, perceived financial situation, and physical illness). Differences in the aforementioned sample characteristics were compared according to cluster membership using independent sample ANOVA and χ^2 tests for continuous and categorical variables, respectively. Due to the exploratory nature of the study, analyses were not controlled for multiple testing.

The analyses were conducted with the R software (version 4.3.1; R Foundation for Statistical Computing) [36]. The packages *cluster* [37] and *fpc* [38] were used to perform and evaluate the cluster analysis. For all tests performed, the significance level was set at 0.05.

Ethical Considerations

The authors assert that all procedures contributing to this work comply with the ethical standards of the relevant national and institutional committees on human experimentation and with the Helsinki Declaration of 1975, as revised in 2008. The study was approved by research ethics committees in all 6 centers (Germany: Hamburg Ethics Committee of the Medical Association No. 2895, Italy: Ferrara No. 0096637 5/11/2009, Israel: Jerusalem No. 0376‐09 -HMO, Spain: Madrid No. 22032010, Switzerland: University Hospitals of Geneva Ethics Committee, Protocol No. 09‐121 and UK: National Research Ethics Service No. 10/H0715/21).

Results

A total of 1479 participants were included in this study. However, 110 were excluded because the information regarding mental health diagnosis (n=5) or demoralization (n=105) was not available, leaving a final sample of 1369 individuals (Ferrara, n=466 participants; Geneva, n=509 participants; and Hamburg, n=394 participants; Figure S1 and Table S1 in Multimedia Appendix 1). Of the 110 missing outcomes, 50.9% (n=56) were female and 49.1% (n=54) were male; 26.4% (n=29) were aged 65 - 69 years, 29.1% (n=32) were aged 70 - 74 years, 29.1% (n=32) were aged 75 - 79 years, and 15.5% (n=17) were aged 80 years or older. Sociodemographic data are summarized in Table 1, while Figure 1 shows a visual representation of the 3 clusters.

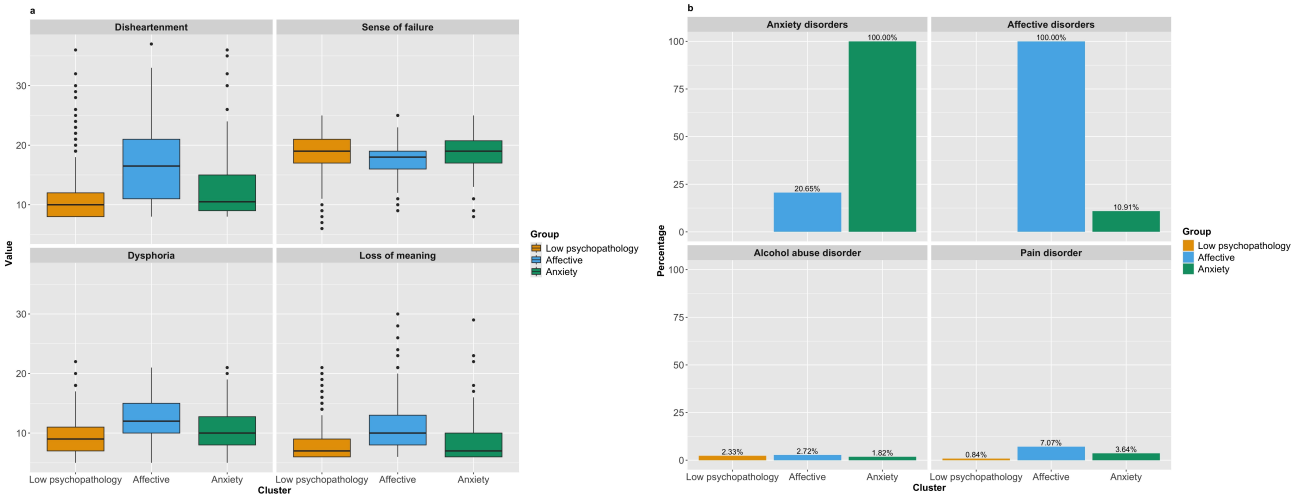
Figure 1. Clusters, as detected by the partitioning around medoids (PAM) algorithm, represented with t-distributed stochastic neighborhood embedding (t-SNE). T-SNE parameters were set as follows: perplexity=30, learning rate=200, iteration=1000, seed=123.

A total of 317/1369 (23.15%) patients were classified as demoralized. Amongst demoralized individuals, 147 (46%) had a comorbid psychiatric diagnosis. Amongst those who did not have any mental disorder (1041/1369), 16% (n=170) were classified as demoralized (Table 2).



XSL•FO
RenderX

Table . Distribution of mental disorders and demoralization in the study sample for the cluster analysis (N=1369).

Characteristics	Demoralization score <30, not demoralized (n=1052), n (%)	Demoralization score ≥30, demoralized (n=317), n (%)	Total, n
Mental health disorders			
Anxiety disorders	83 (7.9)	65 (20.5)	148
Affective disorders	83 (7.8)	113 (35.6)	196
Alcohol abuse	28 (2.7)	4 (1.3)	32
Somatoform pain disorders	9 (0.9)	17 (5.4)	26
No mental health disorders	871 (82.8)	170 (53.6)	1041

The number of clusters that showed the best performance was 3, as it had an adequate average silhouette and elbow shape (Table S2, Table S3, and Figure S2 in Multimedia Appendix 1). The first cluster was characterized by "low psychopathology" (0% anxiety disorders, 0% affective disorders, 2.3% alcohol abuse disorder, and 0.8% somatoform pain disorder); the second was characterized by the presence of affective disorders (100% of participants); and the third by anxiety disorders (100% of participants; Figure 2B). Some individuals had both anxiety and affective disorders: 38 (20.7%) participants in the "affective" cluster also had an anxiety disorder, and 12 (10.9%) participants in the "anxiety" cluster also had an affective disorder (Table 3). All 3 clusters showed a robust structure, as they rarely separated or merged with the others upon resampling: specifically, the Jaccard bootstrap mean was 0.82 for the "low psychopathology" cluster, 0.88 for the "affective" cluster, and 0.83 for the "anxiety" cluster.

Figure 2. Characteristics of the 3 clusters across the variables used as classifiers (a): demoralization domains; (b): mental health disorders).

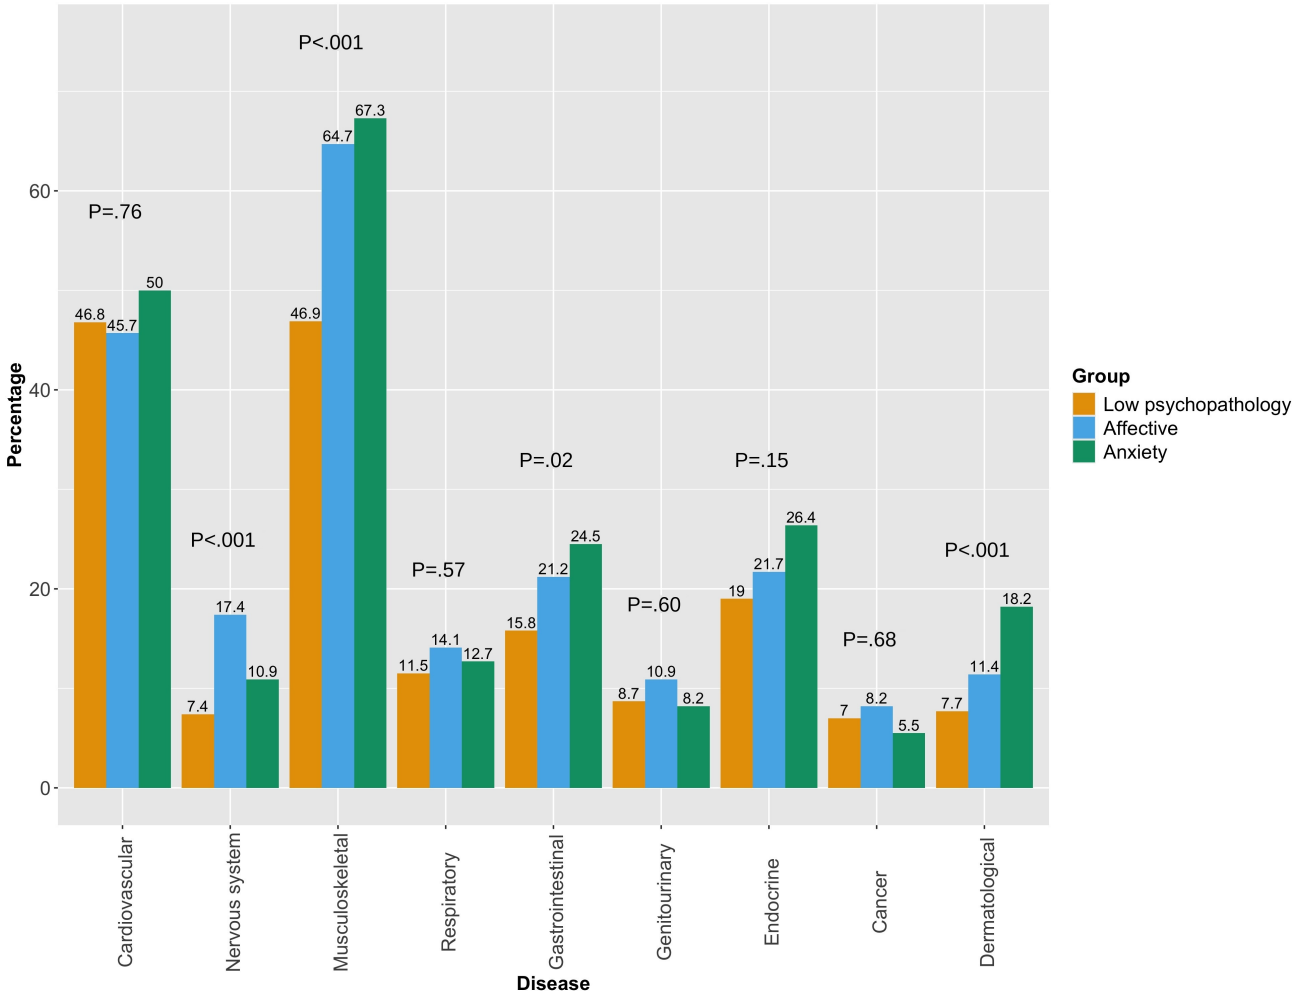
[a]Effect sizes are reported as Cohen d (continuous variables) or Cohen w (categorical variables), as appropriate.



[b]Not available.

Men were more prevalent in the "low psychopathology" cluster (635/1075, 59.1%; *P*<.001), while women were largely prevalent in the "affective" cluster (133/184, 72.3%; *P*<.001) and "anxiety" cluster (79/110, 71.8%; *P*<.001). There was no significant difference in age between clusters (*P*=.20). A difference in marital status was observed between the 3 clusters: in the "low psychopathology" cluster and the "anxiety" cluster, married people were more prevalent (725/1075, 67.4% and 62/110, 56.4%, respectively; *P*<.001), while in the "affective" cluster, separated or widowed or divorced participants were more prevalent (96/184, 52.2%; *P*<.001; Table 1).

The proportion of people living alone was the highest in the "affective" cluster (n=86, 46.7%; *P*<.001), followed by the "anxiety" cluster (n=41, 37.3%; *P*<.001) and the "low psychopathology" cluster (n=278, 25.9%; *P*<.001). As shown in Figure 3 and Table S4 in Multimedia Appendix 1, the "affective" cluster had the highest prevalence of nervous system (*P*<.001) physical comorbidities, while the "anxiety" cluster had the highest prevalence of musculoskeletal (*P*<.001), gastrointestinal (*P*=.02), endocrine (*P*=.15), and dermatological (*P*<.001) comorbidities.

XSL•FO
RenderX

Figure 3. Physical comorbidities across the 3 clusters.

Regarding the different domains of demoralization, the "low psychopathology" cluster had the lowest scores for disheartenment (mean 11.1, SD 3.7; *P*<.001), dysphoria (mean 8.9, SD 2.8; *P*<.001) and loss of meaning (mean 7.9, SD 2.6; *P*<.001) subdomains, but the highest score for the sense of failure domain (mean 19.0, SD 3; *P*<.001). The "affective" cluster had the highest mean score for disheartenment (mean 17.1, SD 6.7; *P*<.001), dysphoria (mean 12.1, SD 3.5; *P*<.001) and loss of meaning (mean 11.8, SD 4.9; *P*<.001), but the lowest mean score for sense of failure (mean 17.4, SD 3.2; *P*<.001; Table 3).

Discussion

This study aimed to identify possible clusters based on mental health disorders and demoralization in a community-dwelling older population across 3 European centers. Using the criteria of the methods described above, we identified 3 distinct patterns. The first group was characterized by low psychopathology, the second by the presence of affective disorders, and the third by the presence of anxiety disorders.

About one fourth (23.2%) of the community-dwelling older individuals in our sample were found to be demoralized. This result is very close to the percentage of demoralized participants previously found in medically ill patients of any age [39,40] and in a more recent study of the older population [16]. This result underlines the need to take demoralization into careful consideration, since it is well known that with age, the burden of medical illnesses increases and that medical illnesses are often associated with demoralization [8,10,11,13].

Some participants had both anxiety and affective disorders. The cluster analysis assigned these comorbid patients either to the "anxiety" cluster or to the "affective" cluster based on the other classifiers included in the analysis, that is, the 4 domains of the DS identified by Grassi et al [7,28]. This finding suggests that the assessment of demoralization can help clarify the characteristics of comorbid mental disorders. This could allow the implementation of tailored interventions in otherwise mixed diagnostic categories.

The "affective" cluster showed higher scores in most of the demoralization domains, for instance, higher disheartenment, dysphoria, and loss of meaning. Affective disorders, especially depression, and demoralization syndrome have some overlapping symptoms, such as suicidal ideation, but are, in fact, separate concepts. Demoralization has been defined as a combination of distress and subjective incompetence, without the lack of motivation that characterizes Major Depressive Disorder [3]. Demoralization and Major Depression, however, are often correlated [5,7]. There might be a two-way relationship: depression, as with any other medical condition,

XSL•FO
RenderX

could result in demoralization, but at the same time demoralization could precede depression [22,41].

Women were more prevalent in the "affective" and "anxiety" clusters, which confirms gender differences in the prevalence of mental disorders. Mental disorders are more prevalent in females than in males, especially anxiety and mood disorders [42]. The underlying mechanisms of this difference remain unclear and may include society-mediated factors, genetics and hormonal fluctuations, the latter especially in the perimenopausal and postmenopausal period [43].

The "low psychopathology" cluster had the lowest levels of disheartenment, dysphoria and loss of meaning, but the highest sense of failure. The presence of a higher sense of failure in this group, especially compared to the relatively low prevalence in the "affective" cluster, has never been reported before. This finding, which could appear contradictory at first, aligns with the concept of *subjective incompetence* [44,45]. In fact, the main source of distress for older adults without an identifiable psychiatric diagnosis may arise from the comparison between the ever-present need for autonomy and age-related functional limitations, which in turn could trigger a more pronounced reactive perception of personal incompetence. This suggests that demoralization and mental health conditions do not necessarily overlap, corroborating the phenomenological difference between demoralization syndrome and mental health disorders such as depression. Furthermore, the elevation in the "Sense of Failure" domain suggests that, in this cluster, demoralization may act as a dimension of existential distress rather than a marker of a mental disorder ([5]M. Belvederi Murri et al., 2020 [3]. As individuals age, their temporal perspective shifts, often leading them to reflect more on past achievements rather than future goals. In this context, the 'Sense of Failure' may capture the appraisal of one's life trajectory rather than acute emotional distress. When this retrospective recollection collides with changes in social roles or functional decline, it can manifest as perceived inadequacy or unfulfilled potential.

The "affective" cluster had a higher prevalence of people living alone, as well as those who were separated, widowed, or divorced. This finding suggests that loneliness plays a role in affective disorders, particularly among older individuals. Previous literature studied this association, but further research may be needed to assess the impact of loneliness on demoralization [46], as also recently indicated in a study of older patients on hemodialysis [47] as well as in older patients with stroke and disability [48].

Nervous system diseases were most prevalent in the "affective" cluster, while musculoskeletal, gastric, endocrinological, and dermatological diseases were most prevalent in the "anxiety" cluster. These findings support the notion that psychopathology correlates with specific physical comorbidities. The correlation between medical conditions and a higher prevalence of mental health diagnoses is well documented in the literature. For example, patients with neurological conditions such as migraines or epilepsy have a higher prevalence of affective disorders compared to the general population [49,50], while anxiety disorders are often associated with gastrointestinal conditions (ie, peptic ulcers or IBS), endocrinological conditions (ie, Graves' disease), and dermatological diseases (ie, psoriasis) [51,52].

To our knowledge, this is the first study to apply a cluster analysis method to examine the relationship between demoralization and mental health disorders in a sample of community-dwelling older participants. Previous studies have mostly focused on demoralization in medical settings, whereas this study assesses on assessing demoralization among older people in the general population. In addition, the cluster analysis method offers a new strategy for understanding the heterogeneity of participants' characteristics within the sample. The identification of different clusters in the presentation of mental health conditions provides the opportunity to design more tailored psychotherapeutic, psychoeducational, and psychosocial interventions for the examined population. For the "affective" cluster, psychotherapeutic interventions tailored to older adults may reduce the psychological distress associated with demoralization. For instance, Managing Cancer and Living Meaningfully (CALM), a psychotherapeutic intervention designed to address end-of-life distress in cancer patients [53], could be adapted to accommodate the care needs of older adults, who share a similar burden of disability and loss of meaning. For the "anxiety" cluster, age-adapted psychotherapy and psychoeducation focusing on emotional regulation and coping strategies may be beneficial in reducing anxiety symptoms.

Some limitations need to be acknowledged. First, due to the cross-sectional design of this investigation, causal inferences are not possible. Second, the geographic limitations of the catchment area, as well as the exclusion of individuals with cognitive impairment and others living in residential facilities, those who are homeless, or those with a language barrier might limit the generalizability of the findings. Third, as in most studies on demoralization, we also used a psychometric tool, while more specific data might have emerged through a clinometric and interview-based approach [54,55], which represent the gold-standard for assessing demoralization. In relation to this, a fourth limitation is that we considered a clinical condition indicating demoralization syndrome by using a standard cut-off score of ≥30, which is, in fact, what we found in a global population of medically ill patients. Studies comparing the demoralization interview vs the DS in older individuals are necessary to define a cut-off that optimizes sensitivity and specificity for this construct. Finally, while the DS has been widely adopted in research and clinical contexts, however, its validation is not yet available in the French language.

As reported, 7% of participants were excluded from the analysis due to missing information on diagnosis or demoralization subscales. Since a relatively small fraction of the data was missing, and the dataset presented an adequate sample size, a complete-case analysis was used to handle missing data [56]. However, a sensitivity analysis to compare the current results (obtained through a complete-case analysis) to an imputed dataset would strengthen the study and ensure the robustness of the findings.

A further limitation that must be acknowledged is that psychiatric diagnosis variables were included as binary variables

XSL•FO
RenderX

within the clustering features; thus, the clustering algorithm might have been strongly incentivized to separate groups by such variables, potentially dominating the structure and reducing the added value of demoralization dimensions. To address this specific aspect, a sensitivity analysis clustering only on demoralization domains could be performed, subsequently comparing diagnoses across resulting clusters, or focusing on variable contribution by observing changes in silhouette scores when iteratively removing variables. Moreover, binary variables were automatically treated as symmetrical, even if potentially unbalanced. Finally, given the exploratory nature of this study, we did not systematically correct for multiple comparisons, which might increase the risk of Type I errors. To mitigate this issue, effect sizes and confidence intervals were reported.

This study identified three different clusters based on the presentation of demoralization and mental health disorders in community-dwelling older individuals, underlining sex-based differences in the presentation of demoralization and specific dimensions of demoralization, mostly associated with certain mental disorders. Further research is needed to guide tailored mental health interventions to address the vulnerabilities of these specific categories in the older population and the role of demoralization in influencing individuals' quality of life [57].

Acknowledgments

The authors would like to thank other collaborators of the Mentdis ICF65+ study: Chiara Da Ronch, Holger Schulz, Maria Dehoust, Susanne Sehner, Anna Suling, Karl Wegscheider, Mike J. Crawford, Yael Hershkovitz, Alan Quirk, Ora Rotenstein, Ana Belén Santos-Olmo, Arieh Shalev, and Jens Strehle. All participants to the study are gratefully acknowledged. We also express our gratitude to all interviewers, dedicated collaborators, and local institutions that made this study possible.

Generative AI tools were used solely for language editing purposes, including correction of grammar, syntax, and wording to improve readability and clarity of the manuscript. No generative AI tools were used for the generation, interpretation, analysis, or modification of scientific content, data, results, references, or conclusions. The authors reviewed and approved all revisions and remain fully responsible for the accuracy, originality, and integrity of the manuscript, including all references and citations.

Funding

This study was funded by a grant from the European Commission (grant 223,105) within the 7th Framework Research Programme of the European Commission. The funding body did not play any role in the design of the study, collection, analysis and interpretation of data nor in writing of this manuscript.

Abstract

Background: Delirium is common among older adults, particularly those with cognitive impairment. However, delirium among patients with dementia or mild cognitive impairment (MCI) in long-term care (LTC) hospitals has received limited attention.

Objective: This study aimed to examine delirium occurrence and associated factors among patients with dementia or MCI in LTC hospitals.

Methods: This cross-sectional study included 142 patients aged 65 years or older with dementia (n=100, 70.4%) or MCI (n=42, 29.6%) at 2 LTC hospitals in South Korea between September 2021 and August 2022. Delirium occurrence was defined as at least 1 positive Short Confusion Assessment Method assessment during twice-daily assessments over 4 weeks, including the first assessment. Multivariable logistic regression examined associated factors overall and within each cognitive group.

Results: Delirium was identified in 55 (38.7%) of 142 patients. The proportion was 41% (41/100) in patients with dementia and 33.3% (14/42) in patients with MCI. Hypoactive delirium was the most common subtype (33/55, 60%). Overall, female sex (adjusted odds ratio [aOR] 4.344, 95% CI 1.794-10.515; *P*=.001), immobility (aOR 4.953, 95% CI 1.857-13.205; *P*=.001), and analgesic use (aOR 3.641, 95% CI 1.262-10.501; *P*=.02) were associated with delirium. Infection was inversely associated with delirium (aOR 0.251, 95% CI 0.101-0.623; *P*=.003). In patients with dementia, female sex, immobility, analgesic use, and pain were associated with delirium. Diaper use was associated with delirium in patients with MCI.

Conclusions: Delirium was common among patients with dementia or MCI in LTC hospitals. The findings support regular delirium assessment, with attention to mobility and pain-related care needs. Further studies are needed to clarify the factors associated with delirium in each cognitive group.

KEYWORDS

delirium; dementia; mild cognitive impairment; long-term care; cross-sectional study

Introduction

Delirium is an acute disturbance in attention, awareness, and cognition that fluctuates over time [1]. Delirium occurs in 21% of patients after hip fracture surgery [2], 48% of patients during follow-up in long-term care (LTC) facilities [3], and 24.6% of patients on admission to acute hospitals [4]. Among hospitalized older adults with dementia, the prevalence of delirium is 48.9% [5]. Although these proportions differ by population and assessment period, delirium is common across care settings. Delirium is associated with cognitive decline [6], increased

XSL•FO
RenderX

mortality, longer hospital stays, institutionalization, higher health care costs, and increased caregiver burden [7-9]. Early recognition is particularly important for older patients with cognitive impairment, whose cognitive and functional difficulties may complicate delirium assessment and care.

Early identification of patients at risk is important for delirium prevention and management [5,7]. Delirium risk is related to both underlying vulnerability and acute clinical stressors [10]. Assessment therefore needs to consider cognitive status, physical illness, medication use, and daily care needs. Multicomponent nonpharmacological interventions can help prevent delirium in hospitalized patients outside intensive care units (ICUs) [11]. However, evidence for preventive interventions in institutional LTC remains limited [12]. Differences in patient characteristics and care needs require attention when applying findings from acute hospitals to LTC hospitals. Identifying factors associated with delirium in LTC hospitals can help nurses assess patients at risk and develop appropriate preventive care.

Most delirium research has focused on patients in ICUs, acute hospitals, and surgical settings. Delirium is also common among patients with dementia in LTC hospitals [3]. Patients with dementia who experience delirium have longer hospital stays and poorer outcomes than those without delirium [5,13]. Changes in attention, cognition, and behavior may be difficult to distinguish from existing dementia symptoms, making comparison with the patient's usual condition important [13]. In residential care, delirium prevalence ranges from 1% to 70.3%, with the highest proportion in a population with dementia. Cognitive impairment and dementia are consistently associated with delirium in these settings [14]. However, the wide variation in patient populations and assessment periods limits direct comparisons across studies.

Patients with mild cognitive impairment (MCI) also require attention in delirium care. MCI is associated with progression to dementia, although the rate varies by population, diagnostic criteria, and follow-up period [15]. Physical inactivity, smoking, diabetes, obesity, and hypertension are modifiable factors associated with dementia [16]. Dementia also places a substantial financial burden on care in South Korea [17]. These clinical and care burdens support the need to address cognitive health in patients with MCI as well as those with dementia. However, the clinical and care-related factors associated with delirium in patients with MCI in LTC hospitals remain unclear. Examining both groups may help identify their delirium care needs.

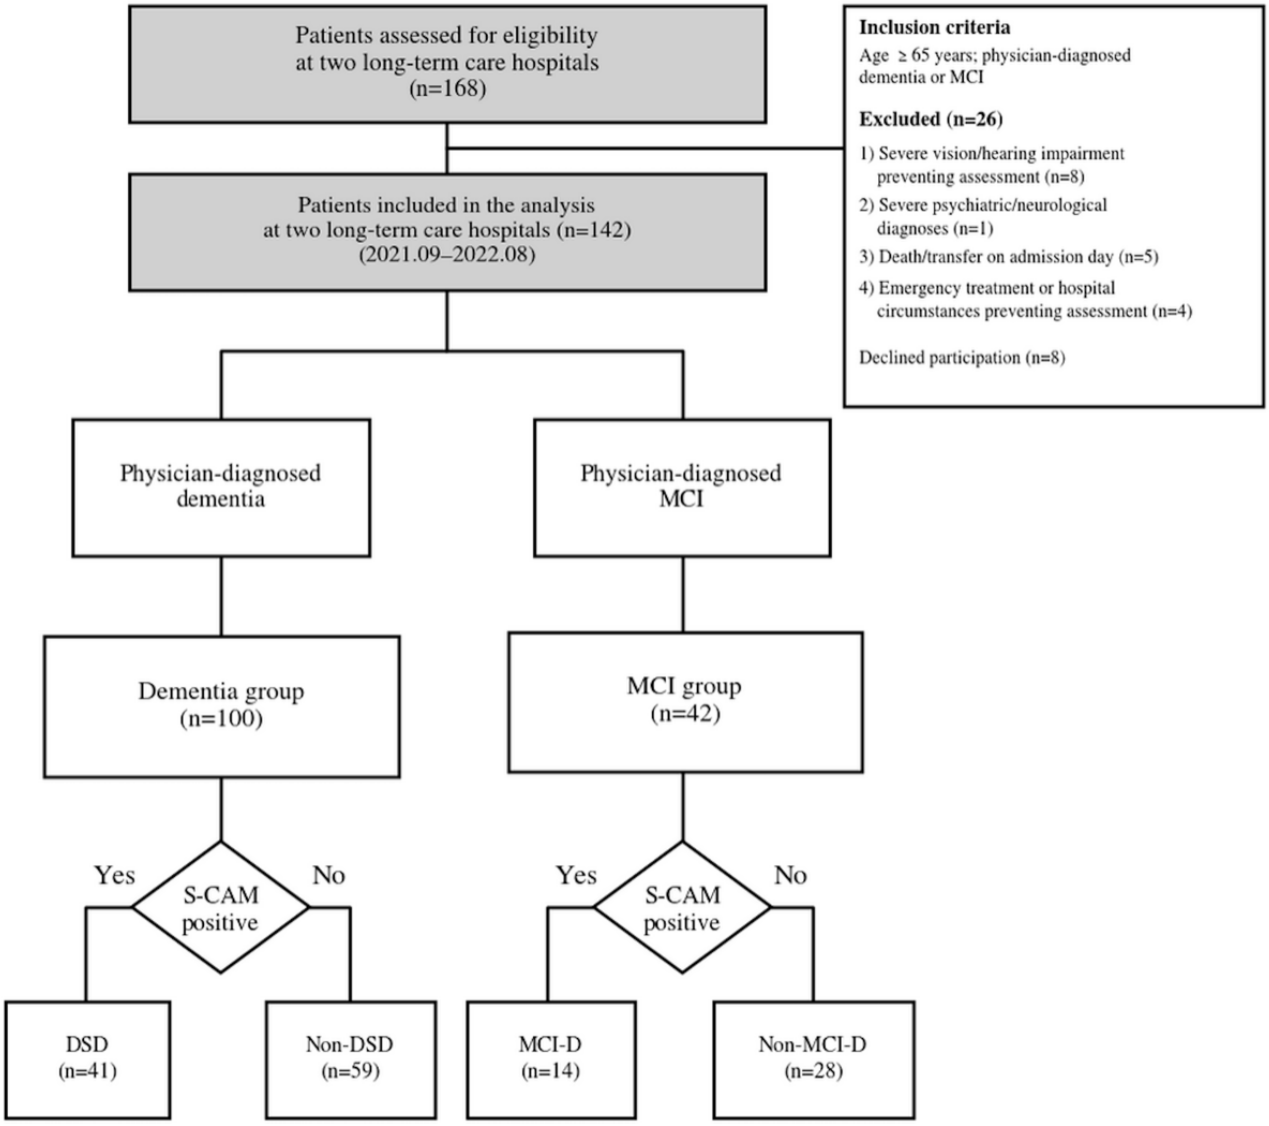
Older patients in LTC hospitals often have chronic illnesses and cognitive impairment that require ongoing nursing care. Nurses observe changes in patients' condition during daily care and have an important role in recognizing possible delirium. Information on delirium occurrence, motor subtypes, and associated factors can help nurses identify patients who need further assessment. Findings from patients with dementia and those with MCI may also help guide care according to cognitive status. However, evidence specific to these patients in LTC hospitals is needed to support delirium assessment and management.

This study examined delirium occurrence, motor subtypes, and associated factors among patients with dementia or MCI in LTC hospitals. Factors associated with delirium were examined in all participants and in the dementia and MCI groups. The findings may help guide nursing assessment and delirium care for patients with cognitive impairment in LTC hospitals.

Methods

Study Design

This observational study used a cross-sectional analysis of patient-level data collected through repeated assessments over 4 weeks. Delirium occurrence was defined as at least 1 positive Short Confusion Assessment Method (S-CAM) assessment during this period, including the first assessment. Each patient was classified once as having or not having delirium, regardless of the number of positive assessments. New episodes after a delirium-free baseline were not analyzed separately. The proportion of patients with delirium therefore represents the observed 4-week period prevalence, not incidence. The study followed the STROBE (Strengthening the Reporting of Observational Studies in Epidemiology) guideline for cross-sectional studies [18] (Multimedia Appendix 1).



Participants and Recruitment

The minimum sample size was 136 patients, calculated using G*Power (version 3.1.9; Heinrich-Heine-University Düsseldorf) for multiple linear regression (f^2=0.15, α=.05, power=0.90, and 8 predictors).

Participants were patients aged 65 years or older at 2 LTC hospitals in cities D and K, South Korea, between September 2021 and August 2022. Each hospital had approximately 250 to 300 beds and mainly cared for older patients, including those with dementia. Patients were eligible if they had a physician-recorded diagnosis of dementia or MCI. After approval from the directors of nursing, recruitment notices were posted on ward notice boards. Head nurses received 2 training sessions and served as research assistants. They checked eligibility and explained the study individually using the recruitment notice and participant information sheet. Patients who expressed interest after reading the notice were also considered. Written consent was obtained from patients or their legal guardians. Of 168 patients assessed, 18 (10.7%) met the exclusion criteria, and 8 (4.8%) declined participation. The remaining 142 (84.5%) patients were included in the analysis (Figure 1).

XSL•FO
RenderX

Figure 1. Recruitment and classification in this cross-sectional study. DSD: delirium superimposed on dementia; MCI: mild cognitive impairment; MCI-D: MCI with delirium; non-DSD: dementia without delirium; non-MCI-D: MCI without delirium.

Patients were excluded because of severe visual or hearing impairment that prevented S-CAM assessment (n=8), severe psychiatric or neurological diagnoses (n=1), death or transfer on the day of admission (n=5), or inability to undergo assessment because of emergency treatment or hospital circumstances (n=4).

Patients were classified into the dementia group (n=100, 70.4%) or the MCI group (n=42, 29.6%) according to their physician-recorded diagnosis. The Korean version of the Mini-Mental State Examination (K-MMSE) cutoffs were not used for eligibility or group assignment. The groups were further divided according to whether patients had any positive S-CAM assessment during the 4 weeks (Figure 1): (1) patients with dementia and at least 1 positive S-CAM assessment (delirium superimposed on dementia [DSD]; n=41), (2) patients with dementia and no positive S-CAM assessment during the observation period (dementia without delirium [non-DSD]; n=59), (3) patients with MCI and at least 1 positive S-CAM assessment (MCI with delirium [MCI-D]; n=14), and (4) patients with MCI and no positive S-CAM assessment during the observation period (MCI without delirium [non-MCI-D]; n=28).

Measures

General and Clinical Characteristics

Baseline characteristics included age, sex, admission source, Charlson Comorbidity Index (CCI) score, BMI (kg/m²), K-MMSE score, number of medications, smoking, alcohol consumption, and comorbidities. The K-MMSE [19] score was used as a continuous measure of cognitive status rather than to classify patients as having dementia or MCI.

Clinical and care-related variables recorded during the 4 weeks included visual or hearing impairment, dehydration (blood urea nitrogen >18 mg/dL), malnutrition, fluid and electrolyte imbalance, infection, pain, sleep deprivation, physical restraint use, immobility, recent surgery, falls, pressure ulcers, analgesic use, blood transfusion, urinary catheterization, enteral feeding, diaper use, and sedative use. Haloperidol was used only in patients with delirium and was not included in the regression models. A clinical condition was coded as present if it was recorded at least once during the assessment period. Infection was identified through a physician diagnosis, laboratory evidence, or antibiotic use. Immobility was assessed through

XSL•FO
RenderX

routine activities-of-daily-living assessments and observation. Pain was assessed using recorded pain scores and pain medication use. Analgesic and sedative use were recorded as yes or no variables.

Delirium Assessment and Classification

Delirium was assessed using the S-CAM, based on the assessment guidelines [20] and previous research [3]. The S-CAM includes acute onset and fluctuating course, inattention, disorganized thinking, and altered level of consciousness. A positive result requires the presence of the first 2 features, along with either disorganized thinking or an altered level of consciousness. Nurses identified acute changes by comparing patients' current condition with their usual cognitive and behavioral status. Motor subtypes were classified as hypoactive or hyperactive according to the main observed pattern. Patients who alternated between hypoactive and hyperactive features were classified as having mixed delirium.

Delirium was assessed twice daily for 4 weeks, in the morning (8-10 AM) and afternoon (4-6 PM). Head nurses served as research assistants, and the nurse in charge of the participating unit performed the afternoon assessments. Before data collection, head nurses received 2 training sessions. A head nurse and a researcher then assessed the same 5 to 6 patients at the same time and compared their checklist ratings. Training continued until an agreement rate of approximately 98%-99% was achieved.

Statistical Analysis

Data were analyzed using SPSS (version 23.0; IBM Corp). Descriptive statistics summarized participant characteristics and delirium occurrence. The proportion with delirium was calculated as the number of patients with at least 1 positive S-CAM assessment during 4 weeks divided by the number analyzed (142 overall, 100 with dementia, and 42 with MCI), multiplied by 100. Group differences were examined using 1-way ANOVA, Pearson chi-square, or Fisher-Freeman-Halton exact tests. Fisher exact tests compared delirium occurrence and motor subtypes between cognitive groups. All tests were 2-sided (P<.05). No analyzed values were missing.

Multivariable logistic regression examined factors associated with delirium in the overall sample and separately within the dementia and MCI groups. The dependent variable was delirium occurrence, coded as at least 1 positive S-CAM assessment during 4 weeks vs none. The overall model included age, sex, CCI score, K-MMSE score, infection, immobility, and analgesic use. Subgroup variables were selected using univariable P<.05, previous research, and clinical relevance. Variables were entered simultaneously, with male sex and absence of binary characteristics as references. Adjusted odds ratios (aORs) and 95% CIs were reported. Each aOR describes the association between a factor and delirium within the analyzed sample, conditional on the other variables in that model. Multicollinearity and model fit were assessed using variance inflation factors and the Hosmer-Lemeshow test.

Ethical Considerations

The study was approved by the Institutional Review Board of Keimyung University (IRB 40525-202012-HR-073-06) and was conducted in accordance with the Declaration of Helsinki. Written informed consent was obtained from patients or their legal guardians. Paper consent and data collection forms were stored in a locked cabinet and later destroyed. Anonymized electronic data are retained in encrypted form. The approved plan specified data retention for 3 years after study completion. Participants received a cotton T-shirt worth approximately ₩10,000 (₩1=US $0.000757 as of August 2022) as compensation.

Results

Participant Characteristics

Of 168 patients assessed for eligibility, 18 met exclusion criteria, and 8 declined participation. The analysis included 142 patients, whose mean age was 80.92 (SD 7.26) years; 58.5% (n=83) were female, and 41.5% (n=59) were male. Smokers accounted for 2.1% (n=3) of patients, and none reported alcohol consumption. Most patients (n=93, 65.5%) were admitted from home.

The mean BMI was 21.97 (SD 3.44) kg/m^2, the mean CCI score was 5.54 (SD 1.81), and the mean K-MMSE score was 10.89 (SD 7.35). Participants were taking an average of 7.50 (SD 4.81) medications. Of the 142 participants, hypertension, diabetes, and degenerative arthritis were present in 53.5% (n=76), 26.1% (n=37), and 2.1% (n=3), respectively. In addition, 54.2% (n=77) had cancer, and 1.4% (n=2) had a history of COVID-19. A history of stroke was recorded in 18.3% (n=26) of patients and a history of brain injury in 10.6% (n=15). Moreover, 1 (0.7%) patient had a visual or hearing impairment.

Among the 142 participants, 4.9% (n=7) had a blood urea nitrogen level above 18 mg/dL, 39.4% (n=56) had malnutrition, and 26.8% (n=38) had a fluid or electrolyte imbalance. A postoperative state was recorded in 7.7% (n=11) of patients, infection in 39.4% (n=56), and pain in 19.7% (n=28). Postoperative state referred to surgery performed at another hospital before admission to the LTC facility and before the delirium assessment period. The maximum interval since surgery and the type of procedure were not recorded.

Sleep deprivation was recorded in 8.5% (n=12) of patients and physical restraint use in 3.5% (n=5). Immobility was recorded in 25.4% (n=36) of patients, a history of falls in 18.3% (n=26), and pressure ulcers in 16.9% (n=24). Analgesics were used by 16.2% (n=23) of patients. Haloperidol was administered to 14 (9.9%) patients: 6 with DSD and 8 with MCI-D. Blood transfusions were recorded in 0.7% (n=1).

Of the 142 participants, urinary catheters were used by 1.4% (n=2), enteral feeding by 6.3% (n=9), and diapers by 60.6% (n=86). Sedative use was recorded in 19.7% (n=28) of participants. Using the full sample (N=142) as the denominator for dementia types, Alzheimer disease was the most common (n=81, 57%), followed by vascular dementia (n=15, 10.6%), Lewy body dementia (n=3, 2.1%), and mixed dementia (n=1, 0.7%; Table 1).

Delirium Occurrence and Motor Subtypes

During the 4-week assessment period, delirium was identified in 38.7% (55/142) of patients, including 41% (41/100) of patients with dementia and 33.3% (14/42) of patients with MCI. Among patients with delirium, the hypoactive type was most common (33/55, 60%), followed by hyperactive (18/55, 32.7%) and mixed (4/55, 7.3%) types. In the dementia group, hypoactive, hyperactive, and mixed delirium accounted for 65.9% (27/41), 26.8% (11/41), and 7.3% (3/41) of patients, respectively. In the MCI group, the corresponding proportions were 42.9% (6/14), 50% (7/14), and 7.1% (1/14; Table 2).

Table 2. Delirium occurrence and motor subtypes.

Comparison of Variables by Cognitive Status and Delirium Occurrence

The 4 groups differed in sex (*P*=.006), admission source (*P*<.001), CCI score (*P*=.005), K-MMSE score (*P*<.001), number of medications (*P*<.001), cancer (*P*<.001), history of COVID-19 (*P*=.047), infection (*P*=.03), immobility (*P*<.001), analgesic use (*P*=.03), urinary catheterization (*P*=.009), and diaper use (*P*<.001; Table 3). Haloperidol use also differed across groups (*P*<.001) and was recorded only in patients with delirium.

[h]BUN: blood urea nitrogen.

Factors Associated With Delirium

Overall, female sex (adjusted OR [aOR] 4.344, 95% CI 1.794-10.515; *P*=.001), immobility (aOR 4.953, 95% CI 1.857-13.205; *P*=.001), and analgesic use (aOR 3.641, 95% CI 1.262-10.501; *P*=.02) were positively associated with delirium, whereas infection was inversely associated with delirium (aOR 0.251, 95% CI 0.101-0.623; *P*=.003). Age (*P*=.69), CCI score (*P*=.69), and K-MMSE score (*P*=.48) were not significantly associated with delirium. The maximum variance inflation factor

XSL•FO
RenderX

was 1.22. The Hosmer-Lemeshow test showed no evidence of poor fit (χ^2 =7.1; *P*=.53). In the dementia group, female sex, immobility, analgesic use, and pain were positively associated with delirium, and infection was inversely associated with delirium. In the MCI group, diaper use was associated with delirium (aOR 20.327, 95% CI 3.005-137.500; *P*=.002; Table 4).

Table 4. Factors associated with deliriuma.

Variable	Overall (N=142)		Dementia (n=100)		MCI[b] (n=42)	
	aOR[c] (95% CI)	*P* value	aOR (95% CI)	*P* value	aOR (95% CI)	*P* value
Age	0.988 (0.931-1.048)	.69	—[d]	—	—	—
Female sex	4.344 (1.794-10.515)	.001	4.013 (1.410-11.423)	.009	5.552 (0.767-40.187)	.09
CCI[e] score	0.952 (0.749-1.211)	.69	—	—	—	—
K-MMSE[f] score	0.980 (0.925-1.037)	.48	—	—	—	—
Infection	0.251 (0.101-0.623)	.003	0.166 (0.052-0.537)	.003	—	—

Falls	—	—	2.252 (0.605-8.387)	.23	—	—
Pain	—	—	6.073 (1.326-27.818)	.02	—	—
Diaper use	—	—	—	—	20.327 (3.005-137.500)	.002

[a]Reference categories were male sex and absence of each binary characteristic.

[b]MCI: mild cognitive impairment.

[c]aOR: adjusted odds ratio.

[d]Not applicable; the variable was not included in the corresponding regression model.

[e]CCI: Charlson Comorbidity Index.

[f]K-MMSE: Korean version of the Mini-Mental State Examination.

Discussion

This study examined delirium occurrence and associated factors among patients with dementia or MCI in LTC hospitals. Delirium was identified in 38.7% (55/142) of patients, and hypoactive delirium was the most common subtype. Female sex, immobility, and analgesic use were positively associated with delirium overall, whereas infection was inversely associated with delirium.

Delirium was identified in 38.7% of patients, compared with 48% in the Korean LTC hospital study by Moon and Park [3], which used the same assessment instrument. Their study included patients with and without dementia and assessed delirium for 3 months, whereas our study focused on patients with dementia or MCI over 4 weeks. Differences in populations and assessment periods also contribute to the wide range of prevalence estimates in residential care (1%-70.3%) [14]. Despite these differences, delirium affected more than one-third of our participants, supporting the need for regular assessment in patients receiving care for cognitive impairment.

Hypoactive delirium was the most common subtype overall (33/55, 60%) and in patients with dementia (27/41, 65.9%), whereas hyperactive delirium was most common in patients with MCI (7/14, 50%). The predominance of hypoactive delirium is consistent with the ICU findings of la Cour et al [21], where this subtype accounted for approximately 50.3% of cases. However, mixed delirium predominated in the LTC hospital study by Moon and Park [3]. Ghezzi et al [22] found poorer cognition in patients with hypoactive than hyperactive delirium, although the effect size was small. These findings highlight the relevance of cognitive status when interpreting motor patterns. Hypoactive delirium may be overlooked when patients appear quiet [9], making observation of changes in activity and attention important [23]. In patients with dementia, nurses need to compare these changes with usual behavior. In patients with MCI, both increased and reduced activity require attention, as hypoactive delirium still accounted for 42.9% (6/14) of patients with MCI who developed delirium.

Female sex, immobility, and analgesic use remained associated with delirium after adjustment for age, CCI score, and K-MMSE score. Patients with dementia may have difficulty expressing pain [24,25], and pain has been associated with delirium in this population [26]. A meta-analysis also identified an association between pain and delirium among older hospital inpatients, although most included studies involved surgical patients [27]. Our finding for analgesic use therefore needs to be interpreted alongside pain and the reasons for treatment. Mobility also warrants attention, as physical dysfunction has been linked to delirium [28], and immobility was associated with delirium in the univariable analysis of older patients undergoing cholecystectomy [29]. Together, these findings support assessing pain in ways suited to patients' communication abilities and considering mobility, pain relief, and changes in attention during daily care.

XSL•FO
RenderX

Infection was inversely associated with delirium in our study. Associations between systemic infection and delirium in residential care have also been inconsistent or nonsignificant [14]. Our infection variable included physician diagnosis, laboratory evidence, or antibiotic use, and its timing relative to delirium was unknown. The inverse association should therefore not be interpreted as a protective effect of infection.

Diaper use was associated with delirium in the MCI group, with use recorded in 64.3% (9/14) of patients with delirium and 7.1% (2/28) without delirium. The association remained after adjustment for sex, but the wide CI indicates limited precision. Diaper use may reflect a need for assistance with continence, mobility, or toileting, although these needs were not established by our data. Clinically, the finding draws attention to the circumstances of diaper use and the patient's functional status. Documenting the reasons for diaper use and changes in toileting ability alongside cognitive and behavioral changes may help nurses assess these care needs. Future studies should examine these factors before delirium develops to clarify the observed association.

Delirium was identified in one-third of patients with MCI, indicating a need for assessment, as well as in patients with dementia. Sabbagh et al [30] emphasized linking MCI recognition with further assessment and appropriate care in primary care. In acute care hospitals, gaps remain in cognitive assessment, documentation, and communication with patients and caregivers [31]. These findings are relevant to continuity of cognitive care in LTC hospitals, where nurses can document usual cognitive and functional status, share changes during handover, and consult familiar caregivers when establishing the patient's baseline. Regular delirium assessment, together with attention to mobility, pain, and toileting needs, provides a focus for nursing care. The effectiveness of preventive care based on these findings requires evaluation in LTC hospitals, where intervention evidence remains limited [12].

This study has several limitations. First, data were collected during the COVID-19 pandemic, when masks and changes in the care environment and social contact may have affected delirium assessment and occurrence. Assessment completeness was not quantified, and formal interrater reliability was not evaluated during data collection. Symptoms of dementia and delirium can also overlap, complicating assessment in patients with moderate to severe dementia despite training [32]. Second, the timing of clinical conditions and care practices relative to delirium was unknown, precluding causal interpretation. Details of sedative use and the interval and type of prior surgery were unavailable. Third, the sample size was calculated for multiple linear regression rather than the logistic models used. The small cognitive groups, particularly the MCI group, limited estimate precision. Fourth, pain assessment included medication use, and infection assessment included antibiotic use, limiting the separation of symptoms from treatment-related associations. We did not adjust for multiple comparisons. Finally, recruitment from 2 LTC hospitals limits generalizability to other settings and patients without cognitive impairment. Larger longitudinal studies are needed to confirm these associations.

Delirium was common among patients with dementia or MCI in LTC hospitals, and hypoactive delirium was the most common subtype overall. Female sex, immobility, and analgesic use were positively associated with delirium, whereas infection was inversely associated. These findings support regular delirium assessment, with attention to mobility and pain-related care needs. Further longitudinal studies are needed to clarify these associations and the findings in each cognitive group.

Acknowledgments

The authors thank the staff and participants of the long-term care hospitals for their cooperation in this study.

Funding

This work was supported by the Basic Science Research Program through the National Research Foundation of Korea, funded by the Ministry of Education (2019R1I1A3A01060561). The funder had no role in the study design; data collection, analysis, or interpretation; manuscript preparation; or the decision to submit the manuscript for publication.

Abstract

Background: Population aging is a global phenomenon that has led to a rise in age-related conditions, particularly dementia. This situation presents significant challenges for health care systems, caregivers, and society as a whole. Technologies have shown potential to address the needs of people living with dementia and their caregivers, offering support in daily activities, communication, and care monitoring. However, only a quarter of countries worldwide have developed national dementia plans, and even fewer have integrated technology-based solutions into these policies.

Objective: This study aimed to analyze existing gaps in dementia plans, with a particular emphasis on the limited integration of technological solutions as essential tools for dementia care and management. Based on this analysis, this study proposes a framework to facilitate context-appropriate technology integration.

Methods: This study presents a narrative review of public policy frameworks for dementia care. The review provides a global overview, examines the context in Latin America, and focuses on Mexico as a case study to analyze how technology is integrated into dementia strategies.

Results: Based on these findings, this study proposes a framework of general recommendations adaptable across multiple countries. Furthermore, it demonstrates the application of this framework in Mexico to strengthen its national dementia strategy through technological solutions tailored to people living with dementia and their informal caregivers.

Conclusions: Given that dementia is recognized as a global priority, countries with aging populations have developed numerous technological solutions. These international experiences serve as valuable references to guide the adoption or rejection of specific approaches, provided that local cultural and social contexts are considered. The applied technologies were merged into a framework that can be adapted to different countries, taking into account social aspects, governance, and region-specific barriers to generate a viable, customized option, as demonstrated in the case study focused on Mexico.

dementia; technologies; policy analysis; literature review; health policy

Introduction

Dementia poses a major challenge for all countries. However, it cannot be addressed without first considering the broader context of aging. Aging is defined by the World Health Organization (WHO) as the gradual accumulation of molecular and cellular damage [1]. These modifications are natural, unavoidable, and start in early adulthood, generating physical and mental changes [2]. In addition to biological changes, aging often entails significant life variations, such as retirement or the loss of close friends and partners [3].

Projections estimate that by 2050, one in 5 individuals worldwide will be aged 60 years or older, totaling between 1.6 and 2.1 billion older adults [4,5]. Aging also increases the risk

XSL•FO
RenderX

of several chronic disorders like neurodegenerative, cardiovascular, and metabolic diseases, as well as other disorders [6].

Among these conditions, dementia is particularly significant. Dementia is a syndrome that may be caused by several diseases and causes cognitive decline [7]. The most common types of dementia include Alzheimer disease (AD), which accounts for approximately 60%-80% of cases, followed by vascular dementia (5%-10%), dementia with Lewy bodies (around 5%), and frontotemporal dementia (approximately 3%) [8]. The most common symptoms of this cognitive impairment may include memory loss, changes in behavior, issues with visuospatial perception, and language problems such as difficulty following conversations [9]. Dementia also impairs the ability to perform daily activities and eventually leads to a loss of individual autonomy [10].

Global costs associated with dementia are typically classified into 3 main categories, including direct medical costs (formal health care services), direct social costs (formal care outside hospital settings), and indirect costs (informal care provided by family members) [11,12].

Because of the importance of this issue and its high cost for governments around the world, as well as the growing number of people affected with between 152 million cases of dementia by 2050 [13], many countries have created public policies to address dementia. These policies aim to meet the needs of people living with dementia and their caregivers.

To effectively address the rising rates of dementia, public policies and action plans must adopt a holistic approach that accounts for the diverse causes and contributing factors of these conditions. In this context, the integration of technology into public policy represents a promising strategy to transform dementia care [14].

The integration of technology into dementia care is increasingly recognized as a key element to enhance early detection, optimize patient management, and improve caregivers' support. Advances in digital health tools, AI, and remote monitoring systems offer promising solutions to address the complex needs of people living with dementia. These technologies can bridge gaps in access to specialized services, particularly in underserved regions, and contribute to more personalized and effective interventions.

One approach to support people living with dementia is the use of assistive technology (AT), along with other technologies for early detection and prediagnosis. AT refers to any devices, tools, or systems that help improve or maintain a person's functional abilities [15,16]. Table 1 shows the types of devices that have been developed based on their specific functions.

Table . Types of assistive technologies. Authors' own creation using data adapted from Klimova et al [16].

Classification	Description
Devices for daily living	Technologies that provide aid with memory, orientation, communication, and other daily activities.
Safety devices	These devices aim to safeguard individuals in cases of disorientation or wandering, and to assist in the prevention of associated safety risks.
Telecare devices	These devices offer services and enable access to support systems, facilitating continuous monitoring and providing assistance when necessary.
Devices to support engagement, social participation, and leisure	Technologies that enhance quality of life by facilitating social interaction and engagement.

This study aimed to evaluate current dementia-related policies from a technological perspective and to propose strategies for the effective integration of technology into dementia care. The analysis progresses from global policies to more specific national policies. It culminates in a Mexican case study that explores potential approaches for integrating technology into national dementia policies.

The first section of this research presents a summary of various global policies and strategies, highlighting their evolution and the extent to which they incorporate technological solutions to address key challenges. Subsequently, an overview of dementia plans in selected Latin American countries and Mexico is provided, as Mexico will serve as the case study in subsequent sections. Thereafter, a framework for technology implementation is presented, taking into account the social context, governance, and regional public policies. Finally, the case study of Mexico is presented to demonstrate the application of this approach.

The main contributions of this paper are as follows:

- Policy-oriented review: a specialized review focused on the integration of emerging technologies within existing public dementia policies.
- Technology identification: identification of current technological tools and their formal inclusion in public health frameworks.
- Adaptive implementation framework: an adaptable decision-making framework designed to bridge the gap between public policies and technological implementation. While Mexico is presented as an illustrative case study to demonstrate its practical application, the framework is fully transferable to other national contexts.

Methods

Objective

The objective of this narrative review was to analyze the global landscape of public policies on dementia, with a specific focus on the application of technological solutions and an emphasis on Mexico, which is subsequently analyzed as a case study.

XSL•FO
RenderX

This analysis was conducted from the perspective of technological implementation, evaluating how official policy frameworks incorporated digital tools and innovation to address the dementia crisis at global, regional, and national levels.

Search Strategy

This review aimed to examine the evolution and current state of the field from the perspective of key stakeholders. Consequently, global analysis incorporated reports and guidelines from the WHO, Alzheimer's Disease International (ADI), and Pan American Health Organization (PAHO), given the review's focus on Latin America.

The search strategy used specific terminology across various databases. For WHO and ADI, the following Boolean query was applied: (public policy OR guide OR plan) AND dementia AND (technology OR tech OR digital OR assistive). The PAHO search was limited to (dementia AND policy) because the platform offered limited search customization. Furthermore, the search was supplemented by a direct review of regulatory documents to analyze the evolution of public policies on dementia, tracing their transition from a general aging context to their current global importance.

Regarding stakeholder websites, publications intended for general awareness or expressing opinions about dementia were excluded. Only reports and guidelines addressing global initiatives focusing on Latin America or discussing the use of technology in dementia care were considered. A screening process was conducted for studies that passed the initial filter, and the relevance of each was discussed with a supervisor. The use of gray literature was selected because it contains the documents related to public policies from different countries. However, the search was limited to the official websites of the main organizations involved in developing or promoting general public policies and dementia-specific policies.

Additional reports referenced within the studies identified during the initial search were also included in order to complement the review.

Data Extraction and Classification

Data extraction was focused on authorship, publication year, primary themes, and document type. For reports, all stakeholders involved in the drafting process were identified. The classification of entries was primarily divided into 3 categories, namely reports, news, and hubs. The latter category served to group related items of the same nature, such as entries that aggregated all dementia-related report results within a specific time period.

Related hubs and news sources were reviewed, and those that did not contain official documents were excluded to retain only official reports.

Results

Overview

The initial search of the WHO website yielded 52 results. Of these, 16 met one of the inclusion criteria, specifically addressing global public policies, focusing on the designated area of interest, or discussing the implementation of technology in dementia care. From these, only 3 official reports were ultimately included.

The search conducted in the ADI database yielded a total of 486 results. However, the most were excluded because they were not formal reports or focused on geographical regions outside the scope of this study.

Consequently, 65 results were selected, of which 25 were reports, primarily consisting of editions of the World Alzheimer Report and supporting documents from From Plan to Impact. Annual follow-up reports on the status of dementia policies were also identified.

The PAHO website search yielded 28 results, of which only one was considered relevant and classified as a technical document. Additionally, other reports cited within the analyzed literature were included. These documents were deemed essential for the development of this review to ensure an exhaustive approach and to provide a comprehensive overview of the current state of public policies on dementia. The review identified key reports with global, Latin American, and Mexican relevance; selected reports are presented in Table 2.

RenderX

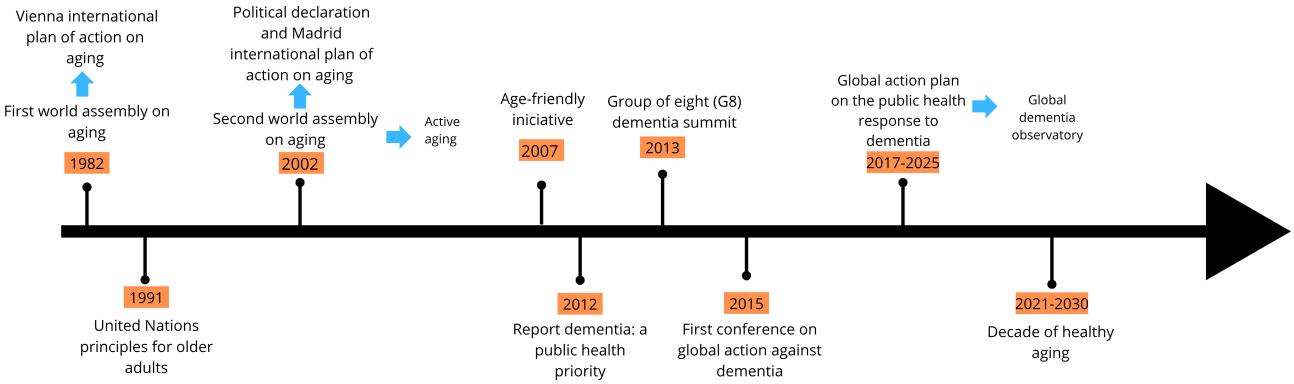
Table . Summary of the main reports identified. Authors' own creation using data adapted from [5,11,17-34].

Title and year	Issuing organization	Geographic scope	Core focus
Global status report on the public health response to dementia (2021) [19]	WHO[a]	Global	Evaluates progress on multisectoral efforts to address dementia globally; identifies implementation barriers of the global action plan and updates dementia burden and cost estimates
Decade of healthy aging: plan of action (2020) [5]	WHO	Global	Ten-year collaborative plan to improve lives of older adults, their families, and communities; placing older adults at the center
Global action plan on the public health response to dementia 2017-2025 (2017) [17]	WHO	Global	Seven priority areas of action to improve the lives of people with dementia and caregivers; include prevention, diagnosis, treatment, care, and caregiver support
The global impact of dementia 2013 - 2050 (2017) [20]	ADI[b]	Global	Policy brief updating prevalence figures, from 44 million in 2013 to 135 million by 2050; 71% will live in low- and middle-income countries by 2050.
Dementia: a public health priority (2012) [18]	WHO and ADI	Global	Joint report published in 2012 that raised awareness of dementia as a public health priority and addressed its global impact, costs, and the need for national and international action
World Alzheimer reports [11,26-34]	ADI	Global	Annual series of comprehensive reports on the global socioeconomic impact of dementia; each report addresses a different topic (2024: attitudes and stigma; 2025: rehabilitation; 2023: risk reduction; 2022: postdiagnostic support; 2021: diagnosis).
From plan to impact reports [21-25]	ADI	Global	Annual series monitoring member states' progress toward the WHO Global Action Plan; 7 chapters cover the 7 action areas of the plan

[a]WHO: World Health Organization.

[b]ADI: Alzheimer's Disease International.

Global Dementia Policies and Technology Integration



To propose a comprehensive approach to technology integration, it is necessary to understand the current state of global strategies and policies that prioritize dementia and the aging population. This understanding helps identify gaps and guide future policy development to better address the needs of individuals living with dementia and older adults.

The significance of this issue is underscored by the efforts of various organizations. In response to the global aging population and its resulting consequences, organizations such as the Alzheimer's Association, WHO, and the United Nations have emphasized the inclusion of this topic on the political agenda. They advocate developing strategies aimed at improving the quality of life for people living with dementia and their caregivers. However, according to the WHO, only a quarter of all countries have implemented a national plan or strategy to address dementia for 2021 [14]. Half of these countries are in Europe, and many of their plans had expired or were nearing expiration.

This global response is further illustrated in Figure 1, which demonstrates the chronological evolution of dementia policies and the primary events that have made dementia a visible and essential issue on the global stage. Because most people living with dementia are aged 60 years or older, early initiatives primarily focused on the needs of the older adults.

XSL•FO
RenderX

Figure 1. Evolution of initiatives and strategies about dementia. Authors' own creation using data adapted from [5,17,18,35-38].

The initial collaborative action addressing dementia was the First World Assembly on Aging in Vienna in 1982 [39]. This early initiative emphasized the imminent aging of the global population and focused on addressing humanitarian and developmental issues, including the needs of older adults and their role within society. As a result of this meeting, the International Plan of Action on Aging was developed. The first Action Plan on Aging sought to increase awareness of the challenges that population aging would present across all sectors. Its objectives included raising awareness of the economic, social, cultural, humanitarian, and socioeconomic implications of population aging [40].

Despite its intentions, the recommendations outlined in the first Action Plan on Aging lacked specificity regarding the actions needed to achieve its objectives. The plan also lacked specific timelines and measurable goals. Nevertheless, it served as a foundational reference for the development of more robust initiatives.

In response to the growing importance of aging, the United Nations established the Principles for Older Persons in 1991 [37]. The 18 principles address 5 areas: independence, participation, care, self-fulfillment, and dignity. By 2002, the primary focus remained on aging as a broad social issue. In response, the Second World Assembly on Aging was held in Madrid, resulting in the adoption of the International Plan of Action on Aging. This political declaration, composed of 19 articles, emphasized the need to incorporate aging into public policy. Its main priorities included older adults and development, promoting health and well-being in old age, and creating enabling and supportive environments [35]. Notably, the document emphasizes the role of technology as a critical tool in addressing the challenges associated with aging.

In 2012, the Global Report on Dementia was published, calling for urgent action on dementia worldwide [18]. Regarding technology, the report discussed ethical issues such as privacy and security, described existing tools, and highlighted the need for more research and evaluation to show the benefits of technology in dementia care.

In 2013, the G8, a group composed of the industrialized countries and representing approximately half of the world's economic activity, held the Dementia Summit in London [38]. At this event, ministers, researchers, and pharmaceutical companies gathered to discuss the importance of addressing dementia and the major challenges it presents, such as the lack of funding for dementia research.

In 2015, the first Conference on Global Action Against Dementia was held. The goal of this conference was to outline future action plans and to strengthen the call for all countries to recognize dementia as a public health priority. The conference also highlighted the importance of developing technological innovations to support people living with dementia, as well as the need for more information on how to effectively integrate these technologies into dementia care. It also stressed that national dementia policies must include a defined role for technology within coordinated care strategies [36].

These collaborative efforts culminated in the presentation of the Global Action Plan on the Public Health Response to Dementia in 2017 [17]. This plan specified objectives to be achieved during the period of 2017 - 2025 and the elements to be evaluated. In this document, technology was mentioned mainly in the seventh strategy action area, dementia research and innovation. The proposal included increasing investment in research focused on technological innovation in health care, particularly in the development of tools to address the needs of people with dementia and their caregivers. It also emphasized the importance of providing access to assistive technologies and encouraging the active participation of individuals living with dementia in the evaluation and design of these solutions.

To monitor progress on the goals of the Global Action Plan, the Global Dementia Observatory (GDO) was created [41]. It defines specific requirements for each area of action. In relation to technology use in care, only one of the ten indicators includes a subindicator that evaluates the availability of care products and assistive technologies. This subindicator considers 3 categories, including adult hygiene products, home modifications, and assistive devices. However, it only includes basic tools such as walking frames and hearing aids, without explicitly mentioning more advanced technologies like tracking systems or ambient assisted living.

Although some health policies address the use of AI and its ethical and legal implications, they often do so from a general perspective, without focusing specifically on dementia. For example, the WHO's Ethics and Governance of Artificial Intelligence for Health (2021) [42] acknowledges the role of digital tools and innovation but offers no specific guidance on their development, implementation, or evaluation in dementia care. This lack of direction limits the effectiveness of current

XSL•FO
RenderX

policies and highlights the need for frameworks that clearly define the role of technology in improving outcomes for people living with dementia.

As a significant milestone, The Decade of Healthy Aging (2021‐2030) [5] is a 10-year initiative aimed at changing perceptions about aging, promoting age-friendly environments, creating integrated and responsive health care systems, and ensuring access to long-term care for older adults. The initiative also emphasizes the role of technology in enhancing care for older adults. Its principal contributions to the technological framework encompass the development of standards for access to information and communication technologies and assistive devices, the promotion of affordable and effective digital tools, and the implementation of innovative long-term care services.

Latin American Dementia Policies: Regional Technology Landscape

Population aging is a phenomenon affecting the entire world, including Latin America, leading to a significant increase in dementia cases. In fact, in Latin America, dementia is the sixth leading cause of death and the primary cause of dependency [43]. Additionally, the prevalence of dementia in the region is 8.5% among individuals aged 60 years and older, the highest in the world; this figure is expected to reach 19.3% by 2050 [44].

The lack of formal studies in various Latin American countries makes it difficult to understand the existing issues and forces the generalization of incidence, prevalence, and cost figures, relying on countries that have conducted more studies, such as Cuba, the Dominican Republic, Mexico, Peru, and Venezuela [43].

The development and evolution of policies and plans to combat dementia have become crucial as countries acknowledge the growing proportion of their populations aged 60 years and older. This demographic shift emphasizes the prevalence of common illnesses and conditions associated with aging. Nations have adopted 2 main approaches: incorporating dementia initiatives within broader national plans that also address other neurodegenerative diseases or developing specific strategies targeting dementia or its most common type, AD. For instance, Mexico's initial plan focused on AD, while countries like Chile and the Dominican Republic have implemented general plans targeting dementia [45].

According to ADI, as of 2024, 8 countries in Latin America (Brazil, Chile, Cuba, Costa Rica, Dominican Republic, Mexico, Puerto Rico, and Uruguay) had a formal dementia plan, with 2 more countries (Panama and Peru) developing their plans. A review of policies from 6 Latin American countries indicates that all these plans align with the recommendations and action areas proposed by the WHO in the Global Action Plan on the Public Health Response to Dementia [17]. These areas include early diagnosis, staff training, public awareness campaigns, and improving the quality of life for people living with dementia. Additionally, each plan includes objectives tailored to their specific context and needs, such as enhancing monitoring and data collection related to the disease [45-49]. All these plans are acknowledged by ADI as the most recent for each country (Multimedia Appendix 1).

Some of these plans were established many years ago and have yet to be updated, such as those of Cuba and Chile [46,48]. Others were designed with a long-term perspective, like Costa Rica's plan, which was set to last 10 years until its deadline in 2024 [50]. Currently, many of these plans are undergoing updates. For example, Mexico's dementia plan, initially created in 2014, was updated in 2024.

In these plans, early diagnosis is prioritized through the training of frontline staff and the use of existing resources, as opposed to creating new services. Another important aspect is the inclusion of action lines aimed at informing people living with dementia about their legal rights.

Most of the dementia plans and strategies reviewed mention technology only as a tool for sharing information with caregivers and people living with dementia. Some also refer to promoting innovation in research. However, only Chile's plan explicitly emphasizes the use of technology to improve quality of life and the development of devices to support people with dementia [46].

Mexico's National Dementia Strategy

Overview

Dementia represents a growing concern in Mexico. Currently, an estimated 1.3 million people in Mexico are living with dementia, and projections indicate that this number could increase to 3.5 million by 2050 [47].

In response to this challenge, the first national plan specifically addressing dementia was introduced in 2014 under the title "Plan de Acción Alzheimer y Otras Demencias." This initiative aimed to enhance the well-being of individuals living with dementia by reinforcing the health care system through 7 key objectives. These included eliminating stigma, improving access to accurate information for patients and caregivers, and developing a comprehensive care system that integrates medical, social, and community support.

Despite the plan's commitment to periodic monitoring and evaluation, a formal update was not introduced until 2024 with the publication of the National Dementia Plan [47]. While this new strategy retains core objectives, such as eliminating stigma and supporting scientific research, it introduces additional measures aimed at strengthening early detection through a comprehensive care model. The primary goal of these enhancements is to improve patient outcomes and reduce the prevalence of dementia-related complications. A key addition to this plan is the strategic involvement of civil associations, which play a critical role in raising awareness and disseminating information about dementia. The plan also prioritizes the reinforcement of the primary health care system by integrating systematic screening processes and equipping health care professionals with improved diagnostic tools and training. These initiatives seek to establish a more effective and accessible support system for individuals living with dementia and their caregivers.

XSL•FO
RenderX

As observed, the application and development of technologies are largely absent from both new and existing plans. Therefore, it is essential to identify the key sectors where the use and development of technological solutions can be effectively integrated and leveraged for their potential impact.

The following points summarize the most pressing needs that must be addressed to build an effective and inclusive dementia care strategy in Mexico related to the application of technologies:

Strengthening Primary Health Care Networks

Primary health care providers, including those within the Mexican Social Security Institute (Instituto Mexicano del Seguro Social [IMSS]) and the Institute of Social Security and Services for State Workers (Instituto de Seguridad y Servicios Sociales de los Trabajadores del Estado [ISSSTE]), should receive training to recognize early signs of dementia, ensure timely referrals to specialized care, and use appropriate technologies for screening and early detection.

Support for Informal Caregivers

Given the cultural significance of family caregiving in Mexico, it is essential to implement policies that provide effective support to informal caregivers. This support may include financial assistance, respite care services, and access to training programs delivered through the Secretariat of Welfare or local community centers to strengthen caregiving capacity and enhance the quality of care provided.

Within this framework, the Mexican government has introduced the Salud Casa por Casa program, which delivers home-based health care services to individuals aged 65 years and older [51]. The program is structured across 4 levels of care that respond to varying degrees of clinical need, encompassing stable conditions as well as complex cases that require continuous medical attention and sustained caregiver involvement.

This initiative presents a valuable opportunity to integrate smart environments into long-term care and advance the development of large-scale technological solutions aimed at monitoring individuals with dementia. Such innovations can support early detection, ongoing cognitive assessment, and personalized care interventions within the home setting. However, this program remains in the process of structuring and implementation, and it is not yet operational.

Public Awareness and Education Campaigns

A nationwide public awareness campaign should be launched to reduce the stigma associated with dementia. The campaign could be spearheaded by the Ministry of Health, in collaboration with nongovernmental organizations (NGOs) like Federación Mexicana de Alzheimer (FEDMA), to educate the public about the importance of early diagnosis and the available resources. Notably, efforts are already underway through the Dementia Friends initiative, introduced in Mexico by FEDMA in 2018, with the primary objective of eliminating stigma [52].

Investment in Research and Innovation

To address the growing challenge of dementia in Mexico, it is crucial to increase funding for research through institutions like the Secretariat of Science, Humanities, Technology, and Innovation (SECIHTI). This funding should focus on studies investigating genetic and environmental factors contributing to dementia within the Mexican population and developing culturally appropriate care models. Using databases with cohorts on the health of the Mexican population offers significant opportunities to analyze data for better policies and informed decisions.

Since 2001, the Mexican Health and Aging Study (MHAS) has gathered essential data for policy development and health care strategies. Based on a nationally representative sample of 15,186 Mexicans aged 50 years and older, this longitudinal study collects information on health status, socioeconomic conditions, family structure, living environments, psychosocial factors, and major life events [53]. MHAS has expanded to include specialized assessments like cognitive evaluations and biological sample collection, providing valuable insights into aging and dementia.

Additional cohorts, such as the Cohorte de Obesidad, Sarcopenia y Fragilidad de Adultos Mayores Mexicanos, offer longitudinal data on sociodemographic information, cognition, nutrition, and other health aspects [54]. The Encuesta Nacional de Salud y Nutrición (ENSANUT) provides data on risk factors like smoking, diabetes, and cardiovascular disease [55]. Integrating these rich data sources can help Mexico advance research, develop effective policies, and create culturally tailored interventions to reduce the impact of dementia and other health challenges.

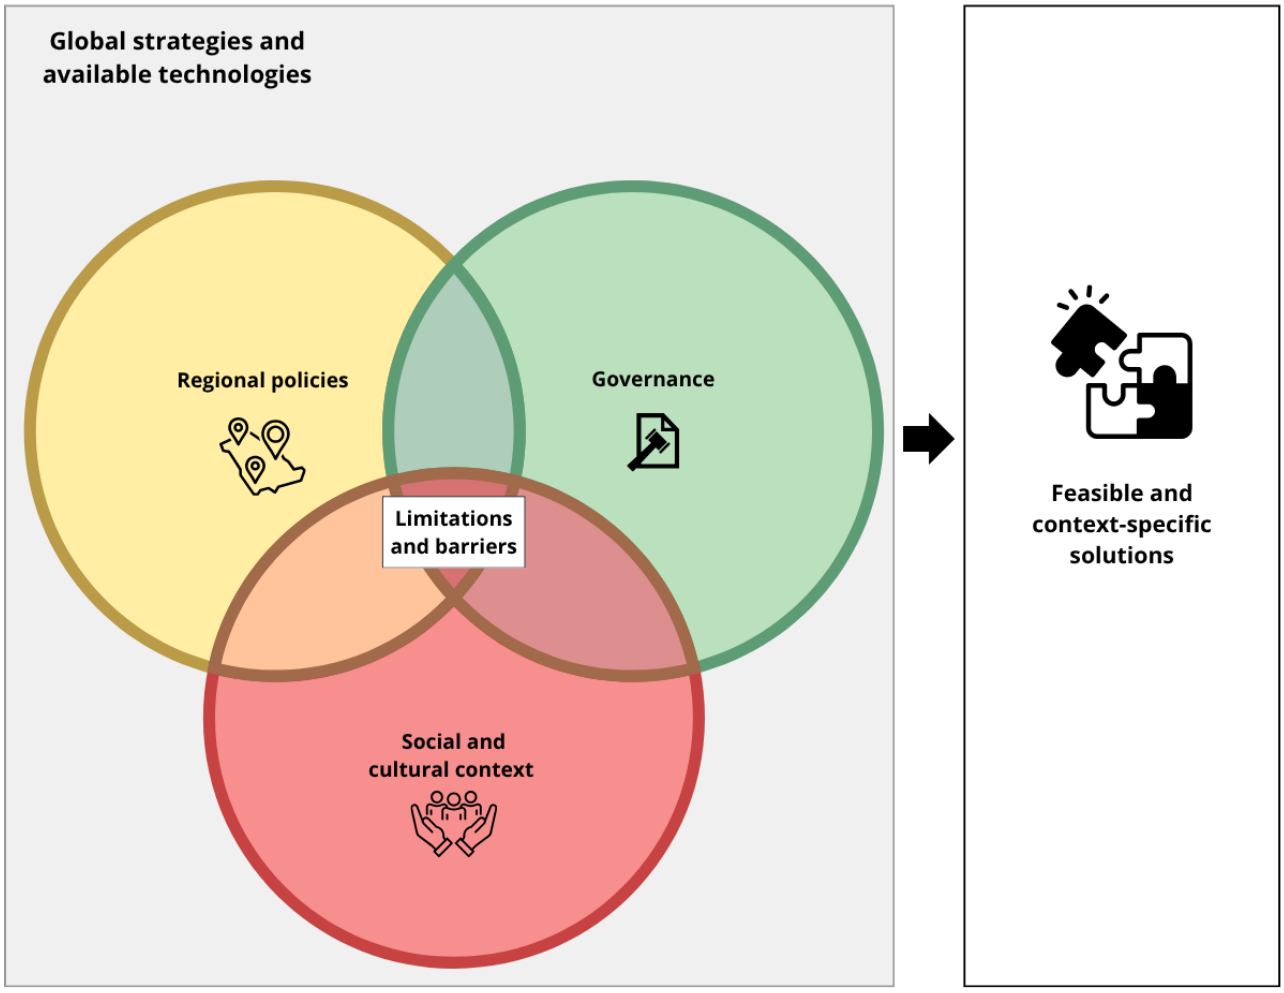
International Collaboration

Mexico should actively engage in international forums and collaborative initiatives focused on dementia care. This participation could involve partnerships with organizations such as the WHO and the PAHO, as well as the establishment of bilateral agreements with countries that have implemented advanced dementia care strategies. Through these collaborations, Mexico could both benefit from and contribute to the exchange of innovative technologies and best practices, particularly in the areas of early diagnosis and nonpharmacological treatment approaches.

Implementation of Community-Based Care Models

Community-based care models, such as those implemented by the Network of Municipalities for Health (Red de Municipios por la Salud) [56], should be expanded to include dementia-specific services. These models could provide localized support and resources for individuals living with dementia and their families. Additionally, they could facilitate the formation of dedicated teams to assess the acceptability, usability, and effectiveness of technological devices designed for people with dementia and their caregivers, thereby promoting more responsive and context-appropriate innovations in care.

Technology Implementation Framework



Technology implementation aligned with global and national strategic goals requires a structured procedure. This procedure considers overarching global expectations before evaluating country-specific conditions. This approach is presented first in

XSL•FO
RenderX

general terms and is subsequently illustrated through a case study focused on Mexico. The objective of this framework is to allow adaptation to the specific characteristics of different national contexts.
